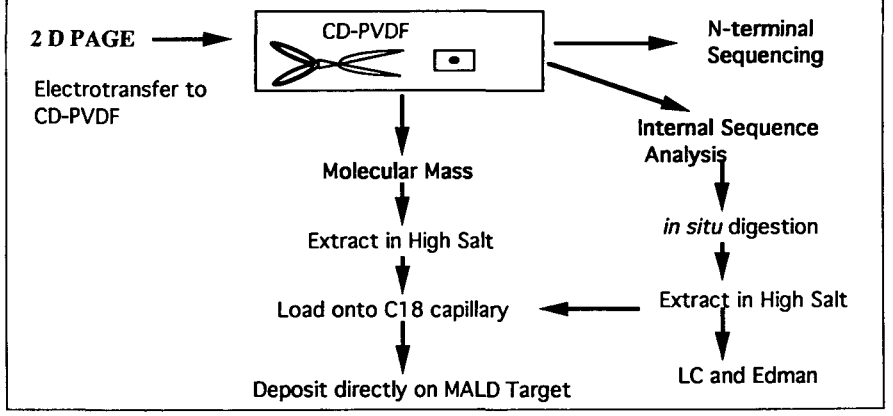
We present a strategy for structural characterization of proteins that combines the use of SDS-PAGE with matrix-assisted laser desorption time-of-flight mass spectrometry (MALD-TOF-MS). The strategy employed is outlined in Figure 1. Sample was separated by SDS-PAGE and electroblotted onto Cationic Durapore-polyvinylidene difluoride (CD-PVDF, Millipore) membrane. After visualization, bands of interest were excised and analyzed in one of the three pathways illustrated in Figure 1. N-terminal sequence analysis was obtained by placing one excised band directly into a modified ABI 477 gas phase sequencer. Molecular mass information was obtained as follows: Protein was extracted from the CD-PVDF membrane in high salt (2 M citric acid) with sonication followed by a desalting step. In this step, sample was loaded onto a 1 m long fused silica (50 μm) that was derivatized with C18 and the sample was washed with 100 μl water. Protein was eluted directly onto the MALD-TOF sample stage with a solution of MALD matrix in 80% acetonitrile and analyzed by MALD-TOF. Internal fragments of proteins were generated by exposing one excised band to cyanogen bromide in 70% trifluoroacetic acid. Resultant peptides were extracted, desalted and analyzed as described below.

Figure 1.



Samples were analyzed on a Finnigan MAT Vision 2000 MALD-TOF mass spectrometer equipped with a movable sample stage (5 kV), Ion reflector, post acceleration detector (20 kV), CCD camera, and a nitrogen laser (337 nm). Data acquistion, instrument control, laser trigger, and beam attenuator are controlled by a Gateway 486 PC. A mixture of 9:1 2,5-dihydroxybenzoic acid (10 g/L) in water : 5-methoxysalicylic acid (10 g/L) in 50% acetonitrile was used as the MALD matrix. Human α1-protease inhibitor (α1-PI) was run on 7.5% SDS gel (60 pmol/lane) and then electroblotted to CD-PVDF. An excised band containing intact α1-PI was placed in an ABI sequencer and N-terminal sequence was obtained out to 18 residues. A second excised band containing intact α1-PI was extracted, desalted and analyzed by MALD-TOF MS (Figure 2). Peptide fragments of α1-PI were also generated by exposing a third excised band of CD-PVDF membrane containing intact α1-PI to cyanogen bromide in 70% trifluoroacetic acid for 2 h. Peptides were extracted in high salt and desalted as described above. Analysis of the fragments by MALD-TOF resulted in the mass spectrum shown in Figure 3. The observed fragments account for over 80% of the amino acid sequence.

CHARACTERISATION OF RECOMBINANT IL4

D.J.Bell, W.A.Neville, M.Haran and A.West,
SmithKline Beecham Pharmaceuticals, Great Burgh, Epsom, Surrey KT18 5XQ, U.K.

Mass spectrometric analyses formed a considerable part of the effort to define the structure of recombinant Interleukin 4 (IL4) The primary structure of the protein was investigated using on-line HPLC/FABMS to characterise peptides generated in a tryptic digest. Molecular masses could be assigned to the majority of peptides observed by UV aborbance thus much of the sequence could also be verified by correlating the data with the molecular masses of predicted tryptic peptides. In some cases, the background subtracted LC/FAB spectra contained fragment ions of sufficient intensity to confirm the sequence of the peptide. As the protein was digested in the native form, the disulphide bridging could be investigated by calculating the possible combinations of cysteine containing peptides and comparing this with the molecular masses observed in the LC/MS analysis. In addition to molecular mass information relating to the intact bridged peptide, the spectra of peptides with disulphide bridges showed facile cleavage at the -s-s- bond. Comparing this data with the possible masses of disulphide linked peptides, the results were ambiguous as fragment ions corresponding to particular cysteine peptides occurred more than once in the chromatogram suggesting scrambling of the bridges. Using reverse phase chromatography to separate components of the lys-C digest of IL4, followed by re-analysis of reduced LC fractions, the disulphide containing peptides were identified. Analysis of the peptides seen to be affected by reducing agents by FAB allowed the nature of the bridging to be determined. The nature of the bridge peptides was confirmed by on target reduction to generate the two free cysteine containing peptides. Observations in the analysis of the tryptic digest were explained as incomplete digestion of the protein producing partial peptides.

Having determined the primary structure of the protein and the position of disulphide linked residues, ^{15}N and $^{13}C/^{15}N$ labelled IL4 were prepared to allow full structural characterisation of the material by NMR. To investigate the degree of isotopic enrichment, two mass spectrometric methods were used. Initially matrix assisted laser desorption/ionisation time-of-flight was exploited to give an average molecular mass although the resolution limitations of the instrument did not permit observation of incompletely labelled protein or the resolution of adduct ions (fig. 1) The result did suggest a high degree of enrichment (>90%) thus the material was digested using lys-C and the subsequent peptides characterised by FAB. The most intense isotope in the pseudo-molecular ion of the peptides was fully ^{15}N or $^{13}C/^{15}N$ labelled. Ions corresponding to incomplete labelling were also observed and, from the composition of the ion and this isotope pattern, the degree of complete enrichment was calculated as ca. 95%. (fig. 2) The sequence of these peptides was confirmed by linked scanning (B/E=constant), with consideration of the isotope labelling effect in the resulting spectra.

Protein Ladder Sequencing in Solid Phase Peptide Synthesis

Sharon M. Walker*[1], Rong Wang[2], Saskia Milton[1], Brian Chait[2] and Stephen Kent[1]

[1]The Scripps Research Institute, 10666 North Torrey Pines Road, La Jolla, CA. 92037 & [2]The Rockefeller University, 1230 York Avenue, New York, N.Y.10021

Introduction

A technique is descibed through which the primary sequence of synthetic peptides can be routinely and quickly verified. A series of sequence-defining peptide fragments was generated during stepwise solid-phase peptide synthesis (SPPS). The peptide sequence was easily determined in one step using matrix-assisted laser desorption mass spectrometry (LDMS).

Approaches

I. In SPPS, the peptide chain is built up from the C-terminal amino acid (attached to a resin support), by adding successive amino acids one at a time in a stepwise fashion. Peptide resin samples were collected at each step, combined, deprotected and cleaved to form a pool of all possible length peptide intermediates. An aliquot of this mixture was analysed in a single operation by LDMS. Mass differences between successive peaks and their position in the data set gave the amino acid sequence of the peptide synthesized. Peptide resin samples may also be subjected to the quantitative ninhydrin reaction--used to determine the efficiency of the coupling reactions--before combining and subsequent analysis (Figure 1). Terminated by-products are readily detected since they are amplified during the sampling process. Figure 2 shows an example of a terminated peptide by-product. The observed by-product mass of 3339.0 Da corresponds to trifluoroacetylation at His 69 of a fragment from HIV-1 Protease (N$^{\alpha}$-Tfa-(69-99)).

II. An alternative method used to generate a sequence-defining ladder was the incorporation of 5 mole% Fmoc amino acid in a Boc synthesis. In this way, a small fraction of the growing peptide chain was terminated at each step of the synthesis. Removal of the Fmoc group, deprotection and cleavage resulted in a mixture containing a sequence-defining set of peptide fragments of all possible lengths, as well as the full length target peptide (Figure 3).

Conclusions

LDMS readout of ladder sequencing fragment sets from stepwise SPPS was used to confirm the amino acid sequences of synthetic peptides. This method can be used for rapid and routine sequence confirmation and by-product identification. In addition, the method provides easily interpretable data which can be used to identify modified amino acids and terminated by-products. Peptide resin samples may also be combined after quanititative ninhydrin and used for sequence confirmation.

Introduction

Implementation of mandatory newborn screening programs in many states is producing a growing volume of uncommon hemoglobinopathies requiring characterization. The cost and efficiency of identification procedures are important factors in the debate whether to pursue all such cases to a final conclusion. The aim of this study is to present advantages of incorporating mass spectrometric techniques at all stages of a hemoglobinopathy analysis: *i.e.* detection, confirmation of the identity of common variants and full structural analysis of uncommon mutants.

Experimental

Mass spectrometry was performed on a VG BioQ quadrupole mass spectrometer (VG BioTech/Fisons, Altrincham, UK). The electrostatic-spray ion source was typically operated at 3.2 kV and the nozzle to skimmer bias was close to 55 V (100 V for the source CID experiments). A Michrom microbore HPLC system (MichromBioresources, Pleasanton, CA) was interfaced with the mass spectrometer through the modified VG BioQ probe and 0.2% TFA in MeOH at the flow rate 2 µl/min was added as a sheath liquid prior to nebulization. Splitting 10:1 of the flow was achieved directly in the UV cell allowing 4 µl/min to be analyzed by mass spectrometer. Globins and peptides were separated on Vydac C4 and C18 narrow bore columns (1x150 mm, 300Å, 5µ), respectively and linear gradients of acetonitrile in 0.1% TFA were employed. Preparative cellulose acetate electrophoresis (CAE) (pH 8) and thin layer isoelectric focusing (TLIF) (agarose plates, Isolab ampholines pH 6-8) were performed using commercially available kits from Helena Laboratories and Isolab, respectively. CAE and TLIF separated hemoglobins were eluted from gels with water and the latter freed from ampholines by ulfrafiltration through Amicon centricon 10 filter units. Either 50% MeOH/1% AcOH or trifluoroethanol were used to deliver separated hemoglobins to the mass spectrometer.

Results

ESI MS has been incorporated into the initial step of hemoglobinopathy evaluation *i.e.* detection of hemoglobin variants in whole hemolysates. MaxEnt® algorithm is being examined as an alternative to deconvolution to provide accurate MW information for variants which are very close in mass and hence poorly resolved from other components of the mixture. An example of a carrier of Hb North Chicago (mass difference between

normal and abnormal β chain 10 Da, measured 10.6 Da) demonstrates the usefulness of the software. Certain mutants cannot be unambiguously analyzed in unfractionated hemolysates. This is the case when variants differ by less than 12 Da from other globin components of the mixture. Also, low abundance mutants which are isobaric with alkali metal adducts of major components pose a serious challenge in routine analysis. Interfacing HPLC of globins with ES MS offers an extension of the screening potential to encompass all hemoglobin mutants regardless of their mass differentials, provided they are separable by reversed phase HPLC.

ESI MS has been interfaced with cellulose acetate electrophoresis (CAE) and thin layer isoelectric focusing (TLIF), the techniques routinely employed in hemoglobinopathy laboratories. Hemoglobins thus isolated are amenable to ESI MS after a very limited work-up although recovery of minor TLIF bands still requires some improvement. Direct mass analysis of abnormal "bands" detected by routine electrophoretic techniques provides a fast way of confirming an identity of a variant hemoglobin or else dismissing certain cases as not being hemoglobinopathies.

Final structural analysis employs micro LC/ESI MS of proteolytic digests derived from the S-carboxyamidomethylated protein, 10% of the material being used for ESI MS and the rest collected for tandem MS sequencing, if required. Selected ion chromatograms aid in locating tentative abnormal tryptic fragments. Whenever possible, CID in the ion source is employed to confirm the sequence of abnormal peptides.

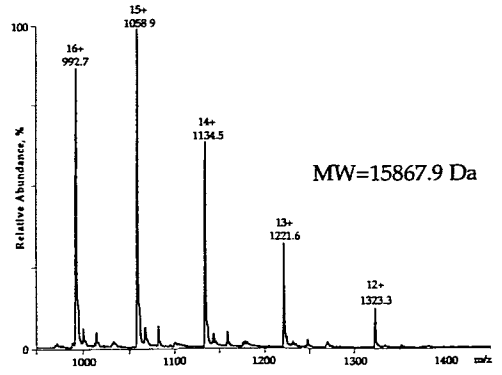

Fig. 1. ESI MS spectrum of Hb H (β_4) isolated by cellulose acetate electrophoresis. The presence of this hemoglobin is indicative of α thallasemia.

Amino Acid Sequence Determination of Neuropeptides by using Electrospray Ionization on a Magnetic Deflection Mass Spectrometer

Jih-Lie Tseng*, Chhabil Dass and Dominic M. Desiderio
University of Tennessee, Memphis, 956 Court Ave., Rm 218,
Memphis, TN 38163.

Mass spectrometry techniques have played a very important role in the analysis of biomolecules such as peptides and proteins. In the past, we have used FAB-MS either alone[1] or in conjunction with linked-field scan at constant B/E to determine the amino acid sequence of several biochemically important neuropeptides.[2] In this study, we explore the use of electrospray ionization to characterize a number of C-terminally extended enkephalin neuropeptides, including methionine enkephalin (ME), leucine enkephalin (LE), LE-Arg, ME-Lys, dynorphin (1-7), dynorphin (1-8). All experiments were conducted on a magnetic deflection mass spectrometer of EBE-qQ geometry (VG AutoSpec Q). Electrospray source was operated at 4 kV. The peptides *were introduced into the source as a flowing solution (3μL/min) of 50 pmole/μL in 1:1* $CH_3OH:H_2O$ containing 1% CH_3COOH.

The positive ion magnet scan spectrum contains mainly the singly and multiply charged ions of the peptides as the voltage between the sampling cone and the skimmer (ΔV) was set at 30 V. The ME and LE give MH^+ ions only, whereas, the peptides containing basic amino acid residues such as LE-Arg and ME-Lys yield the MH^+ and $(M+2H)^{2+}$, the latter type of ions are more intense than the singly charged molecular ions. Similarly, dynorphin (1-7) and dynorphin (1-8) give MH^+, $(M+2H)^{2+}$ and $(M+3H)^{3+}$ ions, the $(M+2H)^{2+}$ ions being the most intense As the ΔV is increased, fragmentation of peptides is also increased For example, only a few fragment ions are seen at ΔV = 30 V for ME (see Table 1) and LE (see Fig. 1). When ΔV is raised to 80 V, most of y- and b- type ions can be discerned easily. On raising the voltage further to 100 V, a complete set of y and b series of sequence determining ions is noted for ME and LE (see Fig. 2 for LE). With respect to LE-Arg, a complete set of a- and z- type ions are seen. ME-Lys provides a complete set of b- and y- type ions In addition, multiply charged sequence determining fragment ions are also observed for these two peptides. For example, complete sets of x- type of LE-Arg and c- type of ME-Lys doubly charged sequence ions are observed (see Fig. 3 for ME-Lys). For dynorphin (1-7), no complete set of sequence determining ion series is found. Fortunately, as the ΔV is changed from 30 to 60, 80 and 100 V, most of the a- and y- type series are observed. Besides, all the doubly charged sequence ions of c- series are also found but are less intense (see Fig 4) For the dynorphin (1-8), a complete set of z- type and most of a- type ions are observed as the ΔV is set at 80 and 100 V Multiply charged sequence determining fragment ions are also noticed.

Electrospray ionization can be readily used to determine the molecular weight of peptide from the multiply charged ions. Furthermore, the strategy of changing the inducing voltage between the sampling cone and skimmer provides the MS-MS-like spectra and can be clearly used for amino acid sequence determination for these enkephalin peptides

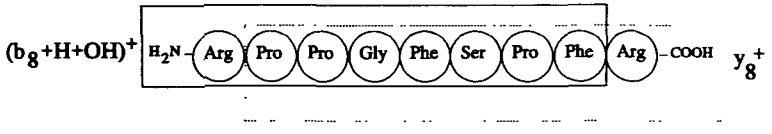
USE OF HIGH RESOLUTION MS^n CAPABILITIES FOR PEPTIDE SEQUENCE DETERMINATION USING A QUADRUPOLE ION TRAP MASS SPECTROMETER

***K.A. Cox and R.G. Cooks, Department of Chemistry, Purdue University, West Lafayette, IN 47907**

Recently developed methods to obtain high resolution and mass measurement accuracy have been combined with the inherent sensitivity and MS^n capabilities of the quadrupole ion trap mass spectrometer for the elucidation of fragmentation mechanisms of some peptides. Generally, the ion trap has less than unit resolution for ions with mass-to-charge ratios greater than 650. However, slowed scan speeds can be employed with the use of an offset/DAC attenuator circuit to dramatically increase the resolution.[1] This method can be used to separate and isolate isotopes of precursor as well as fragment ions in tandem experiments.[2] Calibration methods involving the use of external standards and a peak matching procedure allow masses to be assigned with accuracies generally better than 50 ppm.[3]

These capabilities were utilized in the characterization of bradykinin (MW 1060 dalton) fragmentation. Bradykinin consists of nine amino acids with an arginine residue at each terminus. Since arginine is the most basic amino acid residue, it is assumed to take the positive charge when the peptide is ionized. The MS/MS spectrum of bradykinin reveals a series of structurally characteristic fragment ions including a base peak at m/z 904. This peak corresponds to the loss of an arginine residue from the peptide, but the data is insufficient to determine which terminal arginine is lost.



High energy dissociation methods commonly assign this ion as a y_8^+ (or $Y_8^{\cdot}$) ion, corresponding to the simple cleavage loss of the N-terminal arginine.[4] However, recent reports[5] have suggested that the rearrangement product, $(b_8+H+OH)^+$ [or $(B_8^{\cdot}+OH)$], corresponding to the loss of the C-terminal arginine, dominates in low energy dissociations. An MS^3 experiment was performed on bradykinin (1060 --> 904 --> products) to help determine the structure of the m/z 904 ion. Figure 1 shows the comparison of the MS^3 spectrum of bradykinin with MS/MS spectra of commercially obtained fragments, des arg^1 bradykinin (y_8^+) and des arg^9 bradykinin ($(b_8+H+OH)^+$). The similarity of Figure 1 a) and c) provides clear evidence that the N-terminal arginine retains the charge and the low energy rearrangement $(b_8+H+OH)^+$ ion is formed.

High resolution experiments were used to further confirm this assignment. The ITMS scanning speed was slowed with the offset/DAC attenuator circuit[1] to obtain better than unit resolution of the carbon isotopes of bradykinin. The all-^{12}C isotope was then isolated and dissociated greatly simplifying the product spectrum. Figure 2 compares the all-^{12}C MS^3 spectrum of bradykinin with the MS/MS spectra of the commercial standards. The des arg^1 bradykinin standard shows a very small fragment due to ammonia loss, since the only remaining primary amine is on the arginine carrying the charge. On the other hand, the des arg^9 bradykinin standard leaves the primary amine on the N-terminus, and a much larger ammonia loss fragment is observed. Again, this evidence supports loss of the C-terminal arginine residue.

High resolution experiments on the ITMS require a peak matching calibration method to

be used for mass assignments. A calibration line is constructed relating mass and offset voltage using salt cluster ions as standard masses.[3] Typically, CsI is analyzed as an external standard under the same conditions as the peptide in order to obtain the required calibration. Mass measurement accuracies of less than 50 ppm can be obtained. Greater mass accuracies are attainable when an internal standard is utilized.[3] A split probe tip is used to physically separate the peptide analyte and the salt calibrant, but both are injected simultaneously to eliminate small experimental variations.

Utilization of enhanced resolution capabilities and accurate calibration methods are transforming the quadrupole ion trap into a high performance mass spectrometer capable of analyses of complex reaction sequences.

A MASS SPECTROMETRIC ASSAY FOR THE DETECTION OF PYROGLUTAMIC ACID IN PEPTIDES

Klaus Eckart and Joachim Spiess
Department of Molecular Neuroendocrinology, Max Planck Institute for Experimental Medicine, Hermann-Rein-Str. 3, D-3400 Goettingen

N-terminal pyroglutamic acid (Pyr, Figure 1) plays an important role for the function of many neuropeptides. It has been demonstrated that for example the hypothalamic regulatory peptides thyrotropin releasing hormone (TRH) and gonadotropin releasing hormone (GnRH) require for hypophysiotropic activity the presence of an intact N-terminal Pyr residue. It is probable that the N-terminal Pyr residue is formed during posttranslational processing from intermediate glutaminyl peptides by the enzyme glutaminyl cyclase (QC) which has been earlier structurally characterized by our group (1,2). On the basis of Northern blot analysis (2) it was revealed that the highest amounts of QC mRNA were formed in brain regions such as striatum which to date where not known to contain significant amounts of pyroglutamyl peptides. It was therefore speculated that these regions may produce pyroglutamyl peptides unknown to date.

To identify new pyroglutamyl peptides possibly qualifying as regulatory peptides, we are currently developing a chemical assay which is described in detail in this poster. This assay incorporates the release of N-terminal Pyr from peptides using the enzyme pyroglutamyl aminopeptidase. Pyr is than derivatized to the volatile pyroglutamic acid methyl ester (PyrOMe) in order to enable GCMS detection. We found for this derivative detection limits in the low femtomole range. Possible sources for contaminations are investigated and alternative derivatizations for improved sensitivity are discussed.

Figure 1: Main steps in the Pyr assay procedure

HPLC fractions containing peptides

Digestion with pyroglutamyl amino peptidase

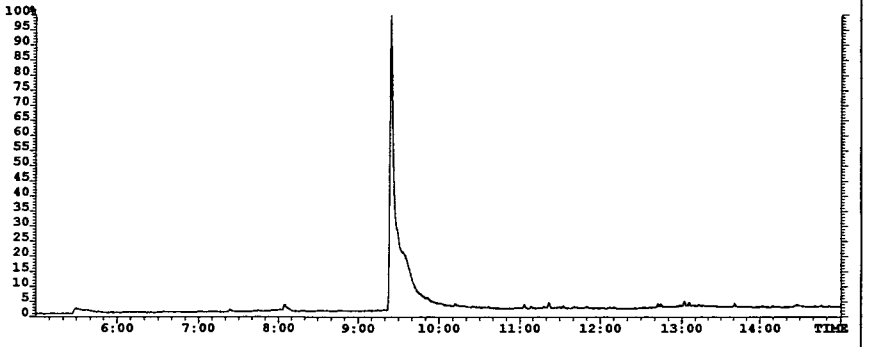
Derivatization of Pyr with diazomethane

Extraction of Pyr with ethyl acetate

Detection of PyrOMe using GCMS

The derivatization of Pyr was performed using diazomethane because of its excellent reactivity and the volatility of the reaction byproduct. Experiments with the synthesized standard compound revealed the best ionization efficiency in EI compared to positive as well as negative chemical ionization. The EI mass spectrum consists mainly of the molecular ion with m/z 143 (10% rel. int.) and the immonium ion of the pyrrolidone moiety with m/z 84 (100% rel. int.). We found using the PyrOMe standard significantly more interferences on the m/z 143 trace compared with the m/z 84 trace. Even the m/z 84 trace represents at 1000 mass resolution after application of 1 pg PyrOMe a noisy base line hampering unambiguous identification. A mass resolution of 3000 was sufficient to obtain a base line allowing the identification of 1 pg or less substrate (Fig. 2). Increasing the mass resolution to 5000 did not improve the sensitivity significantly.

Figure 2: 1 pg PyrOMe injection recorded in the SIR mode on m/z 84 with 3000 mass resolution



GC SIR recordings showed detection limits in the 100 fg (1 fmol) range for the standard compound. Unfortunately, glutamic acid (Glu) contaminating the pyroglutamyl peptide fraction will probably be derivatized to glutamic acid dimethyl ester (Glu(OMe)OMe) by methylation with diazomethane as descibed above. By splitless injection in a heated injection system Glu treated with diazomethane was found to cyclize to PyrOMe on the basis of gas chromatographic and mass spectrometric data. Thus, this chemical assay for the identification of pyroglutamyl peptides is sensitive to (frequently occurring) contamination of fractions with Glu.

The assay requires highly purified solvents. Especially, minor contaminants present in methanol and diethylether seem to be responsible for the formation of interfering products

As an alternative derivative of pyroglutamic acid the Pyr pentafluoro benzyl ester (PyrPFB) is currently tested with negative chemical ionization. Due to the signal to noise ratio of its mass spectrum we anticipated a detection limit in the 1 to 10 fg (3 to 30 attomole) range. Unfortunately, the resolving power of the column used for gas chromatography was quickly lost, probably by substrate absorption which may be enhanced by hydrogen bridges of the lactame ring of the pyroglutamic acid derivative.

In conclusion, it has been observed that pyroglutamyl derivatives can be detected in the low femtomole range by application of GCMS. Therefore, this detection system proved to be a suitable tool in combination with the enzymatic cleavage of the Pyr residue for screening of pyroglutamyl peptides. Problems such as solvent contaminations and possibly glutamic acid cyclization have been addressed. It is expected that derivatization of the lactame nitrogen or the introduction of a cold injection system will reduce the possible cyclization of glutamic acid significantly. Peptides found by this chemical assay will be subjected to sequence analysis with MSMS which will provide sequence information in the low picomole range without prior removal of the Pyr residue.

Interaction between glucose and proteins are relevant processes in both biological and food chemistry fields [1].

The intimate mechanism of such reactions has been proposed to involve a first step in which glucose reacts with free amino groups of proteins to form a labile intermediates (Schiff's base) which undergoes further rearrangements to form a stable adduct usually called "Amadori" product. Its subsequent degradation into a variety of carbonyl compounds, more reactive than the sugar, are responsible for the propagation of the reaction, leading, through a series of rearrangements and dehydration reactions, to yellow-brown, insoluble and fluorescent products, the so called "Advanced Glycation End Products" (AGE)[1]

In the biomedical field these reaction are responsible for the long-term complications of diabetes[1]. In this pathology the high concentration of glucose is responsible for the formation of AGE, indicated as intermediates for cross-linking between proteins [2] and reflecting on severe tissutal modifications.

The relevance of such reactions has induced and induces the development of analytical procedures apt to an evaluation of glycation level of different protein substrates from both qualitative and quantitative points of view

The analytical approaches usually employed pass necessarily through a degradation of the protein (e.g. chemical or enzymatic hydrolysis, pyrolysis): for such reason analytical methods giving information on the intact glycated protein are of high interest.

Matrix assisted laser desorption/ionization (MALDI) mass spectrometry is one of the most powerful methods available for protein structural elucidation [3]. This method is sensitive, rapid and is tolerant of buffers and salts.

In a previous work on glycation of Bovine Serum Albumin (BSA) good results were obtained by MALDI [4]. A clear increase of molecular weight of BSA was found depending on both glucose concentration and incubation time.

In the present paper we report the data obtained by MALDI on the products arising from reaction,under pseudo-physiological conditions, of RNase with two different sugars (glucose and

fructose) at different concentrations (i.e. 0.25 and 0.025 M) for different incubation times (from 0 to 20 days).

The MALDI spectra of samples of RNase incubated with 0.25 M glucose show a progressive increase in molecular weight with respect to incubation time: in fact the maximum of the peak due to RNase passes from 13680 Da at 0 day to 13983 Da at 6 days The latter corresponds to the reaction of 2 molecules of glucose on the protein chain Moreover, after 6 days of incubation, the reaction of 3 and 4 molecules of glucose have been observed, in agreement with what already reported in literature [5] It is to note that just after the addition of glucose (t = 0 day) a small peak, corresponding to the reaction of 1 molecule of the sugar, is well detected With 0.025 M glucose concentration only 2 molecules of sugar react with RNase after 20 days of incubation The glycation reaction is slower, but the presence in the spectra of ions which do not correspond to the simple reaction of glucose suggest that decomposition reactions of the Amadori adducts take place

The MALDI spectra of samples of RNase incubated with 0.25 M fructose are different from those obtained with glucose in the same concentration. A larger peak is always present and, after 6 days of incubation, an indented peak is detected, suggesting that, just after the initial reaction with fructose, decomposition processes take place faster than those observed with glucose With 0 025 M fructose concentration the glycation reaction is slower, but also in this case after 9 days decomposition processes are present. These data are in agreement with literature: fructose reacts faster than glucose in the cross-linking reaction of proteins [6,7].

In conclusion by MALDI technique precious information on extent of glycation can be achieved. Moreover further reactions, different from condensation, can be put in evidence by such technique.

AUTOMATED PEPTIDE MAPPING AND SEQUENCING BY LC/ESI/MS

***K. Mock, I. Mylchreest, M. Hail, M. Sanders, M. Uhrich, I. Jardine**
Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

INTRODUCTION

An ideal system for peptide mapping of proteins includes automated on-line LC/ESI/MS of protein digests on HPLC columns used in conventional chromatography (4.6 mm I.D.) to microbore chromatography (1 mm I.D.) to determine peptide and glycopeptide molecular weight. Towards such a system, we have been able to perform full gradients and the solvent flow to the ESI source was direct at 50 μl/min for a 1 mm column, 200 μl/min for a 2.1 mm column and 1000 μl/min for a 4.6 mm column.

In addition, fragmentation of peptides was generated for structural and sequence information in the capillary-skimmer region of the source, in the rf-only octapole region of the source, and in the octapole collision cell of a triple quadrupole system. The product ion spectra were very similar.

The data obtained demonstrated the ability to now couple single or triple quadrupole mass spectrometers to chromatographic systems for routine use in the biochemistry laboratory with high direct flow rates to the mass spectrometer; and in addition, demonstrate new higher sensitivity.

The combination of LC/ESI/MS with CID sequence information was used as an intelligent tool towards obtaining complete structure information on co-eluting peaks. Examples of proteins used were the protein human growth hormone, cytochrome C, and glycoprotein tissue plasminogen activator.

EXPERIMENTAL

Materials: Tryptic digests of native recombinant human growth hormone, reduced carboxymethylated rt-PA, and cytochrome C were analyzed.

Chromatography: The HPLC systems used in this work consisted of a Michrom (Pleasanton, CA) capable of delivering linear reproducible gradients at low flow rates (e.g. 50 μl/min) and an LDC 4100 for gradients at 1 ml/min. Chromatographic separations were accomplished using Reliasil 150 mm x 1 mm; 150 mm x 2.1 mm; and 150 mm x 4.6 mm columns packed with C18 stationary phase. The mobile phase A consisted of 98% water, 2% acetonitrile, and 0.1% TFA Mobile phase B was 10% water, 90% acetonitrile, and 0.09% TFA.

Electrospray Mass Spectrometry: Experiments were conducted on Finnigan MAT SSQ®710C and TSQ®700 single and triple stage quadrupole mass spectrometers fitted with Finnigan electrospray interfaces (ESI). Collisionally-induced dissociation (CID) spectra of peptides were generated between the capillary and the skimmer, and the API octapole on the SSQ 710C. MS/MS of peptides was generated in the octapole collision cell on the TSQ 700.

RESULTS AND DISCUSSION

Figures 1 and 2 are LC/ESI/MS chromatograms of tryptic digest of cytochrome C. The digest was separated on 150 mm x 1 mm and 150 mm x 4.6 mm columns. Flow rates to the ESI source were 50 μl/min and 1000 μl/min respectively.

Figure 3 is an example of source CID spectra obtained from an on-line LC/MS experiment.

CONCLUSIONS

Due to new developments in API technology, LC/ESI/MS analysis of peptides on single and triple stage quadrupole mass spectrometers:

- is routine, accommodating full LC gradients including TFA with excellent sensitivity.
- the system accepts effluent from 1-4.6 mm HPLC columns as well as packed LC or CE with direct flows 1-1000 μl/min.
- the rf only octapole region provides excellent internal sequence information, with good sensitivity.

Recently electrospray ionization mass spectrometry has been used to study conformational changes in proteins and has been shown to be compatible with deuterium exchange experiments. The rates of exchange and the degree of incorporation can be easily observed as mass shifts during an experiment. Since amide proton exchange is becoming a popular method by which to investigate a protein's structure, the study of simpler systems such as helical peptides and β-sheets is useful for understanding more complex proteins. We have been studying model peptides that are well characterized by a more traditional method, circular dichroism. Peptides designed to be random, α-helical, or β-sheets were investigated. The rate of deuterium exchange can be linked to the stability and extent of the secondary structure. The more stable the secondary structure (the stronger intramolecular interactions) the slower the exchange.

The study of α-helicity consisted of a series of isomeric polyanionic peptides (amphiphilic, helical, and random) that have been characterized by CD and determined to have 98%, 34%, and 17% helicity respectively. Deuterium exchange experiments were performed on these peptides. The measured molecular weight of each peptide vs. time during the deuterium exchange experiment is shown in Figure 1. The observed rates of deuterium exchanged is representative of the peptides structure. The peptide with the greatest amount of helicity experienced the slowest rate of exchange while the most random peptide displayed the fastest exchange rate. To obtain information about the rate of exchange, the data can be plotted as ln(number H's remaining) vs. time. If a peptide experiences first order kinetics then the plot would correspond to a straight line, whose slope would be proportional to the exchange rate, but each amide has a different first order exchange rate, producing a curve instead. The curve can be segmented into groups of amides that exchange with similar rates depicted by linear regions on the graph. Curve fitting the first linear region of the graph of ln(number H's remaining) vs. time, one can calculate the percent helicity from MS data where the y-intercepts represent the initial number of slow exchanging amides. The number of H's in the helix is equal to the number of slow exchanging amides plus 4 (to account for first 4 amides in the helix that can not hydrogen bond). The %helicity equals the number of H's in helix divided by number amides in backbone. This gave rise to amphiphilic 100%, helical 45%, and random 27% helicity. These numbers correspond reasonably well with the information obtained from CD.

Two different peptides Betabellin 12M and Betabellin 14M (single chain thiols) were used to study β-sheets. Air oxidation furnished betabellin 12D and 14D, the disulfide-bridged two-chain protein. All four peptides were used in this study. CD data show that the betabellin 12M, betabellin 12D, and betabellin 14D contained no α-helical but substantial β structure while betabellin 14M was a random coil. Although CD can predict the % helicity from α-helical peptides, equations for predicting the % β-sheet are not reliable. A chemical denaturation using guanidine chloride determined that the order of stability is 12D > 12M > 14D. The dimers are more stable than their respective monomers as a result of an increase in the hydrophobic interaction between the two β-sheets. Deuterium exchange experiments were performed on these peptides. In order to compare the stability of these peptides the mass spectral

information was converted to the % unexchanged amides (number of H's remaining / number of amides in peptide) as a function of time Figure 2. The data indicates that the order of stability is 12D > 12M > 14D > 14M. This correlates to the information obtained from the chemical denaturation of these peptides studied by CD.

Determining the % β-sheet from the mass spectral data (similar to that of the helical peptides) by using the y intercept of the first linear region of the graph of ln(%β-sheet) vs. time (graph not shown) corresponds to 12D 118%, 12M 114%, 14D 96% and 14M 90% β-sheet. These numbers are much higher than expected, especially since 14M is a random coil. The first linear region probably corresponds to amides not involved in the H-bonding network but which do not exchange instantaneously because of neighboring effects. Since 14M is a random coil, the section of the %β-sheet vs time (figure 2) where exchange is slow (after 2 min.) should be indicative of the region β-sheet stabilization for the other peptides. Using the regions of the curves from 2-4 minutes indicates 12D 81%, 12M 80%, 14D 36%, and 14M 25% β-sheet. These numbers are more reasonable. Since amides in turns and in exterior regions are not involved in H-bonding, they should not contribute to the % β-sheet, thus the greatest % of β-sheet that these particular peptides can have is 65-70%. The calculated numbers are probably higher because of some shielding effects on the amides not involved in H-bonding.

We have shown that mass spectrometry coupled with deuterium exchange techniques can be used to determine the relative stability of secondary structures. The results obtained using MS are consistent with those obtained by other methods. Although we cannot distinguish between α-helices and β-sheets by mass spectrometry alone, it may be possible to determine the %α-helix or %β-sheet from the deuterium exchange data. This methodology may prove useful for determining the conformation, structural fluctuations, folding intermediates of a protein, the stability of proteins upon structural modifications, and the effects of ligand binding on an enzyme.

An Atmospheric Pressure Low-Power Microwave Plasma Ionization Source for Liquid Chromatography-Mass Spectrometry (LC-MS)

Nohora P. Vela, Jeffrey J. Giglio and Joseph A. Caruso. Department of Chemistry, University of Cincinnati, Cincinnati, Oh 45221-0172
R. Duane Satzger. U.S. Food and Drug Administration, National Forensic Chemistry Center, 1141 Central Parkway, Cincinnati, OH 45202

Mass spectrometry has developed into a powerful tool for the identification and quantitation of numerous chemical compounds. Because most compounds are thermally labile or non volatile, they are not amenable to GC/MS. There are several LC/MS sample introduction techniques, but most suffer from disadvantages such as high temperatures or introduction of liquid samples into a vacuum system The potential for using microwave induced plasma as a soft ionization source has been previously demonstrated. (1)

The main advantages of this source are that it operates at atmospheric pressure eliminating some of the vacuum pump problems associated with reduced pressure LC/MS sources. It also offers the possibility of obtaining molecular weight information and fragment ions for structural information. This feasibility is demonstrated by varying several operational parameters.

This study demonstrates the effect of microwave power, sample carrier gas flow rate and injector probe configuration in the production of fragment ions using perfluorotributylamine (PFTBA) commonly used for calibration with EI mass spectrometry. A commercial ICP-MS instrument is modified to operate as an MIP-MS system, and there are limitations in the mass range (4 to 246 amu). Response at m/z= 69, 100, 114, 119, 131, 150, 181 and 219 (major fragments in the EI mass spectrum for PFTBA) are selected to monitor the extent of fragmentation obtained with the microwave source.

The use of an injector probe consisting of a stainless steel tube, 1/16" o.d. (Injector Probe "A") produces greater abundance at m/z=69 and minimum of fragments observed at m/z= 219. The use of a ceramic tube inside this stainless steel tube (Injector Probe "B") reduces the interaction between the plasma and the sample with a corresponding reduction in the extent of fragmentation at a given power. A larger diameter stainlees steel tube (1/8") with a ceramic tube inside (Injector Probe "C") used as injector probe produces an increase in the abundance of all fragments. For powers between 22 and 26 w, and considering the limitations in the observable mass range using this quadrupole, there is a shift to greater abundance of higher mass fragments (m/z=219). Ions representing the larger molecular fragments which could not be monitored are expected.

Liquid sample introduction to the MIP is obtained by using a direct injection nebulizer (DIN) that has been designed for ICP-MS. (2) This nebulizer provides a good aerosol, and operates at typical microbore LC flow rates. A 0.025 M tetrabutyl ammonium hydroxide solution is used to demonstrate the possibility of using this nebulizer with the MIP source to obtain structural information in a LC-MS system.

"A COMPARISON OF ANALYTICAL TECHNIQUES (API/MS, GC/MS AND FTIR), FOR THE MEASUREMENT OF COMBUSTION PRODUCTS FROM A VARIABLE-FUELLED AUTOMOBILE"

O.Vega; Universidade de Sao Paulo, IPEN/USP, Sao Paulo, Brazil.
E.Puckrin, W.F.J.Evans, R.J.Hughes and R.E.March
Trent University, Peterborough, Ontario, Canada K9J-7B8

OBJECTIVE: To examine the relative merits of three analytical techniques applied to analyses of gas exhaust from a Chevrolet Lumina car using methanol and/or gasoline fuels. Analytical techniques; 1) Atmospheric Pressure Ionization Mass Spectrometry (API/MS); 2) Gas Chromatography /Mass Spectrometry (GC/MS); 3) Thermal Emission Spectroscopy (FTIR).

I- THE ATMOSPHERIC PRESSURE IONIZATION/MASS SPECTROMETER (API/MS)

The API/MS analyzer was made by SCIEX Co. model TAGA 3000 and utilizes chemical ionization (CI) to produce ions[1].

Evaluation:

The advantages of the API/MS are;

(i) Performs "Real-time analysis" (see Fig. 1).

(ii) Quantitative analysis of methanol; in the CI mode, the methanol concentration can be measured in the range of 500 ppm to 6 ppb.

(iii) Analysis of formaldehyde.

The disadvantages of the API/MS are:

(i) Limitation of the utilization of the H_3O^+ (and $H_2O.H_3O^+$) as CI agents as the proton affinities of these agents exceed those of many combustion products.

(ii) Low detection limits for unleaded gasoline; gasoline is composed mainly of hydrocarbons of relatively low proton affinities.

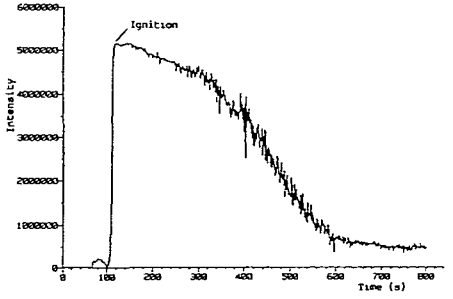

Figure 1: Real-time analysis of protonated methanol (m/z 33) from the M-85 (85% methanol) fuel gas exhaust.

II- GAS CHROMATOGRAPHY/MASS SPECTROMETRY (GC/MS)

The GC/MS analyzer was made by VARIAN Co. model SATURN I which uses an Ion Trap Detector (ITD).

Evaluation: The advantages of GC/MS analysis are:

(i) The range of compounds which could be identified using GC/MS exceeded those of the other techniques discussed here.

(ii) The CI mode presents a greatly simplified mass spectrum, and the degree of fragmentation can be controlled by selection of appropriate protonating agents.

The disadvantages of GC/MS are:

(i) The sorbent/solvent system technique used here blankets the C_2 - C_5 hydrocarbons.

(ii) In this mode, GC/MS does not perform real-time analysis.

III- THE THERMAL EMISSION SPECTROSCOPY ANALYSIS - FTIR

The Michelson-design FTIR analyzer was made by NICOLET Co. (MAGNA-550), having a resolution of 0.1 cm^{-1}.

Evaluation: The advantages of the technique are:

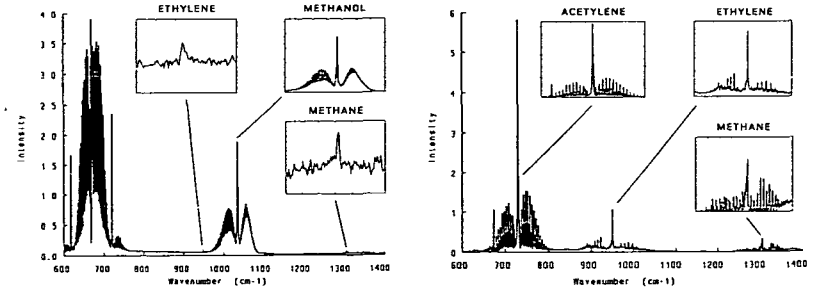
(i) Real-time analysis of the gaseous exhaust products; H_2O, CO_2, C_2H_2, C_2H_4, CH_3OH and CH_4 can be effected (see Fig. 2).

(ii) The light-weight IR emission instrument permits ready portability for analyses outside of the laboratory.

The disadvantages of this technique are:

(i) Emission from compounds other than H_2O, CO_2, C_2H_2, C_2H_4, CH_3OH and CH_4 were not detected.

(ii) Emission data for the observed exhaust gases are sparse.



(a) (b)

Figure 2: FTIR emission spectra, obtained from the Lumina car gas exhaust, fuelled with; a) M-100 (100% methanol) in the absence of water, b) gasoline in the absence of water and carbon dioxide.

CONCLUSION: From the results of the present research the following conclusions may be drawn:

(i) A multi-technique approach must be used in order to extend the range of detectable chemical compounds in gas exhaust analyses from a methanol and/or gasoline fuelled vehicle.

(ii) While methanol as a alternative fuel reduces the production of hydrocarbons, new pollutants (methanol and formaldehyde[2]) are liberated into the environment.

(iii) Real-time analyses of the gas exhaust were performed in this work by API/MS and FTIR.

The Application of HPLC Flow-FAB- and ESI-MS to the Analysis of Pesticide Transformation Products

Robert D. Minard, Guangrui Zou, Jean-Marc Bollag, Penn State University, University Park, PA 16802 and Justin Stroh, Pfizer Central Research, Groton, CT.

INTRODUCTION: The primary goal of this work was to improve the present capabilities for analyzing products from chemical interactions of pesticide-derived anilines and phenols with the organic constituents of soil. The work consisted of two projects:

(1) The assembly of a microbore column gradient HPLC-flow fast atom bombardment (FFAB)-mass spectrometry (MS) system and studies leading to its improved performance.

(2) The utilization of this system for the analysis of the transformation products of the xenobiotic compound 3,4-dichloroaniline and products derived from its coupling with the model humic acid precursor, ferulic acid. Previous research has shown that xenobiotic chloroanilines and chlorophenols can be incorporated into humus substances because of their structural similarity to naturally occurring humic acid constituents (Bollag 1983).

METHODS: A number of parameters are found to be important for achieving the successful operation of combined HPLC-flow FAB-MS. These are shown below along with conditions or interface modifications that were developed in this work. 1.Source temperature, 35-40°C for methanol/water mixtures containing 3% glycerol. 2. Mobile phase flow rate , 30 mL/min (split ratio of 60:1) gave the best compromise between signal intensity and peak width. 3. Sample concentration and injection volume, The best peak shape and sensitivity is obtained at a concentration of ~0.01 M and an injection volume of 3 mL. 4. Peak broadening effects occurring in the LC column and UV detector, Peak widths are approx 10 x's broader than injections directly onto FFAB capillary. 5. Mobile phase degassing , At low flow rates, air is readily absorbed through teflon transfer lines. Use 1/8" O.D. x 1/16" I.D. PEEK tubing. 6. Gradient control for HPLC, The efficiency of solvent blending was improved greatly by using the method of precolumn flow splitting for solvent delivery (Balogh and Stacey 1991).

Enzyme Assay An extracellular enzyme was isolated according to others (Bollag et al. 1979). Enzyme reactions were conducted in 0 1 M phosphate buffer (pH 6 9) with 0 5 unit/mL laccase, 1.0 x 10^{-3} M ferulic acid and 1.0 x 10^{-3} M 3,4-DCA at 30°C for 2 hours. The enzymatic reaction was stopped by adjusting the solution to pH 2.3 with phosphoric acid. The reaction mixture was extracted with an equal volume of ether, the ether extract dried over anhydrous sodium sulfate and evaporated to dryness under a stream of N_2.

High-Performance Liquid Chromatography For the analysis of pesticide transformation products, the dried residue from the enzyme assay was dissolved in 1 mL methanol. Five µL was injected from the injection valve and the reverse-phase separation was achieved on a 30 cm x 1 0 mm Supelcosil LC-18 (bonded octadecylsilane) column of 5 mm particle size. The mobile phase at a flow rate of 30 µL/min was a mixture of aqueous component A (0.5% acetic acid in water, pH 2.75) and organic component B (methanol). Three percent of glycerol was added in both mobile phases as a FFAB matrix. The initial mobile phase composition of 50/50 A/B was held for 5 minutes and then brought to 10/90 A/B in 15 minutes and held at 10/90 A/B for 5 minutes. The column was equilibrated at the initial condition for 30 minutes before each injection.

Flow FAB-MS The 85 cm length of 0.050 mm I.D fused silica capillary (Polymicro Technologies, Inc., Pheonix, AZ) from the flow FFAB probe interface was directly inserted into the 0.030" I.D. x 1/16" O.D stainless steel outlet tubing of the UV detector up to the flow cell exit. The connection between capillary and the stainless steel tubing was not sealed and therefore was at atmospheric pressure. With a pressure differential of one atmosphere across a capillary of these dimensions, the flow in the capillary will be approximately 0.5 µL/min. A split ratio of 1:60 resulted. The FFAB probe used in the system was constructed based on a design by David Smith, Purdue University. A Kratos MS50 RFA mass spectrometer was operated at 4 kV accelerating potential & mass spectra were obtained by magnetic scan at the rate of 3 sec/scan with the range of 130-1500 amu.

HPLC-electrospray-MS The HPLC-electrospray-MS experiment was done by Dr. J. Stroh. A 28 cm x 0.32 mm C-18 column was used for the HPLC separation. (UV detection at 254 nm). The product

mixture of 0 5 mL volume was injected via a micro injector. The mobile phase at a flow rate of 4 mL/min was a mixture of component A (0.1% trifloroacetic acid in water) and component B (80:20:0.075 acetonitrile:water:trifloroacetic acid). The initial mobile phase composition of 50/50 A/B was held for 5 minutes and then brought to 100% B over 30 minutes and held at 100% B for 10 minutes. The column effluent was analyzed on Finnigan TSQ-700 mass spectrometer with an electrospray source. The m/z range 400-2000 was scanned every 2 seconds.

RESULTS: The combined results from HPLC-FFAB-MS and HPLC-electrospray-MS analysis define eight products formed in the reaction of 3,4-dichloroaniline with ferulic acid in the presence of laccase, four of which had been isolated and identified previously(Tatsumi, 1993) Two of these products **1a** and **1b**, are isomeric dimers derived from ferulic acid. A third hybrid dimer, product **4**, involves the loss of the 3-carbon side chain of ferulic acid. Three trimers **2a**, **2b** and **2c** are formed from the cross coupling of two ferulic acids and one 3,4-dichloroaniline. Oligomers derived exclusively from 3,4-dichloroaniline, products **3** and **5**, are also detected in this study but not characterized structurally.

These advantages of HPLC-MS led to the discovery of two oligomerization compounds, **2c** and **4**, not observed by previous off-line analysis.

A QUANTITATIVE STUDY OF CARBAMATE PESTICIDES USING DIRECT INJECTION/ELECTROSPRAY IONIZATION MASS SPECTROMETRY

J. M. Long, U.S. Environmental Protection Agency, Athens Environmental Research Laboratory, Athens, GA 30613
L. J. Sears, Montana State University, Department of Chemistry and Biochemistry, Bozeman, MT 59717

INTRODUCTION

The electrospray ionization (ESI) source, designed and fabricated at MSU, was installed on a VG TRIO quadrupole mass spectrometer. A combination needle was used instead of the conventional stainless steel variety. A gold-coated 50-μm i.d. fused silica capillary was inserted through and ~ 2 mm past the tip of a 0.129-μm i.d. stainless steel needle. Approximately 3 kilovolts potential is applied to the needle producing a spray of charged droplets which is directed toward a resistively heated 20-cm stainless steel transport capillary (0.5mm i.d.) through which the analyte ions enter the ESI source. This transport capillary is held constant at a potential of 65 volts (v) to minimize analyte fragmentation. The ions after leaving the transport capillary are focused through a set of five electrostatic lenses into the analyzer region of the mass spectrometer. These lenses and their potentials are: skimmer (+11 v), extractor (-16 v), focus 1 (+6 v), focus 2 (+11 v), focus 3 (-80 v), and focus 4 (-18 v). Using this ESI a quantitative study of carbamate pesticides spiked into Yellowstone River water was carried out.

EXPERIMENTAL

Environmentally significant compounds (~ 100 - 500 daltons) such as pesticides/herbicides that are polar, nonvolatile and thermally labile are not readily analyzed by conventional gas chromatography/mass spectrometry (GC/MS). A viable alternative is ESI. This technique was used to quantitatively determine carbamate pesticides spiked into Yellowstone River water. The pesticides studied were carbaryl, carbofuran, methomyl, methiocarb and propoxur. Standard curves were generated for the pesticides in 50/50 mixture of methanol/water both individually and collectively and then various spikes within the analytical range of ~ 0.1 to 20 ng/μL were analyzed similarly. Blank samples were also run and showed no evidence of contamination from these pesticides. The solutions of pesticides in Yellowstone River water were buffered with acetic acid/ammonium acetate to a pH of ~ 5 to minimize matrix effects. Individually spiked samples, after being filtered through 0.45-μm Millipore filters, were diluted to the desired concentration with 50/50 methanol/water and then injected directly into the electrospray ionization interface through a Rheodyne injector valve connected to a 50-μm i.d. gold-coated fused silica transport capillary that measured 10 cm in length. This same procedure was used for the collectively spiked samples without the use of any separation techniques. The solution flow rate was maintained at 2 μL per minute using a Sage syringe pump. The interface was maintained at a temperature of 85 °C and a potential difference of 50 v between the skimmer transport capillary and the skimmer lens was used to maximize the $[M+H]^+$ intensity. Figure 1 shows the ESI spectrum of a collectively spiked sample.

RESULTS AND DISCUSSION

Correlation coefficients for all the calibration curves generated for both the individually and collectively spiked samples were on the order of 0.90 indicating good linearity over the analytical range covering 2 to 3 orders of magnitude. The actual ion counts from individually spiked samples agree within a factor of less than 1.5 with predicted values. Those from collectively spiked samples agree within an order of magnitude with predicted values. This is not unusual and can be explained in terms of matrix effects in the collectively spiked samples. Improvements in these results could probably be made by changing the pH of the buffer system. This work indicates that direct injection/ESI shows promise as a candidate for a rapid method for screening natural waters for pesticide contamination. The minimum concentrations detected in these samples were 0.2 ng/μL and 2 ng/μL in the individually and collectively spiked samples, respectively.

This work on the carbamate pesticides is part of a larger study. Thirty pesticides from 13 different classes were analyzed using ESI/MS. Addition of acid to those pesticides, including these carbamates, produced ion signals that were no more intense than those from the neat samples. This observation and the fact that the majority of these pesticides have extremely low pK_{BH}^+'s, as calculated by SPARC, indicate that many of the protonated analyte ions of these pesticides are formed in the gas phase rather than in the condensed phase. This is the first reporting of this gas phase phenomenon of protonated ion formation.

Sensitivity Enhancement in API/MS *via* Gas-Phase Derivatization

R.J.Hughes, R.E.March and P.J. Popp, Department of Chemistry
Trent University, Peterborough, ON, CANADA, K9J 7B8
J.M.Goodings and D.K.Bohme, Department of Chemistry
York University, Downsview, ON, CANADA, M3J 1P3

Our objectives were to collaborate with the Ontario Ministry of the Environment, Air Resources Branch, in order to investigate the possibility of enhancing the sensitivity of their mobile mass spectrometers (Sciex TAGA series) towards certain classes of compounds of environmental interest. The nature of this collaboration was threefold:

1) to investigate the role played by gas-phase chemistry in atmospheric pressure chemical ioniziation (APCI)
2) to suggest modifications to the conventional APCI/MS instrument
3) to suggest alternative methods and protocols for the analysis of problem compounds

A new source arrangement was designed based on the results of our initial experiments. The new source is depicted below and incorporates the following modifications:

1) The sample is injected through a hypodermic needle directly into the corona discharge region which is contained in a glass tube and flooded constantly with high-purity dry air.
2) Samples may be reacted in the gas phase with reagent gases during passage through the heated reactor tube in order to produce derivatives with higher proton affinities and/or more stable hydrates.

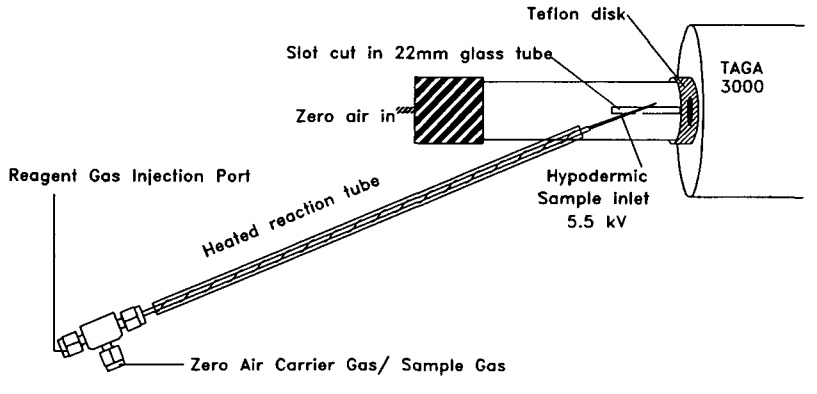

Figure 1 The Low-Volume Heated Reactor Source.

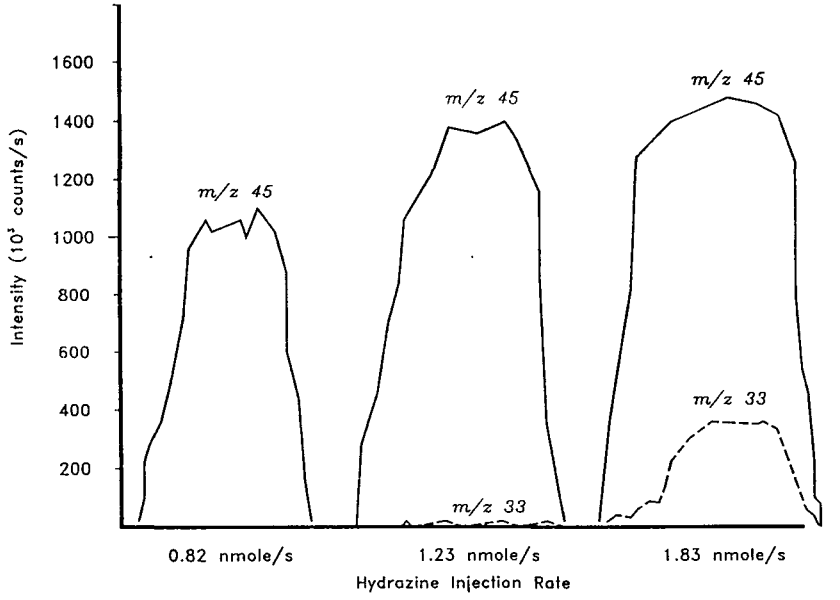
In the dry air environment of the heated reactor source the dominant ionization process appears to be charge exchange ionization with N_{2+} and O_2^+ in the corona discharge region. The resulting mass spectra resemble closely the electron ionization (EI) mass spectra and have been described as *pseudo*-EI mass spectra. These *pseudo*-EI mass spectra are less dependent on the relative proton affinities of the target analytes and may be useful in the detection and quantitation of ion species which produce relatively low signal intensities in conventional proton transfer APCI. For example, a flow of 1 nmole/s of formaldehyde through the heated reactor source produces an ion signal of approximately 10^4 ion counts/second. At this concentration the signal from formaldehyde is not detected in the normal APCI mass spectrum.

By utilizing the gas-phase neutral derivatization reaction of formaldehyde with hydrazine the signal intensity of the hydrazone reaction product is raised to approximately 4×10^6 ion counts/nmole.

Furthermore, the gas-phase neutral derivatization reaction allows one to perform a gas-phase titration. Hydrazine reacts with formaldehyde in the gas phase to produce a product ion signal at *m/z* 45; any excess hydrazine which does not react produces a signal at *m/z* 33. Shown below are the ion signals from both *m/z* 45 and *m/z* 33 in an air sample which contains formaldehyde and hydrazine vapour. The formaldehyde flow rate was 1nmole/s, and it can be seen that the protonated hydrazine signal appears as its flow rate exceeds 1 nmole/s. Such a procedure could be used to determine the approximate concentration of formaldehyde in air in real time.



THE APPLICATION OF THERMOSPRAY LC/MS TO THE ANALYSIS OF SMALL ORGANIC ACIDS IN MIXED HAZARDOUS WASTES

INTRODUCTION

The Hanford reservation is a 560-square-mile site located approximately 120 miles southwest of Spokane, Washington and 220 miles southeast of Seattle, Washington. The Hanford site was built by the Army Corps of Engineers and the Du Pont Corporation in 1943 to produce plutonium for nuclear weapons in support of World War II. The facility was very successful; within two years after its conception, Hanford had supplied the plutonium used for the bomb dropped on Nagasaki in World War II. Plutonium production continued after the war until January 1987 when the last production reactor ceased operation at the Hanford site. Nine production reactors and five reprocessing facilities operated at the Hanford site to support that mission. These operations created a large quantity of radioactive wastes, much of which was and continues to be stored in underground storage tanks.

There are 177 high-level waste storage tanks at Hanford. Of these, 23 tanks are being watched closely because of the possibility that flammable gas mixtures are being produced from the mixed waste contained in the storage tanks. One tank in particular, Tank 241-SY-101, has exhibited episodic releases of flammable gas mixtures since its initial filling in the late 1970s.

Studies of simulated waste mixtures (SWM) have indicated that the gas generation and retention are influenced by chelator concentration. It was postulated that the chelators form hydrophobic surfaces on solids in the SWM. These hydrophobic surfaces are more conducive to bubble attachment, which leads to flotation of the solids and eventually crust formation. The presence of chelators becomes very important for the understanding of crust formation and gas release. Among the degradation products of the chelators are a number of small organic acids, some of which may be linked to the production of flammable gases such as hydrogen and which also possess chelating properties. As a result, we have analyzed actual waste samples from Tank 101-SY for small organic acids.

EXPERIMENTAL

MS

The thermospray analyses were performed using the HP 5988A LC/MS in the isocratic mode. The ion source was 275° C and the stem initial temperature was 100° C. Typical values for the tip and the vapor were 230° C and 272° C, respectively. Filament operation was in both the on-and-off modes. The multiplier voltage was 2692 V and the scan range was either 79-500 or 92-300 amu, depending on the mixtures being analyzed. The injection volume was either 10µL or 20 µL, depending on the concentration of the sample. The instrument was tuned with polyethylene glycol (PEG) tuning solution to give maximum abundance of ions. It should be noted that the thermospray ion source should be cleaned approximately once a week to remove nonvolatile chloride salts resulting from the use of HCl as the mobile phase. Also, water was

flushed through the entire system at the end of the day. As long as these cleaning and flushing procedures were followed, no detrimental effects of the thermospray or chromatographic equipment were observed.

LC

A Bio-rad HPLC Organic Acids column, Aminex Ion Exclusion, HPX-87H, 300 X 7.8 mm, with compatible guard column was used. The mobile phase for this part of the work was 0.001 N HCl (isocratic). The LC oven temperature was 40°C and the flow rate was 0.6 mL/min. A typical run time was 25 min. Organic acids were analyzed using both direct flow injection and through the analytical column.

RESULTS AND DISCUSSION

The thermospray mass spectra for citric acid and glycolic acid are shown in Figures 1a and 1b, respectively. The total ion chromatogram of an actual waste sample is shown in Figure 2. Figures 2a and 2b show the extracted ion plots of citric acid and glycolic acid, respectively in this sample. In addition, a small contribution from acetic acid is visible at about 16 min.

Research is now focusing on identification of the other peaks in the waste sample, particularly the large peaks at 7 and 8-9 min. Other acid standards obtained through commercial sources or synthesis are being used for this purpose. Diglycolic acid has been tentatively identified as the peak at 7.75 min. Some constituents are clearly co-eluting. Future work will also involve analysis of waste samples taken from different layers in the tank. The composition does not appear to be uniform from top to bottom.

**This work was supported by the Department of Energy under contract DE-AC06-76RLO 1830. Pacific Northwest Laboratory is operated by Battelle Memorial Institute.

Capillary Liquid Chromatographic Mass Spectrometric Identification of Arsenic Compounds used as Animal Feed Additives

S. A. Pergantis, W. R. Cullen and G. K. Eigendorf
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Z1

INTRODUCTION

A number of arsenic compounds are approved as additives in feed for poultry and swine. Information concerning the biotransformations of these compounds is very limited. The majority of studies performed to date have been concerned with total uptake and/or excretion of arsenic by animals. The objective of this study is to investigate methods capable of separating and identifying these arsenicals and their metabolites in order to obtain conclusive information concerning the biotransformations of these compounds.

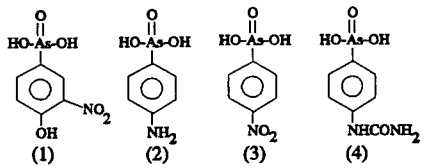

Figure 1 Arsenicals used as animal feed additives for poultry and swine.

METHODS

Capillary columns in a variety of lengths (8, 14.5 cm) and 0.32 mm ID were fabricated and slurry packed with C18 packing material (Spherisorb 3 micron ODS2). Both the microbore (250 mm x 1 mm ID) and the conventional (100 mm x 4.6 mm ID) HPLC columns were C18 Spheri RP-18 (BrownLee Labs). For the Direct Liquid Introduction (DLI) - MS experiments a Nermag R10-10B quadrupole mass analyzer equipped with a desolvation chamber and a cryopump was used. The capillary column was coupled directly to the ion source via a DLI probe equipped with a nickel diaphragm nebulizer. A Kratos Concept II H mass spectrometer was used for off-line Liquid Secondary Ion Mass Spectrometry in both negative and positive detection modes. For the thermospray MS a Kratos MS 80 mass spectrometer was used. A dual syringe pump (Applied Biosystems, Model 140B) was used for the capillary and microbore columns, while a Waters 510 reciprocating pump was used for the conventional columns.

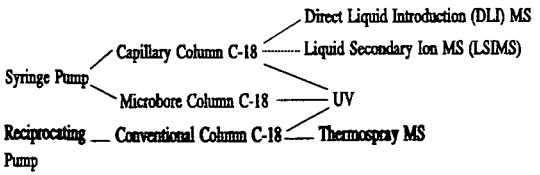

Figure 2 Methods used for the separation and identification of arsenicals used as animal feed additives.

RESULTS

All three column types (capillary, microbore and conventional) showed similar performance characteristics, i.e. resolution, efficiency, although the capillary column allowed for improved detection limits, compared to the others, when used in conjunction with a UV detector.

Figure 3A presents the capillary LC - UV chromatogram of the arsenicals used as animal feed additives, while Fig. 3B contains an additional arsenical (4-Hydroxy), a possible metabolite of 3-Nitro.

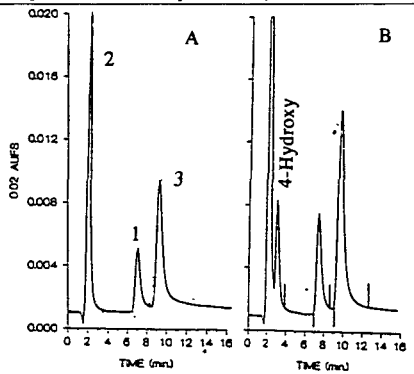

Figure 3(A,B). Capillary LC - UV chromatogram of arsenical mixture

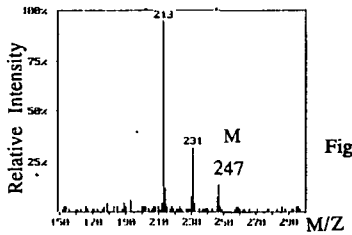

Figure 4. DLI - MS of 4-nitrophenylarsonic acid, mobile phase: water/methanol 90/10, Flow Rate: 20 μL.min^{-1}.

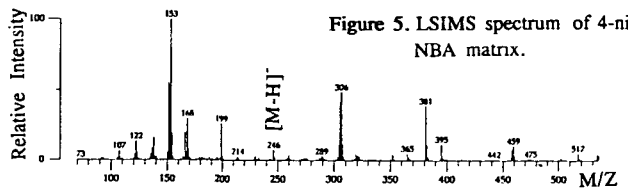

Figure 5. LSIMS spectrum of 4-nitrophenylarsonic acid, NBA matrix.

LSIMS gave spectra that contained the following m/z patterns: $[M+H]^+$, $[M+NBA-H_20+H]^+$, $[M+2NBA-2H_2O+H]^+$ in positive mode, and $[M-H]^-$, $[M+NBA-H_2O-H]^-$, $[M+2NBA-2H_2O-H]^-$ in negative mode (NBA: 3-nitrobenzylalchohol, used as LSIMS matrix).

It was only possible to obtain spectra in negative detection mode for these compounds under DLI-MS experimental conditions.

Thermospray MS spectra resulted in base peak protonated molecular ions, for all the arsenicals analyzed, along with very little fragmentation.

CONCLUSION

The separation and identification of animal feed arsenicals and their metabolites can be achieved with great success using a combination of LC columns and MS techniques. In this study we have shown that these arsenicals exhibit great differences in behaviour when analyzed under different MS techniques (DLI, LSIMS and Thermospray).

Future work will involve the direct coupling of capillary LC to dynamic LSIMS.

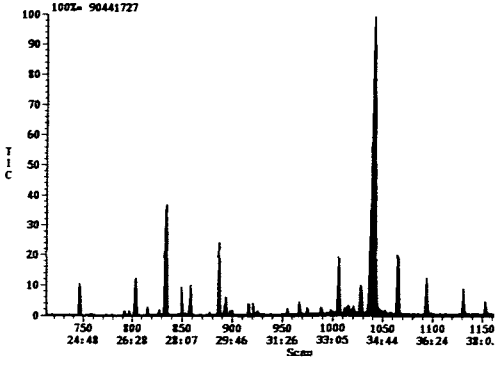
Short Path Thermal Desorption GC-MS for the Analysis of Sodium Carbonate and Sodium Bicarbonate

Noreen A. Klitus* and Ronald E. Shomo, II
FMC Corporation, Agricultural Chemical Group, Analytical Department,
Princeton, New Jersey 08543

Short path thermal desorption GC-MS has dramatically changed the process we use for analyzing volatiles and semi-volatiles of solids in our laboratory. Previous to the short path thermal desorber, an extraction was performed on solids before analysis by GC-MS. This was a time consuming task, and some volatiles were lost in the process.

Our current method is less labor intensive and more of the volatiles are observed by this procedure. Typically a preconditioned (heated to 300 C for 4 hours while dry Nitrogen is passed through the tube) 3 mm id GLT desorption tube is loaded with 10-50 mg of sample. A short fused silica lined SS needle is attached and the tube is placed on the desorber. The needle is injected into the GC injection port and the tube is ballistically heated while carrier gas (He in our case) is passed through the tube into the GC. The GC is cooled to -10C to cryogenically focus the volatiles while the desorption is in progress. After the predetermined desorption time, the needle is retracted and the GC temperature ramp is activated. In our case we used the following temperature program: -10 C held for 5 minutes (the desorption period) ramped to 40 C at a rate of 10 C/minute, than heated to 250 C at a rate of 5 C/minute which was held for 15 minutes. The GC column was a DB-5 0.25 mm id by 30 M with a 0.25 µm film thickness.

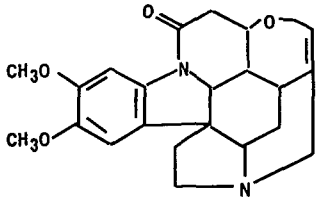
Figure 1 shows the TIC of a commercially available sodium carbonate and sodium bicarbonate based pet deodorizer.



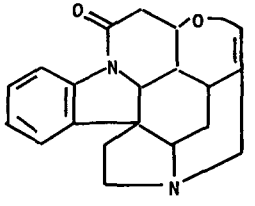
Thermospray LC-MS measurement of brucine in serum and urine

William J. Driskell, Robert H. Hill, Jr., Marianne Gregg, and Sandra L. Bailey
Center for Environmental Health and Injury Control
Centers for Disease Control and Prevention
Public Health Service, U.S. Department of Health and Human Services
Atlanta, Georgia 30333, USA

Denatured alcohol is used in many cosmetic products readily available to the public. One of the most common denaturants is brucine, an alkaloid poison that is a derivative of strychnine. Most commonly used in cosmetic products is the formula "SD alcohol 40", which contains 230 ppm brucine. We developed a thermospray LC-MS method to measure brucine levels in human serum and urine.



Brucine

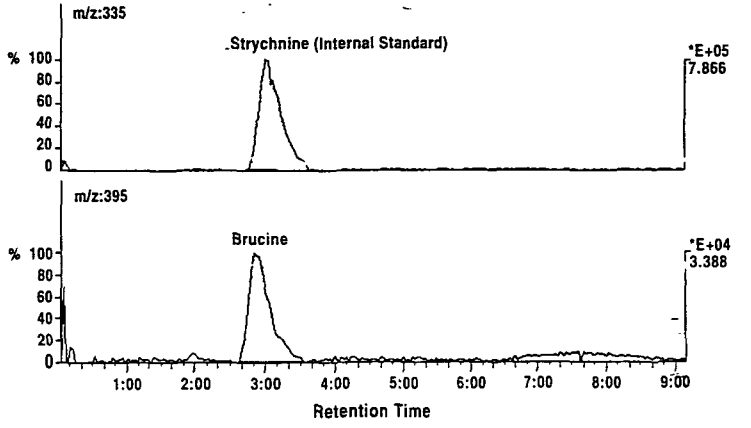


Strychnine

Serum or urine was extracted as follows: Add to 1 ml of urine or serum 10 uL of the internal standard strychnine sulfate (0.2 ug/uL in methanol). Add 0.5 ml of saturated sodium bicarbonate and vortex. To this mixture add 2 ml organic solvent (toluene:n-hexane:isoamyl alcohol; 76:20:4). Repeatedly invert tubes gently for 1 min. Remove the organic layer and evaporate to dryness using a Savant vacuum concentrator. Reconstitute the residue in 100 uL of mobile phase and inject 25 uL.

The chromatography was done with a Hamilton RP-1 reverse phase 15 x 0.4 cm column which was eluted isocratically with a mobile phase of 80% methanol, 19.9% water, and 0.1% acetic acid. The flow rate was 1 ml/min. A UV detector measuring absorbance at 254 nm was online in front of the mass spectrometer. The HPLC equipment consisted of a Waters 600 HPLC pump and controller, a 490 MS UV detector, and a U6K injector. For thermospray the vaporizer was set at 100 C and the block at 240 C. We used filament ionization and alternating single ion monitoring scans of the MH+ ions, 335 amu for strychnine internal standard and 395 amu for brucine. We used a Finnigan TSQ-70 triple quadrupole mass spectrometer with thermospray inlet.

LC-MS Trace of a 1 mL Urine Sample Spiked at 25 ppb with Brucine



Quantitation is by internal standard quantitation with a strychnine internal standard using response factor averaging with standards equivalent to urine or serum concentrations of 10 ppb to 2500 ppb. The range of linearity is from 10 ppb to 2000 ppb. The extraction efficiency from serum or urine is between 70% and 80%. The detection limit is 10 ppb in 1 ml of urine or serum.

We plan to use this method to evaluate brucine as marker for exposure to denatured alcohol (specifically, SD alcohol 40) in cosmetic products. In addition to a marker role, serum or urine brucine levels may be of intrinsic interest, since brucine is toxic, though less toxic than strychnine. Relating health effects to brucine levels is not possible now since there is little information on brucine poisoning incidences.

Formation of Dialkyl- and Diaryl-tin Buffer Adduct Ions Under Electrospray-LC/MS Positive Ionization Conditions.

*T. L. Jones and L. D. Betowski, U.S. Environmental Protection Agency, Las Vegas, NV, 89193-3478.

INTRODUCTION

The organotins, mainly the triaryltins and triphenyltins, have widespread application as fungicides, anti-fouling coatings for porous and non-porous surfaces, herbicides, and insecticides.[1] It is important to be able to differentiate the organic functional groups, as they can impart varying levels of toxicity to different organisms.[1] Other researchers have used ion-spray (IS) mass spectrometry to characterize the alkyl- and aryl-tin isomers under negative ionization conditions[2] and to isolate tributyltin from a sediment reference material.[3] Under electrospray-LC/MS positive ionization conditions we are able to collect distinctive spectra of the dialkyl- and diphenyl-tins.

METHODS

Electrospray/mass spectrometer. All experiments were performed on a Vestec 201 LC-MS System equipped with a Vestec electrospray probe and source. The optimal ES positive ionization conditions were determined to be: 2.0kV, needle voltage; 220V, nozzle voltage; and 12V, skimmer cone voltage.

Liquid chromatograph/mass spectrometer. A Waters 600MS liquid chromatograph, converted for very low (2 to 4 μL/min) flow rates and a Rheodyne injector, equipped with a 5-μL loop was used to introduce the samples. The probe was interfaced to the ES probe with approximately 25-cm of uncoated 100-μm i.d. fused silica capillary column (FSCC). Eluting conditions were 100% methanol with either 1% acetic or formic acid added as a buffer.

RESULTS AND DISCUSSION

Tin has ten isotopes. In the discussions to follow, only the most abundant ion of the cluster will be mentioned. The results are summarized in Tables 1 and 2.

Acetic acid buffer

The dibutyltin dichloride (DBT, MW = 302 amu) spectrum had as the base peak the acetic acid substitution ion $(M\text{-}2Cl+CH_3CO_2)^+$. Also present, were the dibutyltin ion, $(M\text{-}Cl)^+$, and a small contribution from the $(M\text{-}2Cl+H)^+$ ion.

The spectrum of dimethyltin dichloride (DMT, MW = 218 amu), had as the base peak the acetic acid substitution ion, $(M\text{-}2Cl+CH_3CO_2)^+$. The other ion present is the dimethyltin ion, $(M\text{-}Cl)^+$.

In the spectrum of diphenyltin dichloride (DPT, MW = 342 amu) the base peak was the diphenyltin acetic acid substitution ion, $(M\text{-}2Cl+CH_3CO_2)^+$. There were also contributions from the diphenyltin ion, $(M\text{-}Cl)^+$ and the phenyltin acetic acid ion, $(M\text{-}C_6H_5\text{-}Cl+CH_3CO_2)^+$.

Formic acid buffer

In the formic acid buffer spectrum of dibutyltin dichloride, the base peak was the dibutyltin ion, $(M\text{-}Cl)^+$. Also present in the spectrum was the formic acid substitution ion, $(M\text{-}2Cl+CHO_2)^+$.

In the spectrum of dimethyltin dichloride the base peak was the dimethyltin ion, $(M\text{-}Cl)^+$. Also present was the formic acid substitution ion, $(M\text{-}2Cl+CHO_2)^+$.

The diphenyltin dichloride spectrum was similar to the other two dialkyltin spectra. The base peak was the diphenyl ion, $(M\text{-}Cl)^+$, and present was the formic acid substitution ion, $(M\text{-}2Cl+CHO_2)^+$.

CONCLUSIONS

Detection of the organotins was enhanced by the use of acetic acid buffer. Both acetic acid and formic acid give substitution ions when htey are used to elute these compounds. In the spectra the $(M\text{-}Cl)^+$ ion was the base peak when formic acid was used as the buffer. The substitution ion was the base peak when acetic acid was utilized.

Table 1. Mass-to-charge ratios of Organotins (12V repeller voltage; formic acid buffer)

compounds	Most abundant ion fragment	Other fragment ions*
dibutyltin dichloride	269 $(M\text{-}Cl)^+$	279 [34] $(M\text{-}2Cl+CHO_2)^+$
dimethyltin dichloride	185 $(M\text{-}Cl)^+$	195 [22] $(M\text{-}2Cl+CHO_2)^+$
diphenyltin dichloride	309 $(M\text{-}Cl)^+$	319 [47] $(M\text{-}2Cl+CHO_2)^+$

* Intensities relative to the most abundant ion are given in [ ].

Table 2. Mass-to-charge ratios of Organotins (12V repeller voltage; acetic acid buffer)

compounds	Most abundant ion fragment	Other fragment ions*
dibutyltin dichloride	293 $(M\text{-}2Cl+CH_3CO_2)^+$	269 [33] $(M\text{-}Cl)^+$ 235 [10] $(M\text{-}2Cl+H)^+$
dimethyltin dichloride	209 $(M\text{-}2Cl+CH_3CO_2)^+$	185 [22] $(M\text{-}Cl)^+$
diphenyltin dichloride	333 $(M\text{-}2Cl+CH_3CO_2)^+$	291 [13] $(M\text{-}Cl\text{-}C_6H_5+CH_3CO_2)^+$ 309 [19] $(M\text{-}Cl)^+$

Analysis of Ionic Textile Dyes Using Ionspray CE/MS and MS/MS.*

M.D. LeBlanc and L. Ramaley, *Dept. of Chemistry, Dalhousie University, Halifax, Canada B3H 4J3;* R.K. Boyd and P. Thibault, *National Research Council, Halifax, Canada B3H 3Z1;* A. Dietrich, *Virginia Polytechnical Institute and State University, Blacksburg, VA 24061-0246.*

Sulfonated azo dyes are commonly used in the textile industry, and pose environmental problems. Thus, they affect the ecosystem by virtue of their intense light absorption, algal growth and aquatic life are adversely affected, and both the dyes and some of their degradation products (*e.g.* aromatic amines) have been shown to possess mutagenic and carcinogenic properties [1].

Considerable effort has been devoted to developing mass spectrometric procedures for analysis of these dyes and their degradation products in water and wastewater [2-8]. All of these procedures have exploited the facile formation of negative ions from these sulfonated compounds, by LSIMS or Thermospray, or by electrospray and ionspray ionization. Some of these investigators developed LC/MS methodologies. Lee *et al.* [7] exploited the high resolution separatory capability of capillary electrophoresis (CE), for such highly ionized analytes, in a pioneering effort using CE/MS (ionspray ionization).

The present work has extended the approach of Lee *et al.* [7]. All CE development work (Beckman P/ACE instrument) used UV detection at 200 nm in order to ensure detection of impurities with no strong chromophore in the visible -near UV region of the spectrum. It was necessary to find a robust CE buffer system, compatible with negative ion ionspray ionisation (SCIEX API III triple quadrupole). Figure 1a shows a TIC electropherogram obtained by CE/MS for a commercial preparation of Remazol Black B (structure shown, molecular mass of neutral M is 903 Da). Figure 1b shows the mass spectrum acquired at the crest of the major peak in Fig.1a. The spectrum is consistent with formation of doubly-charged anions $[M\text{-}nH+(n\text{-}2)Na]^{2-}$, for n = 4 (m/z 472.5) and n = 3 (m/z 461.5). Also evident is a similar series of ions 120 Da (*i.e.* 60 m/z units), which correspond to expulsion of $NaHSO_4$ in the orifice-skimmer region of the ionspray interface. Support for this assignment was obtained by MS/MS (not shown), in which an intense fragment at m/z 97 corresponded to HSO_4^-, confirming the presence of the sulfate ester groups (see the Remazol Black structure).

When hydrolyzed in base, Remazol Black B yielded a product showing only one set of doubly-charged anions separated by 11 m/z units (replacement of H by Na). No peaks corresponding to expulsion of $NaHSO_4$ were observed. This observation, and the deduced value of 743 Da for the molecular mass of the hydrolyzed product, are consistent with its postulated structure [10], in which the sulfate ester groups are hydrolyzed to the corresponding alcohols. Fragment ion spectra of the $(M\text{-}H)^-$ and $(M\text{-}2H)^{2-}$ ions are shown in Figures 2a and 2b, respectively. Fig.2a is sparse, but Fig.2b shows extensive fragmentation, most of which can be reasonably interpreted as consistent with the proposed structure [10]. The fragment ions at m/z 80 and 81 correspond to $SO_3^{\cdot-}$ and HSO_3^-, characteristic of sulfonates; no HSO_4^- at m/z 97 is observed.

Using these results as a guide similar experiments on an unknown red dye, believed to be structurally related to Remazol Black B, have been interpreted in terms of postulated structures for the dye and its hydrolysis product. Confirmatory experiments are in progress.

Characterization of Maillard Reaction Products by Capillary Electrophoresis-Mass Spectrometry

L.M.Benson, A.J.Tomlinson, K.L.Johnson, G.F.Scanlan and S.Naylor

Biomedical Mass Spectrometry Facility, Dept. of Biochemistry and Molecular Biology and Dept. of Pharmacology, Mayo Clinic, Rochester, MN 55905, USA

Maillard chemistry is the non-enzymic browning reaction of amino acids/peptides/proteins with reducing sugars. Such reactions are important in the formation of flavor, color, mutagens and antioxidants as foods are cooked. The role of this chemistry in the ageing process of humans has also been postulated.

The matrix of reactions known to occur in Maillard chemistry is complex, and that the products formed (Maillard Reaction Products - MRP's) are hydrophilic and structurally similar. We investigated the model reaction system of 5-hydroxymehylfurfural with glycine by capillary electrophoresis (CE)-ESI-MS.

We characterised a number of such MRP's by this method (Table 1). However, using ^{15}N-labelled glycine we were also able to show that in the ESI process cluster ions are formed during the spraying/evaporation process (see Figure 1). A 1:1 mixture of ^{14}N:^{15}N-labelled glycine with 5-HMF gave isotope distributions that were consistent with cluster formation.

Figure 1. Labeled CE-MS Studies of a Maillard Reaction

CAPILLARY ELECTROPHORESIS/ELECTROSPRAY MASS SPECTROMETRY OF SOME HAZARDOUS INDUSTRIAL AND AGRICULTURAL CHEMICALS.

Capillary electrophoresis (CE) coupled to electrospray mass spectrometry (ES) has been applied to environmentally important agrochemicals and industrial diisocyanates which are hazardous to human health. The aims of the investigation are to provide structural specificity, to optimise detection limits and to achieve quantification.

The very low flow rates observed in CE (10 - 40 nl/min) and the higher flow rate (5 - 400 µl/min) required for ES obviate the need for effluent splitting but necessitate a make-up flow. For CE the aqueous phase normally contains an involatile buffer which is detrimental to the ES source. As the solution is diluted considerably for CE/ES, the effect is not serious for involatile buffers such as creatinine and phosphoric acid at low concentration.

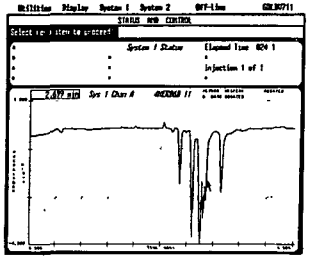
Two CE instruments were used for CE/ES work. The ISCO 3850 system coupled to a VG Quattro instrument and the Beckman P/ACE 2100 interfaced to a VG Platform mass spectrometer. Both CE/MS systems, were equipped for electrospray via a triaxial flow probe interface.

Pesticides such as paraquat and diquat when sprayed as a composite, produce an effective contact herbicide used for weed control and pre-harvest desiccation. In this process accidental human exposure may occur. More commonly, exposure is a result of suicide attempts. We have shown them to be separated rapidly by CE at pH values of 3 to 4. As the pesticides are dicationic, only the doubly charged species, M^{2+}, might be expected to be observed by ES, but both doubly and singly charged species can be seen by manipulation of the source parameters. It is postulated that the singly-charged ions result from electron donation by acetate ions in the make-up flow. This observation illustrates the known action of these pesticides as electron acceptors and provides more specific mass spectral information.

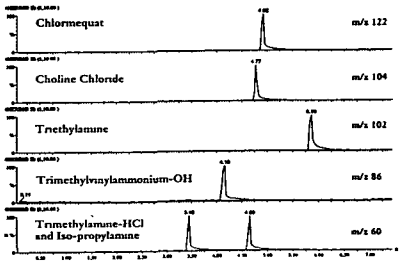
At the present time a convenient analytical procedure for analysing non-chromophoric herbicides such as Chlormequat $[HOCH_2CH_2(CH_3)_3N^+]$ and Choline chloride $[ClCH_2CH_2(CH_3)_3N^+]$ in real samples does not exist. The techniques of CE and CE/ES have been used to examine these compounds, their known by-products and appropriate internal standards. For CE, the visualisation of these non-chromophoric herbicides involves indirect UV detection.

The buffer used contains a highly chromophoric agent (creatinine) to provide a large background absorbance. The migration of samples past the UV window causes a decrease in this absorbance, figure 1. When using CE/MS, each quaternary ammonium species is identified unambiguously by its cation in the ES spectrum, (figure 2) despite the low mass ions associated with chemical background.

CE electropherogram of the herbicide mixture illustrating indirect UV detection



CE/ES of 4 Herbicides and 2 Standard Amines



The CE and CE/ES methods applied to these pesticides and herbicides may be exploited in the UK in connection with the enforcement of FEPA (Food and Environmental Protection Act) and COPR (Control of Pesticide Regulations) by the determination of concentrates. Typically, limits of detection were 5 ppm and linear calibration graphs were obtained (all correlation coefficients were over 0.995).

Hazardous industrial diisocyanates are currently trapped from the air and simultaneously derivatised with an aryl-substituted piperazine to produce uv- and electrochemically-active bases which are determined by dual detection HPLC. The accuracy and reliability of the instrumental procedure are under question. We have shown that the same derivatives, which are cations in acidic solution, can be determined rapidly by CE and CE/MS. For example, 4,4'-diphenylmethane diisocyanate (MDI) elutes with high resolution and exhibits $[M + H]^+$ and $[M + 2H]^{2+}$ ions along with one fragment ion. The method can be applied to the monitoring of the workplace exposure to such compounds. Finally we have shown that other isocyanates (e.g. TDI isomers) can be separated and detected as the same derivatives by CE/ES.

Combined on-line CE/ES allows efficient separation and identification of compounds with greater speed and fewer manipulations than fraction collection in an off-line mode. The data shown here demonstrate the utility of the coupled technique for environmentally significant samples.

Both the Beckman CE and the ISCO instrument along with the VG Platform and Quattro spectrometers have produced results illustrating the feasibility of performing these types of analyses at environmentally significant levels.

Determination of Tin Alkylates in Environmental Samples using Thermospray and Electrospray LC/MS

W. Nigge, U. Marggraf and *M.Linscheid,
ISAS Institute for Spectrochemistry, Bunsen-Kirchhoff-Str.11, 44139 Dortmund; Germany

Organo-tin compounds are used in large amounts as fungicides and stabilizers for plastics, polyurethane foams and paints and some of them and their environmental breakdown products are known as highly toxic.

In continuation of preliminary experiments we have used thermospray LC/MS and, recently, a home made electrospray ion source on a sector field mass spectrometer to determine tin species (mono- and dibutyl - cations) after separation on different HPLC columns. For the development of the procedure, we have evaluated different extraction procedures using complex ligands to enhance the extraction and it was necessary to find the most appropriate chromatographic system in order to achieve sufficient separation and specificity. We have used rather polar diol phases, reversed phases, ion exchange columns and straight phases with different eluent systems. We found that a diol phase with methanol/water/acetic acid 75/25/0.5 was superior to all other separations. Using this separation technique and thermospray MS with positive and negative ion detection, detection limits for dibutyl tin and tributyl tin species of ca. 5 ng absolute have been obtained; concentrations of 0.5 to 1 µg of tin species per g sediment have been analyzed, although the recovery can be improved.

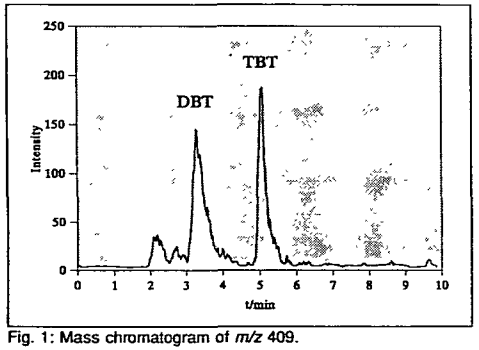


Fig. 1: Mass chromatogram of *m/z* 409.

The determination of the monobutyl tin species still represents a problem in the chromatography and the detection, because that cation has a strong tendency to adsorb to the inner surfaces of the connecting PEEK tubing causing very strong peak tailing.

Our experiments indicate that the detection and quantitation of organo-tin compounds of that type is possible with linear responses down to the low ng level absolute without using an internal standard. To increase the accuracy and the precision of the procedure, internal standards should be used and the synthesis of perdeutero tributyl tin acetate is under way. Furthermore, the use of electrospray MS seems to improve the detection limits by a factor ca. 100 and currently we are developing the required micro HPLC technique to separate the species on a micro column; with that combination, DBT and TBT concentrations in the range of 10 ng/g sediment can be analyzed.

The identification of such compounds by means of their isotopic pattern as a chemometric detector may allow the analysis of complex mixtures from environmental samples.

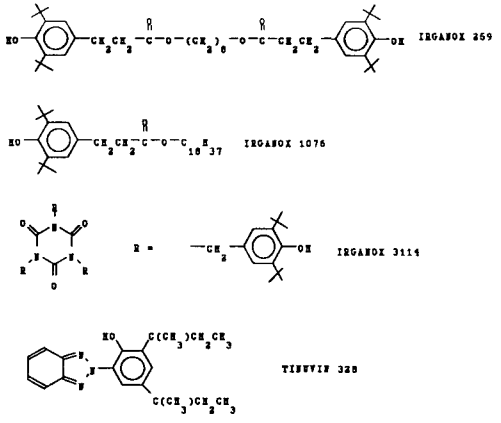
A Study of the Relative Particle Beam Transport Efficiency of Typical Commercial Additives in Common Reverse Phase Solvent Systems.

*A. Taaghol, K.T. Ng, R.F. Siegmund, CIBA-GEIGY Corp., Ardsley, NY, 10502-2699

As the use of commercial polymer additives such as anti-oxidants and UV absorbers have become more prevalent, the need for fast and effective identification of these additives, their associated impurities, and degradation products in manufactured goods have increased. LC/Particle-beam/MS, has proven to be an effective method for the analysis of many classes of commercial additives. However, the sensitivity of the technique is a strong function of the transport efficiency across the particle-beam interface[1]. The transport efficiency, in turn depends both on the compound and the mobile phase[1]. Reverse phase liquid chromatography (LC) is the preferred separation technique used in the analysis of commercial additives. In this paper, we have evaluated the relative transport efficiency of a number of commercial additives in the presence of several common reverse phase LC solvent systems. The model additives chosen are :



These additives were chosen to represent typical classes of compounds that are used as anti-oxidants and UV absorbers in the polymer industry. We have compared the relative transport efficiency of the above additives in methanol, acetonitrile, ethyl acetate and water/methanol systems. We found that for all of the additives, the best transport efficiency is achieved in the presence of 100% methanol. The following table contains the transport efficiency of each additive studied relative to methanol.

	Methanol	Acetonitrile	Ethylacetate
Irganox 3114	100 %	26%	28%
Tinuvin 328	100 %	49%	48%
Irganox 259	100%	79%	67%
Irganox 1076	100%	66%	48%

The transport efficiency is dramatically reduced when water is introduced into the mobile phase. For example, in a 70/30 methanol/water mobile phase, the transport efficiency of Irganox 1076 is only 10% of it's transport efficiency in pure methanol. We also found that the particle-beam transport efficiency is concentration dependant. In other words the LC/MS response is not a linear function of concentration.

THE IDENTIFICATION OF ORGANOSULFUR COMPOUNDS IN PRODUCED WATER BY MASS SPECTROMETRY

*A. E. Witter[1], A. Daniel Jones[1], and R.M. Higashi[2]
[1]Facility for Advanced Instrumentation, and [2]Bodega Marine Laboratory, University of California at Davis, Davis, CA 95616

Produced water is a chemically complex waste effluent generated by offshore petroleum exploration. Produced water may contain trace amounts of petroleum hydrocarbons, phenols, amino acids, fatty acids, alcohols and humic substances, as well as elevated concentrations of metals[1].

Characterization of produced waters taken from an onshore treatment plant at Gaviota, California, by this laboratory has revealed the presence of sulfur-containing heterocyclic species in concentrations of ~1 ppm, while concentrations of petroleum hydrocarbons were much lower, ca. ppb range. These results led to an interest in 1) identifying and quantifying organic compounds found in produced water generated at a petroleum production site near Gaviota, especially those that may act as potential ligands to modulate metal ion bioavailability; and 2) investigating the reactivities of organosulfur compounds with other biological or chemical species under controlled laboratory conditions.

A suite of mass spectrometric techniques were used to characterize the organosulfur compounds found in the dichloromethane extract of produced water including electron ionization, chemical ionization, accurate mass measurements, and MS/MS experiments. The mass spectra of the constituents indicate the presence of many organosulfur compounds, seen in the [M+2] isotope intensities.

The three most abundant peaks which contained sulfur were chosen for further study. Figure One shows the electron ionization spectra of these three peaks, which have molecular ions at m/z of 128 (Compound A), 132 (Compound B), and 146. (Compound C). Chemical ionization using methane as the reagent gas confirmed these molecular weights. Compound A gave a strong [M+H]+ ion at m/z 129, while compounds B and C gave weak $[M+H]^+$ ions, but measurable amounts of the $[M+C_2H_5]^+$. Derivatization of the produced water using acetyl chloride in methanol revealed that Compound C contained a carboxylic acid moiety. High resolution data for m/z 128, 132, and 146 indicate that Compound A has the molecular formula C_6H_8SO, Compound B has the formula $C_5H_8SO_2$, and Compound C has the molecular formula $C_6H_{10}SO_2$. Linked scanning techniques allowed us to elucidate the fragmentation pathway for the m/z 146 ion (Compound C).

Loss of water from m/z 146 (Compound C), possibly through hydrogen migration, gave the fragment at m/z 128 (Compound A). The peak at scan 399 in the TIC also has the molecular weight 128, which indicates that this may be a dehydration product of Compound C. From the electron ionization and high resolution data, we believe the peak at scan 399 has the structure of 6-methyl-(2H)-thiopyran-2-one. Further loss of CO from the m/z 128 fragment gave an intense base peak at m/z 100, seen in the daughter scan for m/z 128.

The m/z 146 ion can also undergo loss of H_2S through hydrogen migration to form the fragment at m/z 112. Studies are in progress to investigate how these compounds may form in the environment, as well as assessing their environmental relevance.

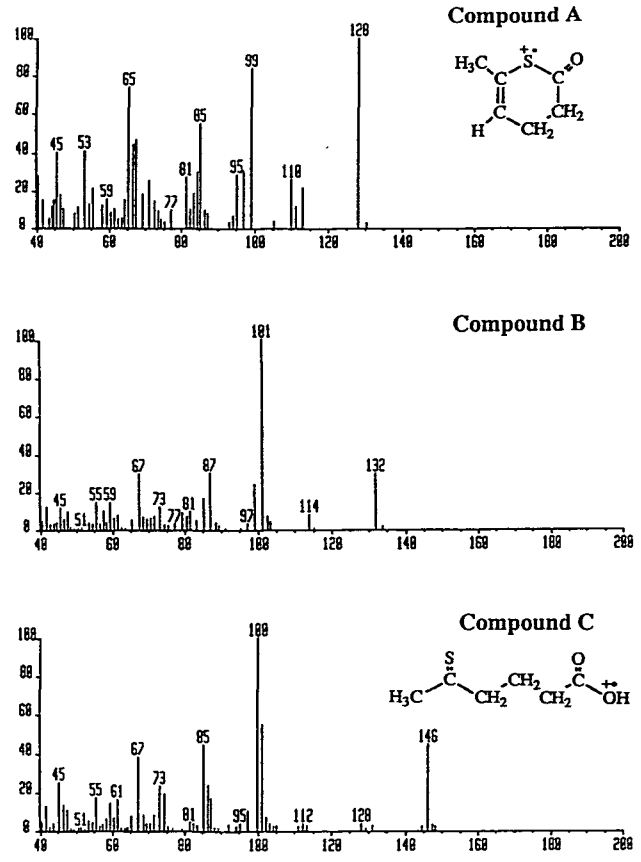

Figure One: The electron ionization spectra of the three most abundant peaks seen in the total ion chromatogram of the dichloromethane extract of produced water are shown above.

DETERMINATION OF HYDROXYATRAZINE IN WATER AT LOW-PPT LEVELS BY USING CARBON BLACK CARTRIDGE EXTRACTION AND HIGH RESOLUTION FAB-MS

*Zongwei. Cai[1], V. M. Sadagopa Ramanujam[1], S. J. Monson[1], M. L. Gross[1], and R.F. Spalding[2], (1) Midwest Center for Mass Spectrometry-Department of Chemistry and (2) Water Center, University of Nebraska, Lincoln, NE 68588

Atrazine is one of the most widely used agricultural herbicides in the United States and has been identified along with its metabolites as contaminants in groundwater. Field-applied atrazine is known to undergo abiotic hydrolysis reactions leading to dechlorination and formation of hydroxyatrazine (HA). There are three obstacles to the analysis of HA in water at low parts-per-trillion (ppt) levels: (a) extraction efficiencies by liquid-liquid extraction with CH_2Cl_2 and solid-phase extraction using C-18 cartridges are low (< 10%), (b) the analyte is too polar and hydrophillic for direct analysis by GC or GC/MS, and (c) HPLC lacks the needed sensitivity and specificity for ultra-trace analysis.

This study focuses on three issues of method development for HA: (1) solid-phase extraction with a carbon black cartridge (250 mg, Supelco), (2) high resolution (HR) FAB-MS for quantitative analysis[1], and (3) tandem mass spectrometry (FAB-MS/MS) for further identification.

Water Samples. Groundwater was collected from multilevel water wells in Grand Island, NE. Tap water was obtained from a Lincoln municipal water supply tap at UN-L.

Sample Preparation. Prior to use, the carbon black cartridge was pre-washed sequentially with 2mL each of CH_2Cl_2, CH_2Cl_2/CH_3OH (60/40, v/v), CH_3OH, and organic-free water. The water sample (200 mL) was spiked with a suitable concentration of $^{13}C_3$-atrazine as internal standard. The sample was aspirated through the pre-washed carbon black cartridge at a flow rate of 10 mL/min. The cartridge was first eluted with 1 mL ethyl acetate. HA and the internal standard were then eluted by 5 mL of CH_2Cl_2/CH_3OH (80/20, v/v). Residual water in the ethyl acetate was removed by adding anhydrous Na_2SO_4 and the eluants were combined. The mixture was evaporated to 20-50 uL by using a slow stream of nitrogen. The recoveries of HA on the carbon black cartridge are 88% and 95% for 5 ppt and 500 ppt levels, respectively.

Quantitative High Resolution FAB-MS: A Kratos MS-50TA (EBE configuration) equipped with an Iontech FAB gun and a Kratos FAB source was tuned to a resolution of 10,000 (10% valley definition). One microliter of the sample eluant was placed in 0.5 uL dithiothreitol/dithioerythritol (DTT/DTE) matrix that had been loaded onto FAB probe tip. Narrow scans (300 ppm sweep width) over the following ions were collected by using a Kratos Mach-3 SIM program: $[HA+H]^+$ (*m/z* 198.1355), $[Atrazine+H]^+$ (*m/z* 216.1016), and $[^{13}C_3\text{-Atrazine}+H]^+$ (*m/z* 219.1117). HA was quantified by comparing the peak areas of $[HA+H]^+$ and $[^{13}C_3\text{-Atrazine}+H]^+$ ions (**Figure 1**).

A seven point calibration curve for HA at 25pg/uL to 1000 pg/uL and $^{13}C_3$-atrazine at 250 pg/uL in methanol is linear (r^2 = 0.9926) with relative response factor (RRF) of 0.93 (RSD = 12%). The analytical results are listed in **Table 1**. Due to difference in desorption rates between HA and $^{13}C_3$-atrazine, RRF was found to vary as much as 30%, depending on the state of the instrument (source and FAB gun current). Therefore, RRF was calibrated between each batch of analysis. To eliminate problems of variability, $^{13}C_3$-Hydroxyatrazine has now been synthesized and will be used as internal standard.

FAB-MS/MS: In the HRFAB-MS, the identification of HA was based on measurement of the accurate mass (*m/z* 198.1355) for the protonated molecule, $[HA+H]^+$. This identification may be compromised by interference and background in the sample extract. Therefore, further confirmation is necessary.

The collision activated dissociation (CAD) experiments were performed by selecting the $[HA+H]^+$ ion (*m/z* 198.1355) and activating it in the third field-free region by collision with helium for 50% beam reduction. Typically 10-15 scans were signal-averaged for each CAD spectrum.

Figure 2 (A-C) shows that the CAD spectra of the extracts from groundwater **(A)** and tap water **(B)** are nearly identical to that of an authentic HA sample **(C)**, giving major fragments of *m/z*: 182 [loss of CH_4],169 [loss of C_2H_5], and 156 [loss of C_3H_6]. Thus, the FAB-MS/MS may be suitable for confirming HA at trace levels.

Identification of Volatiles and Semi-Volatiles in Honey

Santford V. Overton and John J. Manura
Scientific Instrument Services, Ringoes, NJ 08551-1039

Flavor/fragrance qualities of commercial food products are greatly dependent on the volatile and semi-volatile organic compounds present both in the matrix and the headspace aroma. Today, there is a problem in the food industry as to what constitutes the optimum conditions for harvesting honey so as to provide a consistent quality, flavor and aroma of honey to the consumer. Many factors must be considered such as differences between bee colonies, how they are managed by the beekeepers for a specific honey and time of harvest. The most important factor are the plants used by the bees for the production of honey. The flavor and color of the honey depends on the type of plant that produces a nectarine honey. For example, sourwood produces a honey that is different in color and flavor from that of clover or poplar. Analytical techniques are needed to profile and identify flavors, fragrances, off-flavors, off-odors and potential contaminants that may be present as flavor and fragrance additives. Volatile organic compounds were collected from samples of honey using a purge and trap technique (P&T), followed by trapping on an adsorbent resin and subsequent analysis by thermal desorption-gas chromatography- mass spectrometry (TD-GC-MS).

All experiments were conducted using a Scientific Instrument Services model TD-2 Short Path Thermal Desorption System accessory connected to the injection port of an HP 5890 Series II GC interfaced to an HP 5971 Mass Selective Detector. The mass spectrometer was operated in the electron impact mode (EI) at 70eV and scanned from 35 to 400 daltons during the GC run for the total ion chromatogram. A short 0.5 meter by 0.53 mm diameter fused silica precolumn was attached to the injection port end of a 30 meter x 0.25 mm i.d. DB-5MS capillary column containing a 0.25 um film thickness. The GC injection port was set to 300 degrees C and a 5 1 split was used during the injection step. The GC oven was maintained at -40 degrees C during the desorption and extraction process, after which the oven was temperature programmed from -40 degrees C to 300 degrees C at a rate of 10 degrees per minute for the total ion chromatogram.

Nine honeys (wildflower, blueberry, orange, clover, tupelo, alfalfa, apple spread, mixed, and a mild cream) were analyzed to compare the flavor profiles and to quantify the volatile organics of different manufacturers' brands For quantification, an internal standard was spiked into the adsorbent traps after the sample had been isolated. No correction for extraction efficiency of recovery is achieved using this technique; however, it functions as a useful means of quantifying the levels of components present on the adsorbent traps. Sample sizes of 5-6 g of commercial honey were pipetted into a 10 ml test tube and heated to 80 degrees C. Samples were sparged with high purity helium at 20 ml/min with an additional 20 ml/min dry purge for 45 minutes using a Scientific Instrument Services Liquid Purge System. Volatile analytes were gas extracted and carried to a preconditioned 4.0 mm i.d. glass-lined stainless steel desorption tube packed with 100 mg of Tenax TA. Once the samples were collected they were spiked with 100 ng of d-14 cymene internal standard by injecting 1 ul of a 100 ng/ul of a d-14 cymene stock solution in methanol by

syringe injection into the Tenax matrix. The desorption tubes with sample and internal standard were then attached to the Short Path Thermal Desorption System and a syringe needle attached. The desorption tube was injected into the GC injection port at desorption blocks temperatures of 220 degrees C for 10 minutes at a purge flow of 5 ml/min, and a GC injection split ratio of 5:1.

Nine honeys produced from different plants were analyzed to identify, compare and quantify the volatile organics present The honeys were found to contain numerous mono- and sesquiterpenoid compounds and flavors such as benzaldehyde, furfural, isovaleraldehyde and phenylacetaldehyde. The apple honey spread was found to contain numerous monoterpenoid compounds such as alpha thujene, alpha pinene, delta 3-carene, cymene, limonene, linalool, gamma terpinene, beta phellandrene and alpha terpinolene The Merck Index lists these compounds as constituents of several plant derived essential oils which are used as fragrance materials. The flavor compounds benzaldehyde and furfural have an almond-like odor, isovaleraldehyde has an apple-like odor, and phenylacetaldehyde possesses an odor reminiscent of lilac and hyacinth. Linalool oxide and tetra-furfural alcohol also contributed to the aroma in each of the honeys. Diacetyl, found in bay and other oils, was detected in each of the honeys and is used as a carrier of aroma. Isoamyl alcohol was the most abundant aliphatic compound found. In addition, the aromatic compound toluene was detected in each of the honeys with the exception of the apple spread and mixed honeys. The presence of this compound may be the result of a manufacturing process or occur naturally from essential essences.

Nerolidal, which is present in essential oils of many flowers, was identified in the wildflower honey. The wildflower honey also contained benzonitrile which has an almond-like odor and 1H-Indole which has a pleasant odor in dilute concentrations. 2-methyl propionitrile was detected in wildflower as well as in the blueberry, orange and mild cream honeys. This compound has a pleasant ethereal sweetish odor although is poisoness when heated to decomposition. Trace amounts of dihydro-2-methyl-3 (2H)-furanone, p-mentha-1(7), 8(10)-dien-9-ol and 3,5,5-trimethyl-2-cyclohex-1-one were found in blueberry, orange and clover honeys respectively, and probably contribute to the aromas. High concentrations of the flavors cis-jasmone and beta-damascenone were found in tupelo honey. Cis-jasmone present in the volatile portion of oil from Jasmone flowers has an odor of jasmine while beta-damascenone has a nutmeg-like odor. Trace amounts of 3-phenyl acrolein which has a pungent odor was also detected in tupelo honey as well as in the alfalfa honey. The apple honey spread was found to contain myristicin, an aromatic ether extracted from nutmeg and parsley; safrole, a constituent of several different oils, notably sassafras; and asarones which have a familiar and penetrating ginger odor. 3-phenyl acrolein was also present in high concentrations in the apple honey spread. Trace amounts of benzyl cyanide which exhibits an aromatic odor was detected in the mild cream honey. In addition, other middle-chain aliphatic alcohols, aldehydes, and ketones, which are the degradation products of fatty acids, were found in each of the honeys.

Using GC/MS for the Identification of Volatile and Semi-Volatile Components in Food.

Carol A. Haney[1], Jonathan A. Merkle[2], Duane K. Larick[2], North Carolina State University, [1]GC/MS Laboratory, [2]Department of Food Science, Raleigh, North Carolina 27695.

Introduction: Flavor is a key attribute in the acceptability of foods. The mechanisms responsible for creating the taste sensation are not well understood.[1] In general, many compounds may be involved in the generation of a particular flavor. In addition, it is difficult to establish the quantitative importance each compound of a mixture has on flavor. In meat products fat has a large effect on flavor. When cooked, the fat can be oxidized, generating carbonyl compounds or it can release previously stored compounds.[2]

The popularity of beef products coupled with an increasing concern with dietary fat and cholesterol make identification of beef flavor components an obvious target. Currently, processed low-fat and imitation meat products lack quality meat flavorings. Meat flavor is a complex mixture of compounds which has been difficult to reproduce. This note details an analytical approach for the identification of the volatile and semi-volatile organic components in beef fat.

GC/MS is an ideal choice for the identification of volatile and semi-volatile organic compounds. The complexity of the beef fat extracts is an analytical challenge which requires maximum instrument capabilities. The approach used for volatile organic compounds involves supercritical fluid extraction followed by a purge and trap, GC/MS analysis. The procedure used for semi-volatile compounds involves a Likens-Nickerson extraction followed by concentration and GC/MS analysis.

Experimental: Samples were prepared from subcutaneous fat from the loin of 12 Angus-Hereford steers. Fat was ground, once, through a 3/8 inch plate. Fifty gram (50g) samples were used for the supercritical fluid extractions. A commerically available supercritical fluid extractor was used (Newport Scientific). The sample was immobilized in the 0.850L extraction vessel using glass wool plugs. Carbon dioxide (4000 psi) was held constant using a back pressure regulator. Temperature in the system was maintained at 40°C. The CO_2 pressure was reduced to 1500 psi at the separation vessel to help fractionate the extract. The system was depressurized into a 0.50L flask at room temperature. Upon depressurization, the solute condenses out into the flask. Carbon dioxide flow was maintained at 15 liters per minute. A total of 500L of CO_2 was used to extract the sample.

The purge and trap concentrator (Tekmar LSC-3) was equipped with a 25 mL solids sparger and heating jacket (150°C). One hundred milligrams (100mg) of the supercritical fluid extract was used. The purge time was 14 minutes. Desorb temperature was 200°C. The GC temperature program: -30°C hold 2 minutes ramp at 2°C per minute to 290°C. The scan range was 40-400 daltons.

For the Likens-Nickerson extraction, 100g of fat was weighed into a 0.50L round bottom Pyrex flask containing boiling chips. Distilled deionized water (0.150L) was added. Methylene chloride (75mL) was placed into a 0.10L round bottom on the second extractor arm. The extraction was run for six hours. The methylene chloride phase was separated and condensed using a rotary evaporator to a final volume of 2mL. The extract was further concentrated under nitrogen to 100ul. One microliter of sample was injected.

The GC/MS anlayses were performed on an HP5985B/RTE IV mass spectrometer. The column used was a 30M x 0.32 mm DB5, 1.0um film thickness. For the semi-volatile analysis the temperature program: 45°C hold 1 minute ramp at 4°C per minute to 290°C. The scan range in EI was 40-400 daltons. For positive CI, methane was used as the reagent gas, scan range was 70-500 daltons.

Results and Discussion: Supercritical fluid extraction (SFE) has been shown to be an excellent method for extraction and concentration of volatile components. A wide variety of organic compound classes were efficiently extracted by this method. Identifications were based on library search information and, in some instances, by comparison with standards. As expected, there were strong signals resulting from various aldehydes and alphatic hydrocarbons. Aromatic compounds were also detected, but at fairly low-levels. Several ketones and sulfur containing compounds were also identified. The major component identified (based on peak area) was carbon disulfide. The volatile components detected arise through oxidative and free-radical breakdown of fatty acids or through release of stored chemicals in the fat when heated.

The total ion chromatogram from the GC/MS analysis of the Likens-Nickerson extraction is totally different from the SFE. A comparison of the results shows that the two extraction/analysis schemes provide complementary information. The concentration step of the Likens-Nickerson extraction resulted in significant losses of the volatile components. The major components were identified as aldehydes and terpenes and unsaturated hydrocarbon species. These compounds tend not to give molecular ions, or only very weak molecular ions under electron ionization (EI) conditions. Therefore, it was necessary to analyze this mixture using chemical ionization (CI). Identifications were based on the library search of the EI results and the molecular weights based on the CI results. The major components detected in the semi-volatile analysis are the terpenoid compounds, phytane (2, 6, 10, 14 - tetramethylhexadecane), neophytadiene (7, 11, 15 - trimethyl-3-methylene-1-hexadecene), phyt-1-ene (3, 7, 11, 15 - tetramethyl-1-hexadecene) and phyt-2-ene (3, 7, 11, 15 - tetramethyl-2-hexadecene). These components are derived from a component of chlorphyll and thus, are directly linked to forage feeding. These components appear to be responsible for the "off" flavor reported by the sensory panel.

Conclusions: The analysis of foods is by no means trivial. Fat, in particular, contributes significantly to the flavor of beef. Diet is directly responsible for the organic compounds found in fat. Correlations between diet, organic composition and desirability of flavor are important aspects of food flavor investigations. The approach presented here includes supercritical fluid extraction followed by purge and trap concentration and GC/MS to characterize the volatile components. The approach for the semi-volatile compounds includes the Likens-Nickerson extraction procedure and GC/MS analysis by both EI and methane, postive CI. Thus far, 118 compounds in beef fat have been identified.

Photodissociation-Photoionization Mass Spectrometry

Philip L. Ross*, Murray V. Johnston
Department of Chemistry, University of Delaware
Newark, DE, 19716

Introduction

Photodissociation-photoionization mass spectrometry (PDPI/MS) is a technique which probes neutral unimolecular decomposition rather than ionic decomposition. Neutral fragmentation patterns are more directly related to the original molecular structure than ionic fragmentation patterns since rearrangements and isomerizations are less likely to occur. In PDPI/MS, neutral fragmentation is initiated with excimer laser radiation either at 193 nm (ArF) or 248 nm (KrF). The neutral photodissociation products and remaining undissociated parent molecules are photoionized with tunable coherent vacuum ultraviolet radiation (10.5 -9.68 eV) and mass analyzed in a linear time-of-flight mass spectrometer. Recent experiments have focussed on studying the photodissociation pathways of simple alkanethiols in the C_3 - C_8 size range. The primary reactions that have been identified from PDPI/MS experiments involve cleavage of the S-H, C-S and α C-C bond as shown for 1-propanethiol in reactions 1-3 below.

						ΔH_{rxn}
$CH_3CH_2CH_2SH$	→	$CH_3CH_2CH_2S\cdot$	+	$\cdot H$	(1)	368 kJ/mol
	→	$CH_3CH_2CH_2\cdot$	+	$\cdot SH$	(2)	307 kJ/mol
	→	$CH_3CH_2\cdot$	+	$\cdot CH_2SH$	(3)	351 kJ/mol

In this study, the role of structure, molecular size and photodissociation wavelength is elucidated.

Experimental

The photodissociation and photoionization lasers are spatially overlapped between the backing plate and first acceleration grid of the TOF source region. Ions formed by MPI from the UV laser are rejected, and after a suitable time delay, the remaining neutrals are photoionized. The use of tunable VUV radiation (1) makes it possible to reduce the amount of secondary ionic fragmentation so that the photoionized neutral fragments are in most cases observed intact.

Results

A typical PDPI/MS spectrum of 1-propanethiol and 2-propanethiol is shown in **Figure 1**. The primary products from reaction 1-3 are illustrated on the figure. The alkyl radical $C_3H_7\cdot$ (m/z 43) undergoes neutral loss of H_2 to produce $C_3H_5\cdot$ (m/z 41) As seen for 2-

propanethiol, α C-C cleavage to produce a methyl radical as one of the products does not occur. As the molecular size is increased, S-H cleavage appears to be suppressed, and α cleavage gives way to β and γ C-C cleavage.

Figure 2 shows comparative 193 and 248 nm photodissociation of 1-propanethiol. Dissociation of the S-H bond is enhanced with 248 nm radiation, in contrast to the relative energetics of the primary reactions. This increased S-H cleavage is anticipated by SCF and CI calculations (2).

Department of Chemistry, Michigan State University, E. Lansing, MI 48824

Introduction

Protein phosphorylation-dephosphorylation plays a very important role in signal transduction in biological systems. An understanding of the potential role of a protein in signal transduction and of the significance of its phosphorylation requires elucidation of the mechanism of its phosphorylation in response to various stimuli and of the basis for its altered phosphorylation in pathologic states. Of basic importance, is the identification of residues that are phosphorylated in the phosphorylation form(s). While conventional Edman sequencing method can not routinely provide positive identification of the phosphorylated residues, mass spectrometry appears to be the most universally applicable technique to detect protein posttranslational modifications, including protein phosphorylation.

Phosphorylation of the highly conserved cytosolic protein OP18 has been implicated in signal transduction in a wide variety of cell types. While the effect of OP18 phosphorylation on activity of the protein is not known, the findings have emerged that suggest an important role for OP18 phosphorylation. In this investigation we have undertaken an analysis of OP18 phosphorylation in response to treatment of Jurkat T cells with PMA(phorbol-12-myristate-13-acetate), using MALDI/MS combined with enzymatic treatment of the proteolytic fragments.

Methods

Cell culture and metabolic labeling: The human lymphoid leukemic T cell line, Jurkat, was cultured in RPMI 1640 medium supplemented with 10% fetal calf serum. For metabolic labeling, cells($10x10^6$/ml) were suspended in phosphate free RPMI 1640 containing [^{32}P] orthophosphate at 400uCi/ml for 2 h at 37°c. At the end of the labeling period, PMA was added to the cell suspension for 10min and cells were harvested.
Purification of OP18 phosphorylated forms: The major OP18 phosphorylated form , OP18a, was purified by preparative 2-D PAGE using an IPG-based isoelectric separation(pH4-7) in the first dimension and SDS gels with 11.5 to 14% acrylamide gradient for the separation based on the molecular weights in the second dimension. Proteins were then electrophoretically transferred to nitrocellulose.
Proteolytic digestion and peptide isolation: *In situ* tryptic digestion was performed as follows. Nitrocellulose pieces were blocked with polyvinyl pyrrolidone-360 and washed extensively. Digestion was performed with modified trypsin(1:10 enzyme to substrate) in 50mM ammonium bicarbonate pH7.9 at 37°c. At the end of digestion, the solution and a buffer rinse were combined and dried in a Speed Vac. Tryptic peptides were separated using a C18 column. Radioactive fractions were used for phopshorylation site studies.
Secondary enzymatic digestion: Phosphopeptides were dephosphorylated with bacterial alkaline phosphatase at 150 units:0.5-2 pmol enzyme to peptide ratio in 25mM ammonium bicarbonate buffer pH7.9 for 1h at 37°c. Digestion with chymotrypsin and endoproteinase Glu-C was performed in 25mM ammonium bicarbonate buffer pH7.9(1:10 enzyme to substrate ratio) at 37°c for 18h.
Mass spectrometry: Mass spectra were obtained on a VT-2000 linear time-of-flight mass spectrometer with a nitrogen laser. The matrix used for this study was a-cyano-4-hydroxycinnamic acid. 1ul of the peptide solution(0.5-2 pmol/ul in 0.1%aqueous TFA : acetonitrile, 1:1) was added to 1ul of the matrix solution (saturated in 33% aqueous acetonitrile, about 20mM) and applied to a stainless steel probe tip. The mixture was then allowed to air dry before being introduced into the mass spectrometer. Data were acquired with a transient recorder with 5 ns resolution. Potential peptide matches were made to the sequence of OP18 predicted from the cDNA allowing for post-translational modification, using Mac-Pro Mass software.

Results

A highly conserved cytosolic protein OP18 and its phosphorylated forms were first separated by 2-D PAGE, then electrophoretically blotted onto a nitrocellulose membrane. Endopeptidase(trypsin) degradation of the major phosphorylated form OP18a was performed *in situ*, and microbore HPLC was employed to separate the tryptic peptides. An enzyme, BAP, which selectively removes the covalently attached phosphate group aided the identification of this modification. Further proteolytic digests of the tryptic phosphopeptide led to the identification of the phosphorylation site.

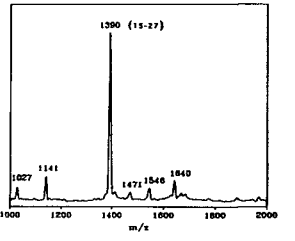

Fig.2 MALDI/MS of BAP treated TP3

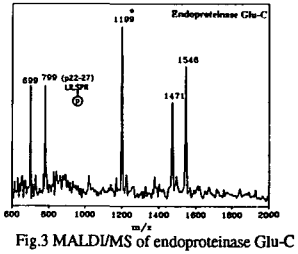

Fig.3 MALDI/MS of endoproteinase Glu-C digested TP3.

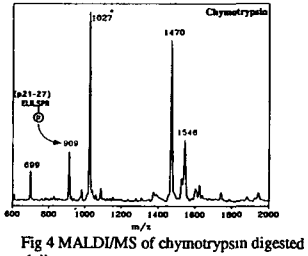

Fig 4 MALDI/MS of chymotrypsin digested TP3

* Present in control digests.

Conclusion

The sequence for TP3 is (R)ASGQAFELILpSPR(S) and the phosphorylation occurred at Ser 25.

In this study we have undertaken the phosphorylation analysis of a highly conserved cytosolic protein OP18, of which the phosphorylation has been implicated in signal transduction in a wide variety of cell types.

We have demonstrated that MALDI/MS in combination with enzymatic digestion can be a useful tool to obtain structural information of phosphopeptides especially in the cases where extremely low sample quantities are available. Each enzymatic treatment and MALDI spectrum in this study consumed 0.5-2 pmol of sample. Other mass spectral techniques may reach this level of sensitivity, but they may not be compatible with the buffer concentrations required for the enzymatic reactions. The relatively poor mass resolution of MALDI/MS makes the multiple enzymatic reactions necessary since many peptides derived from a single protein can yield ions close or identical in mass.

COMPLEX FORMATION BETWEEN BIOMOLECULES IN MATRIX-ASSISTED LASER DESORPTION IONIZATION

P. Juhasz and K. Biemann
Dept. of Chemistry, MIT, Cambridge, MA 02139

The availability of new soft ionization techniques in mass spectrometry, such as electrospray or matrix-assisted laser desorption ionization (MALDI), now makes possible the study of non-covalently bound complexes of biomolecules. This presentation demonstrates how the existence of ionic complexes ("salts") consisting of strongly acidic and basic biomolecules can be detected and utilized by MALDI.

The experiments were carried out on a modified VT2000 (VESTEC) linear time-of-flight mass spectrometer. sources have been utilized: a N_2 laser (337 nm, 3 nsec pulses) for ultraviolet (UV) MALDI and an Er.YAG laser (2.94 μm, 120 nsec pulses) for infrared (IR) MALDI. The basic components for complex formation experiments, referred to as carrier peptides, were peptides rich in basic residues (arginine first of all): dynorphin (1-9), a tyrosine protein kinase substrate, a synthetic peptide with the sequence RRRRRRPYIL, bovine ubiquitin, *etc.* Acidic components were sulfate and phosphate containing biomolecules: peptides with cysteic acid residues, oligonucleotides, and heparin disaccharides A wide variety of matrix/wavelength combinations have been tested including sinapic acid (UV), caffeic acid (UV), α-cyano-4-hydroxycinnamic acid (αCHCA, UV), succinic acid (IR), and 5-(trifluoromethyl)uracil (TFMU, IR). Samples were generally prepared as a 1:1 molar mixture of the carrier peptide and the acidic component at 1-20 pmol/μL level in the matrix. Typically 10 laser shots were averaged in IR experiments and 30 shots in UV experiments.

Complex formation with the oxidized A-chain of bovine insulin Upon oxidation with a strong oxidizing agent (performic acid) chain A of insulin is turned into a strong acid containing four cysteic acid residues (M=2531.7 Da). Complex formation between the carrier peptides and the oxidized A-chain was observed to be a highly matrix specific process: in UV MALDI sinapic acid, in IR MALDI succinic acid was the most efficient. Figure 1 compares the mass spectra of a 1:1 mixture of ubiquitin and the oxidized A-chain in sinapic acid and αCHCA matrices.

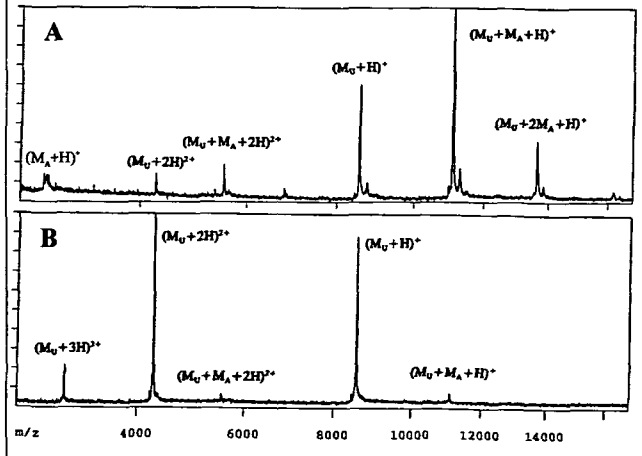

Figure 1 UV MALDI spectra of bovine ubiquitin (M_U) and the oxidized chain A of insulin (M_A) mixed in 1:1 molar ratio. Matrix: **A.** sinapic acid, **B.** αCHCA

Experiments with oligonucleotides. Protein-DNA (RNA) interaction is often driven by the electrostatic interaction of the basic residues on the protein and of the phosphate groups on the nucleotides. Complex formation (mainly 1:1

complexes) could be observed in MALDI for up to about 12mers of DNA and smaller peptides like dynorphin (1-9) (YGGFLRRIR). The relative abundances of the complex ions, however, rapidly declines with the increasing number of nucleotides. For this reason complex formation with the carrier peptides did not improve the sensitivity and efficiency of the analysis of oligonucleotides in the MALDI technique.

Experiments with heparin saccharides. Disaccharide units from glycosaminoglycan heparin have been tested for their complex formation properties. Every disaccharide unit contains 1-3 sulfate groups leading to high density of negative charges in an aqueous solution. These disaccharides attach strongly to basic peptide residues, however the intact complexes could be detected only in IR MALDI using TFMU as matrix (see Figure 2). Loss of the SO_3 group affects the N-sulfated site in the glucosamine residues Unlike oligonucleotides, heparin saccharides can be analyzed with dramatically enhanced sensitivity utilizing a carrier

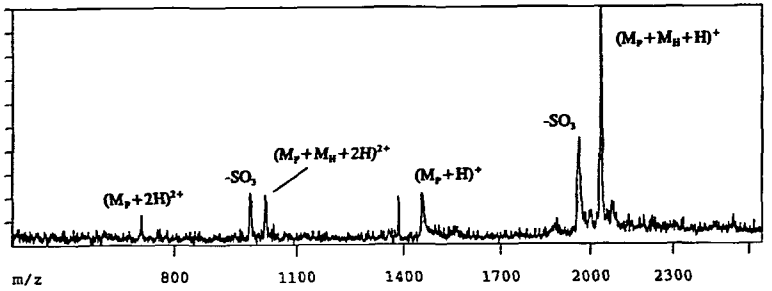

Figure 2 IR MALDI mass spectra of a 1 1 molar mixture of the heparin disaccharide (M_H) ΔUAp2S(1->4)- α- D-GlcNp2S6S [1] with the peptide RRRRRRPYIL (M_P). Matrix. TFMU.

peptide. While for a heparin sample alone at least 100 pmol/μL was necessary to obtain a reasonable molecular ion signal, by admixing a carrier peptide, as low as 150 fmol heparin disaccharide could still be detected. Another advantage of the complex formation that salt contamination does not seem to degrade the quality of mass spectra.

Mechanism of complex formation Several features of the complex formation process (such as matrix specificity, distribution of the abundance of the oligomeric complexes) already suggested that these ionic complexes formed in condensed phase and their structure, in favorable case, was preserved by the matrix. Correctness of this hypothesis was tested by observing the relative abundance of a complex ion as a function of the sample concentration (at 1:1 ratio of the components). Suppression of complex formation with decreasing sample concentration (down to 100 fmol/μL) was observed indeed, however, definite optimum of the relative abundance of complex ions was observed in the range of 1-10 pmol/μL.

Structural Characterization of a Cytosolic Glutathione-S-transferase by Fast Atom Bombardment CID and Matrix Assisted Laser Desorption Mass Spectrometry

*Constance M. Murphy and Catherine Fenselau
Department of Chemistry and Biochemistry
University of Maryland, Baltimore County
Baltimore, Maryland 21228

Glutathione-S-transferases are a diverse group of enzymes which catalyze the nucleophilic attack of glutathione in the cells defense against xenobiotic insult. Cytosolic equine glutathione-S-transferase has been reported to be an alpha class homodimer with a subunit molecular weight on the order of 25,500.[1] At the present no sequence information is available for equine glutathione-S-transferase.

The objective of the present study is to compare results obtained in the process of sequencing the cytosolic equine glutathione-S-transferase utilizing matrix assisted laser desorption mass spectrometry (MALD) with those obtained with other mass spectrometric techniques. Total protein molecular weight determinations by MALD and electrospray mass spectrometry (ES) will be compared. Similarly, MALD and fast atom bombardment mass spectrometry (FAB) will be compared for suitability in the mapping of peptides resulting from protein digestion. All MALD spectra were aquired with a Kompact MALD III (Kratos Ltd., Manchester, England). The MALD spectra were then processed using Tofware (Ilys Software, Pittsburg, PA). All FAB and tandem mass spectrometry spectra were acquired with a JEOL HX110/HX110 (Tokyo, Japan). All ES spectra were acquired with an Hewlett Packard 5988A (Palo Alto, CA) retrofitted with a Vestec electrospray source (Houston, TX)

In efforts to deduce the sequence of equine glutathione-S-transferase the mass balance strategy has been applied [2] Initially the total molecular weight of the protein was obtained via MALD and ES mass spectrometry. Subsequently, equine glutathione-S-transferase was subjected to a number of digests including cyanogen bromide, trypsin, and *S.aureus* V8 protease. After minimal separation by reverse phase HPLC the resultant digest peptides have been mapped by FAB and MALD. Due to the fact that no sequence information exists for this equine glutathione-S-transferase the cDNA sequence for human H_{x2} was used as a template.[3] Methylation of the peptides was used to enhance the FAB analysis, and to aid in peptide mapping. The sequences of two large digest fragments were confirmed by Edman degradation. Digest fragments of suitable size were subjected to MS/MS analysis to confirm their sequence.

Matrix assisted laser desorption mass spectrometry was found to be a fast, efficient means of obtaining the molecular weights of both proteins and peptides resulting from protein digestion. The total molecular weight of cytosolic equine glutathione-S-transferase was found to be 25,543 ± 25 daltons by MALD mass spectrometry (0.1% error based on instrument specification). This molecular weight agrees well with the ES mass spectrometry value of 25,554 ± 6 daltons (error based on standand deviation, n=12). The amount of sample consumed in the MALD analysis was approximately 1/15 th of that consumed in the ES analysis, 74 pmoles and 1 nmole respectively.

With regard to large digest fragments, MALD provided a broader effective mass range than FAB. At the higher mass range of 3000 to 10,000 daltons the MALD affords greater sensitivity while maintaining mass accuracy of ± 0.05% (error based on standard deviation, n = 11). With the aid of chemical derivatization, this mass accuracy was sufficient to map the protein. At the lower mass range of 100 to 3000 daltons MALD consistently detected more digest fragments from a given fraction than FAB (Fig. 1). The differences between peptides detected by MALD and those detected by FAB are not in direct correlation to their relative hydrophobicities or their molecular weight. The MALD analysis required 1/10 th to 1/20 th of the sample consumed in FAB. The advantage of the FAB analysis lies in its mass accuracy. FAB generally provided mass accuracy of ≤0.5 daltons throughout the mass range while in these studies MALD gave ± 0.05% mass accuracy (MALD error based on standard deviation, n =37).

Based on protein mapping equine glutathione-S-transferase has been found to be 90% homologous with human glutathione-S-transferase H_{x2}. Of the 221 amino acids present in human glutathione-S-transferase H_{x2} 199 have been confirmed. The remaining 22 amino acids are either substituted, modified, or deleted. From MS/MS data and Edman sequencing 20 of these amino acid substitutions have been identified.

Gas-phase Ion-molecule Reactions of Peptide Ions with Small Neutral Molecules

*Touradj Solouki, Vincent J. B. Oriedo, and David H. Russell
Department of Chemistry
Texas A&M University
College Station, Texas 77843.

Results from two methods of biological structural mass spectrometry *via* ion-molecule reactions are described. Previous studies indicate that matrix assisted laser desorbed peptide ions are formed with both excess kinetic and internal energies.[1] A question we wish to address is how do internally excited peptide ions react with small molecules? That is, are there available exothermic ion-molecule reaction channels that yield structurally significant fragment ions or do the ions react *via* collisional relaxation? Another aspect of this work is to explore the specific reaction pathways of laser desorbed metal ions with peptides that are specific to particular amino acids or functional groups:

$[Peptide]^+$ or $([Peptide^+])^*$ + Small Molecule ----------> Products

Small Organic Molecule + $[Metal]^+$ or $([Metal]^+)^*$ ----------> Products

In this paper reactions of laser desorbed peptide ions with NO and other small neutral molecules (*e.g.* CO, CO_2, SF_6) are investigated. We also report on the reaction of laser desorbed Fe^+ with small organic molecules such as formamides as models for peptides. These experiments were performed on 7 tesla FT-ICR system. Small neutral molecules were introduced into the system through a leak valve and peptide ions were formed by MALDI. Fe^+ was generated by direct laser desorption from a stainless steel probe. A cartridge type nitrogen laser (337 nm) was used for both LD and MALDI experiments. The matrix used in this study was α-cyano-4-hydroxy cinnamic acid

Results from reaction of the nitric oxide with matrix assisted laser desorbed angiotensin II are striking. Nitric Oxide has an unpaired electron and is very reactive with functionalized organic molecules. We find it particularly interesting that peptide ions react *via* collisional relaxation with nitric oxide as well as with CO, CO_2, and SF_6. For example, NO suppresses the loss of small neutral molecules (*e.g.*, loss of H_2O and NH_3) and formation of fragment ions from the $[M+H]^+$ peptide ions. Figure 1a and 1b show MALDI/FTICR mass spectra of angiotensin II without and with nitric oxide introduce as a collisional gas. Fragmentation is not observed when NO is introduced into the system under otherwise identical conditions. The primary mode of reaction of NO, CO, CO_2, and SF_6 with matrix assisted laser desorbed angiotensin II ions is *via* collisional relaxation. Reaction pathways that lead to the formation of product ions (*i.e.*, fragment and/or adduct ions) are not observed.

Results from the reaction of laser desorption Fe^+ with formamides suggest that these reactions can provide structural information. For instance, reaction of Fe^+ with N-methylformamide yields both intact ion ($[M+H]^+$ of N-methylformamide) as well as fragment ions. Table I shows the major ions formed by reaction of Fe^+ and N-methylformamide.

In summary, we show that peptide ions formed by MLADI are internally excited and this should be considered when measuring proton affinities. Internally excited peptide ions can

be cooled by collisions with small neutral molecules without leading to formation of fragment ions. However, reactions of Fe^+ with amides (model molecules for peptides) yield structurally significant fragment ions.

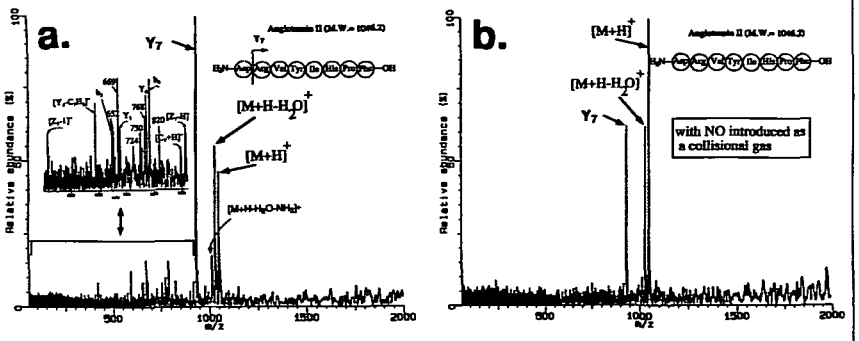

Figure 1. MALDI/FTICR mass spectra of angiotensin II a) without and b) with nitric oxide as a collisional gas. The matrix used was α-cyano-4-hydroxy cinnamic acid. The ions were detected after a two second delay from the desorption event at pressures of $2*10^{-7}$ and $8*10^{-8}$ for a and b, respectively.

Table I. Product ions of the laser desorbed Fe^+ and N-methylformamide.

Ionic Product	m/z	Ionic Product	m/z
$[M+H]^+$	60	$Fe(C_2H_3NO)^+$	114
$Fe(CH_5N)^+$	87	$Fe(C_2H_5NO)^+$	115
$Fe(CH_2NO)^+$	100	$Fe(C_2H_6NO)^+$	116

A COMPARATIVE STUDY OF MATRICES FOR MATRIX-ASSISTED LASER DESORPTION-IONIZATION (MALDI) OF TAXOL AND VARIOUS TAXANES

*Mary E. Gimon, Gary R. Kinsel, David H. Russell,
Texas A&M University, Department of Chemistry, College Station, Texas 77843

Matrix-assisted laser desorption-ionization (MALDI) can be applied to classes of compounds other than peptides and proteins. However, conditions necessary for performing MALDI on non-peptides may need to be altered in order to generate analyte ions. Different matrix-to-analyte ratios or even novel matrices may be required. MALDI of the natural product taxol (Figure 1) and its analogs, commonly referred to as taxanes, presents an example where several standard MALDI matrices and matrix-to-analyte ratios do not efficiently produce analyte ions.

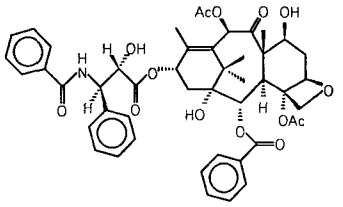

Figure 1: Taxol structure

3,5-Dimethoxy-4-hydroxycinnamic acid (sinapic acid) and α-cyano-4-hydroxycinnamic acid fail to produce useful mass spectra of the taxanes. Sinapic acid generates no intact ions of taxol. Intact ions of taxol are produced when using α-cyano-4-hydroxycinnamic acid. However, α-cyano-4-hydroxycinnamic acid clusters (m/z 200-600) make identification of the low molecular weight taxanes difficult, if not impossible. Successful MALDI is achieved employing either of two less commonly used compounds, 4-nitroaniline and 4-nitrophenol. The optimum matrix-to-analyte ratio is 100:1 and the detection limit is 1 to 2 pmol using either 4-nitroaniline or 4-nitrophenol. Several possible explanations for the different MALDI conditions for the taxanes were investigated.

Sinapic acid and α-cyano-4-hydroxycinnamic acid form monoclinic crystals. 4-Nitroaniline and 4-nitrophenol also form monoclinic crystals having the space group $P2_1/n$-C_{2h}^5 and $P2_1/a$, respectively. Initially, polarized transmission optical microscopy was used to view the crystals of 4-nitroaniline (4-nitrophenol) and 4-nitroaniline(4-nitrophenol) mixed with taxol. The observation of an "hour-glass" included region in the presence of taxol suggests that the matrix-analyte interactions of 4-nitroaniline(4-nitrophenol) and taxol are similar to those observed for sinapic acid and proteins. [1]

4-Nitroaniline produces abundant $[M+Na]^+$ ions of the taxanes. The $[M+H]^+$ ion signal increases by at least a factor of 2 when using 4-nitrophenol. In the case of taxol, enhancement of $[M+H]^+$ by close to a factor of 30 is observed (Figure 2). Enhanced parent protonation suggests that 4-nitrophenol acts as a stronger acid than 4-nitroaniline.

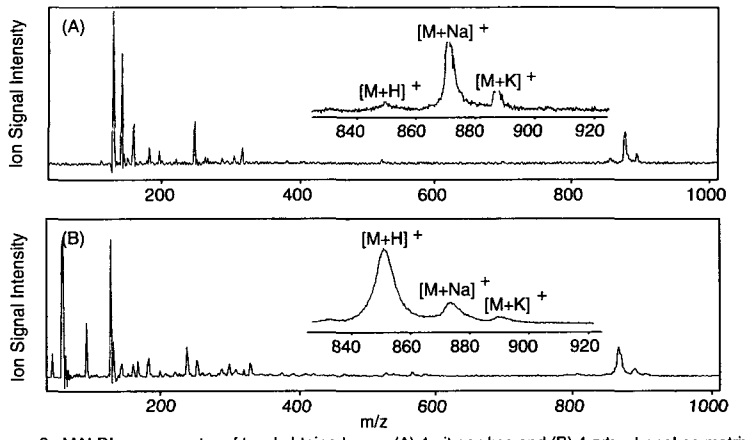

Figure 2: MALDI mass spectra of taxol obtained using (A) 4-nitroaniline and (B) 4-nitrophenol as matrix.

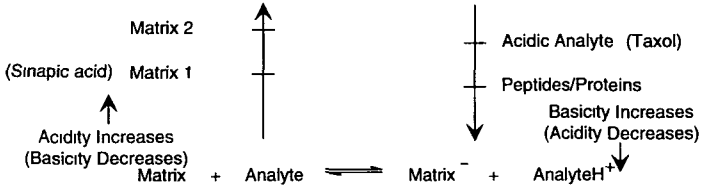
Acidity may be important in determining the effectiveness of a compound as a MALDI matrix. Of equal importance may be the relative basicity of the analyte. A matrix which may be effective for peptides and proteins (*i.e.*, Matrix 1) may not be effective as a matrix for acidic analytes. This may be the case for the taxanes. Taxol and sinapic acid may represent an example of this situation



Classical and semiempirical calculations suggest that both the identity of the electron-withdrawing group (EWG) in the position para to the proton donating group, and the proximity of the EWG to the aromatic ring enhances matrix acidity by stabilizing the resultant anion. Studies using semiempirical calculations to quantify the properties that define the effectiveness of a compound as a matrix for MALDI are in progress. The goal of these studies is to understand the role the matrix plays in the mechanism of MALDI ion formation.

Acknowledgments: Taxanes provided by Timothy Prout, NaPro BioTherapeutics, Boulder, CO.

Matrix-assisted Laser Desorption/Ionization by Fourier Transform Mass Spectrometry.

John A. Castoro and Charles L. Wilkins
Department of Chemistry, University of California, Riverside
Riverside, CA 92521-0403

Matrix-assisted laser desorption/ionization (MALDI) has made possible the generation and observation of molecular ions with masses in excess of several hundred daltons, using time-of-flight mass analyzers. Because of the inherently high mass resolution of Fourier transform mass spectrometry (FTMS) it was logical to adapt MALDI to FTMS. This task was more difficult than anticipated, with the primary difficulty apparently arising from the relatively high kinetic energies of the desorbed analyte ions. However, early last year we reported a procedure (1) involving the use of a carefully timed retarding potential prior to trapping the desorbed ions, which allowed low resolution (50-300 FWHM) FTMS detection of a variety of protein ions including the dimer of myoglobin with a mass of 34,000 daltons. The use of a sugar co-matrix allowed for production of cooler ions which were trapped for longer time periods necessary to obtain high resolution (2).

In this paper, recent studies of the use of a high field FTMS instrument with MALDI techniques designed to yield greater mass range and high mass resolution will be reported. As shown in Figure 1, there is a significant effect of electrostatic deceleration times on signal intensity for single charged MALDI-generated protein ions ranging in mass from 2627 to 29,000 daltons. The optimum deceleration times (intensity maxima) are a linear function of $m^{1/2}$ when a 9.5 V decelerating potential is used. High resolution spectra of small proteins with mass resolution in excess of 150,000 will be presented. As an example, the mass spectrum of α-melanocyte stimulating hormone is shown in Figure 2, with an average resolution of 131,000 for the three most abundant isotopes and a 0.013% mass error for the all ^{12}C isotope-containing ion. Other examples include a synthetic peptide TYQRTRALV, m/z 1107, resolution = 300,000; melittin, m/z 2845 resolution = 99,300; insulin m/z 5734, resolution = 30,000. In addition, positive and negative ion MALDI spectra of a synthetic fulleroid are presented. Slow metastable decay of molecular ions in the absence of a sugar co-matrix is demonstrated for melittin and insulin, with halflives of 11 and 7 msec, respectively. Stability of desorbed insulin molecular ion with respect to energy fluence and the resulting high resolution ca. 30,000 without a co-matrix occurs just above threshold while a broader energy range is possible with the addition of a fructose co-matrix. Detection of a double charged carbonic anhydrase trimer with a mass of 87,000 daltons is also reported.

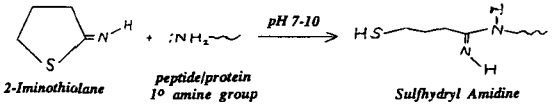
APPLICATION OF MASS SPECTROMETRY TO THE DETERMINATION OF TERTIARY AND QUATERNARY PROTEIN STRUCTURE

Steven L. Cohen and Brian T. Chait
The Rockefeller University, 1230 York Avenue, NY, NY 10021

We report here the use of 2-iminothiolane, a peptide and protein modification reagent, and its application in determining higher-order protein structure. This study was carried out in two parts. The first was an elucidation of the properties of 2-iminothiolane as a peptide modification reagent. The second part involved probing solvent accessibility of the protein ubiquitin by modification with the 2-iminothiolane reagent and the use of pepsin enzymatic digestions for mapping sites of modification. Matrix-assisted laser desorption mass spectrometry (MALDI) was an important component of the investigation and was used to rapidly monitor and characterize the products of the modification reactions and the enzymatic digestions.

The reagent 2-iminothiolane (2-IT; Traut's Reagents, MM 101 u) is a water soluble chemical modification and cross-linking reagent which specifically amidinates the ε-amino of lysine and the N-terminal amine groups. The reaction introduces a free sulfhydryl group positioned 8 Å from the amine functionality being modified. The amidination reaction can be summarized as follows.



We explored the characteristics of chemical modification with 2-IT by investigating its reactivity with various peptides. **Fig. 1** shows the positive MALDI spectra of the modification of the nonapeptide bradykinin (MM 1060) with 2-IT (1:100 molar ratio peptide:2-IT) in a Tris buffer, pH 10, carried out at 0 °C for various times. Bradykinin has only the N-terminal amine group for amidination, and the peak at m/z 1162, corresponding to the modified peptide appears 101 u above the unmodified bradykinin peak. More interesting, however, is the appearance of a peak at m/z 1145, 17 u below the expected product peak. This degradation product increases with reaction time and appears under acidic as well as alkaline conditions. In fact, the degradation product ultimately dominated for all peptides we studied which underwent 2-IT amidination. The degradation product may be a result of recyclization and hydrolysis of the amidine product back to the thiolane ring. Recyclization would mean the loss of the free sulfhydryl group introduced by the original amidination reaction. This loss has implications for protein cross-linking studies which use 2-iminothiolane as a cross-linking reagent. For the purposes of chemical modification, however, we concluded from the peptide studies that handling 2-IT under ice cold conditions with rapid (1 - 100 minutes) modification reaction times results in minimal complications from degradation.

Having established optimal amidination conditions, we turned to the second part of the study, probing of the solvent accessibility of proteins using the 2-IT amidination modification. **Fig. 2** demonstrates the general approach we considered for proteins. It consists of a modification of the solvent-accessible primary amine groups by 2-IT followed by an enzymatic degradation by pepsin. This part of this study involved an investigation of the solvent accessibility of the protein bovine ubiquitin. Ubiquitin (MM 8565) is composed of 76 resides, 7 of which are lysines and one free N-terminal amine, a total of eight potential sites for amidination modification by 2-IT.

We selected ubiquitin for two principal reasons. Ubiquitin is highly resistant to denaturation so it is likely to retain its native conformation during the chemical modification procedure. Second, extensive analyses of the three-dimensional structure and solvent accessibilities of ubiquitin are available from x-ray crystallographic and 2D NMR experiments. This information is useful in evaluating the mass spectrometry findings.

The amidination of ubiquitin with 2-IT was performed at a high molar ratio of 2-IT to protein (300:1). The modification reaction was carried out over a period of two hours and was monitored by MALDI mass spectrometric analysis. Also during this time, aliquots of the reaction mixture were subject to rapid pepsin digestion. Pepsin digest of ubiquitin yields several prominent peptide fragments. Three of these fragments together cover the full length of the protein consisting of amino acid residues # 1-15, 16-45 and 46-76. Mass spectrometric analysis of the pepsin digests revealed the extent to which the these three fragments underwent 2-IT amidination as the modification reaction proceeded. **Fig. 3** summarizes graphically these findings as the fraction of ubiquitin singly amidinated plotted against the modification reaction time. The graph indicates that ubiquitin residues #1-15 are more solvent exposed whereas residues #16 - 76 are less exposed. These findings are in reasonable agreement with the crystallographic data of solvent accessibilities. There are many considerations in interpreting the mass spectrometric results and relating them to higher-order protein structure and we are currently addressing these issues.

Mass Spectrometric Investigations of Proteins Separated by 2-dimensional Electrophoresis

*Wenzhu Zhang [1], Ruedi Aebersold [2], Tom Yungwirth [2], Daniel Hess [2] and Brian T. Chait [1],

[1]The Rockefeller University, 1230 York Ave., New York, NY 10021,

[2]The Biomedical Research Center, University of British Columbia, Vancouver, BC, V6T 1Z3, Canada

2-D electrophoresis is a technique for high resolution separation of proteins in extremely complex mixtures. The separation is performed in an anti-convective matrix, typically a polyacrylamide gel, after which the separated proteins can be transferred to a membrane to facilitate further structural analysis.

We have continued with our program to investigate how proteins are processed and modified in biological systems by obtaining peptide maps of proteins separated by 2-D analysis.

We have established procedures to map proteins at high sensitivity. The blotting membrane is precleaned with pure methanol to selectively remove SDS and stains. Then, CNBr and/or enzyme digestions are directly performed on the separated protein spots on the membrane. The resulting peptide fragments are extracted from the membrane and subjected to matrix assisted laser desorption mass spectrometry (MALDMS), without further separation. The extraction solution used is 30mM 4HCCA in {2.5% aqueous TFA;30%ACN}.

Bovine synapsins Ia and Ib (fig. 1) are neuronal phosphoproteins (MWs 74,519 Da and 70,441 Da) that coat synaptic vesicles and are believed to function, by means of changes in phosphorylation state, in the regulation of neurotransmitter release. They can be phosphorylated at serine-9 (site 1) by cAMP-dependent protein kinase and Ca^{2+}/calmodulin-dependent protein kinase I, and at serine-568 and serine-605 (sites 2 and 3) by Ca^{2+}/calmodulin-dependent protein kinase II. The capacity of the method for the elucidation of post-translational modifications was investigated for two mixtures of synapsins: (1) synapsin Ia and Ib, both unphosphorylated and phosphorylated (site 1). (2) synapsin Ia and Ib, both unphosphorylated and phosphorylated (sites 2 and 3). In both mixtures, unphosphorylated and phosphorylated forms were present at a ratio of 1:1. 2-D electrophoresis clearly resolved synapsin Ia and Ib, but did not resolve the different phosphorylation states. MALDMS peptide mapping of fragments produced by CNBr and/or enzyme digestions confirmed that the upper and lower bands were Ia and Ib respectively and both unphosphorylated and phosphorylated peptide fragments were detected. The technique also proved capable of resolving the different phosphorylation states that were not resolved by 2-D electrophoresis alone. This resolution was accomplished by dividing each membrane band into 3 segments and obtaining peptide maps for synapsins on each segment. Across each band, changes in the relative population of unphosphorylated and phosphorylated synapsins were reflected by the changes in the relative peak heights of the unphosphorylated and phosphorylated fragments (figs 2). The total amount of synapsins initially loaded onto the 2-D gel was ~45 pmol; ~1-5 pmol of each form of synapsin was estimated to be present on each membrane segment.

The combination of 2-d electrophoresis, digestion and matrix-assisted laser desorption mass spectrometry allowed us to identify the different forms of synapsin I and the sites of phosphorylation. The matrix-assisted laser desorption mass spectrometry also allowed the resolution of different phosphorylation states of synapsins that were not resolved by 2-d electrophoresis. The technique is highly sensitive.

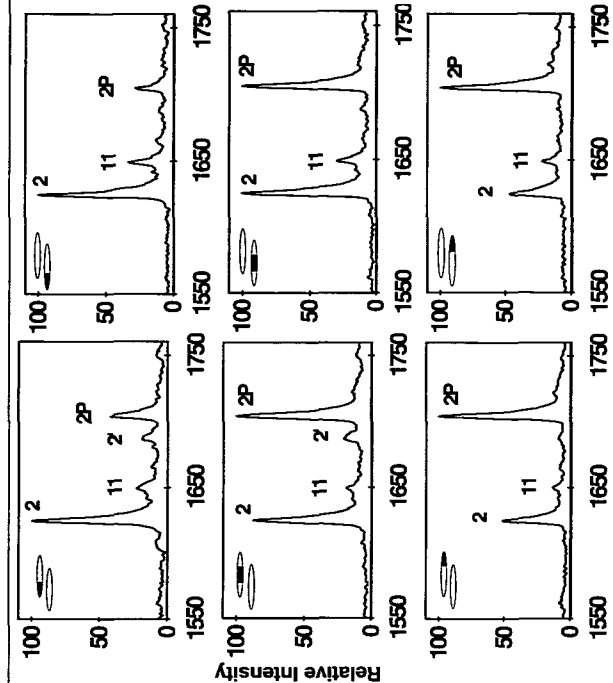

Figure 1. Sequence of bovine synapsin Ib. (Bovine synapsin Ia has 706 amino acids and its 661 n-terminal amino acids are identical to Ib.) Phosphorylation site 1 is contained in CNBr 2 fragment and sites 2 and 3 in CNBr 16 fragment. Endo lys-c digestion can further divide CNBr 16 into two sub fragments 16a and 16b (each containing one phosphorylation site).

Figure 2. MALDMS of CNBr 2 fragment of 2-d electrophoretically separated synapsin mixture (unphosphorylated and phosphorylated at site 1, see fig.1 for sequence). Each spectrum is for a segment as indicated by the darkened region in each cartoon. Relative peak heights of fragments 2 (unphosphorylated) and 2P (phosphorylated) change across each band, indicating changes in relative amount of unphosphorylated and phosphorylated synapsins.

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry as a Probe for Protein Structure.

Introduction:

Determining change in peptide or protein conformation by mass spectrometry (MS) requires that either mass and/or charge of a given ion is influenced by that conformational change Changes in mass spectral intensity can also indicate conformational change but in the case of matrix-assisted laser desorption/ionization (MALDI) it is difficult to decipher if variations in intensity are related to differences in ionization efficiencies due to conformation or variations in the desorption process. As a result, we have attempted to use changes in the distribution of peptide reaction products to probe protein structure using MALDI MS The first method is to relate the Cu binding stoichiometry of a metal binding protein domain with changes in its conformation Since, biospecific Cu binding stoichiometry is known to change with altered conformation, changes in the ion distribution of the series $(MH+Cu_n-H_n)^+$, as compared to solution-phase metal binding, may indicate changes in conformation The second approach is to selectively react specific, surface exposed amino acid residues within a defined protein domain and determine if the distribution of products are influenced by a change in conformation. Any observed differences in the distribution of the covalently modified products may reflect a change in reactivity of specific residues as a result of conformation

The estrogen receptor dimerization domain (ERDD) was chosen as a model peptide in this work because of its importance in the molecular recognition event leading to estrogen receptor dimerization. It has also been studied extensively for its solution phase metal binding properties and has a known and characterized secondary structure consisting of alpha-helix, beta-turn and beta-sheet structural motifs which can be monitored by vacuum UVcircular dichroism (CD)

Results and Discussion

In the case of ERDD, a dramatic difference in the Cu binding profiles were observed in the MALDI experiment depending on the type of matrix used When sinapinic acid (SA) was used as the MALDI matrix no Cu binding was observed. This was in contrast to results obtained with 2,5-dihydroxy benzoic acid (DHBA) and α-cyano-4-hydroxycinnamic acid (α-CN) matrices where up to eight bound copper ions were observed per ERDD molecule. The Cu binding stoichiometry of ERDD in DHBA and α-CN were, however, different The distribution of ERDD-bound Cu in DHBA closely resembled that observed in solution Based on this result, it appears that the conformation of the ERDD peptide is maintained during the drying, ionization and desorption process when DHBA is used, but may not be retained with the other two matrices investigated Relating the loss of peptide or protein conformation to changes in metal binding stoichiometry is difficult, however, because the matrix influences such variables as pH, localized solvent composition and histidine(His) pKa values which are known to affect metal binding. The retention of metal binding stoichiometry, as with the case of ERDD in DHBA, however, is

evidence that conformation is retained since metal binding is not random but is consistent with solution phase stoichiometry

Covalent modifications of His residues was performed using the selective carbethoxylating reagent diethylpyrocarbonate (DEPC) In this reaction, a $(OCOCH_2CH_3)$ group is covalently bound to the imidizole ring of His resulting in a mass increase of 72 amu per modification The extent of covalent modification appears to be dependent on the conformation of the peptide or protein and can be measured by MALDI MS using SA as a matrix (figures 1 and 2) The reaction products can be driven to a higher degree of substitution by raising the concentration of DEPC in the reaction mixture. The degree of substitution was observed to be limited, however, when the ERDD peptide was reacted in its native conformation and gave a distribution of covalently modified products that is shown in figure 1 When the peptide conformation was altered by sonication prior to and during reaction with DEPC under otherwise identical conditions, a higher degree of modification was observed (figure 2) This may indicate an increased accessibility of the His residues as the peptide unfolds to its denatured state. If this is true, then the conformation of a given peptide or protein can be probed indirectly by monitoring the extent of covalent modifications of specific surface-exposed residues Experiments are currently underway to determine if the increase in the highly modified products is a direct result of conformational change or if the sonication was responsible for increasing the rate of reaction for these products.

In both DHBA and α-CN matrices the selective covalent modification of His residues with DEPC resulted in a loss of ERDD signal The loss of signal cannot be attributed to conformational changes directly, but CD results show that even a slight modification of the His residues results in a loss of conformation. The loss of signal could be due to changes in solubility or crystallization of ERDD in these matrices or could be explained by a change in the net charge of the peptide from an overall positively charged peptide to one that is neutral or negatively charged as the extent of His modification increases Efficient coupling of laser energy into the peptide due to the chemical modifications appears not to be responsible for loss of signal since highly modified species are observed out of SA (figures 1 and 2) Likewise, the overall desorption process was shown to remain intact by including myoglobin into a reaction mixture. In this case, the ERDD signal was lost but there was no apparent loss of sensitivity for myoglobin (results not shown)

USDA/ARS Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030

INTRODUCTION

An important class of regulatory mechnisms in biology involve the modulation of protein and peptide structure and function by sequence-specific phosphorylation and dephosphorylation reactions. In addition to the widely recognized role of protein phosphorylation as a principal mechanism for signaling, the effect of phosphorylation on metal-binding and the subsequent modulation of molecular recognition and biospecific metal transfer is also of great significance.

We have developed the use of matrix-assisted UV laser desorption/ionization (MALDI) time-of-flight (TOF) mass spectrometry as a fast and sensitive method to map phosphorylation sites in proteins and to monitor protein phosphorylation/dephorylation specificity, stoichiometry and kinetics. In the case of peptides and/or proteins containing multiple possible phosphorylation sites, MALDI-TOF allows the relative ratios of all possible reaction products to be assessed directly

We now report on the further application of this technique to probe the structural and functional changes associated with varying degrees of phosphorylation. Human β casein is a major milk protein with up to five phosphorylation groups. We have mapped the site to be in the N-terminal region of the protein with a concensus sequence SSSEES found not only in human β casein but also in bovine β, αS_1 and αS_2 caseins. It is the major carrier of Fe, Ca and Mg in the milk and plays a key role in regulating mineral and metal ion absorption and cell growth. Again with the MALDI-TOF mass spectrometric technique we have developed to investigate protein/peptide-metal ion interactions we studied the effect of phosphorylation on the specificity and capcity of metal ion binding of human β casein. Parallel studies with electrospray ionization mass spectrometry and UV spectrophotometric titration are used to support the findings.

RESULTS

Fe(II)-binding study of the whole human β casein molecule performed by standard procedure like spectrophotometric tiration revealed that the binding capacity is highly phosphorylation-dependent. In an effort to map this phosphorylation-dependent metal binding site, unfractionated tryptic peptides of human β casein before and after alkaline phosphatase treatment was determined by sequential MALDI-TOF mass spectral analysis. The result showed that the tetraphosphorylated casein peptide (R1-K18 + 4P) was the major Fe(II)-binding entity in the whole digest.

To understand further how the degree and proximity of phosphorylation affect the selectivity and capacity of metal binding, individual peptides were purified from the tryptic digest. The unphosphorylated (R1-K18) peptide could bind only a barely detectable amount of Fe(II). This was confirmed by ESI even when performed in water or dilute buffer. The monophosphorylated (R1-K18 + 1P) peptide could bind Fe(II) much more readily, however, the original peptide with no bound metal was still the predominant species in the mass spectrum. The tetraphosphorylated (R1-K18 + 4P) peptide could bind up to six Fe(II) with the optimum number bound of around 3 and virtually none of the original peptide remained with no metal ion bound. This was again confirmed by ESI even when sprayed in dilute acid. However, Ca(II)-binding apparently was not as dependent on phosphorylation, since both the unphosphorylated and phosphorylated form could bind equally well with not appreciable difference in stoichiometry. This has great implication in the study of bioavailability of both Ca(II) and Fe(II) in the milk since casein is the major binding protein for both these two important metal ions. Therefore we further attempted to study the interaction and competition between these two metal ions for binding to the same phosphopeptide. The result indicated that each could effectively displaced the other from the casein phosphopeptide.

Finally, we adapted this technique to study some clinical samples. Preterm infant gastric aspirate was analyzed by MALDI-TOF directly without any fractionation before and after alkaline phosphatase treatment and then after in situ Fe(II)-binding. The result indicated that the preterm infant could digest an appreciable amount of the casein in the infant formula to generate phosphopeptides that were capable of binding Fe(II)

Evaluation of Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry as a Clinical Assay

Randall W. Nelson[1], T.William Hutchens[2], Mathew A. Mclean[1], Tai-Tung Yip[2]

[1]Vestec Corp. 9299 Kirby Dr. Houston TX, 77054, [2]Protein Structure Laboratory, USDA/ARS Children's Nutrition Research Center, Dept. of Pediatrics, Baylor College of Medicine, 1100 Bates St. Houston TX, 77030.

INTRODUCTION

In order for the matrix-assisted laser desorption/ionization technique to be of use in a clinical environment, its practical quantitative abilities and limitations must first be investigated. Presented is a methodology, utilizing simple refinement techniques and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry, for the quantitative analysis of a clinically significant protein, lactoferrin, present in a naturally occurring biological fluid, urine.

RESULTS

Experiments were performed investigating various possible methods to enable the production of lactoferrin ion signal during the matrix-assisted laser desorption/ionization process. Fig. 1 shows a typical MALDI spectrum of lactoferrin containing (3pmol/ul) urine with no prior sample workup. Overall the spectrum is of fairly low quality, with poorly resolved lower mass protein signals and no obvious signal at ~81 kDa (molecular weight of the lactoferrin). The speculated reason for no lactoferrin signal present in the mass spectrum is that lactoferrin ion production was inhibited by the presence of an extreme amount of native protein present in the urine. Fig. 2 shows a mass spectrum of the lactoferrin-containing urine after adjusting the pH to 8.0 and the addition of DEAE-Sephlacel anion exchange resin. At a pH of 8.0 the lactoferrin exhibits minimum binding to the DEAE-Sephlacel anion exchange resin, so it was thought that the rapid mixing of urine and anion exchange resin would perhaps sweep enough of the erroneous proteins out of solution to provide an adequate lactoferrin signal. Fig. 2 shows the resulting mass spectrum. While use of the anion exchange resin did not remove all of the interfering protein, it did refine the urine enough to provide a substantial lactoferrin signal.

After enabling the lactoferrin signal from the urine, quantitative analysis followed in a manner previously described /R.W. Nelson, et al, Proc. of the 40th ASMS Conference on Mass Spectrom. and Allied Topics/. Briefly, the technique involves the addition of an internal reference standard, in this case human serum albumin HSA, followed be successive additions of concentrated analyte solution. Fig. 3 shows a plot of lactoferrin signal (normalized to the HSA signal) versus the resultant lactoferrin concentration. A linear relationship is observed over an order of magnitude with the intercept indicating an initial concentration of, after correction for dilutions occurred throughout the experiment, 0.6 pmol/ul.

CONCLUSION / DISCUSSION

A simple method to enhance the performance of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry of natural biological fluids has been investigated. Because of interferences due to the complexity of the analyzed natural biological fluid, urine, simple off-line fractionation techniques were used to refine the solution with respect to a clinically significant protein

species of interest, lactoferrin. Using the refinement techniques, lactoferrin ion signal was obtained, from urine, at yields sufficient for quantitation, hence accomplishing the original objective of the excersise. Quantitative analysis of the refined urine by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry indicated an approximately 20% recovery of the lactoferrin throughout the procedure. Further investigations need to be undertaken concentrating on ways to improve the lactoferrin recovery throughout the refinement process.

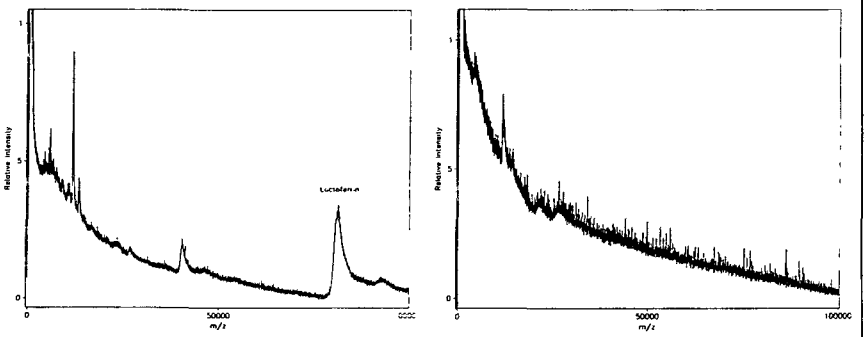

Fig. 1 (left) MALDI spectrum of urine containing human lactoferrin at a concentration of 3 pmol/ul. Fig. 2 (right) MALDI spectrum of the urine used to produce Fig. 1 after refinement by addition of DEAE-Sephlacel anion exchange resin at a pH of 8.0. Reasonable lactoferrin signal is obsered at ~81 kDa.

REAL TIME ANALYSIS OF SINGLE AEROSOL PARTICLES

D. S. Thomson*, D. M. Murphy, and M. Kalyuzhny*

***also with Cooperative Institute for Research in Environmental Sciences**
University of Colorado, Boulder, CO 80306

We have developed an instrument capable of analyzing individual aerosol particles in real time. Using laser ionization and TOF mass spectrometry, we have obtained mass spectra for a variety of laboratory-produced aerosols. Recent improvements in the instrument as well as in our aerosol production capabilities have allowed us to increase the range of particle types and sizes which we can detect and to increase the resolution of the mass spectra. Further improvements are underway which will allow the instrument to perform field measurements in the near future.

Aerosol particles enter the interaction region of the vacuum chamber through a differentially-pumped multi-stage inlet. The passage of the particles through the focus of a continuous laser beam scatters light into an avalanche photo-diode. This scattered light provides information on the size of the particle and triggers a pulsed excimer laser. The pulsed laser produces several milli-Joules of radiation at 248 nm which vaporizes and ionizes the particle. The ions are accelerated down a time-of-flight mass spectrometer to a pair of ion detectors. Logarithmic amplifiers compress the spectra, which are then digitized and transferred to a personal computer for storage and analysis.

The minimum particle size of the instrument is limited by the scattered light detection. Recently, we have obtained spectra of several types of 0.3 μm diameter particles, including latex spheres, sodium iodide, and ammonium sulfate. Since previous measurements were made on particles from 2 μm to 15 μm diameter, this significantly expands our ability to measure particles of atmospheric interest. Due to the reduction in minimum particle size, we have been able to obtain spectra from ambient aerosols present in the laboratory air. Though we have not yet conducted extensive analysis on ambient particles, we are preparing the instrument for a field measurement campaign which will begin late this summer.

The acceleration fields of the mass spectrometer include a time-dependent field used to increase the mass resolution.[1] As a result, we have obtained spectra with better than unit mass resolution for all masses up to about m = 350 using a flight tube only 67 cm long. In addition, we recently completed the circuitry required for reversing the polarity of the mass spectrometer, allowing us to begin recording negative ion spectra as well as positive.

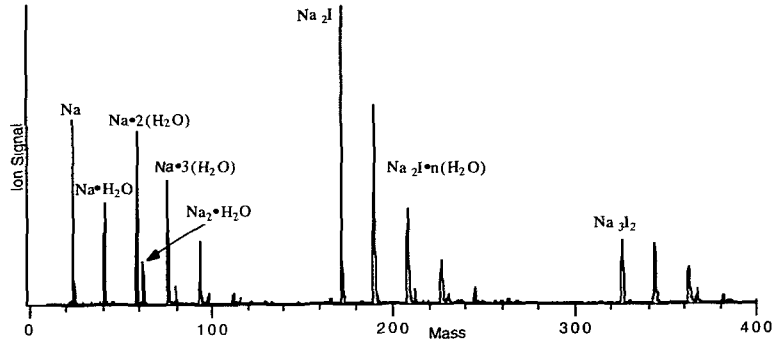

Figure 1) Sample spectrum of 2 μm particle consisting of NaI and water.

As part of the development of the instrument, we have made numerous measurements of the laser energy threshold for ion production as a function of particle type, particle size, and laser wavelength.[2] A limited amount of data were taken with laser wavelengths of 337 nm and 197 nm, and more extensive studies were done using 10.6 μm, 308 nm, and 248 nm. It was found that the shorter wavelengths were more appropriate for this instrument for a number of reasons. Not only were the laser energy thresholds for ion production several orders of magnitude lower at 248 nm than at 10.6 μm, but there was also less variation due to particle size and composition. In addition, at 10.6 μm the threshold for plasma initiation was only a factor of 2 greater than for ion production, while at 248 nm plasma initiation occurs at laser fluences several orders of magnitude higher than ion formation. This allows a broad range of laser energies to be utilized without saturating the interaction region with the space charge effects due to plasma production. The advantages of 248 nm radiation over 308 nm radiation are similar though less pronounced.

We have begun additional measurements on the number of ions produced as a function of laser power. Preliminary data shows that the ion yield is a non-linear function of laser power, but so far the data do not allow for a more precise determination of the functional form.

EXAMINATION OF NATIVE AND DEGRADED IgG ANTIBODIES BY MICELLAR ELECTROKINETIC CAPILLARY CHROMATOGRAPHY AND MATRIX ASSISTED LASER DESORPTION/IONIZATION MASS SPECTROMETRY

Anthony J. Alexander* and David E. Hughes; Bristol-Myers Squibb Co, Pharmaceutical Research Institute, P O. Box 4755, Syracuse, N.Y. 13221.

INTRODUCTION

Monitoring the stability of drug delivery antibodies is a crucial analytical aspect of the IgG production technology. Capillary electrophoresis (CE) has proven valuable for the analysis of proteins (1), and has the potential to separate and detect native antibody components. An ideal complement to CE, which is capable of providing the desired detection specificity, is matrix assisted laser desorption/ionization mass spectrometry (MALDI-MS). Off-line CE-MALDI has been demonstrated (2), but on proteins with molecular weights considerably less than typical for antibodies. Utilizing these techniques we have developed an antibody examination procedure and monitored the degradation of an chimeric (human/mouse) monoclonal antibody.

METHODS

The antibody, at a concentration of 10 mg/mL in buffered saline, was heat-stressed at 60°C for a period of 166 hrs. At discrete time points, sample aliquots were removed and sampled by CE and MALDI-MS. The CE separation was performed using a Beckman P/ACE system with a 50cm x 75µm uncoated capillary. The running buffer was 12 mM borate pH 9 4 containing 25 mM SDS. The separation was performed at 30 kV for 8 minutes at 25°C and monitored at 214 nm. MALDI mass spectra were obtained using a Bruker Reflex Time-of-Flight mass spectrometer equipped with a 337 nm laser. Spectra were obtained using an ion extraction voltage of 30 kV and a time resolution of 10 ns. Samples were diluted 20:1 with an aqueous saturated solution of sinapinic acid (SA) containing 33% acetonitrile. 1 0 µL of this mixture was allowed to air dry on the probe tip Spectra were obtained using the linear detector and represent the summation of 20 laser shots.

RESULTS AND DISCUSSION

Electropherograms of the antibody after 0, 47, 94 and 166 hrs of thermal stress are shown. The unstressed antibody is represented by four major peaks (A,B,C,D assumed to be conformers) and low levels of IgG-related species. As degradation proceeds, peaks 2,4,6 and 7 are formed Peaks 1,3 and 5 also increase in height MALDI mass spectra of the stressed antibody were acquired at the same time points The initial spectrum was obtained from 3.3 pmoles of IgG loaded on the probe tip. At 166 hrs the percentage of ionization carried by the molecular ions M^+, M^{2+}, etc has clearly decreased while that due to additional ion species, particularly below m/z 16,000, has significantly increased. Several ion signals at ca. m/z 125,600; m/z 101,800; m/z 50,900 and m/z 24,070 progressively increase with time. These ions correspond in mass to loss of one and two light chains from the IgG, $(M-LC)^+$ and $(M-2LC)^+$, and formation of separated heavy chain (HC^+) and light chain (LC^+) moieties, respectively.

CONCLUSIONS

CE provides the very selective separation of antibody-related chains and fragments required for the examination of degraded IgG samples MALDI-MS provides a complimentary "fingerprint" or, impurity profile, of an antibody from which it is possible to assess both the degree of degradation, and gain specific MW information on the resulting species formed.

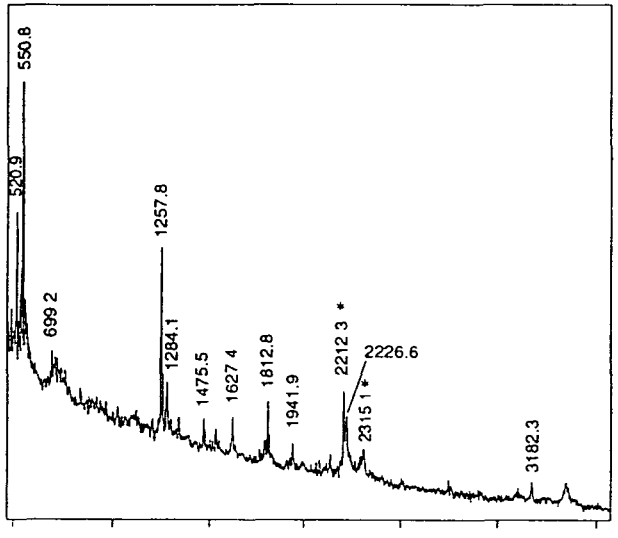
Peptide mapping is a valuable tool for the characterization of proteins. Detailed analysis of each of the component peptides in a protein permits examination of the primary structure in considerable detail. Mass spectrometry is now one of the most useful techniques for peptide mapping. In recent years, matrix-assisted laser desorption/ionization mass spectrometry (MALDI) has emerged as an important technique for the analysis of biomolecules. Characterized by sensitivity in the mid-femtomole to low-picomole range, MALDI has a high (>300 kDa) upper mass limit, relative tolerance to many buffer components, and the ability to analyze unfractionated biomolecular mixtures. As a result, the technique is particularly well-suited for analysis of peptide mixtures that result from proteolytic protein digestion. Despite the advantages of MALDI, several limitations have thus far prevented its routine and widespread application. Each of the common matrices discriminates against mixture components in ways which are sample and matrix specific. Some of these matrices yield abundant, interfering matrix ions that extend up to 1000 Da. The lack of a universally applicable matrix lowers analysis efficiency by requiring the comparison of spectra acquired in more than one matrix. One way to surmount the matrix selectivity problem is to improve known matrices by using matrix mixtures.

Based on the favorable results achieved by Köster *et. al.*[1] we evaluated the effect of incorporating glucose, fructose, fucose, b-lactose, maltose and sucrose in various molar ratios with DHB. Fucose/DHB in a molar ratio of ca. 5000:5000 to one part analyte produced the best results achieved to date.[2] The spectrum of recombinant human growth hormone (rhGH) tryptic peptides in sodium acetate/Tris buffer with a DHB/fucose matrix displays a number of striking enhancements over that with DHB alone. The absolute ion signal for many peptides is increased, affording unambiguous detection of more mixture components. The matrix signal, frequently appearing as the base peak for DHB, was dramatically suppressed in the presence of fucose. Further, the rise in baseline at low masses was minimized. The resolution (FWHM) was likewise improved. Signals corresponding to $(M+Na)^+$ were often more abundant than $(M+H)^+$ in preparations with neat DHB. Overall, 96% of the expected tryptic fragments were detected using as little as 280 fmol of unfractionated material. Analysis of <280 fmol showed a decrease in the relative abundance of the higher molecular weight peptides.

The advantages of the carbohydrate co-matrix are applied to the analysis of digests of proteins isolated from two-dimensional gels. Proteins in a gel are electroblotted to PVDF membrane, followed by *in situ* reduction, alkylation and tryptic digestion.[3] The resulting peptides are analyzed by MALDI. The peptide molecular masses are used as input for a computer program (FRAGFIT) that searches a protein sequence database.[4] This approach permits the rapid identification of known proteins at the sub-picomole level.[5]

To demonstrate this approach, proteins extracted from an hGH-producing *E. coli* fermentation were separated by two-dimensional electrophoresis, blotted onto a PVDF membrane, and stained with Coomassie blue. Ten spots were arbitrarily chosen, and two identical gels were run. One gel was used for N-terminal sequence analysis. The second gel was used for tryptic digestion followed by MALDI mass spectrometry. The amounts analyzed ranged from 75 fmol (3% of the total) in spot 1 to 840 fmol (20%) in spot 8. Masses with $900<m/z<2500$ obtained from MALDI analysis were used as inputs for the FRAGFIT program to identify the protein(s) in each gel spot.[5] The FRAGFIT algorithm cleaves >91 000 entries in the protein sequence database using a specified cleavage reagent each time the program is executed. The program then searches the database for a protein with fragment masses that match the user's list of masses within a tolerance of ±4 Da. A molecular mass range based on the second gel dimension is used to limit the size of the proteins searched in the database. The user may specify the number of mismatched fragments allowed for each search. Typically, a protein may be uniquely identified using as few as 3-5 peptide masses as inputs. A complete search is completed in <5 min on a VAX 8650.



MALDI mass spectrum (above) of spot #1 from a 2-D gel after *in situ* reduction/alkylation/tryptic digestion. Peaks marked with an asterisk are fragments of trypsin that are observed in blanks. The matrix was DHB/fucose. Data were acquired with a Vestec LaserTec ResearcH mass spectrometer using a 337 nm nitrogen laser. The amount loaded on the MALDI probe was estimated to be 75 fmol. The mass range input for the protein was 0.5-45 kDa, based on the SDS-PAGE mass markers. A single protein match was found in the database (Cysteine synthetase *a* from *E. coli*, M_r 34,358). The measured masses input to the program FRAGFIT and the matched sequences are given below.

Introduction

Electrospray ionisation (ESI) and matrix assisted laser desorption ionisation (MALDI) are currently preferred ionisation techniques for large molecules. ESI achieves high mass by multiple charging, to give a spectrum that typically appears below 2500 Da. Ion beams are usually weak but, as the noise level is low, the benefits of increased ion collection offered by a multichannel array detector should enable the sample quantity to be substantially reduced.

The MALDI technique is somewhat different in that intermittent bursts of predominantly singly-*charged ions are produced following each laser pulse and, to date, it has not been considered* appropriate to use this ion source with a scanning mass spectrometer. Time of flight (TOF) mass spectrometers are generally preferred but suffer the disadvantage of poor resolution. Even with a reflectron, mass resolution is typically not greater than 2000 (FWHM) An array detector with a mass range of 20% (1.2:1) also appears to offer a solution to the combination of MALDI with a magnetic mass spectrometer for applications up to about 10,000 Dalton. This detector will allow a decade in mass to be covered with 13 separate exposures and multiple laser pulses may be used for each exposure to improve the ion statistics

Experimental

The mass spectrometer used in this work was an AutoSpec-FPDQ (VG Analytical, Fisons plc, Manchester, UK) having E_1BE_2 geometry and a mass range of 5000 Dalton at 8 keV. An inhomogeneous field ESA mounted between B and E_2 allows the beam to be diverted onto a 50 mm microchannel plate (MCP) array detector optically coupled to a 2048 channel photo - diode array. The dispersion of the inhomogeneous ESA and array detector can be adjusted to give 1.2:1 mass ratio at 2000 resolution (FWHM) to 1.07:1 at 5000 resolution.

A 337 nm pulsed (4 nsec, 180 μJ/pulse, repitition rate 20 Hz) nitrogen laser (VSL-337i, Laser Science Inc., Cambridge, MA, USA,) was mounted horizontally above the ion source housing The laser beam was focused by a lens and reflected by an adjustable mirror, downwards through a sapphire window into a standard AutoSpec FAB source with a thin stainless steel strip (6 mm x 1.5 mm) as the sample stage. Two micrometer drives on the adjustable mirror were used to steer the beam around the sample surface to find the optimum production of signal. During acquisition, typically 1 second duration exposures were taken with the laser synchronised with the acquisition cycle so that between exposures the laser was not firing

Oligosaccharide samples (100 pmol) were mixed with 2,5-dihydroxybenzoic acid (2,5-DHB) (1 μl, 50 μM) on the laser target probe. α-Cyano-4-hydroxycinnamic acid was used for peptides. The samples were allowed to evaporate to dryness in air before loading into the mass spectrometer. Samples from 2,5-DHB were further crystallised from ethanol on the target.

Results and Discussion

ESI with continuous sample infusion was used to allow a direct comparison of the detection efficiency of the array and a conventional point detector using serial dilutions of hen egg lysozyme. The scan time was adjusted to be the same for both acquisition modes. For sample consumptions down to about 200 fmol, both the point and array detectors gave useful data although the ion statistics were always better from the array detector. Below 200 fmol, the point data rapidly deteriorated so that at about 50 fmol the signal to noise was about 1:1. Use of the array detector allowed the sample consumption to be further reduced. At about 12 fmol, the array data were superior to that from the point detector at 230 fmol. Even at 1.2 fmol sample consumption the array data were quite usable with a signal to noise of better than 5:1 .

The array detector produced good spectra of peptides and oligosaccharides using MALDI. Both resolution and signal:noise ratio were superior to that from a TOF instrument as shown by the spectrum of released *N*-linked oligosaccharides from ovalbumin (Fig. 1). High resolution was used to confirm the *absence* of the high mannose oligosaccharide $(man)_9(GlcNAc)_2$ ($[M+Na]^+$ 1905.7 Da) from the peak in Fig. 1 at m/z 1909.1 (shown inset in Fig.1). This peak was produced by $(Hex)_4(HexNAc)_6$ ($[M+Na]^+$ 1907.7 Da, average mass 1908.7 Da). This differentiation would not have been possible with a lower resolution TOF mass spectrometer. Detection limits (5:1 S/N ratio) were 5 fmol for the peptide renin substrate ($[M+H]^+$ 1758 9 Da) and 200 fmol for a typical *N*-linked biantennary oligosaccharide $[(Gal)_2(GlcNAc)_4(Man)_3(Fucose)]$ ($[M+Na]^+$ 1809.6 Da).

COMPARISON OF FIELD DESORPTION AND MATRIX ASSISTED LASER DESORPTION IONIZATION OF AN INDUSTRIAL OLIGOMERIC ADDITIVE

Kenneth Ng, B. Piatek, C. Shimanskas

Analytical Research Department, Ciba-Geigy Corporation, Saw Mill River Rd., Ardsley, NY 10502

Field desorption is still the technique of choice among many of the available soft ionization techniques to characterize industrial polymers. Since the advent both in its improved performance and cost, matrix assisted laser desorption ionization (MALDI) has been recognized as an alternative to characterize such polymers.

Gel permeation chromatography (GPC) and nuclear magnetic resonance (NMR) are complimentary to one another when used in tandem to characterize these polymers but mass spectrometry is a far more superior analytical technique since it can simultaneously provide molecular weight distribution, both M_w and M_n and structural information during the same analysis. Its only weakness is found in the limitation of handling of many extreme high moleuclar weight polymers.

The objective of this paper is to investigate the usefulness of MALDI in characterizing industrial oligomers of medium molecular weight. Five batches of a commercial light stabilizer (Structure I) whose average MW is usually < 5000 daltons were used in this investigation using both FD and MALDI techniques and their spectra were compared. The FD and MALDI spectra from an identical sample are shown as I and II. Results indicated that both FD and MALDI are useful to provide both molecular weight information as well as specific structural information of this type of compounds. This information can be extracted from the same analysis. Many different oligomeric series were discovered during these analyses. The structures of such series were based on their unique molecular weights as represented by either the M^+ or M^+H ions. The structures of the end capping groups, R and R_1 of series had been tentatively assigned. Some significant differences were observed between the two techniques. While FD can generally provide higher ionization efficiency for the higher molecular weight species, it lacks consistency to reproduce spectra from the same sample thus making batch comparison impossible. On the other hand, since the final spectrum of a MALDI experiment which is the composite of many spectra depending on as many laser shots as being rastered across the sample, the MALDI technique is more likely to reflect the sample characteristics as a whole or at least portion of the sample which ionizes.

DIRECT MALD MS ANALYSIS OF PROTEASE DIGESTS: COMPARATIVE STUDY OF ANALYSIS PARAMETERS

Paolo Lecchi and Richard M. Caprioli
The Analytical Chemistry Center and the
Department of Biochemistry and Molecular Biology
University of Texas Medical School, Houston, Texas 77030

Introduction

Analysis of biological molecules by MALD MS (1) provides high sensitivity, a wide mass range, relatively facile sample preparation, and short analysis times. For purified peptides and proteins, this technique is quite successful. However, for complex mixtures of samples, application of the technique is more complex.

We have applied MALD MS to the analysis of tryptic digests of proteins up to the 40,000 da. range. Analysis parameters considered were instrument resolution, laser power, m/z scale calibration, choice of matrices, sample concentration, sample preparation, and, overall, mass assignment accuracy. The objective of this work was to assess the value of MALD MS to the protein chemist for the analysis of tryptic digests. Basically, how complete an analysis can be achieved with reasonable care and what instrumental parameters are critical to the analysis? How effective would the technique be in the analysis of a protein of unknown sequence?

Experimental

A Vestec LaserTec benchtop MALD mass spectrometer was used to obtain the spectra shown here. It employs a N_2 laser, 1.2 meter flight tube, and was operated at 26 kv accelerating voltage. The windows version of LABCALC was used for data analysis. Typically, 30 spectra were averaged to obtain spectra.

The matrix compounds (2-6) were prepared in 0.1 M concentrations in a solvent containing 70% acetonitrile, 30% water, and 0.1% trifluoroacetic acid In the case of DHB acid and fucose, a 98:2 water/acetonitrile containing 0.1 trifluoroacetic acid solvent was used (7). Approximately 1.2 μL of matrix solution is mixed on the target with 0.8 μL of sample solution containing 1 pmol/μL of peptide or protein and the sample allowed to dry.

Matrices used in this study were; sinapinic acid (SA), α-cyano-4-hydroxycinnamic acid (α-CCA), ferulic acid (FA), caffeic acid (CA), dihydroxybenzoic acid (DHBA) plus fucose, and 6-aza-2-thiothymine (ATT).

Results

Instrument calibration: Both external standards (separate analysis of standard peptide mixture) and internal standards (peptide standards added to digest) were used. Generally, potassium (m/z 39) and mellitin (m/z 2848.5) were used as mass standards External standard calibration typically provided ± 0.2% mass assignment accuracy, with some cases showing a constant direction of the error (i.e., 0.2% high or low). Optimal calibration was achieved using added internal standards, typically giving ± 0.03% accuracy.

Effect of laser power: For a number of digests, the laser power was varied from 30% to 80% (relative) power. Spectra were compared from the same sample loading, typically 2 pmol total. Altering the power does not appear to significantly change the relative intensities of the fragments observed. It will, however, be advantageous to change laser power depending on the matrix used so as to minimize interfering peaks from this matrix at low mass.

Background interference: All matrices show significant background up to about m/z 600 with laser power sufficient to produce peptide signals. DHBA gave the least interference, although it was typically not the best matrix for the analysis of tryptic digests. At higher laser power, all matrices gave significant background up to (and beyond) m/z 1000.

Effect of sample concentration: The RELATIVE intensities of peaks in the MALD spectrum may change depending on the concentration of the sample. In some cases, peaks not observed at higher sample loading (e.g., > 5 pmol) can be observed at lower loading (e g., 0.5-1 pmol). The opposite can also occur, perhaps due to different amounts of fragments present.

Choice of matrix: Of the several different matrices used in this study, we found αCCA to be most generally useful, and DHBA + fucose to be especially advantageous in the low molecular weight range (< 1000 da). However, no one matrix provided the identification of all of the fragments in the several digests used here. Generally, 60-80% of the fragments could be seen with most matrices, although the specific fragments identified were not the same for each.

Summary and Conclusions

One can consider two kinds of applications for the MALD MS analysis of protease digests:

A) Survey analysis: In this case, the analytical task is not critical in that not all fragments are required to be identified and mass assignment accuracy need only be approximate.
A single matrix can be used (usually, αCCA is a good choice) with 1 pmol of digest. Typically, external calibration is sufficient, giving ± 0.3% mass assignment accuracy and identifying 50-75% of the fragments present. Total time can be expected to be 30 min or less.

B) Optimal performance: In this case, the analytical task is to identify all fragments at high mass accuracy. We recommend; i) use of several matrices (e.g., αCCA, DHBA + fucose, SA, ATT, FA), ii) use several concentrations with the 'best' matrices for the sample (e.g., 8, 1, and 0.5 pmol loaded), iii) acquire data using several laser power levels, and iv) use of internal standards for calibration. Under these conditions, 90-100% of the fragments can be expected to be found, with ± 0.03% mass assignment accuracy. However, an analysis time of many hours would be anticipated for a single digest.

Identification of the Facile Gas-Phase Cleavage of the Asp-Pro Peptide Bond in MALD-TOF MS

W. Yu, J.E. Vath, M.C. Huberty, S.A. Martin, H.A. Scoble
Genetics Institute, Inc. One Burtt Road, Andover, MA 01810 USA

Abundant ions corresponding to the gas-phase cleavage of the Asp-Pro bond of peptides in the process of matrix assisted laser desorption were observed using a time-of-flight mass spectrometer (Bruker REFLEX) equipped with both linear and reflector mass analyzers. Peptides containing the N-terminal sequence, Asp-Pro... from an endoproteinase Asp-N digest yielded one peak in the molecular ion region in the linear mode and two equally abundant peaks in the reflected mode TOF mass spectra. The lower molecular masses in the reflected mass spectra could be eliminated by removing the Asp residue or derivatizing its side chain carboxyl group. The observed mass differences did not correspond to any amino acid, however, by lowering the potential of the reflector to correct for the energy loss the mass difference was determined to be 115 daltons, i.e. Asp. These results were compared with those obtained using a JEOL HX110/HX110 tandem mass spectrometer in the MS/MS mode of operation without and with a collision gas. These data suggest the Asp-Pro peptide bond is more labile than other peptide bonds in the gas phase and decays after full acceleration but prior to entering the reflector.

The gas-phase mechanism for this decomposition was derived by obtaining the reflected mass spectrum (Figure 1) of a peptide, whose sequence is listed below, which contains two internal Asp-Pro bonds.

AIPSSDPASVSPHQPLAPSMAPVAGLTW	28	*3B, 7-55, m/z 4935.4*
EDSEGTEGSSLLPGEQPLHTVDPGSAK	55	*3A, 1-50, m/z 5065.5*

The reflected mass spectrum exhibits an abundant peak at *m/z* 5506.4 corresponding to the intact molecular mass of the peptide and two additional abundant peaks at *m/z* 5028.8(3A) and 4917.0(3B). The corrected masses for these two peaks, *m/z* 4935.7(3B) and 5047.7(3A) were obtained by lowering the potential of the reflector. The mass observed for 3B agreed with the expected mass for cleavage of the first Asp-Pro bond with charge retention on the portion containing the proline (see above). The mass corresponding to 3A was 18 daltons less than expected for cleavage of the second Asp-Pro bond with charge retention on the portion containing the new C-terminal aspartic acid (see above). These data support the mechanism shown in the upper left corner of Figure 1.

An application of the specific cleavage of an Asp-Pro bond in a peptide is illustrated with a composite reflector mode spectrum of an asialo O-linked glycopeptide from rhIL-12 (Figure 2). This spectrum is obtained by varying the reflector potential from 30 kV to 5 kV in several steps. The two most abundant peaks in this spectrum correspond to the cleavage of the Asp-Pro bond with a distribution of fragment ions corresponding to the N-terminus (b_9, 1338) and the C-terminus (y_{23}, 2686) of the molecule. The mass of the b_9 peak corresponds to the the peptide backbone and one unit each of HexNAc and Hex. In addition to this ion the are two lower mass fragment ions at *m/z* 1175 and 974 which differ in mass form *m/z* 1338 by 163 and 364 daltons, respectively, which corresponds in mass to the loss of Hex and HexNAcHex. These data as well as the observation of the loss of 364 daltons from the molecular ion suggest that there is an O-linked carbohydrate at Thr^7 of this peptide.

We have also observed the cleavage of 10 of 11 Asp-Xxx bonds in *E.coli* Thioredoxin (*m/z* 11674) with less than 2 pmol of material. These were the only major fragments observed suggesting that the cleavage of the Asp-Pro bond is a subset of a more general pathway of cleavage of Asp-Xxx bonds.

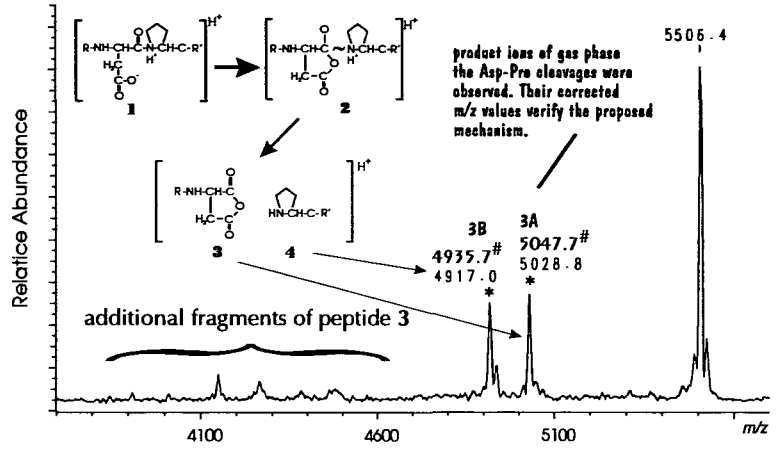

Figure 1. Gas phase cleavages of internal Asp-Pro bond of a peptide are observed in its reflector mode MALD-TOF mass spectrum. The proposed mechanism for such cleavages is shown in the upper left corner. (#: corrected m/z values)

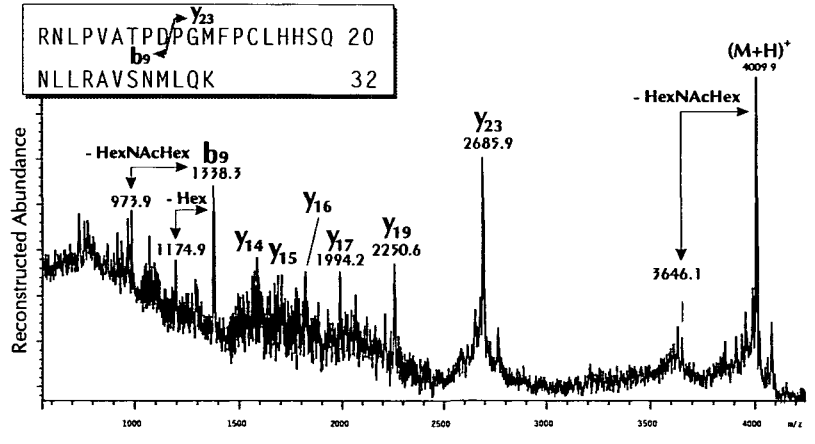

Figure 2. A composite reflector mode MALD-TOF mass spectrum showing the Asp-Pro cleavage (y23 and b9) and other fragment ions for an asialo O-linked glycopeptide isolated from the Achro-K map of the rhIL-12 protein.

MALDI on a Magnetic Sector Mass Spectrometer Equipped with an Integrating Array Detector

R. B. Cody*, J. W. Finch, J. Tamura, and B. D. Musselman
JEOL USA, Inc.
11 Dearborn Rd., Peabody, MA 01960

A commercial matrix-assisted laser desorption ionization (MALDI) source was developed for the JMS-HX110 forward-geometry double focusing mass spectrometer equipped with a "zoom" array detector and quadrupole doublet ion optics. This report describes some of the preliminary results obtained by using the MALDI source.

Experimental A Laser Science Inc. model VSL-337ND laser was used to irradiate the target. This laser operates at 337 nm with a maximum pulse energy of 400 mJ. Beam attenuation and focusing was accomplished by using a dichroic mirror and lens assembly, and visualization of the target surface was made possible by using a CCD camera and video display.

Dihydroxybenzoic acid (DHB) was found to provide the best results as a matrix for laser desorption although mass spectra can also be obtained by using sinapinic acid (SA). The DHB matrix seems to provide a stronger ion signal and the signal persists for a larger number of laser shots than when SA is used as the matrix. Addition of a small amount of ammonium acetate increased the sensitivity for nucleosides detected in the negative-ion mode.

Discussion The results show good mass accuracy (roughly 0.01% without internal calibrant) and resolution (up to 4500 at 5% dispersion). Mass spectral segments can be obtained with a single laser shot, but the best results are obtained by accumulating several laser shots and moving the target during acquisition of successive segments. Although the mass range is substantially less (14,500 at full 10 kV accelerating voltage) than that obtained with time-of-flight systems, the MALDI/sector combination may be useful when good mass accuracy and resolution are needed for small-to-medium sized molecules, or when it is desired to examine a small analyte in the presence of matrix interferences.

An Improved Illumination System for Matrix-Assisted Laser Desorption

Ronald Beavis
Department of Physics, Memorial University of Newfoundland
St. John's, Newfoundland
Canada A1B 3X7
beavis@newton.physics.mun.ca

A linear time-of-flight mass spectrometer was described that has a constant field extraction/acceleration ion source and a sensitive detector with no post-acceleration. The ion source had an open geometry, but a rigid orientation alignment system for the sample, to minimize missalignment of the sample with respect to the detector.

This instrument was used to test configurations of laser illumination optics, in an effect to minimize the undesirable effects of using a gas laser (N_2) with a large beam divergence and an inhomogeneous beam fluence profile. The most stable protein ion signals were produced using a Newtonian telescope as a beam collimator/spatial filter, folllowed by a minimum-deflection Fresnel reflection beam attenuator.

The vacuum system, detector and ion source are shown in Figures 1,2 & 3, respectively. The optical system is shown in Figure 4. The "long" focal length and "large" pinhole design of the spatial filter was used because it was very easy to adjust.

The optical system results in a more stable protein ion signal (shot-to-shot), compared with using a single lens. The telescope serves as a spatial filter and allows the use of

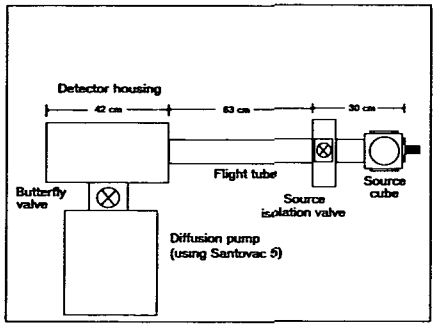

Figure 1 Vacuum system and general layout of the time-of-flight mass spectrometer.

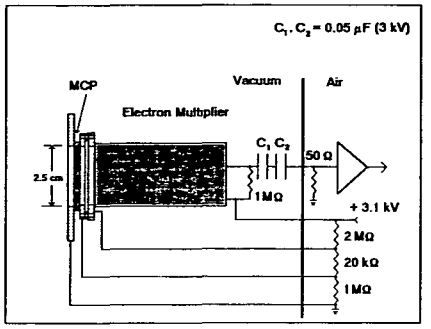

Figure 2 Zero-postacceleration protein ion detector.

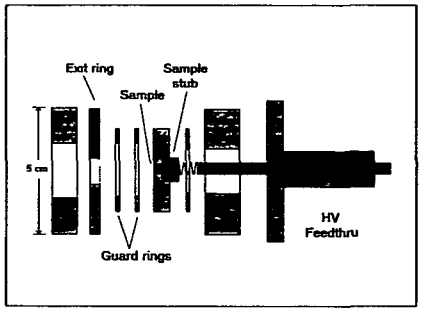

Figure 3 The laser desorption ion source electrode assembly. The ion source was operated at +30 kV on the sample and +20 & +10 kV on the guard rings.

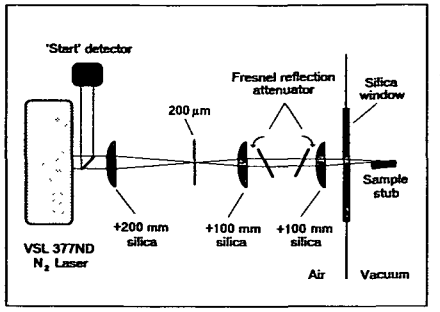

Figure 4 The illumination system of the ion source. Typical incidence angles were >80°.

smaller plates in the Fresnel relection attenuator by reducing the dimensions of the laser beam - this is particularly important at large reflection angles.

Experiments were also performed to determine the effects of raising the sample temperature above room temperature. A copper sample stub was constructed, with a spool section that was wound with 31 Ω/m nichrome wire. The stub could then be loaded with sample, inserted into the instrument and pumped down before heating.

Experiments were performed using sinapic acid. The maximum temperature that could be used was 70° C - higher temperatures produced rapid sublimation of the matrix. Heating the sample did not change the threshold irradiance meaureably. Higher temperatures irreversibly changed the molecular ion peak, by the addition of new adduct species. The peaks obtained were also wider at higher temperatures, but this effect was reversed by cooling.

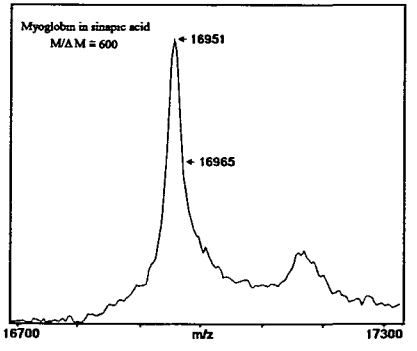

Figure 5 The molecular ion region of a mass spectrum taken using the system described above. The mass resolution is approximately 600 (FWHM).

Spatial Maps of the Polycyclic Aromatic Hydrocarbons (PAHs) in the Allende (CV3) and Bjurböle (L4) Meteorites

C.R. Maechling, S.J. Clemett, and R.N. Zare
Department of Chemistry, Stanford University, Stanford, CA 94305-5080
P.R. Buseck
Departments of Geology and Chemistry, Arizona State University, Tempe, AZ 85287

Chondritic meteorites are extremely heterogeneous. They contain various clasts and inclusions, and the matrix is composed of assemblages of submicron-sized mineral grains. Similary, the organic components of meteorites are distributed in a patchwork manner. To study the spatial distribution of PAHs on meteorite surfaces, we use a microprobe two-step laser mass spectrometer (μL^2MS) [1] with a spatial resolution of 40 µm, mass resolution of routinely 1800 for toluene (92 amu), and zeptomole (10^{-21}) sensitivity.

Meteorite surfaces are prepared for analysis by cutting interior chips of meteorite with a diamond blade saw, using a fresh supply of cold water as a cutting solvent. Checks were performed to ensure that material was not heated or redistributed across the surface. A meteorite wafer was mounted on a sample platter, and introduced into the μL^2MS instrument which is maintained at a base pressure of less than 5×10^{-8} torr. Constituent neutral molecules of the sample were desorbed with a pulsed infrared laser beam (CO_2, 10.6 µm, ca. 10^6 W/cm^2) focused through a Cassegrainian microscope objective to an analysis spot 40 µm in diameter. In a second step, 25 µs after the desorption laser pulse, PAHs in the neutral plume of desorbed material were preferentially ionized by a pulsed ultraviolet laser beam (Nd:YAG, 266 nm, ca. 10^6 W/cm^2) using 1+1 resonance enhanced multiphoton ionization (REMPI). Resultant ions were extracted from the plume and injected into a time-of-flight mass spectrometer. The output of the detector was amplified using a direct-coupled preamplifier and a filter amplifier and digitized every 2.5 ns with a digital oscilloscope. For the PAH mapping studies, five-shot averages were recorded for a spot followed by translation of the sample by 50 µm. After a sample was analyzed, the infrared laser power was increased and position indicators were burned into the surface producing laser-fused beads of the meteorite silicate matrix. These indicators were used to position the sample in the scanning electron microscope (SEM) at Arizona State University.

Previous studies on Allende of the distribution of PAHs were performed *ex situ* [2] and the results were consistent with a study of the spatial distribution of elemental carbon [3]. PAHs occur most abundantly between chondrules and inclusion in the material commonly called matrix. We have performed *in situ* spatial analysis of Allende with our microprobe instrument, and can now to analyze the material surrounding the chondrules and inclusions called dust mantles. This material differs from the matrix (perhaps a remnant of the solar nebula [4]), and we find that the PAH concentrations are larger in this component than the matrix. A mass spectrum is shown for the most PAH-rich region of one of our maps. We have tried to understand our results with respect to the mineralogy of the meteoritic material by performing SEM studies with energy dispersive x-ray detection. The data are not easy to interpret, largely because the 40-µm region analyzed contains many microscopic grains. Although there is a tradeoff between sensitivity and sampling size, we intend to reduce our analysis beam size by using a 1.064 µm Nd:YAG laser beam. This smaller analysis spot size should simplify the comparison between the PAH and mineralogical distribution.

Bjurböle was studied because of its large chondrules, but the meteorite is very friable, and reasonable sample could not be prepared. Not only were we prevented from cutting flat surfaces, but all of the material in the meteorite is grey, which makes it difficult for us to know the type of features we are analyzing. A mass spectrum is shown for what is likely meteorite matrix. The PAH signal is weaker than that of Allende, but shows more high-mass components.

µL2MS spectra of the Allende (CV3) and Bjurböle (L4) meteorites. Several of the PAH skeletons are labelled, and alkylation series [skeleton + n*14, where n=1,2,...] for most of these skeletons are present. Bjurböle contains a smaller concentration of PAHs (scaling factor in lower right of spectrum), but more high-mass components, which is consistentent with its longer exposure to higher temperatures.

Analysis of Polycyclic Aromatic Hydrocarbons (PAHs) in Cosmic Dust

S.J. Clemett, C.R. Maechling, and R.N. Zare
Department of Chemistry, Stanford University, Stanford, CA 94305-5080
P.D. Swan and R.M. Walker

We report the first definitive measurements of specific organic molecules (PAHs) in interplanetary dust particles (IDPs). An improved version of our microbeam-two-step laser mass spectrometer (μL^2MS) [1,2] was used for the analysis. The instrument has a spatial resolution of 40 µm, a mass resolution routinely 1800 for toluene, and zeptomole (10^{-21}) sensitivity.

The upper atmosphere provides an excellent source of cosmic dust, and particles 2-50 µm in diameter are collected from the stratosphere (ca. 20 km) on "flags" mounted on the wings of NASA's high altitude U-2 aircraft [3]. These are later examined in a clean room and particles of interest are removed for further analysis. Extraterrestrial origin is identified by chondritic elemental abundance, that is, similar to class of meteorites referred to as carbonaceous chondrites. In addition isotopic measurements using a modified Cameca IMS-3F ion probe [4] reveals some IDPs to have large isotope anomalies in D/H and $^{15}N/^{10}N$.

The instrument used for the organic analysis is a two-step laser mass spectrometer. In the first step, constituent neutral molecules of the sample are desorbed with a pulsed infrared laser beam (CO_2, λ=10.6 µm) focussed through a Cassegrainian objective to an analysis spot 40 µm in diameter. In the second step, separated both spatially and temporally, PAHs in the desorbed plume of neutrals are preferentially ionized by a pulsed ultraviolet laser beam (frequency quadrupled Nd:YAG, 266 nm) using a (1+1) resonance enhanced multiphoton ionization scheme. Resultant ions are then extracted from the desorbed plume and injected into a reflectron time-of-flight mass spectrometer.

The samples studied were in the form of small, micron sized fragments of original particle that had been pressed into a thin wafer of single crystal KBr. Remaining fragments of the particle were studied by other techniques to gain information on particle morphology, elemental abundances, mineralogy, and isotopes (C, N, and H). The particle fragments were located in the μL^2MS system using sighting markers scribed on to the KBr. Single-shot time-of-flight spectra of each particle were recorded, stored in a computer, and later calibrated and co-added. A minimum of twenty spectra were recorded for each particle, and spectrum acquisition was continued until the signal became indistinguishable from background, this number varied from particle to particle.

A total of seventeen stratospherically collected particles, eight of which are classified as IDPs, seven of which are classified as probable terrestrial contaminants, and two of which have uncertain origins were studied. A rich distribution of PAHs were obtained on two of the eight IDPs, Aurelian (U47-M1-2a) and Florianus (U47-M1-3a), the spectra in each case were similar. Both particles are certainly extraterrestrial; each has a chondritic elemental spectrum and both have large deuterium enrichments (up to $\delta D = 771 \pm 85‰$ for Aurelian and $\delta D = 1120 \pm 100‰$ for Florianus), and in addition Florianus has one of the largest ^{15}N anomalies ever observed ($\delta^{15}N = 441 \pm 20‰$).

The μL^2MS result for Aurelian is shown in figure 1, laser shots made at locations on the KBr mount 100 µm away from the IDP gave integrated signal intensities of less than 3% the value for Aurelian and showed no evidence of PAHs. The spectrum is characterized by three mass envelopes, one near 60 amu, one at moderate mass peaking at 250 amu, and one at high mass peaking at 370 amu. The low mass envelope contains inorganic species such as Na, K, Al and KBr cluster ions which are easily ionized by the UV beam, as well as traces of hydrocarbon fragments (C_4H_x - C_9H_x). It is unlikely that these fragments are decomposition products of PAHs and are attributed to decomposition of other species in the desorbed plume. The moderate and high mass envelopes contain clear signatures of PAHs and there alkylated derivatives, as indicated by sequences of peaks separated by 14 amu as a consequence of the successive addition of methylene (-CH_2-) groups to the PAH skeletons. The virtual absence of low mass PAHs such as alkylbenzenes, alkylnaphthalenes and alkylphenathrenes is consistent with the evaporation of these more volatile, lower mass organic components from an IDP during prolonged exposure in space, as well as loss by heating during atmospheric entry. The distribution of high mass PAHs in the high mass envelope is striking and has not be observed by us before in any other extraterrestrial material we have analyzed which have included, acid residues, meteorites and Antarctic micrometeorites [1,5,2,6].

Due to the zeptomole sensitivity of μL^2MS coupled with the wide scale distribution of PAHs in the terrestrial environment, extensive contamination and blank experiments were performed in order to prove that the observed molecules are not terrestrial contaminants. The silicone oil from the collector panels, materials used in particle selection and curation and samples of lab air were analyzed. All gave no PAH signals. Additional study of terrestrial contamination particles which had

been exposed to the same collection and mounting procedures gave either spectra devoid of PAHs or spectra markedly different to either Aurelian and Florianus.

In conclusion we have demonstrated the application of μL^2MS to the trace organic analysis of micron sized particles with zeptomole detection limits, and have applied this to the organic analysis of cosmic dust. To the extent that IDPs may represent the most primitive materials in the solar system, continued studies of the type described here can be expected to better elucidate the nature of the original organic materials in the solar system. These issues are now amenable to study due to the very high sensitivity and specificity of μL^2MS.

LASER DESORPTION STUDIES OF OXIDATIVE DECOMPOSITION IN K_3C_{60}

C.J. Harper, D.C. Sherrod, D.C.Jurbergs, J.T. McDevitt and D. A. Laude, Jr.
Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX, 78712

The development of fullerenes as high temperature superconductors has caused a need for study of their structures, bulk properties and reactions. In particular, K_3C_{60} exhibits excellent superconducting properties; however, when exposed to ambient air or water, K_3C_{60} undergoes rapid decomposition with consequent loss of conductivity. Careful study of this decomposition process is essential to any practical application of fullerene-derived superconductors.

The effect of the K_3C_{60} decomposition reaction on conductivity has been thoroughly investigated. A resistivity of 10^4 ohms is characteristic of K_3C_{60} before exposure to air or water; however, after decomposition, the resistivity is often 10^{10} ohms or more. It also is found that the decomposition occurs faster when exposed to water vapor than when exposed to air or O_2[2].

Some researchers report that the carbon-based product of decomposition is solely C_{60}. Specifically, Haddon, et. al.[1] have noted from Raman studies that after K_3C_{60} is exposed to air and water that the molecular line of C_{60} (1467cm^{-1}) is restored, suggesting that the potassium doping process is reversible with respect to C_{60}.

Eq. 1 $\quad 3K(g) + C_{60}(s) \longrightarrow K_3C_{60}(s)$

Eq. 2 $\quad K_3C_{60} \xrightarrow{\text{Air \& } H_2O} C_{60} + \text{potassium species}$

However, contradictory evidence exists to suggest that this may not be a solely reversible process (Eqs. 1 and 2) and that C_{60} is not the only decomposition product. For example, although C_{60} is highly soluble in toluene, the decomposition products of K_3C_{60} are not. Nor are the products soluble in water. Additionally, the infrared spectrum of the decomposition products differs from that of C_{60} in that it contains a broad absorption band at 1620 cm^{-1}. These differences between IR spectra cannot be attributed to species such as KOH or $C_{60}O$.

In an effort to reconcile these inconsistencies, laser desorption Fourier transform ion cyclotron resonance (LD/FTICR) was used to generate mass spectra of K_3C_{60}, decomposed K_3C_{60}, C_{60} with KOH added and unadulterated C_{60}. These spectra were used to determine whether the decomposition reaction occurs as bulk or surface phenomenon.

In order to fully examine the various compounds to be compared, several experimental parameters were varied. For example, the laser power density was adjusted to three different levels; 2.2×10^7 W/cm^2 (low), 1.1×10^8 W/cm^2 (medium) and 2.3×10^8 W/cm^2 (high). This was done to distinguish between ions desorbed thermally from the sample and species which were formed in the plasma. Additionally, the trapping voltages were varied at positive and negative potentials of 1V, 3V and 5V in order to capture ions of different kinetic energies.

Samples of C_{60} were prepared by J. T. McDevitt's group (University of Texas). Sandblasted, stainless steel probe tips were first cleaned in both methanol and in deionized water. Next, a 60%/40% mixture of gold and palladium was sputtered onto the tips. The C_{60}, purchased as soot from Texas Fullerenes, was extracted with toluene and then sublimated onto the probe tips. To dope samples with potassium, the C_{60} covered probe tips were suspended above a pool of potassium which was heated to evolve potassium vapor.

Comparison of the spectra of the various compounds gave interesting results. For example, studies of the unreacted K_3C_{60} samples showed that it produces small amounts of ions regardless of the experimental conditions used; however, the decomposed sample yields ions in large abundances. Also, a comparison of the decomposed sample and C_{60} yielded two

main differences between the spectra from these samples. First, the C_{60} sample did not generate any ions at the low power density. Lastly, eventhough sample deposition was conducted simultaneously, the decomposed sample generated many ions after 10 firings on the same position; however, C_{60} did not yield ions after 3 or 4 shots on the same position.

It might be expected that as K_3C_{60} decomposes, positive potassium ions would be produced; therefore, the KOH mixed C_{60} sample was used as a control for potassium ions in the sample which might effect the laser desorption spectra. Upon comparison of the decomposed K_3C_{60} and C_{60} - KOH mix, it was determined that the decomposed sample yielded few positive ions.

The depth profiling studies, which were conducted at the three different laser power levels, did not show any difference between the surface and bulk material. Therefore, the decomposition seems to be a bulk phenomenon. It should be noted, however, that sample thicknesses were on the order of 2000 to 5000 agstroms.

The mass spectra of the K_3C_{60} decomposition products yielded ions of C_{60} and C_{70}. The presence of C_{70} is due to incomplete purification of the C_{60}. There were no spectra which indicated a C_{60} species with heteroatoms such as oxygen attached. Nor were there any indications that the fullerene molecules were broken apart. There were also no potassium-attached C_{60} ions detected within this experiment, suggesting that the association of the potassium with the C_{60} is a weak one. However, because the decomposed K_3C_{60} does not yield positive ions as readily as C_{60} or C_{60} mixed with KOH, it is suggested that the decomposition product is a reduced C_{60}. This hypothesis will be tested by comparing decomposed K_3C_{60} with electrolytically reduced C_{60}.

Analysis of Lipopolysaccharides from Gram Negative Bacteria using FAB and MALDI TOF Mass Spectrometry

Xiaoping L. Hronowski and Robert J. Cotter
the Johns Hopkins University, Baltimore MD;
Nilofer Qureshi and Kuni Takayama, VA Hospital, Madison WI.

Liquid Secondary Ion Mass Spectra (LSIMS) and Matrix Assisted Laser Desorption Ionization (MALDI) mass spectrometry have been employed for structural identification of two strains of lipopolysaccharides (LPS) D21f2-ReLPS and D21f1-RdLPS isolated from *Escherichia coli* K-12 mutants.

LSIMS mass spectra were obtained on a Kratos Concept 1H double-focusing electro-magnetic deflection mass spectrometer. MALDI spectra were performed on a Kratos KAMPACT MALDI III TOF instrument with a maximum laser output of 6 mw at a wavelength of 337 nm.

The LSIMS mass spectrum of D21f2-ReLPS is shown in Fig. 1. Molecular ions $(M+H)^+$ and $(M+Na)^+$ were observed at m/z 2238.2 (2238.3) and 2260.1 (2260.3) respectively. The phosphate cleavage reactions from the reducing end, cleavage of acyl-linked fatty acids and loss of KDO were observed. The major fragment ions are oxonium ions with additional losses of one KDO and two KDO units.

Two fractions separated by HPLC from D21f1-RdLPS were methylated. The samples were characterized using LSIMS and MALDI mass spectrometry.

The LSIMS mass spectrum of penta-acylRdLPS is shown in Fig. 2. Protonated molecule ions appear as six peaks at m/z 2425.4, 2439.5, 2453.5, 2467.5, 2481.5 and 2495.5. Fragmentation results in loss of two HEP, two KDO and phosphate. Further fragmentation cleavages hydroxymyristate chain in the 3'-position. Oxonium ions, further loss of two HEP and two KDO, are major fragment ions. The MALDI spectrum of penta-acylRdLPS, as shown in Fig. 3, gives protonated molecule ions and fragment ions by loss of hydroxymyristate group.

The LSIMS spectra of hexa-acylRdLPS have a fragment partern similar to the one of the penta-acylRdLPS with masses greater by 210 units, corresponding to myristate connected to the hydroxy group on hydroxymyristate in the 3'-position. The MALDI spectrum of hexa-acylRdLPS gives protonated molecular ions and fragment ions from loss of fatty acid at the 3-position, the 3'-position, and loss of two KDO and two HEP units.

D21f2-ReLPS has a molecular weigth of 2237.2 and contains two each of glucosamines, KDO and phosphates, four hydroxymyristates, one laurate and one myristate, as shown in the Fig. 4. D21f1 hexa-acylRdLPS has a lipid A protion similar to D21f2 with two additional HEP groups connected to KDO (Fig. 4). D21f1 penta-acylRdLPS has a basic structure similar to hexa-acylRdLPS, but only has five fatty acid chains.

Matrix-Assisted CO_2 LD/FTMS of Peptides

Long-Sheng Sheng, Joel P. Covey and Joseph E. Campana
Extrel FTMS, Millipore Corporation, 6416 Schroeder road, Madision, WI 53711-2424

Matrix-assisted laser desorption ionization (MALDI) is an important technique for mass spectrometric analysis of biomolecules. Hillenkamp and coworkers have reported MALDI by using an IR laser with succinic acid, caffeic acid, urea and glycerol as matrices [1,2]. The results were very similar to those obtained with UV lasers.

We have analyzed peptides by using succinic acid (SA) or 2,5-dihydroxybenzoic acid (DHBA) as the matrix in an FT/MS instrument equipped with three types of lasers-CO_2, Nd:YAG and N_2. For example, a synthetic peptide (pGlu-Leu-Trp-Pro-Arg-Pro-Gln-Ile-Pro-Pro, M.W.1214) was analyzed. With SA as the matrix, only the protonated molecule $[M+H]^+$ was observed in the mass spectrum (Fig.1). High signal-to-noise ratio spectra were obtained with a single laser shot, and each spectrum represents the equivalent of 20 attomoles of consumed sample. The collisional dissociation spectra (Fig.2) of the $[M+H]^+$ species were also obtained with argon as collision gas and from which some stuctural information about the peptide can be deduced.

With DHBA as the matrix, similar spectra were obtained by using any one of the three lasers (CO_2 laser at 10.6 microns, Nd:YAG laser at 355 nm and N_2 laser at 337 nm). Figure 3 shows the N_2 MALDI mass spectrum of the peptide.

The MS^n spectra of peptides were obtained by using stored wave inverse Fourier transform (SWIFT) techniques. Figure 4 illustrates the MS/MS analysis of the peptide. It was found that there are a series of a and b type ions in these spectra, and the alkali-adduct ions are the water-loss counterparts of the protonated ions.

Introduction

The determination of the sequence of monomeric units in a bacterial polyester, a potentially biodegradable "plastic" with different types of hydroxy fatty acids, is a difficult analytical problem. Boon [1] obtained in-source pyrolysis mass spectra of polyhydroxybutyric acid (PHB) under NH_3 chemical ionization conditions and similarly obtained the in-source spectrum of a polyhydroxyalkanoate (PHA) extracted from octane fed *pseudomonas oleovorans*.

Experimental

These polyester extracts (MW_w = 100,000 to 150,000) were analyzed by Laser Probe FT/MS. A CO_2 laser operated at 10.6 µm was used for these measurements. Direct laser desorption/ionization (LDI) FT/MS spectra and MS/MS spectra confirmed the structures of the samples. The samples were dissolved in chloroform at a concentration of 1 mg/mL. Ten µL of the solution was deposited onto a stainless-steel target and dried at room temperature. A solution of KBr-saturated methanol was deposited onto the sample surface and allowed to air dry.

PHB Analysis

The LDI/FTMS spectrum of PHB was obtained with a single laser shot. The spectrum showed a series of polymer fragments with potassium ion attachment. The peaks observed that are separated by 86 Daltons confirmed the repeating unit is butenoic acid. The m/z 555 peak (hexamer) was isolated by using stored-waveform inverse Fourier transform (SWIFT) techniques. The precursor ion underwent collision-induced dissociation (CID) with argon as the collision gas. The MS/MS spectrum showed sequential loss of butenoic acid moieties

PHA Analysis

Figure 1 shows a LDI/FTMS spectrum of PHA. The spectrum is composed of a series of polymer fragments with potassium ions attached extending up to a mass range of more than 3000 Daltons. The spectrum shows that the peak with highest mass within a repeating unit group is the equivalent to the pure C_8 fatty acid polymer, the lower mass peaks in the group separated by 28 Daltons are the homologures equivalent to 1, 2 and 3 C_6 hydroxy fatty acids mixed into the polymer respectively. The m/z 863 species, which is the copolymer containing five C_8 and one C_6 fatty acid moieties, were isolated by using SWIFT techniques and collided with argon to produce progeny ions. The MS/MS spectrum of the ion shows random loss of the C_8 and C_6 acid as illustrated in Figure 2.

Conclusions

A high-mass molecular fingerprint of these relatively high molecular weight compounds can be obtained easily and rapidly. Multistage mass spectrometry provides another dimension for the structural characterization of the complex copolymer fragment ions observed.

Detection of Large Molecular Ions by Secondary Ion and Electron Emission

G Westmacott, W Ens, K G Standing and A Verentchikov
Physics Dept., University of Manitoba, Winnipeg, Canada R3T 2N2

Detection of molecular ions in time-of-flight mass spectrometry is usually accomplished by secondary electron or ion emission followed by electron multiplication. For a given energy, the ratio of electrons to ions decreases with increasing mass, and for large (singly charged) molecular ions at keV energies, the emission of ions is more likely than the emission of electrons.

We have investigated secondary ion and electron emission using incident molecular ions, produced by matrix-assisted laser desorption, as primary ions in a tandem time-of-flight mass spectrometer (Fig. 1) [1]. Measurements of the ratio of secondary electrons to secondary ions from a stainless steel target were made with a range of projectile masses and energies so that the separate dependence on velocity and mass could be determined. The projectiles ranged in mass from about 300 u to 6000 u (benzoperylene, gramacidin S, LH-RH, and insulin) and in energy from 300 eV to 30 keV. Secondary accelerating voltages down to 20 V were used to reduce spurious contributions to the electron intensity caused by fragmentation of the projectiles or by grid effects.

Fig. 2 shows the electron to ion ratio as a function of velocity for the 4 projectiles. The results indicate that the electron-to-ion ratio is determined almost entirely by the velocity of the projectile; it is largely insensitive to the mass (for a given velocity). The ratio decreases rapidly at first with decreasing velocity but appears to approach as constant value of about 0.10 to 0.20 at a velocitry near 1.4×10^6 cm/s (~ 1 eV/u).

The insensitivity of the ratio to the projectile mass is demonstrated in Fig. 3 which also shows clearly that electrons are observed for projectiles with < 0.5 eV/u. Thus electron emission is a feasible method of detection for large molecular ions.

A strong increase in the absolute electron yield was observed for a fresh CsI target compared to a stainless steel target. We have begun measurements of correlations between the secondary ions and secondary electrons to estimate absolute yields. Preliminary results indicate that the electron yield for 60 keV albumin projectiles (66 000 u) incident on a CsI surface is considerably less than unity, so there appears to be much room for improvement in detection efficiency.

Photodissociation of Precursor Ions Produced by MALDI in a Four-sector Tandem Mass Spectrometer

H.J. Köchling, J.A. Hill, J.E. Biller, and K. Biemann
Department of Chemistry, MIT, Cambridge, MA, 02139 USA

We have previously demonstrated the use of photon-induced dissociation (PID) as an attractive alternative to the more traditional collision-induced dissociation (CID) for the generation of peptide-sequence information in tandem MS/MS experiments on a magnetic sector spectrometer equipped with an integrating focal plane detector. At that time, precursor ions were generated by the fast atom (ion) bombardment (FAB) process. (1)

More recently, we have shown the feasibility of using ions generated by the matrix-assisted laser desorption/ionization (MALDI) process as precursor ions for CID MS/MS experiments on the same instrument. (2) We have continued these investigations to compare the combination of MALDI and PID to MALDI-CID.

EXPERIMENTAL

All experiments were conducted on a JEOL HX110/110 tandem mass spectrometer of $E_1B_1E_2B_2$ configuration, equipped with an integrating focal plane detector. Tandem MS/MS experiments were conducted to record both the MALDI-CID and MALDI-PID spectra of peptides. The desorption/ionization laser generated 600 psec pulses at 337 nm (N_2) at a repetition rate of 10 Hz. Its beam followed the same trajectory as does the Xe^0 beam in the FAB mode, providing an irradiance of approx. $3 \times 10^7 W/cm^2$ at the location of the sample. For CID experiments, a conventional Xe gas collision cell was placed in the region between MS-1 and MS-2. For PID experiments, this cell was irradiated by 12 nsec pulses from an excimer laser at 193 nm (ArF). This beam was attenuated by up to four wire screens (50% transmission each) to produce an irradiance of 10^6-10^8 W/cm^2 at the cell. The excimer laser pulses were synchronously delayed with respect to the N_2 laser desorption/ionization pulses to dissociate the ion packet of precursor ions mass selected by MS-1. The acceleration voltage was 10 kV and the cell was floated at 8 kV.

All samples were dissolved in a saturated aqueous solution of 2,5-dihydroxybenzoic acid (DHB). Several µL of the resulting solution was applied to the gold tip of a FAB probe and allowed to dry in air. The probe was equipped with a micrometer screw for precise translation, allowing different regions of the sample deposit to be irradiated. An integrating detector with variable mass dispersion, placed in the partial focal plane of MS-2, was employed to record the pulsed ion signal generated by MALDI during the experiments, as well as the continuous ion signal generated by the Cs^+ ion gun during calibration. (3)

RESULTS AND DISCUSSION

As expected, the CID product ion spectra of the $(M+H)^+$ ion of a peptide were found to be independent of the mode of ionization that generated the precursor ion. Fig. 1 shows the PID spectrum of the MALDI-generated $(M+H)^+$ ion and it again is in close agreement with the corresponding CID spectrum. This is due to the fact that the PID laser is operated at 193 nm, a wavelength at which the carbonyl group of the peptide bond absorbs. The most remarkable difference is the appearance of a few c_n ions (c_6 and c_7) which are rare in CID spectra. Essentially the same results were obtained when comparing the FAB-CID and MALDI-PID spectra of the $(M+H)^+$ ion (m/z 1296.7) of angiotensin I (D R V Y I H P F H L).

The extent of fragmentation under PID conditions appears to be dependent on the amount of energy contained in the dissociation laser pulse. Fig. 2 shows that the tetra peptide human renin substrate exhibits a MALDI-PID spectrum taken at 8 mJ laser pulse energy that is practically identical with that produced by CID of a FAB-generated $(M+H)^+$ ion. Increasing the PID laser pulse energy to 16 mJ and 32 mJ respectively decreases the abundance of the fragment ions of higher mass in favor of lower mass fragments.

This is most likely due to the higher energy transferred by multi-photon absorption while the ion packet travels through the 25 mm long irradiating region. The proper adjustment of the laser pulse energy is therefore essential, and one should be able to use this feature to optimize fragment ion production by decreasing the laser power while stepping the array detector from low mass to the precursor ion.

CONCLUSIONS

MALDI-PID of several medium molecular weight peptides has been demonstrated. As in earlier PID work @ 193 nm, a correlation between dissociation laser pulse energy and the abundance of product ions was observed (increasing low mass and decreasing high mass ion abundance with increasing laser power and vice versa).

MALDI-Mass Spectrometric Analysis of Proteins Immobilized on Nylon-based Membranes

E. J. Zaluzec[1], D. A. Gage[1], J. Allison[2], and J. T. Watson[1,2]
Departments of Biochemistry[1] and Chemistry[2]
Michigan State University, East Lansing, MI 48824

The types of membranes most commonly used for protein immobilization in, for example, automated protein sequencing or the electrotransfer of proteins separated in polyacrylamide gels, are composed of either nitrocellulose, polyvinylidene difluoride, positively charged nylon, or glass fiber filters. Choice of a particular membrane depends upon the requirements that must be met in a specific application because these membranes differ in their binding capacities, sample retention after multiple washing or extractions, and their resistance to chemicals and/or solvents.

In choosing the appropriate membrane for the direct MALDI analysis of proteins initially adsorbed on an immobilization support, desirable characteristics would be retention during sample manipulation and elution under conditions compatible with MALDI sample preparation. We have found both nylon 66 and positive-charge modified membranes (ZETABIND) suitable to fulfill these requirements. The behavior of protein elution from nylon membranes was found to closely parallel that observed in alkyl-silicate chromatography in that proteins are retained in an aqueous environment, and increasing proportions of an organic phase (acetonitrile) favors sample elution. This is in contrast to the harsh conditions that must be employed to elute proteins from other types of immobilization supports.

MALDI spectra were obtained after (*i*) loading protein mixed with matrix on stainless steel probe tips and (*ii*) first adsorbing protein onto nylon membrane fixed to a probe tip, washing by immersing in distilled water, then applying a solution of matrix prepared in 1:1 0.1%TFA/acetonitrile. Detection limits and resolution are apparently not affected by the immobilization/washing procedure. However, there is a lagging time shift of about 200-ns when analysis is performed from membrane fixed to the probe tip.

Applications of MALDI analysis of proteins immobilized onto inert membrane supports include

1) removal of water soluble contaminants by aqueous washings,
2) sample concentration (vacuum or successive application),
3) microscale derivatization reactions,
4) microscale chemical/enzymatic digestions,
5) analysis of proteins electrotransferred to membranes from polyacrylamide gels.

Figure 1a shows a MALDI spectrum of a DNA-binding regulatory protein, SpoIIId, that was isolated by SDS-PAGE. In this instance, elution of SpoIIId from the gel required 6M guanidine for solubilization. Sample dilution provided no useful data. This was likely due to guanidine interference, insufficient sample concentration, or both. Spectra were recorded after both concentration and guanidine removal by 4 sequential applications and water washings on nylon 66 membrane fixed to a probe tip. Figure 1b shows a MALDI spectrum of similarly prepared sample of immobilized SpoIIId that was digested with Asp-N endoproteinase on the probe tip. Peaks for which assignments have been made represent total coverage for cleavage at aspartic acid.

Figure 2a shows a MALDI spectrum of 200 pm of native β-lactoglobulin first immobilized on ZETABIND membrane fixed to a probe tip. Derivatization of a similarly prepared sample with p-hydroxymercuribenzoic acid (figure 2b) showed a minor leading shoulder with a mass corresponding to the unmodified protein, and two signals that parallel results obtained from analysis of the native protein, but with mass shifts indicative of mercurial modification of the single free sulfhydryl group. Mass spectral shifts of 322 u for both the major and tailing shoulder of the native protein suggests a heterogeneous sample lot.

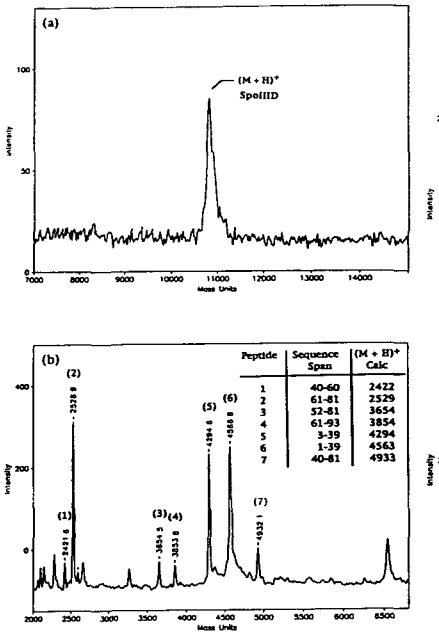

Figure 1
MALDI spectra of a DNA-binding regulatory protein SpoIIID recorded from sample applied to ZETABIND membrane fixed to a probe tip:
(a) after 4 sequential application/washing/drying steps to facilitate guanidine removal and concentration before adding matrix solution, and
(b) same application as in (a) followed by a 6-hr ASP-N endoproteinase digestion on the membrane before adding matrix solution.

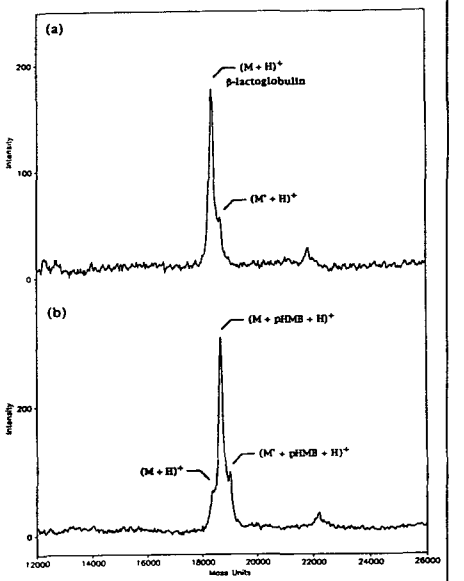

Figure 2
MALDI mass spectra of 200 pm of β-lactoglobulin adsorbed on ZETABIND immobilization membrane fixed to the probe tip:
(a) native protein, $(M + H)^+_{calc} = 18{,}367$,
(b) β-lactoglobulin derivatized with pHMB, $(M + H)^+_{calc} = 18{,}689$. (Mass spectral shifts of 322 u for both the major peak and tailing shoulder of the native protein suggests a heterogeneous sample lot.)

Time-of-flight mass spectrometry studies of laser desorption neutral gramicidin S molecules

*Kuang Jen Wu and Christopher H. Becker
Molecular Physics Laboratory, SRI Internationl, Menlo Park, CA 94025

Experimental

The cyclic peptides Gramicidin S has been studied by time-of-flight mass spectrometry in conjunction with: (1) direct laser desorption by placing the molecules on top of a layer of anthracene, or directly placed on a bare copper sample stage, and (2) matrix assisted laser desorption with several different matrix molecules (e.g., 3-hydroxypicolinic acid, sinapinic acid and DHB). Two wavelengths UV light: 308 nm and 355 nm were used for desorption/ionization of gramicidin S with a typical energy density of 0.1 - 1 mJ/cm^2. Both direct positive and negative ions have been measured with TOF-MS running at linear and reflecting mode. The desorbed neutral material was post-ionized using 118 nm single photon ionization.

Results

We found that the formation of gramicidin S positive ions is much more favorable than negative ions. Direct laser desorption of gramicidin S from on top of an anthracene film has been measured to be very effective in producing/ejecting gramicidin S ions and neutrals with an efficiency generally comparable to matrix-assisted laser desorption under similar laser irradiance. Direct laser desorption of gramicidin S from a bare copper substrate produces weaker signal than desorption from the anthracene layer and requires much higher laser power density. In addition to $[M + H]^+$, the strongest base peak, $[M + Na]^+$, $[M + K]^+$ and $[M + 14]^+$ were always observed, but the intensity of these adduct peaks varied depending upon the sample handling and preparation.

Direct and matrix-assisted laser desorbed neutrals were post-ionized by 118 nm photons. M^+ and series of peaks due to the loss of multiples of m/z 14 as well as an occasional small $[M + 14]^+$ were measured. Since no fragmentation of directly formed ions was observed, these $[M - n(14)]^+$ peaks result from the 118 nm photons. The structure of gramicidin S suggests that such fragmentation is mainly due to the fragmentation of the side groups isobutyl $(CH_3)_2CHCH_2$- from L-leucine and isopropyl $(CH_3)_2CH$- from L-valine.

Discussion

In addition to gramicidin S, we have also investigated a few linear peptides (mass < 2000) such as substance P and gramicidin D in an effort to understand the photoionization of laser desorbed neutrals. We observed no 118 nm photoionized signals above noise for any of the linear molecules. There are two possible explanations for our observation comparing single photon ionization between linear and cyclic peptides.

(1) Both of the cyclic (ring) and linear peptides suffer one random backbone cleavage. This scission results in diminishing signal for linear molecules whereas for gramicidin S ring opening still maintains total mass (except for lose of side chains).

(2) Backbone cleavage occurs in the linear peptides and not in the gramicidin S ring, i.e., ring remains intact.

Linear and cyclic peptides have been successfully photoionized by multiphoton ionization followed by supersonic jet cooling and no significant fragmentation was measured.[1-3] Two major differences exists in experimental conditions employed in this work and those reported previously:[1-3]

(1) the internal temperature and

(2) the photoionization scheme. (single photon event vs. multiphoton ionization)

It is likely that high internal energy of the desorbed neutrals in our non-jet experiment is the main cause for the fragmentation of the cyclic gramicidin S molecules and the null results for linear peptides.

CONSIDERATIONS FOR THE SIZE AND POWER REDUCTION OF A FIELD TRANSPORTABLE ION TRAP MASS SPECTROMETER*

Introduction

The versatility, sensitivity, and mechanical simplicity of ion trap mass spectrometers makes them an excellent choice for use as field instruments. Applications include on-site environmental monitoring, process monitoring, leak and spill detection, contraband detection, indoor air monitoring, and workplace monitoring, among others. Although modified versions of the Finnigan ITD and ITS-40 have been successfully used as field transportable mass spectrometers, increased analytical capabilities as well as further reductions in size, weight, power consumption, and instrument complexity are needed to expand the range of potential field applications. We have approached this task by modifying the electronics and developing down-sized replacements for many of the associated components. Small, high-efficiency vacuum pumps have also been used to reduce the weight and power consumption. The result has been the development of a field instrument which has all of the capabilities of a full-sized laboratory ITMS in a package occupying approximately 8 ft^3 and weighing approximately 100 pounds.

Instrumentation

Modification of the ion trap electronics has resulted in significant size and power reductions. A major accomplishment has been the development of a considerably smaller rf drive. A fundamental frequency of 550 KHz was chosen in order to reduce the rf power consumption to approximately 1/16 that the 1.1 MHz commercial ion traps (for the same mass range). Peak rf voltage is 1,875 volts which gives a mass range of 10 to 650 amu. The rf coil, tuning capacitor, and drive transistors are enclosed in a shielded box having dimensions of 6" x 4" x 2" and weighing approximately 2 pounds. Modular high voltage power supplies (0 to 5,000 volts) having dimensions of 4" x 6" x 1" are used to bias the multiplier dynodes. A programmable dc power supply for dc mass isolation was developed using high voltage op-amps. The output of this device is +/- 180 volts with 12 BITS of resolution and the components are mounted on a circuit board which is 5" x 5" x 1". The main power supply for the electronics is 24 volts at 8 amps. It is used to power the high voltage modules directly and dc-to-dc converters are used to boost the voltage to 98 volts for the rf driver and reduce the voltage to 5 volts for digital circuits. Mass zoom electronics have also been incorporated into the system which enable the resolution of the mass spectrometer to be enhanced by reducing the mass scan rate.

Weight and power reductions have also been achieved through the use of a light-weight 60 L/s turbopump which is backed by a Drytel Micro molecular drag pump. Power consumption by the pumps after initial pumpdown is approximately 50 watts with a gas flow into the vacuum chamber of 1.5 standard mL/min. The instrument is enclosed in an aluminum cabinet which is 34" high x 20" wide with all pumps and power supplies contained inside. Maximum power consumption is 550 watts which is drawn during the initial pumpdown and manifold heating. The inlet is an open/split capillary restrictor with sampling modules for direct air monitoring, the analysis of water or soil samples, or for the thermal desorption analysis of sorbent tubes. In addition, an atmospheric sampling glow discharge ionization source is being developed for this instrument to enable detection of explosives.

Results:

Initial evaluation of this instrument has indicated that sensitivity is comparable to that of the full-sized laboratory-based ITMS. Even though the fundamental rf frequency is 550 kHz, the MS/MS efficiency is quite good and no significant loss of ion trapping efficiency has been observed. Demonstrated applications have included the detection of volatile organic compounds (VOCs) in water, the detection of PCBs in soil extracts, the detection of drugs of abuse in urine, real-time quantification of chemical warfare agent simulants in air, and real-time detection of VOCs in air.

Conclusion:

A prototype field instrument has been completed which is versatile, rugged, and has all of the features of a full-sized laboratory-based ITMS. Preliminary tests have shown that targeted analytes can be detected in variety of matrices with good sensitivity. Advanced versions of this instrument will include further improvements in the electronics, vacuum pumps, and the development of more efficient manifold heating.

The Next Horizon in Portable GC/MS for Air Monitoring Applications

Wenhu Du, Neil S. Arnold, Paul A. Cole, Bob Watteyne, Dale T. Urban and Henk L.C. Meuzelaar
Center for Micro Analysis and Reaction Chemistry,
University of Utah, Salt Lake City, UT 84112

A fully man-portable TLGC/MS (transfer-line gas chromatography/mass spectrometry) system, based on the combination of an automated vapor sample inlet, a "transfer-line" gas chromatography module and a modified Hewlett Packard Model 5971A quadrupole MS system has been developed in our laboratory [1-3]. The system operates over two hours on a 24 V, 28 A-hr Li battery system with a total system weight of ~45 lbs, utilizing a unique hybrid bulk/ion getter pumping system. Data acquisition is provided remotely via a 200 m coaxial cable using standard HP-Chemstation software. This pumping system will maintain operating pressure for several days.

The GC oven module consists of a heated aluminum oven which houses the capillary GC column; 2 m long, 100 µm i.d. fused silica capillary coated with a 0.17 mm layer of a methylphenyl silicone (DB5) stationary phase. H_2 is approx. 0.3 ml/min. (In the present experiments this column is unheated.) Air samples are introduced using a special automated air sampling inlet [3]. This technique provides very short switching times (i.e., as short as 20 ms, with 100 ms typical) for high speed, high resolution TLGC separations which can be repeated within seconds.

Figure 1 illustrates chromatographic separation of 4 different test mixtures which represent anticipated environmental contaminants. These chromatograms are obtained in full scan mode at ~5 scans/second. While typical concentration in these standards are on the order of 100 ppm, limits of detection typically range between 1 and 10 ppm in full scan acquisitions. Figure 2a shows a similar full scan chromatogram of a gasoline headspace, illustrating identification of various compounds in a complex mixture. The full impact of GC separation is seen in Figures 2b and c where SIM acquisitions at m/z 57 and 55, respectively, are obtained at 15.6 points/second. Initial peak widths are on the order of ~180 ms with a 100 ms sampling pulse (sampling duration in Figure 2a was .5 s).

The SIM offers significantly enhanced detection limits. Figure 3 shows a chromatogram in SIM mode (m/z 91) for the same alkylbenzene mixture shown in Figure 1, but at ~120 ppb concentration. The LOD (S/N = 3) values are between 40 and 100 ppb without any preconcentration technique applied using a .5 s sampling pulse. The result of a field simulation is illustrated in Figure 4. A container with a 5 cm opening, containing 1 l of unleaded gasoline was placed in the center of a semi-enclosed hanger area and allowed to equilibrate for 1 hour. The concentration of several aromatic hydrocarbons were measured based on retention time and SIM (m/z 91). Actual concentrations at a local gasoline station were also measured during a busy spring afternoon (~20 C, calm winds) at various positions about the perimeter of the station. Typical concentrations are listed in Table I. Actual gasoline concentration is estimated from various constituents.

It is clear that this high speed, high sensitivity, low power and light weight TLGC/MS system offers a useful tool for a broad spectrum of field applications ranging from hazardous waste sites and industrial or natural disaster areas to reconnaissance drones, space station, interplanetary probes and autonomous vehicular robots.

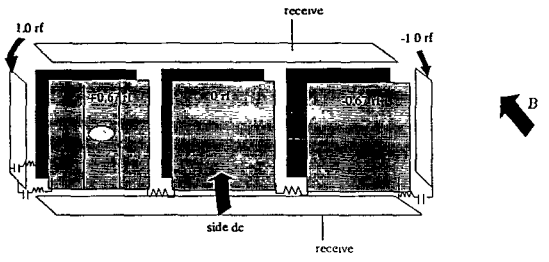
LARGER CELLS FOR ICR SPECTROMETERS WITH ELECTROMAGNETS, Joey A. Hatcher and John E. Bartmess, (Department of Chemistry, University of Tennessee, Knoxville TN 37996-1600)

Signal intensity is directly related to the number of ions trapped in an Ion Cyclotron Resonance (ICR) mass spectrometer. Space charge restrictions set an upper limit to the number of ions a reaction cell can hold. Therefore it is postulated that a larger cell would produce signals with greater intensity than a standard cubic cell. There are limitations in construction of such a cell: the z-dimension is limited due to the gap of the electromagnet, and the receiving plates must be relatively close to the ions for appreciable signal linearity at small excitation levels. This leaves only the third dimension for expansion. We have built such a cell, four times the length of the standard cubic cell. In this elongated cell, a uniform excitation rf field gradient is achieved by utilizing segmented trapping plates with appropriate fractions of the excitation rf on them.



Three dimensional view of three section cell from filament side

Calculations to approximate the cell's treatment of the rf potential were done. It was found that the cell exhibited linearity in the location where the ions would position themselves, the midline of the cell. This proves that three sections will provide the rf levels necessary to cause the ions to accelerate uniformly throughout the cell.

All experiments were done using an ICR mass spectrometer with an electromagnet. Data were collected using an IBM PC interfaced with a Tecmar analog to digital board, under "rapid scan" conditions. Standard experimental conditions were pressure of 1 μtorr, emission current of 1 μA, side plates at 2 V, electron energy of 30 eV, rf amplitude of 178 mV, magnetic field at 10 kG, experiment detect delay of 100 msec, grid pulse length at 20 msec.

Experiments were done to compare the three sectional and standard cubic cells. By observing the benzene molecular ion, information was studied pertaining to the signal intensity, signal to noise ratio, and the signal's full width at half maximum. Experiments were conducted to test the signal dependence on emission current, excitation rf level, side plate voltage, grid pulse length, and transmit plate voltage.

In a study of rf level under standard conditions, the signal intensity of the benzene molecular ion was observed while changing the rf level. It was expected that, under similar conditions for both cells, the sectional cell would have the capacity to hold more ions

and therefore produce signals of greater intensity. By observing the data, the two cells seem to exhibit the ability to contain approximately the same number of ions at different rf amplitude values.

Through further studies it was found that signal intensity in the sectional cell was dependent on the grid pulse length. Another rf study was conducted under standard conditions except the grid pulse length was kept at 100 msec and the detect delay of 200 msec. It was found that the new cell achieved fifty percent greater signal output.

Although we had achieved increased signal intensities with the longer grid pulse length, it was necessary to consider the signal to noise ratio. In studies to compare the two grid pulse lengths it was found that the longer grid pulse achieved the same signal to noise ratio. Therefore the increased signal intensity of the longer grid pulse length had also delivered an increased noise level.

A study of the side dc under standard conditions was conducted. The signal intensity of the benzene molecular ion was observed while varying the side plate voltage. It was again expected that the sectional cell would produce signals of greater intensity. A plot of each cell's behavior shows that there is a linear dependence of signal intensity with side plate voltage up to 3 V. These voltages are within the normal range of experimentation in ICR. The two cells exhibited the capacity to trap the same number of ions.

Further side dc studies were done under standard conditions except the grid pulse length was kept at 100 msec and the detect delay at 200 msec. It was found that the sectional cell at the side dc of 3 V achieved one hundred percent greater signal output.

The signal to noise ratios for the three sectional cell with the two side dc studies were compared. This showed that the signal to noise ratio for the grid pulse length of 20 msec was 15. The signal to noise ratio for the grid pulse length at 100 msec was 45. The increased signal intensity of the longer grid pulse length had not been met with an increased noise level.

The three sectional cell has achieved greater signal output with the extended grid pulse length. With the rf level, it has increased by fifty percent. Through signal to noise ratio studies it has been found that this increased signal output has been met with an increased noise level. The elongated cell reached one hundred percent greater signal output at the tested dc side voltages. It has also been found that the increased signal output has not been coupled with an increased noise level. This is still not the increase expected for the larger cell.

In the future we plan to put a voltage on the upper and lower (receiver) plates, presently at ground. This should result in the ions localized near the electron beam of the cell moving to other areas of the cell to fill the sectional cell with ions more completely, by magnetron motion.

Laser Desorption Ion Trap Mass Spectrometry of the Polymeric Component of Coal

John A. Burroughs, Brian M. Cadre, and Luke Hanley*,
Department of Chemistry, University of Illinois at Chicago,
Chicago, IL 60607-7061.

Coal has long been postulated to be a two component mixture composed of a highly crosslinked polymeric matrix in which are trapped small molecules [1]. However, traditional mass spectrometric methods cannot directly examine the polymeric component because thermal volatilization leads to its chemical decomposition. A laser desorption ion trap mass spectrometer is utilized here to search for this polymeric component.

All experiments have been performed using a modified Finnigan MAT Ion Trap Detector (ITD 700). The ion trap electrodes are mounted inside a new vacuum chamber and equipped with a 6 kV conversion dynode. The end cap electrodes are connected to a function generator (Stanford Research Systems model DS-345) to allow resonant ejection experiments to be performed. The timing and data collection are controlled by custom software through an 80386/AT computer with multifunction data acquisition boards (National Instruments). 266, 355, 532, or 1064 nm pulses from a Nd:YAG laser are focussed onto a stainless steel probe onto which the sample is dried. Samples are prepared by Soxhlet extraction in pyridine of Illinois No. 6 coal from the Argonne Premium Coal Sample Program. These extracts are either used neat or mixed with a UV absorbing matrix or an alkali metal salt.

Figure 1 shows a positive ion spectrum of the coal extract produced by using 355 nm laser pulses, displaying a distribution of ions between roughly 150 and 1500 m/z with the center near 500 m/z. Laser desorption of the extract with 266 and 1064 nm pulses shows similar results, as do negative ion spectra obtained with 355 nm pulses. Polycyclic aromatic hydrocarbons (PAHs) have been used as model compounds for coal in mass spectrometric studies since it is believed that coal is composed largely of aromatic ring systems. Previous experiments have shown laser desorption successful in producing molecular ions from PAH samples [2]. Therefore, we believe the mass distributions found in our experiments to be directly representative of the masses of molecules contained in the extract.

The presence of carbon clusters can be also observed in spectra obtained with both UV and IR pulses. Figure 2 displays a spectrum similar to that shown in Figure 1 except that in addition to the broad distribution near 500 m/z, a number of carbon cluster ions up to 2000 m/z are detected. The carbon cluster ions are shown as sharp peaks in the spectrum spaced by 24 m/z with a particularly intense peak at 720 m/z corresponding to C_{60}^{+}. The appearance of these clusters can be controlled by adjusting the incident laser intensity and the trapping potential during ion injection into the trap.

Matrix assisted laser desorption ionization (MALDI) using sinapinic acid, nicotinic acid, 2,5-dihydroxybenzoic acid, and 3-hydroxypicolinic acid has also been attempted on these coal extracts. No higher mass or other ions are observed in the MALDI experiments beyond those seen in samples of the neat extract. Neither

positive nor negative ions besides carbon clusters have been observed above 2000 m/z in any of these tests. Although species ranging in size from 1000 to 10,000 amu in pyridine extracts of coal have been postulated to exist from results obtained using size exclusion chromatography [3], we have been unable to generate ions higher in mass than those shown here. It is our belief that such high mass compounds are not present in these samples.

Isotopic Masses at ppb Precision (!) from FT/ICR Mass Difference Measurements

Michael V. Gorshkov and Evgeny N. Nikolaev
Institute of Energy Problems of Chemical Physics, Academy of Science, Moscow 117829, Russia
Shenheng Guan, Karl Vermillion, and Alan G. Marshall†
Departments of Chemistry (and Biochemistry†), The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

FT/ICR mass spectrometry offers the prospect of ultraprecise (10^{-8} or better) determination of the mass difference between two ions of closely-spaced mass-to-charge ratio, because the (otherwise large) systematic error resulting from Coulomb-mediated interactions (namely, ion-ion and ion-image charge forces) may be eliminated from a mass difference determination by appropriate choice of experimental conditions. For more widely spaced mass doublets, even an absolute mass measurement can be highly precise.

The difference between ions of a given mass-to-charge ratio and ions of a second (well-known) mass-to-charge ratio is related to the unperturbed ion cyclotron frequencies, $\nu_{c,1}$ and $\nu_{c,2}$, of the two types of ions according to

$$m_2 - m_1 = \frac{m_2}{\nu_{c,1}}(\nu_{c,1} - \nu_{c,2}) \qquad (1)$$

To use Eq. 1, we must evaluate the shift of the measured FT/ICR cyclotron frequency from the unperturbed cyclotron frequency due to the following effects:

Magnetron shift. In an actual ICR ion trop, non-quadratic terms in the radial component of the trapping electric potential lead to dependence of magnetron frequency shift on the ion radial position. It is therefore necessary to extrapolate the observed cyclotron frequency to zero trapping potential.

Space charge effect. Unexcited ions of other mass-to-charge ratios, if left unexcited on or near the z-axis, ions produce a collective space charge which adds to the electrostatic trapping potential. Following excitation of the mass doublet to larger ion cyclotron orbital radius, the radial component of the space charge potential is directed outward (away from the z-axis) and shifts the doublet ion cyclotron frequencies further downward. This effect may be eliminated by extrapolating the observed cyclotron frequency to zero number of ions.

Relativistic effect. The observed ion cyclotron orbital frequency decreases as the ion cyclotron radius increases due to the relativistic increase in ion mass as the ion speeds up during excitation. This effect may be reduced by extrapolating the cyclotron frequency to zero ion cyclotron radius.

Higher precision in the masses of neon isotopes is important for quantitating energetics of nuclear reactions involving neon isotopes, and as an independent check on nuclear reaction "Q" values (rest mass energy difference between products and reactants in, e.g., an $n \rightarrow p + e + \nu_e$ process). Moreover, systematic error in the masses of neon isotopes can propagate and thereby increase the error in masses determined from other nuclear reactions. Here, we report 24-fold (and 6-fold) improvement in precision of measurement of the mass of ^{20}Ne (and ^{22}Ne), based on FT/ICR/MS. Supported by NSF (CHE-9021058) and Ohio State Univ.

APPLICATION OF A MECHANICAL SHUTTER FOR PRESSURE CONTROL IN EXTERNAL SOURCE ELECTROSPRAY FTICR

*V. L. Campbell, Z. Guan, and D. A. Laude, Jr.; Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, Texas 78712

To achieve the optimum performance of which Fourier transform ion cyclotron resonance (FTICR) mass spectrometry instruments are capable, low pressures are essential. Higher pressures can cause a deterioration of the quality and quantity of ion signal by promoting radial ejection of ions, incoherence of the ion bundle, and ion loss from ion/molecule reactions.

The problem with restricting pressure in the analyzer region is particularly acute for atmospheric sources including electrospray ionization. Low analyzer pressures are typically achieved through the use of numerous stages of differential pumping which extend beyond the magnet bore. As an alternative, it should be possible to insert an inexpensive mechanical shutter along the ion and neutral beam path to reduce the necessary stages of differential pumping. In particular, our use of concentric tubes for differential pumping allows improved ion spray signal to reach the analyzer region by reducing the distance from the source which is positioned in the magnetic field. However the directed flow of neutrals into the source is much higher and the shutter would be expected to provide a substantial benefit in terms of performance.

All spectra were obtained with a 3.0T FTICR mass spectrometer coupled to an electrospray ionization source. The essential components of the vacuum chamber and interface consist of four concentric vacuum chambers of increasing diameter which extend into the high-field region of the magnet. The mechanical shutter was mounted onto the concentric tube positioned adjacent to skimmer. The shutter is a 1.5 cm stainless steel disk with an inset Teflon O-Ring that acted as a self-lubricating seal. The shutter covers a 5 mm conductance limit in the end of the concentric tube, and is manipulated externally via stainless steel bevel gears which control the rotation of the shutter.

The shutter has potential as an alternative to the pulse valve for cooling in the remeasurement experiment. Gating of the ion beam at the skimmer is performed to let a specific ion population into the cell after which the ions are deflected for the balance of the experiment. The shutter is then used in concert with the FTICR pulse sequence to facilitate cooling of the excited ion cloud as an alternative to quenching. In this experiment, rather than employ a separate pulsed valve, the directed neutral beam is shuttered into the cell after FTICR detection to cool the excited ions. The shutter is then closed again for the next detection event.

Typically pressures could be varied over a two order of magnitude from 1 x 10-8 torr to the mid 10-6 torr range with pumpdown times of a few hundred milliseconds. Even when repeated several hundred times for several minutes, the water-methanol spray was pumped away and base pressures with the shutter closed quickly returned.

Variable delay times were inserted between ion injection and detection with the shutter both open and closed. Horse heart myoglobin spectra were compared for 20 and 40 s cooling delays with the shutter opened and closed. It was observed that if the shutter is left open for extended time periods, ion loss occurs, evidently due to radial ion loss at high pressure. However, if the shutter is closed during the cooling, ion signal magnitude remains constant for extended time periods. Once interesting feature of the spectra obtained with the shutter closed is that adduct formation is observed in the low pressure environment.

Using a 30 mm conductance limit between the shutter and cell, the pressure was 4 x 10-6 torr when the shutter was open and 6 x 10-8 torr when closed. The initial S/N ratio was enormous, but at the expense of broader peaks and extremely short ion residence times (Figure 1). Any delay before the excite with the shutter open resulted in complete signal loss due to severe radial ejection (Figure 2). However, if the shutter was closed during the delay, the ions were retained with adequate S/N (Figure 3).

A 4 mm conductance limit delivered 1 x 10-7 torr to the cell when the shutter was open and 1x 10-8 torr when closed. However, the cell pressure was inadequate to trap ions from among the 20 pA of current entering the cell. Instead ions were only trapped when background pressures into the 10-6 torr range were used.

As a compromise between the large and small orifices, a 7 mm conductance limit was evaluated. In this case the cell pressure from the neutral beam was 2 x 10-6 torr when the shutter was open and 2 x 10-8 torr when closed. However, in contrast with the 30 mm case, it was possible to retain ions with the shutter open during a delay. Additionally, improved resolution was obtained with the shutter closed during the delay.

A Novel Benchtop Ion Trap Mass Spectrometer for GC/MS/MS

Nathan A. Yates, Timothy P. Griffin, and Richard A. Yost
Department of Chemistry
University of Florida, Gainesville FL 32611-2046

Peggy R. Borum
Department of Food Science and Human Nutrition
University of Florida, Gainesville FL 32611-0370

A new ion trap mass spectrometer has been developed to overcome many of the problems that have restricted the ion trap's use for gas chromatography/tandem mass spectrometry (GC/MS/MS) analyses. In the past, three problems have made ion trap GC/MS/MS impractical: shifts in an ion's secular frequency of motion due to changing ion abundances (1), the need for real-time ionization control to limit space charge for MS/MS experiments, and complicated setup and tuning procedures required for MS/MS scan functions (2).

The instrument used in these studies was a modified Finnigan MAT ITS-40 that has been adapted for MS/MS operation. The key features of this instrument include: Automatic Ionization Control to automatically adjust the ionization time (AGC) and reaction time (ARC) for the amount of sample injected, Two-Step (3) isolation to remove sequentially ions of higher and lower m/z along the $\beta_z = 0$ and $\beta_z = 1$ stability edges, and SWIFT broadband excitation to excite a (10 kHz) range of frequencies, thus minimizing the loss in CID efficiency that can occur over a GC peak due to shifts in the parent ion's secular frequency. Figure 1 shows a diagram of the components that make up the GC/MS/MS ion trap system. Instrument control is handled by a host PC that downloads method files for the autosampler, GC, arbitrary waveform generator, and MS. The new software that we have developed allows the instrument to run unattended, injecting up to 200 samples, while switching between GC/EI/MS, GC/PCI/MS, GC/EI/MS/MS and GC/PCI/MS/MS scan modes.

Figure 2 shows the MS (upper) and MS/MS (lower) calibration curves that were obtained for the parent (m/z 182) and product (m/z 77, 105, 153) ions of benzophenone using electron ionization. The PCI MS (upper) and MS/MS (lower) calibration curves for benzophenone are shown in Figure 3 The 10 fold reduction in signal observed for MS/MS is due to ion losses that occur during the Two-Step isolation process and is not indicative of the efficiency of CID. Figures 4 and 5 show the spectra and selected mass chromatograms for the injection of 83 pg of benzophenone. Note the improvement in signal-to-noise ratio between MS and MS/MS scan modes. The use of SWIFT broadband excitation in place of single frequency resonant excitation results in comparable full scan product ion spectra at 80 pg and 300 ng levels, without manual adjustment of the voltage of frequency. We believe that a benchtop GC/MS/MS instrument that incorporates new features similar to those demonstrated here can reduce GC/MS/MS analysis on the quadrupole ion trap to routine practice. The authors wish to thank Finnigan MAT and NASA Ames Research Center for technical and financial support respectively.

Infrared Multiphoton Dissociation Studies in the Quadrupole Ion Trap using a Multi-pass Optical Arrangement

Stephenson Jr., J.L.; Booth, M.M.; Shalosky, J.A.; Eyler, J.R.; and Yost,R.A.
Department of Chemistry, University of Florida, Gainesville, FL 32611

INTRODUCTION

Infrared multiphoton dissociation (IRMPD) has been used extensively with ion trapping techniques to investigate gas-phase ion chemistry. A continuous wave (cw) CO_2 laser is used in combination with a quadrupole ion trap utilizing resonance ejection The inner surface of the ring electrode is modified with a series of mirrors to facilitate higher photodissociation cross sections than those observed with single pass designs.

EXPERIMENTAL

All experiments are performed on a Finnigan MAT ITMS mass spectrometer. The ITMS manifold is equipped with a modified flange containing a ZnSe window to pass IR radiation. The CO_2 laser employed is an Apollo Model 570, line-tunable over a wavelength range of 9.10-10 82 μm, with a spot size on the order of 1 cm. The ring electrode is modified by incorporation of three spherical concave mirrors mounted on the inner surface of the ring as shown in Figure 1. The modified optical arrangement allows for eight laser passes across the ring electrode of the ion trap, thus increasing the optical path length and the amount of absorption obtained A pulsed valve is mounted on the opposite flange from the ZnSe window and is used to pulse helium into the ion trap to increase trapping efficiency With pulsed valve operation, laser delay times of up to several seconds are needed for the collision-free conditions required by IRMPD.

RESULTS AND DISCUSSION

In a typical IRMPD experiment, a 15 ms ionization period is followed by a reaction time of 400 ms, and the resulting protonated diglyme (m/z 135) is apex isolated. A laser delay time of 0.4 s is included to allow for removal of any excess internal energy by radiative and/or collisional cooling. Depending on the experiment, the laser irradiation time varied from 5 ms to 250 ms, which is then followed by a laser decay table and mass analysis. The characteristic photodissociation spectrum of the $(M+H)^+$ ion is shown in Figure 2 First order kinetics can be applied to the photodissociation process, with typical rate coefficients on the order of 100 s^{-1}. This value is significantly higher than the 2-30 s^{-1} values obtained at higher laser irradiances reported in the literature (see Figure 3). In Figure 4 the wavelength dependence of the IRMPD spectrum of protonated diglyme is shown. The maximum photodissociation efficiency is found at 944 cm^{-1}. Pulsed valve experiments are employed to determine if the increase in trapping efficiency associated with the addition of He buffer gas to the ion trap analyzer would interfere with the collision-free requirements needed for IRMPD. In order for photodissociation to occur, the rate of photon absorption must be faster than that of collisional deactivation. Therefore, long ion storage times are required to sufficiently pump away the He buffer gas used to efficiently trap the protonated diglyme ions. In figure 5 is shown the photodissociation efficiency as a function of the laser delay time. After a 2 s delay between the He gas pulse and laser trigger, the photodissociation efficiency levels off at over 90% The effect of exciting the $(M+H)^+$ ions of diglyme using resonance excitation is seen in Figure 6. With increasing voltage applied to the endcaps, the axial excursions of the ions increase, thus the fraction of time the ions spend in the radial plane of the multi-pass ring electrode and therefore the extent of interaction between the stored ions and photons is decreased. This leads to the decrease in photodissociation efficiency observed for increasing resonant excitation voltage.

Introduction. A combined experimental and simulation study is described of the action of a quadrupole field on trapped ions when the working point is moved to the vicinity of a stability boundary, particularly the $\beta_z=0$ boundary. Ions are accelerated under the influence of the field and, as a consequence of collisions with helium buffer, dissociate; this process is known as 'boundary-activated dissociation'[1] or 'border effect'.[2] When ions are subjected to a collisional cooling period prior to the border effect, the duration of the pre-cooling period (or number of collisions) can have a profound effect upon the fragmentation channels accessed subsequently.

Experimental. A simulation study[3] of consecutive ion isolation[4] in the quadrupole ion trap indicated that, when the working point is moved to the proximity of the $\beta_z=0$ boundary of the stability diagram, ion kinetic energy is enhanced. The effect of helium buffer gas during and after the ion-isolation process, for ions with randomly-chosen co-ordinates and velocities, was to moderate ion kinetic energies. Such cooling behaviour in the ion trap is now well-recognised. However, the effect of helium buffer gas during and after the ion-isolation process for collisionally-cooled ions is to enhance rather than moderate ion kinetic energies while the working point is close to a boundary, from an average of 14 *eV* to 34 *eV*. **Thus, contrary to the normal collisional behaviour when the working point is located well-within the stability diagram, the presence of buffer gas leads to kinetic energy enhancement when the ions are cooled previously and the working point is moved subsequently close to a boundary.**

An experimental study of boundary-activated dissociation was carried out by Traldi and Catinella using a Finnigan MAT Ion Trap Mass Spectrometer. The model compound chosen was a benzoquinolizidine derivative (compound **1**, 2,6-dimethyl-9-methoxy-4h-pyrrole [3,2,1-ij] quinolin-4-one) which had been studied previously.[5] The scan function here consisted of a constant ionisation time of 300 μs, a two-step isolation of $M^{+\bullet}$ of **1** (*m/z* 227), a variable cooling time, and a plateau time of 90 μs during which a positive DC potential was applied. This sequence was followed by the usual analytical ramp of the RF potential. The sole scan parameter which was changed during a given set of experiments was the cooling time duration. The cooling time was varied from 0-420 μs for each of the helium pressures, 1×10^{-5}, 4×10^{-5}, 8×10^{-5}, and 1.2×10^{-4} *torr*. The results obtained with the ITMS were compared with those obtained with a triple stage quadrupole in which the selected ion energy could be varied prior to collision.

At 1×10^{-5} and 4×10^{-5} *torr*, only fragments *m/z* 212 and *m/z* 198 originating from CH_3 and CHO losses, respectively, were detected. The situation changed dramatically at 8×10^{-5} *torr*. New fragment ions of *m/z* 183, 184, and 154 appeared and their relative abundances showed almost linear increases with increasing cooling time.

At a helium pressure of 1.2×10^{-4} *torr*, which is the typical helium pressure employed in daughter ion spectroscopy experiments by ITMS, the situation changed further to that which is shown in Fig. 1. The intensities of $[M-CH_3]^+$ and $[M-CHO]^+$ decreased with increasing cooling time but, for this helium

pressure, the dependencies on cooling time of the remaining fragment ions showed a maximum; this behaviour is particularly clear for *m/z* 184 ions and indicates that a specific range of cooling time is most effective for maximizing the yield of a specific collisional product ion.

Figure 1. Boundary-activated dissociation of $M^{+\bullet}$ of 1 as a function of pre-cooling time.

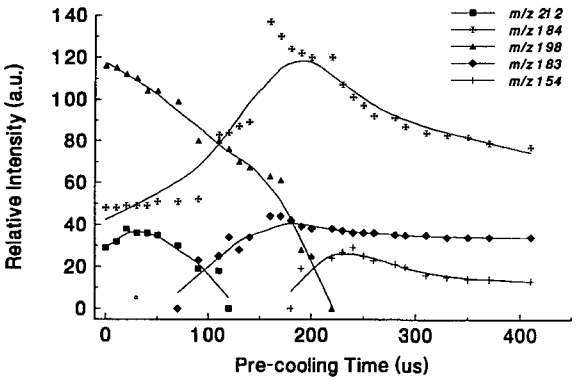

Figure 1 shows a remarkable resemblance to ion break-down curves wherein fractional ion abundances are plotted versus energy in the center-of-mass frame. Clearly, information concerning the appearance energies of fragment ions which can be obtained from such curves should be extractable from the curves shown in Fig. 1, once a suitable calibration procedure can be evolved. In order to estimate the kinetic energies experienced by ions subjected to the boundary effect and to tickling, the above results were compared with those obtained from collision experiments carried out with a triple stage quadrupole (TSQ) instrument. The tickling data were similar to those achieved by ions having 5 *eV* of kinetic energy, while the boundary effect data were similar to those achieved by ions having 100 *eV* of kinetic energy. Further comparison of the ITMS and TSQ data showed an additional and important aspect of instrument performance; daughter ion detection efficiency (60%) for the ITMS experiments exceeded those for the TSQ instrument which were *ca.* 20% and 10% for collisions of 5 *eV* and 100 *eV* ions, respectively.

In a further boundary-activated dissociation study, carried out with M^+ of 4-nitro-o-xylene, similar dissociation behaviour was observed as the cooling time was increased. Again, comparison with a TSQ instrument indicated that boundary-activated dissociation produced a fragmentation pattern which resembled both that obtained with a kinetic energy of 100 eV and upon electron impact.

Nature and Effect of Non-Linear Resonances in Ion Traps

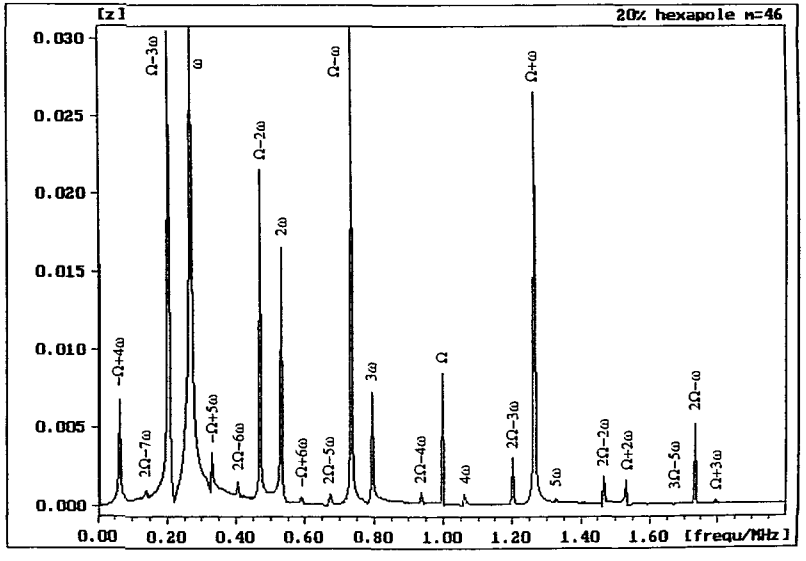
J. Franzen, Bruker-Franzen Analytik GmbH, Bremen

The simple physical nature of non-linear resonances in quadrupole fields with superimposed multipole fields is presented in a comprehensable way, and the law for ion ejection by resonances with multipole field of any order is given.

1. The secular oscillations of ions within pure quadrupole fields with an rf driving frequency Ω consist of the basic secular frequency ω and sideband frequencies of the form $\nu\Omega+\omega$ and $\nu\Omega-\omega$, in accordance with the Mathieu theory. The pure quadrupole field behaves as a harmonic oscillator, sometimes called "pseudo-harmonic" because of the additional sideband frequencies superimposed on the basic secular oscillation. The superposition of higher multipole fields makes the storage field non-harmonic and creates higher harmonics $n\omega$ (overtones), as it is known from non-harmonic oscillators in other areas of physics. In addition, sideband frequencies of the general form $\nu\Omega+n\omega$ and $\nu\Omega-n\omega$ (ν and n are arbitrary integers) of the higher harmonics are generated.

The nature of non-linear resonances is extremely simple: ***Non-linear resonances occur if harmonics match with sidebands***. Such matches do not simply consist of two superimposing frequencies, instead, complete series of frequencies come together in a single match.

Fig. 1 below exhibits the frequency spectrum of an hexapole superposition.



This frequency spectrum was calculated by computer simulation of the ion oscillation in z direction, and a Fourier analysis of the computed oscillations. Superposition of odd multipoles create all higher harmonics, even multipoles create odd harmonics only, as known from non-harmonic oscillators. A rather strong 20 % hexapole field superposition was chosen here to enhance the higher harmonics. The higher harmonics and the sideband frequency series are identified in fig. 1.

2. Simulations of the ejection processes in stationary fields reveal the law for the amplitude growth caused by different types of resonances. The general equation

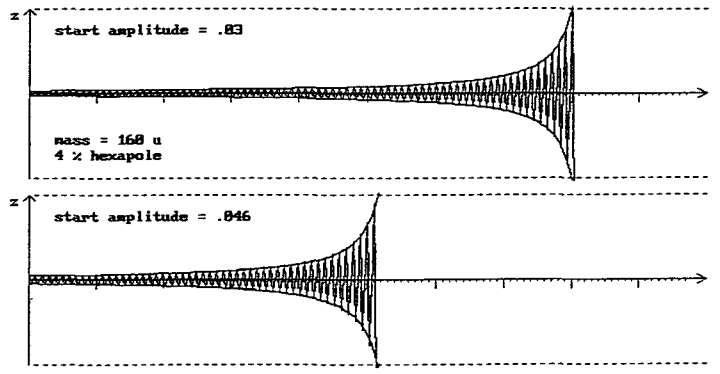
$$dz/dt = C_{n-1}z^{n-1}$$

is valid for resonances caused by multipole fields of order *n*, as long as the ejection is not disturbed by frequency shifts. This law is valid in all cases of resonances, may it be a resonance with a dipole field generated by an additional AC across the end caps, or may it be a non-linear multipole resonance created by the shape of the electrodes.

The equation can be easily undertstood: The energy pick-up of the ion is proportional to the field strength of the multipole field as seen by the momentary oscillation width of the ion. It clarifies that the energy is taken up from the rf component of the multipole field, not from the basic quadrupole field.

Integration of the basic law of ion ejection gives a linear amplitude growth for the dipolar excitation (with externally applied excitation voltage), an exponential growth for the quadrupole field (in the non-stability area), and a hyperbolic growth (of hyperbole order n-2) in case of non-linear resonances by superimposed multipole fields. Because hyperboles exhibit a mathematical pole, the ejection by higher multipoles is extremely pointed.

Fig. 2 demonstrates the hyperbolic growth of the oscillation in z direction for an ion in resonance with the hexapole non-linear resonance condition $\beta_z = 1/3$.



Quadrupolarized ICR Cubic Ion Trap

Hyun Sik Kim, Ruidan Chen and Alan G. Marshall†

Departments of Chemistry (and Biochemistry†), The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

The electrostatic trapping potential in any ICR ion trap is approximately quadrupolar near the trap center. Away from the center, the deviation of trapping potential from pure quadrupolar form can lead to non-linear response (harmonics, combination modes, peak splitting) [1]. Efforts have been made to improve the electric potentials in various ion traps, as recently reviewed [2]. Here we show that the electrostatic potential field in a conventional ICR cubic ion trap may be shimmed to near-perfect quadrupolar form without change in overall trap shape (cubic in this case) by segmenting the excitation and detection electrodes and coupling them by an appropriate RC network.

The quadrupolar trapping field is established by fitting the electrostatic trapping potentials of every segment to a quadratic function of the distance from the center plane. The electrostatic trapping field is separated from the rf excitation/detection fields by capacitors of carefully chosen values. The trap design has been refined theoretically by use of SIMION [3]. Although the simulated trapping potential well in a conventional trap is deeper than that of a quadrupolarized trap, the overall trapping potential profile in the quadrupolarized trap approaches a perfect quadrupolar field much more closely than does that of a conventional trap.

A striking advantage of the quadrupolarized trap is evident from comparison of benzene molecular ion FT/ICR mass spectral peak shapes for quadrupolarized and cubic ICR ion traps at different ICR orbital radii (Figure 2). (Although FT/ICR peak height increases with increasing ICR orbital radius, each set of plots has been scaled to a common peak height to facilitate comparison of peak shapes.) The elimination of peak splitting in the quadrupolarized trap shows that peak splitting previously observed for conventional ICR ion traps arises from non-quadrupolar electrostatic trapping potential [4], because the splitting is eliminated in the quadrupolarized trap. Moreover, mass resolving power is enhanced by ~10% in the quadrupolarized trap. Finally, even the quadrupolarized trap produces a potential which deviates from pure quadrupolar near the edges of the trap, as shown by the small change in ICR frequency at increasingly large ICR orbital radius (Figure 2, right-hand spectra). This work was supported by NIH (GM-31683), NSF (CHE-9021058) and The Ohio State University.

Contaminant Analysis Using Novel Sampling Strategies and Laser Desorption Mass Spectrometry

M.E. Cisper, W.L. Earl, G.C. Eiden, P.H. Hemberger, and N.S. Nogar. Los Alamos National Laboratory, Los Alamos, NM 87545.
J.E.P. Syka. Finnigan MAT, San Jose, CA 95134.

We have combined two sample collection/sample introduction techniques with laser desorption ion trap mass spectrometry for rapid contaminant screening. Direct laser desorption of material affords several advantages over less direct methods: Rapid sample turnaround, little or no sample preparation, reduced waste generation and disposal, and inexpensive and easily prepared sampling materials. Contaminants are sampled in one of two ways: Through zeolite absorption or through solid-phase microextraction on a fiber probe. The two methods are convenient in that they provide both a method to sample for contaminants and a means by which compounds, including volatile organics, are available for laser desorption.

Instrument configuration, described in detail previously,[1] consists of an excimer laser aligned with the ion trap assembly contained in a large vacuum chamber. The ring electrode, drilled through on opposite sides, provides access for a direct insertion probe upon which a pulsed laser beam impinges (308 nm, 15 nsec duration, 3×10^6 W/cm^2). The timing of the laser firing is carefully coordinated with the leading edge of a rising RF step in the scan function to effect a 10 to 100-fold signal increase.[2] Detected signal also tracks the phase of the ring electrode RF.

Zeolites (molecular sieves) are crystalline, alkali-aluminum silicates which form cage-like structures. They are attractive adsorbents because cavity size, determined by the aluminum-silicon ratio, can be controlled for selective sampling of volatile and semi-volatile compounds. The zeolite matrix, after exposure to the suspect airborne contaminant, is tamped into the concave end of a stainless steel probe tip.

Laser sampling of zeolite-entrapped dimethyl methyl phosphonate [$CH_3P(O)(OCH_3)_2$, M.W. 124] produced the mass spectrum shown in Figure 1.

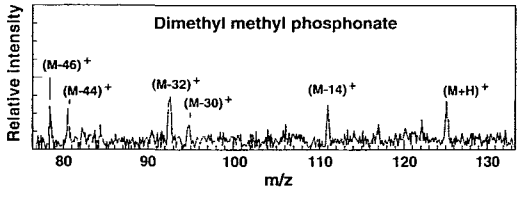

Figure 1. Laser ion trap analysis of dimethyl methyl phosphonate entrapped in zeolite.

Interest in solid-phase microextraction (SPME) on fused silica fibers led to the development of the second sample collection/introduction technique presented here. SPME is a relatively recent method[3] used for the extraction of organic compounds from aqueous samples. A length of optical fiber is exposed to an aqueous solution. Equilibrated partitioning of the organic analytes from the liquid phase to the stationary phase on the fiber can occur within minutes. Conventionally, contaminant analysis by SPME is obtained through thermal desorption in a heated GC injection port.

We used stripped and cleaned fused silica fibers (0.6 to 1 mm in diameter) as sampling probes in organic solutions. The fiber was dipped in solution to a depth of 0.5 to 1 cm, after which it was directly inserted through the drilled-through ring electrode for laser interrogation of the microextracted sample. Pyrene (M.W. 202) served as the benchmark compound for most studies but optical fibers were also used to extract other PAHs, laser dyes, pesticides, trimethyl phenyl ammonium iodide, p-dichlorobenzene, and peptides. Figure 2 shows the typical mass spectrum obtained from laser desorption of a fiber exposed to a soil sample containing 10 ppm anthracene and pyrene. One mL of methanol was added to the spiked soil. The fiber was exposed to the soil/solvent slurry for 3 minutes with no attempt to achieve equilibrium microextraction. We have detected pyrene on fibers exposed to 1 ppb solutions.

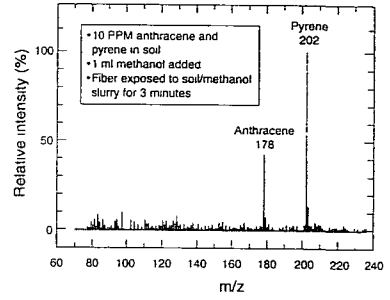

Figure 2. Laser desorption analysis of PAH mixture microextracted on fiber.

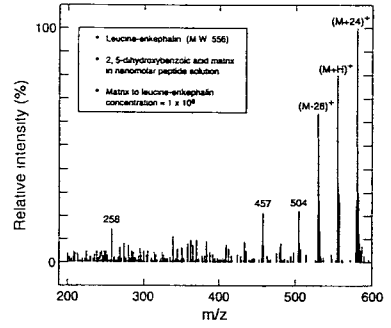

Figure 3. Laser desorption analysis of microextracted peptide on fiber.

Laser desorption of a fiber exposed to a solution containing the peptide leucine-enkephalin and a matrix compound resulted in the mass spectrum shown in Figure 3.

Zeolite absorption and fiber microextraction show great promise as rapid sampling/sample introduction methods. These techniques extend the variety of compounds amenable to laser desorption ion trap mass spectrometry. However, the data are semi-quantitative in nature and zeolite-adsorbed materials may undergo catalysis. We plan to further investigate the fiber surface-laser probe interaction, fiber coatings, improvements in microextraction under equilibrium conditions, and laser ablation/RF step interaction.

AN IMPROVED CALCULATION OF PEAK SHAPE IN FTMS

D. L. Rempel and M. L. Gross

Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304.

In light of recent work for the Fourier transform mass spectrometer (FTMS) that shows that both trap electric field compensation[1] and ion cloud pressure focussing are required to obtain the best improvement in the detection of diffuse ion clouds,[2,3] the connection between experimental parameters and the ions' spectral peak shape needs a more carefull examination.

Here, Lie transforms[4] are used to build a peak shape model with relaxed assumptions and improved rigor over that done in ref 1. The strategy for building peak shapes involves two basic parts.

First, a common factor of 1/m was removed from the single ion Hamiltonian by writing $t=m^*\gamma$. After the Hamiltonian for a single ion was transformed to action-angle variables for the cyclotron, magnetron and z- oscillation modes,[5,6] the Deprit perturbation series[4] was used to calculate a canonical transform for the action-angle variables that removes angle dependence of all terms of the first three orders in the Hamiltonian except those electric field terms which are associated with excitation of the ion motion. The Deprit method was used because old and new variables are not mixed in the generating function for the canonical transform. Because of this, all state variables can be explicitly computed to the desired order.[4] This is in contrast to the perturbation method used by Kretzschmar.[6,7]

The charge displacement caused by the ion's position was "pulled back" to the action-angle variables and then pulled back to the new canonical variables by the inverse of the canonical transform used to transform the Hamiltonian. Only those terms which depend the cyclotron angle and no other angle were retained for computing the peak shape.

The excitation terms in the Hamiltonian were pulled back just as the charge displacement was.

A secular perturbation theory[4] was used in the second basic part to compute the change in state due to an RF-burst excitation. The change in the action-angle variables caused by the excitation was computed by separately transforming the action-angle variables for each mode into "position-momentum" variables, carrying out the secular perturbation calculation to first order, and then converting the result back into action-angle variables. This strategy avoids a result that becomes undefined when the initial actions go to zero.

All results are are written as a function of dimensionless parameters such as MMC = m/m_e, geometry factors, and outer-segment-to-disk voltage ratio.

The effects of compensation, mass and magnetron motion on the cyclotron frequency computed from the tranformed Hamiltonian can be seen by comparing graphs of the cyclotron frequency versus cyclotron and z-mode normalized actions.

The frequency surface of an uncompensated cubic trap shows contours that are tangent to the cyclotron vs z-mode action graph that results from an RF burst excitation only at higher z-mode actions. Only ions with actions in the region where this tangent condition occurs are expected to give high resolution signals. Driving the outer segment of each trap plate of a compensated trap

at 1.7 times the potential of the 50% center disk decreases the frequency variation for low z-mode actions and intermediate cyclotron-mode actions. The region of the tangent condition moves to low z-mode and intermediate actions.

The frequency surface becomes much deeper when the mass is increased by a factor of ten as MMC is increased from 0.01 to 0.1, but otherwise, has nearly the same shape.

Increasing the magnetron mode radius to about 50% of the maximum radius distorts the frequency surface so that the local minima would exist only at lower cyclotron actions and high z-mode actions with lower frequencies. As a result, ion clouds with broader magnetron-mode distributions (high mass ion clouds, for example) are expected to have wider peaks that are shifted to lower frequencies.

The calculated peak shape for which a simple z-mode distribution with a temperature of 1844 K is used shows a dominating high resolution part. This temperature is the expected lowest temperature of the z-mode shortly after electron ionization in a cubic trap with 1 V applied to the trapping plates. The corresponding experimental peak shape (benzene, m/z=78, low ion number, 1x10-7 torr in a 1 V, 0.0254 m cubic trap, 1.2 T) shows the same feature with a resolution of 13.3K for a ionization to excitation/detection delay of 1 ms.

The calculated peak shape for a simple z-mode distribution with a temperature of 300 K shows that the high resolution part of the peak has been lost. The corresponding experimental peak shape also shows the loss of the high resolution part for an ionization to excitation/detection delay of 4 s. The measured half-height resolution has decreasedto 3.2K.

This is a problem for pressure focussed ion clouds that is solved by compensating the trap as shown by calculated peak shapes that show much reduced change with z-mode temperature. Both experimentally measured half-height resolutions are 26.3K for delays 1 ms and 4 s.

The fact that improved performance is achieved while not making the trap more quadrupolar suggests that there is another strategy for improving performance in the trap. This strategy might be described as matching the low z-mode action portion of a level set (contour) of the frequency surface with the low z-mode action portion of the cyclotron action verses z-mode action graph that results from excitation.

SWIFT Excitation/Ejection of Ion Axial Motion in Quadrupole Ion Trap Mass Spectrometry

Shenheng Guan and Alan G. Marshall†

Departments. of Chemistry (and Biochemistry†),The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

Stored waveform inverse Fourier transform (SWIFT) excitation is a powerful excitation method for FT/ICR/MS introduced by Marshall and coworkers (1,2). Demonstrated advantages of the SWIFT method over prior excitation methods include: uniform excitation over specified m/z range(s), high excitation/ejection selectivity, extension of FT/ICR detection dynamic range, and convenience in use. The theoretical foundation of the SWIFT method is linear response theory (3,4).

In a quadrupolar Paul ion trap, the high-frequency, high-amplitude rf voltage applied between the ring and end-cap electrodes forms a pseudopotential in the z-direction that may be approximated as a quadrupolar electrostatic potential; ion motion may then be modeled as a harmonic oscillator if $q_z = (4qV_{rf}/mr_0^2\Omega^2)$ is small. The equation of z-motion of ions subjected to dipolar z-excitation in the Paul ion trap is then linear, just as for cyclotron motion in an ICR ion trap.

An important tool for ion trap applications is dipolar (i.e., excitation voltage applied between the two end-cap electrodes) resonant excitation of axial z-motion, applied at the ion "secular" or "natural" z-oscillation frequency corresponding to a given q_z-value. By solving analytically the equation for forced ion z-motion with a collisional damping term

$$\ddot{z} + \gamma\dot{z} + \omega_z^2 z = \eta V_z(t)\ ,\ \eta = \frac{c_1 q}{2 z_0 m}$$

in which γ is a collisional damping factor, ω_z is z-frequency, and c_1 (=0.8) is the trap geometrical factor, we develop a linear response theory for dipolar z-excitation. Post-excitation ion z-oscillation amplitude is proportional to the magnitude spectrum (at the ion secular frequency) of the time-domain excitation voltage signal.

A general algorithm generates an excitation waveform which excites ions to any desired z-amplitude over arbitrary m/z range(s) and provides for selective ion isolation or ejection. The present theory closely follows that previously developed for ICR, except that the ion axial motion in the Paul trap is linear, whereas the ion cyclotron orbital motion is circular. Therefore, SWIFT techniques developed previously for ICR cyclotron excitation (3-7) are easily adapted for high-resolution z-excitation and z-ejection in RF ion traps (8). The effect of collisional damping may be treated theoretically (9). Work supported by Amoco and Ohio State University.

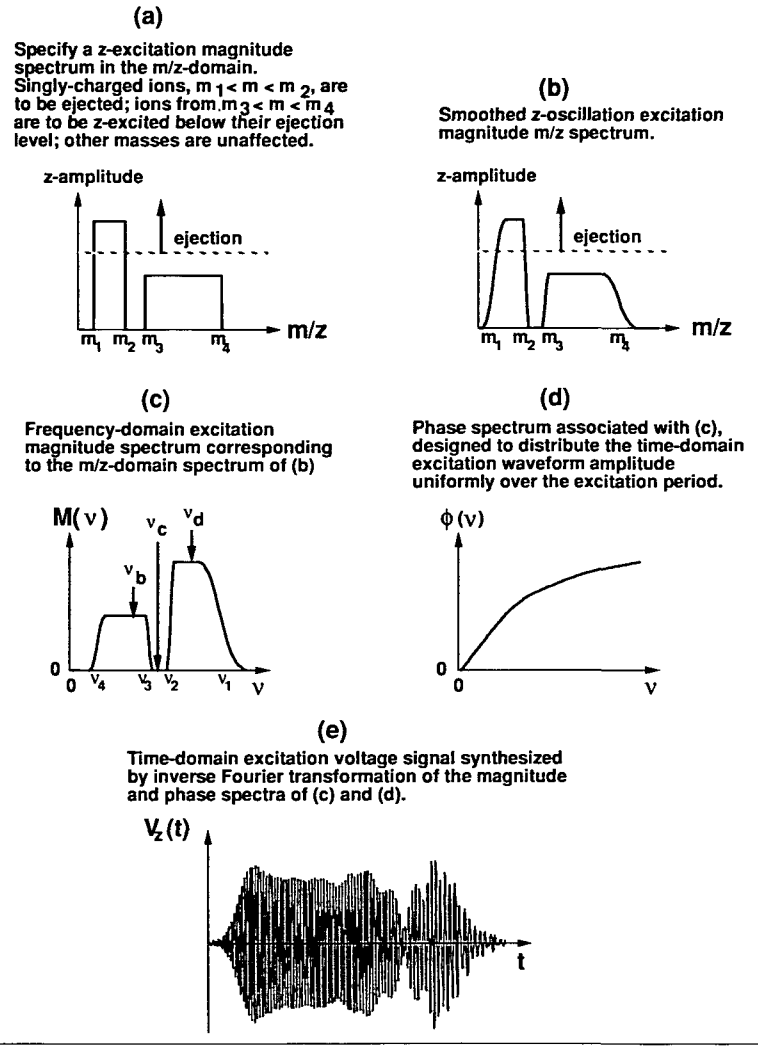
Construction of a SWIFT Time-Domain z-Excitation Waveform for Mass-Selective Axial Excitation and Ejection



RADIAL ELECTRIC FIELD MINIMIZATION IN OPEN CELL GEOMETRIES FOR EXTERNAL SOURCE FTICR

*Victor H. Vartanian and D. A. Laude, Jr.; Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712-1167

The open-ended trap with trap electrodes positioned as a linear extension of the excite and detect electrodes is finding increased use in external source FTICR applications. Advantages include minimal electrode charging, greater gas conductance, and greater charged particle access to the cell interior. One distinction between the conventional closed cell and the open cell is the increased freedom in selecting electrode dimensions used to define the cell geometry. This offers the possibility of finding improved figures of merit for a cell of specified volume constrained by magnetic field homogeneity. Of particular interest is radial electric field minimization.

Five different cell designs were constructed and evaluated to experimentally verify possible reductions in radial electric field including a new type of open cell in which a single trapping electrode positioned in the cell center surrounded by the excitation and detection electrodes with a biased potential of opposite polarity. Thus to trap positive ions a negative potential is applied to the center electrode. This open cell geometry can be classified in a general scheme for open cells as the complement of a cell with positive trap potentials applied to narrow trapping rings positioned at the cell boundaries.

Cylindrical cells were appended to the analyzer side of a dual cell assembly within an Extrel 2000 3.0-T, 150 mm bore superconducting magnet controlled by a Nicolet 1280 data station executing Extrel FTMS software version 6.0r.1. Cells of 0.030" thick OFHC copper were mounted onto aluminum frames utilizing Teflon spacers. For the radial electric field data, benzene was introduced at 7.0×10^{-7} torr. Frequency shifts for the benzene were measured for each spectrum as a function of increasing trap potential.

For an open cell aspect ratio is defined as the distance between potential maxima located at the approximate midpoint of the trap electrodes ***c***, divided by cell width, ***a***. If the gaps between electrodes are considered negligible then ***c*** is approximately c_e (excite/detect dimension) + c_t (trapping dimension). Often the open cell is generalized as having equal electrode segments producing a cell of constant volume for a given aspect. This unnecessary restriction results in a radial electric field for the open cell that is similar to the closed cubic cell but inferior to the elongated cell (Figure 1). However the versatility of the open cell in the selection of electrode dimensions does not require that aspect ratio remain constant for a given cell volume. If ***a*** and ***c*** are kept constant within the homogeneous region of the magnetic field, c_t and c_e can be varied producing cells of varying aspect without changing cell volume. A range of potential well depths and radial electric fields are then possible.

For a cubic configuration where $c_t + c_e = a$, SIMION data indicates that the well depth for a 1.0 V applied trap potential is 0.328 V. Experimental benzene data for a 5 cm cubic open cell exhibits a frequency shift of -74.3 Hz/V at the cell center.

In an elongated configuration where $c_t \to 0$ and $c_e = 1.5a$ the well depth for a 1.0 V trap potential is 0.28 V. Experimental benzene data for a 7.5 cm x 5 cm cell exhibits a frequency shift of -21.8 Hz/V at the cell center. The actual cell was constructed with the actual trap electrode equal to 3/16".

For a compressed configuration where $c_e \to 0$ and $c = c_t$ the well depth is only 0.05 V. A 4 cm x 5 cm cell with aspect ratio of 0.8 exhibits a frequency shift of -380 Hz/V at the cell center. The actual cell was constructed with the excite electrode equal to 3/16".

Shimming is often used to correct for non-ideal fields in the trapped ion cell; specifically an effort is made to reduce the radial electric field. In this case, c_t is sectioned into n slices (here n = 2), electrostatically shimming the cell so that $c = c_{t1} + c_{t2} + c_e$. The well depth is 0.35 to 0.38 V

depending on the voltage on the shim. A 5 cm x 5 cm shimmed open cell with aspect ratio of 1.0 positioned in a 3.0 T magnet exhibits a frequency shift of -27.8 Hz/V at the cell center.

The complementary single trap electrode cell (Figure 2) traps ions in a potential depression of 0.22 V for a 1 volt applied potential. The excite isopotential contour exhibits linearity along the cell centerline despite the presence of the trapping ring in the center of the cell volume (Figure 3). The PFTBA spectrum in Figure 4 was collected at -2 volts applied (about -0.44V effective potential). Additional study is underway to evaluate the performance and potential utility of the trap. One possibility is that because externally generated ions do not have to overcome a potential barrier to enter the cell, a more efficient accumulated trapping process is possible.

SIMION data in Figure 5 reveals that increasing the cell aspect ratio decreases radial electric field and increases the homogeneous excite region. However the potential well depth decreases. A compromise open cell geometry can be utilized in which a cell approaching the geometry of the open elongated cell is used. For this type of cell, the radial electric field approaches the reduced magnitude of the closed elongated cell without the increase in cell length associated with the conventional open cell.

A NEW METHOD OF OPERATION FOR THE QUADRUPOLE ION TRAP

PAUL KELLEY, DON HOEKMAN AND STEPHEN BRADSHAW, Teledyne MEC, 1274 Terra Bella Avenue, Mountain View, CA 94039-7244

We have developed a new method of operation (1) that makes more efficient use of the space charge capacity of ion traps. In this new method, the ion trap is operating using a Filtered Noise Field (FNF). For the quadrupole ion trap, the new field is comprised of a 3-D quadrupole (Q) field and a notch filtered broadband signal (σ) that combines to form the FNF which traps, or operates on, only m/z's or mass ranges of interest (Figure 1). The broadband signal is composed of a sufficient number of frequency components with sufficient amplitude to present, by design, an effective power band that spans the secular motion of the trappable mass range of the ion trap. This broadband signal can be applied with sufficient power to, for example, resonantly eject all m/z's from an ion trap. The broadband signal can be generated by analog or by digital means and can be designed to be a known waveform. If, for example, the broadband signal is constructed by digital means to be a known waveform, it can be notch filtered in real-time to operate on the physical system (Figure 2). The broadband signal needs to be constructed only once and can be used in combination with the 3-D Q field to generate a wide variety of FNFs by using real-time notch filters.

The FNF can be used, for example, during the ion storage portion of an experiment to store only wanted m/z's. The wanted m/z's can be a single m/z, multiple adjacent or non-adjacent m/z's (Figure 3), a mass range, discontinuous mass ranges, or a combination thereof. Since frequency components are present with sufficient power at the unwanted m/z's, they are resonantly expelled while only wanted m/z's are being stored. This allows the dynamic range of an ion trap to be used more efficiently and results in increased sensitivity for the wanted m/z's. We are routinely observing one to three orders of magnitude improvement in sensitivity. The FNF can be used for a host of ion trap experiments such as Selected Ion Monitoring (SIM), Selective Reagent Ion Chemical Ionization (SRI-CI), MS, MS/MS, MS/MS/MS, etc. The development of FNF technology, for use with ion traps, also overcomes the present day limitations of chemical matrix effects such as identifying target compounds that co-elute or are masked by excesses of non-target compounds.

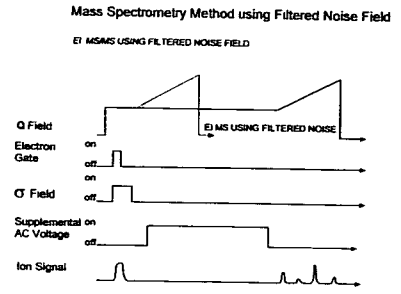

Figure 1 Electron Ionization MS and MS/MS Method of Operation for the Quadrupole Ion Trap using a Filtered Noise Field (FNF) In this example, the σ Field is used in combination with the Q Field to store only m/z's of interest during ionization.

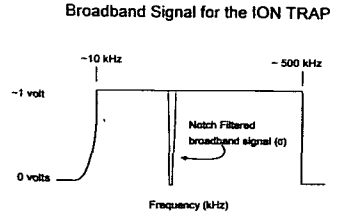

Figure 2. Broadband Signal for the Ion Trap. The broadband signal is composed of a sufficient number of frequency components with sufficient amplitude to present, by design, an effectively flat power band that spans the secular motion of the trappable mass range of the ion trap It can be notch filtered in real-time to create σ Fields The σ Fields can be combined with the Q Field to trap, or operate on, m/z's of interest.

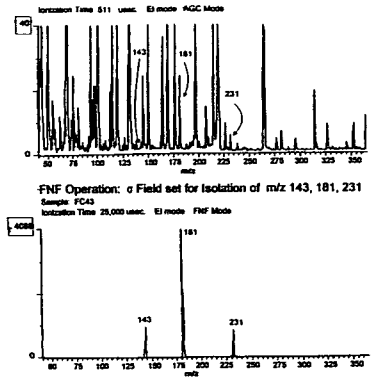

Figure 3. These data demonstrate the ability to isolate m/z's of interest and the resulting sensitivity gain by using an FNF with the quadrupole ion trap. Once isolated, the masses of interest can then be used for SIM or MS/MS.

Time Dependent Behavior of Multiply Charged Electrosprayed Ions Trapped in a Fourier Transform Ion Cyclotron Resonance Mass Spectrometer

James E. Bruce, Steven A. Hofstadler, Gordon A. Anderson, Steven L. Van Orden, and Richard D. Smith Chemical Sciences Department, Pacific Northwest Laboratory, Richland, WA 99352

The technique of electrospray ionization (ESI) has proven to be effective for the production of multiply charged gas phase ions and, as such, has been coupled to many types of mass spectrometers. Recent developments in this laboratory have led to the successful integration of an ESI source with a Fourier transform ion cyclotron resonance (FTICR) mass spectrometer and electrospray mass spectra of many proteins and glycoproteins have been acquired[1]. Time domain signals lasting longer than 80 seconds have been recorded for bovine insulin and ubiquitin. Although the theoretical resolution for these transients is ~3 million, a maximum resolution of only 700,000 was produced by Fourier transformation of the last 40 seconds of the insulin transient. Resolution produced by transformation of the entire data set was much poorer (~100,000, as shown in Figure 1) due to shifts in cyclotron frequencies observed during the evolution of the ion packets after excitation. The broadening as well as splitting of the isotope peaks, as illustrated in the inset of Figure 1, was found to be a result of cyclotron frequencies shifting toward higher frequency. The split appearance of the peaks is an artifact of the Fourier transformation of a time-dependent frequency. Fourier transformation of small segments of data at various times along these transients, shown for the 4+ charge state of bovine insulin in Figure 2, demonstrates very clearly how the detected *m/z*, and thus cyclotron frequency, varies over the course of the detection period.

The present work[2] illustrates successful attempts to correct the frequency shift present in the data and thus realize the ultrahigh resolution potential of long transients. Two different approaches for the correction of observed frequency shifts, both of which involve measuring and fitting the variation in detected *m/z* were employed, as shown in Figure 2. The first technique involved a frequency modulated-discrete Fourier transform (FM-DFT), where each test frequency of the DFT is modulated at the same rate as the measured frequency shift. The second and more highly optimized approach involved time-base correction of the raw data prior to fast Fourier transformation. This technique is effectively a post acquisition modification of the sampling frequency at a rate inversely equal to the fit obtained as described above. Magnitude mode Fourier transformation of the time-base corrected, apodized data produced a significant increase in resolution, 2.5 x 10^6 for the 4+ charge state of bovine insulin, as shown in Figure 3. Results obtained without apodization were of slightly lower resolution and produced slightly worse peak tailing toward lower *m/z*. A poor fit to the frequency shift at early times in the transient has been determined to be the cause of this tailing (apodization reduces the contribution of frequencies at these times) and consequently, a better fit is being developed. The present results demonstrate that correction for frequency shifts can provide higher resolution and, perhaps more importantly, higher mass measurement precision.

A Method of Increasing The Sensitivity for Laser Desorption in an Ion Trap Mass Spectrometer

Gregory C. Eiden, Mary E. Cisper, Michael L. Alexander, Philip H. Hemberger, and Nicholas S. Nogar
Chemical and Laser Sciences Division, Los Alamos National Laboratory.

In this work we describe laser desorption, carefully timed with respect to the finite risetime (~175 μsec) of the RF potential in the Finnigan ITMS apparatus.[1] Trimethylphenylammonium (TMA) iodide is ablated by a 308 nm pulse, phase loced to the RF. The probe tip is flush with the inner surface of the ring electrode. Laser desorbed ions, produced when the RF potential is low, can penetrate the trap, but are unable to escape because by the time they have reached the center of the trap, the increase in the RF potential produces a deeper trapping well (Fig. 4). The most intense peaks in the mass spectrum of TMA occur at m/z 58, 121, 136 (parent), 197, 273, 349, 423, 499, and 575; these peaks correspond to methyl loss from TMA (121) and sequential addition of a 76 Da moiety to the 121 mass (197, 273, etc). Compared to the m/z 121 intensity, we observe approximately twice as many ions above m/z 121; that is, most of the observed ions are from ion-molecule reactions occurring in the desorbed plume. Fig. 1 shows the 121^+ signal detected at different values of V_{max}, the steady state RF potential, as a function of laser-to-RF delay. The signal increases by several orders of magnitude at short delays. The maximum signal depends on ion mass, laser-to-RF phase and V_{max}. The maxima shown in Fig. 1 do not coincide when the data are plotted against pseudopotential well depth. However, the pseudopotential well model only applies near the center of the trap and at constant RF potential. Fig. 2 shows the time delay at which the maximum signal occurs (i.e., the maxima of the curves in Fig. 1) as a function of V_{max} and for three different ions. The maximum trapping efficiency occurs at longer delays for heavier ions. This also corresponds to higher RF potentials, since the RF potential is closer to reaching V_{max} at long delay times. We have also measured the signal versus laser-to-RF delay for 20-50 nsec time increments, thereby mapping out the laser-to-RF phase dependence of the signal. Fig. 3 shows the phase dependence for m/z 197 at 40-95 μsec delays, which covers the full range of the 760 V curve in Fig. 1. Zero phase angle corresponds to firing the laser at the positive slope zero crossing of the RF potential. The signal maxima occur at a phase of ~270°, suggesting that deceleration near the ring electrode by the rising RF potential can aid in trapping. The data show that the phase at which the maximum signal occurs shifts to lower values for longer laser-to-RF delays. We have also observed a mass dependence of the phase shift at short delays. For a laser-to-RF delay of 40 μsec and V_{max} = 508 V, the maxima in the 121 and 273 signals occur at 280° and 340° phase respectively. At delays of 75 μsec or longer, the 121^+ and 273^+ signals are in phase. In the future, we will present a quantitative model of these results and new data on the ablation of other atoms and molecules and the effects of different ring DC and RF waveforms and endcap AC voltages on the trapping efficiency.

The Reduction of Matrix Effects in Quadrupole Ion Trap Mass Spectrometry

*M.E. Bier, J.N. Louris, D.M. Taylor, J.C. Schwartz, and M.D. Uhrich
Finnigan MAT, San Jose, CA 94025

Matrix effects in ion trap mass spectrometers are the result of a high abundance of non-analyte ions and/or neutral reactive molecules. Matrix ions may be filtered from the ion trap by the application of tailored waveforms, but these waveforms do not directly affect the abundance of neutrals. Neutrals may react with analyte ions and result in "impure" spectra. Ion/molecule reactions occur in the ion trap even at low pressures of neutrals because of the 10 to 1000 ms of ion storage time. Ion/molecule reactions such as self-CI can be reduced by orders of magnitude by placing the ion source external to the trap[1].

Three ion trap configurations were used in this study: a Finnigan ITS40, an external source ion trap system, and an external source ion trap system with a baffle for improved differential pumping. The external ionization systems included: a TSQ-70 ion source, a scan editor, 670 L/sec turbo pumping (split for the differential pumping configuration), and a 10 kv conversion dynode. A GC was interfaced to all instruments.

Figure 1 shows that for 1 μg of hexobarbital (MW 236) no $(M+H)^+$ is observed in an external ionizing ion trap. A 1μg methyl stearate (MW 298) mass spectrum shows m/z 299 $(M+H)^+$ as the base peak using internal ionization. The ratio of $299^+/298^+$ for methyl stearate is dramatically improved using external ionization as shown in Figure 2. An additional reaction time of 500 ms, however, allows time for methyl stearate to form the "self-CI" m/z 299 and adducts as shown in Figure 3. The mass spectrum of 1 μg methyl stearate obtained after replacing the baffle and waiting for the 500 ms shows little evidence of self-CI and very little adduct formation. This adduct formation was further explored by removing low mass EI fragment ions by using a low mass rf cut-off. The data suggest that many fragment ions form adducts with the neutral analyte species. A methyl stearate sample impurity (MW 270) was identified by GCMS and is believed to also contribute to this adduct formation. Ion m/z 227 from methyl stearate was isolated and allowed to react with neutral analytes during a 500 ms reaction period (see Figure 4). The adduct ions formed are from the attachment of MW 270 (impurity) and 298 to the isolated ion m/z 227. Some of the other ions observed are believed to be formed during the isolation period. By increasing the rf low mass cut-off a reduction in the $299^+/298^+$ ratio is observed for methyl stearate (Figure 5). This ratio reduction suggests that m/z 299 may be formed from proton transfer from many EI fragment ions.

Hart and coworkers[2] used 1,4-dichlorobenzene and an ITMS (internal ionization) to study the daughter ion m/z 111 reaction with methane to form m/z 91. In our work, external methane CI followed by MS/MS showed extensive daughter ion/molecule production of m/z 91 in the non-baffled ion trap system. A baffle placed between the source and ion trap reduced the pressure of methane and thus improved the $91^+/111^+$ ratio significantly (see Figure 6).

Protein Structural Elucidation by Electrospray Ionization Tandem Fourier-Transform Mass Spectrometry

Deborah S. Gross, Paul D. Mills, Lydia T. Tien, Paul J. Johnson, Evan R. Williams
Department of Chemistry, University of California, Berkeley, CA 94720

Electrospray ionization has become a powerful method for obtaining high accuracy molecular weights of large peptides and proteins. The combination of ESI with Fourier-transform mass spectrometry has many exciting possibilities for extracting even more information from biomolecules through high resolution and MS^n measurements including the ability to identify mutations in proteins, and sequence proteins of unknown structure, even those present in mixtures, using multiple stages of MS. In cases where sample quantity is limited, such as detecting biomolecules separated by capillary electrophoresis, high sensitivity is of key importance.

For this, we are developing einzel lens ion introduction system based on the pioneering work of Smalley (1), for guiding electrospray-generated ions into the FTMS cell (Figure 1). Ions are formed using a two-stage differentially-pumped electrospray source with a heated metal capillary introduction system (2). Ions are trapped in an elongated 5x5x10 cm cell and detected at a cell pressures of ~2 x 10^{-8} and magnetic field strength of 2.7 T.

Spectra of equine myoglobin (MW 16,951 Da) and bovine cytochrome C (MW 12,231 Da) obtained with this system are shown in Figure 2. We find the charge distributions for a variety of peptides and proteins are consistently at a higher *m/z* ratio (lower charge state) than expected. For example, our charge distribution for myoglobin peaks at the +14 charge-state vs +18 measured previously by ESI/FTMS (3). This appears to be a function of our source design rather than our ion introduction/detection system and is currently under investigation.

Ion introduction efficiency is estimated by comparing electrospray current measured on the conductance limit in the first high vacuum stage to the current measured on the back trapping plate. In preliminary experiments with cytochrome C, we measure 7 pA on our rear trapping plate corresponding to a transfer efficiency of ~18%. Acceleration voltages as low as 200 V result in a negligible decrease in ion transfer efficiency, but efficiency rapidly decreases to zero below this voltage.

Ions are trapped using static trapping voltages (4); three volts was found to provide the highest signal for both gramicidin S (MW 1140.7 Da) and myoglobin (MW 16,951 Da), despite the nearly 15-fold difference in mass. This is inconsistent with a supersonic expansion taking place in our electrospray source, as ion energy would be expected to increase nearly linearly with mass resulting in more efficient trapping at higher voltages. For cytochrome C, a S/N of 13 is obtained with 10 s ion introduction corresponding to 9 picomoles of sample introduced. Our trapping efficiency is estimated to be approximately 0.001% for these ions, and remains a key area for future improvement.

With our current cell pressure, a resolution of 14,000 has been obtained for the resolved isotopes of the +3 charge-state of melittin (MW 2845 Da). From the separation between isotopes, the charge-state of an ion can be directly determined, an important advantage for interpreting MS^n spectra of large proteins.

ION TRAP MASS SPECTROMETRY COMBINED WITH INDUCTIVELY COUPLED PLASMA/MASS SPECTROMETRY (IT-ICP/MS)

*Charles J. Barinaga and David W. Koppenaal, Materials and Chemical Sciences Center, Pacific Northwest Laboratory,** PO Box 999, Richland WA 99352

We have been intrigued by the possible gains that might be obtained by combining the robust, intense ion source of an inductively coupled argon plasma (ICP) with the unique features of a three dimensional quadrupole mass spectrometer (ion trap or ITMS), claimed by many to be the most sensitive of mass spectrometers. The effectiveness of an ICP to yield ions at high efficiency using various sample introduction schemes is demonstrated by the exploding use of ICP/MS in elemental analysis (1). The current combination of an ICP with a linear quadrupole mass filter, although very effective, has certain limitations that might be circumvented. The ICP and the vacuum interface yield significant ion currents (possibly hundreds of nanoamps) of argon, argon polyatomics (e.g. Ar_2^+, ArO^+, $ArCl^+$, ArN^+, ArH^+, $ArOH^+$) and other matrix related polyatomics (e.g. ClO^+). The limited mass resolution capability of linear quadrupoles precludes the possibility of separating nominally isobaric ions, both analyte-interferant and analyte-analyte. Sensitivity, although impressive, is limited by instantaneous signal-to-noise levels. The ITMS could help in these areas by providing collisionally induced dissociation (CID) capabilities to reduce the polyatomic ion interferences, by offering greater mass resolution using slow scan techniques, and by improving detection and abundance sensitivity using prolonged trapping times and selected ion ejection techniques.

We were encouraged by the reports of successful external ion injection (2) and atmospheric pressure sampling with ion traps (3). To avoid anticipated complications, including space charge effects and unwanted ion/atom or ion/molecule reactions from the high intensity matrix ions during ion injection, we decided to employ a notch-filtering linear quadrupole (4) preceding the ion trap (5) in order to selectively filter out the unwanted ions (e.g. Ar^+ and others).

A prototype instrument combining an ICP, a notch-filter linear quadrupole, and an ITMS has recently been fabricated, as illustrated in Fig. 1. The IT-ICP/MS utilizes major and modified components from a Fisons/VG PlasmaQuad I and a Finnigan MAT ITMS. Analyte ions from an ICP and prefilter quadrupole can be injected into an ion trap and trapped with a helium pressure of about a millitorr. No estimate has yet been made of transmission and trapping efficiencies, however the current detection limit for lead is better than one part-per-billion. At this time no extensive efforts at sensitivity optimization have been made thus some improvement is expected. Many metals yield good responses as unadducted ions (see Fig. 2), however certain metals (U, Th, La, other strong MO formers) react with background water and oxygen to produce significant levels of metal oxides and hydroxides (Fig. 3). Different pumping arrangements and direct heating of the trap itself will likely decrease this effect. Water from the nebulized aqueous samples appears to not contribute as a dry plasma of laser ablated LaO yielded the same oxides and hydroxides as the aqueous sample. Surprisingly the matrix-related polyatomic interferants do not survive the multiple collision environment in the IT region and are completely eliminated from the spectrum without resorting to MS/MS or high mass resolution techniques. In addition the trapped argon ions undergo relatively fast charge exchange reactions and disappear from the spectrum after approximately 10 ms of unexcited

reaction time thus allowing the observation of ^{40}Ca (6), the most prominently interfered m/z in ICP/MS. The use of rf-only or rf/dc notch-filter modes with the linear quadrupole has also been demonstrated in precluding argon ions from entering the ion trap.

These initial results are encouraging. Additional experiments using improved mass resolution techniques, enhanced abundance sensitivity approaches, and broadband noise filtering methods are planned. Development of an optimized atomic ion trap mass spectrometry system is also underway.

Effects of Ion Trap Parameters on Mass Axis Stability: Influence of Manifold Temperature, Pressure and Axial Modulation Voltage on Mass Spectra of Hydrocarbons

Robert D. Brittain, David Speltz and Barbara Bolton, Varian Chromatography Systems

Although most molecules analyzed by ion trap GC/MS provide library-searchable mass spectra under a wide range of conditions, some compounds have been reported with low molecular ion abundance and/or non classical mass spectral ion intensities. Lower molecular and fragment ion intensities may be attributed to unimolecular and bimolecular decomposition processes that can occur during the storage process. We have studied several classes of molecules vulnerable to decomposition on the time scale of ion storage. We used a constant analyte flow to rapidly characterize the dependence of ion stability upon instrument tuning parameters. Using this approach, it is possible to recommend ranges of column flow rate, Axial Modulation (A/M) voltage and ion trap manifold temperature which minimize molecular ion decomposition.

A constant flow of analyte was introduced from a heated glass vial connected via the CI port of a Varian Saturn II GC/MS system The mass spectrometer was auto-tuned and spectra in either peak profile or centroid mode were observed in the instrument page as instrument parameters were varied. Helium flow through a DB-5 30M x 0.25 mm ID column was calculated from air sample retention time

Figure 1 shows the menthol ion at 138u with He flow rates from 0.5 to 1.4 ml/min. The peak profile asymmetrically broadens (doubling the FWHM) and appears to shift to lower m/z with increasing helium flow A/M reduction from 4.0V to 3.0V is shown to improve resolution for a given flow rate. Reduction of manifold temperature from 220°C to 100°C also improved resolution of this ion in a similar manner Results for other compounds are shown in the poster presentation The peak broadening phenomenon is consistent with a premature decomposition of unstable ions (subject to collisional dissociation) as they approach resonant ejection from the ion trap into the multiplier. The process would be:

$$(A^+)^* + He \text{ -------> } B^+ + C$$

where $(A^+)^*$ is the unstable molecular or fragment ion and B^+ is a lower-mass fragment that will be ejected from the ion trap and detected by the multiplier as soon as it is formed. High A/M voltage, flow rate, and manifold temperature increase the number and/or energy of bimolecular collisions One possible effect of the asymmetrical peak broadening in Figure 1 is mis-assignment of the molecular ion M to a value of M-1. He flow rate ≤ 1 ml/min, ion trap manifold temperature ≤ 120°C, and A/M ≤ 3V all reduce decomposition of unstable ions. Shown in Figure 2 is the mass spectrum of heptadecane run at optimum trap conditions. Note the excellent levels of molecular ion in the ion trap spectra compared to the NIST library entry. For some hydrocarbons, the molecular ion is an order of magnitude higher in the ion trap spectrum than the NIST library entry.

OPTIMIZING ION ACCUMULATION IN EXTERNAL SOURCE FOURIER TRANSFORM MASS SPECTROMETRY

C. F. Ijames and S. P. Markey, Section on Analytical Biochemistry, National Institute of Mental Health, Bethesda, MD 20892.

A differentially pumped external source permits Fourier transform mass spectrometry to incorporate conventional high pressure sources, while maintaining the low cell pressure necessary for optimum performance. Ions are transported through one or more pressure-limiting orifices, through the fringe field of a superconducting solenoid magnet, and delivered to the FTMS cell. Transport can be achieved via radio frequency quadrupoles or electrostatic lenses. The greatest difficulty lies in trapping the injected ions for analysis. Gated trapping (manipulating the trap potentials to admit brief pulses of ions) suffers from a very low duty cycle, 0.5% to 0.01%.

To increase FTMS detection sensitivity, a method of continuously accumulating ions in the cell for an extended period of time, raising the duty cycle to greater than 50 %, is needed. Because the trapped ion cell is a symmetric box, no static arrangement of potentials should result in accumulation of ions injected on the z axis. However, there have been reports of ion accumulation with static trap potentials. To explain this the following mechanism is proposed. Ions whose kinetic energy is slightly less than the trap potential will be able to enter the cell because of the potential depression in the center of the entrance hole in the trap plate. If the entrance is not on the z axis or a potential is applied between the transmitter or receiver plates to move the electrical axis of symmetry off of the z axis, the ions will have a non-zero magnetron radius, and thus will undergo magnetron motion around the electrical axis of symmetry. After reflection at the rear trap plate, the returning ions will no longer approach the potential depression at the entrance hole, but will instead approach a solid region and encounter the full trap potential. The ions will again be reflected and thus trapped. Only if the combined trapping and magnetron oscillations return the ions to the entrance hole will they be able to exit. Any collisions will most likely redirect some energy into the x-y plane and reduce the trapping oscillation amplitude, further closing the trap. Ions whose kinetic energies fall between the trap potential and the minimum potential in the cell opening will be trapped. Deflection plates can be added to the cell opening to move ions off of the z axis (by ExB motion) as they enter the cell, allowing the electrical axis to remain on the z axis for best detection efficiency and maximum ion capacity. Deflection plates also define the potential of the cell opening independently of the trap potential to permit accumulation of ions with a wide range of kinetic energies. The ion cloud will be in the form of an annular cylinder centered on the z axis.

The ratio of the trap oscillation period to the magnetron period in a cubic trap is: $(A\ V_t\ m\ /\ q\ d^2\ B^2)^{0.5}$, where A is a geometry factor (1.3869 for cubic cells), V_t is the trap potential, m is the mass of the ion, q is the charge on the ion, d is the trap plate separation, and B is the magnetic field strength. Under typical trapping conditions an ion with m/z 39 will traverse 1.3 % of a magnetron orbit before returning to the entrance, while an ion with m/z 2000 will traverse 9.2 %. This was experimentally confirmed by determining that the optimum deflection voltage decreases as the mass-to-charge ratio increases. Also, the detected signal intensity was found to increase with increasing pressure, to a maximum at 5×10^{-7} torr where the intensity was 70 times greater than that recorded at 1×10^{-8} torr.

Because the signal increases with accumulation time while the noise remains constant, the maximum signal-to-noise in a given time period will be achieved by accumulating for the entire period, followed by a single excite/detect sequence. For currents of 15 pA and greater, the space charge limit of the cell is reached within approximately 90 seconds. For lower currents, however, longer accumulation periods yield approximately constant signal intensity, so that very weak ion currents can not be completely compensated for by increasing the accumulation time. In this case averaging of 90 to 120 second accumulations is best.

Experiments were performed on a 3 tesla FTMS-2000 (EXTREL FTMS, Madison, WI) with a differentially pumped external source, equipped with electron impact, thermal ionization, and single stage electrospray ionization sources. A computer-controlled gate valve separates the external source chamber and the first trapped ion cell. There are deflection electrodes at the entrance to the cell. To maximize mass resolution without sacrificing sensitivity, the capillary in the ESI interface was chosen to yield a first cell pressure of $2\text{-}2.5 \times 10^{-7}$ torr. Spectra of proteins can be acquired by averaging 2 to 4 accumulations of 90 seconds each, while electrospraying 10 to 100 μM solutions in water/methanol/acetic acid at flow rates of 2 to 8 μL/min.

Results include spectra of Gramicidin S (30 μM, 4 scans, signal-to-noise ratio 50 for the $[M+Na]^+$ ion with m/z 1163) and Cytochrome C (100 μM, 4 scans, signal-to-noise ratio 30 for the $[M+8H]^{+8}$ ion with m/z 1542). The mass resolution can be improved by closing the gate valve after the accumulation period. A 45 second accumulation followed by a 15 second delay to reach the system base pressure, 0.5×10^{-8} torr, allowed the $[M+Na]^+$ ion of Gramicidin S to be detected with a resolution of 90,000. The spectrum of bovine insulin, molecular weight 5733, was recorded at a resolution of 8,500 for the $[M+3H]^{+3}$ ions with m/z 1911, and 14,000 for the $[M+4H]^{+4}$ ions with m/z 1435. Four scans were averaged, with an accumulation time of 45 seconds per scan. The concentration was 100 μM and the flow rate was 3 μL/min.

ELECTROSPRAY ON AN ION TRAP MASS SPECTROMETER: COMPARISON OF AXIAL VS. DIAGONAL INJECTION OF IONS INTO THE TRAP

Robert D. Voyksner and Hung-Yu Lin, Analytical and Chemical Sciences, Research Triangle Institute, P. O. Box 12194, Research Triangle Park, NC 27709

INTRODUCTION

The majority of work using external soft ionization sources involves the axial injection of ions into the ion trap mass spectrometer (ITMS). Axial injection has limited trapping efficiency resulting in a loss of up to an order of magnitude of ion current. An alternative method that may prove more efficient involves injecting the ions diagonally (on the ion trap asymptote) into the trap. This method should minimize the losses from ions with improper energies to cross field lines to enter the trap and provide a longer distance for collisional dampening ions injected into the trap. This paper reports on the optimization of axial and diagonal ion injection for electrospray-ITMS. The parameters that were evaluated for each mode of ion injection include helium gas pressure, q_z value during ion injection, desolvation times and ion energy.

EXPERIMENTAL

Sample: Arginine (mw 174) and gramicidin S (mw 1141) 100 ng/µL introduced at 2 µL/min in 50% ACN in water, 1% acetic acid.

Electrospray: Analytica of Branford Electrospray interface modified with a tubular lens to fit into the end cap and serve as a gate.

ITMS: Finnigan MAT ITMS modified for electrospray interface as described in Anal. Chem., 65, 451-456, 1993, for axial ion injection. The ion trap was modified to rest on a diagonal with the multiplier mounted on the trap assembly for diagonal ion injection.

The following parameters were optimized in the ranges given in the evaluation: end cap aperture 1-6 mm, ionization time 0-200 ms, helium pressure 2-9 x 10^{-4} torr, q_z 0.02 - 0.6, ion energy (skimmer 1), 10-50 V, desolvation time 0-200 ms.

RESULTS AND DISCUSSION

The diameter of the ion entrance aperture in the end cap was varied from 1-6 mm. It was determined that a 3-4 mm end cap opening was optimal for ion injection. Diagonal injection was less dependent on the opening diameter, showing a broad optimum. Larger end cap openings resulted in a decrease in signal levels possibly due to inhomogeneities in the trapping field, which are less important with diagonal injection due to the location of the opening in the edge of the end cap.

Ion injection time into the trap indicated that both axial and diagonal modes had a similar optimal time (50-70 ms) for loading the trap with ions. The diagonal mode appeared to fill the trap faster, possibly indicating better trapping or ion injection efficiency. Longer ionization times appeared to decrease signal levels due to space charging, as well as, decreased mass resolution.

The ion energy (set by skimmer 1, on the electrospray interface) for injecting ions into the trap showed similar patterns between axial and diagonal injection. However, the optimization curve for ion energy was mass dependent. Arginine

showed a broad optimum while gramicidin S exhibited a narrow optimum between 20-30 V. These patterns were most likely due to ion transmission and collisional dampening of the different mass ions.

Helium pressure played a major role in optimizing signal level and the qualitative appearance of the spectra. In general, higher helium pressures were optimal for trapping ions. However, there is a mass dependence in which lower molecular weight ions are trapped at lower pressures while higher molecular weight compounds (gramicidin S) are efficiently trapped at the highest operating pressures. This trend can be explained in terms of the inability of helium to collisionally dampen high mass ions relative to low mass ions. The qualitative appearance of the mass spectra for arginine and gramicidin S could be drastically different, depending on the helium trapping pressure. To enhance trapping of high mass ions, pulsing helium into the trap during ion injection was investigated. In this way, high helium pressure could dampen the ions, then a one second pump out time reduced the pressure before mass analysis was initiated. The pump out time reduced the pressure by a factor of 3-4, minimizing multiplier noise and mass spectral peak broadening.

The q_z for ion injection was nearly identical for axial and diagonal injection. The q_z value was mass dependent for both modes of ion injection with arginine optimizing near a q_z value of 0.15 and gramicidin S near a q_z value of 0.05.

Desolvation time was very important for diagonal ion injection. Diagonal ion injection required a long desolvation time to generate the optimal signal intensity. On the other hand, axial ion injection exhibited about the same signal levels over the desolvation times evaluated. It appears the diagonal ion injection favors trapping lower energy solvated ions (compared to axial mode), therefore requiring some collisional warming to desolvate these ions to generate $[M+H]^+$ ions. It appears that ions trapped in the ITMS that are injected diagonally are less energetic and/or do not undergo collisional activation in the trapping fields. Also, the absolute intensities for parent ions for the test compounds (arginine and gramicidin S) were slightly greater for diagonal ion injection compared to axial injection.

CONCLUSIONS

The optimal ionization time, helium pressure, q_z and ion energy for axial and diagonal injection of ions into the trap were similar. Furthermore, the helium pressure, q_z and ion energy exhibited more dependence on m/z values of the ions that are trapped than the mode of ion injection. The desolvation time was the major difference between the two modes of ion injection. Longer desolvation times were necessary for diagonal injection to minimize cluster formation. Diagonal injection appeared to trap lower energy ions, showing less fragmentation and slightly better sensitivity compared to axial ion injection.

Off-Center ICR Cubic Ion Trap: Reduction of Space Charge and Manipulations of Coherent Magnetron Motion

Ruidan Chen, Shenheng Guan, and Alan G. Marshall†
Dept. of Chemistry (and Biochemistry†), The Ohio State University,
120 W. 18th Avenue, Columbus, OH 43210.

Here we describe two kinds of experiments based on an ICR cubic ion trap in which benzene molecular $C_6H_6^+$ ions are formed along an axis parallel to the magnetic field, but displaced by a distance (magnetron radius) from the trap symmetry axis (see Fig. 1). First, if the ionization event is long compared to the magnetron period, $(1/\nu_m)$, ions spread out along the surface of a cylinder at the magnetron radius. Space charge (and its resultant shift in the effective cyclotron frequency, ν_+) is greatly reduced (see Fig. 2), and signals at $\nu_+ - \nu_m$, ν_c, and $\nu_+ + \nu_m$ appear due to the strong coupling of ion magnetron motion with ion cyclotron motion (see Fig. 3). Of these, the signal at ν_c yields ion mass-to-charge ratio directly (unaffected by trapping potential): $m = (qB/2\pi\nu_c)$, for simple mass calibration. Moreover, by asymmetric detection, we can in addition detect a signal at twice the trapping frequency.

Alternatively, if the ionization event is short compared to the magnetron period, then magnetron motion is coherent. Conversion of coherent magnetron motion to coherent cyclotron motion [1, 2], may be visualized by either dipolar detection (at ν_+) or quadrupolar detection (at ν_c and $2\nu_+$) as a function of the product of excitation amplitude and duration (see Figs. 4&5). Fig. 4 shows the detected signal after different excitation periods. In Fig. 5, the solid lines are theoretical curves and the circles are experimental data. Coherence of cyclotron motion may be observed directly by measurement of the signals induced by two sequentially produced ion packets. Different peak height oscillation patterns are observed for dipolar detection (Fig. 6a) and quadrupolar detection (Fig. 6b). Work was supported by NSF (CHE-9021058) and Ohio State University.

Non-Resonance Excitation and Ejection in Ion Trap

Mingda Wang and Greg Wells

Varian Chromatography System, 2700 Mitchell Dr., Walnut Creek, CA 94598

Tandem mass spectrometry (or MS/MS) has widely been used to identify chemicals and to study ion-neutral reactions in quadrupole ion traps. The single frequency resonance excitation used in current ion trap tandem mass spectrometers requires a manual tune operation for each individual ion studied, because the requirement of the applied excitation frequency matching the secular frequency of the ion motion. Thus, it is difficult to achieve the practical GC/MS/MS operation with a single frequency resonance activation. Based on resonance excitation, several methods[1-6], have been proposed to tackle the problem of secular frequency mis-matching.

We present here a new and novel universal ion excitation and ejection method in an ion trap. The new method is **independent of the ion mass and the number of ions** because it does not require the matching of the supplemental wave frequency (typically, 100-500Hz) with the secular frequency (usually more than 10KHz) of the ions of interest for CID. In the new method, ion energy deposition is achieved by the combination of z direction dipole and rf trapping fields. When the dipole field turns on, the ion oscillation center is moved to a new position[7] instantly with no change of ion space location. Therefore, ions acquire kinetic energy from the perturbation of the trapping field and oscillate around the new center. When ions have lost their energy by collision, they may be re-excited by simply turning off or reversing the dipole field. The process may be repeated for a number of times if needed.

Another disadvantage of resonance excitation process is low energy deposition resulting in ions that preferably decompose through a low energy channel. Our non-resonance excitation provides an effective means of higher energy deposition without compromising yield of product ions. N-butylbenzene has been used as a thermometer to evaluate the amount of internal energy in a variety of activation process. Figure 2 shows that the **91/92 ratio** of product ions can be **more than 100** with our new ion activation method without compromising dissociation efficiency. The highest 91/92 ratio reported by Cooks group[8] is 20 with dissociation efficiency of 5% . Simulations show that ions can easily absorb **a few ev to 40 ev** energy by adjusting the amplitude of the applied dipole field. Figure 1 shows the GC-MS/MS chromatogram of **100pg** N-butylbenzene using the non-resonance excitation method. The signal to noise ratio (**S/N**) in the chromatogram is **3624**.

The method, providing a means to eject ions with mass above a specified mass value, may be applied as a low mass pass filter technique, and be used in the CI mode to eject unwanted sample EI fragments.

A SIMPLE MODEL FOR THE ORIGIN OF THE $2\omega_z$ RESONANCE IN FT-ICR

Dale W. Mitchell, Bryan A. Hearn and Stephen E. DeLong
Department of Geological Sciences
University at Albany, Albany, NY 12222

It is well known that for certain ICR cell geometries that there is a major mode of motion at ω_z. ICR excitation on the x-plates at $2\omega_z$ or at $\omega_+ \pm 2\omega_z$ (rather than at ω_z) are the primary frequencies at which this mode is excited. Leading excitation z-force inhomogeneities in a cubic FT-ICR cell[1] is given by[2]

$$f_z \propto xz\cos(\phi_e), \qquad \phi_e = \omega_e t + \beta_e$$

Assuming that x(t) and z(t) remain basically unperturbed from the quadrupolar motion and letting

$$x = r_+\cos(\phi_+) + r_-\cos(\phi_-) \quad \text{and} \quad z = r_z\cos(\phi_z), \quad \text{where } \phi_\pm = \omega_\pm t + \beta_\pm \text{ and } \phi_z = \omega_z t + \beta_z$$

$$\text{Then } f_z(t) \sim r_+r_z[\cos(\phi_+ + \phi_z - \phi_e) + \cos(\phi_+ - \phi_z - \phi_e)] + r_-r_z[\cos(\phi_z - \phi_- - \phi_e) + \cos(\phi_z - \phi_- - \phi_e)]$$

It turns out that the only values of ω_e which give $f_z(t) \propto \cos(\omega_z t)$ are when $\omega_e = 2\omega_z \pm \omega_-$ and when $\omega_e = \omega_+ \pm 2\omega_z$. Therefore, the present model, shown below, carries over to the $\omega_+ \pm 2\omega_z$ resonance as well

The figure shown on the next page illustrates the simple visual model which shows that excitation at $2\omega_z$ on the x-plates gives a force in the z-direction with a strong frequency component at ω_z rather than $2\omega_z$. The force on the ion will drive the ion as a simple harmonic oscillator at ω_z. The behavior at $\omega_+ \pm 2\omega_z$ is more difficult to explain graphically, but the equations given above show that these resonances excite the z-motion in a similar manner.

Also, from the simple visual model, we can see that with a zero magnetron radius, there is no net z-excitation over a cyclotron period. This is due to the z-forces cancelling each other in alternate sectors of the ICR cell: during one half of a cyclotron period, the ions will experience a force in one direction, and the opposite force during the next half-period.

A Basic Theoretical Approach for the Description of Non-linear Ion Trap

Y. Wang[a),b)] and K.-P. Wanczek[b)],

a) Bruker-Franzen Analytik GmbH, 2800 Bremen 33, Germany

b) Inorganic Chemistry, University, 2800 Bremen 33, Germany

In practice, it is not really possible to generate an ion trap with a pure quadrupole field inside. However, a non-linear ion trap can achiev better performance. Non-linear ion trap can be generated with (1) stretched end-cap distance, (2) modified hyperbolic angle and (3) the superposition of one or two kinds of requried higher multipole fields directely. The potential distrbution in those non-linear ion traps are theoretically expressed with two methods. Method I [1][2]: the variation calculus method described by Ritz. This method transforms the solution of Poisson or Laplace equation with the boundary into the problem of searching an extremum of the variation about the functional. A reasonable approximation of the potential distribution is derived. Method II [1][3]: series expansion with spherical polynoms. With this method, the general potential distribution is expressed in a series of orthogonal functions. Each of them is a solution of Laplace equation. The unknown weight factors of the multipole components are determined by the given boundary. With the least square technique, the weight factors are derived by approximating the series of orthogonal functions to match the special boundary condition of the ion trap until the square deviation is a minimum. The method is applied to the ion trap with stretched end-cap distance and with the superposition of one or two kinds of higher multipoles directely.

A important effect caused by superposition of higher multipole fields is the non-linear resonance of ions. The ion motion can be treated with the Hamilton formalism [1][4]. The original hamiltonian function, at first, is transformed with linear canonical and periodical transformation. This first transformation eliminates the explicit time dependence for the quadrupole component. Its result is a harmonic oscillation with the trap's secular frequencies perturbed by the highter-order multipole components of the trapping potential. The second trasformation is a non-linear canonical and periodical one. Its perpose is to simple the non-linear contributions in the Hamiltion function. The complex variables are intruduced and further expanded with Taylor series. Their coefficients with time are expanded into Fourier series because of the periodicity. The series expanded equations can be solved from lower order to higher order. In final, the non-linear resonance conditions are derived when the expansion breaks down. The non-linear resonance

conditions for the rotationally symmetric ion traps are

$$n_r\beta_r + n_z\beta_z = 2\nu,$$

where n_r, n_z and ν are whole numbers. Due to the symmetry, some resonance lines vanishes. For example, n_r is even integer for all types of multipoles, n_z is even for even higher multipoles and odd for odd multipoles. If in the original Hamilton function (or in the higher multipole potential) terms of order $n \geq 3$ (for example, hexapoles or octapoles) are present, every one of these can in principle excite resonance lines of any order. However, a term of order n will have the strongest effect on the resonance conditions of order $N = n, n-2, n-4$ and smaller effects on the others.

The resonance intensity is defined as the mean rate of energy increase over the time average. The theoretical equation [1][4] expresses that any increase of the mean energy of a trapped ion is due to non-linear components in the trap. With this equation, the intensity of two important non-linear resonance lines for hexapole superposition are calculated and shown in the figures.

An New Type of Structures of Linear Quadrupole Mass Filters and Ion Traps with and without FT Techniques

Y. Wang[a),b)] and K.-P. Wanczek[b)],
a) Bruker-Franzen Analytik GmbH, 2800 Bremen 33, Germany
b) Inorganic Chemistry, University, 2800 Bremen 33, Germany

With conventional method and technique, two- and three-dimensional quadrupole fields were generated by an array of metallic electrodes with isopotential surfaces. The corresponding structures of the quadrupole mass filters consist of four metallic rods with hyperbolic or round cross-secction; and the ion traps consist of a ring electrod and two end-caps.

Indeed, the exact two- and three-dimensional quadrupole fields can be generated by closed boundaries with continuously varied potential [1][2], In principle, if the potential value at each point of a selected curved surface corresponds to the value of the defined quadrupole electric fields at this point, the quadrupole electric fields can be generated within the interior region of the closed boundary.

Especially, the potential value along the boundaries can be linearly varied. For example, Fig. 1 shows the structures of the exact three-dimensional quadrupole field with linearly variable potential. In the ideal case, there exists a simple rhombic closed-plane (curve (D), cone structure in three-dimensional space) with the gradient $\sqrt{8/3}$ V/cm. The quadrupole isopotential curves within the structure (D) are exact quadrupolar. By comparison to the three-dimensional case, there are similar rectangle or square structures for the two-dimensional case [3].

Interestingly, within the same structure (D), a homogeneous ideal field in the direction of the symmetry axis z can be generated and superimposed without interaction with the quadrupole field. The potential lines of electric field are exact homogeneous. In two-dimensional case, there are similar results [3], but the direction of the homogeneous field can be arbitrarily selected.

Fig. 2 shows an example of electrode structure for three-dimensional fields. The upper part of Fig. 3 shows an example of electrode structure for two-dimensional quadrupole fields. The ceramic plates are deposited with a layer of Cr-SiO thin film of the specific resistivity (lower part). The new three-dimensional structure can be employed not only as an ion trap, but also as a FT ion trap. This mass spectrum can be well compared to the spectrum obtained with a FT-ICR mass spectrometer. The FT ion trap is like an ICR spectrometer, but without magnat.

For two-dimensional structure, experiments with electron beam tubes show good agreement with the theory and the practicability of the proposed structures. FT ion trap employed to mass analysis are in progress.

Introduction

Glow discharge mass spectrometry (GDMS) has expanded in both scope and application throughout the last decade due to the demand for analytical methods for a wide range of sample types. The advent of radio frequency GDMS has expanded sampling capabilities to include not only conductive materials, but also matrices such as glasses and ceramics. A major limitation that still exists for plasma source mass spectrometry is the existence of pseudo-isobaric interferences. One method of effectively eliminating these interferences is to utilize the higher resolving powers afforded by Fourier transform ion cyclotron resonance mass spectrometers (FT-ICR or FTMS). We presented data at the 1992 ASMS meeting from a prototype lensless external ion source instrument which combines the sampling versatility of radio frequency glow discharges with the resolution advantage of Fourier transform mass spectrometry.[1] Ion trajectory simulations have been performed in order to better understand and improve the ion transfer mechanism in the lensless external ion source.

Experimental

Ion trajectory simulations were performed using SIMION Version 4.0. The modeling was broken into two segments due to the limitation on computational array size and the need to maintain scale over a long ion path length. The first modeling phase (Phase I) examines ion trajectories in the GD source, sample cone, and the differential pumping chamber regions. The second modeling phase (Phase II) includes the remainder of the ion flight path from the conductance limit of the differential pumping chamber to the center of ICR cell and is the region where the magnetic field becomes significant. The total distance traveled was ≈ 127.9 cm. Ions starting in Phase I were given a kinetic energy of 15 eV, a mass to charge ratio of 63 (Cu^+), and an angular deviation of 5° in the Y and Z directions. Ion positions in the X, Y, and Z plane, final kinetic energy, and exit angle relative to both the Y and Z axes were used as starting parameters for computing 10 trajectories in Phase II. Trajectory simulations were performed for a variety of conditions including variations in sample cone voltage, conductance limit voltage, ion launch position and angle, and ion kinetic energy.

Results and Discussions

The results of the Phase II modeling indicate that all the ions from Phase I that are transmitted through the conductance limit orifice biased between +5 and -4 volts will follow the magnetic field lines down to and through the analyzer trap plate opening. Hence, for these conditions, the limiting factor for overall ion transmission to the ICR analyzer cell is the throughput characteristics of the differential

pumping chamber conductance limit. A positive DC potential of 25 V or greater on the conductance limit repels ions. An applied potential of -4 V forces the ions to the center of the magnetic field, resulting in stronger magnetic focusing at the ICR cell.

In all cases studied, a maximum of four of the ten ions exiting Phase I were transmitted through the 4.0 mm diameter conductance limit. As a result of poor ion focusing between the sample cone and the conductance limit, it will be necessary to add a lens stack to the differential pumping region to increase transmission efficiency. It does not appear that an additional focusing scheme is required once the ions leave the conductance limit; however, a deceleration grid may be required to optimize ion trapping in the ICR cell.

These simulations demonstrate that ions from an energetically well defined source can be efficiently transferred from an external ion source to an ICR analyzer cell using only the focusing of the converging magnetic field lines. Hence, for an energetically well defined source, high trapping efficiencies can be expected with no external lensing. The results presented here corroborate the experimental data collected in preliminary experiments and presented at the 1992 ASMS meeting.

Selected Ion Storage Target Compound Analysis in Complex Matrices Using Ion Trap GC/MS

Barrie A. Shaffer, Joe Karnicky, and S. E. Buttrill, Jr.
E. L. Ginzton Research Center, Varian Associates
3075 Hansen Way, Palo Alto, CA 94304-1025

The high sensitivity of the ion trap results from its ability to accumulate ions for a relatively long time compared to the time required to scan them out into an ion multiplier detector. For fairly clean samples, detection limits can easily be only one or two picograms. However, when the compound of interest co elutes from the gas chromatograph with a large amount of sample matrix, then the fixed storage capacity of the ion trap is occupied by uninteresting matrix ions, and sensitivity for the target compound is reduced. Following a suggestion by J. Franzen [1], this situation can be greatly improved by selectivly storing in the ion trap only the ion masses charactistic of the target compound. The Selected Ion Storage (SIS) capability for the ion trap described last year [2] has been automated,[3] making it a practical technique for target compound analysis in complex matrices.

In setting up a target compound analysis using SIS, there are three factors to be considered: (1) the rf storage level at which ions are accumulated, (2) the mass range(s) to be stored, and (3) the quantitation mass or masses.

The rf storage level determines the lowest mass ion which will be stable in the trap. It also affects the relative efficiency with which ions of higher mass will be stored. Figure 1 shows the signal intensity for some ions in the FC-43 calibration compound spectrum as a function of their q value. $q = 4eV/mr^2\Omega^2$ and thus depends on both mass and rf voltage amplitude V. For most ions, an rf storage level of 300 dacs, corresponding to a low mass cut off of about m/z 48, results in a storage efficiency within a factor of two of optimum

In contrast to the selected ion monitoring experiment used on transmission mass spectrometers, the sensitivity of the ion trap decreases only slowly with the number of masses monitored. Therefore the selection of the mass range or ranges to be stored should be designed to include as many of the target compound's characteristic ions and isotopic clusters as possible while rejecting all of the strong matrix ions A total scan range of 100 to 150 daltons while storing 40 to 60 masses gives excellent results

The lower detection limits of the target compounds will almost always be determined by the chemical noise (from the matrix) at the same mass as the quantitation ion(s). The quantitation ion(s) should therefore be chosen by examining the mass chromatograms of the best candidates in a spiked matrix sample. The best signal to noise will be determined by which ions experience the least contribution from matrix ions at the same integer mass. Figure 2 shows the detection of 20 pg of Aldrin in a bell pepper extract. The signal-to-noise for the less intense ion at m/z 293 is better than that for the more intense ion at m/z 263.

Because of the importance of isotopic chlorine ion clusters in their mass spectra, library searchable spectra were obtained for aldrin, heptachlorepoxide, chlordane, and 4,4'-DDE spiked into bell pepper extract at the 20-40 pg level.

Optimization of a New API Ion Trap System for On-Line HPLC and CE Applications,

A.V. Mordehai and J.D. Henion, Drug Testing and Toxicology, NYS College of Veterinary Medicine, Cornell University, 925 Warren Dr., Ithaca, NY 14850

Recently we reported a novel design for implementing atmospheric pressure ionization (API) on an ion trap mass spectrometer [1]. Encouraging, low picogram detection limits have been demonstrated for ion spray-micro HPLC and CE applications [2,3]. However, in all applications it was found that chemical noise is the major limiting factor to improving sensitivity. The purpose of this report is to demonstrate system performance with two different API ionization techniques (ion spay [IS] and atmospheric pressure chemical ionization [APCI]) and higher flow rates as well as to address the chemical noise problem by implementation selected window ion monitoring (SWIM).

The previously-designed API ion trap-mass spectrometer was used in all experiments. The spectrometer was equipped with Saturn II data station (Varian, Palo Alto, CA). Thei on trap mass analyzing region was maintained at high helium pressure (5×10^{-3} Torr) to facilitate trapping externally produced ions. For accomplishing selected window ion monitoring (SWIM) a second computer (IBM 486) and arbitrary wave form generator (AWFG) board (Keithley, Taunton, MA) have been used. A fast electronic switch (constructed in house) allows us to connect either an axial modulation circuit from the Saturn electronics or AWFG to the ion trap end-caps. The AWFG board is connected to the end-caps during ionization-accumulation events while the axial modulation circuit is connected to the end-caps during the detection scan. To isolate ions of interest we use the resonance ejection technique with computer designed digital wave-functions (similar to the SWIFT technique in FT/ICR [4]). We have developed a simple mathematical procedure for creating broad-band wave functions with low dynamic range and a given frequency spectrum. Briefly, we use a modified quadratic phase encoding approach (step quadratic phase encoding) where the total frequency range is divided into ~20 equal segments and the quadratic phase encoding is applied separately on each of the segments. The resulting wave function is is produced by direct addition wave functions produced for each frequency segment. In contrast to the SWIFT technique no inverse Fourier transformation has been used; instead we use a direct sum of the harmonic waves separated in 1kHz frequency intervals. Finally, for use in our experiments we synthesize a wave function containing all frequencies in the range from 25 kHz to 500 kHz with a 1 kHz interval and one frequency notch. Frequencies ranging from 40 to 60 kHz have been omitted during the addition process so as to create a 20 kHz frequency notch.

Figure 1 illustrates extending API operation from IS to the APCI ionization. The HPLC analysis of five benzodiopine drugs (10 ng injected on column) performed using standard (Sciex, Thornhill, Ontario) heated pneumatic nebulizer at a low rate of 1 mL/min (40/25/35% CH_3CN/CH_3OH H_2O, using a Zorbax C-18, 4.6 x 150 mm) using no pre or post-column split. The sensitivity in the full-scan mode (no SWIM) is at least twice that previously reported using our Sciex TAGA 6000E updated to API 3 instrument [5].

Figure 2 demonstrates the SWIM technique with ion spray infusion analysis of a model synthetic mixture containing four quaternary ammonium compounds(TBAH, m/z=242; THAH, m/z=354; TOAH, m/z=466; TDAH, m/z=578 [1]) at 500 fmol/μL concentration of each compound dissolved in a common HPLC buffer (50/50% CH_3CN/H_2O; 15 mM ammonium formate). Figure 2a was acquired with full-scan ion trap operation. Figure 2b shows the isolation of two ionic species in the trap by application of a computer-

designed wave function applied to the end caps (SWIM mode). The window for mass selective accumulation is ~ 100 Da width and it can be easily moved across the mass range to accumulate ions of interest by adjusting the main RF storage level.

Particle beam HPLC-MS on ion trap, quadrupole and sector spectrometers for pharmaceutical analysis.

Colin S. Creaser and *James W. Stygall, Dept. of Chemistry and Physics, Nottingham Trent University, Clifton Lane, Nottingham NG11 8NS

A particle beam interface has been used to couple HPLC to quadrupole ion trap (ITMS), sector and triple quadrupole mass spectrometers. These systems have been evaluated by EI, CI and MS/MS analyses of a pharmaceutical sample separated by normal phase chromatography. For HPLC-PB-ITMS operation a novel transfer line design permits particle volatilisation outside of the trap volume by use of an independently heated probe tip. Also, customised ion trap scan routines have been written which minimise space charge and solvent-CI effects in EI acquisition.

A schematic of the interface(1) is shown in figure 1. The nebuliser and heated glass desolvation chamber were constructed in-house. The momentum separator and transfer lines were made by ASH instruments (Manchester, UK) to our design and coupled to two 18 m^3/h 2-stage rotary pumps. The ITMS transfer line consisted of two concentric stainless steel tubes, between which passed the connections for a heater and a thermocouple both located at the probe tip. The assembly was introduced into the manifold via the solids probe lock. The ion trap mass spectrometer was operated at 180°C and 1×10^{-4} torr manifold pressure after addition of helium buffer/collision gas (base pressure with PB in operation was 1.8×10^{-5} torr). The transfer line heated tip was operated at 240°C. The sector (VG 7070E) and quadrupole (VG TRIO 3) transfer line had no internal heater as particle volatilisation occurred in the source, but was fitted instead with a machinable ceramic insulating tip. Connection to both instruments was made *via* the solids probe locks. The 7070E was operated at 4KV source potential, 300°C source temperature. The TRIO 3 triple quadrupole was also operated at a source temperature of 300°C with MS/MS experiments performed using xenon collision gas at 4eV collision energy. Chromatography was performed on a 2.1 x 250mm silica column (HPLC technology, Manchester, UK).

The PB interface was successfully coupled to each spectrometer using the appropriate transfer line, and its performance was evaluated using Fluconazole (I), an antifungal pharmaceutical(2), and its product related impurity(II). Figure 2 shows the normal phase analysis of (I) and (II) on the ITMS system. The spectra obtained are good matches to spectra from probe-EI and HPLC-PB-sector MS analysis, with little interference from solvent observed. To eliminate the adverse effects of excess trapped solvent ions in the ITMS, the scan routine used was composed of repeated ionisation / low mass ejection steps before spectral acquisition, (figure 3). This was found to give good analyte signal without compromising spectral quality.

Ammonia CI was performed on both compounds using the sector machine. Figure 4a shows the spectra obtained, with prominent $[M+H]^+$ ions evident. However the base peak for (I) is m/z 222, which had very low intensity in the probe-EI spectrum, but was similarly intense on another commercial particle beam-MS system. Figure 4b shows the solvent-CI spectra obtained on the HPLC-PB-ITMS system using the RF/DC isolated $[CH_3OH_2]^+$ reagent ion. Surprisingly, as methanol has a smaller proton affinity than ammonia and the methanol-CI reaction is therefore more exothermic, fewer ions are observed in the ITMS spectrum suggesting the presence of processes other than proton transfer in the sector source.

Tandem mass spectrometry was performed on both triple quadrupole and ion trap devices, using collisionally activated dissociation in both cases. Figure 5 compares the HPLC-PB-MS/MS spectra obtained from fluconazole and shows a greater degree of fragmentation occurring in the optimised ion trap routine. Notably, the m/z 169 and 197 products, absent from triple quadrupole MS/MS data, were detected by probe-EI linked scan MS/MS in a previous study, suggesting that the energy imparted during axial excitation in the trap was greater than the 4eV applied in the triple quadrupole experiments.

In conclusion, EI, CI and MS/MS data, on-line with HPLC separations, has been obtained using both conventional and ion trap mass spectrometers coupled to a two-stage particle beam device with an appropriate transfer line. Successful separation and identification of Fluconazole and a related impurity has been demonstrated. Future work will apply the technique to different analytes and explore the use of alternative ionisation and dissociation techniques

An Electrostatic Ion Guide Interface for SIMS with an FT/ICR Mass Spectrometer

Jarrod A. Marto, Shenheng Guan, Patrick A. Limbach, Markus C. Wahl†, and Alan G. Marshall†

Departments of Chemistry (and Biochemistry†), The Ohio State University, 120 West18th Avenue, Columbus, OH 43210

External ion injection for FT/ICR mass spectrometry allows high-pressure ion sources to be coupled, through one or more stages of differential pumping, to the low-pressure mass analyzer region. In this way, the ultra-high resolution capability of FT/ICR/MS is maintained. The magnetic mirror effect, i.e., the repulsive force ions encounter if they are not aligned on the z-axis as they enter the magnetic fringe field, is the chief obstacle encountered in this approach. Quadrupole and Einzel lenses have been used to focus externally generated ions on the z-axis, thereby minimizing their interaction with the radial magnetic field gradient.

Here, we report a Secondary Ion Fourier Transform Ion Cyclotron Resonance Mass Spectrometer (SI/FT/ICR/MS) for the analysis of biological materials. The external ion source consists of a primary Cs^+ beam which allows for pulsed-mode operation at up to 10 keV Cs^+ ion energy. Externally formed ions are transferred to the mass analyzer by use of an electrostatic ion guide, recently demonstrated on an FT/ICR instrument [1]. The ion guide consists of an outer stainless steel tube with a thin wire suspended down the center. The guide extends from the sample probe to approximately 25 cm into the bore of a 3 tesla superconducting magnet. When a small potential difference (~10 V) is maintained between the wire and tube, the electrostatic force on the ions in the fringe field of the magnet is greater than the magnetic force, such that the trajectory of the ions is determined solely by the ion guide, thereby effectively defeating the magnetic mirror effect. In addition, the diameter (3.8 cm) and length (84 cm) of the ion guide allow for an order-of-magnitude pressure differential to be maintained between the ion source and analyzer regions (as determined by ion gauges #1 and #2 in Fig. 1). To maximize the observed ICR signal, an open-ended cylindrical analyzer trap is used.

Figure 2 shows a single-scan broadband FT/ICR mass spectrum of gramicidin S obtained from 1 μl of sample solution (2 μg/μl in methanol) deposited onto a glycerol matrix (2 μl, 0.1N HCl); under these conditions, a pressure of 3.0×10^{-8} torr was realized in the analyzer region. A primary Cs^+ beam pulse 5 s in duration (at 6 keV) was used to desorb the secondary ions. A potential difference of 11 V was maintained between the tube and wire of the guide to transport the ions into the ICR trap; the ions were allowed to accumulate for 20 s prior to excitation (frequency sweep from 5 kHz to 800 kHz at 50 Hz/μs). Besides the abundant protonated molecular ion at m/z=1142, several fragments are readily identified. A standard double resonance excitation sequence, with heterodyne detection over a 20 kHz bandwidth, was used to generate a high-resolution ($m/\Delta m \approx 10{,}000$) spectrum (not shown) of the molecular ion. This work was supported by grants to A.G.M. from NIH (GM-31683), NSF (CHE-9021058) and The Ohio State University.

Determination of Ion Frequencies in a Quadrupole Ion Trap Using a Fast DC Pulse as Pump and a Laser Probe

Stephen A. Lammert†, *Curtis D. Cleven, R. Graham Cooks, Purdue University, Department of Chemistry, West Lafayette, IN 47907-1393

†Present Address: Oak Ridge National Laboratory, P.O. Box 2008, MS 6120, Oak Ridge, TN 37831-6120

A new technique has been developed which allows the direct measurement of frequencies of ions trapped in a quadrupole ion trap mass spectrometer. This pump/probe method employs a fast DC pulse (pump) to displace a kinetically cooled ion population from the center of the trap, and a laser (probe) which recognizes when ions reappear at the center of the trap by the formation of photodissociation fragments. The translationally excited ions undergo periodic motion within the confines of the ion trap, and this periodic motion can be followed by recording the intensity of the photodissociation fragment as a function of the delay time between the DC pump and the laser probe. The DC pulse has a rise time of 15 ns; data are taken 1 ms after its application to allow stable ion motion to be sampled. Sampling of the ion cloud is done at 50 ns intervals and Fast Fourier Transform (FFT) of the time-based data yields the ion frequencies and their relative magnitudes. Data are reported for ions derived from acetophenone (m/z 105 -> m/z 77) and 1,4-cyclohexadiene (m/z 80 -> m/z 79) under various trapping conditions corresponding to different Mathieu q_z values.

An example of the data taken is shown in Figure 1 where a DC pulse is applied axially at a q_z-value of 0.6. The measured apparent frequency, f_z, of 502 kHz corresponds to an actual ion frequency of 251 kHz. This agrees surprisingly well, given that the q_z-value is greater than 0.4, with the value of 254 kHz estimated from the Dehmelt pseudopotential well model.[1] Contributions to the ion motion by higher order frequencies increase as the q_z-value is increased as can be seen with $f_{1,z}$ and $f_{-1,z}$ as well as $f_{1,r}$ and $f_{-1,r}$. The fundamental RF frequency, f_{RF}, also contributes to the ion motion.

The measured secular frequencies are found to agree well with those predicted by the Dehmelt pseudopotential model, within the range of its applicability. The ability to experimentally measure ion frequencies under operating conditions provides a new tool for comparing simulated and experimental data. Simulation data from the program ITSIM[2] modified to account for the effects of collisions, are shown to predict all major frequency components observed in the experimental data.

Evidence for "Black Holes" during EI in a Quadruupole Ion Trap Mass Spectrometer

S.A. Lammert*, C D. Cleven and R.G. Cooks
Purdue University, Department of Chemistry, West Lafayette, IN 47907
**current address: Oak Ridge National Laboratory, P.O. Box 2008, Oak Ridge, TN 37831-6120*

Since their observation by Traldi and co-workers in 1991[1], *black holes* in a quadrupole ion trap mass spectrometer have commanded the attention of several research groups[2], including our own[3] In that initial observation, it was reported that during MS/MS in the ion trap, if a parent ion is resonantly excited to produce fragment ions which subsequently appear at specific q_z-values, these fragment ions would be inadvertently ejected from the ion trap In effect, there was a "hole" in the stability diagram through which ions escaped if they were brought near it under certain conditions In a later report[4], these "holes" were reported to be, in fact, "canyons" which occurred not only at the a_z=0 axis, but along non-linear resonance lines[5,6] (at β_z=0.5, β_z=0 67) in the stability diagram. Since the strength of the non-linear fields, which give rise to these resonances, increases as the distance from the center of the trap increases, these ion losses are only observed under the circumstances where the ion's trajectory is moved away from the center of the trap In the above experiments, this was accomplished using a resonant AC to excite the parent ions to a new, larger trajectory It was later reported, however, that the supplemental AC was not needed to promote this ion loss and in fact the *black canyons* could be observed in single stage MS using chemical ionization and no resonance AC.[2]

Experiments discussed in this paper show that electron impact ionization alone can give rise to conditions where ions are lost by way of these *black canyons* through the same non-linear processes discussed above In addition, this effect can be generated and probed using fast DC pulses to rapidly move the ion population away from the ion trap center, either axially or radially, where the non-linear field strength is increased In this way both the ions' β_z-value and its position in the trap can be controlled to examine the ejection process

The scan function for these experiments is represented schematically in Figure 1. The first variation ("RF step" in Figure 1, square data points in Figure 2) employed a low ionization RF level (β_z=0.02 for the m/z 77 fragment from the EI ionization of acetophenone) Under these conditions, no ions are near the βz=0.67 hexapole non-linear resonance line. After the ionization stage, the RF was stepped, in single DAC step increments, across an RF level which corresponds to β_z values of between approximately 0 64 to 0 69 Then, after an approximately 5 ms delay, a small amplitude, 2 μs DC pulse could optionally be applied (either axially or radially) at this new RF value In the second variation ("no RF step" - Figure 1, circle data points in Figure 2), the RF level was held constant throughout the entire ionization period (this time at values which placed the m/z 77 fragment ion near the β_z=0.67 region) The RF level was again stepped in single DAC step increments across the β_z=0.67 region

The results for the axial activation experiment are shown in Figure 2 For both the RF step and no RF step variations, a pronounced dip in ion intensity for the m/z 77 fragment ion is observed at a β_z-value of just over 0.66 The effect of the DC pulse is considerably more pronounced in the RF step experiment where ions formed at larger distance from the center are less likely to be lost during the ionization process Similar results are obtained when the ions are translated radially with the DC pulse.

Ions whose β_z-values are at non-linear resonance points, and which are created at large distances from the center of the ion trap are prone to ejection. Under these conditions, the DC pulse has little additional effect. If the ions are formed under stable conditions, however, and allowed to cool to the center of the trap, subsequent RF level changes which result in an ion acquiring a β_z-value near a non-linear resonance line do not effect appreciable ion loss. These ions can be subsequently ejected if a small DC pulse is used to rapidly move the ion with these β_z-values to positions away from the trap center.

Ion Isolation and Modulated Ion Excitation for GC-MS/MS in an Ion Trap Mass Spectrometer

Barbara Bolton, Gregory Wells and Mingda Wang, Varian Chromatography Systems, 2700 Mitchell Drive Walnut Creek, CA 94598 USA

INTRODUCTION

Several methods(1-2) have been used for parent ion isolation; **Mass-Selective Instability**-where ramping the rf voltage causes ejection of low mass ions. The parent ion as well as ions of higher m/z value will remained trapped; **RF-DC Apex Isolation**-where rf and dc potentials are simultaneously applied which moves the parent ion to the apex of the stability curve, ejecting low and high mass ions; and **Sequential Ejection**-where the parent ion is moved to a high q value and an applied -dc voltage is used to eject low mass ions, return parent ion to low q value and an applied +dc voltage is used to eject high mass ions. These methods have the disadvantage of bringing the parent ion close to one or two stability boundaries which causes their kinetic energy to increase with a concomitant loss of intensity due to CID and ejection of ions outside of the range to be isolated. The limitations of these techniques have been compared(3). This problem can be severe with ions that can dissociate easily (i e. butylbenzene) and when the isolation range of m/z values is a single m/z value For GC-MS/MS applications on the ion trap, the instrumentation requirements must include easy mass calibration for parent isolation, unit mass resolution for isolation of the parent ion, independence of sample concentration and minimal CID losses during the isolation process We describe a novel method of ion isolation and a new method of ion excitation that when coupled with Gas Chromatography meet these instrument requirements for target compound analysis in the ion trap.

METHODS

The scan function is shown in Figure 1. The low mass ions are ejected by resonance scanning using an applied supplemental frequency of 460 kHz to eject up to <m, with a slower scan rate up to the m-1 ion With a small drop in rf level, a multi-frequency wave form was applied to the end caps of the trap to resonantly eject all of the high mass ions simultaneously The rf level is reduced and an off resonance supplemental AC field is applied for CID, simultaneously with the modulation of the fundamental RF trapping field. The next period utilizes normal analytical scanning techniques The multifrequency broadband wave form was generated by a Varian Wave~Board.

RESULTS & DISCUSSION

Figure 2 shows an example of ion isolation for the relatively high mass 502 of PFTBA. The low mass tailing indicates a relatively unstable ion. With broadband ejection the 503 isotope band is eliminated, without peak distortion and minimum attenuation (<10%) of m/z=502.The single frequency dissociation of butylbenzene mass 134 to m/z 92 & 91 is a sensitive probe(4) for excitation since it has two energetically different dissociation channels; the m=92 as the low energy channel and m=91 as the high energy deposition channel. Figure 3 shows a chromatographic peak of n-butylbenzene using rf/resonance ejection with AGC off or on. The mass spectra varied with concentration; both the 91/92 ratio as well as relative intensities of other ions. To control the energy deposition process, a new method of RF field modulation was added during the CID step.RF field modulation causes the secular frequency of the parent ion to successively pass in and out of resonance with the applied supplemental field. The amount of energy coupled into the ion motion is determined by applied field amplitude, the rate of RF field modulation and the number of modulation cycles. Figure 4 shows the peak of n-butyl- benzene using rf/resonance ejection

with rf modulation and AGC is off or on. The mass spectra appeared invariant with concentration; both the 91/92 ratio as well as relative intensities of other ions.

CONCLUSIONS

1. The difficulty of calibration of low volatility samples for isolation and excitation has previously limited the application of MS/MS techniques for GC-MS/MS. A novel method has been developed that provides high resolution ion isolation (unit mass resolution), easy mass calibration (using the PFTBA mass calibration curve) and higher isolation efficiency (minimized ion loss in isolation process).
2. A modulated field for CID has provided controlled energy disposition and uniform fragmentation. Modulating the trapping field compensates for uncertainties and shifts in the secular frequency of the parent ion caused by non-ideal trap geometry and changes in sample concentration, RF trapping voltage and supplemental field frequency.
3. The prescan for AGC has been modified to use the daughter ion TIC in the algorithm so as to maximize sensitivity and minimize space-charge perturbation. This new method of isolation and excitation has provided a GC-MS/MS method that is reliable and easy to implement(5)

Ion Energy-Modulated Stored Waveform Ion Modulation (SWIM) Two-Dimensional FT/ICR MS/MS

Charles W. Ross III, Shenheng Guan, and Alan G. Marshall†

Dept. of Chemistry (Dept. of Biochemistry†), The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

Fourier transform ion cyclotron resonance mass spectrometry (FT/ICR/MS) offers high resolution, wide mass range, and the ability to manipulate trapped ions for collision-induced dissociation, MS/MS, and determination of ion-neutral reaction pathways, kinetics, equilibria, and energetics. However, establishing a given ion fragmentation or reaction pathway optimally requires isolation of that ion (e.g., by ejection of ions of all other m/z) followed by a reaction period and then broadband excitation/detection of the various product ions. Thus, the FT multiplex advantage is available for the product ions, but not the various possible parent ions.

With the implementation of Stored Waveform Ion Modulation (SWIM) 2D-FT/ICR/MS[1] it is now possible to identify simultaneously *all* ion-neutral reactions in a single automated experiment. The familiar one-dimensional mass spectrum appears as peaks along the diagonal of a two-dimensional display. Off-diagonal peaks result from forward and reverse ion-neutral reactions. The parent ion cyclotron orbital radii (and thus parent ion speeds, and hence the relative abundances of product ions formed by ion-neutral reactions of those parent ions), may be modulated by applying a series of sinusoidal *single*-pulse excitation magnitude-mode stored inverse Fourier transform waveforms of increasing frequency over a given bandwidth.

However, in some endoergic reactions there is a minimum energy threshold that must be overcome for a reaction to occur. Hence, a simple sinusoidal modulation of parent ion cyclotron radius leads to a clipped sinusoidal signal of the product ion abundance in the second dimension, which upon Fourier transformation produces signals with harmonic and combination ion cyclotron resonance frequencies. Moreover, ion-molecule reaction rates may vary directly with ion kinetic energy rather than with ion cyclotron radius.[2] Since ion kinetic energy varies as the square of ion cyclotron radius and is proportional to the cyclotron frequency, a sinusoidal modulation of ion cyclotron radius will *not* produce a sinusoidal modulation of parent ion kinetic energy (or product ion abundance, Fig. 2) in such a case. However, with SWIM, it is possible to tailor the excitation profile so as to produce a sinusoidal modulation of ion kinetic energy as a function of cyclotron frequency (Fig. 1), so that SWIM 2D-FT/ICR MS/MS could remain linear even in that situation. We denote the energy-modulation SWIM 2D experiment as SMOKE (stored-waveform modulation of kinetic energy).

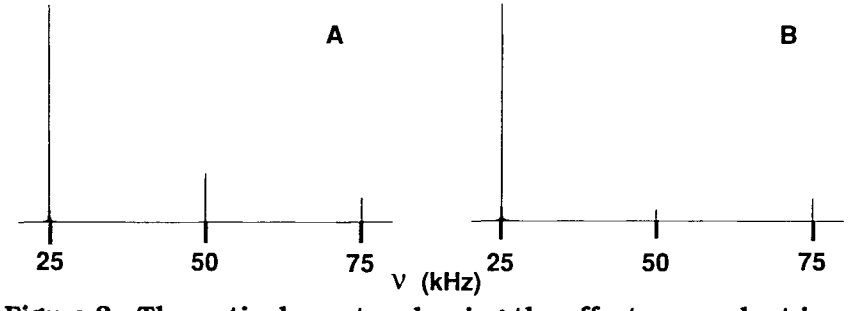

Figure 2. Theoretical spectra showing the effect on product ion signal (cyclotron frequency = 25 kHz) due to sinusoidal modulation of parent ion radius, for the case that the number of product ions varies linearly with energy (spectrum A). Spectrum B shows the additional effect of a non-zero energy threshold for the formation of product ions.

Activation of Aromatic Compounds in Gas Phase Metal Ion Reactions

R. Marshall Pope and Steven W. Buckner, Department of Chemistry, University of Arizona, Tucson, AZ 85721

The activation of aromatic compounds by transition metals has been a topic of recent interest for gas phase chemists. A range of interesting reactivities has been observed including C-H, C-halogen, C-O, and C-C activation, polymerization of halobenzenes[1], and CO extrusion from phenols[4]. Some of these reactions have even found use in the mass spectrometric differentiation of isomeric disubstituted benzenes and isomeric polycyclic aromatic hydrocarbons[3(b)]. We have recently observed the cleavage of stable aromatic rings in the thermal energy reactions of some early transition metal ion complexes in the gas phase[6]. Experimental studies of possible intermediate structures and the effects of methyl substitution on the reactions are discussed here.

Metal ions are generated by pulsed laser vaporization of pure metals and trapped in a FT-ICR mass spectrometer. After a collisional cooling period (> 0.5 sec) or complex formation by appropriate ion-molecule reactions followed by a similar cooling period, the metal ion-arene reactions listed in table 1 are observed. There are two proposed intermediates for this reaction. The first is a metallanorbornadiene complex involving a bent arene and the second is a direct ring inserted structure following the formation of a norcaradiene. The reaction of the quinoline and isoquinoline isomers gives insight into which mechanism prevails. Isoquinoline reacts with Nb^+ and NbO^+ in an analogous fashion to pyridine with HCN loss occurring exclusively. Quinoline, however, is unreactive. If the intermediate is the 7-membered ring structure (structure 1, directly inserted), reaction should be possible with both bicyclic rings. However, for the metallanorbornadiene intermediate reaction is only possible with the isoquinoline. The isoquinoline metallanorbornadiene intermediate is favorable, structure 2, but the quinoline metallanorbornadiene intermediate involves loss of aromaticity in both rings, strucure 3, making this high energy intermediate inaccessible. This suggests the ring cleavage reaction proceeds by the metallanorbornadiene at least for the bicyclic systems.

Reactions with the methylated rings show unusual behavior. Methylation of benzene shuts-off the ring cleavage pathway for Ta^+ with $2H_2$ loss occurring exclusively. This suggests methyl C-H activation is kinetically v\favored over the ring cleavage. Methylation of pyridine also provides for unusual reactivity. In addition to the ring cleavage (by HCN or CH_3CN loss) for picolines and lutidines, a molecule of H_2 is also lost. This occurs when the complex formed by ring cleavage results in formation of a d^2 metal center. This highly reactive metal center can then undergo cyclometallation by C-H attack on the pendant methyl group.

COMPLEXES IN DISSOCIATIONS OF PROTONATED ALKYL ETHER IONS

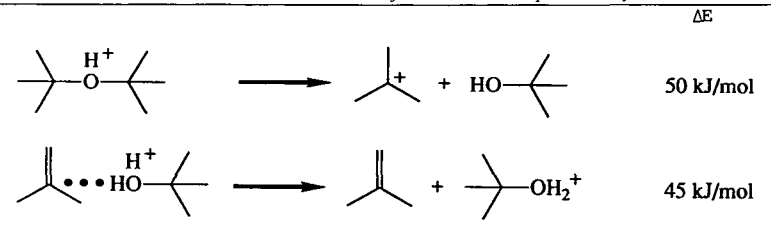
Henri E. Audier[1], Dorothée Berthomieu[2], Jeanine Tortajada[2], and T.H. Morton[3]

[1] Laboratoire des Mécanismes Réactionnels, Ecole Polytechnique, 91128 Palaiseau, France
[2] Laboratoire de Chimie Organique Structurale, Université Paris VI, 75230 Paris, France
[3] Department of Chemistry, University of California, Riverside, CA 92521-0403 USA

Unimolecular dissociations of protonated tertiary alkyl ethers are often preceded by hydrogen exchange. For tert-Bu$\overset{H^+}{O}$R, where the R-group is iPr, decomposition to tBu^+ competes with decomposition to $(CH_3)_2C{=}OH^+$ in the metastable ion mass spectrum. The latter ion must be formed concomtantly with isobutane as the expelled neutral, a reaction that is likely to involve an ion-neutral complex. When the parent ion is isotopically labeled, the former ion is found to have undergone partial exchange of the methyl hydrogens of the tert-butyl group and the hydrogen on oxygen. For tert-Bu$\overset{D^+}{O}$R complete exchange between methyl and oxygen would result in an m/z 57: m/z 58 ratio of $\frac{1}{9}$. Experimentally observed ratios are

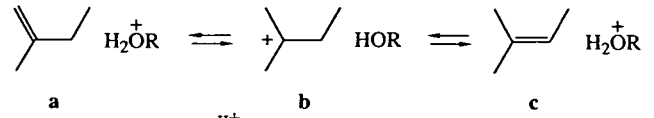
R	m/z 57:m/z 58
iPr	0.24
Et	0.28
Me	0.8
H	10

Both the exchange and alkane loss can be accounted for by invoking interconversion of [tBu^+ alcohol] and [isobutene protonated alcohol] complexes, but it is not obvious that these are not hydrogen-bonded complexes that need not fulfill the reorientation criterion. Therefore SCF calculations have been performed to explore the stabilities and structures of such complexes. Protonated alcohol···isobutene complexes are found to be quite stable, with dissociation energies that are nearly the same as the heterolytic R—O bond dissociation energies of the corresponding protonated ether. For example, the calculated ΔE_0 values for $(tBu)_2OH^+$ and its isomeric complex (at 6-31G**//6-31G**, including BSSE correction and zero point energies calculated at 3-21G) are summarized at the top of the next page. For this system there is also a stable structure corresponding to tBu^+···HOtBu, with C-O distances of 1.44 and 2.86Å. By contrast, the stable geometry for $(tBu)_2OH^+$ has two C-O bond lengths of 1.56Å, while tert-Bu$\overset{H^+}{O}$Me is calculated to have unequal C-O bond



lengths of 1.44 (Me-O) and 1.59Å. The tBu^+···HOtBu complex appears to be hydrogen bonded, and its energy is only 7 kJ/mol higher than that of the protonated ether.

We have been unable to find a similar hydrogen-bonded complex of tBu^+ and methanol. But, because protonated methyl tert-butyl ether nevertheless exhibits hydrogen exchange (although not isobutane expulsion, since the heat of formation of $H_2C{=}OH^+$ is too high), such a complex must intervene. Therefore we infer that the presence of an ab initio potential energy minimum is not essential for a complex to operate.



Metastable tert-Amyl-$\overset{H^+}{O}$-R have also been examined. The sites where exchange takes place depend on the identity of R. When the [alkene protonated alcohol] complexes lie close in energy to the protonated ether (as when R=iPr), isotopic labeling shows that both of the reactions a ⇄ b and b ⇄ c take place. But when the complex is higher in energy (as when R=Me) only the exchange corresponding to b ⇄ c is detected. This result is consistent with the fact that 2-methyl-2-butene is more stable than 2-methyl-1-butene.

Calculated carbon-oxygen distances in [alkene protonated alcohol] complexes do not show a great dependence on the identity of the alcohol. In isobutene···H_2^+OMe the distance is 3.18 Å, while in isobutene···H_2^+OtBu it is 3.26 Å. Therefore we discount steric factors in the regiochemistry.

On the Role of Ion-Neutral Complexes in the Alkene Loss from the Molecular Ions of Alkyl Phenyl Thioethers

Margot W. van Amsterdam, *Steen Ingemann and Nico M. M. Nibbering
Institute of Mass Spectrometry, University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

The molecular ions of ethyl and n-propyl phenyl thioether react predominantly by α-cleavage and elimination of an alkene in the ion source and the field free regions (FFR) of a double-focussing hybrid quadrupole mass spectrometer. Deuterium labelling reveals that α-cleavage of ionized ethyl phenyl thioether (eq. 1) occurs without hydrogen atom interchange prior to dissociation and that ethene elimination in the ion source as well as on the μs time-scale proceeds by a specific transfer of a hydrogen atom from the β-position of the ethyl group to the remaining part of the ion (eq. 2).

$$C_6H_5SCH_2CD_3^{+\cdot} \rightarrow C_6H_5SCH_2^+ + CD_3^\cdot \quad (1)$$

$$C_6H_5SCH_2CD_3^{+\cdot} \rightarrow C_6DH_5S^{+\cdot} + C_2D_2H_2 \quad (2)$$

The loss of an ethyl radical from the metastable molecular ions of n-propyl phenyl thioether is to a minor extent accompanied by hydrogen atom interchange between the alkyl and phenyl groups (eq. 3). Moreover, the product ion of propene loss incorporates a hydrogen atom originating from any of the three positions of the alkyl group. A certain preference for transfer of a hydrogen atom from the β-position is observed, however, and this selectivity is particularly pronounced for the metastable ions (see Table).

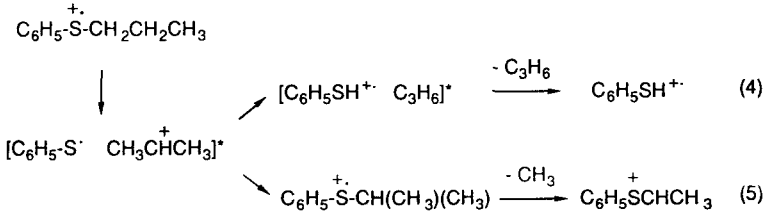
$$C_6D_5SCH_2CH_2CH_3^{+\cdot} \xrightarrow{94\,\%} C_6D_5SCH_2^+ + C_2H_5^\cdot \quad (3a)$$

$$C_6D_5SCH_2CH_2CH_3^{+\cdot} \xrightarrow{6\,\%} C_6D_4HSCH_2^+ + C_2DH_4^\cdot \quad (3b)$$

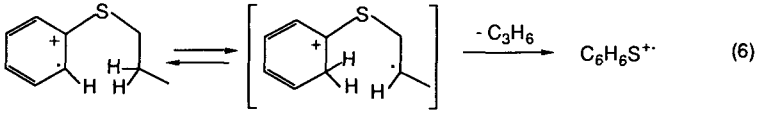
The incorporation of a hydrogen atom from the α- or γ-position of the n-propyl group *indicates the occurrence of a reaction sequence involving cleavage of a C-S bond with* formation of an ion-neutral complex of a thiophenoxy radical and a secondary propyl carbenium ion. This complex can react further by proton transfer prior to dissociation into the thiophenol radical cation and propene (eq. 4). Evidence for this mechanism is obtained also by the observation that the metastable ions of $C_6H_5SCH_2CD_2CH_3$ expel $CH_3^\cdot$ and $CDH_2^\cdot$ to a minor extent and in a ratio of approximately 1:1 as expected from the occurrence of an isomerization of the n-propyl group to an isopropyl group (eq. 5).

Table. Normalized abundances of the ions formed by competing transfer of a hydrogen and deuterium atom in the propene loss from the molecular ions of labelled n-propyl aryl thioethers.

compound	H-transfer : D-transfer			
	ion source		2nd FFR	quadrupole section
	70 eV	10 eV		
$C_6H_5SCD_2CH_2CH_3$	82:18		90:10	94:6
$C_6H_5SCH_2CD_2CH_3$	65:35	33:67	30:70	22:78
$C_6H_5SCH_2CH_2CD_3$	70:30		85:15	92:8
$2,6\text{-}(CH_3)_2C_6H_3SCH_2CD_2CH_3$	70:30	70:30	42:58	32:68



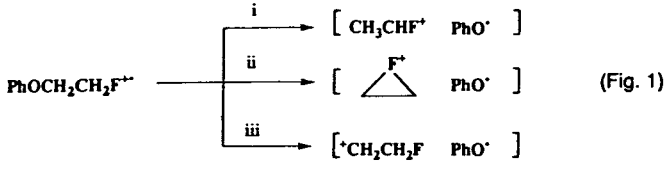
The preference for transfer of a hydrogen atom from the β-position at relatively low internal energies may be a result of a 1,5-H shift to the 2- or 6-position of the phenyl group followed by and/or concomitant with propene loss (eq. 6). This leads initially to the keto-form of the thiophenol radical cation, which subsequently may rearrange to the thiol-form. The preference for transfer of β-hydrogen atom in the propene loss on the μs time-scale is observed also for the molecular ions of 2,6-dimethylphenyl n-propyl thioether (Table) suggesting that a 1,3-H shift directly to the sulfur atom can compete with the *partially reversible 1,5-H shift (see eq. 3b) and the reaction involving ion-neutral* complexes.



Fluoride Shifts in The Fragmentation of β-fluorophenetole radical cations and in The Rearrangement of 1-fluoropropyl to 2-fluoropropyl cations.

Viet Nguyen and Thomas Hellman Morton
University of California, Riverside, CA92521-0403

The m/z 94 /95 ratios ($PhOH^{+\bullet}$/ $PhOD^{+\bullet}$) resulting from bond cleavage and hydrogen transfer from C_α and C_β of deuterated β-fluorophenetole metastable ions differ markedly from those seen in the mass spectrometer source.[1] Recent studies of neutral vinyl fluorides from $PhOCD_2CH_2F$ and $PhOCH_2CD_2F$ using EBFlow techniques reveal that phenol ion comes from three competing pathways involving ion-neutral complexes: (i) via hydride shift, (ii) fluoride shift to form fluoriranium ion, (iii) vicinal elimination.[2] EBFlow radiolysis has also been done on $PhOCH_2CHDF$. Relative amounts of vinyl fluoride isomers measured from these experiments allow us to determine kinetic isotope effects as well as branching ratios of the three fragmentation pathways. Assuming the same kinetic isotope effects, branching ratios can also be estimated for the corresponding metastable ions.



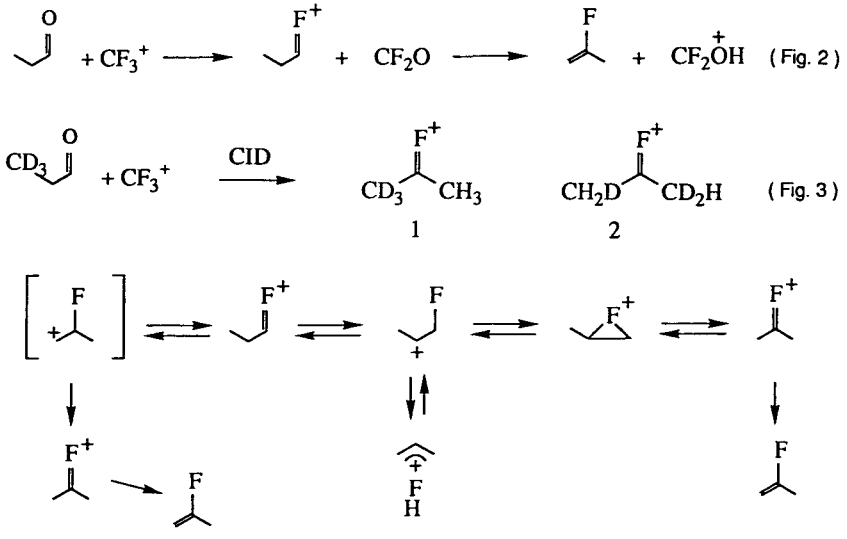
(Fig. 1)

BRANCHING RATIOS	i	ii	iii
Ion source	1.00	0.43	0.18
metastable ions	1.00	0.75	1.30

The difference in peak ratios between the MIKES and the source spectra of β-fluorophenetole can be attributed entirely to an approximately seven-fold increase in the proportion of ions undergoing vicinal elimination in the metastable ion decomposition s as compared to the 70eV ion source. This can account for the reported decrease in the net average kinetic isotope effect with increasing ion lifetime[1] without having to invoke significant changes in isotope effect values for the individual pathways. Threshold energy measured for the simple cleavage to expel $FCH_2^\bullet$ is 11.3 eV , 0.1eV higher than the threshold energy for the complex-mediated pathways.[3] *Ab initio* calculation supports the view that vicinal elimination comes from an ion-neutral complex that contains an unarranged primary carbocation structure.

In the gas phase, 1-fluoropropyl cation converts rapidly to 2-fluoropropyl cation.[4] The reaction of propionaldehyde with CF_3^+, depicted in figure 2 , in EBFlow reactor yields only 2-fluoropropene. CID spectrum of CD_3CH_2CHO with CF_3^+ produces both **1** and **2**. Previous studies have shown that **1** does not transpose deuterium,[4] this means that intramolecular hydrogen exchange takes place prior to or in the course of isomerization of 1-fluoropropyl cation . ^{19}F NMR analysis of collected neutrals from EBFlow radiolysis of

1-^{13}C-propionaldehyde with CF_4 shows all three 2-fluoropropene isomers with the ratio $^{13}CH_2{=}CFCH_3$: $CH_2{=}^{13}CFCH_3$: $CH_2{=}CF^{13}CH_3$ = 1.37:1:1.37. While reaction of 1-^{13}C- acetone only gives $CH_2{=}^{13}CFCH_3$ .To accomodate all available data, equation 1 is invoked as a possible mechanism for the isomerization of 1-fluoropropyl to 2-fluoropropyl cation.



(Eq. 1) Possible mechanism for the isomerization of 1-fluoropropyl to 2-fluoropropyl cation.

Structure and Vibrational Frequencies of Ionized Ethane: A Fluctional Molecule?

Charles E. Hudson*[1], C.S. Giam[1] and D.J. McAdoo[2]
[1]Texas A&M University, Galveston, Texas 77551
[2]Marine Biomedical Institute, Galveston, Texas 77555

In neutral ethane the weakest bond in the molecule is the C-C bond: $2\Delta H_f(CH_3) = 291.6$ kJ/mol while $\Delta H_f(C_2H_5 + H) = 118 + 218.0 = 336$ kJ/mol. However in the ion a C-H bond is weaker: $\Delta H_f(C_2H_5^+ + H) = 902 + 218 = 1120$ kJ/mol while $\Delta H_f(CH_3^+ + CH_3) = 1093.3 + 145.8 = 1239.1$ kJ/mol. This is easy enough to understand if the ionization takes place from an orbital devoted to C-H bonding. However the best calculations have disagreed whether the lowest energy state of $C_2H_6^+$ results from C-C ionization or from the degenerate HOMO devoted to C-H bonding.[2] The ESR spectrum of the ion has been recorded in matrices of low reactivity and is in good accord with the latter prediction and definitely not the result of C-C ionization,[3] but this has been attributed to the effect of the matrix.[4] We have extended the calculations using the general methods of reference 2 with larger basis sets and evaluation of the energies with more extensive treatments of correlations. We have also calculated the vibrational frequencies at the MP2/6-311+G** level to assess zero point effects.

Since the HOMO is a degenerate orbital devoted to C-H bonding, removal of an electron from it gives rise to two states (^2A_g and ^2B_g) after Jahn-Teller distortion. Removal of an electron from the slightly lower C-C bonding orbital gives rise to a symmetrical $^2A_{1g}$ ion. We have characterized all these structures at the MP2/6-311+G(2df, 2p) level of theory. The ^2A_g state with a normal C-C bond length and the $^2A_{1g}$ state with a long (1.9A) C-C bond length are of the same symmetry and can mix. As the bond is lengthened, the structure changes gradually from one state to the other.

Table 1

MP2/6-311+G(2df,2p) parameters of ethane ions

	^2A_g	$^2A_{1g}$	^2B_g
Energy[a]	-79.231005	-79.227955	-79.225833
ZPVE[b]	182.73	183.25	186.20
Rel energy[b]	0	4.70	20.56
RC-C	1.5558	1.9078	1.4272
RCH1	1.1406	1.0809	1.0799
H1CC[c]	82.87	98.38	118.74
RCH_2[d]	1.0804	1.0809	1.1346
H2CC[d]	115.95	98.38	112.26
H2CCH1[e]	70.55	60.0	45.80
QCISD(T) energy[a]	-79.236585	-79.236678	-79.227826
Rel energy[b]	0	0.28	26.47

a. in Hartrees b. in kJ/mol c. bond length (angle) to the two hydrogens on the plane of symmetry. d. bond length (angle) to the other four equivalent hydrogens e. dihedral angle between the plane of symmetry and

the H2CC plane.

The C-C stretching vibrations of the ^2A_g and $^2A_{1g}$ states are easy to identify because their reduced masses are 4 times as large as that of any other. As calculated at the MP2/6-311+G** level the frequencies are 531 and 509 cm^{-1} respectively, with about 3.0 kJ/mol of ZPVE in this mode. Preliminary indications are that this 3.0 kJ/mol exceeds the total variation of electronic energy between C-C bond lengths of 1.56-1.91A, hence the ethane ion may not have a well defined bond length over this range.

ESR theory holds that the hyperfine splittings are proportional to the spin density at the nucleus.

$$a^H(x) = a^H(H)\ \rho^H(x)/\rho^H(H)$$

where $a^H(x)$ is the splitting in question, $a^H(H)$ is the hydrogen atom splitting of 506.86G, $\rho^H(x)$ is the spin density at the hydrogen nucleus in question which is printed in the Fermi contact analyses of the Gaussian[5] output, and $\rho^H(H)$ is the spin density of the hydrogen atom at the nucleus, in electrons per cubic bohr. Our calculated splitting at the MP2/6-311+G(2df,2p) level is 137.2G compared to the experimental value of 152.5G if the analytically correct number ($1/\pi$) is used for $\rho^H(H)$. However if the value of $\rho^H(H)$ as calculated in the same basis set (0.28744) is used, the resulting prediction is 151.9G, in good agreement with experiment.

Theoretical Study of the Ring Closure of the 1,7-Octadiyne Cation.

Ronny C. Robbins, James Jensen
U.S. Army
Aberdeen Proving Ground
Edgewood Area
APG, MD 21010-5423

The ring closure of the 1,7-octadiyne cation is studied using the GAUSSIAN92 program. The calculations were done at the SCF and CASSCF levels of theory using the 6-31g set. The "Thru-Space" interaction of the pi systems on two alkyne fragments is examined. All calculations were run using Gaussian 92 rev B on a Kubota Pacific ST3000 and a Convex 3820. Possible starting geometries for the open structure were generated using the AVS Chemistry viewer program. These structures were then optimized at the Restricted-Hartree-Fock level using a 6-31g basis set. The structure with lowest energy was then taken for further study. A global search of all geometric configurations was not possible. However, the structure chosen had the largest negatively charge carbon atom as measured by a Mullikan charge in close proximity to the carbon atom with the largest positive charge. The starting geometry for the ring structure was generated by taking the open structure and rotating a single dihedral angle(D5 in the Z-matrix) from 60 degrees to -40 degrees until the carbons on the ends of the two triple bonds were approximately a bond length apart. This rotation of the dihedral angle was monitored using the AVS Chemistry viewer program. In order to make the ring stay closed, the C-C-H angle of each alkyne group had to be manually changed from approximately 180 degrees to 120 degrees. This structure was then optimized at the RHF level using a 6-31g basis set. Using the optimized open and ring structure, a guess structure for the transition state was generated using the Linear Synchronous Transit capability of the Gaussian 92 package. This transition state was then optimized at the RHF 6-31g level. An RHF energy Hessian matrix was generated at each step of the optimization. Single point CASSCF calculations of the ring and open structures showed that the open structure was well described by a single configuration and that the ring structures was somewhat less well described by a single configuration. Therefore, it was decided to optimize all three structures(open, ring, and transition state) at the CASSCF level of theory. An 8 in 8 CAS was used in order to completely correlate the four pi and four pi-star orbitals of the two triple bonds. An RHF energy Hessian was generated for each structure to start the optimization. A frequency calculation (8 in 8 CAS 6-31g) is to be run at the optimized open and ring structures. The ring closure is exothermic by approximately 5 Kcal/mole.

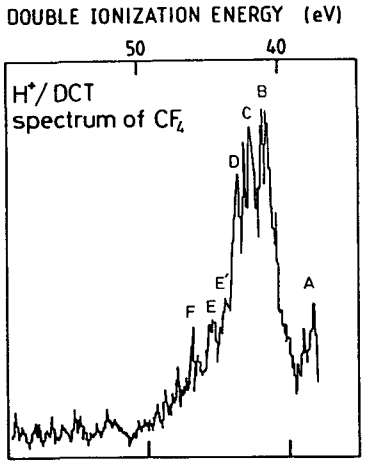
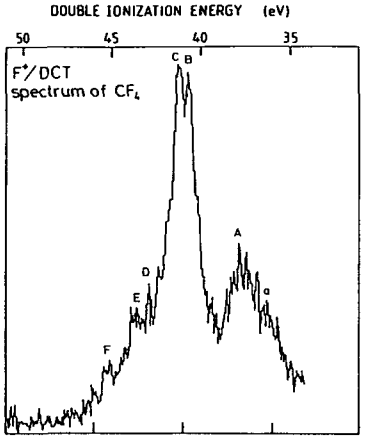
DOUBLY IONIZED STATES OF FLUORINATED METHANES

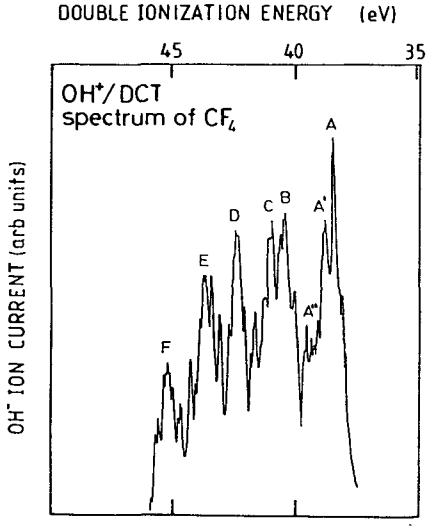
*W.J.Griffiths, S.Svensson, A.Naves de Brito, N.Correia, C.J.Reid, M.L.Langford, F.M.Harris, C.M.Liegener and H.Ågren Institute of Physics, Uppsala University, Uppsala, S-75121, Sweden.

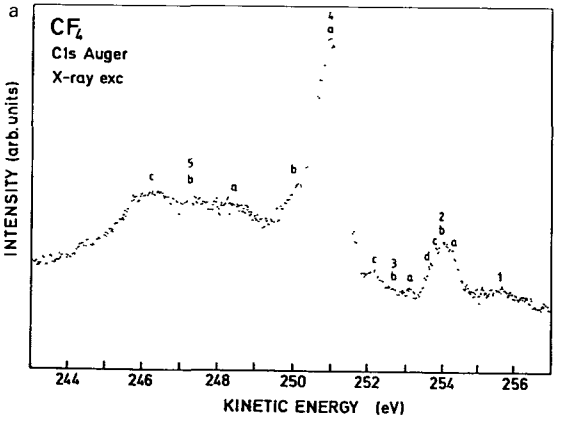
High resolution Auger-electron, and double-charge-transfer (DCT) spectra have been recorded of the molecules CF_4, CF_3H, CF_2H_2, and CH_3F. Both forms of spectroscopy give information as to the energy levels in dications. Auger-electron spectra are dominated by transitions to states of singlet symmetry and give double ionization energies to such states. In the present work double-charge-transfer spertra have been recorded using the OH+ and the F+ projectile ions. Both of these ions populate triplet states in the dications formed, and double ionization energies to triplet states are measured. DCT spectra have also been recorded using the H+ projectile, where singlet state dications are formed. Auger- electron and DCT spectroscopies provide complimenatry information as to the energy levels in dications. The spectra recorded have been interpreted with the aid new of theoretical calculations obtained by a two-particle Green"s function method. The ageement between theory and experiment is found to be good.

Shown below are the H+, F+, and OH+ DCT spectra of CF_4 and also the C1s Auger-electron spectrum. Double ionization energies are caluclated from Auger spectra by subtracting Auger-electron kinetic energies from core binding energies. In CF_4 the C1s binding energy is 301.96 eV.









Singlet state energy levels of $C_2H_4^{2+}$

M L Langford[2], P G Fournier[1], J Fournier[1] and F M Harris[3]

[3]Mass Spectrometry Research Unit, Chemistry Department, University College of wansea, Swansea.

The Double Charge Transfer (DCT) spectra of singlet states of $C_2H_4^{2+}$ are determined at high resolution and compared with the results of two previous DCT studies [1,2]. Both of these studies were carried out using proton projectile ions but there are substantial differences in the measured energies of the dication states. The present results are also compared with the double ionisation energies and vertical ionisation spectrum predicted using the two particle Green's function method with the second order algebraic diagrammatic construction (ADC(2)) [3].

The present experiments involve the measurement of the translational energy lost by H^+ ions in the reaction

$$H^+ + M \rightarrow H^- + M^{2+} \qquad (1)$$

where two electrons are transferred from a target molecule M to produce a doubly charged ion M^{2+}. The experiments were carried out on a double mass spectrometer. Calibration of the energy scale was carried out with particular care in this experiment in order to resolve the controversy generated by the two previous DCT studies. Due to spin conservation only singlet states of $C_2H_4^{2+}$ are expected to be observed in this study.

The spectral resolution obtained in the present investigation is much higher than in the two previous studies and has enabled an accurate measurement of five singlet states of $C_2H_4^{2+}$ with the energies 30.9, 34.3, 36.2, 38.8 and 42.8 eV. The Figure shows that peak A is a well defined

peak with a sharp onset at approximately 28.8 eV, an energy distribution of 0.8 eV at 90% intensity and a FWHM of 3 eV. (The instrumental broadening in these experiments is 1.3 eV). The energy separations between the three lowest energy singlet states (S1 and S2; S2 and S3) are computed [3] to be 1.73 and 2.62 eV respectively. The energy distribution exhibited by peak A suggests that strong contributions from only one of these states are involved in its generation. Calculations have shown that the ground state of the dication has a radically changed geometry from the planar neutral molecule [3]. Vertical transitions from the neutral ground state would be to an unstable planar configuration leading to poor Franck-Condon transition factors and resulting in a broadened low intensity peak quite unlike peak A. Thus it seems likely that Peak A represents the population of S2 which has a stable planar configuration and not the ground state S1.

INTRODUCTION

The results of a combined experimental and theoretical study of the double ionization of CH_3I were reported in 1990[1]. Since that time, similar studies of CH_2I_2, CHI_3 and CI_4 have been completed, the results of which form the basis of this paper. Experimentally, double-charge-transfer (DCT) spectroscopy was used to measure double-ionization energies to various electronic states of the dications. Computationally, these energies have been calculated using a modified form of the Multiple Scattering Xα (MSXα) method[2] of molecular orbital calculations.

EXPERIMENTAL PROCEDURE

In DCT spectroscopy, high-velocity singly charged positive ions undergo double-electron-capture (DEC) reactions in collisions with the molecules under investigation. Since the iodides studied have low volatilities, an MS9 spectrometer was used which has a heated sample reservoir and heated lines to the collision-gas cell. The projectile OH^+ ions had 8keV translational energy so the DEC reaction

$$OH^+ + M \rightarrow OH^- + M^{2+} \qquad ..(1)$$

with a molecule M must, therefore, have taken place very rapidly because of the high velocity of OH^+, resulting in vertical transitions from M to M^{2+}. If E_p and E_n represent the translational energies of OH^+ and OH^-, respectively, then

$$E_p - E_n = IE_2(M) - E(OH^+ \rightarrow OH^-) \qquad ...(2)$$

where $IE_2(M)$ represents the double-ionization energy to the ground electronic state of M^{2+}, and $E(OH^+ \rightarrow OH^-)$ is the energy released in the charge inversion of OH^+. In the experiments, E_n was kept constant and E_p varied; a peak in the OH^- ion current against E_p spectrum was obtained when eqn. (2) is satisfied. Calibration of the energy-loss scale was achieved by obtaining a DCT spectrum with xenon atoms in the cell for which the double-ionization energy is known.

The populating of higher-lying states of M^{2+} will occur at higher values of E_p, giving additional peaks in the DCT spectrum.

COMPUTATIONAL PROCEDURE

Double-ionization energies to triplet states of the dications were calculated since there is now ample evidence[3] to show that the use of OH^+ in the study of closed-shell molecules will populate triplet states of the corresponding dications because of spin conservation in the DEC reaction. Values were obtained by carrying out separate calculations of the total energies of the initial target-molecule ground state and final dication state of interest. It has been found[4] that if the double-ionization process is regarded within a single-configuration approximation as the creation of two holes in molecular orbitals *a* and *b*, which then experience a repulsive interaction energy V_{ab}, then this implies

$$DIE_{ab} = E_{ia} + E_{ib} + V_{ab} \qquad ...(3)$$

where E_{ia} and E_{ib} are the single-ionization energies for each orbital. Experimental single-ionization energies were used in this equation thus rendering the method semi-empirical.

RESULTS

As a result of the computational method, the double-ionization energies to ground and electronically excited states of CH_3I^{2+} were calculated. The data agreed well with the previously published[1] experimental data. Because of space limitations, it is not possible to present all the data for the three molecules studied. One has been chosen (CHI_3), and the calculated and experimental results are presented below.

CHI_3^{2+} state populated	Calculated DIE	Calculated Average	Experimental DIE
$^3A_2$	24.4		
^3E	24.5		
^3E	25.1	24.9	24.8 ± 0.3
$^3A_2$	25.2		
^3E	25.2		
^3E	25.8		
$^3A_1$, $^3A_2$, ^3E	25.9	26.1	26.1 ± 0.4
$^3A_2$	26.6		
^3E	27.8		
^3E	28.2	28.2	28.0 ± 0.5
$^3A_1$, $^3A_2$, ^3E	28.4		
$^3A_2$	29.1		
$^3A_1$, $^3A_2$, ^3E	29.2		
$^3A_1$	29.6	29.6	30.0 ± 0.5
^3E	29.7		
^3E	30.5		

It can be seen that the number of states predicted to exist in the range 24.4 eV to 30.5 eV is large. As shown, logical groupings of the states are possible, and the average state energies of these groups agree well with the energies determined experimentally. For CH_2I_2, the density of calculated states is higher making it more difficult to group the states. For CI_4, however, the density of states is lower than that for CHI_3, so that groups with no more than two components were identified which gave average values in agreement with those measured.

Full details of this investigation will appear in a paper[5] to be published this year.

The Relative Migratory Aptitudes of Fluoride and Methyl in a Gas Phase Carbocation

*Thomas A. Shaler and Thomas Hellman Morton
Dept. of Chemistry, University of California, Riverside, CA 92521-0403

It is well known that carbocations undergo facile rearrangements through the migration of alkyl groups and hydrogens. For carbocations that are substituted by the halogens Cl, Br, or I, there are many examples in the gas phase and in solution of halogen bridging or migration. In contrast, for those that are substituted by fluorine, there are but a few examples of fluorine's participation in bridging or migrating through a bridged transition state.[1]

We would like to report that the recently proposed[2] 1,2-fluoride migration in the decomposition of electron-impact ionized **1** has been confirmed through the use of EBFlow[3] experiements on the ^{13}C-labeled compound **2**. Primary alkyl phenyl ethers such as these are known to decompose through intermediate ion-neutral complexes when ionized.[4] The neutral alkenes that are expelled can be collected and analyzed to allow inferences about the structures and rearrangement pathways of the carbocation within the ion-neutral complex to be made.

Since experiments on **1** could not distinguish between the two possibilities depicted in Scheme 1, one of which involves only methyl shifts and not a fluoride shift, compound **2** was prepared and subjected to EBFlow radiolysis. The formation of C_4H_7F neutral fluoroalkenes having fluorine bonded to ^{13}C has allowed us to unambiguously establish that a 1,2-fluoride migration has occurred. Our results allow us to obtain a direct measurement of the relative migratory aptitude of fluorine and methyl. When corrected for the 2:1 statistical preference for methyl migration, the ratio of the amounts of methyl-shift products to the amounts of fluoride shift products is 2.1:1.

Mechanism of Gas Phase Aldose-ketose Isomerization: A Study using Tandem Mass Spectrometry and Theoretical Calculations

*Ya-Jun Zheng and Julie A. Leary
Department of Chemistry, University of California, Berkeley, CA 94720

Fast atom bombardment (FAB) tandem mass spectrometry (MS/MS) of lithium coordinated oligosaccharides has been shown to be an effective method of determining the linkage position of various isomeric oligosaccharides [1-3]. Collision induced dissociation (CID) of either the monolithiated ($[M + Li]^+$) or dilithiated ($[M + 2Li - H]^+$) species produces product ions of the isomers which are different and very specific to the linkage position. In these earlier studies we postulated that in order to observe the different losses for each isomeric disaccharide, the reducing ring hemiacetal must first undergo ring opening to produce the hydroxy aldehyde [2]. Subsequent retro-aldol rearrangement then gives rise to specific two, three, and/or four carbon neutral losses from the reducing ring. In one particular isomer, the 1,3 linked disaccharide, transposition of the carbonyl function from C-1 to C-2 of the hydroxy aldehyde is required prior to the retro-aldol rearrangement [2,3]. Labeling studies employing ^{18}O and ^{2}H indicated that the 1,3 linked disaccharide must rearrange to transpose the carbonyl to the C-2 position prior to the retro-aldol reaction in order to observe the characteristic three carbon chain neutral loss ($C_3H_4{}^2H_2O_3$) as shown in Scheme 1.

Fast atom bombardment (FAB) tandem mass spectrometry (MS/MS) and semiempirical molecular orbital method (MNDO) were used to investigate the mechanism of gas phase aldose-ketose isomerization. Two reaction pathways were investigated. Both involve ring opening, but differ in the aldehyde-ketone isomerization step. In reaction pathway A, the isomerization follows a keto-enol tautomerization via a 1,3 H shift while reaction path B involves a proton transfer from the C-2 hydroxyl to the carbonyl oxygen (C-1) followed by a hydride transfer from C-2 to C-1. The MNDO calculations suggest that Path B is favored over Path A by 29.2 kcal/mol. Metastable and CID studies in all three reaction regions of a hybrid mass spectrometer (BEgQ) indicate this reaction is observed in FFR 2 and 3, but not in 1. Because we do not see this same reaction during CID of the protonated precursor, it is very likely that the hydride transfer mechanism is being catalyzed by the presence of lithium.

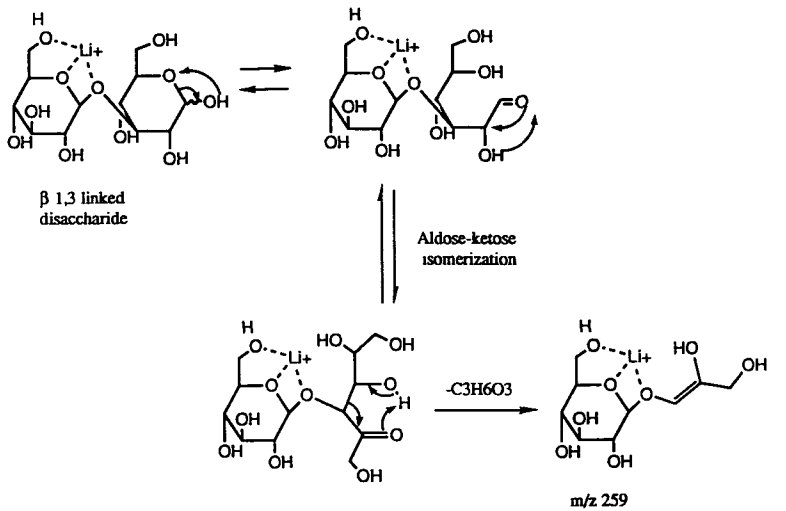
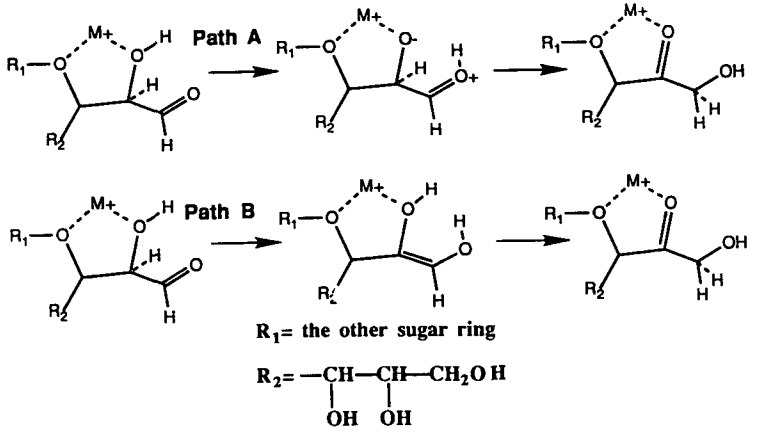


Scheme 1



Competing Dissociation of and Bond Formation between CH_3CHOH^+ and $^{\cdot}CH_2CH_3$ formed by Bimolecular Processes.

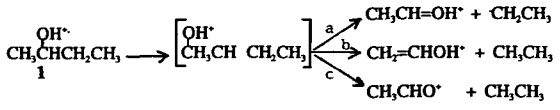
Mohammed S. Ahmed[a,b], C.S. Giam[b] and David J. McAdoo[a]
[a] Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77555

[b] Dept. of Marine Sciences, Texas A&M University at Galveston, Galveston, Texas 77553

Introduction

Ion-neutral complexes are often invoked to rationalize unimolecular decompositions of ions in the gas phase. Relationships between those decompositions and corresponding ion-molecule reactions have recently begun to be explored. Whether energetic or angular momentum differences cause significant variations in reactivity between unimolecular and bimolecular processes is of interest. Comparisons between unimolecular and bimolecular processes suggested that they are linked by a common intermediate,, albeit differences in product distribution with mode of reaction exist. These differences have been attributed to reaction on different regions of the potential energy surface.

(1)



Ionized 2-butanol undergoes complex-mediated decompositions (1a and 1b) which diminish rapidly with increasing energy in the system. We chose to study a variety of ion-molecule reactions to enter the $C_4H_{10}O^+$ potential energy surface in the vicinity of 1 at different energies (Fig. 1). The ion-molecule reactions we characterized include those of $CH_3CH_3^+$ with CH_3CHO, CH_3CHO^+ with CH_3CH_3, $CH_3CH_2OH^{+\cdot}$ with $CH_2{=}CH_2$, and $CH_2{=}CH_2^{+\cdot}$ with CH_3CH_2OH. Our objectives were to determine how closely ion-molecule reactions reproduce the complex-mediated unimolecular decompositions of 1 and how well C-C bond formation and H-transfer compete with dissociation of CH_3CHOH^+ and $^{\cdot}CH_2CH_3$.

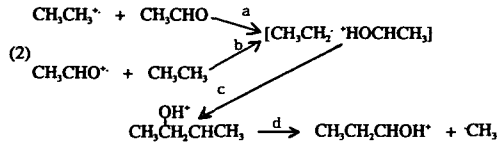
Experimental

All experiments were performed on an Extrel FTMS-1000 equipped with a 3 Tesla superconducting magnet. The typical reagent pressures were $5\text{-}7\times10^{-8}$ torr except for ethanol a lower pressure was used ($2\text{-}3 \times 10^{-8}$ torr) to minimize unwanted proton transfer reactions. Spectra were recorded in the broad band mode at a sweep rate of 1 KHz/µs. The reactants were collisionally cooled by pulsing argon to a peak pressure of 2×10^{-5} torr. The ionizing electron energy was 12 eV. All samples were purchased from commercial sources.

Results and Discussion

Reaction of $C_2H_6^{+\cdot}$ with CH_3CHO produced predominantly CH_3CHOH^+, with lesser amounts of CH_3CO^+, $C_2H_4O^+$. (8:5:100:1). These reactants are about 162 kJ mol^{-1} above the threshold for forming $CH_3CHOH^+ + {}^{\cdot}CH_2CH_3$ (Fig. 1).

(2)

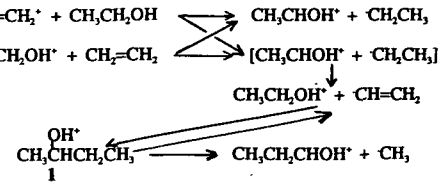


Reaction of $C_2D_6^{+\cdot}$ with CH_3CHO produced m/z 43, 44, 45, 46, 62 and 65 in the relative abundances 11:10:75:100:1:0.3. The formation of m/z 65 demonstrate that reaction 2ac took place. The formation of m/z 65 demonstrate that reaction 3 also occurs at these higher energies.

(3) $CH_3CHO + CD_3CD_3^+ \longrightarrow CH_3CHOCD_3^+ + {}^{\cdot}CD_3$

The oppositely charged ethene/ethanol pairs differ in energy by only 4 kJ mol^{-1} (Fig. 1). $C_2H_4^+$ reacted with ethanol to produce $CH_3CH_2OH_2^+$, $CH_3CHOH^{+\cdot}$ and $C_3H_7O^+$ in about a 2.5:1:10:.05 ratio, but did not produce detectable CH_3CHOH^+.

(4)



Reaction of $CH_3CH_2OH^+$ with $CH_2{=}CH_2$ also gave $CH_3CH_2OH^+$ and CH_3CHOH^+ but did not yield any detectable $C_3H_7O^+$. The low abundance to absence of C_3 products demonstrate that collapse of CH_3CHOH^+/CH_2CH_3 pair to 1 was slight relative to their dissociation.

Conclusions

1. Bond formation or a second H-transfer infrequently follows initial H-transfer in ion-molecule reactions.
2. C-C bond formation followed by opposite C-C bond cleavage was 12 to more than 50 times less frequent than the prior proton and hydrogen transfers in the reactions studied.
3. Energy and angular momentum in the system generated by ion-molecule reactions could contribute to the differences observed between ion-molecule reactions and metastable decompositions.

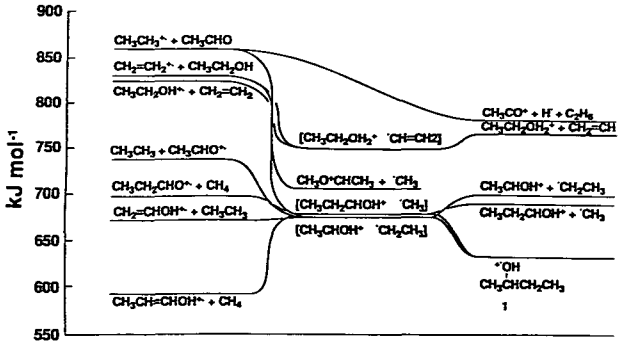


Fig. 1 Potential energy surface for $C_4H_{10}O^{+\cdot}$ system

Gas-Phase Radical Cation Rearrangements of 4-Vinylcyclohexene to Bicyclo[3.2.1]-2-octene

D. L. Vollmer, D. L. Rempel M. L. Gross, Univeristy of Nebraska, Lincoln, NE 68588

The potential energy surface of the C_8H_{12} radical cation has been investigated by several methods including mass spectrometry[1], theoretical calculations[2], and ESR[3]. The reaction of 1,3-butadiene radical cation with 1,3-butadiene neutral was studied by using high-pressure chemical ionization[1] and *ab initio* calculations[3] and was concluded to proceed through an acyclic intermediate to form the 4-vinylcyclohexene radical cation, 1. Investigation by matrix-isolation ESR, however, has shown that 1 undergoes radical cation rearrangement to bicyclo[3.2.1]oct-2-ene, 3 [3].

Here we report the occurrence of this rearrangement in the gas-phase by use of tandem mass spectrometry (MS/MS) on a sector mass spectrometer and a Fourier transform (FT) mass spectrometer. The sector mass spectrometer involves utilization of conventional MS/MS techniques for isomer differentiation. The FT mass spectrometer, however, incorporates a new methodology recently demonstrated in our laboratory[4] which allows for control, in part, of the rearrangement of 1 to 3.

With the sector mass spectrometer, the radical cation of each C_8H_{12} compound was formed, in separate experiments, in a chemical ionization (CI) source by electron-impact ionization. The radical cations were then mass selected by using the first stage of a tandem mass spectrometer, collisionally activated, and a spectrum of its decomposition products taken by scanning the second stage. The collisional-activated decomposition (CAD) spectra are similar; both C_8H_{12} radical cations fragment to form structurally significant ions via losses of ·H (to give *m/z* 107), ·CH_3 (*m/z* 93), C_2H_4 (*m/z* 80), C_2H_5 (*m/z* 79) and C_3H_6 (*m/z* 66).

The addition of a CS_2 bath gas to the CI source in the aforementioned experiment, however, yields distinctive CAD spectra (See **Figure 1**); the abundance ratio of *m/z* 93 to *m/z* 66 is particularly informative. For 1, the abundance ratio changes from 0.5 to 1.8 with CS_2 addition whereas 3 remains constant at 0.4. We attribute this difference to the ability of CS_2 to act as a charge-exchange reagent as well as a collisional stabilization gas to produce low-energy radical cations, which are less likely to rearrange than higher-energy radical cations.

To study the rearrangement further an FT mass spectrometer was utilized. This spectrometer has the ability to form, via the rf-only-mode event, near-thermal ions as well as select and store ions for extended periods of times. In separate experiments, the C_8H_{12} radical cations were produced by low-energy charge exchange with preformed toluene radical cations. During this time, the rf-only-mode event, along with a high-pressure (~10^{-3} Torr) helium pulse, was implemented for collisional stabilization of the radical cations. Following the charge-exchange reaction, the radical cations were isolated by ejecting all other ions. The remaining C_8H_{12} radical cations were collisionally activated by ion excitation in the presence of residual helium.

The CAD spectra of the two C_8H_{12} radical cations display similar fragments to those seen with the tandem mass spectrometer with the exception of loss of ·H (*m/z* 107). The relative abundances of the ions, however, are different for each radical cation. Again, the abundance ratio of *m/z* 93 to *m/z* 66 is the distinguishing feature. For 1, the abundance ratio is 4.9 whereas 3 produces a ratio of 0.1.

Upon addition of internal energy to the aforementioned experiment, by way of ion excitation, during the rf-only-mode event and in the presence of a high-pressure of helium, the CAD spectrum changes for 1; the abundance ratio of *m/z* 93 to *m/z* 66 is 0.5. The abundance ratio remains approximately the same (0.05) for 3, as in the experiment without ion excitation. The higher ratio of 0.5 for 1 in these experiments can be explained by an incomplete rearrangement of 1 to 3.

The ability to excite ions during the rf-only-mode event offers a unique way of controlling, in part, the molecular structure of the vinylcyclohexene radical cation. This is demonstrated by varying the

amplitude of the ion excitation for 1 (See **Figure 2**). At low ion excitation, the relative abundance of *m/z* 66 is greater than that of *m/z* 93 indicating characteristics of 1. Increasing the ion excitation, however, shows an inversion of relative abundances for each mass. At high ion excitation, the relative abundances indicate a structure of 3. A similar experiment was performed on 3 in which no inversion was observed, at low or high ion excitation.

Both MS/MS and FTMS results are in accordance with the matrix-isolation ESR investigation, which suggests that 1 rearranges to 3 at higher internal energy, but is thermodynamically stable at lower internal energy[3]. A mechanism was previously proposed to explain this rearrangement which involves cation attack from the C-2 of the ene radical cation, 1, to form a distonic ion (charge-radical site-separate radical cation), 2, with the carbon skeletal structure of 3 (See **Scheme 1**). A 1,4-H· transfer can then be invoked to reach 3.

DYNAMICS OF THE UNIMOLECULAR DISSOCIATION OF DIMETHYLFORMAMIDE RADICAL CATION

INTRODUCTION

In studies of the electron ionization (EI) mass spectra and metastable dissociation spectra of $(CH_3)_2NCHO^+$, Ann and Adams[1] observed products that corresponded to loss of CHO and CH_3 neutral fragments.

$$\left[(CH_3)_2NCHO^+\right]^* \rightarrow C_2H_6N^+ + CHO$$
$$\left[(CH_3)_2NCHO^+\right]^* \rightarrow CH_4NO^+ + CH_3$$

Although the products can be explained readily in terms of simple bond cleavage reactions, deuterium labeling at the formyl position revealed a more complicated mechanism for the CHO loss pathway. For the higher energy EI spectra, d_1-DMF^+ decomposed by loss of 29 amu (CHO), whereas metastable d_1-DMF^+ lost 30 amu (CDO) in this dissociation channel.

Loss of CHO from $(CH_3)_2NCDO^+$ requires rearrangement, whereas loss of CDO requires only N-C bond cleavage. Rate constants for simple bond cleavage typically increase faster with energy than do those for rearrangement reactions. Thus it seems curious that a rearrangement reaction would dominate the kinetics at high energies (EI conditions) but not at lower energies (metastable conditions). Recently, Baer and Riley (UNC Chapel Hill) conducted photoelectron-photoion coincidence (PEPICO) experiments with $(CH_3)_2NCHO$, and observed loss of CHO and CH_3. Based on the time-of-flight spectra, they concluded that the dissociations are nonstatistical.

APPROACH

We decided to study this reaction further, using Mass-Analyzed Ion Kinetic Energy Spectrometry to measure kinetic energy release distributions for the products of metastable unimolecular dissociation. Ab initio molecular orbital calculations were carried out to characterize the potential energy surface and to obtain vibrational frequencies and rotational constants for relevant species. These parameters were then used with statistical phase space theory to model the PEPICO kinetics measured by Baer and Riley, in order to fine-tune the transition state energies. Finally, these modified transition state energies were incorporated into the complete model for the calculations of kinetic energy release distributions.

RESULTS

Metastable dimethylformamide radical cation dissociates to form three sets of products: $C_3H_6NO^+$ + H, $C_2H_4NO^+$ + CH_3, and $C_2H_6N^+$ + CHO. The KERDs measured for these processes are shown below.

Theoretical calculations turned up three low-energy isomers of the DMF^+ ion. These isomers are separated from the molecular ion by energetic barriers of 1.5 eV or more. Investigations of structures for the $C_2H_6N^+$ and $C_2H_4NO^+$ products also revealed multiple

isomeric structures. The singlet products CH_3-N-CH_3^+ and CH_3-N-CHO^+ that would arise from direct cleavage of the carbon-nitrogen bond in DMF^+ were found to be unstable with respect to rearrangement by 1,2-hydrogen shifts. Three transition states for the 1,2-hydrogen shifts in DMF^+ were found. In one, the H-shift is concerted with cleavage of the methyl - nitrogen bond.

Our investigations suggest that simple direct cleavage of the carbon-nitrogen bonds in DMF^+ leads only to high energy species, and that rearrangements of the fragments to lower energy isomers occur spontaneously.

From modeling the kinetics measured in the PEPICO experiments of Baer and Riley, we changed the transition state energies slightly from those calculated by MO theory. All other parameters were used unchanged. Below are shown the calculated KERDs for each of the sets of fragments, plotted over the experimental data. It can be seen that the KERDs are in general nonstatistical, but that each reaction channel has unique dynamics. Hydrogen atom loss results in a broader translational energy distribution than predicted by statistical theory, indicating repulsive interactions in the exit channel. This would be consistent with a reverse activation barrier and the weakness of the attractive interactions expected for an ion with an H atom (due to low polarizability). For the methyl loss channel, the KERD is bimodal, indicative of two or more mechanisms. This is consistent with the results of the ab initio calculations, which show at least two transition states that can lead to methyl loss, one by a concerted pathway, and another by a stepwise H-shift, methyl loss pathway. Finally, the KERD for CHO loss is narrower than predicted by statistical phase space theory, indicating that the products are internally excited. This may result from rotational excitation resulting from the unfavorable ion-dipole interactions that develop as the N–CHO bond is stretched.

Kinetic Energy Release Distribution Calculations

FRAGMENTATION OF DIETHYL DICARBOXYLATES UNDER EI AND CI CONDITIONS

Jan Malát and Alex. G. Harrison
Department of Chemistry
University of Toronto
Toronto, Canada M5S 1A1

The major primary fragmentation route of ionized diethyl dicarboxylates is by elimination of $C_2H_5O^{\cdot}$. The same ion is formed by elimination of C_2H_5OH from the MH^+ ion in Brønsted acid chemical ionization. The present work has concentrated on the further fragmentation of this $[M - OC_2H_5]^+$ ion and on the structures of the fragment ions so-formed. Two sets of isomeric diethyl dicarboxylates were studied, diethyl succinate and diethyl methylmalonate and diethyl glutarate, diethyl ethylmalonate and diethyl dimethylmalonate. Isotopic labelling and metastable ion studies, including kinetic energy releases, have been used as structural probes.

The $[M - OC_2H_5]^+$ ion from diethyl succinate fragments exclusively by elimination of C_2H_4 on the metastable ion time scale. Comparison with the $C_2H_5^+$ adduct of succinic anhydride shows that the $[M - OC_2H_5]^+$ ion has the ethylated succinic anhydride structure and fragments to form protonated succinic anhydride. By contrast, the $[M - OC_2H_5]^+$ ion from diethyl methylmalonate fragments entirely by loss of CO on the metastable ion time scale. The resulting ion is, in part, the destabilized carbenium ion, $CH_3CH^+COOC_2H_5$, although H-rearrangement to form $CH_2{=}CHCOOC_2H_5.H^+$ occurs to a significant extent prior to further fragmentation of the $[M - OC_2H_5 - CO]^+$ ion.

The $[M - OC_2H_5]^+$ ions of diethyl glutarate, diethyl ethylmalonate and diethyl dimethylmalonate, whether formed by EI or CI methods, show different metastable ion characteristics, that from the glutarate fragmenting by loss of C_2H_4 and CO, that from the ethylmalonate fragmenting by loss of CO and $[CH_2CO + CO]$ and that from the diemthylmalonate fragmenting by loss of CO only. The reacting configuration for loss of C_2H_4 from the $[M - OC_2H_5]^+$ ion of the glutarate is ethylated glutaric anhydride and protonated glutaric anhydride is formed. Loss of CO from the $[M - OC_2H_5]^+$ ion of diethyl ethylmalonate forms, in part, the destabilized carbenium ion $CH_3CH_2CH^+COOC_2H_5$, although rearrangement to $CH_3CH^+CH_2COOC_2H_5$ and $CH_3CH{=}CHCOOC_2H_5.H^+$ occurs to some extent prior to further fragmentation of the $[M - OC_2H_5 - CO]^+$ ion. The $CH_3CH^+CH_2COOC_2H_5$ ion fragments on the metastable ion time scale by loss of CH_2CO. Loss of CO from the $[M - OC_2H_5]^+$ ion of diethyl dimethylmalonate forms the destabilized carbenium ion $(CH_3)_2C^+COOC_2H_5$, although some rearrangement to $CH_2{=}C(CH_3)COOC_2H_5.H^+$ occurs prior to further fragmentation of the $[M - OC_2H_5 - CO]^+$ ion.

Presented at the 41st ASMS Conference on Mass Spectrometry

A COMPARATIVE STUDY OF THE DYNAMICS OF LOW AND MEDIUM ENERGY COLLISION-INDUCED DISSOCIATION OF ISOMERIC IONS

Runzi Zhao, Rahul Chawla, Anil Shukla* and Jean Futrell
Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

INTRODUCTION

Isomerization processes are widely known to play an important role in ionic characterizations by mass spectrometry. Isomerization, being slow, usually results in a metastable decay process. Collisional activation and dissociation processes, on the other hand, are fast enough that isomerization is usually not considered important. However, recent studies of the dynamics of CID of nitromethane ions showed that the NO_2^+ fragment, formed by direct bond cleavage, behaves differently than the NO^+ fragment, which is produced following isomerization of nitromethane to methyl nitrite. To explore the role of isomerization processes in CID dynamics, we have studied the CID of methyl nitrite ions to NO^+ and the enolic form of acetone ions to CH_3CO^+. The latter is known to proceed via isomerization to keto form and its metastable dissociation process leads to a bimodal kinetic energy release distribution.

RESULTS AND DISCUSSION

Nitromethane vs. Methyl Nitrite Ion : Figures 1 and 2 show the contour diagrams for the CID of nitromethane and methyl nitrite ions to NO^+ at 3.1 eV collision energy, respectively. Distinct peaks in forward and backward scattering regions in Figure 1 were suggested to be due to two dynamically distinct pathways rather than an orbiting complex formation. Since nitromethane ions have to isomerize to methyl nitrite ions for NO^+ formation (barrier height 0.45 eV), the forward scattered peak, resulting from large impact parameter soft collisions, was suggested to be due to the dissociation of those nitromethane ions that are very near the barrier approaching the transition state configuration. The backward scattered peak is due to dissociation of nitromethane ions that are somewhat lower in the potential well and are activated by small impact parameter hard collisions. CID of methyl nitrite to NO^+ does not require isomerization and dissociation proceeds as soon as sufficient energy is transferred into the ion. The energy transfer into the methyl nitrite ion is close to thermochemical threshold and does not change significantly when collision energy is increased further suggesting no change in the CID mechanism for this process.

Keto v Enolic Acetone Ion : Figure 3 shows a contour diagram for CH_3CO^+ fragment ions formed from CID of the keto- acetone ions at 3.2 collision energy; a similar diagram for the CID of enol- acetone ions at 3.9 eV collision energy is shown in Figure 4. The keto ion has two peaks in forward and backward scattering regions corresponding to transfer of 2.2 eV into internal modes and release of 2.2 eV into translational mode prior to dissociation, respectively. The latter process is due to long-lived excited electronic A state of the acetone which releases excess internal energy into translation. The threshold for this dissociation process is only 0.7 eV, however, energy transfer is 2.2 eV and it increases further with collision energy. Figure 4 for the CID of the enolic ion shows only a single peak corresponding to transfer of 2.8 eV energy into internal modes which is close to the energy barrier to isomerization to keto form. It suggests therefore that after isomerization, dissociation proceeds following complete energy

randomization as against the suggestion that it proceeds from both ground state and first excited state simultaneously. As the collision energy is increased further, dynamical behavior is not changed in any respect in this case. It may be interesting to point out that bimodal kinetic energy release distribution was obtained for metastable dissociation, a slow process with a narrow energy distribution compared to CID process.

These results suggest that CID of both methyl nitrite and enolic acetone ions follow normal dissociation pathway, i.e. dissociation proceeds as soon as internal energy reaches the threshold for dissociation or the isomerization barrier is crossed. Also, the energy randomization process is completed before dissociation takes place.

Internal Energy Effects on the Fragmentation of Ions and Neutrals

Ilan Vidavsky,* Russell A Chorush, Fred W. McLafferty
Chemistry Department , Cornell University, Ithaca, NY, 14853-1301

Fatty acid esters were the first "large" molecules whose mass spectra were thoroughly studied [1] Their most abundant peak arises from the McLafferty rearrangement,[2] a rearrangement which should be a low energy process However, Murphy,[3] Harvey[4] and their co-workers found this peak missing in low energy CAD spectra, which we have found true also for metastable ion dissociations of straight and branched chain fatty methyl esters In high energy CAD spectra this peak is present in significant abundance only in the shorter chain fatty acids esters As proposed by Murphy, these results and isotopic labeling suggest a rearranged molecular ion The almost equal abundance of alkyl loss from either end of the hydrocarbon chain suggests a migration of a protonated carbomethoxy group to a radical site within the chain, this is followed by cleavage of one of the two hydrocarbon chains to form an ion of a protonated 2-alkylacrylate structure In contrast to the previous mechanism,[1,3] this is more consistent with that postulated for MI spectra of 2-methylbutyric acid [5] The predicted fragment ion structures indicated by MS/MS/MS of alkyl loss ions in MI and CAD spectra of protonated alkyl acrylates

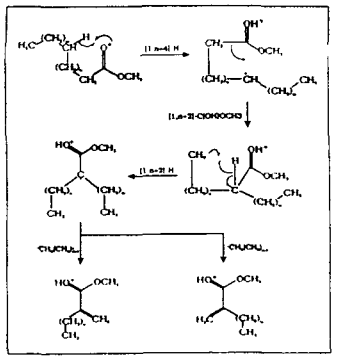

Fig 2 The proposed mechanism for the formation of the alkyl loss ions

Neutralization-reionization mass spectrometry (NRMS) is a uniquely useful technique for the differentiation of isomeric ions that yield similar CAD spectra.[6] Such ionic characterization by NRMS can be improved by increasing the internal energy of the dissociating neutrals,[7,8] enhancing entropically favored direct dissociations over entropically disfavored rearrangements The use of surface-induced

neutralization (SIN) in a NRMS experiment provides a method for increasing the internal energy deposited in the neutrals beyond that currently attainable using gas-phase targets [9] The energy deposited into the neutrals can be approximated by correcting for dissociation following reionization With a Ag surface deposited on an in-line Si substrate, NR efficiencies of 0 01% are achieved using 9.8 keV $CH_4^{+\cdot}$, with ~50% of the neutral CH_4 receiving >14 eV of internal energy; with metallic K vapor neutralization the efficiency is 0 4% with ~50% of the neutrals receiving >8 9 eV The energy deposition can be increased by increasing the potential deflecting ions into the surface (Fig 3), in this way ~15% of CH_4 neutrals can be given >20 eV of internal energy. Thus, despite much lower sensitivity than gas-phase targets (using the present collision cell), SIN is unique in the large amount of energy that can be deposited in the neutral and in the facile control over the average energy deposited In addition, SIN avoids the high gas load and contamination caused by conventional gas-phase targets

Decomposition of the Ethyliodonium Ions in the Gas Phase.

Dmitri V.Zagorevski and John L.Holmes
Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5.

Unimolecular decomposition of EtI⁺R ions produced by ion molecule reactions have been studied by tandem mass spectrometry (MI, CID and NR). Metastable ion decompositions of EtI⁺H and EtI⁺Pr involve alkyl cation formation. EtI⁺Me and Et_2I^+ decompose with ethene loss. PhI⁺Et ion loses I, PhEt and C_2H_4. The latter leads to the 1-iodocyclohexadienyl cation, which is characterized by I elimination.

Collisional activation induces some other dissociations involving simple C-I and C-C bond cleavages and rearrangements with C-C or C-H bond formation. Methyl loss from the ethyl group in EtI⁺D and EtI⁺Me ions leads to the ylid ions, $RICH_2^+$ (R=D, Me). Their dissociation includes CH_2 loss, which is not a characteristic of isomeric RCH_2I^+ ions. Formation of I^+ and RCH_2^+ indicates a partial ylid to alkyliodide isomerization.

The MI and CID mass spectra of D-analogs of EtI⁺R (R=Me, Et, Ph) have been studied in order to elucidate the mechanism of ethene loss. Kinetic energy releases have also been measured. The experimental data obtained can be rationalized by the two barriers in the following energy diagrams (Figs. 1-3; asterisks denote the labelled species). The first barrier (TS_1) corresponds to the irreversible β-hydrogen (deuterium) shift to the iodine atom and the second is responsible for ethene loss (TS_2). The transition states for the species with an I-D bond are higher in energy than those for the species with an I-H bond, i.e. $TS_1^D > TS_1^H$, and $TS_2^D > TS_2^H$. Competition between simple hydrogen migration and hydrogen mixing as well as between H and D migration from the ethyl group is determined by the relative energies of these barriers.

For EtI⁺Me ion TS_1^H, $TS_1^D < TS_2^D$, TS_2^H (Fig. 1), which results in complete hydrogen mixing prior to ethene loss and the preference for loss of the most deuterated ethene.

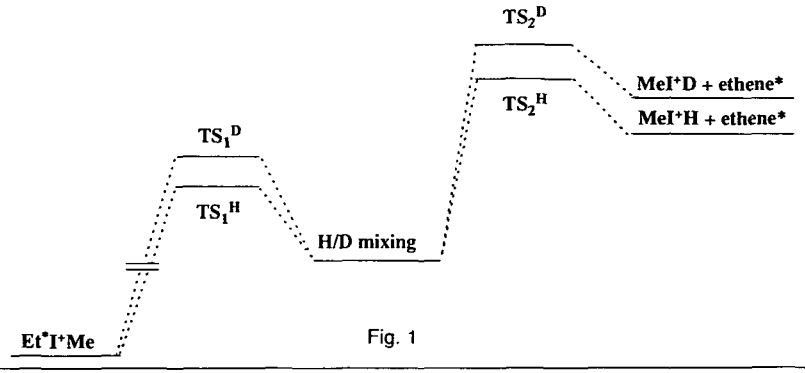

Fig. 1

For Et_2I^+ ion $TS_1^H < TS_2^H$, $TS_2^D \leq TS_1^D$ (Fig. 2), which leads to a large hydrogen isotope effect for ethene loss following H/D-mixing in the CH_3CD_2 group, and makes the direct elimination of $C_2H_2D_2$ from CD_3CH_2 competitive with hydrogen mixing.

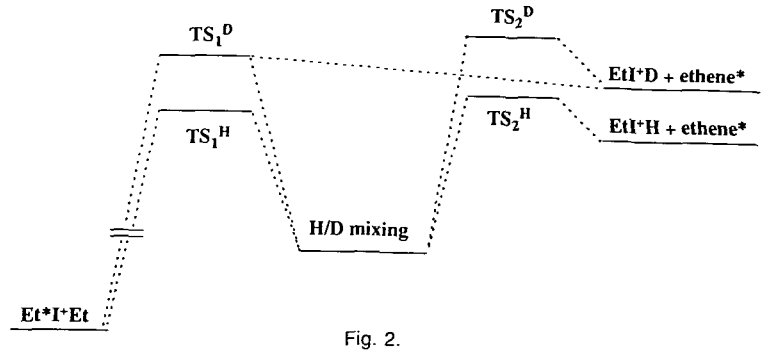

Fig. 2.

For PhI⁺Et ion $TS_1^D > TS_2^D > TS_1^H > TS_2^H$ (Fig. 3), which permits a single step ethene loss from both the CD_3CH_2 and CH_3CD_2 groups to be competitive with hydrogen atom mixing.

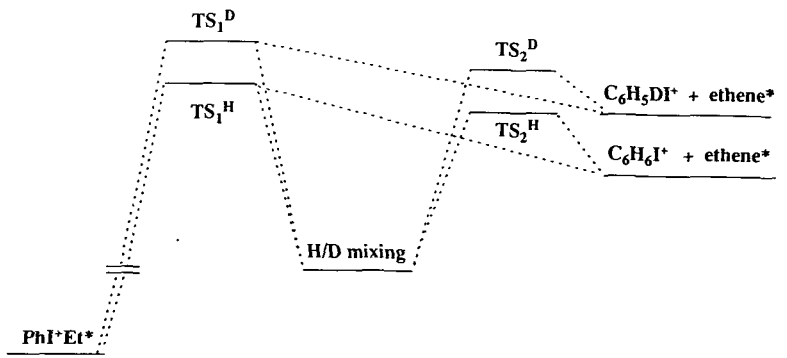

Fig. 3.

The increased $C_2H_3D/C_2H_2D_2$ loss ratio for $CH_3CD_2I^+Et$ ions (originating from $(CH_3CD_2)_2CO$/EtI and $CH_3CD_2NO_2$/EtI mixtures) and $C_2HD_3/C_2H_2D_2$ loss ratio for $CD_3CH_2I^+Et$ and $CD_3CH_2I^+Ph$ ions (originating from $CD_3CH_2NO_2$ mixtures with EtI and PhI) is due to hydrogen pre-mixing in the "classical" form of the ethyl cation reacting with neutral ethyl- and phenyliodide.

Dechlorination of PCB's in Electron Capture Negative Ion Chemical Ionization Mass Spectrometry

***F.Lépine[1], S.Milot[1], M.L.J.Reiner[2] and O.A.Mamer[2]**

1 **Institut Armand-Frappier, Université du Québec, Laval, Qc, Can. H7N 4Z3**

2 **Biomedical Mass Spectrometry Unit, McGill University, Montréal, Qc,Can. H3A 1A3**

The dechlorination mechanism of Polychlorinated Biphenyls (PCBs) was studied using 36 ^{35}Cl mono- and di-labelled penta- and hexachlorobiphenyls. These were synthesized using unselective chlorination with $^{35}Cl_2$ of all the symmetricals tetrachlorobiphenyls, namely congeners **40**, **47**, **52**, **54**, **77** and **80** according to IUPAC nomenclature. Upon chlorination, each of these congeners generates a mixture of penta- and hexachloro congeners containing one and two ^{35}Cl label respectively. The identification of each of these compounds, and consequently the position of the label in these, was performed using their relative retention times as described by Mullin et al. (1,2).

The methane electron capture negative chemical ionization (ECNCI) spectra of the labelled PCBs show ions at $[M-34]^-$ and $[M-68]^-$ which correspond to the loss of one and two chlorine atoms from a PCB molecule which added one and two hydrogen atoms. For pentachloro congeners, only the $[M-34]^-$ ions were sufficiently intense to be analyzed. Within the 27 labelled hexachloro congeners produced, many have the same substitution pattern but for the position of the labels within the pattern. There are three series of such congeners. Being symmetricals, these congeners, upon dechlorination in the mass spectrometer, can only generate three pentachloro intermediates. Assuming that these intermediates are structurally similar to neutral molecules, it is possible to calculate the relative intensities of the $[M2H-2Cl]^-$ ions if the relative proportions of the three pentachloro intermediates contributing to the $[MH-Cl]^-$ ions are known and if the relative intensities of the $[MH-Cl]^-$ ions generated by these pentachloro

intermediates can be obtained. Because the hexachloro congeners are initially produced by chlorination of pentachloro congeners, these corresponding pentachloro congeners can be observed and the intensity of their $[MH-Cl]^-$ ion measured. The relative proportions of the pentachloro intermediates can be obtained from the label loss in the $[MH-Cl]^-$ ions of the hexachloro congener bearing the labels at the corresponding position.

A good correlation can be obtained between the calculated and the observed $[M2H-2Cl]^-$ ion intensities, thus proving that the pentachloro intermediates are similar in structure to the corresponding pentachloro congener. Also, the residual label content of these $[M2H-2Cl]^-$ ions is similar to the calculated value obtained from the $[MH-Cl]^-$ ions of the corresponding pentachloro congeners. These two conclusions strongly suggest that the pentachloro intermediates formed upon dechlorination of an hexachloro congeners are very similar to the corresponding pentachloro congeners studied and that they undergo dechlorination in a similar way. This imply that the incoming hydrogen has to be located at the same position than the departing chlorine atom. This would be compatible with an electrophilic hydrogen radical addition mechanism with rapid loss of the chlorine atom on the carbon undergoing hydrogen attack. The relative intensities of the $[MH-Cl]^-$ ions was found to be dependent of the number of ortho chlorines in the molecules. The relative intensities of the $[MH-Cl]^-$ ions decrease with increasing number of ortho chlorines. However, within a given congener, ortho chlorines, when present, are lost preferentially. These two phenomenon can be explained in terms of the stability of the radical intermediate formed after attachment of the hydrogen radical.

EI-LINKED SCAN STUDIES OF DIMETHYLAMINOMETHYLENE-O-TRIALKYLSILYL NUCLEOSIDES

E. Y. Osei-Twum, L. A. Litorja, and N. M. Abbas, Research Institute, King Fahd University of Petroleum & Minerals, Dhahran 31261, Saudi Arabia.

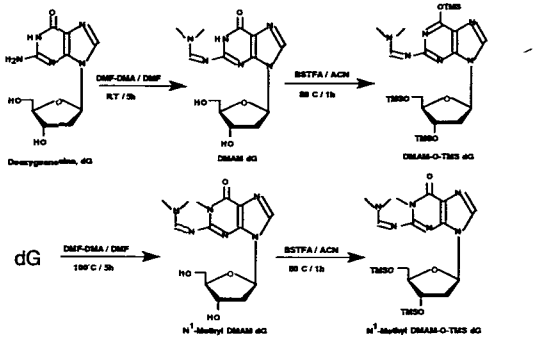
Introduction

The mass spectral fragmentation and rearrangement reactions of the trimethylsilyl derivatives of nucleosides have been extensively discussed. Recent studies indicate that the fragmentation and rearrangement reactions of the dimethylaminomethylene-O-trialkylsilyl nucleosides are much similar to those of the trialkylsilyl derivatives. Present in the mass spectra of these dimethylaminomethylene (DMAM) derivatives are ions that are postulated to arise from the DMAM group.

In this study we have used linked scan techniques to investigate the metastable transitions of the molecular ions (and other ions derived from them) of the DMAM-O-TMS derivatives of dA, dC, dG and N^1-methyl dG.

Methods

The DMAM-O-TMS derivative of each nucleoside (dA, dC, dG) was synthesized by allowing a mixture of 0.1 mmole of the compound and 1 mmole of dimethylformamide dimethylacetal (DMF-DMA) to stand in 500µL of dry DMF at room temperature for approximately 5 hours. Water (100-fold) was added and the sample was evaporated to dryness under a stream of nitrogen. [**Note**: The sample should not be heated during evaporation; doing this may lead to hydrolysis of the DMAM group.] The resulting residue was dissolved in 250 µL of dry acetonitrile and 200 µL of BSTFA was added. The reaction mixture was heated at 80°C for 1 hour (Scheme 1).



Scheme 1: Derivatization of Deoxyguanosine

The structure of each intermediate DMAM nucleoside was determined by ^1H nmr spectroscopy and by FAB+ MS. The nmr spectra of the samples, dissolved in DMSO-d_6, were obtained on a JEOL (Tokyo, Japan) JNM-GX270 spectrometer.The FAB mass spectra were obtained on a JEOL JMS-HX100 tripple sector (EBE) spectrometer equipped with a

saddle field neutral beam gun. Xenon fast atoms were used to bombard the samples, dissolved in glycerol, on a stainless steel probe.

EI mass spectra were obtained on the HX100 spectrometer. Samples were introduced into the ion source via a direct insertion probe. The probe temperature was programmed from 50°C to 250°C at 30°/min.

Results

The nucleosides react readily with excess DMF-DMA at room temperature to provide the DMAM derivatives. It had previously been observed that at higher temperatures, the guanine nucleosides reacted slowly to yield a product which is methylated at N^1. However, this reaction was never quantitative. In this study, the reaction was repeated at 100°C for 5 hours (Scheme 1). The mass spectrum of the O-TMS derivative indicated that the methylation went to completion.

The region between **M-15** and **BH+29** in the EI mass spectra of these compounds is populated by ions of low intensities. The B/E linked scan spectra of the molecular ions (Fig. 1) show that all four compounds give a prominent **M-28** which may be **M-CO** due to the sugar or **M-CH_2N** due to the base. Another prominent ion common to all the compounds is **M-TMSiOH**. The molecular ions also give the ions **M-C_2H_5N**, **M-C_2H_6N** and **M-C_2H_7N**. The guanine derivatives show ions which are prominent in both the molecular ion and base series. The purine nucleosides give ions of the base series **B**, **B+H**, **B+2H** and **BH+CHO** while the pyrimidine nucleoside, dC, gives the ions **B+C_2H_2O** and **B+C_2H_3O+TMS**.

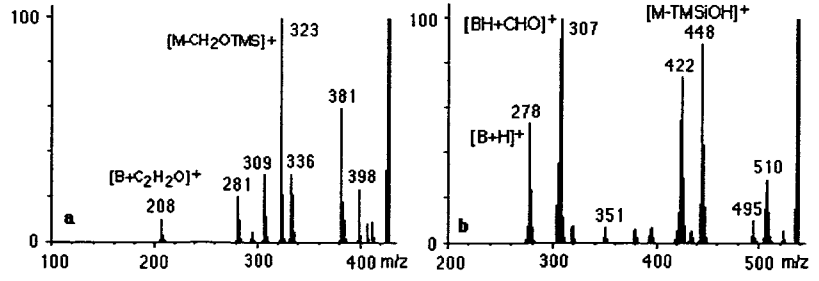


Figure 1: B/E Linked Scan Spectra of M^+ of DMAM-O-TMS (a) dC and (b) dG.

Conclusions

The first-formed ions in the region between **M-CH_3** and **BH+CHO**, a region normally populated by ions of low intensity, appear to be fairly unstable and fragment (rapidly) to other ions.

Fragmentation of dC differs considerably from those of the purine nucleosides, dA and dG; glycosidic bond cleavage is not observed for the molecular ion of the dC derivative. Glycosidic bond cleavage is a prominent feature in the fragmentations of DG and N^1-Me dG.

The nucleobases show fragmentation and rearrangement reactions which are predominantly of the DMAM group.

At higher temperatures the guanine nucleosides react completely with DMF-DMA to give the N^1-Me DMAM derivatives.

The Neutral Products from the Remote Site Fragmentation of Fatty Acid Derivatives.

Marcela M. Cordero and Chrys Wesdemiotis
Department of Chemistry, The University of Akron, Akron OH 44325-3601.

Tandem mass spectrometry (MS/MS) is an established technique for the structural characterization of biomolecules. Since MS/MS reveals only the ionic fragments originating from the biomolecular ion under investigation, a great deal of structural and mechanistic information is forfeited with the undetected neutral losses. Neutralization-reionization mass spectrometry (NRMS) makes possible the study of these neutrals by collisionally ionizing them, so that they can be detected and characterized in the corresponding neutral fragment-reionization (N_fR) mass spectra. In the present study, NRMS is applied to $[M-H]^-$ and $[M-H+2Li]^+$ ions from fatty acids in order to evaluate the information hidden in the neutral products which are simultaneously produced during the CAD process and, thus, obtain insight into the mechanism of charge remote fragmentation.[1-4]

The CAD spectra of the $[M-H]^-$ and $[M-H+2Li]^+$ ions from several saturated (undecanoic, myristic, palmitic, stearic) and monounsaturated (undecylenic, palmitoleic) fatty acids show a series of fragment ions corresponding to formal losses of C_nH_{2n+2}. These eliminations occur at the alkyl (or alkenyl) chain, *i.e.* remote from the charge site residing at the carboxylic group ("charge-remote" site fragmentation). They have been proposed to proceed via 6-membered ring transition states leading to cleavages of H_2 plus C_nH_{2n} (alkenes) instead of intact C_nH_{2n+2}.[3] Alternative mechanisms have been postulated that include loss of alkyl radicals by homolytic cleavages of the fatty acid ion.[4]

The CAD and N_fR spectra of $[M-H]^-$ from palmitic acid are shown in Figures 1a and 1b The CAD spectrum records the ionic fragments produced upon collisional activation with He. The N_fR spectrum shows the coproduced neutrals after reionization with O_2. The N_fR spectrum contains a dominant alkenyl ion series (*m/z* 27, 41, 55, 69) which is characteristic for a mixture of alkenes according to the electron impact spectra of hydrocarbons. The alkyl ion series (*m/z* 15, 29, 43, 57, 71), is much less important

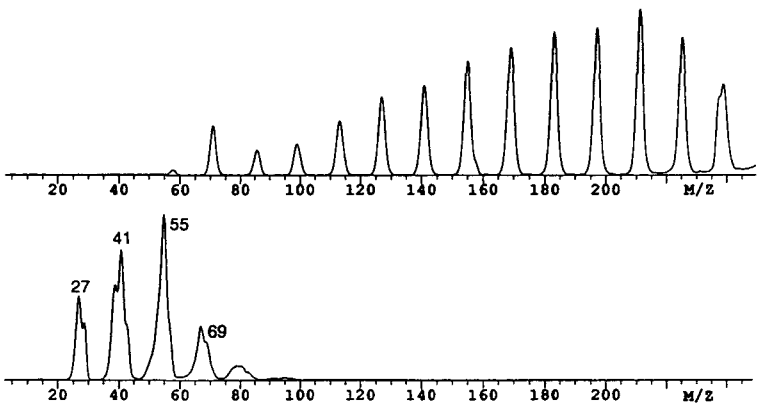

Figure 1. a) CAD, He and b) N_fR He/O_2 spectra of $[M-H]^-$ from palmitic acid.

Undecanoic, myristic and stearic acids also show predominance of the indicative alkenyl ions, consistent with alkene losses. As the chain size increases, so does the abundance of higher mass ions, as expected with the increasing size of the neutral losses.

The N_fR spectra of both $[M-H]^-$ and $[M-H+2Li]^+$ for each fatty acid, shows that the N_fR spectra are very similar, indicating that the neutral fragments from CAD of both precursors are essentially the same. Alkenoic fatty acids (undecylenic and palmitic) present N_fR spectra with more unsaturated ions (*m/z* 39, 54, 67, 79) because *diene* losses are possible with these acids. This is shown in Figure 2 for palmitoleic acid.

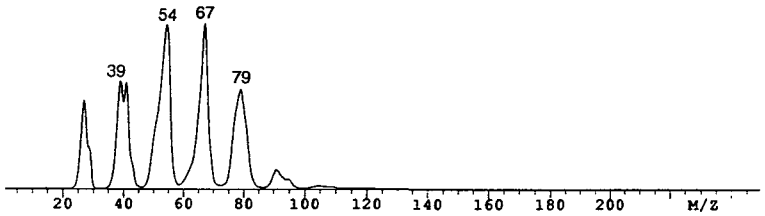

Figure 2. N_fR He/O_2 spectrum of $[M-H]^-$ from palmitoleic acid.

Reference spectra of alkanes and alkenes were obtained for the systems: hexane/1-hexene and heptane/1-heptene, by NR of the molecular ions. The results parallel those of electron impact spectra: alkanes give a predominant alkyl series, meanwhile alkenes preferably produce an alkenyl ions series These findings confirm that if alkanes were present in the neutral mixture, then prominent alkyl ions should be observed in the fatty acid N_fR spectra.

Alkyl radicals reference spectra were obtained from N_fR of ionized cyclohexylamine and cyclooctylamine, which have been found to lose alkyl radical mixtures upon CAD.[5] The spectra show that if alkyl radicals were eliminated during CAD of fatty acids, alkyl ions should also be present.

The relative NR yields (and, hence, R)[6] for isobutane/isobutyl/isobutene ions are similar Therefore, alkanes and alkyls would be expected to produce a detectable alkyl ion series if present in appreciable amounts in the neutral loss mixture.

In summary, the N_fR spectra are complex because many neutrals are eliminated simultaneously. Nevertheless, based on the available reference spectra, it can be concluded that under our experimental conditions the *predominant* neutral losses are *alkenes* (or *dienes*, in the case of monounsaturated fatty acids), not alkanes or alkyl radicals. This is consistent with the originally proposed mechanism for keV CAD of fatty acids ions.[3]

Collisional Dissociation Technique for Assignment of Metalloporphyrin Cation Electronic Structure

J. Ha and D. A. Laude, Jr., Department of Chemistry and Biochemistry,
The University of Texas at Austin, Austin, TX, 78712

Our study on porphyrin chemistry has been done using laser desorption/ionization Fourier transform ion cyclotron resonance mass spectrometry(LDI/FTICR). Metalloporphyrin products generated by metallation reactions of free-base porphyrins in plasma ignition LDI are used to study the electronic structure of metalloporphyrin cation. The metalloporphyrin cation has two extreme oxidized forms, a metal-oxidized form and a porphyrin ring-oxidized form (π cation radical), in catalytic and biological system. The metal-oxidized form is important in enzyme systems and has been used as a catalyst. Metalloporphyrin π cation radical play crucial roles in the primary photosynthetic events involving chlorophyll or bacteriochlorophyll which contains magnisium porphyrins and the oxidative metabolism involving heme(iron porphyrin) proteins such as the catalases, peroxidases, and cytochrome P-450s. Furthermore, metalloporphyrin cation radicals are classified into two ground state categories corresponding to removal of an electron from either of two high-lying porphyrin π molecular orbitals, a_{1u} or a_{2u}. The substituents on the porphyrin ring are important factors in determining whether the $^2A_{1u}$ or $^2A_{2u}$ π cation radical will be formed. For example, $[Zn\text{-}OEP]^+$ and $[Mg\text{-}OEP]^+$ belong to $^2A_{1u}$ system, while $[Zn\text{-}TPP]^+$ and $[Mg\text{-}TPP]^+$ belong to $^2A_{2u}$ system. Solution studies indicate that the electronic structure of metalloporphyrin cations depends strongly on many factors including ring substituents, incorporated metal, temperature, counter ion, and solvent. These factors have made the assignment of metal oxidation state in metalloporphyrin cation controversial.

We have developed a gas-phase collision-induced dissociation(CID) technique that readily distinguishes the electronic configuration of a particular metalloporphyrin cation incorporated by a first-row transition metal, Mg or Al. The biological model M-TPP cation in which M is a first-row transition metal, offers the following advantages: (1) It yields simple CID product spectra in which ions are produced by cleavage of the bond between the *meso*-carbon and phenyl substituents. (2) All cation radicals are known to belong to the A_{2u} ground state. (3) It has a planar structure which is not significantly distorted by the incorporated metal. This assumes that collision phenomena are independent of geometrical structures. Thus, CID results predict the effect of incorporated metal on the electronic structure of a metalloporphyrin.

Shown in figure 1 are CID spectra of $[Cu\text{-}TPP]^+$ obtained from controlled translational energy applied to ions. Abundance profiles of fragment ions, $[M\text{-phenyl}]^+$ and $[M\text{-(phenyl)}_2]^+$, *increase with laboratory translational energy. Shown in Figure 2 are the abundance curves for the* ratio of fragment ions to precursor ions obtained from the energy-resolved CID spectra of $[M\text{-}TPP]^+$. $[Zn\text{-}TPP]^+$ favors the cation radical form because Zn(II) has a stable d^{10} electronic structure. $[Cu\text{-}TPP]^+$ favors π cation radical form but exhibits exchange coupling between Cu and porphyrin ring. Determination of metal oxidation state in $[Ni\text{-}TPP]^+$ depends on the temperature in solution (D. Dolphin et. al. J. Am. Chem. Soc. 1975, 97, 5288) with $[Ni(III)\text{-}TPP]^+$ existing at 77K and $[Ni(II)\text{-}TPP]^+$ existing at 300 K. However, in the gas phase $[Ni\text{-}TPP]^+$ appears to be the intermediate between $[Ni(II)\text{-}TPP]^{+\cdot}$ and $[Ni(III)\text{-}TPP]^+$. $[Cr\text{-}TPP]^+$ which has almost same slope as $[Ni\text{-}TPP]^+$ belongs to the intermediate. The closeness of $[Fe\text{-}TPP]^+$ to $[Ni\text{-}TPP]^+$ in fragmentation pattern indicates that $[Fe(II)\text{-}TPP]^{+\cdot}$ is also in equilibrium with $[Fe(III)\text{-}TPP]^+$. This supports the suggestion that in cytochrome *b5* and *c* electron transfer to and from the iron occurs via porphyrin π cation radical transients. $[V\text{-}TPP]^+$ exhibits less fragmentation than $[Fe\text{-}TPP]^+$. $[Co\text{-}TPP]^+$ which has the least fragmentation favors the cation form.

$Fe(II)cyt \rightarrow [Fe(II)(cyt^{+\cdot})]$ (oxidized porphyrin) $\leftrightarrow$ $[Fe(III)cyt]^+$ (oxidized metal)

Two ground state systems (A_{1u} and A_{2u}) which metalloporphyrin π cation radical form has depending on different ring substituents were examined by CID. As shown in Figure 3, bacteriochlorophyll and chlorophyll model porphyrins, Al and Mg porphyrins exhibit quite different CID spectra. Al porphyrin cations, ($[Al\text{-}TPP]^+$ and $[Al\text{-}OEP]^+$), favor $[Al(III)\text{-porphyrin}]^{+\cdot}$, while Mg porphyrin cations, ($[Mg\text{-}TPP]^+$ and $[Mg\text{-}OEP]^+$), favor $[Mg(II)\text{-porphyrin}]^{+\cdot}$. Al(III) and Mg(II) incorporated into the porphyrin ring have the same stable electronic structure as Ne. The $[Mg\text{-}OEP]^+$ fragments more readily than $[Mg\text{-}TPP]^+$. This difference in the extent of fragmentation supports the argument that $[Mg\text{-}TPP]^+$ belongs to the $^2A_{2u}$ ground state, while $[Mg\text{-}OEP]^+$ has the $^2A_{1u}$ ground state. $[Zn\text{-}OEP]^+$ ($^2A_{1u}$ system) favors $[Zn(II)\text{-}OEP]^{+\cdot}$. $[Co\text{-}OEP]^+$ exhibits a similar fragmentation pattern to $[Zn\text{-}OEP]^+$. This suggests that in $[Co\text{-}OEP]^+$ Co has an exchange coupling with the porphyrin ring and $[Co\text{-}OEP]^+$ is inclined to favor the $[Co(II)\text{-}OEP]^{+\cdot}$ form.

It is found that positive charge distribution between metal and porphyrin ring in a metalloporphyrin cation is sensitive to the incorporated metal into porphyrin ring. The above CID results indicate that metalloporphyrin cation has two resonance forms rather than two seperated forms.

FRAGMENTATION OF TAXANE ANIONS

Steven H. Hoke, II and R. Graham Cooks, Department of Chemistry, Ching-jer Chang, Department of Medicinal Chemistry and Pharmacognosy, Purdue University, West Lafayette, IN 47907, U.S.A.

The ability to promote microtubule assembly exhibited by the natural product, taxol, is associated with promising cytotoxic properties[1]. Taxol has shown significant activity in the clinical trials of many types of cancers[2]. However, the promise of taxol as an anti-cancer drug is offset by its natural shortage. The bark of the Pacific yew tree, *Taxus brevifolia*, is currently a major source of taxol, but it has been estimated that this source of taxol will be depleted within the next 5-10 years[3]. As a result, sensitive and specific analytical methodologies are needed to rapidly screen plant extracts and tissue cultures in the search for alternative sources of taxol. The results presented here describe the development of a rapid method for the quantitation of taxol and the analogs cephalomannine and baccatin III as well as the utilization of other MS/MS scans to screen for known compounds and novel taxol analogs in a methanol extract of *Taxus mairei* needles.

Radical anions of taxanes were produced by desorption chemical ionization with ammonia as the reagent gas A Finnigan Triple Stage Quadrupole (TSQ) 700 mass spectrometer was used for the development of the analytical methodology. Fragmentation patterns of the radical anions of taxol, 10-deacetyltaxol, cephalomannine, and baccatin III are examined with 0.5 mTorr of argon as the collision gas and variable collision energies. Taxol and cephalomannine fragment producing the C13 side chain as an abundant peak in the product ion spectra; however, these compounds also have abundant peaks at m/z 525 and 526 in the collision energy range of 10-40 eV. The product ion spectrum of baccatin III, which has only a hydroxy substituent at the C13 position, shows a neutral loss of 60 mass units, producing an abundant peak at m/z 526. 10-Deacetyltaxol fragments quite differently than taxol as shown in Figure 1 The peaks at m/z 284 and 285 are the only fragment ions with greater than 10 % relative abundance in the mass range from 200 - 900 Da at collision energies ranging from 10-40 eV.

An MS/MS method of quantitation has been developed to simultaneously determine the compounds taxol, cephalomannine and baccatin III in crude plant extracts based on a parent ion scan of m/z 526. Quantitation of taxol, cephalomannine and baccatin III has been achieved by the method of standard addition and the quantitation of taxol has been demonstrated with the use of 10-d_3-acetyltaxol as an internal standard.

For quantitation by the method of standard addition, the sample was analyzed alone followed by analysis at two levels of standard addition, where each level was run in triplicate, for a total of nine runs. The quantitation was performed at the high femtomole to low picomole level with an analysis time of 35 minutes and a relative standard deviation of approximately 30 % for n = 3. 10-d_3-Acetyltaxol was used as an internal standard for the quantitation of taxol. No internal standard was available for cephalomannine or baccatin III; however, the ion current from these compounds was recorded and simultaneous quantitation could be performed with appropriate compounds. Quantitation of taxol with the 10-d_3-acetyl internal standard was demonstrated at the low picomole level with an analysis time of less than 5 minutes per sample and a relative standard deviation of approximately 12 % where n = 3.

Screening for some taxanes, such as 10-deacetyltaxol, cannot be performed with the parent ion scan of m/z 526 because of different fragmentation patterns. As described above, the fragmentation of 10-deacetyltaxol is substantially different from that of taxol. As a result, to

screen for this compound in plant extracts, a parent ion scan of m/z 284 (the C13 side chain of taxol) is performed. This scan was used with a *Taxus mairei* needle extract. The presence of taxol and 10-deacetyltaxol was confirmed in this methanol plant extract. In addition, the presence of several unknown compounds is observed. This parent ion scan reveals analogs of taxol with the same side chain as taxol but with chemical modifications to the diterpene skeleton. In the future, structural characterization of these new analogs of taxol by MS/MS will be studied.

Investigation of Fluoroformic Acid, Its Radical Cation, and Its Protonated Form by Tandem Mass Spectrometry Techniques.

Fred Wiedmann, Sarka Beranova, Jinnan Cai,
Marcela M. Cordero, Michael J. Polce, and Chrys Wesdemiotis

Department of Chemistry, The University of Akron, Akron, OH 44325-3601

Fluoroformic acid, FCOOH (M), is a simple molecule that does not exist freely, presumably because of autocatalytic decay into HF + CO_2. Recently, it was predicted to be kinetically stable if a single molecule could be isolated.[1] Neither have the ionized (M^+) nor the protonated (MH^+) forms of FCOOH been detected yet. Here, we report the first experimental characterization of these species.

It was thought that $FCOOH^{+\cdot}$ (*m/z* 64) could be produced from ethyl fluoroformate ($FCO_2CH_2CH_3$), which can be easily synthesized,[2] via the McLafferty rearrangement. However, collisional activated dissociation (CAD) shows that the small *m/z* 64 in the EI spectrum is $CH_3CH_2OF^+$. Thus, $FCOOH^{+\cdot}$ cannot be formed directly from ethyl fluoroformate due to the high ionization energy of fluorinated compounds. FCOOH + $C_2H_4^{+\cdot}$ is produced instead.

Protonated fluoroformic acid ($FC(OH)_2^+$, *m/z* 65) is formed from $FCO_2CH_2CH_3$ via the McLafferty +1 rearrangement. Its metastable ion (MI) spectra contains abundant ^+COOH (*m/z* 45) and FCO^+ (*m/z* 47) fragments, arising by FH and H_2O losses, respectively. Upon CAD, additional products appear, including $FCOOH^{+\cdot}$ (H loss, *m/z* 64). The MS/MS/MS spectra (MI , CAD) of the later radical ion are dominated by the structurally indicative fragments ^+COOH (*m/z* 45) and FCO^+ (*m/z* 47), corresponding to the elimination of $F^\cdot$ and OH, respectively. The neutralization-reionization (NR) mass spectrum of $FCOOH^{+\cdot}$ (see Figure 1) also shows the structurally indicative fragments ^+COOH (*m/z* 45) and FCO^+ (*m/z* 47). Additionally, a peak at *m/z* 44 ($CO_2^{+\cdot}$) suggests that some FCOOH undergoes consecutive decomposition into HF + CO_2 and a recovered parent ion in the NR spectrum shows that FCOOH is stable for at least microseconds. The NR spectrum of $FC(OH)_2^+$ (see Figure 2) contains a recovered parent ion and also all of the peaks found in the NR spectrum of $FCOOH^+$.

The charge reversal spectrum of protonated fluoroformic acid ($FC(OH)_2^+$, *m/z* 65) shows the expected large peaks at *m/z* 16, *m/z* 17, *m/z* 19, and *m/z* 63, that correspond to $O^\cdot$, $OH^\cdot$, $F^\cdot$, and $FCOO^\cdot$, respectively.

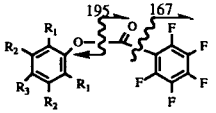
Negative Ion Chemical Ionization/Collisionally Activated Dissociation Studies of Some Aryl Pentafluorobenzoates.

M.-Y. Zhang, N. Molinaro, J. Cantone, T. Cinque and K. Chan
Wyeth-Ayerst Research, Princeton, NJ 08543.

Electron capture negative ion chemical ionization (ECNCI) mass spectrometry can achieve very low detection limits because it is a low energy process as well as a selective process. Pentafluorobenzoyl derivatization is often used to increase the EC cross section of many nonelectrophoric compounds. The ECNCI mass spectrum of phenyl pentafluorobenzoate (PPFB) (1) has been previously reported by Hunt *et. al.*, and only the molecular anion $M^{-\cdot}$ was observed[1]. Apparently the conjugated carbonyl-aromatic system was capable of stabilizing the additional electron, and fragmentation was minimal. However, upon chlorination of the phenyl ring, an increase in the intensity of the fragment ions has been observed by Vouros *et. al.*[2]. In addition to the fragment ions generated by simple bond cleavages, Vouros *et. al* have observed a fragment ion at $[M-64]^{-\cdot}$, and they postulated a rearrangement reaction[2]. However, the site specificity and the mechanism of this elimination process has not been investigated. In this study, ECNCIMS combined with collisionally activated dissociation (CAD) in a triple stage quardrupole instrument has been employed to study the mechanism of the rearrangement-dissociation reaction proposed by Vours[2]. Instead of chlorinated phenyl pentafluorobenzoates, we have studied a similar dissociation mechanism on the following aryl pentafluorobenzoates.

Figure 1



1. $R_1 = R_2 = R_3 = H$
2. $R_1 = R_2 = R_3 = D$
3. $R_1 = R_2 = H, R_3 = D$
4. $R_1 = R_3 = H, R_2 = D$
5. $R_1 = R_3 = D, R_2 = H$
6. $R_1 = H, R_2 = R_3 = CH_3$
7. $R_1 = R_2 = H, R_3 = CH_3$
8. $R_1 = R_3 = H, R_2 = CH_3$
9. $R_1 = CH_3, R_2 = R_3 = H$
10. $R_1 = R_3 = CH_3, R_2 = H$

The molecular anions $M^{-\cdot}$ of PPFB and deuterated PPFB's formed from ECNCI were quite stable, and only yielded a few low intensity fragment ions upon CAD. The daughter ion spectrum of the molecular anion of PPFB (1) showed the $[M-64]^{-\cdot}$ ion, and several fragment ions formed by simple bond cleavages of the ester anion. These ions are similar to those observed in the ECNCI spectrum of chlorinated PPFB reported by Vouros [2]. The exact mass of the $[M-64]^{-\cdot}$ ion obtained by high resolution (HR) measurement is 224.0246, confirming an elemental composition of $C_{12}H_4F_4$ (Δ=0.5 mmu). This observed elemental composition indicated that the $[M-64]^{-\cdot}$ is formed by the loss of CO_2 and HF from the molecular anion. From a parent ion scan experiment, the $[M-64]^{-\cdot}$ ion was observed to be formed from both $M^{-\cdot}$ and $[M-HF]^{-\cdot}$ ions. In the CAD spectrum of PPBF-d_5 (2), the $[M-64]^{-\cdot}$ anion was quantitatively displaced by $[M-65]^{-\cdot}$ indicating the source of the H in the HF loss is from the phenyl ring. However, both $[M-HF,-CO_2]^{-\cdot}$ and $[M-DF,-CO_2]^{-\cdot}$ ions were observed in the CAD spectra of 4-d_1-, 3,5-d_2- and 2,4,6-d_3-PPFB's (3, 4 and 5) with $[M-64]^{-\cdot}/[M-65]^{-\cdot}$ ratios of 95/5, 92/8 and 9/91, respectively. The parent ion spectra of the $[M-HF,-CO_2]^{-\cdot}$ and the $[M-DF,-CO_2]^{-\cdot}$ ions showed that they were produced from $[M-HF]^{-\cdot}$ and $[M-DF]^{-\cdot}$, respectively. The results implied the existence of two possible disso-ciation pathways to form the $[M-64]^{-\cdot}$ ion ($[M-65]^{-\cdot}$ for PPFB-d_n). As indicated in scheme 1, direct loss of HF from the molecular anion formed an intermediate I, and further loss of CO_2 from I produced the tetrafluorobiphenylene anion II. This elimination proceeded by the specific loss of the ortho-H atom and was the major dissociation pathway. On the other hand, the loss of HF could also involve the meta- and para-H atoms and formed an unstable intermediate I' which then rapidly isomerized to I through hydrogen rearrangements.

The proposed mechanism has been further supported by the ECNCI/CAD studies of the methylated PPFB's. In these studies, the $[M-64]^{-\cdot}$ ions were observed in the CAD spectra of 3,4,5-$(CH_3)_3$, 4-CH_3-, and 3,5-$(CH_3)_2$-PPFB's (6, 7 and 8). The parent ion mass spectrum of the $[M-HF,-CO_2]^{-\cdot}$ ion indicated that this ion was formed from the dissociation of the $[M-HF]^{-\cdot}$ and the $[M-CO2]^{-\cdot}$. Apparently, the methyl substitution

on the aromatic ring decreased the bond strength between the carbonyl group and the pentafluorophenyl ring. No $[M-64]^{-\cdot}$ ions were observed in the CAD spectra of 2,6-$(CH_3)_2$- and 2,4,6-$(CH_3)_3$-PPFB's (9 and 10), although the $[M-HF]^{-\cdot}$ ions were formed from both molecular anions upon CAD. The results demonstrated that the elimination of the 64 amu (HF and CO_2) only proceeded by the specific loss of the ortho-H atom (except in 7). Evidently, the hydrogen rearrangement proposed in the minor process was hampered by the ortho-methyl group of the compounds 9 and 10; no $[M-64]^{-\cdot}$ ions could be formed from the further dissociation of the $[M-HF]^{-\cdot}$ ion. These results also suggested that the formation of other ring closed intermediates which would directly produce the $[M-64]^{-\cdot}$ ion by further loss of CO_2 was unlikely.

In conclusion, ECNCI/CAD mass spectral data presented here suggested that there were three possible unimolecular dissociation pathways to form the $[M-HF,-CO_2]^{-\cdot}$ from the molecular anions of the aryl PFB's. The majority of $[M-HF,-CO_2]^{-\cdot}$ was generated from the specific loss of ortho-H atom. Formation of this ion by the loss of meta- or para-H atom through hydrogen rearrangement reactions was a less favorable process. No $[M-HF,-CO_2]^{-\cdot}$ ions were observed in the spectra of ortho-methylated phenyl penta-fluorobenzoates, since the hydrogen rearrangement reactions were hampered by the ortho-methyl group. The intermediates $[M-HF]^{-\cdot}$ (I, I' or I") were detected in the elimination process of all compounds examined; the intermediate $[M-CO_2]^{-\cdot}$ (III) was only observed in the dissociation reactions of the methylated PPFB's. Finally, the presence of the m/z $[M-64]^{-\cdot}$ ion in the ECNCI mass spectra of aryl PFB derivatives might be used as evidence for the occurrence of this system in unknown spectra.

H-Te-Te-H is stable in the gas phase

Cornelis E C A. Hop
Department of Chemistry, University of Wisconsin-Madison
1101 University Avenue, Madison, Wisconsin 53706.

Hydrogen peroxide, HOOH, has a strongly oxidizing nature and is consequently of significant commercial interest. HSSH has been isolated as well Although HSSH is unstable with respect to the reaction

$$H_2S_2 \rightarrow H_2S + S$$

this reaction, which is believed to be free-radical in nature, is sufficiently slow for HSSH to be stable for considerable periods.[1] Experimental data concerning the properties of the higher homologues, HSeSeH and HTeTeH, is rather sketchy, due to their high tendency towards dissociation into H_2Se + Se / H_2Te + Te. Here the gas phase stability of HTeTeH will be examined It has been suggested that HTeTeH is formed at the tellurium cathode in 0 003-0 02 N HCl solutions, but the evidence is not conclusive.[2] HTeTeH has been the subject of two theoretical studies[3,4] The optimized structure in the most recent study[4] has a TeTeH angle of only 72° and a dihedral angle of 76°. The cis and trans rotational barriers were calculated to be only 13 and 6 kJ mol^{-1}, respectively. These data suggest (i) that the potential energy curve is rather flat around the minimum and (ii) that the structural deformation required for dissociation into H_2Te + Te is remarkably small. No data have been presented regarding the stability of HTeTeH relative to the dissociation products H_2Te + Te

Neutralization-reionization (NR) mass spectrometry has established itself as an effective technique for examining the stability of supposedly marginally stable species in the gas phase. In the NR mass spectrum a signal at the same m/z value as the mass selected ions indicates that the neutral counterparts of the mass selected ions are stable on the time scale of neutralization-reionization experiments.

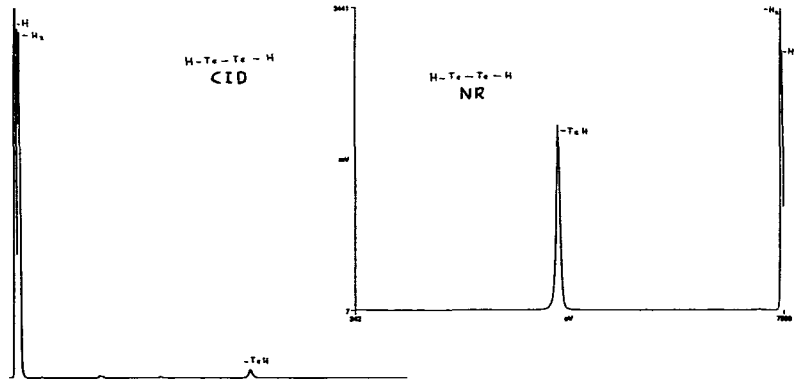
All metastable ion (MI) and collision-induced dissociation (CID) mass spectra were recorded with a VG Analytical ZAB-2F at the University of Wisconsin-Madison. He (80% transmission) was the target gas for CID The NR mass spectra were obtained with a VG Analytical ZAB-R[5] at McMaster University The NR mass spectra were acquired with N,N-dimethylaniline as neutralizing gas and O_2 as reionization agent

CH_3-CH_2-$CH(CH_3)$-Te-Te-$CH(CH_3)$-CH_2-CH_3 was synthesized as follows Sodium metal was added to liquid ammonia After the sodium had completely dissolved, tellurium was added. Addition of sec-butyl bromide to this solution gave the desired product, CH_3-CH_2-$CH(CH_3)$-Te-Te-$CH(CH_3)$-CH_2-CH_3. Analysis of the material via ^{13}C and ^{125}Te NMR and mass spectrometry confirmed the structure and showed no detectable impurities.

The mass spectrum of CH_3-CH_2-$CH(CH_3)$-Te-Te-$CH(CH_3)$-CH_2-CH_3 displays intense signals due to loss of one and two 2-butene molecules. Loss of Te from the molecular ions is not observed. This behavior contrasts that of other ditellurium compounds such as diphenyl ditellurium, ditolyl ditellurium and dinaphthyl ditellurium[6] The mass spectra of the latter compounds display intense loss of one and two Te atoms.

The molecular ions of CH_3-CH_2-$CH(CH_3)$-Te-Te-$CH(CH_3)$-CH_2-CH_3 lose 2-butene metastably The $[M - 2\text{-butene}]^{+\cdot}$ ions lose 2-butene and sec-butyl metastably in the ratio 10

8 The fragment ions due to the loss of two 2-butene molecules must have the formula $[H_2,Te_2]^{+\cdot}$ and their CID mass spectrum is shown below Since the TeH^+ signal is much more intense than the Te^+ signal, we assume that these ions have the H-Te-Te-H connectivity. (It is noteworthy that the $HTeTeH^+$ ions lose H_2 metastably and not Te.) Next, the HTeTeH ions were mass selected and subjected to neutralization-reionization (see below). An intense recovery signal proves unequivocally that H-Te-Te-H is stable on the time scale of neutralization-reionization experiments. Moreover, the NR mass spectrum resembles the CID spectrum quite closely.



As an extension of this work, the molecular ions were examined as well. The CID spectrum is dominated by signals due to loss of one and two 2-butene molecules Neutralization-reionization gave a spectrum which contains the same fragment ions as the CID mass spectrum (see above). However, obviously more extensive fragmentation occurs in the NR mass spectrum, giving rise to low molecular weight fragment ions. The recovery signal indicates that (a fraction of) the CH_3-CH_2-$CH(CH_3)$-Te-Te-$CH(CH_3)$-CH_2-CH_3^+ ions survives neutralization-reionization intact. The CID mass spectrum of the $[M - 2\text{-butene}]^{+\cdot}$ ions indicates that they have the H-Te-Te-$CH(CH_3)$-CH_2-CH_3^+ structure. The NR mass spectrum closely resembles the CID spectrum and an intense recovery signal indicates that H-Te-Te-$CH(CH_3)$-CH_2-CH_3 is a stable species in the gas phase.

Thus, neutralization-reionization experiments demonstrate that H-Te-Te-H and H-Te-Te-$CH(CH_3)$-CH_2-CH_3 are stable species in the gas phase.

Organic Sulfur Radicals by Neutralization-Reionization Mass Spectrometry

Scott A. Shaffer*, Thuy B. Tran, David Kuhns, and Frantisek Turecek
Department of Chemistry, BG-10, University of Washington,
Seattle, WA. 98195

Photochemical oxidation of atmospheric dimethyl sulfide (DMS) with the hydroxyl radical is presumed to proceed via two competing channels, i.e. hydrogen atom abstraction and attack at the DMS sulfur atom.[1] The former reaction yields the methylthiomethyl radical ($CH_3SCH_2\cdot$). Here we report on the preparation, properties, and dissociations of $CH_3SCH_2\cdot$ and $CD_3SCH_2\cdot$ as studied by neutralization-reionization ($^+NR^+$) mass spectrometry and ab initio calculations.

$CH_3SCH_2\cdot$ radicals are generated by collisional neutralization with a target gas of 8 keV $CH_3SCH_2^+$ formed by α-cleavage of $CH_3SCH_2CH_2SCH_3$, followed by product analysis after reionization with O_2. The measurements were taken on a tandem quadrupole acceleration-deceleration mass spectrometer described previously.[2] The $CH_3SCH_2\cdot$ radical is stable up to 4 microseconds with the highest % surviving ion (38% of CHS^+ base peak after reionization with O_2, Figure 1a.) obtained upon neutralization with trimethylamine or NO while Xe, cyclopropane, and dimethyldisulfide give much smaller yields.

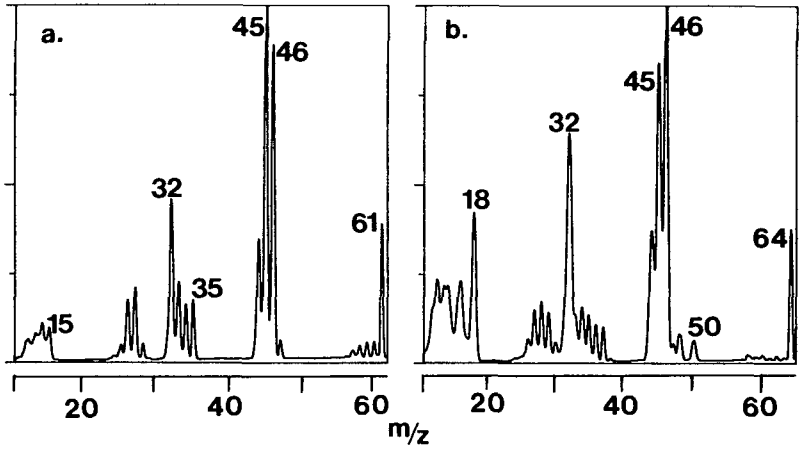

Figure 1 (a.) $^+NR^+$ spectrum of CH_3SCH_2 (TMA/ O_2 70/70 %T) and (b.) $^+NR^+$ spectrum of CD_3SCH_2 (TMA/O_2 70/70 %T).

The radical dissociates by losing CH_2 and CH_3; these are direct bond cleavages unaffected by hydrogen migrations, as evidenced by deuterium labeling (Figure 1b.). The CAD spectra (not shown) of $CH_3SCH_2^+$ and $CD_3SCH_2^+$ show losses of CH_3, CH_4, and C_2H_2 with hydrogen scrambling occuring in a near random manner. The $^+NR^+$ spectra show much less scrambling (-CHD_3 and CH_2D_2, 86.4 % and 13.6%, respectively (60/40% random)). Ion dissociations, such as the formation of H_3S^+, are less abundant in the $^+NR^+$ spectrum. The $^+NR^+$ spectra of other C_2H_5S isomers, generated by α-cleavage of 2-propanethiol and isobutane CI of ethlyene sulfide, differed markedly from CH_3SCH_2 generated above suggesting that isomerization to a common species does not occur.

Ab initio calculations (MP4(SDTQ)/6-311G** + ZPVE + ΔH_{298}) show $CH_3SCH_2\cdot$ as a stable structure with a relatively small Franck-Condon factor (40 kJ/mol, Figure 2.). Its dissociation by loss of methyl requires 103.6 kJ/mol. The calculated vertical and adiabatic ionization energies of the neutral are 6.94 and 6.59 eV, respectively. The calculated vertical recombination energy of the ion is 6.96 eV. These calculations support the overall stability of the radical as do the $^+NR^+$ spectra.

Neutralization-Reionization Mass Spectrometry (NRMS) Studies of Ethylene Glycol Polymers.

*Thomas L. Selby,[1] Marcela M. Cordero,[1] Robert P. Lattimer,[2] and Chrys Wesdemiotis,[1]
Department of Chemistry, The University of Akron, Akron OH 44325-3601,[1] and BF Goodrich R&D Center, 9921 Brecksville Road, Brecksville OH 44141.[2]

Tandem mass spectrometry (MS/MS) is widely used in the analysis of polymers. Conventional MS/MS, e.g. via collisionally activated dissociation (CAD), reveals only the charged species resulting from the unimolecular dissociation of the precursor ion. Using NRMS, the coproduced neutral species can also be detected. Previous studies of ethylene glycol polymers have been carried out at low energy and revealed a possible fragmentation mechanism by charge-site initiated cleavage. Using NRMS the neutral species resulting from these cleavages were investigated.

For the three linear ethylene glycol polymers polyethylene glycol (PEG), polyethylene glycol methylether (PEGME), and polyethylene glycol dimethyl ether (PEGDME) the ionic fragments from MH^+ were of the form $^+CH_2CH_2$-(-O-CH_2CH_2-)$_n$-O-R (A, R=H; B,R=CH_3). The corresponding neutral fragments resulting from this dissociation were of the form H-(-O-CH_2CH_2-)$_n$-O-R' (C, R'=H;D, R'=CH_3).

For the PEG (R=H) decamer the complete ion series (series A figure 1) was observed in the high energy (8 keV) CAD spectrum (n=0-9). The corresponding neutral-fragment reionization (N_fR) spectrum contains fragments that are characteristic of C (figure 2), which supports the mechanism previously proposed for charge-site initiated cleavage. The CAD spectrum of PEGME shows ions primarily of the form A and B (figure 1). As with PEG, the complete ion series were observed for the decamer. The corresponding neutral losses yielded ions characteristic of C and D (figure 2). PEGDME yielded a complete ion series (figure 1) for the decamer (n=0-9); as expected, the A series was of very low abundance in this case (figure 1). Correspondingly, the neutral losses detected in the N_fR spectrum are consistent with type D. From these results, it is clear that the ionic and neutral fragments for PEGME are a combination of the ionic and neutral fragments from PEG and PEGDME. These results corroborate the proposed mechanism.

A cyclic ether, 18-crown-6, was also investigated under the same conditions. The precursor ion (m/z 265) yielded daughter ions in a complete series separated by 44 Da. The base peak of the spectrum is at m/z 177, indicating a neutral loss of 88 Da. From the N_fR spectrum it is apparent that the fragmentation pathway occurs primarily through the loss of dioxane, all structure indicative fragments of which are found in the N_fR spectrum.

A Mass Spectrometric Study of Monoazo dyes

Jia-shen Wang
Clairol Inc., Stamford, CT 06922

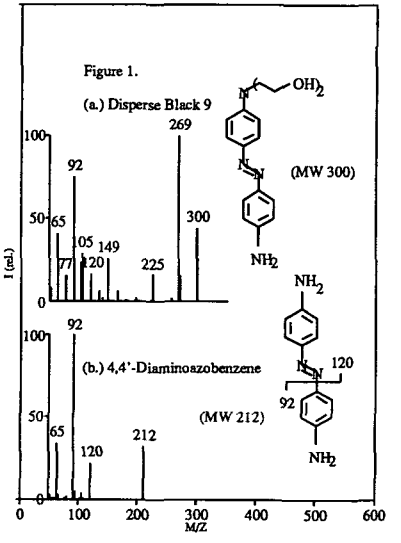
INTRODUCTION:

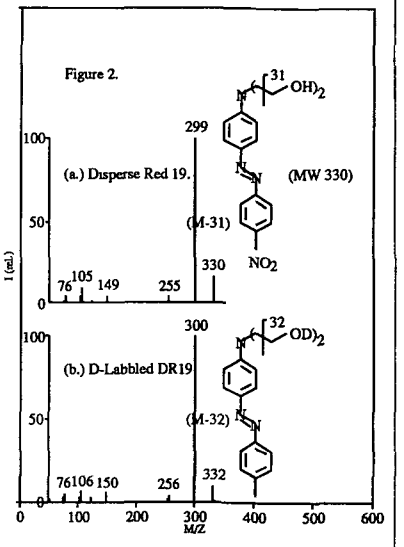
In the dye industry, azo dyes are by far the most important class, accounting for over 50% of all commercial dyes. There is great interest in characterizing the impurities of these dyes in industrial preparation, since these impurities are also color compounds. The monoazo dyes have a common structure of Ar-N=N-Ar'. Disperse Black 9 (shown in Figure 1a) is a typical one. We have successfully applied mass spectrometry to identify the structures of four common impurities of this dye. This report is about the spectral features of these compounds and their common patterns for structural elucidation applications.

RESULTS AND DISCUSSION:

One common impurity of Disperse Black 9 is 4,4'-Diaminoazobenzene. The spectrum (Finnigan 4500 GC/MS) of this impurity is shown in Figure 1b. This compound is a azo dye without a N-substituted amino group. The spectrum shows the typical fragment pattern of this compound type. The main fragment ions of this compound type are formed by cleavage of one Ar-N bond. In conjunction with a molecular ion peak, this spectral feature provides key structural information for one to derive the basic structure of an unknown.

Disperse Red 19 is also an impurity of Disperse Black 9. The mass spectrum of Red 19 is shown in Figure 2a. The base peak is formed by the cleavage of the C-C bond beta to the amine nitogen. We have verified this process by a D-labelled compound (Figure 2b). This fragment ion peak provides the key structural information for the amino functional group ($-NCH_2R$). The fragment ions resulted from this process can be easily found since they appear as M-R peaks for these compounds. In the present case, it is the M-31 peak.





Two other commonly found impurities of Disperse Black 9 are 2-(2-hydroxyethylamino)-4'-amainoazobenzene, 4-(2-hydroxyethylamino)-4'-amainoazobenzene. The basic structures of these two were derived based on the characteristic fragment ion peaks discussed above. The positions of the substituents were assigned by NMR (QE-300, Bruker) analyses.

CONCLUSION:

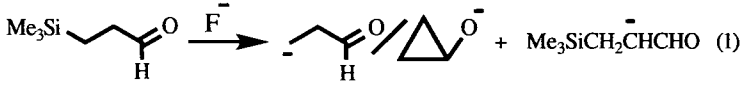
The results shown here demonstrate that mass spectrometry is a suitable technique for a structural elucidation application of monoazo dyes. The fragment ions initiated from an azo unit and an amino group are two types of peaks most important in this application. Four common impurities of Disperse Black 9 are 4,4'-diaminoazobenzene, 2-(2-hydroxyethylamino)-4'-amainoazobenzene, 4-(2-hydroxyethylamino)-4'-amainoazobenzene, and Disperse Red 19.

Do Reactivity Probes Reveal Ion Structure? The Case Against Dipole-Stabilized Ions

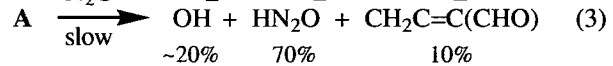
Gregg Dahlke and Steven Kass
Department of Chemistry
University of Minnesota, Minneapolis, MN 55455

The $C_3H_5O^-$ ion can exist in an open (β-formylethyl anion, $^-CH_2CH_2CHO$) or a closed (cyclopropoxide, c-$C_3H_5O^-$) form. We set out to tackle the following questions: What is the preferred structure of this ion? How important is dipole stabilization? and Can chemical probes be used to elucidate the structure? These queries were addressed by carrying out reactivity studies, ab initio molecular orbital calculations, and a negative ion photoelectron spectroscopy investigation.

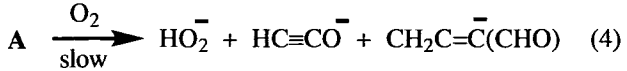
3-Trimethylsilylpropanal reacts readily with fluoride in our flowing afterglow device to afford a mixture of two ions as shown in equation 1. The reactivity of the $C_3H_5O^-$ ion was explored with a variety of reagents including D_2O, N_2O and O_2 (eqs. 2 - 4). The same results were also obtained when the $C_3H_5O^-$ ion was generated from cyclopropanol and its trimethylsilyl ether (c-$C_3H_5OSiMe_3$).



A
~25% 75%

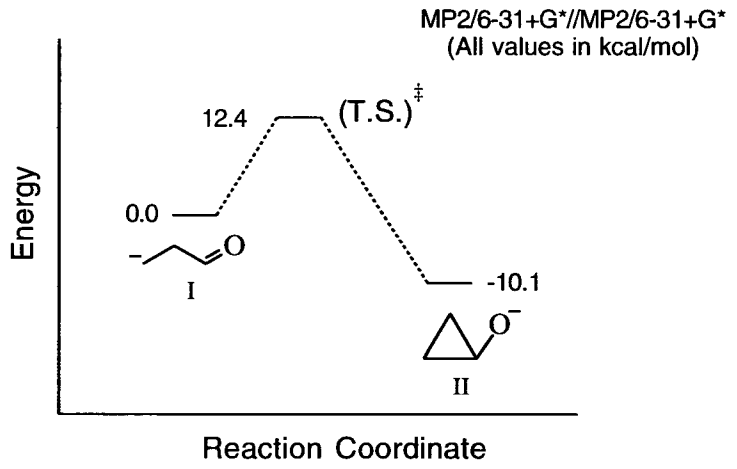


~20% 70% 10%



~50% 25% 25%

Molecular orbital calculations reveal that dipole-stabilization is not a dominant factor in stabilizing the open ion, cyclopropoxide is more stable than the open isomer, and that the inter conversion barrier is small (figure below). Consequently, the reactivity studies are misleading i.e. the Curtin-Hammett principle applies.



These results are supported by negative ion photoelectron spectroscopy studies which were carried out in collaboration with Professor Doreen Leopold and Mr. Sean Casey. It is also found that conjugation to a cyclopropane ring is nearly as good as to a vinyl group (17.1 vs 22.8 kcal/mol).

THE STRUCTURES OF $C_7F_7^+$ IONS.

Robert W. Holman, Jeffrey P. Kiplinger, Albert A. Tuinman, John E. Bloor, John E. Bartmess*,
Dept. of Chemistry, Western Kentucky Univ., Bowling Green KY 42101
Dept.of Chemistry, Univ.of Tennessee, Knoxville TN 37996-1600

Whether $C_7H_7^+$ has the benzyl or tropyl structure is one of the classic problems in mass spectrometry; variation in the C_7H_8 or C_7H_7X precursor structure results in a considerable change in the benzyl/tropyl ratio produced by electron ionization[1]. The tropyl cation is favored thermochemically by ca. 12 kcal/mol.[2] Perfluorination is known to drastically alter the properties and reactivity of molecules. Access to some rare C_7F_8 species[4] has prompted us to examine the benzyl/tropyl question here.

The benzyl/tropyl ratio of $C_7F_7^+$ ions from EI of the C_7F_8 precursors perfluorotoluene (PFT), perfluoronorbornadiene (PFN), perfluorobicyclo[3.2.0]-2,5-heptadiene (PFH) have been examined, using both chemical reactivity in an ICR spectrometer, and low energy CID.

The ion/molecule work was done on an ICR spectrometer: homebuilt, 1.4 T electromagnet, running in either rapid scan or FT mode. $C_7F_7^+$ ions were produced by 30 V EI; EI at 13 eV did not affect the results. The low energy CID spectra were obtained on a VG ZAB-EQ, BEqQ geometry: EI at 70 eV (no change at 12 V EI or $C_7F_7^+$ from metastable decay); $C_7F_7^+$ ions at 50 eV KE (lab); Ar collision gas pressure: nominally 6 x 10^{-6} torr, actual ca. 10^{-3} torr.

Arene nucleophiles used to detect the protio-benzyl (reactive) and tropyl (non-reactive) populations are not reactive with these stabilized perfluoro cations. $(Me_3Si)_2NH$, more nucleophilic with a structure sensitive to the presence of fluorine atoms, reacts as shown ($k = 1 \times 10^{-10}$ at 305 K. The entire (>96%, based on signal/noise) $C_7F_7^+$ population from PFT reacts in this fashion.

$$\underset{m/z\ 217}{C_6F_5CF_2^+} + (Me_3Si)_2NH \rightarrow \underset{m/z\ 286}{C_6F_5CF{=}\overset{+}{N}HSiMe_3} + FSiMe_3$$

In contrast, $C_7F_7^+$ ions from PFN and PFH are unreactive with $(Me_3Si)_2NH$ ($k < 1 \times 10^{-12}$) no product ion at m/z = 286 is observed above the noise level.

For PFT, the IE in the ICR is 10.2 eV (lit: 9.9 eV[2]), and $AE(C_7F_7^+)$ = 13.6 eV. The relative value of these two measurements is probably more accurate than their absolute values, indicating that fluorine loss requires ca. 3.4 ± 0.4 volts (78 ± 10 kcal/mol) of energy above ionization. This is a reasonable value for a bond strength in a radical cation.

The low energy CID results support the above conclusions: spectra of $C_7F_7^+$ from PFH and PFN are very similar, and somewhat different from that from PFT. Although the CID spectra of all three consist of the same masses (Table), in PFT the m/z 69 (CF_3^+) ion is 60% more intense relative to the base fragment peak at m/z 167 ($C_6F_5^+$) than in the spectra from either PFH or PFN. The latter two CID spectra are identical to within 3%. CF_3^+ is more intense in the spectrum of the (presumed) benzyl form, where there is more than one fluorine atom on some carbon in the precursor structure.

The m/z $69^+/167^+$ intensity ratio for PFT is constant for ionizing electron energies of 70 eV vs. 12 eV: internal energy effects on the

CID results are minimal. $C_7F_7^+$ metastable ions from 1, formed in the first FFR, show essentially the same CID spectrum as those produced by direct EI. The $69^+/167^+$ ratio in this metastable/CID experiment was 10% greater than for the source-produced $C_7F_7^+$ ions, but all other ions' abundances relative to 167^+ were the same to within 3%. There was insufficient sample of PFN and PFH to carry out the metastable/CID experiments with these isomers.

Ab initio MO calculations [enforced symmetry, Gaussian 90] indicate that the $C_6F_5CF_2^+$ is -9.7 kcal/mol more stable 9MP2/6-31G*) than c-$C_7F_7^+$. AM1 semi-empirical calculations [geometry optimized, near symmetric, MOPAC 5.0] put the perfluorobenzyl form 25.5 kcal/mol more stable than the perfluoro tropyl cation. The AM1 minimum energy reaction pathway (MERP) for species on the $C_7F_8^{+\cdot}$ and $C_7F_7^+$ hypersurface is shown below.

Why the reversal of stabilities for protio vs. fluoro benzyl vs. tropyl? Fluorine stabilizes an adjacent cation by a pi-donation interaction, so it should have a larger stabilizing effect when the bulk of the charge is localized at a site where this donation effect can operate. In the perfluorobenzyl cation, by AM1 calculations there are 0.59 charge units on the exo $-CF_2$ group, while in benzyl cation itself there are 0.47 charge units on the exo $-CH_2$ group. The fluorines are thus localizing the charge at the α-carbon, relative to the protio case.

We thank NSF for support of RWH through the Summer Research Program in Chemical Analysis, grant CHE-9023377. We also thank Professors D. M. Lemal and W. P. Dailey for the generous gift of PFN and PFH.

STRUCTURAL INVESTIGATION OF IMPURITIES IN SYNTHESIS OF LY255582.

*A. T. Murphy, A. P. Breau, J. A. Werner, D. K Robbins, Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285

Introduction:

Impurities in the synthesis of LY255582 have been shown to originate from the chemical intermediate LY272922. GC/MS analysis of the LY272922 intermediate detected desmethyl and methylated impurities. The site of demethylation of the intermediate presumably occurs at the 4-carbon of the piperidine ring, but was not confirmed in this investigation. The site of methylation was confirmed by solutions of LY272922 in methanol-d_4. The exchangeable protons of LY272922 occur on the phenolic oxygen and the secondary amine. The deuterated and non-deuterated standards were compared by electron impact GC/MS. The LY272922 in deuterated methanol showed the exchange of only one deuterium in the methylated peak imputiry while the peak corresponding to LY272922 incorporated two deuteriums. Analysis of fragment ions confirmed the site of methylation on the secondary amine as evidenced by the relative abundance of the 84, 72, 71, and 70 amu fragments.

Methods:

A Finnigan 4500 GC/MS was used for all analyses. The GC was equipped with a 30m x 0.32mm i.d. fused silica capillary column coated with DB-1 (d_f of 1.0 mm). LY272922 standard solutions were prepared in methanol and methanol-d_4 and injected in the split mode at a ratio of 15:1. The injector temperature was set at 250°C. The column flow was set at 35 cm/sec. The column temperature was set at an initial temperature of 100°C for 1.5 minutes and then ramped at a linear rate of 5°C/minute until the final temperature of 280°C was achieved. The column was held at the final temperature of 280°C for 5 minutes.

The mass spectrometer was operated in the electron impact ionization mode. The source temperature was set at 170°C. The spectrometer was scanned from 30 to 450 amu at a rate of 1 second/scan. The electron multiplier was set at 1150 eV in the positive ion detection mode. The electron energy was set at 70eV while the ionization energy was set at 180 mA. Data were collected using SuperIncos software.

Results and Discussion:

The site of methylation was determined by examination of the fragment ions of the methylated peak in methanol and methanol-d_4 solutions. Comparison of the mass spectra of the methylated 272922 peaks show that only one deuterium was exchanged as evidenced by the increase in molecular weight from 219 amu (Figure 1) to 220 amu (Figure 2). The 84 amu fragment ion of the methylated impurity is the most abundant ion in the spectrum (Figure 1). The proposed mechanism for the formation of the 84 amu ion is shown in Scheme I[1]. The methylated 272922 also shows a 70 amu fragment resulting from the loss of the neutral radical as proposed in Scheme II[1]. The 272922 (unmethylated) shows a major fragment ion of 71 amu which is proposed to originate from the mechanism shown in Scheme III[1].

The deuterium labeled 272922 showed the incorporation of one deuterium on the 3-methyl piperidine as evidenced by the 1:1 ratio of 71/72 amu fragment ion not seen in the 272922 standard in methanol (Figure3 and 4). Failure of the methylated 272922 to incorporate deuterium in the piperdine ring, as evidenced by no mass ratio increase of the 70/71 amu ions, and the relative abundance of the 84 amu ion in the methylated impurity suggest the site of methylation to be the secondary amine.

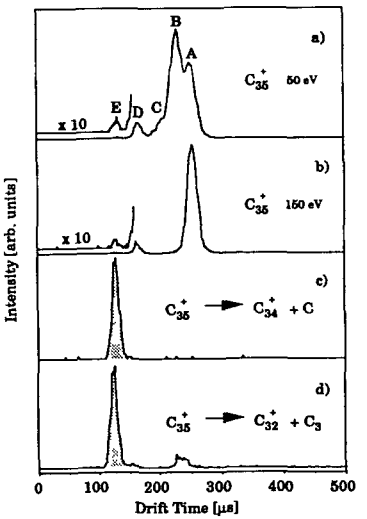
Where do Fullerenes come from, Anyway.

Gert von Helden, Nigel G. Gotts and Michael T. Bowers
Dept. of Chemistry, University of California, Santa Barbara, CA 93106

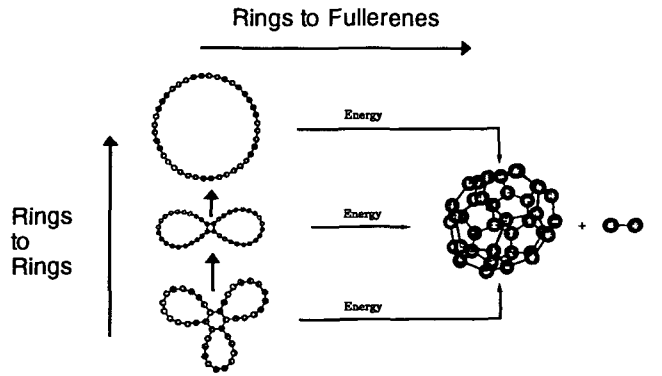
The structure and stability of carbon clusters and carbon cluster ions have long been a highly debated issue. Small clusters with less than 60 atoms are precursors for fullerene formation and understanding their structure and energetics is therefore crucial for understanding the fullerene formation processes. We recently applied "Ion Chromatography" (IC) to carbon cluster cations[1] and anions.[2] Various structural families have been identified. However, "cup" shaped clusters, that long have been believed to be the precursors for fullerenes, are completely absent for all clusters in our experiment. This results is intriguing since, for large clusters, we do observe high abundances of fullerenes.

We will demonstrate here that IC, in combination with annealing studies and computer modelling, is a powerful tool that allows us not only to characterize cluster structure and isomeric forms but also gives unique insight into the processes involved in fullerene formation.[3] Experimental details can be found in the literature[1,2,3] and only a brief outline will be given here. carbon cluster anions or cations are generated in a laser vaporization/supersonic expansion source. After mass selection using a mass spectrometer, a pulse of ions is injected into a high pressure drift cell. Different isomeric form have different drift times in the cell and therefore exit the cell at different times. Ions exiting the cell are mass analysed and time resolved detected.

A typical "arrival time distribution" (ATD) is shown in Fig.1, trace a. Computer modelling of the drift time allows us the assign the different peaks as resulting from a monocyclic ring (A), a bicyclic ring (B), a tricyclic ring (C), a 3-D ring (D) and a fullerene (E), similar to those in Fig. 2.(see also ref. 1). If the ions are injected into the drift cell at higher energies, annealing and/or collision induced dissociation (CID) can occur. Trace b shows the ATD for C_{35}^+ when injecting C_{35}^+ at 150 eV into the cell (about 5-30 % of this energy will be transfers into internal modes). Clearly, the bicyclic ring (B) and the tricyclic ring (C) are completely absent. Scanning the quadrupole mass filter after the cell, we noticed a substantial amount of fragmentation is occurring. This fragmentation happens right in the beginning of the cell so that, by setting the quadrupole to the right mass, ATDs for the products can be obtained. ATDs for the main CID products C_{34}^+ and C_{32}^+ are shown in Fig. 1, trace c and d.



Computer modelling of the drift times allows us to unambiguously assign the shaded peaks in Fig. 1 as fullerenes. From our data it seems that two processes are happening when carbon clusters with more than 33 atoms are injected at high energy into the drift cell:



a) annealing of bi- and tricyclic rings to monocyclic rings and b) CID of planar rings with the resulting fragment ions being nearly 100% fullerenes.

We performed annealing experiments with all C_n^+ clusters with $30 \leq n \leq 40$ at 150 eV injection energy. The probability of collision induced dissociation (CID) and fullerene formation increases dramatically as cluster size increases For example C_{31}^+ undergoes only to a small amount of CID (<5%) whereas C_{39}^+ dissociates 77% of the time with almost all dissociation products being fullerenes. The first fullerene observed is C_{30}^+ resulting from C_3 loss in the annealing of C_{33}^+. This process is fairly inefficient for C_{33}^+, with only 13% of all clusters undergoing CID and only 17% of the CID products being fullerenes. For precursors with an even number of atoms, the first fullerene fragment observed is C_{34}^+, resulting from the loss of C_2 from C_{36}^+.

This data implies that the fullerene formation via CID and annealing of large ring systems is not only important in laser vaporization sources but also in C_{60} carbon arc reactors. Fullerene formation via "cup" structures as intermediates is not occurring since none of these structures is observed for either carbon cluster anions or carbon cluster cations.

The Resilience of C_{60} Towards Decomposition and Ionization

Y. Gotkis, J. Laskin and C. Lifshitz

Department of Physical Chemistry and The Fritz Haber Research Center for Molecular Dynamics, The Hebrew University of Jerusalem, Jerusalem 91904, Israel

Buckminsterfullerene, C_{60} demonstrates delayed ionization up to the μsec range. C_{60}^+ is very resilient towards SID and CAD. Is C_{60} the most stable large molecule known? The energy required to fragment C_{60} has been calculated to lie in the 11-14 eV range. Experimental values are considerably lower: 4.6 - 7.64 eV.

We have performed two types of calculations: (1) Breakdown graphs were calculated for the decomposition reaction:

$$C_{60}^+ \rightarrow C_{58}^+ + C_2 \qquad (1)$$

(2) Rate energy dependences were calculated for the dissociation and ionization of C_{60}, assuming the latter process is due to thermionic emission. In both sets of calculations, the critical energy for reaction (1) and for the neutral analogue of (1) were varied between two recent extreme experimental values.

Time resolved breakdown curves are shown in Fig. 1. While at $t=1\mu s$ (the typical time under SID) C_{60}^+ is intact even for a transferred energy of 40 eV, it is completely dissociated at t=1S. This result demonstrates that even for a critical energy of only 6.9 eV, the resilience to dissociation under SID is understood - not enough time is available for dissociation - and a higher critical energy of activation need not be invoked. Competition between dissociation and ionization is observed in Fig. 2. Critical energies for the neutral analogue of (1) were calculated through a simple thermochemical cycle to be 0.54 eV higher than those of the ionic reaction. Those for (1) span the range from ~5.2 eV[1] to ~7.1 eV[2]. Neutral products of C_{60} were observed experimentally.[3] Dissociation cannot compete with thermionic emission if E_o is much higher than ~8 eV. The known heat of formation of C_{60} dictates a neutral binding energy[4] of 7.8 + Δ eV, with $\Delta > O$. Theory predicts $\Delta >> O$, but experimental results to date give a rather small Δ value.

Isotope Effects on the Mass Spectral Fragmentation of the Mixed Glycerol/d_5-Glycerol Clusters

Chhabil Dass
University of Tennessee, Memphis, TN 38163, USA.

Glycerol is the most frequently used liquid matrix in FAB and LSIMS modes of ionization. During desorption/ionization, the energy acquired by the matrix ions in excess of their ground state causes them to dissociate into smaller fragments. Thus, several monomeric and oligomeric ions of matrix and their fragments are observed. All these ions, on one hand, constitute a chemical background noise and often interfere in the FAB analysis. On the other hand, they facilitate mass assignment by acting as reference ions. Therefore, a clear understanding of the fragmentation behavior of matrix ions is very important. Isotope substitution leads to differences in the rates of the gas-phase fragmentation reactions. Therefore, it is important to have knowledge of isotope effects associated with these fragmentations.

To investigate fragmentation characteristics of the proton bound gas-phase ions of glycerol and its oligomers and to determine the associated secondary isotope effect (SIE), the following experiments were conducted: (a) obtain CID-MIKE spectra of the $(M+H)^+$ ions of monomer, dimer, trimer, and tetramer of glycerol (G) and of d_5-glycerol (dG), (b) obtain precursor ion spectra of a few important fragment ions derived from the $(G+H)^+$ and (c) determine the SIE from the CID-MIKE data of the proton bound mixed clusters of G and dG.

This study used a VG AutoSpec Q mass spectrometer of E_1BE_2-qQ geometry and Cs^+ ions of 30-35 keV energy as the source of ionizing beam. The ions were accelerated out of the source to a potential of 8 kV. The precursor ion spectrum was obtained in the first FFR under linked-field scan at constant B^2/E_1. The product ion spectrum was acquired by using MIKES technique; the precursor ion was mass-selected in the third FFR by adjusting E_1 and B and its spectrum was obtained by scanning E_2. Helium was used as the collision gas in both these experiments. All spectra were acquired under computer-control scans.

The gas-phase $(G+H)^+$ ion predominantly fragments *via* the losses of H_2O to yield *m/z* 75 and 57 (Figure 1 and Scheme 1) and *via* the loss of CH_3OH to yield *m/z* 61. The losses of CH_2O, CH_2OH, and CH_3OH from the *m/z* 75 lead to the formation of *m/z* 45, 44, and 43. A loss of H_2O from the *m/z* 61 provides an alternative route to *m/z* 43. The precursor ion spectrum reveals that the *m/z* 31 ($^+CH_2OH$) and 29 (^+CHO) are predominantly derived from *m/z* 45 and 57, respectively. The presence of *m/z* 34 in the CID-MIKE spectrum of the $(dG+H)^+$ ions reveals that a small population of *m/z* 31 also exists as CH_3O^+. The proton bound dimer, trimer and tetramer undergo mainly the loss of glycerol molecules (Figure 2). The *m/z* 93 in these spectra corresponds to the $(G+H)^+$ ion and exhibits all the fragmentations noted in Scheme 1.

Isotope substitution affects the rate of unimolecular gas-phase fragmentations. The effect is very profound when H and D are considered because of a large difference in their mass. The primary isotope effect results when cleavage of the isotopically substituted bond occurs (e.g., C-H, O-H, etc.). The rate of cleavage of the bond remote from the site of isotope substitution is also affected but to a lesser extent and leads to SIE. Isotope effect is caused by the fact that the critical energy of the reaction involving lighter isotope is lower than that involving heavier isotope. These are the direct consequence of the small differences in the zero point energies of the transition states of the two competing reactions.

To determine the SIE associated with fragmentation of the proton bound oligomers of glycerol, the CID-MIKE and metastable ion spectra of $(G+dG+H^+)$, (G_2+dG+H^+), $(G+dG_2+H^+)$, and $(G_2+dG_2+H^+)$ were acquired (Figure 3). The SIE, defined as SIE = k_h/k_d (where, k is the rate of the reaction), was calculated for the competing reactions leading to the loss of labeled and unlabeled glycerol molecules. As shown in Table 1, normal isotope effect was observed. The effect is greater for metastable ions, and is in agreement with the RRKM theory, according to which SIE is expected to increase with decrease in internal energy.

The Effects of Molecular Size, Alkali Metals and Charge Type on the Metastable Unimolecular Decomposition of Oligosaccharides in an External Ion Source Fourier Transform Mass Spectrometer

Lambert C. M. Ngoka and Carlito B. Lebrilla. Department of Chemistry, University of California, Davis, CA 95616.

Studies on the metastable decomposition of oligosaccharides in a liquid SIMS Fourier transform mass spectrometer were reported recently[1]. The present studies examine the effect of molecular size, alkali metal cationizing agents and charge type on the metastable unimolecular decomposition of linear and cyclic oligosaccharides in this instrument.

A 30% solution of thioglycerol in glycerol was used as the matrix. Sample preparation and loading were accomplished by placing about 10 µl of the matrix on a copper probe tip and depositing 5 µl of approximately 0.50 M aqueous solution of the oligosaccharide on top of the matrix drop on the probe tip before introduction into the ion source. A 10-millisecond pulse was used for ion production and injection into the analyzer cell.

Figure 1 shows the metastable decay profiles of Protonated α-cyclodextrin, maltohexaose, maltopentaose and maltotetraose through 10 milliseconds detection delay time. Oligosaccharides studied exhibit an exponential decay of the protonated parent, $[M+H]^+$, which levels off at five milliseconds after ion injection and remains essentially invariant at a background level. These decompositions are accompanied by concomitant increases in the intensities of lower ion fragments. As evident in the diagram, the unimolecular decomposition rate increases with molecular size. This has been attributed to a sequential fragmentation mechanism in which a fragment ion has sufficient internal energy to fragment further. As well, it is conceivable that the energy imparted into the ions by the Cs^+ primary beam is commensurate with molecular size.

Figure 2 shows a plot of the first order rate constants for the metastable decay of cationized and deprotonated α-cyclodextrin. The fact that protonated oligosaccharides decay faster than metallated oligosaccharides could be due to the substantial weakening of the glycosidic bonds by protonation, borne out by the much greater exothermicity of the proton-oxygen attachment reaction. The exothermicity of the ion attachment to the oxygens of the oligosaccharide could be inferred from the aqueous phase hydration energies, which are 1091, 519, 406, 322, 293 and 264 kJ/mol for H^+, Li^+, Na^+, K^+, Rb^+, and Cs^+ respectively[2]. More exothermic ion attachment coordination is seen to bring about greater degree of fragmentation and faster rate of metastable decomposition.

Oligosaccharide anions decay about two times slower than the corresponding cations. This may be due to the weakening of glycosidic bonds by cationization in the latter.

MECHANISMS OF FRAGMENTATION OF CATIONIC PEPTIDE IONS

Hong Zhao and Jeanette Adams, Department of Chemistry, Emory University, Atlanta, GA 30322.

Sequence-specific product ions are formed by collision-induced decomposition (CID) of either $(M + Cat^{2+} - H)^+$ ions cationized with alkaline earth metal ions (1), $(M + Cat^+)^+$ ions cationized with alkali metal ions (2), or $(M + H)^+$ ions (3). Fragmentation mechanisms that involve hydrogen transfer have been studied and different mechanisms have been proposed. Here, we use deuterium-labelled peptides to address the source(s) of hydrogen transferred in formation of several commonly observed sequence product ions (4). The peptides include GGV, YPFAG, YPFA(CD_3)G, YPFAG(CD_2)-NH_2, G(CD_2)(CD_2)V, and GGV-d_5. Fast atom bombardment is used to form the gas-phase ions. CID spectra of decompositions that occur in the first field-free region of a VG 70-S forward geometry mass spectrometer are acquired by using linked scans at a constant ratio of B/E.

Results from the above peptides indicate that the amide group of the *n-m* amino acid can be a source of hydrogen transferred in the formation of $(a_{n-m} + Ca - 2H)^+$, $(a_{n-m} + Li - H)^+$, and $(a_{n-m})^+$ ions. In addition, the CH(R) group of the *n-m+1* amino acid also can be a source for formation of $(a_{n-m} + Ca - 2H)^+$ ions. Either the amide group or the CH(R) group of either the *n-m+1* or the *n-m+2* amino acids can be the source of hydrogen transferred in the formation of $(y_{n-m} + Ca)^+$ and $(y_{n-m} + Li + H)^+$ ions. Only the former serves as the source in the formation of $(y_{n-m} + 2H)^+$ ions. Either the CH(R) group of the *n-m+1* amino acid or the C-terminus can be the source of hydrogen transferred in the formation of $(c_{n-m} + Ca)^+$ ions.

Our results support some previously proposed mechanisms and provide evidence for others. Our study, however, does not reveal some chemistry that has been observed by others. Thus, it is clear that sources of hydrogen transferred in the formation of particular product ions can vary with both the starting peptide molecule and with the type of positive ion studied (cationized with either Ca^{2+}, Li^+, or H^+). Consequently, our study in conjunction with the previous ones shows that several mechanisms can account for formation of each product ion, and the preference of one mechanism over another will be dictated by peptide structure and the type of cation studied.

FUNDAMENTAL PROCESSES IN DECOMPOSITIONS OF SIMPLE AMINE AND AMIDE IONS

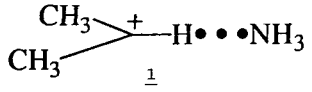
Henri E. Audier[1], Gérard Provot[2], Jean-Pierre Morizur[2], and T. H. Morton[2]

[1]Laboratoire des Mécanismes Réactionnels, Ecole Polytechnique, 91128 Palaiseau, France
[2]Laboratoire de Chimie Structurale, Université Paris VI, 75230 Paris, France
[3]Department of Chemistry, University of California, Riverside, CA 92521-0403, USA

Simple primary alkylamines and simple N-alkyl amides exhibit rearrangements in their mass spectra. Many of these correspond to pathways by which sequence information is lost in the course of CI, FAB-MS, and other techniques used for the mass spectrometric analysis of polypeptide structure. Molecules with primary alkyl groups attached to nitrogen represent a case in point. In studies of metastable protonated n-propyl amines we find that seven alkyl hydrogens scramble, followed by expulsion of propene. Isotopic labeling gives the following proportions:

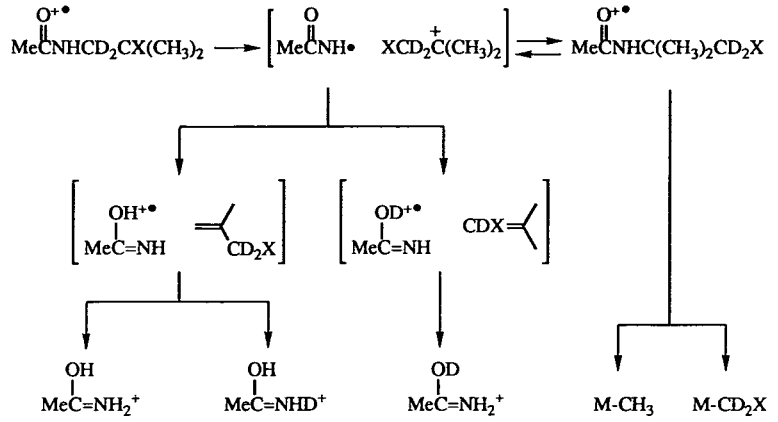
Parent Ion	Proportion NH_3D^+	Proportion NH_4^+
$CH_3CH_2CD_2NH_3^+$	30%	70%
$CD_3CH_2CH_2NH_3^+$	47%	53%
$CH_3CD_2CH_2NH_3^+$	15.5%	84.5%
$CD_3CH_2CD_2NH_3^+$	81%	19%
$CH_3CHDCH_2CH_3^+$	7%	93%

Given experimental uncertainties on the order of ±1% we infer that all of the α and γ C-H hydrogens scramble with one of the β-hydrogens, and that these 7 are the ones that end up on the ammonium ion, without any exchange between CH and NH hydrogens. This implies that the n-propyl has rearranged to an isopropyl group, presumably via an ion-neutral complex. The question remains whether the [iPr^+ NH_3] complex collapses back to isopropylammonium (which might then eliminate propene via a concerted pathway via a 4-member cyclic transition state[1]). We have examined the dynamics of the reformation of the covalent bond using SCF calculations on the potential energy surface. If the distance between the center of mass of the iPr^+ and the N-atom is held fixed, the most stable geometry looks like the structure 1 for distances > 3 Å (at 6-31G**//6-31G**). A stable energy minimum, in which the N and the three C's are nearly coplanar,



1

is found at a distance of 3.2 Å and is about 60 kJ/mol lower in energy than free iPr^+ and ammonia. To form a covalent C—N bond (which lies about 220 kJ/mol below free iPr^+ and ammonia), the ammonia has to move out of the plane of the carbons. The question posed by rearrangement in n-alkylammonium ions is related to the issue of hydrogen scrambling seen in protonated dialkyl ether ions.[2,3]



Rearrangements of n-alkyl amides also exhibit hydrogen scrambling. N-Isobutylacetamide yields a "McLafferty + 1" ion (presumably $CH_3C(OH)=NH_2^+$), as a major peak in its electron impact (EI) mass spectrum, as well as in its chemical ionization (CI) mass spectrum. When the parent ion is $MeCONHCD_2CH(CH_3)_2^{+\cdot}$ approximately $\frac{2}{9}$ of these ions contain deuterium. When the parent ion is $MeCONHCD_2CD(CH_3)_2^{+\cdot}$ approximately $\frac{1}{3}$ of these ions contain deuterium. If, as depicted above, tBu^+-containing complexes intervene, the presence of $[M-CHD_2]^+$ in the CAD of the former and $[M-CD_3]^+$ in the CAD of the latter implies that recombination can take place.

Measurement of Long-Chain Fatty Acyl CoA Species by GC/MS

Keith L. Clay and Christopher A. Johnson

National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson Street
Denver, CO 80206

Long-chain fatty acyl coenzyme A thioesters (FA-CoA) play a central role in many of the important reactions of lipid biochemistry. FA-CoA are important intermediates in catabolic reactions such as beta-oxidation and in synthetic reactions such as triacylglycerol synthesis, phospholipid synthesis, cholesterol ester synthesis and in protein acylation. In addition, these molecules may have such disparate activities as roles in activation of protein kinase C; regulation of cytosolic free Ca^{++}; and modulation of the nucleoside translocase activity. It is clear that this range of postulated activities implies substantial ignorance about the real roles of these molecules in cellular biochemistry.

FA-CoA are established as important intermediates of phospholipid biochemistry. In particular, the activities of Acyl-CoA:phospholipid acytransferase with various substrates has been thoroughly investigated. It is clear that this enzymatic activity is critical to the establishment of the fatty acid composition of membranes and the incorporation of exogeneous fatty acids into cellular phospholipids. Our studies on the composition of membrane phospholipids and the effects of fatty acids on the biosynthesis of platelet activating factor (PAF, 1-O-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) led to the hypothesis that FA-CoA are critical determinants of the cellular capacity for PAF biosynthesis. To test this hypothesis, direct measurement of FA-CoA is required. The goal of this study has been to identify appropriate GC/MS procedures for the measurement of cellular FA-CoA.

We have characterized a number of derivatization procedures for conversion of FA-CoA into molecules amenable to GC/MS analysis. An extension of an aminolysis procedure and consideration of the unique reactivity of the thioester bond led to the use of heptafluorobutylamine in combination with silver ion catalysis as a useful procedure to prepare volative derivatives of the acyl moiety of FA-CoA. In essence, the procedure involves heating FA-CoA with heptafluorbutylamine and an equimolar amount of silver nitrate in pyridine at 60° for 30 minutes. This procedure has been used to measure the concentration of the two most abundant species of FA-CoA in human neutrophils. Palmitoyl-CoA was present at 6.2 ng/10^7 cells; stearoyl-CoA concentration was 2.3 ng/10^7 cells. Further application of this procedure to measurement of both concentration and turnover of FA-CoA will give valuable insight into the biochemistry of this class of compounds.

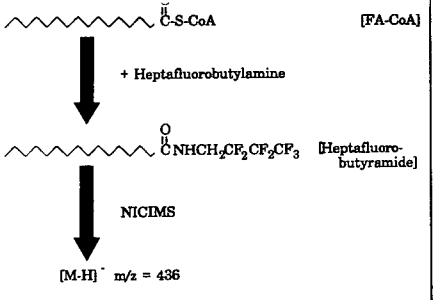

Figure 1. Derivatization procedure for formation of heptafluorobutyramide from acyl-CoA.

The negative ion chemical ionization mass spectrum of the heptafluorobutyramide of nonadecanoyl-CoA is presented in Figure 2. This amide was made by aminolysis with heptafluorobutylamine of nonadecanoyl-CoA on the silicic acid scraped from a TLC plate. 0.25 ml of each solution, 10mM silver nitrate in pyridine and 10 mM HFBA in pyridine were added to a tube containing the TLC scraping and heated at 60° for 30 min. After addition of water, the amide was extracted with ethyl acetate, taken to dryness and re-dissolved for injection into the GC/MS. The reaction will go to completion without silver ion catalysis, but very long times (greater than 24 hours) are required. This reaction does not form the amide from phospholipid oxoesters nor from free fatty acids and is quite specific for the thioester linkage of acyl-CoA species.

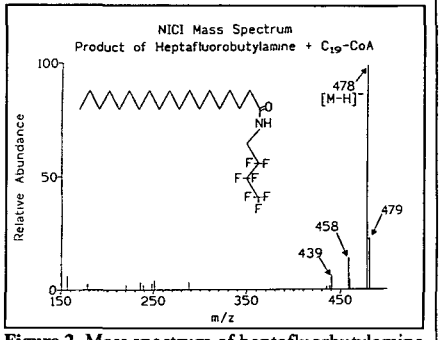

Figure 2. Mass spectrum of heptafluorbutylamine derivative of nonadecanoyl-CoA.

This derivative forms negative ions primarily by proton abstraction rather than resonance electron capture, which increases the minimal detection limit, relative to a species which is formed by electron capture. The minimum amount detected (expressed as acyl-CoA equivalents) was just less than 1 picomole (1 nanogram) of palmitoyl-CoA. This relatively high limit of detection, however, is adequate for experiments with small numbers of cells. Confidence in the procedure is enhanced by the specificity of the reagents for the thioester bond.

The effect of silver ion on the speed of the reaction is quite marked as illustrated in figure 3. Silver ion complexation with the thio group of the thioester of acyl-CoA allows the aminolysis with HFBA to go to near completion in 30 minutes. Without silver ion, the reaction was complete only after more than 24 hours.

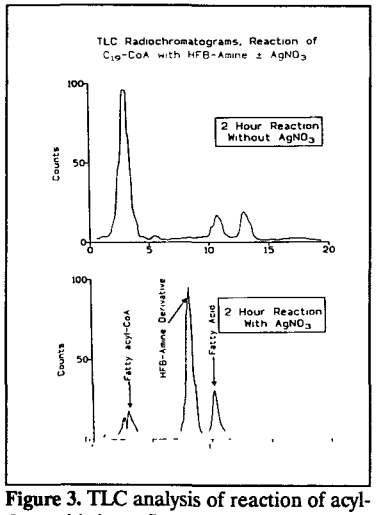

Figure 3. TLC analysis of reaction of acyl-CoA with heptafluorobutylamine. Effect of silver nitrate.

Low-energy Tandem Quadrupole Mass Spectrometry of Unsaturated FAME
A Revealing Study of Unique Ion Chemistry

*Joseph A. Zirrolli and Robert C. Murphy
National Jewish Center for Immunology and Respiratory Medicine
Denver, Colorado, 80206

Introduction: The electron ionization mass spectrometry of fatty acid esters has been studied extensively and, in particular, the EI of saturated fatty acid methyl esters (FAME). The EI spectra of FAME are characterized by the McLafferty rearrangement ion, m/z 74 (the base peak), and a series of carbomethoxy ions, $[(CH_2)_nCO_2CH_3]^+$, observed at m/z 73, 87, 101, 115...., where n=1, 2, 3, 4, ..., etc. The formation of these ions is known to involve complex processes and extensive rearrangements of hydrogen and carbon atoms (1). Collisional activation of the molecular ion and analysis by tandem mass spectrometry yields a different story. Collisional activation of the molecular ion did not yield the McLafferty ion, but extensive rearrangements of the carbon skeleton were observed, using stable isotope-labelled FAMEs (2). A mechanism was proposed to explain these observations which was later refined (3). Independent of this work, a similar mechanism had been reported, based upon the MIKES analysis of deuterium-labelled macrocyclic amines (4,5). These mechanisms propose carbon rearrangement with multiple hydrogen transfers resulting in a symmetrical decomposition pathway. The work presented here extends that previous analysis with new data with FAMEs labelled in the middle of the alkyl chain and with unsaturated FAMES.

Methods: Methyl esters of fatty acids were obtained by treatment with diazomethane. FAMES were introduced into a triple sector quadrupole mass spectrometer (TSQ70, Finnigan Corporation) by solid probe. Collision-induced dissociation of molecular ions of FAMES was performed with varying offset potentials on the second quadrupole (1-50 eV) and argon pressures (0.1-0.5 mTorr). Product ion spectra were obtained by scanning the third quadrupole from m/z 50 to the molecular ion in two seconds.

CID of Saturated FAME: Figure 1 illustrates a typical low-energy CID of a FAME molecular ion generated by electron ionization. No McLafferty ion at m/z 74 appears but rather a regular series of carbomethoxy ions are observed beginning at m/z 101. When deuterium is incorporated into the 2 position, the resulting CID spectra of the molecular ion indicates that the formation of these product ions is not by simple radical cleavage mechanisms but the result of extensive hydrogen and carbon atom rearrangements. For example, the first ion of the series is not observed at m/z 103 but instead at m/z 101 and 102. This is the result of loss of carbons 2,3,4 as well as hydrogen rearrangements.
It is of interest to note that a single radical site can yield complementary ion pairs through symmetrical reactions.

CID of Mono-Unsaturated FAME: A study of six monunsaturated FAMEs also yielded unexpected results. All molecular ions of mono-unsaturated FAME produced similar CID spectra regardless of double bond position and geometry. The fatty acids studied ranged from 14 carbons in length to 24, with the single unsaturation in positions 9, 11 or 15. As shown in Figure 2 for methyl 9(z)-hexadecenoate, these spectra are characterized by the formation of two abundant ions, loss of methanol and formation of m/z 141. The unique ion at m/z 141 was found to contain the carbomethoxy group

from analysis of the ethyl ester derivative and this ion shifted by 14 u to m/z 155. The lack of any influence of double bond position implied a stabilization of the radical site before rearrangement of the $M^{+\cdot}$ and decomposition to this common product ion. This stabilization may occur as an initial allyl radical. After rearrangement it is proposed to yield a cyclohexenylcarbomethoxy ion, as supported by the common abundant ion, m/z 81, observed in the CID spectrum of the ion, m/z 141.

Di- and Tri- Unsaturated FAME: Three series of product ions were formed by CID of molecular ions of di-unsaturated FAME. These ions were all even-mass, odd-electron ions with the most abundant arising from loss of methanol. The other two series of product ions were formed by loss of alkenes and either retained or lost the carbomethoxy group (Figure 3). Decomposition of $M^{+\cdot}$ from tri-unsaturated FAME did not result in the loss of methanol but rather two other ion series; one by loss alkyl radicals from the carbomethoxy group and the other from loss of an alkene from the carbomethoxy group (Figure 4).

INTRODUCTION

Angiosperm plants contain complex mixtures of neutral lipids, primarily triacylglycerides, which are used as edible and industrial oils. As part of a seed oil modification project at this Institute, it is necessary to characterize the neutral lipids in the seeds of a variety of these plants.

Currently, the acyl composition of storage lipids is usually extrapolated from fatty acid profiles obtained from trans-methylation experiments, but these experiments reveal little about the structure of the intact neutral lipids. Although gas chromatography/mass spectrometry (GC/MS) has been used for neutral lipid mixtures with some success, preliminary experiments conducted in this laboratory showed that this technique is not useful when the mixture of analytes contain hydroxy-containing fatty acyl components and/or long chains. We have reported a method for the characterization of castor bean neutral lipids (which contain hydroxy-fatty acyl components) using tandem mass spectrometry.

However, when we applied a similar technique to the analysis of triacylglycerides from *Onosmodium hispidissimum*, that are known to contain multi-unsaturated acyl groups without any hydroxy moieties, the CID product spectra of the M^+ ions contained diagnostically important product ions of unexpected *m/z* values.

This report provides a study of the EI and CI (NH_4^+) magnetic scanned spectra as well as the corresponding CID product ion spectra obtained for a set of reference TAGs varying in the degree of unsaturation of the acyl moieties (1 to 4 double bonds) and discusses the usefulness of tandem MS for the analysis of these compounds using these ionisation modes.

EXPERIMENTAL

The triacylglycerides were obtained from Sigma Chemical Company, St. Louis, MO except for the tristearidonin which was synthesized at this Institute. All analyses were done using a VG 70-250 SEQ hybrid mass spectrometer. Samples for EI and CI analysis were introduced (approx. 1 μg) via the solids probe (heated ballistically to 320° C). The source temperature was maintained at 250° C. Magnetic scanned spectra (both EI and CI) were obtained by scanning from *m/z* 1300 to 130 at a rate of 5 sec/decade. Collision induced dissociation product ion spectra were obtained by fragmenting the EI molecular ion or the CI $[M+NH_4]^+$ ion and scanning the quadrupole analyser from *m/z* 100 to 1000 in 7 sec. Xenon was used as the collision gas at a pressure of 9 X 10^{-5} torr. The collision energy was 16 eV (laboratory frame).

RESULTS AND DISCUSSION

Four reference TAGs, *triolein, trilinolein, trilinolenin and tristearidonin*, each varying in unsaturation by one double bond per acyl group, were chosen for this study. The ions $[M-RCOO]^+$ and $[RCO+74]^+$ were considered to be the most important for diagnostic purposes. In the EI magnetic scanned spectra these diagnostic fragment ions occur at the expected *m/z* values in all the spectra except that of tristearidonin. The $[RCO+74]^+$ ion in this spectrum is expected at *m/z* 333 but the only significant ion in this region of the spectrum appears at *m/z* 335.

Furthermore, the collision induced dissociation (CID) product ion spectra obtained from the EI molecular ions only show the correct diagnostic ions for the triolein. In the other spectra, the $[M-RCOO]^+$ ions are not observed and the $[RCO+74]^+$ fragments appear 2 mass units higher than expected (data not shown).

The reference compounds were studied under Fast Atom Bombardment (FAB) and ammonia CI conditions to determine if the same structural rearrangements were observed under the more gentle ionization processes. Although FAB spectra were obtained for these compounds, the protonated molecular ions were of such low intensity that it was impossible to obtain the corresponding CID product ion spectra. The ammonia CI magnetic scanned spectra for the 4 reference compounds showed the diagnostic ions, $[M-RCOO]^+$ and $[RCO+74]^+$ at the expected m/z for each compound. More importantly, the corresponding CID product ion spectra of the $[M+NH_4]^+$ ions (Fig. 1) also showed the expected diagnostic ions.

Therefore, characterization of mixtures of TAGs can be accomplished by subjecting the $[M+NH_4]^+$ ions to CID and studying the product ion spectra. The $[M-RCOO]^+$ and $[RCO+74]^+$ ions in these spectra provide much more reliable structural information than do similar ions in CID product ion spectra derived from EI molecular ions.

CHARACTERIZATION OF DAIRY TRIGLYCERIDES ISOLATED USING SUPERCRITICAL FLUID FRACTIONATION BY FIELD DESORPTION, DESORPTION CHEMICAL IONIZATION, AND TANDEM MASS SPECTROMETRY

George Spanos, Steven J. Schwartz, and Richard B. van Breemen
Departments of Food Science and Chemistry
North Carolina State University, Raleigh, NC 27695

Although bovine milk fat is a major product of the the dairy industry, its consumption in developed countries has been decreasing due to consumer concern over the high content of saturated fatty acids and cholesterol. In order to expand the desirability and utilization of bovine milk fat, a continuous supercritical carbon dioxide extraction method was developed to isolate milk fat fractions with varied physical properties and triglyceride content. Surprisingly, the triglyceride composition of bovine milk fat has never been determined. Therefore, an HPLC method was also developed to separate as many triglycerides as possible for collection and mass spectrometric identification.

METHODS

Supercritical Fluid Fractionation. Butter oil was donated by Danish Maid Butter Co. (Chicago, IL). Fractionation of butter oil was carried out using a Newport Scientific Inc. (Jessup, MD) continuous supercritical fluid extraction system. Supercritical CO_2 at a flow rate of 12-17 L/min, 900 L/fraction (1 atm, 25°C) was used to sequentially extract a 15g butter oil sample as follows: 1500 psi at 40°C; 2200 psi at 40°C; and 3600 psi at 40°C. Extracts were condensed from depressurized CO_2 in a U-shaped tube.

HPLC. Three Waters Model 510 and 501 HPLC pumps were used with two C18 HPLC columns (Spherisorb and Zorbax), each 25 cm x 4.6 mm, in tandem at a flow rate of 0.7 mL/min. A gradient was used from acetonitrile to propionitrile over 50 min, followed by a second gradient to methylene chloride over 70 min. 900 µg milk fat was injected per analysis. A Varex evaporative light scattering detector was used to monitor elution of triglycerides, which were collected for mass spectrometric analysis.

Mass Spectrometry. Positive ion mass spectra were obtained using a JEOL HX110HF double focusing mass spectrometer equipped with a DA5000 data system. The resolving power was 1,200 for all analyses. Field desorption (FD) mass spectra were acquired using a silicon emitter loaded with approximately 1 µg of supercritical fluid extract. Desorption chemical ionization (DCI) was carried out using isobutane reagent gas and an ion source temperature of 150°C. Approximately 0.5 µg HPLC-purified triglyceride sample was loaded on the DCI filament per analysis. The DCI Filament was heated at 0.25 mA/min. Tandem mass spectrometric measurements were carried out using DCI ionization, and B/E linked scanning with CAD of protonated molecule precursors.

RESULTS

Field desorption mass spectra of each butter oil supercritical fluid extract showed the average molecular weight and mass distribution of the constituent triglycerides. Using reversed phase HPLC with an evaporative light scattering detector, 58 triglyceride peaks were collected, which were then analyzed using DCI mass spectrometry and DCI MS/MS. For example, the positive ion DCI mass spectrum of HPLC Peak 15 is shown in Figure 1. Two different triglycerides were detected in Figure 1 with $[M+H]^+$ ions at m/z 639 and 665. The B/E linked scan of m/z 639 is shown in Figure 2. Fragments ions at m/z 578, 409 and 383 identify this triglyceride as 4,14,18:1.

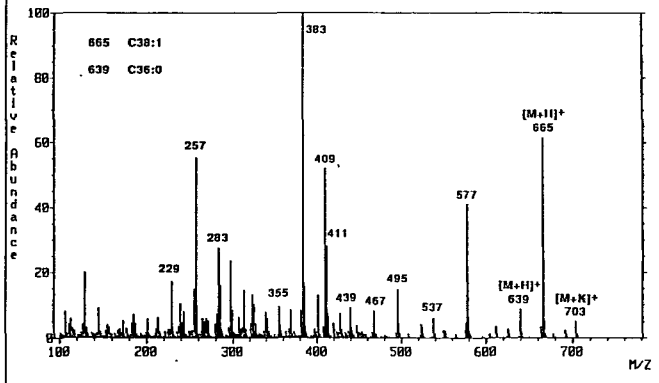

Figure 1.

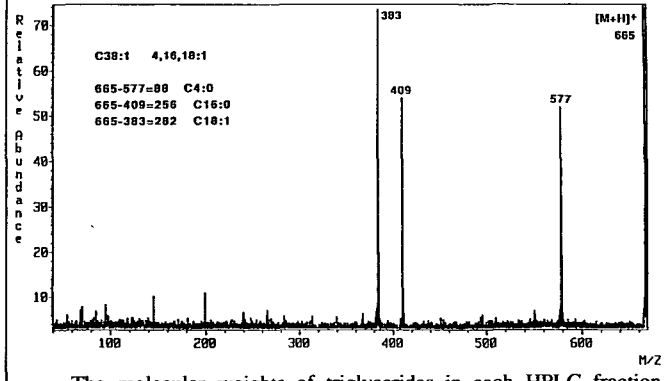

Figure 2.

The molecular weights of triglycerides in each HPLC fraction were determined from $[M+H]^+$ ions in DCI mass spectra. Fragmentation facilitated the identification of fatty acid content of each isolated triglyceride. When HPLC fractions contained triglyceride mixtures or impurities, MS/MS analyses facilitated fatty acid identification. These results are the first identification of the most abundant triglycerides in milk fat.

Analysis of Bull Sperm Plasma Membrane Phosphatidylcholines by Negative Ion FAB-CAD-MS/MS.

T. Tighe, B. Minard, J. Nolan, R.H. Hammerstedt, Departments of Chemistry and Molecular and Cell Biology, Penn State University, University park, PA 16802; D. Fabris, Department of Chemistry and Biochemistry, University of Maryland Baltimore County, Baltimore, Maryland 21228.

The ultimate goal of this research is to better understand the molecular level changes that occur in sperm cells as they mature and become viable after passage through the epididimus. Specifically, changes occur in the biochemical make-up of the cell membrane that allow penetration of the egg cell wall. The phospholipid composition is altered in the process. In order to study these complex compositional changes, an analytical method that is sensitive, universal, and provides structural insight is absolutely essential.

Phosphatidylcholines (PCs) were isolated from the lipid fraction of the plasma membrane removed from the arcosomal region of bull sperm.[1] The phosphatidylcholine fraction was analyzed by FAB-MS, HPLC-Flow FAB-MS, and FAB-MS/MS. Negative-ion FAB-MS/MS with high-energy collisions (CAD) was used to identify the length and position of the fatty acyl side chains. FAB-MS/MS of the $[M-15]^-$, $[M-60]^-$ and $[M-86]^-$ parent ions showed that the major components in the phosphatidylcholine fraction were 1-O-alk-1'-enyl-2-acyl glycerophosphocholines (plasmalogens), specifically $C_{16:0}/C_{22:6}$ plasmalogen and $C_{16:0}/C_{22:5}$ plasmalogen.

METHODS

Isolation of Sperm Cell Membrane Phospholipids was by published methods[2,3]. Normal phase HPLC was used to separate the phospatidylcholine The column used to separate the bull sperm plasma membrane lipids was a 25cm x 10mm id 5 micron silica prep column (Supleco). An isocratic mobile phase, $CH_3CN/MeOH/H_2O$ (50:45:6.5 v/v/v), flowed at 2mL/min. The UV detector was set at 208 nm. The PC fraction was isolated and frozen under N_2.

Probe (-) FAB-MS: Triethanolamine (Sigma Chemical Co., St. Louis, MO) matrix (1-2 uL) was applied to the copper probe tip followed by 2 µL bull sperm plasma membrane phospholipids in chloroform. The matrix and sample were then mixed on the probe target The FAB gun was operated with xenon gas at 4-6 KeV and a beam current of 40-60 µA. A Kratos MS50 RFA double focusing mass spectrometer was operated at a 4 kV accelerating potential and an resolving power of 1000. The mass range m/z 130-1600 was scanned at 10 sec/decade and acquired by a KRATOS DS90 system.

Tandem Mass Spectrometry[4] Negative FAB-MS of plasma membrane phosphatidylecholines (PC) from bull sperm was performed on the first two sectors (EB) of a Jeol HX110/HX110 mass spectrometer (Tokyo, Japan) at an accelerating voltage of 10kV, 100-Hz filtering, a resolution of 1000, a scan rate of 1.5 min./scan and a mass range of m/z 0-1000. The FAB gun was operated at 6kV with xenon. Spectra were recorded with a Jeol DA5000 data system. Negative FAB-MS/MS was performed on the same PC sample by using all four sectors (EBEB) on the Jeol HX110/HX110. Precursor ions were mass selected on the MS1 at a resolution of 1000 and linked B/E scans were made in MS2. Collision-induced dissociation (CID) occurred in the third field free region, with helium used as the collision gas. The CID spectra were recorded at a resolution of 1000. Triethanolamine was used as the matrix.

RESULTS AND DISCUSSION

It has been shown[5,6] that PCs do not give $[M-H]^-$ anions, but reveal a trio of characteristic fragment ions: $[M-H-CH_3]^-$, $[M-H-HN(CH_3)_3]^-$ and $[M-H-CH_2{=}CHN(CH_3)_3]^-$. However, while this information is present in the (-) FAB-MS spectra of PCs, the complexity of the sample and resulting spectra make it impossible to correctly determine the individual PC species. In order to do this, we have tried both HPLC-Flow FAB-MS and FAB-MS/MS. The LC-MS method proved to be quite difficult and non-reproducable, whereas, considerable information was obtained by tandem MS methods in a very short amount of time.

CID tandem MS was carried out on prominant ions derived from two components with molecular weights of **790** and **806**. The corresponding negative pseudomolecular ions $(M-H)^-$ at **789** and **805**

are very low abundance, and rapidly eliminate fragments of the choline moeity to give fragment ions774, 729, 703, 790, 745, 719. The MS-CID-B/E linked scan MS spectra of the six ions above (in bold) were recorded and their interpretation is given in the figures to the right.

The predominant species (MW **790**) gave a very strong spectra that were readily interpretable and very consistent with a plasmalogen PC that had a $C_{16:0}$ alkenyl group at position 1 and a $C_{22:6}$ acyl group at position 2.

MS/MS spectra of the three ions derived from MW 806 species were much more complex and can be interpreted in terms of at least four species being present: two diacyl species ($C_{16:0}/C_{22:6}$ and $C_{16:1}/C_{22:5}$) and two plasmalogens that appeared to have oxidized C_{22} side chains.

On the basis of these results, the single MS-FAB data was rationalized as shown in the table below:

Bull Sperm Plasma Membrane PCs -- Negative Ion FAB-MS Data

$(M-H)^-$	R1	R'1	R2	$[(M-H)^--15]$	$[(M-H)^--60]$	$[(M-H)^--86]$	Comment

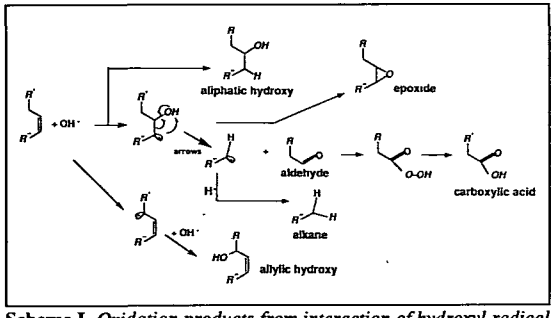
Characterization of Oxidized Phospholipids Using Fast Atom Bombardment Tandem Mass Spectrometry

Kathleen A. Kayganich-Harrison and Robert C. Murphy
National Jewish Center for Immunology and Respiratory Medicine
Denver, CO 80206

Generation of oxygen free radicals in vivo results in peroxidation of polyunsaturated fatty acids esterified in phospholipids. This damages cellular membranes and may also produce biologically active molecules from membrane phospholipids. Peroxidation of endothelial cells has been shown to produce modified glycerophosphocholine (GPC) that activates human neutrophils through the platelet activating factor receptor (Patel, K.D. et al, J. Biol. Chem., 267:15168-15175 (1992). Smiley, P.L. et al, J. Biol. Chem., 266:11104-11110 (1991)). However, the exact identity of the bioactive component(s) has not been determined. The analytical characteristics of oxidized phospholipids are largely unstudied. We are using Cu(I)/H_2O_2 to initiate oxidation of 1-palmitoyl,2-arachidonoyl GPC (PAGPC) in order to determine the FAB and CID characteristics of oxidized phospholipids. Oxygen radicals such as superoxide anion and hydroxyl radical can easily abstract an allylic proton or react directly with the pi bonds in arachidonoyl-GPC. Several types of oxidation products can be obtained, as shown in Scheme I. The FAB and CID characteristics of some of the oxidation products were quite different from those of non-oxidized GPC.



Scheme I *Oxidation products from interaction of hydroxyl radical with unsaturated lipids.*

Methods

Oxidation of PAGPC. PAGPC (2 mg) and 2 μCi of palmitoyl-[1-^{14}C]-arachidonoyl GPC was suspended in 1 ml of distilled water to form liposomes. $CuCl_2$ (100 uM) and hydrogen peroxide (70 mM) were added for 24h. Oxidations of palmitoyl-linoleoyl GPC and $^2H_9$ PLGPC were carried out identically.

Synthesis of $^2H_9$-GPC- 16:0/nonanedioyl-$^2H_9$-GPC was synthesized by treating 16:0/18:2 glycerophosphatidylethanolamine with $^2H_3$-methyl iodide for 50 min, followed by oxidation as described above.

Reverse-phase HPLC- products of PAGPC oxidation were separated using a Beckman 5 micron ODS (4.6mm x 25cm) column eluted at a flow rate of 1.5ml/min for 50 min with methanol:water, 1 mM ammonium acetate, pH 7 (85:15) The gradient was increased to 100% methanol over 40 min. Phospholipids were extracted from HPLC fractions by addition of $CHCl_3$ and water to each fraction (1:1:1,v/v/v).

Mass Spectrometry- FAB/MS (6kV xenon) was carried out on a Finnigan MAT TSQ70B triple quadrupole mass spectrometer. For CID the second quadrupole was pressurized with ca. 0.5 mTorr argon. Collision offset energy was 30eV (E_{lab}). Diethanolamine was used for the FAB liquid matrix.

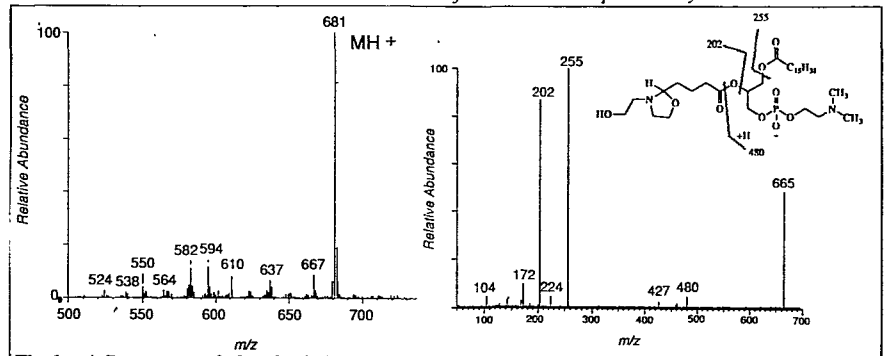


Fig 1. *a) Precursors of phosphocholine ion (m/z 184) in HPLC fraction (13-14 min) from oxidized PAGPC. The odd m/z 681 could arise from reaction with the diethanolamine liquid matrix. b) Negative product ions of m/z 665 [M-CH$_3$]$^-$. M/z 202 corresponds to the carboxylate anion from the sn-2 substituent. Reaction of an ω-aldehyde could result in an oxazole as shown, which would account for the odd m/z and the 87u increase.*

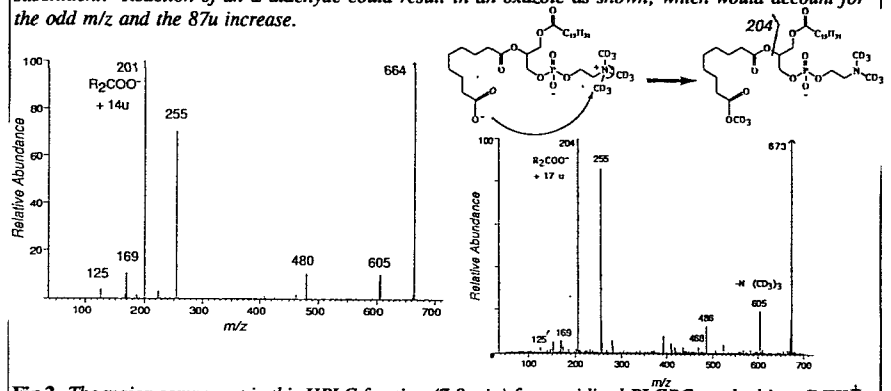

Fig 2. *The major component in this HPLC fraction (7-8 min) from oxidized PLGPC resulted in a [MH]$^+$ ion at m/z 666 and a [M-H]$^-$ at m/z 664. Normally GPC forms [M-CH$_3$]$^-$ ions. This product must possess another ionizable site, such as an ω-carboxyl. a) The CID of m/z 664 results in an sn-2 carboxylate anion that is 14 u higher than expected. b) CID of m/z 673, [M-H]$^-$, from palmitoyl-nonanedioyl-$^2H_9$-GPC shows that this increase is the result of transfer of one of the N-methyl groups to the ω-carboxy of the sn-2 substituent.*

Conclusion - FAB/MS and CID of oxidized phospholipids obtained from Cu(I) /H_2O_2 oxidations of PAGPC and PLGPC suggest that aldehydic compounds form covalent derivatives with the diethanolamine FAB matrix. This can be used to confirm the presence of this functional group. In FAB of oxidized phospholipids having an esterified dicarboxylic acid, [M-H]$^-$ formation is favored over the [M-CH$_3$]$^-$. Also, a methyl group is transferred from choline to the ω-carboxy of the sn-2 substituent resulting in an ω-methylated carboxylate anion.

Thermospray LC/MS Analysis of Phospholipid Molecular Species in Rat Brain Mitochondria

Y. C. Ma and H. Y. Kim, Section of Mass Spectrometry, LMBB, NIAAA, NIH, Bldg. 10, Room 3C-102, 9000 Rockville Pike, Bethesda, MD 20892

Conventional methods of analyzing phospholipid molecular species involve isolation of individual phospholipid classes by either thin layer chromotography (TLC) or HPLC followed by separation of each molecular species using reversed-phase HPLC or argentation TLC. Separated molecular species then have to be identified by GC analysis after transmethylation. The multiple processes are time consuming and results in less accurate analysis. Previous studies (1,2) have shown that with filament on thermospray ionization, phospholipids give simple and characteristic fragment ions which can be used to identify the head group and the constituent fatty acids. In this study, we use thermospray LC/MS to determine the major phospholipid molecular species in rat brain mitochondria. Partial quantification was performed using selected ion monitoring (SIM) in the presence of 18:0d_{35} 20:4-phosphatidylethanolamine (PE) as an internal standard.

Rat brain mitochondria were isolated using sucrose gradient method and the lipids were extracted according to Bligh & Dyer (3). Extracted lipids were dried under nitrogen, redissolved in chloroform, and analyzed using an Extrel ELQ-400 mass spectrometer coupled with a Hewlett-Packard 1050 LC system via a Vestec thermospray interface. Typical analysis conditions were the following: Injection amount: approximately 5 ug of mitochondria phospholipid mixture for SIM. HPLC column: EM Supersphere C18 (4.6 mm i.d. x 12.5 cm, 5 u). Flow rate: 1 mL/min. Mobil phase: 1% NH_4OH in water: hexane:1% NH_4OH in methanol, changing from 10:0:90 to 0:10:90 in 20 min after holding at the initial composition for 3 min. Post-column addition: 2% acetic acid in water at 0.1 ml/min. Vaporizer tip temperature: 200 °C. Source block temperature: 250 °C.

Thermospray LC/MS is a powerful tool for studying phospholipid molecular species. With proper internal standards, both qualitative and quantitative results can be obtained within relatively short time. In this study, the diglyceryl fragment ions were monitored selectively because they were usually the base peak in the spectra and also provided the molecular species information (1,2). Figure 1 shows SIM trace and the relative intensities of the major diglyceryl fragment ions found in rat brain mitochondria, including the diglyceryl fragment ion trace of 1 ug of the internal standard, 18:0d_{35} 20:4-PE. The most abundant phospholipids were 16:0 16:0-PC, 16:0 18:1-PC, 18:0 22:6-PE and 18:0 20:4-PE. Some minor species observed include 16:0 16:1-, 16:0 20:4-, 16:0 22:6-, 18:0 18:1-, 18:0 20:4-, and 18:0 22:6-PC, 16:0 18:1-, 16:0 20:4- and 18:0 18:1-PE, 16:0 18:1- and 18:0 22:6-PS, 16:0 18:1- and 16:0 20:4-PI. Standard calibration of 18:0 18:1-, 18:0 20:4- and 18:0 22:6-PE with 1 ug of 18:0d_{35} 20:4-PE showed a linear response in 20 ng to 1 ug range. Above 1 ug, however, nonlinear calibration curve was observed (Figure 2). With these calibrations, the amount of 18:0 22:6 PE, 18:0 20:4 PE, and 18:0 18:1 PE injected were estimated to be 1.62, 1.48, and 0.15 ug respectively. Using this technique, the effect of ethanol in the composition of phospholipid molecular species as well as decarboxylation of PS to PE in mitochondria is now under investigation.

Positive Ion LSIMS and Four-Sector Tandem Mass Spectrometry of Aminophospholipids Using Scanning-Array Detection

Su Chen and Peter. J. Derrick, Institute of Mass Spectrometry and Department of Chemistry, University of Warwick, Coventry CV4 7AL, UK

INTRODUCTION

Structures and functions of aminophospholipids in biological system have been widely reviewed. In recent years, studies on the characterisation of the phospholipid molecular species by LSIMS (FAB) coupled to tandem mass spectrometry have been reported. Experiments were performed mostly by negative ion mode since this method can provide structural information including the molecular mass of the species, the characterisation of the polar-head groups, the composition of the fatty acyl chains and the positions of the chains esterified to the glycerol backbone. In this presentation, we report the identification of aminophospholipids (phosphatidyl-serine and -ethanolamine as well as their lyso derivatives) by positive ion LSIMS combined with high-energy collisionally induced dissociation (CID) and four-sector tandem mass spectrometry of $[M+H]^+$ ions of the molecular species of the four classes.

EXPERIMENTAL

Tandem mass spectrometric analyses were performed on a CONCEPT II HH four-sector mass spectrometer (Kratos Analytical Ltd., Manchester, UK) of BEBE configuration. The ion source of MS-I was operated at an accelerating voltage of 8 kV, ionized by a liquid caesium gun with 15 keV translational energy. The experiments were controlled by MACH3 system. The sample was dissolved in chloroform/methanol/water (58/4/0.2), and this solution was transferred to the surface of diethanolamine, used as liquid matrix, without mixing (1). All GPE and GPS molecular species were prepared by the described methods (2). LysoPS and LysoPE were obtained by the treatment of phospholipase A_2.

RESULT and DISCUSS

Fig.1 shows the CID MS/MS spectrum of the $[M+H]^+$ ion of LSIMS of GPE 16:0-18:2. The ion at m/z 575 is formed by the loss of the polar-head group from the species (Scheme 1). The two fatty acids can be detected by the presence of three pairs of fragment ions (ions c,d and e; see Scheme 1), and the location of the chains esterified to the glycerol backbone can be identified by the significant intensity differences of C_1 and C_2 ions, at m/z 307 and 283. Plasmalogen-PE and -LPE are characterised by the absence of the peaks due to the cleavage occurred at the sn-1 position in the spectra (see Scheme 2; spectra not shown). Fig. 2 exhibits the CID MS/MS spectrum of the $[M+H]^+$ ion of LSIMS of GPS 18:0-18:1. The loss of phosphoserine from the molecule gives an ion at m/z 605. Signals due to b, c and d cleavages (Scheme 3) are structurally informative for the analysis of the fatty acid chains. However, abundances of the three pairs of ions show opposite ratio, relative to the GPE 16:0-18:2. This phenomenon was also found for the negative ion CID MS/MS of $[M-H]^-$ ion of LSIMS of GPS. It presumably relates to the diversity of the kinetic energy of the chosen precursors (3). The hypothesis advanced here is that the $[M+H]^+$ "fragment ion" of the GPS species is derived from a solvated protonated molecule, $[M+H+DEA]^+$ ion (4). This is evident by the presence of identical patterns of ions resulting from the MS/MS analyses of glycerophosphatidic acid precursors, the fragmentation of glycerophospholipids (2). Scheme 4 shows the cleavage mode of LysoPS species.

Characterisation of glycolipids and sphingolipids by matrix-assisted laser desorption.

D. J. Harvey

Glycobiology Institute, Department of Biochemistry, University of Oxford, South Parks Road, Oxford OX1 3QU, UK.

Introduction.
Lipids have received less attention than other compound types as targets for matrix-assisted laser desorption although a recent report[1] demonstrates the production of good spectra from gangliosides using matrices such as 2,5-dihydroxybenzoic acid (2,5-DHB). This paper examines qualitative and quantitative aspects of several matrices for glyco- and sphingolipids.

Experimental.
Lipids were obtained from commercial sources. Samples were prepared by mixing the lipid (1 - 100 pmol), dissolved in methanol or methanol:chloroform with the matrix solution (1 µl, 50 nmol) on the mass spectrometer target and allowing it to dry at room temperature. Samples with 2,5-DHB as the matrix were further crystallised with ethanol (0.2 µl). Spectra were acquired with a Finnigan Lasermat mass spectrometer (nitrogen laser, 337 nM). Quantitative data were obtained by averaging the signal from 5 laser shots fired at each of 16 target spots.

Results and Discussion.
Good molecular ions were obtained from all compounds at the low pmol level with α-cyano-4-hydroxycinnamic acid, esculetin or 2,5-DHB showing the best matrix properties. Sinapinic acid usually gave weaker spectra. However, the strongest signals from particular compound types showed a considerable degree of matrix and polarity dependence. Sphingosine, cerebrosides, sphingomyelins, ceramides and galactosyldiglycerides produced the strongest signals from α-cyano-4-hydroxycinnamic acid (Fig. 1) with generally good resolution of individual molecular species (Fig. 2). Sphingosine gave a $\{[M + H]^+$ ion with a prominent loss of ammonia whereas compounds containing sugar residues were generally cationised.

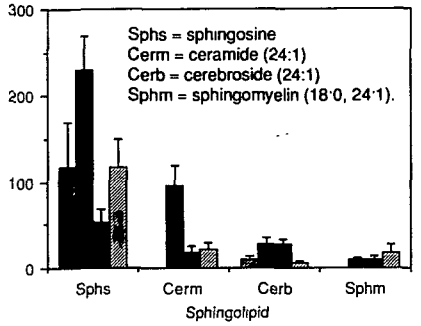

Fig. 1. Responses of sphingolipids (25 pmol) in various matrices.

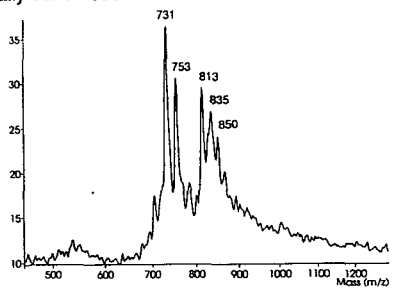

Fig. 2. Molecular ion region of the MALD spectrum (2,5-DHB) of sphingomyelin (10 pmol) from bovine brain. Major peaks are produced by the C-18:0 and 24:1 species.

Monosialylganglioside-M_1 gave a good positive and negative ion signals from 2,5-DHB with the molecular ions corresponding to $[M + Na]^+$ and $[M - H]^-$ respectively. With esculetin and α-cyano-4-hydroxycinnamic acid, fragmentation resulting in loss of sialic acid occurred in the positive ion mode but was absent in the negative ion spectra (Fig. 4).

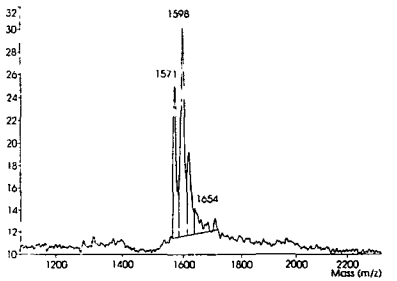

Fig. 3. Positive ion MALD spectrum (2,5-DHB matrix) of monosialylganglioside-G_{M1} (25 pmol) from bovine brain.

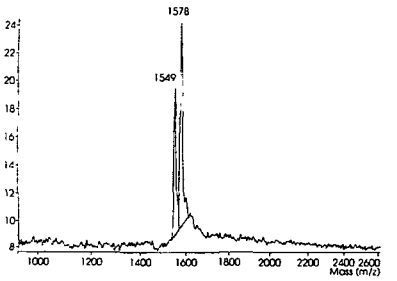

Fig. 4. Negative ion MALD spectrum (esculetin matrix) of monosialylganglioside-G_{M1} (25 pmol) from bovine brain.

Disialylganglioside-G_{D1a} gave similar results. Esculetin and α-cyano-4-hydroxycinnamic acid produced spectra containing, in addition to the molecular ions (mainly $[M + Na]^+$), two broad, unresolved peaks produced by loss of one or both sialic acid groups (Fig. 5). In the negative ion spectra, only one such fragment ion was observed. 2,5-DHB, on the other hand, produced both positive and negative ion spectra that were nearly free of fragment ions (Fig. 6)

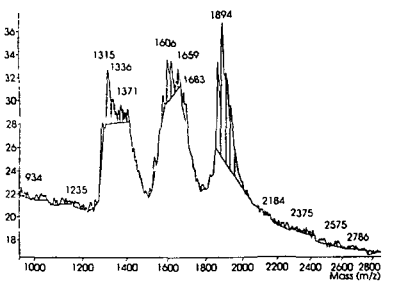

Fig. 5. Positive ion MALD spectrum (α-cyano-4-hydroxycinnamic acid) of disialylganglioside-G_{D1a} (25 pmol).

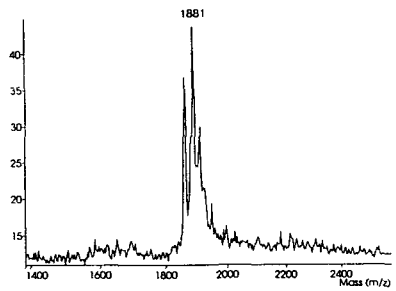

Fig. 6. Positive ion matrix-assisted laser desorption mass spectrum (2,5-DHB matrix) of disialylganglioside-G_{D1a} (25 pmol).

Examination of phospholipids by matrix-assisted laser desorption.

D. J. Harvey

Glycobiology Institute, Department of Biochemistry, University of Oxford, South Parks Road, Oxford OX1 3QU, UK.

Introduction.

Although matrix-assisted laser desorption has been used for examination of many compound types, particularly peptides and oligosaccharides, its utility for lipid analysis has received little attention. This paper presents data on its use for the characterisation of various types of phospholipid using a variety of matrices.

Materials and methods.

Phospholipids were obtained from commercial sources. Samples were prepared by mixing the lipid (0.1 - 100 pmol), dissolved in methanol or methanol:chloroform with the matrix solution (1 µl of a 50 µmol/ml solution) on the mass spectrometer target and allowing it to dry at room temperature. Samples with 2,5-dihydroxybenzoic acid (2,5-DHB) as the matrix were further crystallised on the target with ethanol (0.2 µl). Spectra were obtained with a Finnigan Lasermat mass spectrometer (nitrogen laser, 337 nM) using matrices as described below (obtained from Aldrich Chemical Co. Ltd.,). Quantitative data (100 fmol - 100 pmol) were obtained by averaging the signal from 5 laser shots fired at each of 16 target spots. Methylation was performed by allowing the phospholipid to stand with an excess of an ethereal solution of diazomethane for 15 min. at room temperature.

Results and Discussion.

Phosphatidylcholine, which contained a cationic group, gave very intense signals (M^+) in the positive ion mode (Fig. 1), particularly with α-cyano-4-hydroxycinnamic acid (detection limit 100 fmol) or esculetin as the matrix. These matrices generally proved to be the most satisfactory for the majority of phospholipids tested (Fig. 2). Weaker signals were obtained with 2,5-DHB, 1,4-dihydroxy-2-naphthoic acid and other substituted benzoic acids and coumarins. Phospholipids lacking a cationic site generally gave a mixture of $[M + H]^+$ and $[M + Na]^+$ ions in the positive mode and $[M - H]^-$ ions in the negative spectra. No negative ions were observed with phosphatidylcholines. Where negative ion spectra were produced, these were more satisfactory than the positive ion spectra as molecular weight indicators on account of the absence of sodium adduct ions. However, reduction in the relative abundance of the $[M + Na]^+$ ions in the positive ion spectra could often be achieved by methylation of the phosphate group with an ethereal solution of diazomethane. A good linear response was observed between sample loading and response as shown in Fig. 3 for dilauryl phosphatidylcholine..

Extensive fragmentation occurred with all compounds (see Fig. 1), particularly when α-cyano-4-hydroxy-cinnamic acid was used as the matrix. Fragmentation increased as a function of laser power and was the result of cleavages around the phosphate moiety. This fragmentation produced a prominent diacylglycerol ion which provided information both on the size of the combined acyl chain length and on the nature of the phospholipid (given by the mass loss).

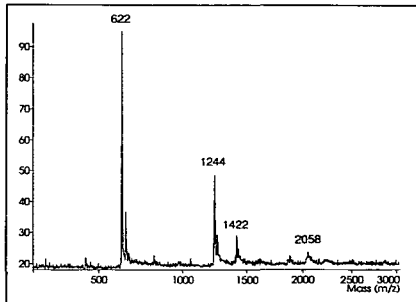

Fig. 1. Matrix-assisted laser desorption mass spectrum (2,5-dihydroxybenzoic acid matrix) of dilauryl phosphatidylcholine (10 pmol).

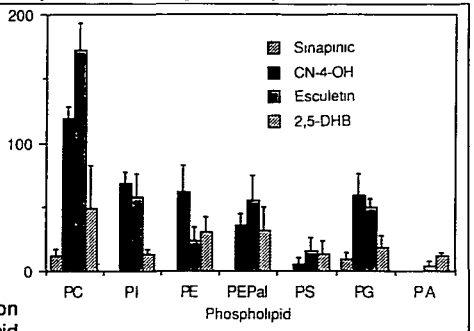

Fig. 2. Relative responses (laser power 25) of phospholipids (25 pmol) in various matrices. Error bars are ± SD of 5 laser shots fired at each of 16 target spots.

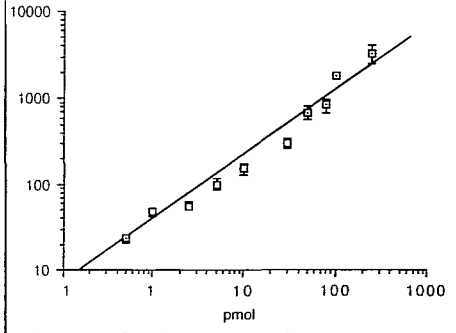

Fig. 3. Graph showing the relationship between sample loading and signal strength for dilauryl phosphatidylcholine in α-cyano-4-hydroxycinnamic acid.

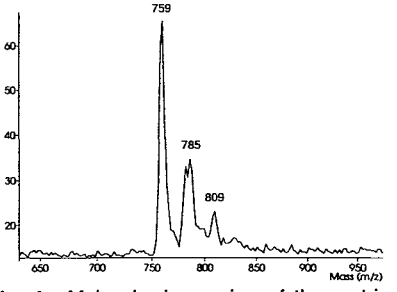

Fig. 4. Molecular ion region of the matrix-assisted laser desorption mass spectrum (2,5-dihydroxybenzoic acid matrix) of di-lauryl-phosphatidylcholine (10 pmol) from egg lecethin.

Phospholipids which had free hydroxy groups, such as phosphatidylinositol and phosphatidylglycerol, tended to form mainly $[M + Na]^+$ ions after methylation of anionic and amino groups with diazomethane. Other phospholipids gave mainly $[M + H]^+$ ions.

In addition to fragmentation, considerable cluster (particularly dimer) formation occurred with many phospholipids. Dimer formation was particularly prominent with phosphatidylcholine, presumably as the result of zwitterion pairing.

Resolution on the TOF instrument was sufficient to resolve many of the molecular species differing in acyl substitution (Fig. 4) but was less satisfactory in assignment of the degree of unsaturation, particularly when adduction with alkali metal ions occurred.

Comparison of Several Contemporary Ionization/Mass Analyzer Techniques for Large Components of Complex Fossil-Derived Materials†

Jerry E. Hunt, Donald E. Drinkwater[a], and Randall E. Winans

Chemistry Division, Argonne National Laboratory, Argonne, IL 60439

[a]Present address Texaco, Inc., Beacon, NY 12508

Introduction

Fossil fuels are a complex mixture of large macromolecular species. Coal- and petroleum-derived samples, therefore, provide a unique mixture for development and comparison of mass spectrometric techniques for high molecular weight analyses. The Argonne Premium Coal samples, a broad array of research grade standards collected, prepared, and stored under controlled conditions, are convenient for assessing classical and novel mass spectrometric techniques. Resiudal compounds from petroleum processing represent complementary high molecular weight materials for such studies. Traditional EI mass spectra of these complex mixtures are dominated by fragment ions and contain little parent molecular ion information.

A number of complementary approaches have been used to investigate fossil fuel-derived materials and model compounds. LD, DCI, and FAB are compared as methods of volatilizing high molecular weight species present in coal and petroleum samples. DCI on a high resolution three-sector tandem mass spectrometer is compared to laser desorption and laser photoionization on a time-of-flight instrument for high mass mixture selectivity.

Experimental

The EI, DCI, and FAB mass spectra were recorded on a Kratos MS 50 triple analyzer. The reagent gas for the DCI studies was isobutane. The solids and extracts were heated in the source on a small platinum wire coil from 200 °C to 700 °C at 100 °C/min. with the source heated at 200 °C. The laser desorption and laser ionization mass spectra were recorded on a linear time of flight mass spectrometer constructed in house. The LDMS spectra were produced by exposing the samples distributed as thin layer on a stainless steel sample holder to laser pulses from either a Nd:YAG or a nitrogen laser. The fluence of the desorption laser is held constant at 10-100 mJ/cm^2 at a repetition rate of 20 Hz. For the prompt ion desorption the laser is operated close to the ionization threshold to minimize fragmentation of the desorbing material. The laser is operated at lower fluences for neutral ion desorption. The neutral molecules are then ionized by vacuum ultraviolet light. The 118 nm laser pulses are produced by third harmonic conversion of 355 nm light from the Nd:YAG laser in a high pressure Kr cell. The flight path is approximately 1.3 m.

Results

Figure 1 shows a broader mass distribution is with FAB than either LD or DCI. where there is a small number of low intensity peaks below m/z=200. The peaks at m/z<200 in the FAB spectra probably result from fragmentation and the matrix (nitrobenzyl alcohol). Several homologous series are observed in the LD and DCI data. Possible structures can be assigned to each of these series based on PyHRMS results from the same coal sample. The prominent series (especially in the LD data) at m/z=230, 244, 258, 272 is assigned to alkyl-pyrenes of fluoranthenes. Another major series contains two different species, alkylphenyl–naphthalenes and alkylhydroxy-pyrenes or fluoranthenes. In contrast, in FAB the major cluster of peaks do not coincide with clusters seen in DCI or LDMS.

At higher masses there is good agreement between all three techniques. Several homologous series appear at these higher masses. A series at m/z=292, 306, 320, 334, 348, 362, 376 is possibly alkylphenylpyrenes. Another series between 306 and 362, form an oxygen containing series with a suggested structure of methylbenzopyrenofuran.

Single photon ionization of neutral molecules desorbed from the sample surface of coal-derived material produce the spectrum shown in figure 2. Coupled with time of flight mass spectrometry, the

spectra exhibit parent ion abundance which conventional 70 eV electron impact lack. The peaks near m/z=800 do not appear in the DCI MS spectra.

Conclusion

The mass spectra show different molecular weight distributions. In general FAB gives the highest molecular weight distribution, while LD, DCI, and EI give progressively lower distributions. Furthermore, the ions present in the LD and DCI spectra are directly comparable, while FAB and EI produce different ion distributions. Information on neutrals is available from PyGC/MS and LD-photoionization/TOF.

FAB-MS and SIMS Characterization of Polyamic Acid Precursor Formation from BPDA and ODA

J.-P. Wang, Y.-P. Lin, M.-K. Lee, and Y.-C. Ling*

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 30043, R.O.C.

INTRODUCTION Polyimide (PI) synthesized from BPDA (BiPhenyl tetracarboxylic DiAnhydride) and ODA (4,4'- OxyDiAniline) has attracted interest for its process flexibility gained from increasing solubility in organic solvent. The synthesis consists of two reaction steps. First, a soluble, high molecular weight PAA (PolyAmic Acid) is formed. Secondly, the soluble PAA is converted to the PI with the aid of a dehydrating agent. This conversion step affects the property of subsequently prepared PI films in many ways. Hence, a better understanding about PAA formation is crucial to the quality of subsequently produced PI films. This research aims to achieve this goal by using SIMS and FAB-MS to investigate the relationships between the composition of BPDA and ODA reactants, PAA precursor, and PI product.

CHARACTERIZATION All SIMS characterizations were carried out with a CAMECA IMS-4f secondary ion mass spectrometer. FAB-MS characterizations were carried out with a JEOL SX-102A mass spectrometer.

SIMS RESULTS Positive ion SIMS spectra of BPDA and ODA powders are obtained, respectively. In the BPDA spectrum, representative peaks are with m/z ratios of 103, 105, 107, 117, and 152. Peaks with m/z = 113 and 115 are ascribed to the In isotopes. In the ODA spectrum, representative peaks are with m/z ratios of 108 and 199. The peak at m/z = 108 is assigned to $OC_6H_4NH^+_2$, a fragment formed by cleavage of ODA to include the ether oxygen. The peak at m/z = 199 is assigned to $(M-1)^+$ or M^+. Comparing the positive SIMS spectra of PAA and PI,peaks with m/z ratios ranged from 100 to 200 represent characteristic structural fragments. The general appearance of the spectra of PAA and PI are alike. The m/z ranges and intensities of the peaks in PI are narrower and weaker. This is attributed to the increasing hardness in PI after the curing treatments. The sputtering yields are generally lower with harder materials. Peaks with m/z = 115, 117, 119, 153, and 178, which are characteristic of BPDA, appear in both spectra of PAA and PI. We therefore conclude that the surface of PAA and PI are BPDA enriched.

FAB-MS RESULTS In comparison with SSIMS technique, FAB-MS is a bulk analysis technique. In the positive ion FAB-MS spectrum of PAA ,the peaks with m/z = 98, 99, and 100 are from the NMP solvent. Peaks with m/z = 115, 128, 141, 152, 165, 178, and 202 also appear in the SSIMS spectrum of PAA. Other peaks with m/z = 101, 108, 110, 112, 156, 167, 185, 197 do not appear in the SSIMS spectrum of PAA.

Some of them are ascribed to solvents (101, 112, 197) and matrix (185). The remains are equally ascribed to the BPDA (114, 115, 152, 165, 178) and ODA (108, 114, 115, 128, 156). We therefore conclude the bulk of PAA contains equal amounts of BPDA and ODA.

IN-SITU MONITORING OF CURING PROCESS The formation of PI from PAA precursors via curing process was investigated using a home-built FAB probe with heating capability. PAA solutions were placed in the probe which was preheated to 50, 100, 150, 200, 250 and 300 °C. FAB-MS spectra were acquired after the steady-state conditions were observed. Dominant peaks with m/z = 108, 112, 124, 133, 151, 155, 172, 181, and 197 appear in every spectrum. Matrix peaks are not observed because the matrix was not added into the samples. It is noted that the number of fragments decrease with increasing temperature, i.e., peaks with m/z between 400 and 500. It is also noted that the intensity of peak with m/z = 133 decreases with increasing temperature; while that of peak with m/z = 151 shows the reversed relationship. This is expectable because the former fragment comes from the PAA while the later comes from the PI. The degree of imidization increases with higher temperature and therefore fragments from the PI would increase.

The Detection of Polymer Ions by Matrix-Assisted Laser Desorption/Ionisation Time-of-Flight Mass Spectrometry.

PO. Danis[2] A. Holle[1] D.E. Karr[2], F.J. Mayer-Posner[1] C. Koester[1]

Introduction

The technique of matrix-assisted laser desorption/ionization time -of-flight (MALDI-TOF) has proven to be very powerful for the analysis of biopolymers and synthetic polymers up to a mass range of 10^5 dalton (1-3).
Several investigations of large biopolymers indicate that the dominant detection mechanism is not electron conversion but sputter processes of small surface contaminants of either charge (4,5).
By analyzing a number of synthetic polymers we investigated weather these findings are also applicable to this class of compounds and which kind of the sputtered particles are most suitable for MALDI-TOF analysis. For that purpose we designed a detector which allows the detection of sputtered particles of either charge.
This is achieved by setting the appropriate polarity of the voltage of +/- 5 kV after the conversion dynode. The corresponding particles strike a second conversion dynode and cause another ion-electron- or electron-electron conversion. A successive SEV than provides the analog signal feeding into the data acquisition system.
As opposed to commonly used double channel plate detectors this detector shows no saturation at a high ion current. This prevents a discrimination of high masses which is especially important in the determination of molecular weight distributions of synthetic polymers.

Experimental

Measurements were performed using a Bruker REFLEX™ TOF mass spectrometer. All measurements were performed in the linear mode of the instrument.
A number of polymer standards were analyzed i.e. Polyethylenglycol (PEG 3.4k, 5.0k, 8.0k, 20 k), Polyethylenoxid (PEO 3.0k) and polystyrenesulfonic acid PSSA, 100k. The PEG`s were purchased from Aldrich, Germany , the PEO were provided from MPI für Makromolekulare Chemie, Mainz and the PSSA 100k was purchased from Polymer Laboratories as the neutralized sodium salt of the acids. It than was prepared in the acid form by ion-exchange with a column of Amberlite IRN-77.PEO was dissolved in Chloroform and the PEG`s and the PSSA were dissolved in water with a concentration of about 10 g/l and mixed 1:1 (v/v) with a solution of 1.5 g/l HABA (water : acetonitril ,1:1) as matrix. 2 μl of the mixture was placed on a stainless steel probe tip and air dried.
Ions were produced by a laser desorption at 337 nm (N2-laser, 3 ns, 3 MW/cm2) and accelerated to 15 keV.

Results

The comparison of the mass spectra using the secondary species of opposite charge shows a significant higher detection efficiency for negatively charged particles. Fig. 1-4 shows the mass spectra of PEG recorded by using negatively charged particles (upper spectra) and positively charged ions (lower spectra). Fig. 5 shows the PEO 3k and Fig. 6 the PSSA 100k.

Some of the spectra using negatively charged secondary ions or electrons show a slight shift of the mass centroid of the distribution towards lower masses compared to the mass spectra using positively charged secondary ions. PEO for instance shows a shift of about 10 % (Fig. 5) and PEG (Fig.1-4) a shift of about 1 to 4 %. The PEG measurements do not indicate an increasing shift with increasing mass. The measurement of PSSA (Fig. 6) show a 1 % deviation of the mass centroid.
All the measurement show a significantly higher sensitivity for the detection of negatively charged particles, in favourable cases up to a factor of 20. Fig. 7 shows a comparison of the yield of PSSA 100k . The spectra are sums of 200 single spectra.

RAPID EVALUATION OF POLYMERS USING PARTICLE BEAM/CHEMICAL IONIZATION MASS SPECTROMETRY

Joe M. Wood*, Vistakon Johnson & Johnson Vision Products, Inc.,
P.O. Box 10157, Jacksonville, FL 32247

Ulrich R. Bernier, Jodie V. Johnson and Richard A. Yost,
Department of Chemistry, University of Florida, Gainesville, FL 32611

INTRODUCTION

Mass spectrometry using desorption ionization has become one of the fastest growing techniques for the analysis of low molecular weight polymers. Recent studies using matrix assisted laser desorption ionization (MALDI)[1], fast atom bombardment (FAB)[2], and desorption chemical ionization (DCI)[3] have all demonstrated the power of this methodology. However, these techniques require modest sample preparation and are not suitable for rapid and/or automated sample introduction.

The results presented in this study show that the introduction of polymer samples into a mass spectrometer via a particle beam interface allows rapid evaluation of the samples with results that compare favorably with those obtained using desorption chemical ionization (DCI).

Conventional mass spectra were acquired using both ionization techniques to characterize selected polymers. DCI was employed for MS/MS analysis acquiring both parent and product-ion spectra. Multiple ion monitoring using particle beam/CI was used to demonstrate that both qualitative and quantitative information can be derived in a short period of time with a large sample throughput.

EXPERIMENTAL

Polyethylene glycols (PEG), polypropylene glycols (PPG) and polystyrene (PS) were examined in this study. For particle beam/CI analysis solutions of these samples were injected into an HPLC with no column and introduced into a TSQ-70 triple quadrupole mass spectrometer via a three-stage particle beam interface. $[M+H]^+$ ions of low molecular weight polymers (<2000 Da.) were formed by isobutane chemical ionization following desorption vaporization in the 190°C ion source.

For analysis using DCI, aliquots (μL) of the solutions were deposited upon rhenium wire filaments and the solvent was allowed to evaporate. Temperature profiles of the DCI probe varied between experiments and CI was achieved using ammonia or isobutane.

MS SPECTRA:

Analyses were initially performed using particle beam/CI (iosbutane) and alternating between positive and negative ions (PPINICI). Samples with differing average molecular weights from each of the three polymers were injected into the HPLC and analyzed. Positive CI was shown to be more efficient than negative CI by an order of magnitude. Particle beam/CI of PEG_{600} and PPG_{725} yielded mainly $[M+H]^+$ ions for n>7 and fragment

ions corresponding to $[M+H-H_2O]^+$ for n<7. The positive CI spectrum of PS_{946} (repeating unit = 104 amu) contained two series of ions reflecting a difference in end groups. Extensive fragmentation in the negative CI spectrum of PS makes further characterization difficult.

PPG_{425} was examined using DCI with ammonia as the reagent gas. The positive spectrum was composed of $[M+NH_4]^+$ ions and the negative spectrum was composed of $[M-H]^-$ ions. Both spectra yielded information which can be used to calculate molecular weight distributions.

MS/MS SPECTRA:

Tandem mass spectrometry experiments were utilized to characterize and identify polymers in mixtures. The parent spectrum of the fragment ion m/z 133 (isobutane DCI) in an experiment examining a sample of PEG_{600}/PEG_{1000} was acquired to determine the distribution of protonated molecular ions present in the solution. The product-ion spectrum (ammonia DCI) of the ammonium adduct m/z 442 from a sample of PPG_{425} was acquired to screen samples for the presence of PPG. To further the sensitivity of the MS/MS experiment reaction monitoring of m/z 442 -> m/z 117 was performed. The limit of detection was determined to be 20 picomole.

QUANTITATIVE ANALYSIS:

Particle beam/CI and multiple ion monitoring experiments were employed for detection and quantitation of PEG_{400} in unknown samples. Only the most abundant molecular ions were scanned which led to a lower limit of detection (low picomole) as well as an increase in the selectivity of the experiment. The peak area of the reconstructed ion chromatogram was determined and quantitation was achieved using external standards used to construct a calibration curve. Using this methodology, samples could be evaluated in rapid succession with no detectable carryover. Typical times between injections were two minutes. Further information can be gained by comparing the average %RIC of detected PEG ions in the samples with those from PEG_{400}.

CONCLUSIONS

Particle beam/chemical ionization mass spectrometry is a rapid and sensitive technique for the analysis of low molecular weight polymers (<1000 amu). Very little sample preparation is required and the data obtained using this technique is similar to that acquired using desorption chemical ionization. Both qualitative and quantitative information can be derived in a short period of time. Additionally, the HPLC interface will allow automation of sample evaluation.

Structural Characterization of Dimer Fatty Acids by DCI Mass Spectrometry

*Larry Sallans and C. William Blewett
Henkel Corporation, Emery Group
4900 Este Ave., Cincinnati, Ohio 45232

Dimer fatty acids are among the most unusual polybasic acids commercially available. While high in molecular weight, these acids are still liquid and find utility in many diverse applications including surface coatings, synthetic lubricants, polymer modifiers, and polyamides for inks and adhesives. The product is produced by the oligomerization of two unsaturated, mainly C_{18}, fatty acid molecules. The raw product is a complex mixture of oligomers (mainly dimer), structural types (linear, cyclic, aromatic, etc.) with many isomeric forms, homologous chain-length distributions, and a slight amount of other functional groups (interester, lactones, decarboxylation products, etc.). The results presented in this study, are based on hydrogenated Dimer acids purified by distillation. Although low in other oligomers and functional groups, they nevertheless contain a broad distribution of structural types with respect to the dimer linkage. This distribution which correlates with a large variation in performance characteristics, is related to the fatty acid source and manufacturing conditions. The focus of the study is primarily the quantitation of the various structural types in hydrogenated, distilled C_{36} dimerized fatty acid.

These products are difficult to analyze. They represent a very complex mixture of components with low volatility and which may fragment or undergo ion-molecule reactions to yield ions representing other components of the mixture. A technique that is successful, involves electron capture of the pentafluorobenzyl derivatives introduced by means of a Desorption Chemical Ionization (DCI), probe. The pentafluorobenzyl derivatives undergo dissociative electron capture to yield carboxylate anions that are representative of the Dimer's structural types. These pseudomolecular ions, each representing a large isomeric distribution, are deconvoluted for isotopic contribution. Components comprising the various structural types are listed in Table 1 along with the representative carboxylate anion's mass.

Data representing structural types for three hydrogenated Dimer samples from different fatty acid sources are illustrated in Table 1. Immediately evident is the high precision demonstrated by the technique. In addition, a more detailed breakdown of the material's components and quantitation of components (polycyclic aromatics) which have not been previously identified for Dimer, are obtained. The results compare extremely well with other methods and techniques.

McMahon and Crowell[1] combined EI mass spectrometry for nonaromatic components with UV analysis for the aromatic constituents in tall oil and oleic acid based Dimers. They list four structural types, three non-aromatic (linear, monocyclic and polycyclic) and one aromatic. Even though different samples were analyzed, the agreement between the two techniques, is excellent. NMR and UV analysis for the aromatic content of the samples listed in Table 1 also agreed very well with results presented by this study.

Hydrogenated Dimer is not without olefinic unsaturation as Iodine-Value and NMR results attest. In an attempt to further characterize the structural classes, a short-exposure bromination on oleic Dimer was performed. All the Dimer components with the exception of the "polycyclic, nonaromatic" (pseudomolecular ion at 741 amu), remain unchanged. Approximately half of the component at 741 amu underwent reaction. While the results are still preliminary, it is proposed that the olefinic species in oleic Dimer is largely monocyclic with a tetrasubstituted double bond.

In conclusion, electron capture of pentafluorobenzyl derivatives by DCI mass spectrometry, provides an accurate, highly precise technique for the quantitation of the structural components in Dimer acids.

[1]McMahon, D. H., and Crowell, E. P., *JAOCS*, **1974**, *51*, 522-527

Table 1. Hydrogenated Dimer - Comparison with the acid source

Dimer Component[1]	Soya 26-A	Tall 26-B	Oleic 26-C
Linear (acyclic) - 745	23.7±1.1	12.7±0.7	38.2±0.8
Monocyclic, nonarom. - 743	48.2±0.8	57.8±0.9	47.9±1.4
Polycyclic, nonarom. - 741	8.7±0.6	14.7±0.8	7 2±0 9
Polycyclic, nonarom. - 739	1.5±0.6	2.6±0.4	1.0±0.2
Monocyclic aromatic - 737	7.7±0.2	5.2±0.3	3.2±0.4
Polycyclic arom. - 735	8.5±1.0	6.1±0.2	2.1±0.4
Polycyclic arom. - 733	1.8±0.2	1.0±0.1	0.4±0.1
Total acyclic nonaromatics	23.7±1.1	12.7±0.7	38.2±0.8
Total cyclic nonaromatics	58.4±2.0	75.1±2.1	56.1±2.5
Total aromatics	18.0±1.4	12.3±0.6	5.7±0.9

[1]These hydrogenated samples still contain a small amount of olefinic unsaturation (see text). "Polycyclic aromatic" components contain only one aromatic ring with additional saturated ring(s) or olefinic functionality.

Application of MALDI Mass Spectrometry to Different Classes of Synthetic Polymers

Ute Bahr, Andreas Deppe, Michael Karas, Franz Hillenkamp
Institute for Medical Physics and Biophysics, University of Münster,

Ulrich Gießmann, Andreas Overberg
Finnigan MAT, PO box 140162, 28088 Bremen, FR Germany

The feasibility of using MALDI mass spectrometry for determination of average molecular weight and characterization of the polymer distribution has been shown for various synthetic polymers in the mass range between 1000 and 100,000 Dalton. Different matrix/solvent systems are required to match the specific solubility of e.g. polyanionic compounds or unpolar hydrocarbons. Whereas water- or water/organic solvent soluble polymers are investigated using well-known "protein" matrices, dissolving the polymer sample directly in a liquid nitrophenyl octyl ether matrix yielded best results for e.g polystyrene; Ag-trifluoroacetate addition is used to promote Ag cationization. Reproducible and reliable mass determination of polymers, however, requires a careful control of the experimental parameters. This is documented for same examples :

- a) For polymers of low average molecular mass the determined mass is depending on the ion impact energy at the detector surface with a shift to too low mass at low ion energies. Ion energies of 10 keV and larger are required to avoid these problems. For larger polymers this effect is not observed, higher ion impact energies at the detector, however, are generally preferable because of higher ion intensities.
- b) Cationization of low molecular mass polymers shows a distinct influence on the alkali-metal ion yielding a shift of the polymer distribution to smaller n-values for Li and Na. Sample cleaning by ion exchange and addition of KI yields reproducible results; cationization by K^+ forms the best compromise between obtainable ion intensities (efficiency of cationization) and imaging of the accurate polymer distribution.
- c) Polyanionic polymers, such as poly(methacrylic acids) usually show broad unresolved signals also in the low mass range due to a widely varying number of free acid and salt groups and different cations present. Well-resolved signals displaying the units of repeat are obtained (also) in the positive ion mode by cation exchange (H^+-activated) pretreatment and addition of KI to induce uniform cationization.
- d) Due to locally heterogeneous mixing with the matrix polyanionic polymers, such as poly(acrylic acids) may show different polymer distributions from spot-to-spot. Optical control of preparation and scanning of the sample/matrix layer under microscopic observation is required to avoid misleading results.

Future improvements for MALDI of polymers is possible by searching and choosing new matrices. E.g. 2(4'-hydroxybenzylazo)-benzoic acid yields superior results e.g. for PEOs with respect to signal intensities and mass resolution. In addition, use of IR wavelengths (Er-YAG-laser emitting at 2.94 μm) with a succinic acid matrix showed considerable improvement in the quality of the mass spectra obtained for polyanionic oligomers.

Direct Analysis of Polypropylene Compounds by Thermal Desorption and Pyrolysis Mass Spectrometry.*

Robert P. Lattimer, The BFGoodrich Research and Development Center, Brecksville, Ohio 44141.

This report describes the mass spectrometric identification of components (particularly residual volatile chemicals, organic additives, and degradation products) in five polypropylene compounds of known composition. Direct probe heating of the compounded polymer was carried out over the range 20-400°C, using a Finnigan MAT 95Q hybrid (BEoQ) mass spectrometer. "Survey" mass spectra were acquired with three different methods of ionization: 70eV electron impact (EI-MS), isobutane chemical ionization (CI-MS) and field ionization (FI-MS). For the polypropylene compounds, residual volatile chemicals and most organic additives were desorbed at lower temperatures (less than ≈300°C), while polymeric components were thermally decomposed (pyrolyzed) at higher temperatures (greater than ≈300°C). It was found that field ionization gives a very convenient overview of the composition of the evolved chemicals, since essentially all of the ions observed are molecular ions for the various components. In some cases, tandem mass spectrometry (MS/MS) was used to obtain fragmentation patterns (product ion scans) for chemical structure elucidation. High resolution mass measurements were also carried out to obtain elemental formulas (or atomic compositions, AC-MS) for particular chemical components.

Of particular interest was the detection of the oligomeric hindered amine light stabilizers (HALS) Tinuvin[R] 622 and Chimassorb[R] 944. It was possible to confirm the presence of Tinuvin 622 in polypropylene by CI- or FI-MS analysis of pyrolyzates evolving in the temperature range 300-350°C. The presence of Chimassorb 944 in polypropylene could be confirmed by detection of one of its low molecular weight components (cyclic monomer) by thermal desorption CI-MS. Pyrolysis products from polypropylene were observed above ≈350°C at every carbon number to masses >1000 Da. Overall, the direct mass spectral analysis of the polypropylene compounds was found to be a very effective means for detection and identification of various organic additives and polymeric components

Our general approach to analysis of the polypropylene compounds was to use field ionization as a "survey" or screening technique to obtain an overview of the chemical composition, *i.e.*, to determine the number of components and their molecular weights. Then the supplemental techniques of MS/MS and AC-MS were used, in EI and/or CI mode, to elucidate or verify chemical structures. To illustrate this approach, a composite FI mass spectrum showing the thermal desorption region for one of the compounds is included. The recipe for the compound is as follows: Himont 6301 polypropylene (100 parts), Irganox[R] 3114 (0.10 parts), Ultranox[R] 626 (0.08 parts), calcium "stearate" (0.10 parts), Tinuvin[R] 770 (0.40 parts). The most intense ion in the FI spectrum is m/z 480, which is $M^{+\cdot}$ for Tinuvin 770, a HALS additive. A small methyl-loss fragment is observed (m/z 465). Other additive molecular ions in the figure are m/z 530 (Irganox 1076), m/z 604 (Ultranox 626), and m/z 783 (Irganox 3114). (The Irganox 1076 is present as an additive in the Himont polypropylene.) Product ion scans for the various components were readily obtained directly from the polymer compound (EI- or CI-MS/MS), despite the fact that the concentrations of the additives were only ≈0.1%. High resolution mass measurements could also be made for ions from the additives directly from the polymer compound. Lower mass ions in the figure include m/z 206, 256 and 284. MS/MS and AC-MS data indicate that these are molecular ions for 2,4-di-*t*-butylphenol, palmitic acid and stearic acid, respectively. The substituted phenol is a degradation (hydrolysis) product from Ultranox 626. The acids arise from degradation of calcium palmitate/stearate.

CTD-(GC)-MS SYSTEM [CONTROLLED THERMAL DEGRADATION-(GAS CHROMATOGRAPHY)-MASS SPECTROMETRY]

Ted T. Chang and M. J. Piquette
Cytec Industries, 1937 W. Main St., Stamford, CT 06904

Many industrial products incorporate various additives at small concentrations intended to modify or improve their performance. Typical examples are sizing agents in paper, UV absorbers and plasticizers in polymers and cross-linking agents in coating materials. The thermal behavior of these additives can be as important as the thermal behavior of the major components. Because of their insufficient sensitivity, currently available TGA/MS systems are unable to address these types of problems.

A Controlled Thermal Degradation-(Gas Chromatography)-Mass Spectrometry [CTD-(GC)-MS] system was constructed to overcome the inadequacies relating to poor sensitivity. The sensitivity of this system is approximately 2-3 orders of magnitude higher than that of most commercial TGA/MS systems. Therefore, the proposed system is capable of specifically targeting minor components. A high-resolution mass spectrometer is used to remove interfering ions in the same nominal mass. The system accepts a wide range of sample sizes from low ug to low mg level depending on the target compound concentration. Temperature is controllable within +/- 5°C, which is sufficient to produce thermal degradation patterns comparable to TGA. The system is capable of on-line MS observation of thermal decomposition (similar to TGA/MS), on-line GC/MS analysis of the the degraded mixture, and collection of degraded material for subsequent analysis by other analytical techniques.

The most important advantage of the CTD-(GC)-MS system is its capability to observe the thermal behavior of a selected compound, especially a minor component in a complex sample matrix. The sample size is in the 10 ug range comparing to the 1-10 mg range for pyrolysis GC/MS and TGA/MS. Utilization of a high-resolution mass spectrometer adds a powerful mass ion separation capability.

Thermal degradation products usually are complex mixtures. The unit-mass resolution mass spectrometer used in most TGA/MS systems is highly subjected to interfering ions with the same nominal mass. The collecting device of the proposed system is capable of selecting a desired degradation temperature and obtaining the composition profile of degradation products.

The CTD-(GC)-MS system has many potential applications. It can be used to study the thermal behavior of a sample, the fate of a certain component in a sample, identification of evolved

gases, analysis of complex degradation mixtures, etc. Three typical examples are included in this presentation.
The first example is study on the curing behavior of a commercial monomeric cross-linkng agent. The operation is similar to TGA/MS but with a sensitivity 100 times higher than TGA/MS.

The second example shows the application of the system to study the thermal behavior of a minor component. The sample is a paper containing approximately 0.05% of a common sizing agent. It was found that the sizing agent evolved at the early stage of degradation.

The third example is the CTD-GC-MS operation. It shows the capability of the system to focus on a selected degradation temperature. Many samples exhibit complex thermal degradation processes. Their decomposition products are different at different temperatures and heating rates. Collection of the degradation products and separation by a GC unit prior to MS analysis are essential steps to provide useful analytical information.

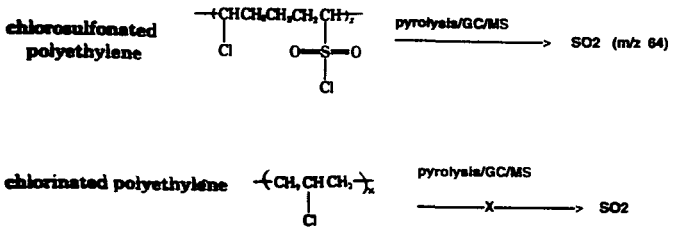
A Method for Distinguishing Chlorosulfonated Polyethylene from Chlorinated Polyethylene Using Pyrolysis/GC/MS

*Aris A. Gallon and John Glass Green, The DOW Chemical Company, Research and Development, Analytical and Engineering Sciences Laboratory, Plaquemine, Louisiana 70765-0400.

Often it is not possible to distinguish between chlorosulfonated polyethylene (CSM) and chlorinated polyethylene (CPE) by elemental analysis for sulfur content because of sulfur containing additives used in CPE formulations. A method was developed to distinguish between the two based on the formation of sulfur dioxide during the pyrolysis of CSM. Both types of polymers pyrolyze by a side group elimination mechanism. This mechanism of pyrolysis produces SO2 from the pendant -SO2Cl groups on the CSM backbone. The SO2 is detected indicating the presence of -SO2Cl groups in the polymer.



Experimental:

The pyrolysis was done using a CDS 122 coil pyroprobe connected to a Hewlett Packard 5987 GC/MS. The following pyroprobe and GC/MS conditions were used:

Coil Probe:	GC/MS:
Interface= 200 C	column= DB 1701 30 m X 0.32 mm
final temperature= 1400 C	initial temperature= 30 C
rate= 20 C/ms	rate= 15 C/min
interval= 20 sec	final temperature= 250 C
	mass range scanned= 30-500 amu

The pyrolysis/GC/MS chromatograms of a CSM polymer formulation and a CPE polymer formulation that was cured with thiadiazole are shown in Figures 1 and 2. The extracted ion chromatogram for m/z 64 of the CSM polymer pyrolysis products (Figure 1b) shows an intense peak at a retention time of 1.32 min.

The mass spectrum (Figure 1c) indicates that the component is sulfur dioxide. The extracted ion chromatogram for m/z 64 of the CPE polymer that was thiadiazole cured (Figure 2b) also shows a peak at a retention time of 1.35 min. The mass spectrum (Figure 2c) indicates that the component is butadiene.

Comparative results for several other samples will be shown to further illustrate the method. Pyrolysis/GC/MS chromatograms of pure polymers and formulated polymers will be presented.

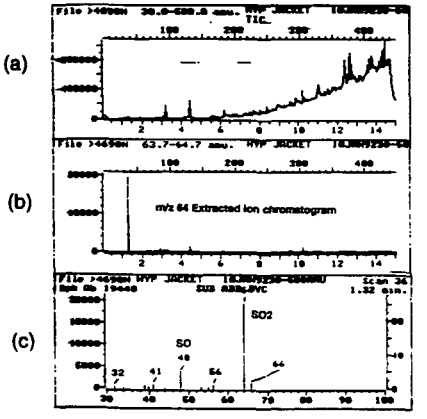


Figure 1:

Chromatogram of chlorosulfonated polyethylene pyrolysis products. (b). Extracted ion chromatogram for m/z 64. (c). Mass spectrum identifying the peak as sulfur dioxide.

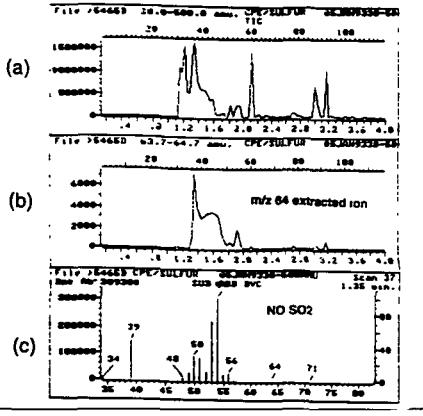

Figure 2:

Chromatogram of chlorinated polyethylene. (b). Extracted ion chromatogram for m/z 64. (c). Mass spectrum identifying the peak as butadiene.

GC/MS Determination of Aromatic Isocyanates and Amines as Degradation Products in Polyurethane Foams Used in Breast Implants.

Frank M. Benoit
Health and Welfare Canada
Ottawa, Ont, Canada K1A 0L2

INTRODUCTION

The Même breast prosthesis consists of a gel filled silicone envelope covered with a thin layer (1-2 mm) of soft polyurethane foam (Microthane TM) which is manufactured from toluene diisocyanates (2,4- and 2,6-TDI ratio 4:1) and polydiethyleneglycol adipate. However, 2,4- and 2,6-TDI react with water to produce 2,4- and 2,6-toluene diamines (TDA) which are commonly found at the ppm (ug/g) level in polyurethane foams. Under harsh conditions of temperature (T = 150 °C) and alkalinity (3N NaOH), polyurethane foams are completely decomposed. We have examined the degradation reaction under the milder conditions of temperature (T = 37 °C) and alkalinity (pH = 7.4) that exist within the human body. In preliminary experiments, we found that the foam contained toluene isocyanate amines (TIA) and TDI in addition to the expected TDA. To test the degradation hypothesis properly, it was imperative that the initial TDA, TIA and TDI contaminants be removed completely from the foam. Despite our best efforts this proved to be an impossible task. Low ppm levels of TDA, TIA and TDI were consistently observed despite extensive washing of the foam. Furthermore, we observed that TDA has a low aqueous solubility; consequently, degradation products from the foam will be preferentially retained on the surface of the foam rather than migrate into the aqueous phase. Hence, in any study of the degradation of the foam in aqueous medium, the foam itself must be examined along with the aqueous phase following exposure.

EXPERIMENTAL

The following protocol was adopted for incubation of the foam. Precleaned (6 days Soxhlet extraction) foam was divided into two fractions A and B. Fraction A was stored in the dark at room temperature while fraction B was incubated in Ringer's solution at 37 °C for periods of 6 to 35 days. Following the incubation both fractions were analyzed and the results compared. A similar experiment wherein fractions C and D were incubated dry at 37 °C was also carried out. The Finnigan MAT-90 GC/MS was operated in EI mode. The on-column injector was operated at 110 °C, hold 0.1 min, ramp to 300 °C at 180 °C/min. The SPB5 30 m x 0.32 mm id column (0.25 micron film) was held at 100 °C for 1 min then ramped to 180 °C at 5°/min, then to 250 °C at 20°/min and held for 3 min. TDA and TDI were identified and quantified as the HFBA amide derivatives by monitoring m/z 514, 495, 345, 317 and 302 for TDA, m/z 344, 325 and 175 for TIA and m/z 174, 145 and 132 for TDI within the appropriate GC retention time windows.

RESULTS AND DISCUSSION

Every foam sample tested in the current study was initially contaminated with 2,4- and 2,6-TDA, TDI and TIA. The TDA levels in the virgin foam samples ranged from 2 to 71 ppm for 2,6-TDA and 18 to 692 ppm for 2,4-TDA. The average sum of TDA, TIA and TDI removed from the foam samples during the cleaning process was 1104 (+/- 644) ppm. The results from the extraction of the Ringer's solution from the foam samples incubated at 37 °C did not show any apparent relationship with the duration (6 to 35 days) of the incubation. On average, 1.88 ppm of total TDA, TIA and TDI were extractable from foam samples into 250 ml of Ringer's solution at 37 °C over periods of 6 to 35 days. In all twelve incubation experiments the levels of TDA, TDI and TIA were all higher in the B fraction than in the A fraction. The average incremental (B - A) amounts of TDA, TIA and TDI produced during incubation and retained on the foam surface were considerably higher (74 ppm) than the average amounts (1.9 ppm) released into the aqueous phase. Not only was there an increase in the levels of TDA but there was also an increase in the levels of TDI and TIA. However, the reaction between TDI and water is slow because of the low solubility of TDI in water. In the present experiments, most of the degradation products are adsorbed on the surface of the foam following the incubation and hence protected from hydrolysis. Nevertheless, TDI and TIA were not expected as products of the hydrolysis of polyurethanes which suggests that the observed degradation process is more complex than simple hydrolysis. The average daily total increments in the amounts of TDA, TDI and TIA was 4.6 ppm. In the dry incubation experiments the foam fraction C was stored at ambient temperature (20 °C) in the dark and fraction D was stored at 37 °C for periods of 7 and 15 days. In both instances (two duplicate samples) the amounts of TDA, TIA and TDI were higher in fraction D than in fraction C. Hence, thermal decomposition of the foam does indeed occur at body temperature. The average daily sum of degradation products was 1.5 ppm, which corresponds to ca 33 % of the daily degradation in aqueous solution.

CONCLUSIONS

The behaviour of polyurethane foams under simulated physiological conditions is complex. The foam surface exhibits strong adsorbent properties and is contaminated initially at the low parts per thousand level with residues of TDA, TDI and TIA, that are difficult to remove completely from the foam. Degradation of the foam occurred under mild hydrolytic (pH 7.4) and thermal conditions (37 °C) and produced an average of 4.6 ppm of TDA, TIA and TDA daily under simulated in vivo conditions and 1.5 ppm under mild thermal conditions (37 °C) alone. Examination of the degradation products showed that TDI and TIA were formed as well as the TDA. Because the ratio of 2,4-TDI and 2,6-TDI used in the production of polyurethane foams is 4:1, 80 % of the TDA, TIA and TDI in the foam have the 2,4-orientation of the nitrogen atoms and, hence, the potential to become 2,4-TDA within the human body. Consequently, the assessment of the risk to health associated with the presence of 2,4-TDA in polyurethane foams must include consideration of the 2,4-TDI and 2,4-TIA precursors as well.

GPC-LC/MS Using a Particle Beam Interface

*R.A. Ludicky, G.B. Kenion, D.E. Doster and P.D. Souchek
Morton International, Woodstock IL 60098

Gel permeation chromatography coupled to mass spectrometry is a technique that is in use in a number of laboratories. This technique requires little development time for analyses of smaller molecules and is a good screening method for such analyses. Many people underestimate the size of molecules which can successfully be transported across a particle beam. A series of polystyrene standards of known molecular weight were passed through a particle beam interface in order to see how transport efficiency varies with molecular weight.

A six component standard made from five polystyrenes of known molecular weight and α-methyl styrene dimer was separated by a two column set of GPC columns. The GPC columns utilized were a Jordi-Gell 300 Angstrom column and a Jordi-Gell mixed bed column. The effluent from the columns was then passed through an Extrel particle beam interface and into an Extrel ELQ 400 mass spectrometer. The six component standard was utilized to perform two different experiments. In the first experiment the standard was analyzed by LC/MS. In the second experiment the components of the six component standard were trapped at the end of the particle beam interface inside the mass spectrometer. The transport efficiencies of the components in the standard were then calculated by comparing the particle beam trappings to the initial standard solution. The particle beam trappings were compared to the initial standard by traditional GPC using a refractive index / viscosity detector operating in the refractive index mode.

The particle beam recoveries are given below in Table One

Table One: Particle Beam Recoveries

Component	% Recovery
Polystyrene MW = 1,600,000	Undetermined, Baseline problems
Polystyrene MW = 400,000	2.7 %
Polystyrene MW = 47,500	6.6 %
Polystyrene MW = 4,000	4.3 %
Polystyrene MW = 826	7.7 %
α-Methyl Styrene Dimer MW = 236	Pumped Away

It appears that most of the components of the six component standard are transported by a particle beam interface. Even the Mw = 1,600,000 can be seen in the particle beam trappings when the sample is analyzed by traditional GPC using a viscometer instead of a refractive index detector.

The GPC-LC/MS total ion chromatogram looks quite different from the GPC refractive index chromatogram of the particle beam trappings. The GPC-LC/MS total ion only features one good sized peak. This peak originates from the MW = 826 polystyrene. The GPC refractive index chromatogram of the particle beam trappings shows good peaks for all the components of the standard except the MW = 1,600,000 polystyrene which appears to get lost in the baseline and for α-methyl styrene dimer, which is pumped away. The difference between the GPC-LC/MS total ion chromatogram and the refractive index trace appears to be due to poor ionization of high molecular weight species by electron impact and chemical ionization. The analysis of high molecular weight compounds by particle beam LC/MS appears more limited by ionization efficiency then lack of transport.

Poly(Amic Acid) Polyimide Characterization Using Both GC/MS and Particle Beam LC/MS

Timothy MacMahon and Mark Chace
IBM, Hopewell Junction, New York, 12533

The analysis of polyimides is becoming increasingly more and more important as this class of polymers become more prevalent in today's electronic packaging technology.[1] Polyimides are noted for their high glass transition temperatures and thermal stability. In some cases, this thermal stability allows heating to temperatures as high as 400°C for many hours without a critical drop in physical or mechanical properties.[1] In addition to the use of polyimides as dielectric layers, there is also interest in developing photosensitive polyimides that could be used as both lithographic and insulating dielectric material; thus, unlike resists currently in use the new polyimide resists would not have to be removed after lithography saving numerous processing steps and shortening cycle times.

The high thermal stability of these polymers make them difficult to analyze by traditional analytical techniques. In particular, mass spectrometry has been able to do little toward understanding these polymeric systems.[2] Plat and Chace developed a mass spectrometric technique for the analysis of these polyimides which uses an Ing-Manske hydrolysis reaction to hydrolyze the polyimide.[3] Once the hydrolysis is complete, information about the amine and acid portion of the molecule can be probed via mass spectrometry. The amine portion can be detected via an ethyl ether extract, but in order to detect the acids their volatility must first be increased through derivatization to the methyl ester or the trimethylsilyl ester making them more amenable to gas chromatography / mass spectrometry (GC/MS).

The advent of liquid chromatography / mass spectrometry (LC/MS) has opened up new capabilities in the analysis of these polyimides. LC/MS can be used on thermally unstable molecules and/or molecules of low volatility i.e. operating temperatures are considerably lower.

In order to evaluate this new technology, a comparison was made between GC/MS and particle beam LC/MS. A number of polymers were hydrolyzed in NH_4OH and studied using gas chromatography / mass spectrometry (GC/MS) and particle beam liquid chromatograph mass spectrometry (LC/MS). The polymers studied in this report were as follows: 3,3',4,4'-biphenlytetracarboxylic dianhydride - phenylene diamine (BPDA-PDA); BPDA-PDA-4'-oxydianiline (ODA); pyromellitic dianhydride - 4,4'-oxydianiline (PMDA-ODA); and finally, 3,3',4,4'-benzophenonetetracarboxylic dianhydride - 1,3-bis(4-aminophenoxy)benzene (BTDA-APB).

Some of the polymer samples were hydrolyzed in both their acid and imide forms to see if any mass spectrometric differences could be detected. In all cases, the acid and imide spectra looked the same. GC/MS was unable to determine either the amine or acid portion of these polymers via a direct injection of the sample, but when the samples were first extracted with diethyl ether and this ether extract was injected into the chromatograph the amine portion of the polymers were readily detected. The acid portion was not detected in either the sample or the ether extract. The LC/MS was able to detect both the amine and acid monomeric units in the non-extracted aqueous sample.

Direct Chemical Analysis of UV Laser Ablation Products of Organic Polymers Using Reflectron Time-of-Flight Mass Spectrometry (Re TOF-MS) and Gas Chromatography/Mass Spectrometry (GC/MS)

Yeong Choi, Heewon Lee, Scott T. Fountain, and David M. Lubman
Department of Chemistry
The University of Michigan
Ann Arbor, Michigan, 48109

The interactions of UV laser radiation with organic polymers have been studied extensively for their potential applications in technology and medicine. Although physical aspects of laser ablation are relatively well understood, direct chemical analysis of the ablation products is still a challenging task that needs to be explored. Some difficulties associated with chemical analysis of the laser ablation products involve the complexity and trace quantities that may result. Even more problematic in some cases is the lack of a technique for direct chemical analysis of laser-induced ablation products in trace quantities.

Recent studies have shown that use of an appropriate masking polymeric fluid in excimer laser surgeries can improve the smoothness of the corneal surface in these surgical procedures and thus there has been an effort to develop new polymer masks for this purpose (1,2). A potential drawback of the use of masking polymeric fluid in excimer laser surgeries is the formation of photochemically induced products which may be toxic. If such species were produced in sizable amounts, then this might preclude the use of these polymers in these surgical procedures, particularly in human subjects. Thus, such problems have motivated us toward developing direct analytical methods for detecting and identifying the UV laser-induced ablation products of polymers.

In the present study, a commercial gas chromatography/mass spectrometry (GC/MS) system has been modified so that trace quantities of ArF excimer UV laser-induced ablation products of a potential masking fluid may be introduced into the capillary column directly for chemical analysis. By obtaining the chromatogram in the SIM (Selective Ion Monitoring) mode which increases the sensitivity of the detector significantly, the presence and/or absence of the potentially toxic fragments that may result from the laser ablation of poloxamer have been monitored.

Poloxamer is an organic polymer which has a potential to be used as a masking fluid. From the photochemistry and structural considerations, the possible laser ablation products of poloxamer include ethylene oxide and acetaldehyde. Upon laser ablation, the chromatogram of the poloxamer shows 4 peaks with different composition as shown in Figure 1. Of particular interest is the peak B in Figure 1 which, when compared with the chromatogram of ethylene oxide/acetaldehyde mixture, shown in Figure 2, has the same retention time as that of acetaldehyde. In addition, the relative ratios of ions, $[C_2H_3O^+(m/z = 43)]/[C_2H_2O^+(m/z = 42)] > 2$ and $[C_2H_2O^+(m/z = 42)]/[C_2HO^+(m/z = 41)] \simeq 3$, identify the peak B as that due to acetaldehyde and exclude the possibility of the presence of ethylene oxide as a laser ablated product of poloxamer.

Complementary information on the laser ablation products of poloxamer was obtained by using the Reflectron Time-of-Flight Mass Spectrometer (Re TOF-MS) and the possible species, which included larger mass fragments, were identified. For comparison, structurally similar polyethylene glycol (PEG) was also studied.

Analysis and Quantification of Polymer Additives in Polyolefins by Particle Beam LC/MS

Matthew J. Dilts, Millipore/Extrel Mass Spectrometry,
575 Epsilon Drive, Pittsburgh, PA 15238

INTRODUCTION

The additive packages used for polyolefins can be quite complicated, containing several antioxidants, both primary (such as hindered phenols) and secondary (also called synergistic), as well as antistats, slips, pigments, etc. It is very important to the processing and longevity of the fabricated material that the correct amount of each additive be present. Failure to choose the correct additive package may result in degradation during processing or premature oxidation/aging and early failure in the field.

EXPERIMENTAL

Traditionally, these compounds have been chromatographically separated by reverse phase liquid chromatography and detected by UV. This study will demonstrate the ability to use a mass spectrometer as a secondary detector to confirm peak identification and quantification of additives.

Gradient: (A) Water

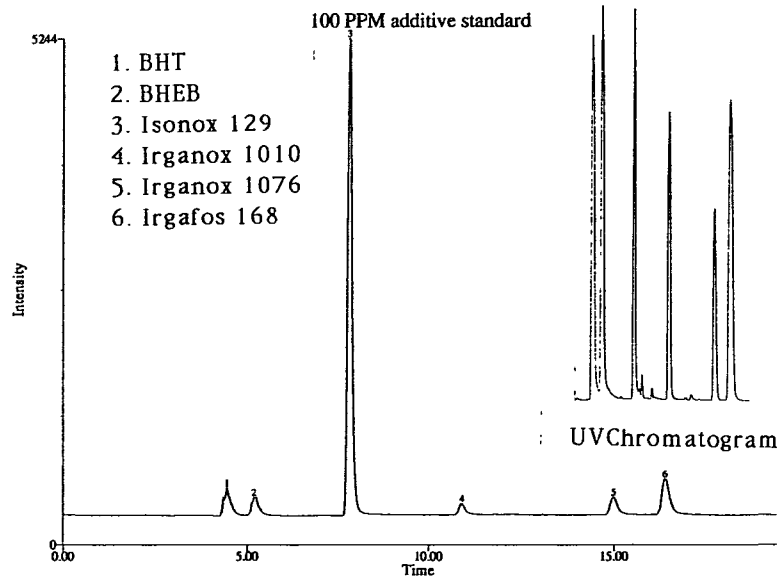
(B) Acetonitrile

60% - 100% B in 6 minutes hold for 20 minutes

flow rate 0.3 ml/min

CONCLUSION

LC/MS can be used as a secondary detector for quantification of polymer additives. The spectra presented are interpretable electron impact type spectra. The mass spectrometer can also be used for quantification of polymer additives. The next phase of this study is to analyze actual polymer extracts and quantitate the data.



Surface Additives on Bulk PET Studied with High Mass Accuracy ToF-SIMS

S.Reichlmaier*, J.S.Hammond Perkin-Elmer Physical Electronics Division,
Eden Prairie, MN 55344, USA
M.J.Hearn, D.Briggs, ICI Wilton Research Centre, PO Box 90 Wilton,
Middlesbrough, Cleveland TS6 *JE, England

Introduction

The routine analysis of polymer surfaces involves detection of additives that in many cases show molecular ions or unique fragment ions in the mass range up to m/z=1000. The static SIMS technique employing a ToF mass analyzer is most appropriate for the sensitive detection of these materials. The potentials of the technique have been described frequently. For the routine use in a analytical laboratory, however, the reproducibility of the instrument is very important. We studied therefore a very common polymer matrix (poly(ethylene terephthalate), PET) over a 6 month period of time to extract statistical information on the accuracy of the mass assignment as well as on mass resolution and signal intensities. The results obtained from the PET matrix were then used in a study of a very common additive material (glyceryl monostearate, GMS).

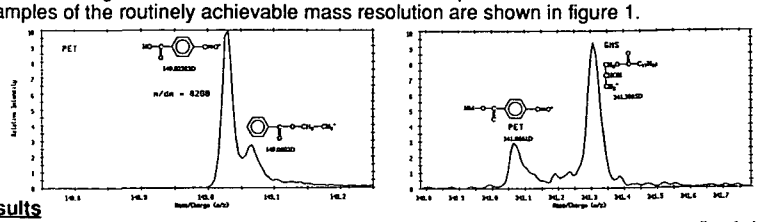
Experimental

A Perkin-Elmer PHI 7000 ToF-SIMS instrument was used to analyze the PET polymer films of about 0.1mm thickness. The Cs primary ion gun was used to generate SIMS mass spectra over a range of m/z=10 to 600. The acquisition time per spectrum was less than 2 minutes and the employed primary ion dose was well below10^{12} ions/cm^2. Charge neutralization was established with a low energy electron flood gun. The automated peak finder routine of the instrument software was used to determine the measured masses of selected peaks of known exact mass. The accuracy of the mass assignment was then calculated. The evaluated peaks in positive SIMS and their exact mass are listed in table1.

Species PET	C7H4O	C9H8O2	C10H9O4	M+C2H5O	M+C8H5O3	2M+H	3M+H
Mass	104.0262	148.0524	193.0501	237.0763	341.0661	385.0923	577.1346
Species GMS	C18H35O	C18H37O2	C21H42O3	M+H	M+Na	C39H75O4	
Mass	267.2688	285.2794	341.3055	359.3161	381.2981	607.5665	

Table 1 Evaluated mass peaks of PET and GMS on PET (note that m/z=607 is a low level distearate contamination).

An automated calculation routine was used for the evaluation of the obtained mass resolution and signal intensity. The GMS was studied under similar conditions as the plain PET samples. The analysis was carried out on GMS deposited as thin (non charging) film deposited on an Al disk and as coating on PET substrate. The evaluated peaks are also summarized in table 1. Examples of the routinely achievable mass resolution are shown in figure 1.



Results

The calibration of ToF-SIMS spectra is performed by calculating a least square fit of data pairs from a set (up to 20) of measured flight times for known mass peaks. In this study we distinguish between a system calibration that was performed before the spectrum was measured and

calibrating the spectrum after the acquisition was finished. The system calibration used only well known low mass fragments (CH_3, C_2H_3, C_3H_5) to calculate the calibration constants. For the calibration of the spectra we investigated different combination of calibration mass peaks. The results from 34 individual spectra acquired between November 1992 and April 1993 evaluating the 238 individual peaks for each calibration are summarized in table 2.

Calibration	System	3Peak	6Peak	8Peak	4Pi
Acc. of Aver [ppm]	11.1	10.4	5.3	6.5	6.2
Standard Deviation	32.2	13.0	13.5	16.2	13.7

Table 2: Accuracy of the mean mass value and standard deviation from 238 evaluated peaks.

Results from five different calibrations are shown. The system calibration was described above, the remaining four were applied to the spectra after the acquisition was finished. The 3Peak calibration involved the same peaks as the sytem calibration. For the 6Peak calibration the C_4H_7 C_6H_5 and C_4H_7O ions were added to the calibration. The 8Peak calibration included also the $C_9H_8O_2$ and $C_{10}H_9O_4$ ions. All these calibrations are regarded as extrapolating, because all evaluated peaks have higher masses than the calibration peaks. In contrast to the above the 4Pi calibration includes the three low mass peaks as the system calibration plus the protonated monomer peak at m/z=193. It therefore includes two peaks with interpolated calibration.
The FWHM mass resolution of the 238 individual peaks was measured and the results are plotted in table 3. The peak areas, calculated within the FWHM around the peak maximum are also included in table 3. The intensities decrease more than 2 orders of magnitude with increasing peak mass.

Peak m/z	29	104	148	193	237	341	385	577	
FWHM m/Δm	6048	7777	7250	7332	6955	6371	7649	8090	
Peak Area	n.a.	20728	5419	2805	631	706	455	115	[cts]

Table 3: Average mass resolution and peak area fom 34 individual measurements.

Results from 16 individual GMS spectra are summarized in table 4. For the typical measured accuracies we calculated the number of possible species assignments for a C,H,O and N containing organic substance at the mass of the GMS protonated molecular ion at m/z=359.3161.

Peak m/z	267	285	341	359	381	607
Accuracy [ppm]	7 6	8 2	5 2	11.2	4 0	37.9
Standard Deviation	10.5	14.6	15 4	11.9	12.1	23.4

Table 4: Average mass accuracy of the evaluated GMS peaks of 16 individual spectra.

The results show that the number of possible choices for assigning a species to a given mass peak is substantially reduced with improved mass accuracy (e.g. 4 @ 10ppm vs. 20 @ 70ppm).
The mean values of mass resolution at m/z=359 of GMS on Al and PET from 16 individual spectra compare as m/dm=10,800 ± 700 on the conductor and m/dm=8400 ± 700 on the PET.

Conclusion

The statistical investigation of the routine performance of the Perkin-Elmer PHI 7000 ToF-SIMS instrument for polymer analysis resulted in achievable mass accuracies better than 20ppm. This kind of perfomance is required for typical additive characterization because it allows species assignments based on accurate determination of the ions mass.
For achieving good mass accuracy it is very important to maintain good routine mass resolution on insulating samples. Only very slight degradation was found in this study on GMS.

Nonpolar Polymer Analysis by Continuous Flow Fast Atom Bombardment Mass Spectrometry (CF-FAB/MS)

Robert L. Dilliplane, Rohm and Haas Company, Spring House, PA 19477

INTRODUCTION

CF-FAB has several advantages compared to static FAB: increased sensitivity, decreased intensity of background and matrix ions, improved background subtraction, and quantitation using flow injection comparisons. Since many compounds are not water soluble and not compatible with the commonly used CF-FAB solvents, I explored alternate solvents to increase the application of CF-FAB to include nonpolar compounds.

The first attempts used organic solvents with 3-nitrobenzyl alcohol, the matrix of choice for many nonpolar compounds analyzed by FAB. Tetrahydrofuran dissolved the compounds of interest and promoted ionization without the addition of a matrix.

EXPERIMENT

Using tetrahydrofuran without additional matrix, CF-FAB was used to determine the molecular weights of both polymer oligomers and polymer additives.

Stable operation can be achieved using 20uL/minute tetrahydrofuran delivered to the FAB tip through a 26um I. D. fused silica line with a source temperature of 30°C. If the flow rate is too low or the source temperature is too high, the rate of evaporation of tetrahydrofuran causes the sample to deposit on the FAB tip. The flow rate of the tetrahydrofuran has to be maintained at a rate high enough to ensure the sample remains in solution for ionization to occur.

The FAB tip is insulated from the ion source so that a potential, independent of the source potential, can be applied.

ADDITIVE RESULTS

Tinuvin 770 was analyzed by CF-FAB using tetrahydrofuran. Applying a potential to the FAB tip was done to enhance ion extraction, a technique reported by M. Linscheid (Ref.). A potential of +9V on the FAB tip had the additional benefit of reducing the solvent adduct ions, enhancing the m/z 481.

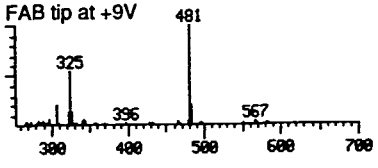
FAB tip at +9V

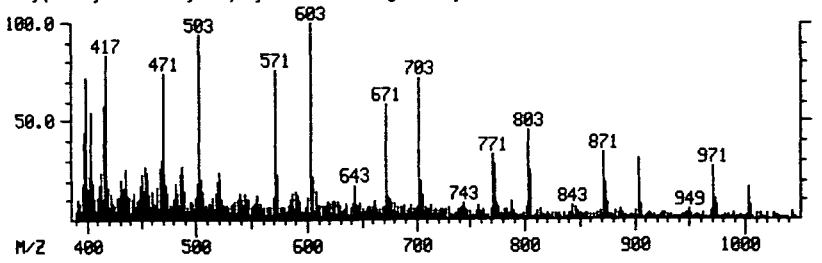


POLYMER RESULTS

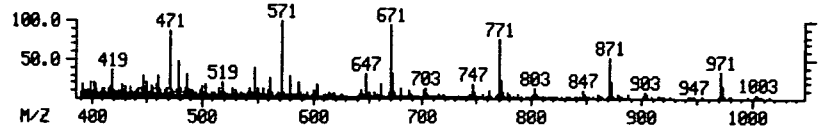
Poly(methyl methacrylate) was analyzed by CF-FAB using tetrahydrofuran producing protonated molecular ions at m/z 403, 503, 603, 703, 803, 903, and 1003, corresponding to oligomers 4 thru 10. A second series of ions separated by m/z 100 from 371 to 971 was also detected. When the poly(methyl methacrylate) was analyzed by static FAB, this second series of ions predominated the mass spectrum indicating these ions were not adducts related to tetrahydrofuran since 3-nitrobenzyl alcohol was the matrix. Desorption chemical ionization (DCI) also showed both the m/z 371 series and the m/z 403 series. The m/z 503 ion was collisionally dissociated showing a loss of m/z 32, suggesting a neutral loss of methanol, which corresponds to the m/z 371 series.

The CF-FAB spectrum of poly(methyl methacrylate) enhances the protonated molecular ions while the fragment ions predominate in the static FAB spectrum.

Poly(methyl methacrylate) by CF-FAB using tetrahydrofuran



Poly(methyl methacrylate) static FAB using 3-nitrobenzyl alcohol



CONCLUSIONS

The use of tetrahydrofuran as a solvent for CF-FAB has made possible the analysis of compounds not soluble in polar mobile phases. Since tetrahydrofuran does not require the addition of a matrix, the mass spectra are not complicated by additional matrix ions. As demonstrated, the background ions produced by tetrahydrofuran are minimal; also stability can be achieved and maintained.

CF-FAB using tetrahydrofuran can be used to analyze both nonpolar polymers and polymer additives providing molecular weight information as demonstrated with poly(methyl methacrylate) and Tinuvin 770.

ANALYSIS OF ACYLCARNITINES IN BIOLOGICAL FLUIDS BY ELECTROSPRAY LC/MS: APPLICATION TO HUMAN METABOLISM STUDIES.

Barbara M. Kelly, Malcolm E. Rose, Dept of Chemistry, The Open University, Milton Keynes, MK7 6AA, UK.
Alison E. Ashcroft, Stephen Lowes and Mark A. McDowall, Fisons Instruments/VG BioTech, Altrincham, WA14 5RZ, UK.

Acylcarnitines are important metabolites for the diagnosis of several human genetic diseases, including defects in the ß-oxidation of fatty acids and in the metabolism of branched-chain amino acids.

This poster reports preliminary applications of positive-ion electrospray mass spectrometry to underivatised acylcarnitines. This approach would not require derivatisation and the routine nature of electrospray instruments offers an affordable and attractive method of analysis.

In the carrier solution for electrospray (water/acetonitrile, 50:50), acylcarnitines exist as cations (protonated molecules). The singly charged protonated form of each acylcarnitine gives the only significant peak in its positive-ion electrospray mass spectrum.Octanoylcarnitine is a principal metabolite for the diagnosis of medium-chain acyl-CoA dehydrogenase deficiency (MCADD). Its electrospray mass spectrum consists of $[M+H]^+$ ions at m/z 288. For examining acylcarnitines in humans, the most appropriate medium is blood because the range of acylcarnitine concentrations in blood is much more limited and stable than that in urine. In addition, the profile of acylcarnitines in blood provides a more direct insight into biochemical status. Blood spots are taken from all newborns in the UK and USA, ideally within the first week of life. Typically, four blood spots are taken onto Guthrie paper (a type of filter paper) and in this form are stored and/or transported for analysis. Mass spectrometry was performed using a VG Platform, benchtop, single quadrupole mass spectrometer (Fisons Instruments/VG BioTech).

Prior to the examination of clinical examples, 0.5ml aliquots of fresh blood from a healthy adult were spiked with different octanoylcarnitine concentrations and spotted onto Guthrie paper such that the spots contained down to about 200pmol of the carnitine ester. The acylcarnitine content was then recovered from a spot of 6mm diameter punched from the Guthrie card. Each spot was sonicated twice for 10 mins in chloroform/methanol (2:1). The combined extracts were then dried and the residue dissolved in the solution for LC/electrospray mass spectrometry.

LC/MS was performed using an Applied Biosystems, Aquapore RP-30, 100 x 1.0mm column. Gradient elution at 4µl/min was performed using a linear gradient from 95% 0.01M ammonium acetate, 5% MeOH to 100% MeOH over 20 mins. The LC eluent was introduced directly to the electrospray source.

Figure1 shows the LC/MS analysis results from a) a blood spot spiked with 5nmol of octanoylcarnitine, b) a blood spot taken as a blank from a healthy adult andc) a blood spot from a

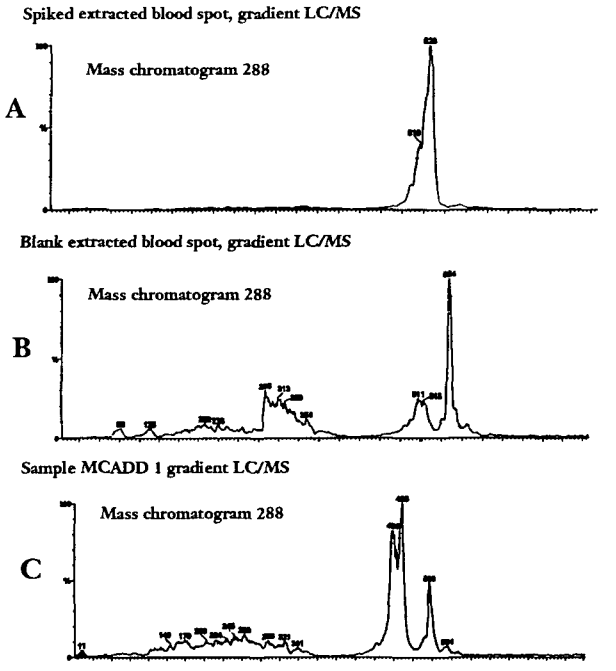
neonatal MCADD patient The spiked blood sample gave a peak which eluted at 18.5min. The m/z 288 mass chromatogram clearly shows the acylcarnitine peak and the mass spectrum is consistent with octanoylcarnitine.

The normal blood sample gave a low response on the m/z 288 mass chromatogram at 18.5min. This may be due to the normal levels of octanoylcarnitine present in healthy patients. The peak eluting with a retention time (RT) of 20 mins was attributed to a non-acylcarnitine component.

The sample from the MCADD patient clearly gives an elevated response in the m/z 288 mass chromatogram at the retention time for octanoylcarnitine. From the mass spectrum, it is proposed that an additional component, producing a base peak at m/z 235, co-elutes with the octanoylcarnitine. Other ions recorded in the spectrum are consistent with the acylcarnitine.

Acylcarnitines are readily and directly compatible with electrospray mass spectrometry. To all intents and purposes, the mass spectra obtained comprise only protonated molecules. The limits of detection, reproducibility and linearity of the method have yet to be assessed. These aspects will be studied before the method is applied to quantitative analysis of biological fluids for a broad range of acylcarnitines. However, our initial results suggest that it is worth investigating electrospray mass spectrometry as a new, direct approach to the determination of acylcarnitines in clinical samples.

We thank the Foundation for the Study of Infant Deaths for a research assistantship (to B.M.K.).



Derivatives for Detection of Anabolic Ketosteroids by Positive Electrospray Mass Spectrometry

Kuruppu A. N. Dharmasiri[1], Z.-H. Huang[2], and J. Throck Watson[1,2], Departments of Chemistry[1] and Biochemistry[2], Michigan State University, East Lansing, MI 48824

In today's society, with the emphasis on physical fitness and "win-at-all-cost" philosophy, it is no surprise that abuse of "miracle drugs" such as anabolic steroids are such a widespread problem. Recent reports show that abuse of performance-enhancing steroids has even reached high school student athletes. This situation creates a practical need for sensitive, selective, and rapid methods for screening and confirmation of steroidal drugs in biological samples.

The atmospheric pressure chemical ionization (APCI) and thermospray approaches are the most widely used in LC/MS techniques to detect steroids and their conjugates. Recently, several research groups have developed negative electrospray mass spectrometry (ESI/MS) for the detection of steroid sulfate conjugates[1,2]. However, positive ESI/MS has not shown advantage in analyses of free steroids because of lack of sensitivity. In this report, we describe modification of anabolic steroids using Girard's T reagent[3] or hydroxyl amine to produce derivatives that greatly enhance their detectability by positive ESI/MS. Girard's T reagent carries a positively charged quaternary ammonium moiety that enhances the ESI response of the derivatives[4]. We have investigated reaction conditions for derivatizing testosterone analogs: testosterone, methyltestosterone, and nandrolone. This procedure is advantageous because it forms water-soluble hydrazone derivatives quickly under mild conditions and it introduces a pre-formed positive charge onto the steroid structure, thereby creating a sensitive means for detecting the steroid using positive ESI/MS. These derivatives are detectable at the low femtogram level using the selected ion monitoring mode. The derivatives are separated by reversed phase HPLC with a C_{18} column and mobile phase gradient of acetonitrile/*i*-propanol/TFA (60/40/0.1 %v/v) and H_2O/0.1%TFA. ESI/MS studies were carried out with a home-built ESI interface coupled to a HP 5985 single quadrupole mass spectrometer. The ESI mass spectrum of testosterone hydrazone is shown in fig. 1. The rate of the reaction with Girard's T reagent is greatly increased (see fig. 2) by adding acetic acid to the reaction mixture. The dependance of reaction rates on temperature and time are as shown in fig. 3.

We also investigated oxime formation of anabolic steroids with hydroxyl amine hydrochloride. Preliminary results indicate that the oxime derivative can be formed

rapidly with ketosteroids, and that it increases the detectability of the steroid to positive ESI/MS. The oxime derivatives can be detected at the femtogram level.

We are presently investigating the applicability of these derivatives to the analysis of other anabolic steroids with the view toward their quantitative determination in urine samples.

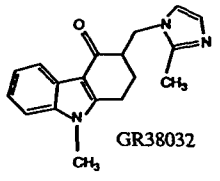
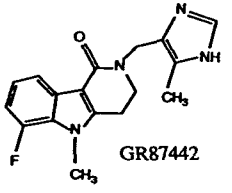
Determination of 5HT$_3$ Antagonists in Serum Using Heated Nebulizer and Electrospray LC/MS and LC/MS/MS, K.A. Halm, M.A. Moseley and S.E. Unger, Department of Drug Metabolism, Glaxo Inc. Research Institute, Five Moore Drive, Research Triangle Park, NC 27709

5-Hydroxytryptamine (5HT$_3$) antagonists such as ondansetron (GR38032) are effective in the prevention of nausea and emesis in patients receiving chemotherapy and radiotherapy. These selective 5HT$_3$ antagonists are potent drugs, and highly sensitive, selective analytical methods are needed to determine their levels in serum.



GR38032



GR87442

Using 1 mL of serum, some 5HT$_3$ antagonists such as GR87442 can be quantified with fluorescence detection to 0.2 ng/mL; others such as GR38032 exhibit weak fluorescence and can only be quantified with UV absorption to higher levels (1 ng/mL). Radioimmunoassay (RIA) has been useful in determining lower serum levels of GR38032 and is capable of detecting as little as 50 pg/mL. The RIA shows cross-reactivity with human metabolites but, by using solid phase extraction to resolve the interfering metabolites, can be made more specific. Mass spectrometry offers both detection sensitivity and specificity in analysis. Provided analysis times are short, it also offers high throughput and therefore can be cost-effective.

While GR87442 is capable of analysis using gas chromatography (GC), it exhibits considerable tailing and poor sensitivity. GR38032 degrades upon injection in either split-splitless or on-column modes, making GC/MS a poor choice for analysis. Both drugs perform well using LC/MS and prior analytical methodology developed for determining higher levels of the 5HT$_3$ antagonists could be adapted to LC/MS.

Thermospray LC/MS was capable of detecting GR87442 in 0.2 mL of serum to 5 ng/mL but showed poor precision and accuracy. The SCIEX heated nebulizer (HN) interface gave significantly better response and allowed drug to be measured accurately to 0.2 ng/mL from 0.2 mL of serum. Similarly, GR38032 showed good promise for detecting low picogram amounts. For GR38032, adsorption on the interface was noted as high nebulizer and orifice temperatures gave best response and peak shape. However, no less than 2 pg (Fig. 1) could be reliably detected using heated nebulizer with LC/MS or LC/MS/MS detection.

Electrospray (ESI) detection exhibited better sensitivity for GR38032 or GR87442 in either MS or MS/MS modes. As little as 0.5 pg could be measured (Fig. 2). Using LC/MS, the electrospray response showed a considerable bias at low levels. It was therefore necessary to use MS/MS detection (10% Ar:90% N$_2$; CGT = 550; 30 eV) to accurately determine low drug levels.

Compound	Parent	Fragment 1	Fragment 2	Fragment 3
GR38032	294	212	184	170
d3-GR38032	297	212	184	170
GR87442	313	219	176	95

Solid phase extraction of drug from serum was used. The strong adherence of drug to the Varian C8 cartridge allowed considerable purification before elution in 80:20 methanol: 2 mM ammonium acetate. Following evaporation, 25 uL of mobile phase, 50:50 2 mM ammonium acetate (pH 4.5):ACN, was used to reconstitute the sample for analysis. Five microliter aliquots were injected from the Alcott 738 autosampler onto a 1 x 100 mm, 5 micron Keystone Hypersil BDS C8 column at 50 uL/min. This allowed a minimum of three injections of analyte.

Several internal standards were evaluated for GR38032. GR38032 in which the 2-methyl had been deuterated was available and chosen as internal standard. Since the internal standard gave identical HPLC retention and MS/MS fragmentation, detection sensitivity was limited by the need to adequately (mass) resolve the m/z 294 analyte from the m/z 297 deuterated internal standard.

Figure 3 shows representative chromatograms at the 20 pg/mL level from serum. A standard curve from 10-200 pg/mL gave acceptable precision with the limit of quantification determined by the need to adequately resolve the stable isotope internal standard. More sensitivity could be gained by degrading mass resolution; however, the resulting bias at the 10 pg/mL level was unacceptable.

For determining low serum levels of 5HT$_3$ antagonists, electrospray LC/MS/MS offers the lowest limits of detection. While the heated nebulizer allows larger injection volumes and LC flow rates, its (on-column) sensitivity is 5x less than electrospray. Both methods have been used effectively with SPE serum extracts. More recently, a heated capillary electrospray interface (Finnigan Corp.) has shown comparable performance for the analysis of GR38032 to the SCIEX API-3.

Identification of Xenobiotic Conjugates by Positive and Negative Ion Electrospray Mass Spectometry

*C. E. Parker[1], L.T. Burka[2], and K. B. Tomer[1]
1. Laboratory of Molecular Biophysics, and
2. Environmental Toxicology Branch,
National Institute of Environmental Health Sciences,
Research Triangle Park, NC 27709

Identification of metabolites is an important component of the characterization of compounds undergoing toxicity and carcinogenicity studies in the National Toxicology Program. Most of these metabolites are polar, non-volatile, and thermally-labile. We have recently been successful in applying electrospray ionization mass spectrometry (ESI/MS) to a variety of xenobiotic conjugates isolated from rat bile and feces, and rat and mouse urine. Compounds studied included oxazepam (an antianxiety agent and a metabolite of Valium), ethoxyquin (used as an antioxidant in pet food and to preserve the vitamin A content in feed), and methacrylonitrile, a monomer used in the plastics industry.

Metabolites identified included glutathione, glucuronide, and sulfate conjugates:

Two sulfate conjugates and a glucuronide of oxazepam were isolated from rat feces, rat urine, and mouse urine, respectively, and identified. The positive ion ESI mass spectrum of one of these is shown in Figure 1. NMR spectra were obtained and were consistent with structures shown.

Five metabolites of ethoxyquin were also identified. These included two glucuronides from rat and mouse urine (one of which is shown in Figure 2), and three glutathione conjugates from rat bile. Positive identification was obtained for the glucuronides and for the EQBM-B glutathione (Figure 3) by a combination of NMR and ESI/MS. The two other glutathione conjugates are positional isomers, whose absolute configurations have not yet been established. Interestingly, in a previous study of ethoxyquin metabolism using GC/MS (1), no sulfur-containing metabolites were found, probably due to thermal degradation.

A glutathione conjugate of methacrylonitrile, and a glutathione conjugate of its cytochrome P450 oxidation product were identified in rat bile. Postulated structures for these two compounds were confirmed by NMR, synthesis, and co-chromatography.

Protonated molecules were obtained by positive ion ESI/MS for the glutathione conjugates. Both positive and negative ion spectra were useful for the identification of the glucuronide conjugates. No useful positive ion ESI mass spectra were obtained for the sulfate conjugates, but these sulfate conjugates did give $(M-H)^-$ ions in the negative ion mode.

ESI/MS has been very useful in providing molecular weight information for these conjugates, but, in general, little structural information was obtained. ESI/MS has assisted in the identification of these conjugates, including some compounds where other mass spectral techniques, including fast atom bombardment (FAB)/MS, had been unsuccessful.

Identification of Metabolites of RG 12915A in Human Urine Using API-LC/MS and LC/MS/MS Techniques

***Tang, S.-Y.; Bordeaux, K.; Berger, P.; Rhone-Poulenc Rorer Central Research, Collegeville, PA, 19426**

RG 12915A, 4-[N-(1-Azabicyclo[2,2,2]octan-3(S)-yl]-2-chloro-5[a(S)-9a(S)-(5a,6,7,8,9,9a-hexahydro)]dibenzofuranocarboxamide hydrochloride, is both an orally and intravenously active anti-emetic agent. Its efficacy has been demonstrated for the prevention of cisplatin-induced emesis in ferrets and dogs, and, it is currently undergoing clinical trials.

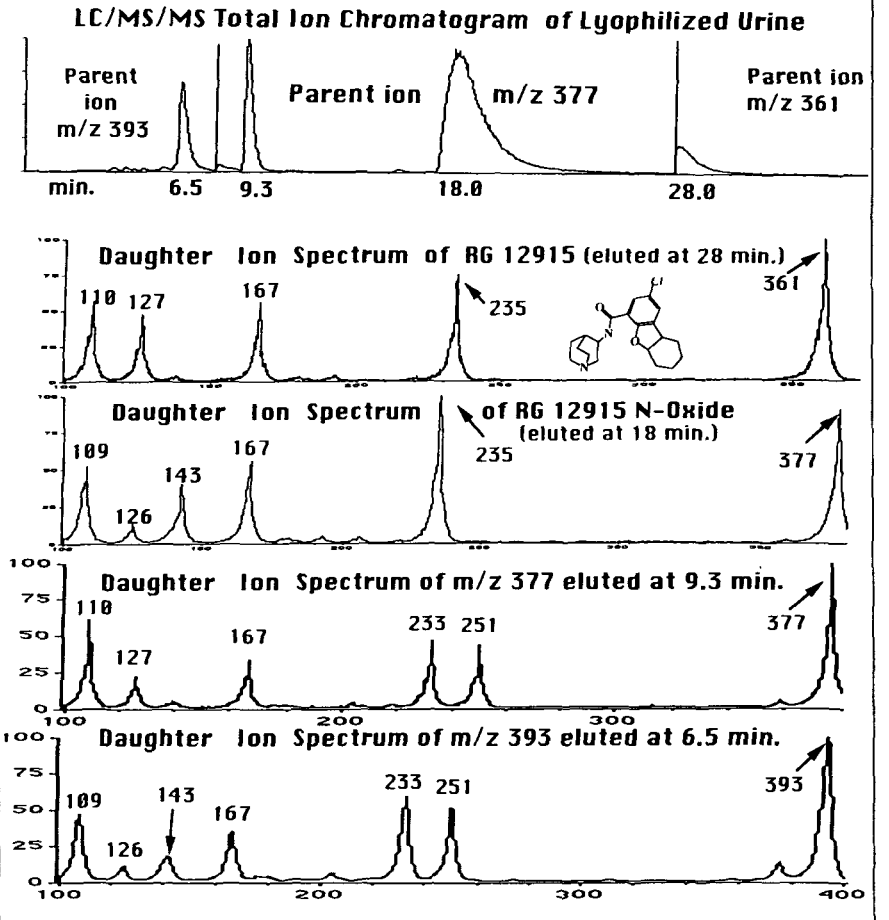
Urine samples from human subjects dosed with 200mg of RG 12915A were collected and pooled up to 12 hours after dosing. Samples were lyophilized without any prior treatment or cleaned up by solid phase extraction using CN Bond Elut cartridges. HPLC was performed using a 250 X 4.6 mm column packed with Zorbax CN, 5um bonded phase. The mobile phase was acetonitrile/0.1M ammonium acetate containing 0.2% acetic acid (35:65 v/v). The components were detected by UV absorption at 254nm and then passed into the Heated Nebulizer (SCIEX) interface and ionized by API corona discharge.

The molecular weight of each component was determined by APCI/MS and confirmed by IonSpray using a micro-bore column. LC/MS data have revealed that the protonated molecular ions of two major metabolites were m/z 377 and one other major metabolite was 393, respectively, 16 and 32 amu more than the parent drug. Each contains one chlorine atom.

To elucidate the structure of each metabolite, on-line LC/MS/MS was carried out to obtain the daughter ion mass spectra for each parent ion using argon as a collisional gas at energy of 50 to 100eV. The daughter ion spectrum of RG 12915 has shown characteristic fragments and provided structural information concerning the metabolites. The major metabolite eluted at ~18 min. has been confirmed as the quinuclidine N-oxide of RG 12915 by its molecular weight, retention time, and daughter ion spectra. An N-oxide metabolite is very common with drugs containing a tertiary nitrogen such as a quinuclidine moiety. By comparing of the daughter ion spectra of synthetic standards with unknown metabolites, we have identified two additional major metabolites as a hydroxylated RG 12915 and an N-oxide of hydroxylated RG 12915 . The daughter ions also indicated that the hydroxylation occurred on the tetrahydrobenzofuran ring. The daughter ion spectrum of one minor metabolite has also indicated an isomer of hydroxylated RG 12915.

In summary, the API Heated Nebulizer is a very sensitive LC/MS interface for phase I metabolite identification. Using on-line LC/MS and LC/MS/MS, we have identified the major metabolites of RG 12915 in human urine as 1). N-oxide

of RG 12915, 2). Hydroxylated RG 12915, and 3). N-oxide of the hydroxylated RG 12915. At least two isomers of hydroxylated RG 12915 have been found.



Characterization of Biliary Rapamycin Metabolites by Ionspray Liquid Chromatography / Mass Spectrometry.

K. Chan, P. Wang, †T. Sakuma, J. Scatina, D. Cochran, L. Humber, and S. Sisenwine,
Wyeth-Ayerst Research, Princeton, NJ 08543, and
†Perkin-Elmer Sciex Instruments, Thornhill, Ontario L3T 1P2, Canada.

Rapamycin (AY-22,989) is an antitumor, antifungal, and immunosuppressive agent isolated from the fungus *Streptomyces hygroscopicus*. It is currently under development as an immunosuppressant after transplantation. In metabolic studies related to other immunosuppressants such as FK506 and cyclosporin, some biotransformation products were observed to have activity or toxicity. Therefore, it is important to characterize the metabolites of rapamycin so as to investigate their activity and toxicity. Although two *in vitro* metabolites of rapamycin had been reported by Christians *et. al.* [1], this is the first report of the *in vivo* metabolites of the drug. In the earlier study, Christians *et. al.* isolated the metabolites by HPLC and characterized them by DCI and FAB MS. In addition to DCI and FAB, we have observed that the negative ion ionspray (IS) mass spectrum of rapamycin showed structurally informative fragments [2]. Since IS mass spectrometry can be easily coupled with HPLC, we have employed on-line IS-LC/MS and LC/MS/MS to characterize the *in vivo* (biliary) metabolites of rapamycin in rats.

All LC/MS experiments were carried out on a PE Sciex API III triple stage quadrupole mass spectrometer equipped with the ionspray interface. The bile sample was extracted with ethyl acetate, evaporated to dryness and reconstituted in 65/35 methanol/water. HPLC separations were achieved by a 2 mm x 15 cm Beckman Ultrasphere C_{18} column. The mobile phase consisting of water and methanol, each containing 50 mM ammonium acetate, was delivered by a Perkin Elmer Model 250 Binary LC pump at a flow rate of 200 µl/min. A linear gradient of 58% methanol to 85% methanol in 80 minutes was used. The LC eluant was split 3:1 with 50 µl/min entering the ionizer of the mass spectrometer.

The reconstructed ion chromatogram (RIC) obtained from the LC/MS analysis of the biliary metabolite sample shows more than twenty one peaks (Figure 1). In IS MS, rapamycin generates mostly $[M-H]^-$ and $[M+CH_3COO]^-$. Assuming the metabolites of rapamycin generates the same molecular ion species, the MWs of sixteen of the twenty one components can be deduced from their mass spectra. Simple mathematics then suggests these metabolites are formed by mono- and di- hydroxylation, or a combination of demethylation and hydroxylation of rapamycin as shown in Table 1. The rest of the peaks in the RIC may contain a mixture of unresolved components or some low mass compounds.

In attempts to gain information on the sites of metabolic transformation, LC/MS/MS experiments were carried out. Useful data were obtained on only the five major components, peaks 4, 10, 13, 18, and 19 depicted in Figure 1. For example, Figure 2 shows the MS/MS spectrum obtained from peak 13. The MW of this metabolite has been derived from the LC/MS experiment to be 929.5, suggesting a single hydroxylation. The MS/MS spectrum of this compound shows that the northern fragment is the same as the parent compound at m/z 321. The southern fragment of this metabolite is detected at m/z 606, indicating one additional oxygen relative to rapamycin. The ion at m/z 240 can be assigned as a carboxylate ion containing C12 to C23 of rapamycin. This fragmentation can be promoted by the hydroxylation at any one of the carbon from C8 to C11. Other ions observed in the MS/MS spectrum of this metabolite can be assigned as further decomposition products of the southern fragment.

Our results on the *in vivo* metabolites are in general agreement with the *in vitro* data reported by Christians *et. al.* However, the structures of the metabolites reported here are drawn in the macrolide ring opened form. This proposal is derived from the FAB MS data on isolated samples of these metabolites: macrolide ring closed rapamcycin analogs generate $M^{-\cdot}$ while the ring opened isomers yield $[M-H]^-$.

Furthermore, the addition of 16 amu can also be assigned as epoxidation across a double bond instead of hydroxylation. Data from other spectroscopic techniques such as nuclear magnetic resonance spectroscopy should be obtained to verify these structure proposals.

SAXITOXIN DETECTION IN RAT URINE BY HPLC AND CE-ESIMS

H.B. Hines, E.E. Brueggemann, and R.G. Stafford

Toxinology Division, United States Army Medical Research
Institute for Infectious Diseases, Ft. Detrick,
Frederick, MD

Paralytic shellfish poisoning (PSP) is caused by a group of toxins produced by several species of marine dinoflagellates. High toxicity and repeated occurrence have prompted the establishment of shellfish monitoring programs in the United States, Canada, and other countries to prevent PSP. Several instrumental methods were developed to analyze shellfish tissues. In addition to these capabilities, it would also be beneficial to have a diagnostic tool for assessing human exposure. Consequently, we conducted an initial evaluation of HPLC and CE-ESIMS detection capabilities for saxitoxin (STX) spiked in rat urine. STX was chosen because it is typically associated with PSP. Urine was selected because a previous study with tritiated saxitoxinol (reduced STX) demonstrated that excretion may occur principally in urine (Hines et al., Toxicon, in press).

Urine was collected from male Fisher 344 rats housed individually in metabolic cages. One ml aliquots of filtered rat urine were spiked with varying levels of STX and applied to solid-phase extraction columns. A double ion-exchange procedure was used to isolate the toxin. After isolation, HPLC and CE-ESIMS were used to identify STX.

The HPLC method used in this study followed the prechromatographic oxidation method of Lawrence et al. (JAOAC, 74: 404, 1991). Fluorescence detection of oxidized STX was accomplished with wavelengths of 346 and 408 nm for excitation and emission, respectively.

For CE-ESIMS analyses, an untreated fused silica column (50 μm x 100 cm) was fitted to a Finnigan Mat 700 mass spectrometer. An UV detector was placed in-line approximately 45 cm from the anode end of the column. A 1.0% acetic acid buffer and 23 kV were used for CE analysis. Electrokinetic injections were made by applying 8 kV to the sample (dissolved in water) for 15 sec. A sheath liquid consisting of 75% isopropanol and 5% acetic acid was utilized at 2 μl/min as the make-up flow. Either selected ion monitoring of the STX pseudomolecular ion at m/z 300 or scanning from m/z 250 to 350 in 0.5 sec was used to detect STX, depending upon the concentration in urine.

STX recoveries from rat urine averaged 82 ± 1.5 % when STX concentrations were kept below 50 ng/ml. This average recovery from urine was slightly higher than the 75% reported by Mirocha et al. (Rapid Commun. Mass Spec., 6: 128, 1992), who used a weak cation exchange column to isolate STX from urine spikes.

Figure 1 displays results for standard STX, STX from rat urine (2 ng/ml), and a rat urine blank (Fig. 1A, B, and C, respectively). The STX peak is identified with an S.

The most consistent and lowest level of detection with CE-ESIMS was 500 ng/ml (Fig. 2). STX was clearly identifiable in the SIM electropherogram. The peak is marked with an asterisk in Figure 2 in the SIM trace (A), the UV trace (B), and the RIC (C).

These results for HPLC and CE-ESIMS paralleled those obtained previously for shellfish and rat urine. For example, STX detection limits of 10-15 ng/g of tissue (s/n = 3:1) were reported by Lawrence et al. (JAOAC, 74: 404, 1991) with the prechromatographic oxidation, HPLC procedure. A C_{18} SPE procedure was employed for sample preparation for that work. Pleasance et al. (Rapid Commun. Mass Spec., 6: 14, 1992) reported a detection limit of 0.8 - 1.0 μg/ml for STX with nebulization-assisted electrospray ionization, SIM, and reversed-phase chromatography. Mirocha et al. (Rapid Commun. Mass Spec., 6: 128, 1992) established an injection detection of 200 pg/200 nl for standard STX with CF-FAB and SIM. STX was detectable in spiked urine samples at 20 μg/ml with the same conditions. STX identification was verified with HPLC and nebulization-assisted electrospray ionization mass spectrometry.

The prechromatographic, HPLC method was directly applicable to urine analysis. More effort will be required to improve the CE-MS detection limit to achieve the 1 - 5 ng/ml detection limit thought to be required for in vivo assays. It may be necessary to use capillary HPLC combined with ESIMS to achieve the balance between separation efficiency and sensitivity.

Confirmation of Des-Methyl Danofloxacin Residues in Swine Liver by HPLC/ESI-Tandem Mass Spectrometry

Mark J. Cole, John F. Ericson, Hassan G. Fouda, and Marty J. Lynch

Drug Metabolism Department, Central Research Division, Pfizer Inc, Groton, CT 06340.

A specific assay was developed for the confirmation of des-methyl danofloxacin residues in swine liver. The assay utilizes HPLC and tandem mass spectrometry with electrospray ionization. Collisionally-activated dissociation of the des-methyl danofloxacin protonated molecule results in the formation of four product ions, two of which are present in greater abundance (Figure 1). Monitoring the precursor/CAD product reactions for the two most abundant product ions during HPLC provides the specificity and sensitivity required for a confirmatory assay.

Danofloxacin is a novel fluoroquinolone antibacterial agent for the treatment of respiratory diseases in food producing animals. The metabolite des-methyl danofloxacin is considered the marker residue in swine liver. The present assay was developed to satisfy regulatory requirements for the confirmation of des-methyl danofloxacin residues in swine liver. Des-methyl danofloxacin produces a protonated molecule at m/z 344 under positive ion electrospray conditions. Collisionally-activated dissociation of this ion produces the two product ions (m/z 326 and 255) used in this assay. These ions result from intramolecular dehydration (m/z 326) and the subsequent cleavage of pyrrolidine from the bicyclic piperazine moiety (m/z 255).

The present method provides confirmation of des-methyl danofloxacin residues in swine liver at the 50 ppb level. The analysis of blank liver gave no response under the assay conditions. The ratios of the two CAD product ions were similar for des-methyl danofloxacin standard solutions, fortified tissue extracts, and incurred tissue extracts. Representative chromatograms for injections of 6 replicate samples of blank and fortified (50 ppb) extracts are shown in Figures 2 and 3, respectively.

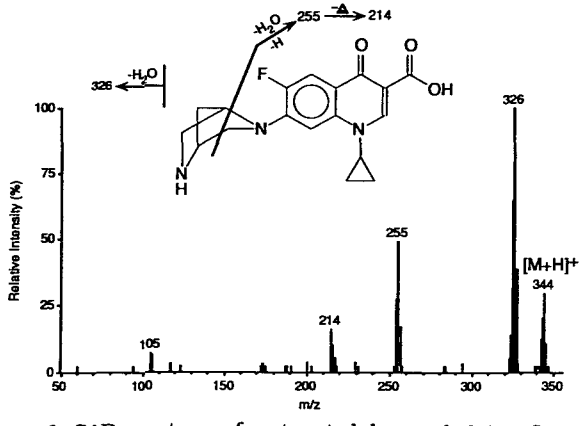

Figure 1. CAD spectrum of protonated des-methyl danofloxacin.

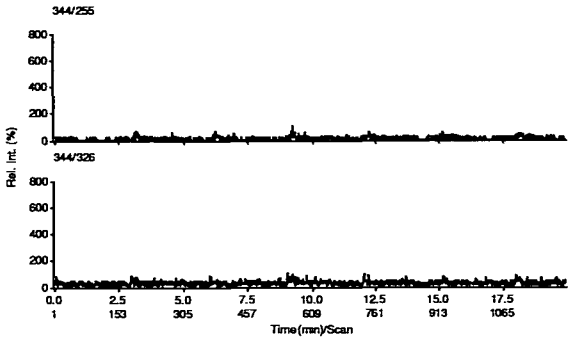

Figure 2. Chromatogram of multiple (n=6) samples of blank swine liver extracts.

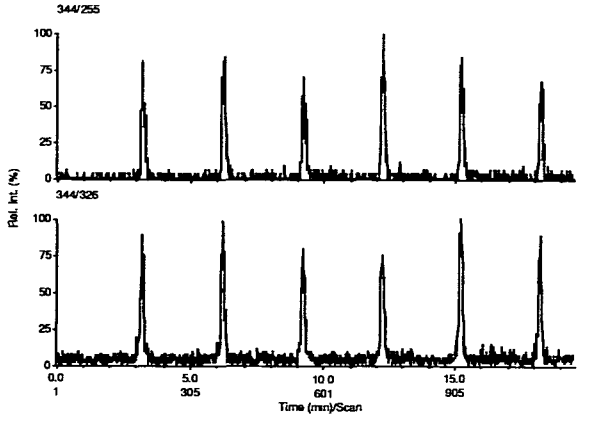

Figure 3. Chromatogram of multiple (n=6) samples of swine liver fortified at 50 ppb.

An HPLC/ESI-Tandem Mass Spectrometry Method for the Confirmation of Doramectin Residues in Cattle Liver and Fat

Mark J. Cole, Joanne Lukaszewicz, Mark A. Nowakowski, and Hassan G. Fouda

Drug Metabolism Department, Central Research Division, Pfizer Inc, Groton, CT 06340.

A specific assay was developed for the confirmation of doramectin residues in cattle liver and fat. The assay utilizes HPLC and tandem mass spectrometry with electrospray ionization. Collisionally activated dissociation of the ammoniated doramectin molecule results in a product ion spectrum rich in structural information (Figure 1). Monitoring the precursor/CAD product reactions for three of these product ions during HPLC provides the specificity and sensitivity required for a confirmatory assay.

Doramectin is a fermentation-derived, broad spectrum ectoparasiticide for cattle and swine. The present assay was developed to satisfy regulatory requirements for the confirmation of doramectin residues in cattle liver and fat. Doramectin produces an ammoniated molecule at m/z 916 under positive ion electrospray conditions. The ammonium is part of the HPLC mobile phase, and its doramectin adduct is formed more efficiently than the protonated doramectin molecule. Collisionally activated dissociation produces the three product ions (m/z 899, 593, and 145) used in this assay. These ions result from loss of ammonium (m/z 899), further dissociation through the loss of the disaccharide (m/z 593), and the formation of the α-L-oleandrosyl product ion (m/z 145).

This method provides confirmation of doramectin residues in cattle liver and fat at the 25 ppb level. The analysis of blank liver and fat gave no response under the assay conditions. The commercial anthelmintic, ivermectin, did not interfere with the assay. The ratios of the three CAD product ions were similar for doramectin standard solutions, fortified tissue extracts, and incurred tissue extracts.

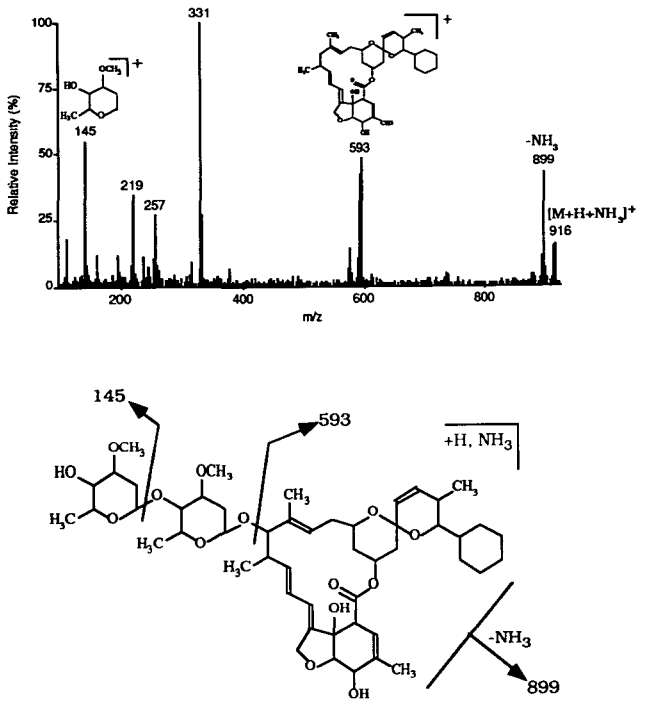

Figure 1. CAD spectrum of the protonated doramectin ammonium adduct. Assignments of the CAD product ions monitored in this assay are shown in the bottom part of the figure.

Identification of the Anticonvulsants Felbamate and Phenytoin and their Metabolites by Thermospray Tandem Mass Spectrometry in Clincial Human Urine Samples.

Robert E. Sparadoski., Leslie A. Romanyshyn, Joseph K. Wichmann, Norbert Kucharczyk, and R. Duane Sofia, Wallace Laboratories, Division of Carter–Wallace, Inc., Cranbury, NJ 08512

INTRODUCTION

Assessment of the metabolite disposition of felbamate, a novel antiepileptic drug currently under clinical development (1,2,3,4), and phenytoin in a drug–drug interaction study required determination of total urinary levels of felbamate, felbamate metabolites, phenytoin and metabolites. An HPLC/UV method was developed and used for analysis of clinical study urine samples following β–glucuronidase hydrolysis. The presence of an unknown and absence of a known phenytoin metabolite prompted the current investigation. The clinical urine sample hydrolysis and extraction procedures and the reverse phase HPLC conditions were presented. The TSP–LC/MS/MS conditions affording positive identification of felbamate, three felbamate metabolites, phenytoin, *p*–HPPH (5–(4–hydroxyphenyl)–5–phenylhydantoin), and partial identification of the unknown are discussed. Only trace levels of *m*–HPPH (5–(3–hydroxyphenyl)–5–phenylhydantoin) were found in the clinical samples.

RESULTS

TSP–LC/MS/MS and DCI tandem mass spectrometry analyses were performed on the clinical human urine hydrolysates, solvent standard mixes and isolated HPLC fractions from the clincial human urine sample. Clinical human urine sample 13608, obtained at steady state felbamate and phenytoin therapy, contained high levels of felbamate, felbamate metabolites and *p*–HPPH as well as detectable levels of the unknown, *m*–HPPH, and phenytoin by HPLC and TSP–LC/MS/MS. Clinical human urine sample 13621, obtained at steady state phenytoin mono–therapy, contained high levels of *p*–HPPH and detectable levels of the unknown and phenytoin by HPLC and TSP–LC/MS/MS. Figure 1 illustrates the simultaneous determination by HPLC/UV and TSP–LC/MS/MS of felbamate, felbamate metabolites, phenytoin, phenytoin metabolites and the unknown. First generation TSP–LC/MS/MS product spectra were obtained for $[M+H]^+$ or $[M+H+CH_3CN]^+$ precursor ions for W–2986, W–2992, W–873, felbamate (W–554), *p*–HPPH, *m*–HPPH, and phenytoin (PHT) confirming the identity of these compounds in the samples. Figure 2 represents the isobutane DCI–MS/MS spectra obtained from the $[M+H]^+$ ions of the isolated HPLC fraction of the unknown metabolite from clincial sample 13621 and from a phenytoin standard.

CONCLUSIONS

The presence of felbamate W–554 (2–phenyl–1,3–propanediol dicarbamate), three felbamate metabolites W–2986 (2–(*p*–hydroxyphenyl)–1,3–propanediol dicarbamate), W–2992 (2–hydroxy–2–phenyl–1,3–propanediol dicarbamate), and W–873 (2–phenyl–1,3–propanediol monocarbamate) and phenytoin (5,5–diphenyl–2,4–imidazolidinedione) and two metabolites *p*–HPPH (5–(4–hydroxyphenyl)–5–phenylhydantoin) and *m*–HPPH (5–(3–hydroxyphenyl)–5–phenylhydantoin) in clinical human urine hydrolysates was confirmed by simultaneous TSP–LC/MS/MS. A new phenytoin metabolite was partially identified by TSP–LC/MS/MS and DCI tandem mass spectrometry techniques. Only trace levels of *m*–HPPH (5–(3–hydroxyphenyl)–5–phenylhydantoin) were found in the clinical urine samples. The TSP–LC/MS/MS, EI and DCI–MS/MS spectra obtained for the unknown support the structure indicated, hydroxylation and methoxylation of a single phenyl ring of the phenytoin molecule. The exact placement of these moieties on the phenyl ring cannot be made from the data.

The use of TSP–LC/MS/MS for analysis of human urine sample extracts confirmed the identity of two drugs and five known metabolites quantitated by an HPLC/UV method. TSP–LC/MS/MS combined with direct probe techniques provided rapid partial elucidation of the structure of an unknown phenytoin metabolite.

Identification of the Felbamate Metabolite 3–Carbamoyloxy–2–Phenylpropionic Acid (W–3049) in Human and Dog Urine by Negative Ion Thermospray Tandem Mass Spectrometry

**Robert E. Sparadoski., Joseph K. Wichmann, Norbert Kucharczyk, and R. Duane Sofia, Wallace Laboratories, Division of Carter–Wallace, Inc., Cranbury, NJ 08512*

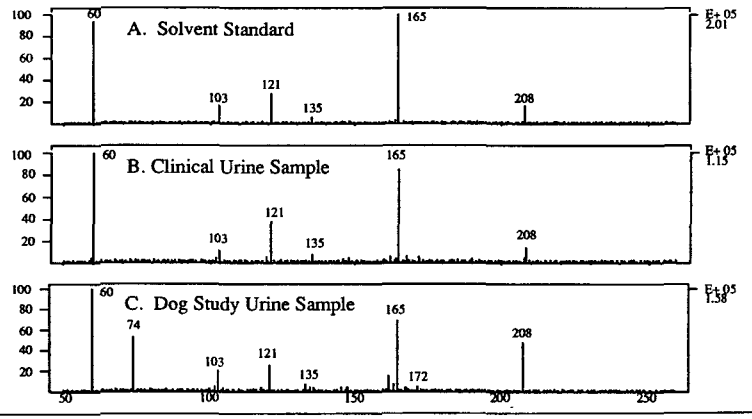
INTRODUCTION

The identification of 3–carbamoyloxy–2–phenylpropionic acid as a biotransformation metabolite of felbamate, a novel antiepileptic drug currently under clinical development (1,2) is discussed. Several metabolites have been previously reported in a quantitative positive ion HPLC/tandem mass spectrometry (TSP–LC/MS/MS) assay for felbamate and metabolites in dog urine (3). Negative ion TSP–LC/MS/MS afforded adequate sensitivity and selectivity to allow positive identification of W–3049 in urine samples without extensive sample preparation or concentration.

RESULTS

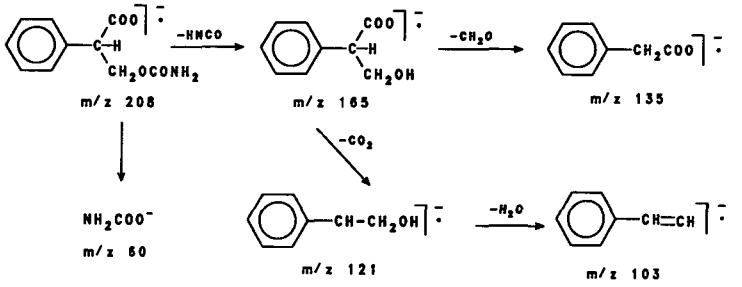
Ethyl acetate extraction of acidified urine samples was performed on human urine samples obtained from a bioavailability study in healthy volunteers who received a single oral dose of 1200 mg of felbamate and on dog urine samples collected during a metabolism study from a mature male beagle dog 0–8 hr after a single oral dose of 60 mg/kg of felbamate (unpublished data). The presence of free CPPA (W–3049) in the unhydrolyzed 0–4 hr postdose human urine sample and in the dog urine sample was confirmed by on–line negative ion thermospray tandem mass spectrometry (TSP–LC/MS/MS) of the extracts. Figure 1 illustrates the TSP–LC/MS/MS first generation product spectra of the m/z 208 $[M–H]^-$ ion from the CPPA peak from the standard, the clinical urine sample and the dog study urine sample, respectively. First generation product spectra were also obtained for the TSP fragment ion m/z 165 for the clinical urine sample and the dog study urine. Differences in the product spectrum of m/z 165 were observed in the dog study urine sample. The differences were due to endogenous interferences also found in blank dog urine.

FIGURE 1: TSP LC/MS/MS of m/z 208



The proposed negative ion CID fragmentation pathway for the m/z 208 $[M–H]^-$ ion of CPPA is shown in Figure 2.

FIGURE 2: Proposed Negative Ion CID Pathway



CONCLUSIONS

HPLC separation of CPPA in human and dog urine samples coupled with on–line thermospray tandem mass spectrometric techniques confirmed the identity of the metabolite as CPPA. The negative ion CID fragmentation scheme of the precursor CPPA $[M–H]^-$ ion, m/z 208, is proposed. The base peak in the first generation product spectra of m/z 208 is m/z 60, corresponding to the carbamate anion $[H_2NCOO]^-$.

The metabolite CPPA is the carbamoyl derivative of the natural product tropic acid (3–hydroxy–2–phenylpropionic acid), a constituent of tropane alkaloids, especially atropine. An easy synthetic procedure starting with the monocarbamate felbamate metabolite allowed us to obtain in good yield an authentic synthetic sample of CPPA. The procedure also confirmed the resistance of the carbamate group to chemical oxidation and to strongly acidic media.

We conclude that CPPA is a human urinary metabolite of felbamate contained in free form in the polar, water–soluble metabolite fraction.

Analysis Of The Squalestatins By On-line Packed Capillary LC-Dynamic LSIMS Mass Spectrometry

*S.J.Lane[1],K.Brinded[1],N.L.Taylor[2]

1. Mass Spectrometry,Structural Chemistry Department.
2. Mass Spectrometry,Department Of Natural Products Discovery .
Glaxo Group Research Limited,Greenford Road,Greenford Middlesex,UB6 OHE.

INTRODUCTION

The squalestatins are novel inhibitors of squalene synthase produced from a species of *Phoma*[1].Their structures were recently determined by a combination of spectroscopic,X-ray crystallographic and chemical methods[2].These structural studies defined the squalestatins as a new class of compounds which incorporate the highly functionalised bicyclic core, [1S-(1α,3α,4β,5α,6α,7β)]-4,6,7-trihydroxy-2,8-dioxabicyclo [3.2.1]-octane-3,4,5-tricarboxylic acid (Fig 1). Mass spectrometric characterisation of this class of compound was achieved using high and low resolution negative ion FAB which typically afforded strong $[M-H]^-$ molecular ions coupled with structurally informative fragment ions.

On-line negative ion thermospray LC/MS methods developed for biotransformation studies and minor metabolite characterisation were found to lack sensitivity and specificity.

The development of a packed capillary LC/UV/DLSIMS negative ion method showed improvements in sensitivity and specificity compared to TSP methods.

Fig 1

EXPERIMENTAL

A gradient of 20%B held for 1min→85% B in 20 mins (A=H_2O + 0.1% TFA and B=CH_3CN + 0.1% TFA,100μLmin^{-1}) from a dual syringe pump was delivered to an Acurate™ micro flow processor (LC Packings,The Netherlands) where it was mixed and split such that 3 μLmin^{-1} was delivered to a 1μL injector (Valco Instruments Co.Inc.TX,USA). The Vydac C18,300A,320μm id X 15 cm packed capillary column with a microguard column (LC Packings) used for the separation was connected to an ABI 759a UV absorbance detector (Applied Biosystems,UK) fitted with a U-Z

view capillary flow cell (LC Packings) The detector was connected to a "Tee" (Valco Instruments Co,Houston,TX,USA). 2μLmin^{-1} of a matrix solution (50:50 CH_3CN/H_2O + 0.1% TFA + 0.5% glycerol + 0.5% thioglycerol) was introduced post column through the "Tee" via a syringe infusion pump (Harvard Apparatus,Mass.,USA). The 5μLmin^{-1}resultant flow was directed to the dynamic LSIMS probe tip of a VG Analytical Autospec. The probe tip featured a screen/wick target The source was heated to 50C.

RESULTS

The in-line LC trace at 210nm and corresponding ion chromatograms resulting from the injection of 40ng of each squalestatin is shown in Fig 2.

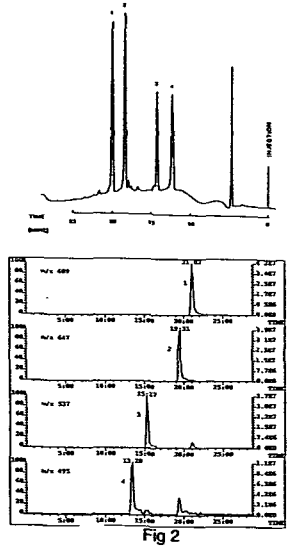

Fig 2

CONCLUSION

Spectra for the individual components were of good quality and the approach provides a routine method for the LC/MS of mixtures where LSIMS ionisation is necessary for the required specificity and sensitivity for a given compound class.

DCI, ESI and TSP investigations of ß-carbolines

*M.M. Brudny-Klöppel, W. Kuhnz, Schering AG, Berlin, Germany
K.D. Klöppel, GBF, Braunschweig, Germany

Introduction:

Benzodiazepines exhibit sedative, anxiolytic, anticonvulsant and muscle-relaxant effects by binding to the benzodiazepine receptor. ß-Carboline derivatives bind to the same receptor. Some of these drugs act as full agonists, others as partial agonists or antagonists. Abecarnil (isopropyl-6-benzyloxy-4-methoxymethyl-ß-carboline-3-carboxylate, ZK 112119, [1]), a representative of this class of compounds is being developed as an anxiolytic agent and studies in phase III are presently ongoing. During preclinical studies and clinical development it is necessary to determine and identify small amounts of drugs and their mostly unknown metabolites in several biological matrices (plasma, urine, bile, etc.). Because these matrices cause a high background in the mass spectra the knowledge of fragmentation reactions specific for the analyte under different ionization conditions is of great importance. Therefore, abecarnil and other structually related compounds were investigated systematically with several mass spectrometrical techniques. In this paper only a selection of the results obtained in positive DCI, ESI and TSP mode can be discussed.

Materials and Methods:

The experiments were performed on two different TSQ 700 triple stage quadrupole mass spectrometers (Finnigan MAT), one equipped with a DCI or TSP 2 (Finnigan) ion source, respectively and the other with an ESI ion source (Analytica). Standard solutions were prepared from the pure substances diluted in HPLC grade methanol (E.Merck). In all cases except ESI the sample concentration was 1 ng/µl. For the DCI experiments 4 µl of the standard solutions were placed on a rhenium wire dip The DCI probe was heated to a final temperature of 800°C. After each run the wire was cleaned at 1000°C for 30 seconds. The temperature of the ion source was 150°C. Methane was used as reactant gas. For ESI experiments 100 ng of the standards diluted in 10 µl methanol were introduced into the ion source at a flow rate of 2 µl per minute using a Harvard 980 532 syringe pump (Harvard Apparatus). The eluent consisted of a 2:1 (v/v) mixture of 5 % acetic acid and methanol Temperature of the shielding gas (N_2) was 190°C. For TSP analysis the instrument was equipped with a Waters 600 MS HPLC system (Waters Millipore). The ion source temperature was set to 240°C; the vaporizer temperature was found to be optimal at 115°C, the repeller voltage at 160 V, respectively. Routinely 100 µl of the standard solutions were used for each run. TSP-MS/MS experiments were performed using 200 µl of the samples and xenon as collision gas. A collision energy of 15 eV was applied.

Results:

Table 1 shows an overview of the investigated ß-carboline derivatives and figure 1 gives the basic structure of the abecarnil derivatives.The **DCI** results show that nearly in all spectra the molecular ion $[M+H]^+$ is the most abundant ion. The only exception is ZK 113944, because its t-butylester-group can easily be split, resulting in the free acid of abecarnil represented by the ion at m/z 363. Since methane was used as reactant gas, $[M+29]^+$ ions were detected in all cases. $[MH-32]^+$ ions indicate the loss of methanol from the methoxymethyl-group at C4. Very characteristic for the investigated compounds are the ions at m/z 345 and 331 for all those substances carrying an ether group at C5 or C6, and m/z 255 or 241 for the corresponding hydroxy compounds. These "abecarnil-derivative specific" ions at m/z 345 or 255 represent the loss of the alcohol from the ester group at C3. The ions at m/z 331 or 241 were formed by an additional

loss of a methyl group from the chain at C4, according to the neutral loss of the alcohol-methylether. The **ESI** spectra show intense $[M+H]^+$ and $[2M+H]^+$ ions. Application of skimmer fragmentation to these samples produced an additional attachment of sodium to this molecules. In this case also the upper mentioned "abecarnil-derivative specific" ions could be detected with high intensities. **TSP** spectra are dominated by the $[M+H]^+$ ions. Applying **TSP-MS/MS** experiments to the samples yielded the "abecarnil-derivative specific" ions in all cases (fig. 2). An additional ion at m/z 363 represents the free acid of abecarnil or gedocarnil derivatives, that at m/z 273 the corresponding hydroxy compound at C6 or C5, respectively. These results clearly support the structural assignments which were derived from the results obtained with the other ionization methods.

Conclusion:

The mass spectra of the investigated ß-carboline derivatives are characterized by the presence of abundant molecular ions, suitable for molecular weight determination and structure specific fragments. Fragmentation patterns are controlled by the loss of the alcohol from the ester side chain at C3 and an additional loss of a methyl group from the chain at C4, according to the neutral loss of an alcohol-methylether. The appearence of these "abecarnil-derivative specific" ions and the formation of m/z 363 representing the free acid of the benzoylic compounds or m/z 273 for the corresponding hydroxides in all ionization modes can be used for the determination of ß-carbolines and their metabolites in biological matrices.

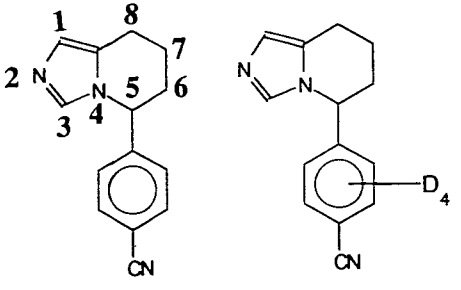
Fadrozole (CGS 16949A), a novel tetrahydroimidazopyridine, is currently under development at CIBA-GEIGY Corporation as an orally active aromatase inhibitor for the treatment of estrogen-dependent mammary tumors. The identification of the human metabolite profile has been studied by pattern recognition stable isotope techniques using both GC/MS and ESI/LC/MS. Six healthy female subjects were given a single 8 mg aqueous solution of a 4:5 mixture of unlabelled Fadrozole:[4-^{2}H]-Fadrozole. Structures are shown in Figure 1.

Figure 1



Urine samples were purified by solid-liquid extraction using C-18 reverse phase columns followed by elution with methanol. Extracts were analyzed both by GC/MS and electrospray (ESI) LC/MS. The major compounds found were unchanged parent drug and the 8-O-glucuronide metabolite. The 8-keto metabolite was also identified in significantly smaller amounts when compared with the other major species. The use of both GC/MS and ESI/LC/MS provided complimentary information. ECI/LC/MS was particularly useful for the identification of the 8-O-glucuronide. Figure 2 summarizes the proposed chemical structures of the human metabolites.

DRUG METABOLISM STUDIES USING "INTRINSIC" AND "EXTRINSIC" LABELS: A DEMONSTRATION USING ^{15}N vs Cl IN MIDAZOLAM

Hengchang Song and Fred Abramson, Department of Pharmacology
George Washington University Medical Center, Washington DC 20037

Introduction: Isotopes play an important role in evaluating metabolic pathways. In this work, we move beyond isotopic tracers to explore the concept that CRIMS (Chemical Reaction Interface Mass Spectrometry) could allow an elemental "label" to trace a drug metabolite pattern. To allow us to simultaneously evaluate the two types of label we used $^{15}N_3$-labeled midazolam, a structure that contains one chlorine, as the intrinsic elemental label, and three atoms of ^{15}N, as the extrinsic isotope label.

The CRI completely decomposes analytes in an effluent flow from a chromatographic column and leads to a reformulation of the atomic species originally contained in each analyte. With SO_2 as the reactant gas, the reactions in the CRI are:

$$C_xH_yO_zN_iCl_j + SO_2 \rightarrow CO_2 + NO + HCl + ..$$

The ^{15}N in the metabolites is determined by the enrichment of NO (m/z 30 *vs* m/z 31) and the Cl is simultaneously detected as HCl (m/z 36 and 38). CO_2 is the nonspecific carbon channel.

Experimental: The GC/CRIMS system consists of a 30m long, 0.25mm id and 0.25 μm film DB-5 column, a microwave powered reaction chamber, and an Extrel C50/400 mass spectrometer. The GC column was initially at 80° for 1.5 min, programmed at 30°/min to 110°, then at 8°/min to 280° and held for 5 min. The ^{15}NO was calculated as:

Enriched ^{15}NO = observed ^{15}NO - (.00403 · observed ^{14}NO).

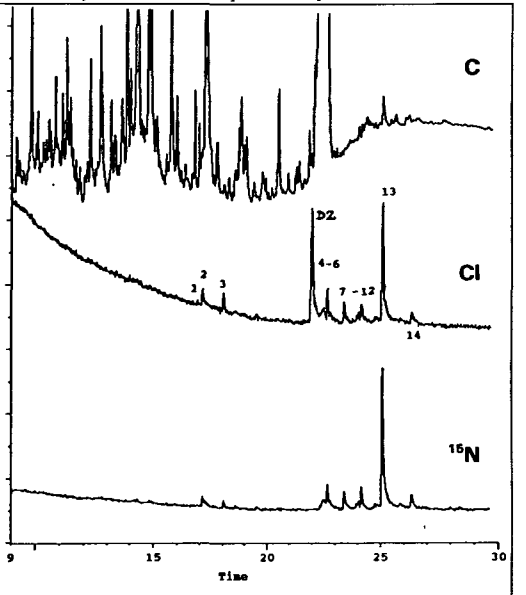
Urine was collected from two dogs 0-24h before and 0-48h after the oral administration of 5 mg/kg $^{15}N_3$-midazolam. A 10 mL aliquot from each of the urines was spiked with 20 μg unlabeled diazepam, filtered, and incubated at pH 4.5-5.0 and 37° for 24h with glucuronidase/sulfatase. The sample was then extracted with an Amberlite XAD-2 column, eluted with 20 mL of CH_3Cl/iso-C_3H_7OH (3/1, v/v) followed by 20 mL methanol. The dried elute was derivatized with 250 μL MSTFA and 250 μL acetonitrile at 100° for 30 min. 1 μL of sample was injected using the splitless mode.

Results and Discussion: Figure 1 shows the dog urine chromatograms with C, ^{15}N, and Cl detection. The channels for ^{15}N and Cl are highly selective. Although midazolam has three atoms of ^{15}N but only one Cl, the result shows that the intrinsic elemental "label" Cl is equally successful in tracing the metabolites of midazolam as is the extrinsic isotope label ^{15}N.

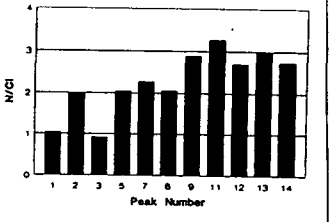
In contrast to the 4 midazolam metabolites reported in the literature, 14 metabolite peaks were easily detected with CRIMS in both the extrinsic labeling (^{15}N) and the intrinsic labeling (Cl) channels. Since CRIMS detection is quantitative and structure independent, the peak areas of the chlorine channel were used to produce a quantitative metabolite profile of each dog despite not having standards for the unknown metabolites. The result indicates that the metabolite concentrations range from 100 pmol/mL to 10 nmol/mL. Figure 2 is the ratio of ^{15}N/Cl in each metabolite peak with the known α-OH-MDZ as the standard. Peaks 1, 2, 3, 5, 7, and 8 appear to have lost one or two ^{15}N atoms, and this information becomes useful in interpreting mass spectra of these metabolites.

The configuration of GC/CRIMS permits use of the GC/MS in its normal mode by turning

off the microwave power. The sample was reinjected and mass spectra were obtained at the retention times indicated in the selective CRIMS chromatogram. All the four known metabolites (peaks 7, 12, 13, and 14) were easily identified and confirmed by comparing their mass spectra and GC retention times with the reference nonlabeled compounds. Without analytical standards, only tentative identifications are made for other metabolites. However, the mass spectral characteristics of several metabolites strongly suggest that ring opening at bond 5-6 and/or imidazole occurred, and this was supported by the loss of one or two ^{15}N. (Figure 2)



This work clearly shows the equivalence of elemental and isotopic labels in drug disposition. It also provides new information regarding midazolam metabolism. The impact of this demonstration should be greatest for investigations of new chemical entities in the pharmaceutical industry where the totally structure-independent principles of CRIMS permits detection of metabolites without requiring that the analyst make any *a priori* judgements to locate metabolites by traditional means. At the present time, CRIMS can selectively detect Cl, Br, and S, and we are considering analytical strategies to add F and P to the list. Any of these atomic species in an organic compound from a pharmaceutical or biological source makes its detection selective.



Conclusions: We find equally high selectivity and comparable signal/noise characteristics for chlorine as for isotopic nitrogen. The chlorine in midazolam is itself an effective label; special syntheses to incorporate isotopic labels are not necessary. The power of either mode of CRIMS is shown by detecting 14 metabolites while only 4 had been previously reported. The ratios of ^{15}N/Cl for each metabolite peak along with conventional mass spectra provide clues to the structures of these new metabolites.

INTRODUCTION

Quinolinic acid, a kynurenine pathway metabolite of tryptophan, has been found at substantially elevated concentrations both in cerebrospinal fluid and brain tissue of patients with broad spectrum infections, and other inflammatory, neurologic diseases including AIDS. This has led to increased interest in metabolic profiling of kynurenine metabolism in various systems, including interferon gamma (IFN-γ) stimulated cell lines. The various methods developed for analysis lack adequate selectivity, and they assay only single metabolites. In this poster we discuss the development of an HPLC/CRIMS (Chemical Reaction Interface Mass Spectrometry) method that simultaneously detects all known kynurenine pathway metabolites. We have profiled media from six different cell lines with this method.

EXPERIMENTAL

Six cell lines, A-498 (renal carcinoma), H4 (neuroglioma), MRC-9 (lung), U-373MG (glioblastoma), THP-1 (human monocytes), and Macro (human macrophages) were tested. Each cell line grown in D_5-tryptophan-supplemented (100 μM) media was stimulated with IFN-γ (100 U/mL) and incubated for 72h along with unstimulated control cell lines. D_5-methyltryptophan was the internal standard. Tryptophan metabolites were separated by reversed phase HPLC using a C-18, 150 X 4.6 mm Altima column (Alltech). The solvent system was water with 0.1% trifluoroacetic acid (TFA) (A) and 20% acetonitrile and 0.1% TFA in methanol (B). The gradient system for elution was 1-4% B in 6 min, 4-24% in 20 min, 24-54% in 20 min and 54-100% in 10 min. Adequate reversed-phase separation of these compounds required a high carbon load column (15%). The peaks are fully separated and little tailing is observed. In addition, the retention times of the early eluting peaks are markedly increased (Fig. 1). The sample eluting from the HPLC was detected with an HPLC/CRIMS apparatus that used a Vestec Universal Interface and a Dupont 21-492 double-focusing mass spectrometer. Hydrogen was the CRIMS reactant gas and the reaction products C_2H_2 at mass 26 generally monitored carbon and HD at mass 3.022 selectively monitored deuterium.

RESULTS AND DISCUSSION

When stimulated cells are incubated with media containing D_5-tryptophan, the metabolites produced contain deuterium. These metabolites can be detected with deuterium-selective CRIMS methods. We then analyzed various IFN-γ treated cell lines and their respective untreated controls. Area ratios of the various peaks to the internal standard provided quantitation. Most of the stimulated cell lines show peaks due to kynurenine and unmetabolized tryptophan with the occasional appearance of one or two peaks that do not correspond precisely to any known metabolites. In contrast, the chromatogram from media of some stimulated human macrophages contains at least nine peaks only three of which correspond to any of the known tryptophan metabolites (Fig. 2),

however human macrophages do not routinely demonstrate this level of metabolic diversity. The presence of this many unknown metabolites clearly demonstrates the generality of the system including the transmission through the Universal Interface and the efficiency of the CRI. The differences in retention times between Figs. 1 and 2 resulted from having changed columns.

The effect of interferon on tryptophan disappearance at 72 hrs has also been studied. The majority of the cells metabolized more than 90% tryptophan upon stimulation with IFN-γ. A-498 cells have metabolized less than 10% of the tryptophan. Only unstimulated H-4 cells metabolized tryptophan substantially.

CONCLUSIONS

A new HPLC-CRIMS method using deuterium-selective detection has been successful in studying the kynurenine pathway of tryptophan metabolism from media and cell cytosol. Numerous metabolites with markedly different retention times from known metabolites were detected. CRIMS has been used to quantitatively profile the metabolites from various cell lines. In this way CRIMS simultaneously measures the disappearance of tryptophan as well as the appearance of the metabolites. CRIMS could also detect ^{13}C and ^{15}N if they were incorporated in a substrate molecule.

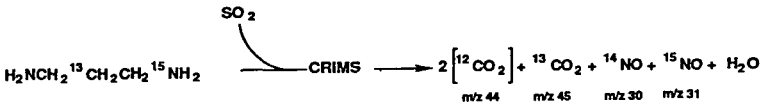
The Application of Liquid Chromatography/ Chemical Reaction Interface Mass Spectrometry (LC/ CRI MS) to Quantitative Studies in Drug Metabolism

*Charles A. Goldthwaite, Jr.[1], Brian Nobes[2], Ian A. Blair[1,2], Robert F. Mayol[3] and Lewis J. Klunk[3].
Departments of [1]Chemistry and [2]Pharmacology, Vanderbilt University, Nashville, TN 37203; [3]Bristol-Myers Squibb Co., Pharmaceutical Research Institute, Wallingford, CT 06492.

Chemical reaction interface mass spectrometry (CRI MS) is a new technique for identifying and quantifying stable isotope labeled compounds. The CRI MS unit (Figure 1) consists of a microwave powered device interfaced with an electron impact (EI) mass spectrometer. Compounds are combusted in the microwave chamber and subsequently oxidized by SO_2 to yield stable products such as CO_2, NO and H_2O (Scheme 1). These products are then monitored in a quadrupole mass spectrometer, and the amount of compound is determined by comparing intensity levels with those of a known standard. By using single ion monitoring (SIM), m/z channels corresponding to stable isotope oxidation products (i.e. m/z 31 for ^{15}NO and m/z 45 for $^{13}CO_2$) can be examined.



Scheme 1.

A CRI MS unit has been coupled to an HPLC via a Vestec Universal Interface. This interface vaporizes and desolvates the HPLC effluent prior to introduction into the CRI chamber. Analytes are swept through the interface using helium, and a helium particle beam enriched in the sample is formed. This particle beam travels into the momentum separator, where the remaining solvent and the bulk of the helium are removed using a two-stage pumping system. SO_2 is added and the analytes are combusted upon entrance into the microwave-induced plasma (MIP) chamber.

The system was optimized to reduce background in the m/z 30, m/z 31 and m/z 44 channels by employing reduced solvent flow rates (0.2 mL/min to 0.5 mL/min) in addition to optimizing the desolvation gas flow rates and the SO_2 pressure. Several methods of vaporization, including the use of a helium-assisted nebulizer, were examined to determine optimal vaporization conditions. The system has been tested using *in vitro* incubations of $^{14}C/^{15}N$ buspirone (an anti-anxiety agent) with rat liver microsomes as a biological model. Results shown in Figure 2 depict an LC/CRI MS chromatogram of the buspirone incubation mixture. The major sites of hydroxylation of buspirone are the 3', 6' and 5 positions. An intramolecular attack on the carbonyl within the 6' OH metabolite yields oxa-buspirone. Each of these metabolites was identified by comparison with known standards. Independent quantification studies were performed using ultraviolet absorbance data (254 nm) and radioactivity.

The CRI MS technique has been proven to be very precise between injections. Results of quantification studies indicate a large variability in CRI MS response among the buspirone metabolites. This variability is due to solvent composition changes imposed by the gradient used to separate the metabolites. Future studies will focus on methodology aimed at optimizing particle formation during the vaporization process, thus reducing the solvent-dependent variability in the CRI MS response.

Supported by Bristol-Myers Squibb.

ANALYSIS OF CATECHOLAMINE METABOLITES BY ELECTRON CAPTURE MASS SPECTROMETRY.

S.T. Weintraub[1], C. Marquez[2], R. Benavides[3] and J.W. Maas[3]
Departments of [1]Pathology and [3]Psychiatry, The Univ. of Tx. Health Science Center, San Antonio TX and [2]Departmentt. of Pharmacy, The Univ. of N. Carolina, Chapel Hill NC.

Long term studies in our laboratories have focused on measurement of endogenous levels of catecholamine metabolites as a means of characterizing various psychiatric conditions, in particular schizophrenia. Quantitative analysis has been accomplished by GC/MS using electron impact ionization of pentafluoropropyl/pentafluoropropionyl (PFP) ester derivatives. The method has proved highly satisfactory for monitoring levels of substances such as 3,4-dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA, 4-hydroxy-3-methoxyphenylacetic acid) and 5-hydroxyindoleacetic acid (5-HIAA) in urine and cerebrospinal fluid. However, problems with extraction efficiency and chromatographic interferences have seriously hindered analysis of DOPAC and HVA and have essentially prevented monitoring of 5-HIAA in plasma. Moreover, the derivatives are not very stable; as a consequence, sample analysis must be completed on the same day as derivatization.

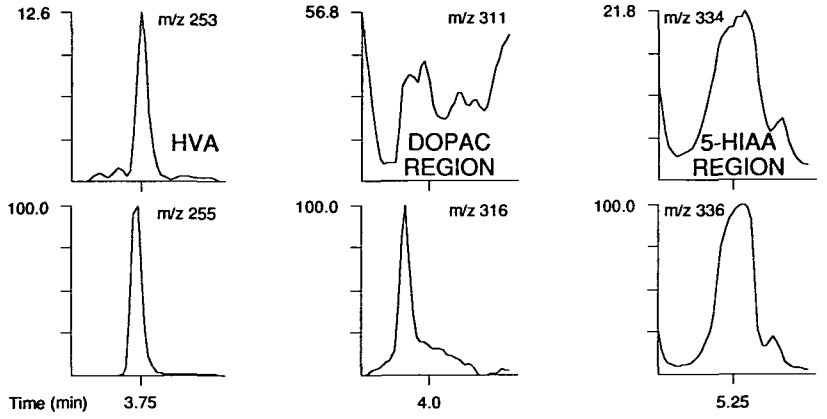
Our first attempt to solve this problem involved a switch to electron capture mass spectrometry (ECMS) with negative ion detection as a means of obtaining better sensitivity. Although orders of magnitude increase in response were observed, the anions formed from the PFP derivatives by this ionization technique proved unacceptable for our purposes. One major difficulty is that molecular anions are not observed for these PFP derivatives when methane is used as the chemical ionization reagent gas, and formation of the most intense ion involves loss of deuterium from the internal standard.

A different approach was definitely mandated. In view of the success attained for quantification of extremely low levels of prostaglandins, we next evaluated pentafluorobenzyl (PFB) esters as a way to achieve the necessary sensitivity and sample stability. We found that in a manner analogous to prostaglandins, formation of the trimethylsilyl ethers could be readily accomplished after esterification with PFB bromide, yielding a very stable product with excellent GC/ECMS properties. As expected, $[M\text{-}PFB]^-$ ions predominate, with little additional fragmentation observed. Low pg levels of standard samples were easily detected at modest detector gain settings.

This appeared to be an ideal way to achieve quantitative analysis of these catecholamine metabolites, and when the derivatization was carried out on at least 10 µg of each compound, uniform recoveries were obtained. However, when lower quantities were reacted, the recovery of DOPAC was much less than the other two metabolites (relative recoveries: HVA, 1.0; DOPAC, 0.09; 5-HIAA, 0.5). To see if the decreased yield of DOPAC was occurring at the trimethylsilylation step, 100 ng of each compound was reacted directly with BSTFA/1% TMCS. Analysis by GC/EIMS revealed a similarity in peak heights in the reconstructed total ion current chromatogram as well as in the selected ion retrieval chromatograms for $[M]^+$ and $[M\text{-}15]^+$. These results suggested that formation of the TMS ether/ester derivatives was comparable for all three compounds. We next produced the PFB esters using 10 µg of each metabolite and then removed an aliquot equivalent to 100 ng per component. In most experiments, the yield of DOPAC was significantly less than HVA or 5-HIAA. On occasion, however, better recovery of

DOPAC was obtained. Neither increasing the concentration of PFB bromide, nor using silanized reaction vials yielded any consistent improvement in recovery of DOPAC.

At this point it was decided that even with a reduced yield for DOPAC, there would be sufficient sensitivity afforded by ECMS to permit detection of endogenous levels of DOPAC in 1 ml of plasma. We, therefore, carried out our usual procedure involving ethyl acetate extraction of acidified plasma, followed by formation of the PFB/TMS derivatives. Linear standard curves for analysis of ng levels of metabolite in the presence of 100 ng of deuterated internal standard were obtained, with correlation coefficients routinely ≥ 0.98. Below are typical selected ion retrieval chromatograms for the respective ions and elution times for the PFB/TMS derivatives of HVA (m/z 253), DOPAC (m/z 311) and 5-HIAA (m/z 334) and corresponding deuterated internal standards isolated from human plasma.



The quantitative results for HVA (10.7 ng/ml) were comparable to those obtained by GC/EIMS analysis after PFP derivatization of another aliquot of the same sample. A distinct advantage of the ECMS method for HVA was that intense signals were observed for significantly smaller aliquots at much lower detector settings than required for the EIMS method. Excellent recovery of HVA was also obtained. However, the traces clearly indicate that our current extraction protocol is not capable of yielding a sufficiently "clean" sample for measurement of DOPAC and 5-HIAA in plasma. It is likely that an additional solid-phase extraction step will provide the necessary purification. In future studies, we also plan to evaluate the phenylboronate/PFB derivative of DOPAC as a means of improving product yield.

Acknowledgements. These studies were supported in part by NIH grant MH40935 to J.W. Maas. We are grateful to Dr. James Yergey for advice on derivatization with PFBBr.

STUDIES OF NITROGEN METABOLISM USING CRIMS 15N-LABELED GLUTAMINE AND ASPARAGINE SUBSTRATES IN CELL CULTURE

Jozef J. Kusmierz and Fred P. Abramson, George Washington University Department of Pharmacology, 2300 Eye Street NW washington D.C. 20037

INTRODUCTION

The unique ability of CRIMS (Chemical Reaction Interface Mass Spectrometry) to selectively detect ^{15}N has been utilized to elucidate metabolic pathways that transfer nitrogen in cultured cell media and cell cytosol. We detect nitrogen selectively as NO using masses 30 and 31 where the natural abundance of M+1 is 0.00403 and atom % excesses as low as 0.004 can be measured. In the present study we demonstrate how CRIMS can trace ^{15}N metabolism, using either α-^{15}N-labeled glutamine or asparagine in the media of cultured hepatoma (HEPG2) cells.

EXPERIMENTAL

Sample preparation. HepG2 cells ($3 \cdot 10^6$) were plated in the 50 ml (25 cm^2) flask (Costar Corp.) and cultured in 10 mL phenol red-free medium (DMEM, Biofluids Inc.) containing 10% calf serum. The cells were incubated in presence of either α-^{15}N-glutamine (12 mM) or α-^{15}N-asparagine (12 mM) respectively. Samples of culture media (100 μL) were taken every 24 hours during incubation and kept at -20° until analysis. The incubation was terminated after 144 hrs. The remaining cells were harvested using 1 ml of methanol. One hundred μL of this was used for analysis of cell cytosol. After protein precipitation, the supernatant was evaporated to dryness and the residue silylated with 50 μL of N-methyl-(N-trimethylsilyl)trifluoroacetamide (MSTFA) and 50 μL of acetonitrile. The mixture was then heated at 80° for 2 hrs.

GC/CRIMS Analysis. The analytes eluting from a capillary GC column are decomposed in the chemical reaction interface in the presence of helium and converted into stable molecules using sulfur dioxide as the reactant gas. The samples were separated on a 30 m long, 0.25 mm i.d., 0.25μ film thickness DB-5 capillary column with 20 psi column head pressure. Four minutes after injection of a 2 μL sample in the split mode (1:10) at 70°, the temperature was programmed 3°/min to 270° and kept constant for 15 min. The microwave power and mass spectrometer were turned on 5 minutes after injection. With CRIMS we monitored carbon as CO_2 using mass channel 44 and nitrogen as NO using mass channels 30 and 31. An enrichment chromatogram of ^{15}N was produced by subtracting the natural contribution of NO at m/z 31. This was generated as follows:

$$\textbf{Enriched } ^{15}N = m/z\ 31 - (0.00403 \cdot m/z\ 30)$$

The percent enrichment of each peak was:

$$100 \cdot \textbf{Enriched } ^{15}N/(\textbf{Enriched } ^{15}N + \textbf{Total } ^{14}N)$$

RESULTS

The CRIMS chromatogram of medium containing ^{15}N-GLN incubated for 144 hrs is shown in Fig.1. The carbon channel chromatogram (top) is complex and difficult to interpret, while the enriched ^{15}N channel (bottom) showed only the relevant peaks. Next, the CRI was turned off and full scan mass spectra of the peaks containing ^{15}N were acquired and

their structure elucidated. The ^{15}N-GLN was completely converted to ^{15}N-glutamic acid during the first 24 hours of incubation. ^{15}N-GLU disappearance (actually measured as pyroglutamic acid), expressed as % of total ^{15}N, and ^{15}N-alanine and ^{15}N-proline production during incubation were measured. GLU was steadily metabolized and declined to 18% of total ^{15}N. ALA peaked at 60% of total ^{15}N after 48 hours of incubation, while PRO maximizes at 20% of total ^{15}N at 144h. The enrichments of ^{15}N of ALA and PRO during GLN incubation reached 46% and 42% at 144h, respectively.

As a substrate, asparagine was degraded more slowly than glutamine. The production of ALA and PRO reached 13% and 5% of total ^{15}N respectively. Glutamic acid contained 2.8% of total ^{15}N. The enrichment of ^{15}N in ALA and PRO increased linearly during course of the incubation and reached 20% and 19% respectively. The enrichment of ^{15}N in asparagine could be measured and was a constant 50.5% during the incubation.

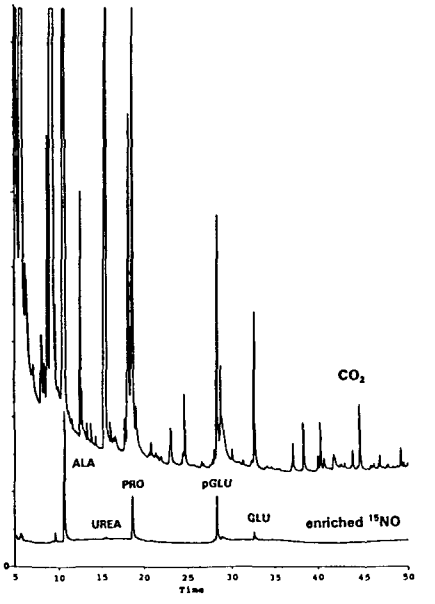


Fig.1 GC/CRIMS chromatogram of culture media incubated with α-^{15}N-glutamine.

The GC/CRIMS analysis of the cell cytosol following asparagine incubation, revealed that the carbon channel is even more complex than from the medium, but the ^{15}N-selective chromatogram is still relatively simple. The cytosol peaks containing ^{15}N were identified by mass spectrometry and were the same metabolites as in the medium in which experiment was performed. The total amount of label in the cell cytosol was estimated at 10% of that in the culture media.

CONCLUSIONS

The special ability of the CRIMS method to trace ^{15}N has been utilized in two studies of amino acid metabolism in cell culture. CRIMS successfully generated ^{15}N-selective chromatograms from both the medium of the cell culture experiment and the cell cytosol. These isotope-selective chromatograms provide both quantitative metabolite patterns from each labeled substrate as well as the fractional enrichment for each metabolite. The selectivity of CRIMS for detecting compounds containing ^{15}N facilitates subsequent experiments to elucidate metabolite structures.

HEPATIC FIRST-PASS METABOLISM OF DIPHENHYDRAMINE IN SHEEP

G. R. Tonn, E. Kwan, C. Hall, F.S. Abbott, J.E. Axelson, and D.W. Rurak
Faculties of Medicine and Pharmaceutical Sciences, University of British Columbia, Vancouver, B.C., Canada.

Diphenhydramine (DPHM) is a H1 receptor antagonist used in the treatment of a variety of allergy mediated conditions. Previous experiments conducted with sheep have shown that DPHM is rapidly removed from the plasma with less than 1% excreted as intact drug in the urine. This data suggests that some form of non-renal clearance is the predominant route of elimination of DPHM in sheep. With the aid of a deuterated stable isotope analog of DPHM (i.e. $^2H_{10}$-DPHM), the *in vivo* hepatic first-pass metabolism of DPHM in sheep was assessed as an indicator of hepatic elimination. Biological studies employed 5 female Dorset-Suffolk cross sheep. Chronic catheters were aseptically implanted in the femoral and mesenteric veins, and the femoral artery. Administration of labelled and unlabelled drug was randomized, such that a dose of either DPHM or $^2H_{10}$-DPHM (50 mg or 52 mg free base, respectively) was administered *via* the femoral vein with the alternate compound simultaneously administered *via* the mesenteric vein. Serial samples were drawn from the femoral artery from -5 to 720 minutes. Following liquid-liquid extraction (0.05M triethylamine in 2% isopropanol: 98% hexane) of plasma samples, both DPHM and $^2H_{10}$-DPHM were simultaneously quantitated by GC-MS (select ion monitoring; m/z 165 DPHM and m/z 173 $^2H_{10}$-DPHM [Fig 1A and 1B]) using a Hewlett-Packard (HP) 5890 series II gas chromatograph equipped with a HP 5971A mass selective detector. The plasma concentration *vs.* time data was fit with PCNONLIN. The area under the plasma concentration *vs.* time curve (AUC) for both DPHM and $^2H_{10}$-DPHM was calculated using the method of trapezoids. The pharmacokinetic data obtained from the five ewes is presented in Table 1, and a representative plot of the concentration vs. time data is presented in Figure 2. The ratio of the AUC obtained from drug administered *via* the mesenteric vein to the AUC following femoral vein administration was calculated as the bioavailability (F) [extraction ratio; E = 1-F]. The bioavailability of DPHM following mesenteric administration was roughly 5% ± 3%, suggesting that roughly 95% of the dose administered to the mesenteric vein was metabolized prior to reaching the plasma. From the data presented, it appears that hepatic clearance (CL_H) is a significant component of the total body clearance (CL_T) of DPHM in sheep. An estimate of hepatic clearance using a literature value for hepatic blood flow (3.3 L/hr/Kg) was 3.1 ± 0.1 L/hr/Kg ($CL_H = Q_H \times E$). The calculated total body clearance of DPHM in these sheep was 3.3 ± 1.1 L/hr/Kg suggesting that, based on our estimate of CL_H, the CL_H accounts for a significant proportion of DPHM total body clearance in sheep. In summary, these results suggest that the ovine liver is very efficient in eliminating DPHM following mesenteric administration, and that hepatic elimination is likely responsible for a large portion of the observed CL_T of DPHM in sheep.

Studies on the Metabolism of Cyoctol: Characterization of the Urinary Metabolites of Cyoctol Present in the Rat by GC-MS. *MJ Hauer, BA Thornburgh, PE Sanders, AJ Wickrema Sinha and JJ Vrbanac*, Drug Metabolism Research, The Upjohn Company, Kalamazoo, Michigan

Cyoctol (Figure 1) is classified as an androgen receptor blocking agent. When administered topically to the rat, rabbit, or human cyoctol was observed to be rapidly absorbed, metabolized and excreted, primarily in the urine. The metabolites of cyoctol present in rat urine following oral administration were characterized by GC-MS. Characterization of metabolites was severely compromised by the complexity of the urinary milieu and by the low concentrations of metabolites. Metabolites were partially purified into eleven fractions by reversed phase HPLC. Attempts at sufficient purification of metabolites for NMR analysis using several approaches were not successful. Attempts to characterize metabolites by on-line LC-MS (particle beam) and by LSIMS analysis of purified fractions were not successful. Suppression of ionization by the biological milieu was a major problem in the failed LSIMS analysis. We describe the characterization of the metabolites found in two of the HPLC fractions which represented approximately 28% of the radioactive metabolites excreted. Structures were assigned based on the interpretation of the EI and PCI mass spectra of the methyl ester-trimethylsilyl (ME-TMS) derivatives. Because of the inability to purify metabolites for NMR analysis we decided interpretation of the EI and PCI mass spectra of the ME-$^2H_9$-TMS derivatives was necessary to facilitate greater confidence in assignment of structures. *Representative metabolite identification:* The EI mass spectrum of the ME-TMS derivative of Metabolite **10A** is shown in Figure 2. The assignment of $M^{+\cdot}$ as 284 was straightforward with the presence of $M^{+\cdot}$ - 15 (m/z 269) and $M^{+\cdot}$ - 90 [$(CH_3)_3SiOH$, m/z 194]. Also, $M^{+\cdot}$ - 31 ($CH_3O\cdot$, m/z 253), $M^{+\cdot}$ - 47 ($CH_3\cdot$ + CH_3OH), $M^{+\cdot}$ - 60 (CH_3COOH, m/z 224) and $M^{+\cdot}$ - 73 (CH_3O-OC-$CH_2\cdot$, m/z 211) were observed indicating this compound was a ME. The acidic structure is consistent with the observed $M^{+\cdot}$ -31, $M^{+\cdot}$ -60 and $M^{+\cdot}$ -73. A neutral losses of 90 daltons from $M^{+\cdot}$ - CH_3-OOC-$CH_2\cdot$ was also observed (m/z 121). The ion at m/z 162 apparently results from loss of methanol by *r*H from m/z 194 and the ion at m/z 135 could result from the loss of $CH_3OCO\cdot$ from m/z 194. The ion at m/z 145 could result from the loss of HO· from m/z 162. Sequential losses of C_2H_4 from m/z 135 produce the ions at m/z 107 and 79. Loss of C_2H_4 from 121 produces the ion at m/z 93. Thus, the ion at m/z 107 represents the intact ring structure, minus $(CH_3)_3SiOH$. The EI mass spectrum of the ME-$^2H_9$-TMS derivative of Metabolite **10A** is displayed in Figure 3. The addition of one TMS group was supported by the observation that $M^{+\cdot}$ has shifted to 293 (CI data supported this assignment). The ion observed at m/z 275 results from an expected neutral loss of 18 ($CD_3\cdot$). The loss of methanol from m/z 275 was also observed (m/z 243) and has shifted by 6 daltons from m/z 237. Loss of 99 daltons, $(CD_3)_3SiOH$, was also observed at m/z 194, the same ion observed in Figure 2. As expected, the ions at m/z 79, 107, 121, 135 and 153 are unchanged from Figure 2 (assignment of structures for these ions was straightforward and their presence was indicative of cyoctol metabolites). Figure 1 displays the structures of metabolites identified in Fractions 9 and 10. In view of the lack of NMR data the use of $^2H_9$-TMS derivatives greatly facilitated confidence in the assignment of structures. These and other metabolites identified indicated that *O*-demethylation, β-oxidation, initial oxidative loss of the terminal 3 carbons, hydroxylation of the cyclopentane ring and reduction of the cyclopentane ring carbonyl to an alcohol were the primary metabolic transformations occurring in the rat.

The Metabolism of Essential Fatty Acids in Humans: Studies on the Effects of Dietary Fats on the Conversion of $^2H_5$-18:3w3 & $^2H_5$-18:2w6 to Long Chain Polyunsaturates.

Robert J. Pawlosky, Brent Wegher, and Norman Salem Jr.
Laboratory of Membrane Biochemistry and Biophysics, DICBR, NIAAA, Bethesda, MD. 20892

ABSTRACT

Through a series of elongation and desaturation steps linoleic (18:2w6) and linolenic (18:3w3) acids are metabolized to arachidonic (20:4w6) and docosahexaenoic acids (22:6w3), respectively. Using a negative ion GC-MS technique and the labeled fatty acids, $^2H_5$-18,18,18,17,17-18:2w6 and $^2H_5$-17,17,18,18,18-18:3w3, we investigated the effects of low and high amounts of long chain polyunsaturate fat diets on the *in vivo* biosynthesis of 20:4w6 and 22:6w3 in eight individuals.

Subjects were given a single dose of the isotopes during the first two weeks of the study, at which time they maintained their usual diets and kept food records. Then, for three weeks, subjects were placed on a controlled (low amounts of long chain polyunsaturated fat) diet which included beef and turkey. They were given the isotopes again beginning the fifth week of the study. Subjects were then placed on a second controlled (high amounts of long chain polyunsaturates) diet beginning the sixth week where fish was substituted for the beef. They were given the isotope again during the eighth week. Throughout the controlled diet periods, olive oil and margarine made up much of the remaining dietary fat.

METHODOLOGY

One gram each of the labeled fatty acid ethyl esters were given orally to the subjects and 20 mL of blood was drawn from the forearm at various times throughout a seven day period. The plasma was separated from the red blood cells and the lipids were extracted using the Bligh & Dyer total lipid extraction method. The fats were saponified in a 10% KOH methanolic solution, acidified with HCl, re-extracted into hexane and derivatized to the PFB esters using pentafluorobenzyl bromide. The extracts were analyzed on a Hewlett Packard 5989 gas chromatograph-mass spectrometer in the negative ion mode with methane (99.99%) as the reagent gas. The terminally labeled fatty acids chromatographically resolved from the non-labeled materials using a 25 m X 0.25 mm polar FFAP capillary column (J&W) using splitless injection with an oven temperature program of 80°-185°@20°/min, 185°-240°@10°/min and held for 30 min.. The source temperature was 200° and pressure 4 X 10^{-4} torr. The [M-PFB] ion was used to detect deuterium-labeled metabolites. The fatty acids were quantified using relative response factors and 23:0 as an internal standard (1). The plasma fatty acids were also analyzed as their methyl esters by GC-FID.

RESULTS & DISCUSSION

- The amount of plasma $^2H_5$-18:3w3 was lower than that of $^2H_5$-18:2w6 as measured in the plasma. This suggested that 18:3w3 may be more easily oxidized than 18:2w6 and that based on a per-gram amount more 18:2w6 is available for metabolism than 18:3w3.
- The production of most long chain fatty acids up to and including the 24-carbon compounds were detected using this methodology.
- All deuterium-labelled metabolites could be quantified reliably using a single internal standard.

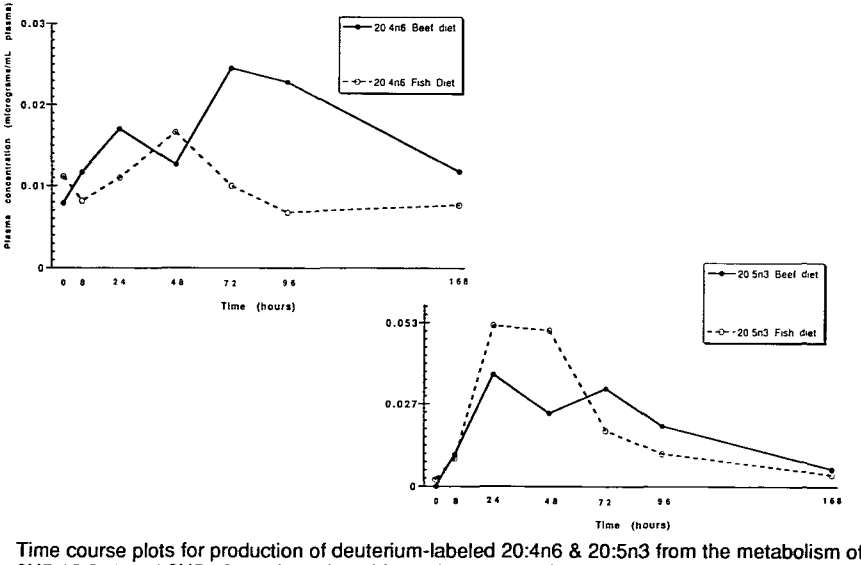
- The production of 20:4w6 from the time course plots appeared to be diminished while subjects were on fish diet compared to the production when on the beef diet. However,the production of 20:5n3 did not appear to be lowered by the fish diet.

A typical Washington DC diet is more similar to the beef diet where plasma long chain w-3 fatty acids are present in low amount. Our results show that high amounts of long chain polyunsaturates especially those containing w-3 fatty acids (fish diet) contribute to a decreased production of 20:4w6 which may lead to lower amount of 20:4w6 reflected in the plasma. Unexpectdly, the fish diet did not appear to significantly reduce production of the arachidonic acid homologue, 20:5w3.

Table 1. Lipid composition of Controlled diets

	Beef Diet	Fish Diet
18:1	35.23	36.83
18:2w6	4.85	5.43
18:3w3	1.53	1.76
20:4w6	0.06	0.18
20:5w3	-*	0.19
22:5w3	-	0.07
22:6w3	-	0.43

* Data taken from USDA Handbook 8.



Time course plots for production of deuterium-labeled 20:4n6 & 20:5n3 from the metabolism of 2H5-18:2n6 and 2H5-18:3n3 in eight subjects that were maintained on a Beef diet or Fish diet for a period of three weeks. The data is the result of GC-MS data take at the time points indicated.

The Metabolism of Fluorinated VPA Analogues

Wei Tang*, Guenter Eigendorf+ and Frank Abbott*, Faculty of Pharmaceutical Sciences* and Department of Chemistry+, University of British Columbia, Vancouver, B.C , Canada, V6T 1Z3

Valproic acid (VPA, 2-propylpentanoic acid), an anticonvulsant agent, causes a rare but severe hepatotoxicity which is thought to be induced by one or more metabolites. Two metabolites, 4-ene VPA (2-propyl-4-pentenoic acid) and 2,4-diene VPA (2-propyl-(E)-2,4-pentadienoic acid), were found to induce microvesicular steatosis in rats [1], a feature also evident in patients who died from liver failure while on VPA therapy. As a mechanism for the toxicity, it has been hypothesized that 4-ene VPA-CoA undergoes β-oxidation to 2,4-diene VPA *to either deplete the mitochondrial glutathione pool [2] or to yield an electrophilic intermediate,* 2-propyl-3-oxo-4-pentenoic acid which alkylates and thereby irreversibly inhibits fatty acid β-oxidation enzyme(s) [3] Thus, based on either of these hypotheses, *if the β-oxidation pathway is blocked, the formation of toxic metabolites and the hepatotoxicity of VPA should be prevented.* In order to test this, we reasoned that α-fluorinated VPA analogues would not undergo β-oxidation to form toxic metabolites, because, while fluorine closely mimics hydrogen in size the stronger C-F bond is resistant to many forms of metabolism.

Thus, α-fluoro VPA (2-fluoro-2-propylpentanoic acid) and α-fluoro-4-ene VPA (2-fluoro-2-propyl-4-pentenoic acid) were synthesized through the deaminative fluorination of the *corresponding α-amino acids using Olah's reagent [4]. The in vivo metabolism of α-fluoro* VPA and α-fluoro-4-ene VPA was investigated by GC/MS and compared with their counterparts VPA and 4-ene VPA. Fluorinated or non-fluorinated compounds were administered to rats (Sprague Dawley, 250g) by i.p. injection of 200mg/kg per day for 3 days. Urine was collected over a 24 h period on the second day Blood was collected following decapitation, 2h after the last dose. Urine and serum samples were acidified to pH 2, extracted with ethyl acetate, concentrated under nitrogen, and derivatized with MSTFA or MTBSTFA at 60°C for 1h. GC/EIMS analysis was carried out using a HP 5971A GC/MS: column, DB-1701 (30m x 0.25mm i.d., 0.25μm film thickness), He (15psi), GC program, 80-100°C (10°C/min), 100-130°C (2°C/min), 130-260°C (30°C/min) *Under these conditions, the β-oxidation metabolites 2-ene* VPA (2-propyl-(E)-2-pentenoic acid) and 2,3'-diene VPA (2-((E)-1'-propenyl)-(E)-2-pentenoic acid) were detected in the serum and urine of VPA treated rat (Fig. 1) and 2,4-diene VPA was detected from 4-ene VPA treated rat. The N-acetylcysteine (NAC) conjugate of 2,4-diene VPA was detected in urine using a HP 5989A GC/MS (column: DB-1, 12m x 0 25mm i d., 0.33μm film thickness; He, 3 psi; GC: 50-200°C (30°C/min), 200-300°C (10°C/min)). *The major serum metabolite,* 2-ene VPA could not be detected in serum or urine of the α-fluoro VPA treated rat (Fig. 2). Neither 2,4-diene VPA nor its NAC conjugate was found as a metabolite of α-fluoro-4-ene VPA. Therefore, we have seen a total elimination of β-oxidation products from the metabolism of α-fluorinated VPA analogues

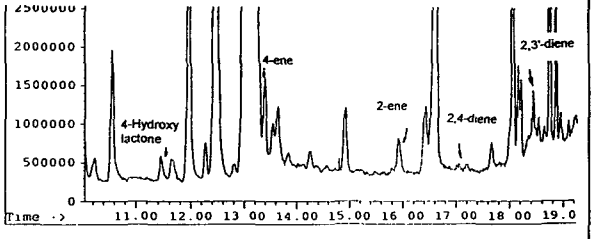


Fig. 1. GC/MS total ion current chromatogram of tBDMS derivatives of an extracted urine sample from a VPA treated rat.

An abundant fragment ion, m/z 77, was found to be characteristic of the TMS or tBDMS derivatives of the α-fluorinated acids (Fig. 3) and proved useful as a diagnostic peak for the detection of metabolites arising from the α-fluorinated compounds. High resolution mass spectra of the derivatives, including the TMS-d_9 derivative, were recorded on a Kratos MS50 or MS 80 mass spectrometer and *confirmed that the m/z 77 ion possessed the chemical structure* $[F\text{-}Si(CH_3)_2]^+$. The mechanism accounting for the formation of fragment ion $[F\text{-}Si(CH_3)_2]^+$ is similar to that proposed by White, et al [5] for the migration of a halogen ion from halo acid TMS derivatives to the silicon charged center (Scheme 1).

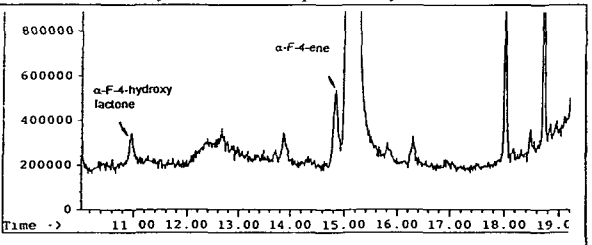

Fig. 2. GC/MS total ion current chromatogram of tBDMS derivatized extract of a urine sample from an α-fluoro VPA treated rat.

This research was funded by a grant from the Medical Research Council of Canada.

IDENTIFICATION OF GLUTATHIONE CONJUGATES OF *tris*(2,3-DIBROMOPROPYL) PHOSPHATE BY TANDEM MASS SPECTROMETRY: APPLICATIONS OF STABLE ISOTOPES AS MECHANISTIC PROBES

Gregory L. Weber, Sidney D. Nelson[†], and Paul G. Pearson

Drug Metabolism Research, The Upjohn Company, Kalamazoo, MI 49001
[†]Medicinal Chemistry, School of Pharmacy, University of Washington, Seattle, WA 98195

The halogenated alkyl phosphate, *tris*(2,3-dibromopropyl)phosphate (Tris-BP) was used extensively as a flame retardant in children's sleepwear prior to the observation that Tris-BP, or its metabolites, were highly mutagenic. Tris-BP is bioactivated by cytochromes P450 to the potent direct acting mutagen, 2-bromoacrolein (2-BA). In an alternative P450 independent mechanism, it has been proposed that Tris-BP may be bioactivated by conjugation with glutathione (GSH) to form reactive episulfonium ions. The episulfonium ions may interact with critical macromolecules or rearrange to form stable GSH conjugates. The objective of this study was to identify GSH conjugates of Tris-BP to elucidate the respective roles of GSH conjugation and cytochromes P450 oxidation in the bioactivation of Tris-BP. The mechanism of GSH conjugate biogenesis was addressed by the use of a per-deutero-analog of Tris-BP (D_{15}-Tris-BP) as a mechanistic probe and the application of mass spectrometry to assess deuterium retention in GSH conjugates.

Experimental: GSH conjugates excreted in the bile of male Sprague-Dawley rats administered Tris-BP (100 mg/kg) or D_{15}-Tris-BP were converted to their *N*-(benzyloxycarbonyl) dimethyl ester derivatives, separated by HPLC and examined by fast atom bombardment tandem mass spectrometry (FAB/MS-MS) FAB/MS-MS spectra were recorded on a VG AutosecQ hybrid tandem mass spectrometer of EBEqQ geometry. Analytes were desorbed from a dithiothreitol/dithioerythritol (5:3) matrix by bombardment with a primary beam of Cs^+ (10 keV) and conventional FAB spectra were recorded at an accelerating voltage of 8 kV. Collision-induced dissociation (CID) daughter ion spectra of the MH^+ ions of metabolites was performed in the first (rf-only) quadrupole (q) employing argon as a collision gas (2 x 10^{-6} Torr) and collision energies of 20-30 eV. Deuterium retention in the analytes was determined by a precursor ion (MS-MS) scan technique in which precursors of m/z 159 were monitored with Q while a magnet (B) scan was performed across the molecular ion region of the chosen analyte.

Results and Discussion: Three GSH conjugates derived from Tris-BP were identified by mass spectrometry as: *S*-(2,3-dihydroxypropyl)GSH (**III**), *S*-(3-hydroxypropyl)GSH (**IV**) and *S*-(2-carboxyethyl)GSH (**V**). The CID product ion spectra for all the GSH conjugates displayed a series of structurally-informative fragment ions that arose from expulsion of methylglycine (-89u), or the derivatized γ-glutamyl moiety (-277u). Representative product ion spectra of metabolite **III** derived from Tris-BP or D_{15}-Tris-BP are shown in Figure 1a and 1b. In this case ions retaining the alkyl side chain (eg. ion **a** and **e**) were shifted by 5u. Precursor ion scans of m/z 159 demonstrated that metabolite **III** retained 5 atoms of deuterium while metabolites **IV** and **V** retained 3 and 2 atoms of deuterium, respectively. The retention of 5 atoms of deuterium in **III** is consistent with direct GSH conjugation of Tris-BP or Bis-BP and subsequent formation of two reactive episulfonium ion intermediates (Figure 2). The retention of 3 and 2 atoms of deuterium in **IV** and **V** suggest the involvement of cytochromes P450 and possibly the intermediacy of 2-bromoacrolein (Figure 2).

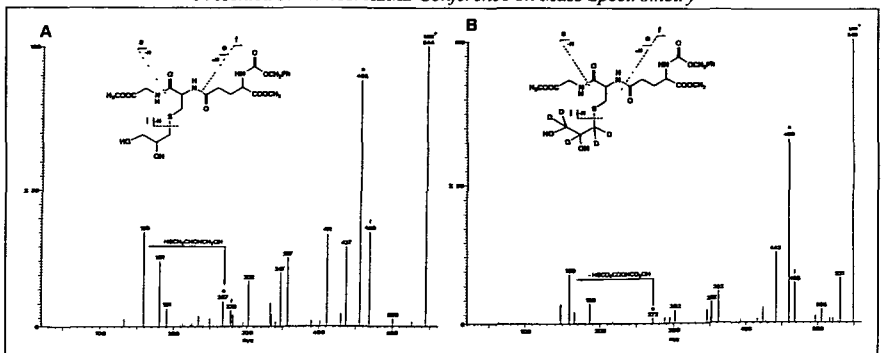

Figure 1. Product ion spectra of *S*-(2,3-dihydroxypropyl)GSH *N*-(benzyloxycarbonyl) dimethyl ester (**III**) isolated from bile of a rat administered (**A**) D_0-Tris-BP; and (**B**) D_{15}-Tris-BP illustrating retention of 5 atoms of deuterium.

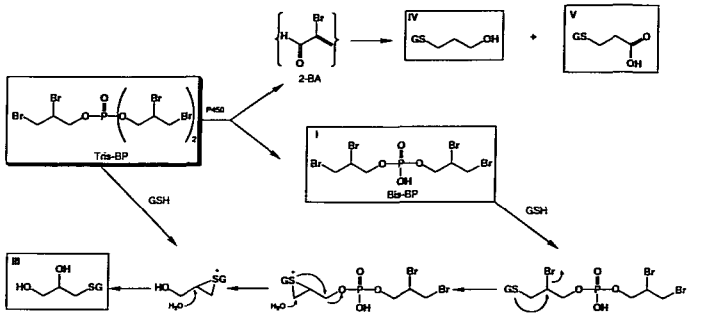

Figure 2. Proposed metabolic scheme for the formation of *S*-(2,3-dihydroxypropyl)GSH (**III**), *S*-(3-hydroxypropyl)GSH (**IV**)and *S*-(2-carboxyethyl)GSH (**V**). Oxidation at C-3 affords 2-bromoacrolein (2-BA) and Bis-BP (**I**). Conjugation of Tris-BP or Bis-BP with GSH, sequential formation of two reactive episulfonium ion intermediates, followed by hydrolysis would afford **III** with retention of five atoms of deuterium from one dibromopropyl side chain of D_{15}-Tris-BP. Conjugation of 2-BA with GSH followed by metabolic reduction affords **IV** with net retention of 3 atoms of deuterium. Additional oxidation of the aldehyde precursor of **IV** affords **V** with net retention of two atoms of deuterium from one dibromopropyl side chain of D_{15}-Tris-BP.

A GC-MS-MS SCREENING STRATEGY FOR THE IDENTIFICATION OF *N*-ACETYLCYSTEINE CONJUGATES DERIVED FROM CHEMICALLY-REACTIVE DRUG METABOLITES OF HALOALKANES

Gregory L. Weber and Paul G. Pearson.

Drug Metabolism Research, The Upjohn Company, Kalamazoo, MI 49001

The endogenous tripeptide glutathione (γ-glutamyl-cysteinyl-glycine; GSH) exists at millimolar concentrations in mammalian systems, and conjugation with GSH serves an important physiological role in the detoxication of reactive electrophilic species. These reactive species, which are generated metabolically from drugs or other xenobiotics, have been implicated in various xenobiotic-induced toxicities. The glutathione conjugates are excreted following a cascade of metabolic events as *N*-acetylcysteine conjugates in urine. As a consequence, therefore, analytical strategies to identify *N*-acetylcysteine conjugates in biological matrices are important, as the structural information thus obtained affords a unique insight into the nature of the chemically-reactive drug metabolite. Analytical approaches based upon fast atom bombardment tandem mass spectrometry (FAB-MS-MS) have been described for the identification of glutathione conjugates in biological matrices (Pearson *et al*, 1990). Here we describe a gas-chromatography tandem mass spectrometry (GC-MS-MS) screening strategy for the facile identification of *S*-(3-chloro-2-hydroxypropyl)-*N*-acetylcysteine (**I**), *S*-(2,3-dihydroxypropyl)-*N*-acetylcysteine (**II**), and *S*-(3-hydroxypropyl)-*N*-acetylcysteine (**III**) derived metabolically from the haloalkane nematocide 1,2-dibromo-3-chloropropane (DBCP).

Experimental: *N*-Acetylcysteine conjugates excreted in the urine of male Sprague-Dawley rats that had received ^{14}C-DBCP (80 mg/kg; 77 mCi/mmol) were converted to methylester derivatives and purified by reverse-phase HPLC. Lyophilized HPLC fractions containing *N*-acetylcysteine conjugates of DBCP were treated with *N*-methyl-*N*-(*tert*-butyldimethylsilyl)-trifluoroacetamide (25µl) in acetonitrile (25µl) at 80°C (60 min.). The samples were evaporated to dryness and reconstituted with acetonitrile (25µl). Aliquots (1-2 µl) were subjected to GC-MS-MS analysis. Separations were performed on a 20 M x 0.18 mm DB-17 column interfaced to a Finnigan TSQ-70 tandem quadrupole mass spectrometer (Finnigan MAT, San Jose, CA) operating in electron ionization mode (70eV). Product ion spectra were recorded by selecting the $M^{+\cdot}$-57 species of choice with Q_1 and scanning Q_3 from 50 - 500 amu. Precursor ion spectra to detect the $M^{+\cdot}$-57 species of **I**, **II** and **III** were recorded by monitoring m/z 144 in Q_3 while scanning Q_1 from 150 - 500 amu.

Results and Discussion: GC-MS analysis of **II** as a *bis*-(*t*-BDMS) methyl ester employing electron ionization afforded a weak M^+ ion (m/z = 479) and an intense M^+ -57 ion (m/z = 422). A product ion (MS-MS) mass spectrum of M^+ -57 ion displayed a series of structurally-informative fragment ions and a base peak at m/z 144 arising by fragmentation adjacent to the sulfur atom (Figure 1A). Analysis of **I-III** by GC-MS-MS indicated that m/z 144 was the base peak in their respective product ion mass spectra. The presence of a common product ion at m/z 144 facilitated a highly specific (GC-EIMS-MS) precursor ion screening strategy for the identification of M^+ -57 of *N*-acetyl-*S*-(hydroxypropyl)cysteine methyl ester derivatives. The reconstructed ion chromatogram (RIC) from a GC-EIMS-MS precursor ion experiment for the identification of NAC conjugates derived from a perdeutero analog of DBCP ($^2H_5$-DBCP) display an intense GC peak at t_r = 10 min. (Figure 1B). Examination of the precursor ion mass spectrum of the GC peak at t_r = 10 min. revealed the presence of a M^+ -57 species at m/z 427, that corresponded to *N*-acetyl-*S*-(2,3-dihydroxy-[$^2H_5$]-propyl)cysteine *t*-BDMS methyl ester (Figure 1C). The general utility of the GC-MS-MS approach was established for a series of *N*-acetyl-*S*-(hydroxypropyl)cysteine conjugates (**I-III**), and *N*-acetyl-*S*-(2-hydroxypropyl)cysteine; GC-EIMS-MS analysis facilitated the separation and identification of $M^{+\cdot}$-57 species for each analyte. Thus by using precursor ion MS-MS scans of m/z 144, $M^{+\cdot}$-57 species of **I**, **II** and **III** were identified in HPLC fractions of urine obtained from rats administered DBCP. These data indicate the selectivity of this GC-MS-MS screening strategy for the identification of *N*-acetylcysteine conjugates as biological markers for metabolic activation of haloalkanes to chemically-reactive drug metabolites.

Pearson, P.G., Howald, W.N., and Nelson, S.D. (1990). Screening strategy for the detection of derivatized glutathione conjugates by tandem mass spectrometry. *Analytical Chemistry*, **62**, 1827-1836.

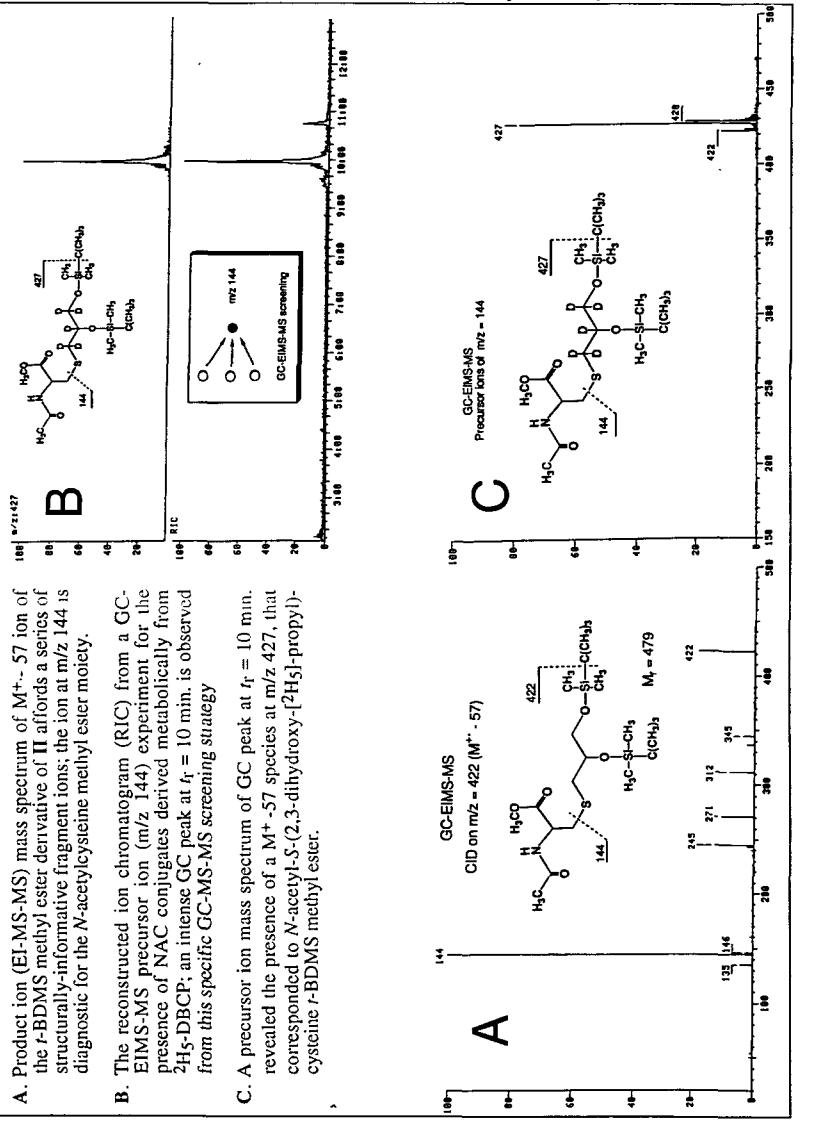

FIGURE 1. *A GC-MS-MS SCREENING STRATEGY FOR THE IDENTIFICATION OF N-ACETYLCYSTEINE CONJUGATES OF DBCP.*

A. Product ion (EI-MS-MS) mass spectrum of $M^{+\cdot}$- 57 ion of the *t*-BDMS methyl ester derivative of **II** affords a series of structurally-informative fragment ions; the ion at m/z 144 is diagnostic for the *N*-acetylcysteine methyl ester moiety.

B. The reconstructed ion chromatogram (RIC) from a GC-EIMS-MS precursor ion (m/z 144) experiment for the presence of NAC conjugates derived metabolically from $^2H_5$-DBCP; an intense GC peak at t_r = 10 min. is observed *from this specific GC-MS-MS screening strategy*

C. A precursor ion mass spectrum of GC peak at t_r = 10 min. revealed the presence of a M^+ -57 species at m/z 427, that corresponded to *N*-acetyl-*S*-(2,3-dihydroxy-[$^2H_5$]-propyl)-cysteine *t*-BDMS methyl ester.

Application of Negative Ion Chemical Ionization Isotope Dilution Gas Chromatography/Mass Spectrometry to Pulse Dose Bioavailability Studies of Mefloquine

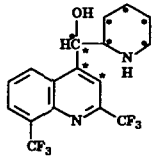
Department of Medicinal Chemistry University of Washington, Seattle, WA 98195

INTRODUCTION

The antimalarial drug mefloquine (I), racemic erythro-α-(2-piperidyl)-2,8-bis(trifluoromethyl)-4-quinoline-methanol, is formulated in both Europe and the United States and has been proven effective against chloroquine- and quinine-resistant strains of *Plasmodium falciparum*. To evaluate the comparative bioavailability of these two tableted dosage forms, each of the unlabeled formulations was orally co-administered with an aqueous solution of isotopically-labelled $^{13}C_3$-mefloquine to adult subjects and blood samples drawn over a 84 day period.

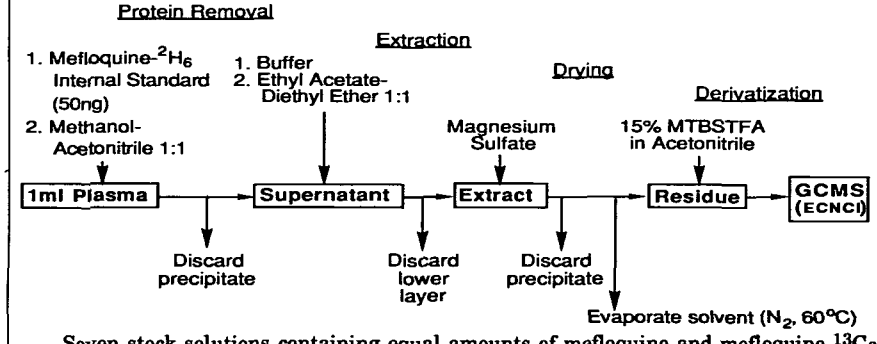


I
(*)mefloquine-$^{13}C_3$
(•)mefloquine-$^{2}H_6$

While an electron ionization (EI) GC/MS method has been reported[1] for the quantification of mefloquine, fragmentation analysis of mefloquine-$^{13}C_3$ using this ionization technique was found to be unsuitable due to significant loss of label in the formation of its diagnostic ion. As a result, a negative ion gas chromatographic mass spectrometric [GC/(NCI)MS] method was developed to quantify the amount of unlabeled mefloquine and co-administered mefloquine-$^{13}C_3$ in plasma in support of this study. This work describes this analytical methodology incorporating a stable isotope labelled internal standard (mefloquine-$^{2}H_6$) and offers an assessment of the sensitivity, precision and accuracy of the technique in the quantification of these compounds.

METHODS

Plasma Extraction and Derivatization



Seven stock solutions containing equal amounts of mefloquine and mefloquine-$^{13}C_3$ at a concentration of 0.02, 0.10, 0.20, 1.00, 2.00 and 4.00 μg mL^{-1} each were used in the preparation of standards by the 50 μL addition of each to 1mL aliquots of blank plasma. Quality assurance plasma samples containing 5, 90 and 150ng mL^{-1} each of mefloquine

and -$^{13}C_3$ were assayed with each sample set to monitor the precision and accuracy of the method.

GC/MS

Analysis of the derivatized extracts was carried out using a VG Trio 2000 quadrupole mass spectrometer (VG BioTech, Cheshire, UK) fitted with an HP 5890 Series II GC and 7673A Autoinjector (Hewlitt Packard, Palo Alto, CA).

GC Parameters:
- Column: J & W 30m DB-1 (0.32mm i.d., 0.25μm film).
- Injector: 250°C with purge on at 1min.
- Oven: 140°C for 1 min, 30°C/min to 290°C, hold 1min.
- Injection volume: 1μL
- Carrier gas: Helium at 10psi head pressure

MS Parameters:
- Ionization mode: ECNCI
- Moderating gas: Methane
- Source temperature: 200°C
- Interface temperature: 300°C
- Data collection mode: SIR with 300ms/ion dwell.
- Ions monitored: [M-TBDMSOH]$^-$; *m/z* 360.1, 363.1 & 366.1

Quantification

Quantification was based upon the ratio of the area measured for each analyte to the the area of the $^{2}H_6$ labelled internal standard. Individual ion intensities were integrated using standard VG Lab-Base™ software. Response ratios for each analyte relative to internal standard were calculated and used for the generation of the standard curves and the determination of analyte concentration in submitted and control samples.

RESULTS

The fragment ions at *m/z* 360, 363 and 366, corresponding to the [M - TBDMSOH]$^-$ ions of the TBDMS derivatives of mefloquine (M_r=492), -$^{13}C_3$ (M_r=495) and -$^{2}H_6$ (M_r=498), respectively, were monitored. These TBDMS derivatives showed a high detection sensitivity in ECNCI for the SIM method with no observed interferences.

Standard curves generated by plotting the peak area ratios of the analyte to the I.S. against known mefloquine concentrations over the concentration range of 1 to 200 ng mL^{-1} were found to be linear with correlation coefficients ≥ 0.990. The intra- and inter-day coefficients of variation were determined by the analysis of duplicate extracts of control samples throughout the study and were found to average ≤ 5% in both cases.

CONCLUSIONS

An ECNCI GC/MS method has been developed which allows the quantification of both mefloquine and its $^{13}C_3$ analog as their TBDMS ethers from plasma.. The high sensisitivity and specificity of the ECNCI GC/MS in combination with the exact control of sample recovery, using mefloquine-$^{2}H_6$ as an internal standard, provides precise and accurate determination of the analytes, with a detection limit of 50fg on-column. The method has proven to be rapid and reliable, and has been utilized to measure over 1000 plasma samples in a three month period.

ACKNOWLEDGEMENTS

We wish to thank Hoffman-La Roche (Nutley, New Jersey) for their gift of mefloquine labeled analogs and support of this work.

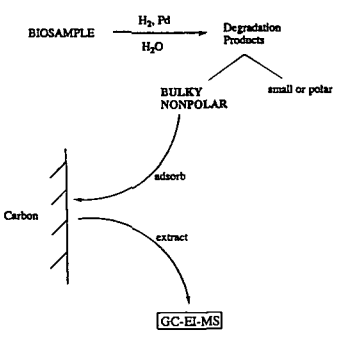
EXTRACTIVE HYDROGENATION OF BIOLOGICAL SAMPLES PRIOR TO GAS CHROMATOGRAPHY.

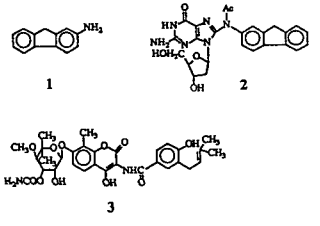
Mohammed Itani and Roger W. Giese. Department of Pharmaceutical Sciences in the Bouve College of Pharmacy and Health Sciences, and Barnett Institute, Northeastern University, 360 Huntington Avenue, Boston, MA 02115

INTRODUCTION:

A new technique, "extractive hydrogenation", is combined with gas chromatography (GC) to analyze biological samples. In this method, the sample is subjected to intense hydrogenation under aqueous conditions in the presence of excess (in terms of mass) palladium/carbon catalyst. Products with a saturated hydrocarbon framework result, the larger of which adsorb onto the carbon of the catalyst. These larger products are separately recovered by extracting the washed catalyst with an organic solvent, and then detected by GC. Here, the GC was fitted with a flame ionization or mass spectrometry detector. Unlike pyrolysis (similarly used prior to GC), which tends to convert a biological sample into a char, the hydrogenation reaction turns the sample into a clear, aqueous solution. Most importantly, the technique brings a broad variety of biological samples and organic substances in a simple way into the scope of GC-EI-MS and its computerized library of spectra. The concept is as follows, along with the structures of the compounds that we tested.

CONCEPT FOR
EXTRACTIVE HYDROGENATION / GC-EI-MS





RESULTS AND DISCUSSION:

From 2-aminofluorene (1) a carcinogen, we obtained perhydrofluorene (as a mixture of five isomers), plus a corresponding isomer mixture of 2-hydroxyperhydrofluorene (data not shown). N-(Deoxyguanosin-C8-yl)-2-acetylaminofluorene (100 ug, 2) spiked into 1 mg of DNA was detected (Fig. 2D, cluster of peaks at 14.2 min). The detection by H_2/GC-FID of 1.5 ug of novobiocin (3) spiked into 15 ml of milk is demonstrated in Fig. 2B relative to a blank chromatogram from unspiked milk, shown in Fig. 2A. The former chromatogram is distinguished by the pair of peaks (a, b) which were seen when standard novobiocin was subjected to extractive hydrogenation.

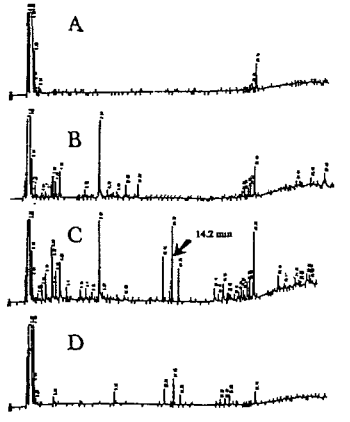


Fig. 1. GC-FID chromatograms from hydrogenation of: A (blank), 50 mg Pd/C in 2.5 ml of water; B,5 mg DNA and 50 mg Pd/C in 2.5 ml H_2O; C, similarly 5 mg DNA spiked with 1 mg of 2; D, similarly 1 mg of DNA spiked with 0.1 mg of 2, but 10 mg Pd/C. Hydrogenation conditions: 150°C, 3 h, 60-80 bar. From a final volume (ethyl acetate solution) of 50 ul, 1 ml was injected.

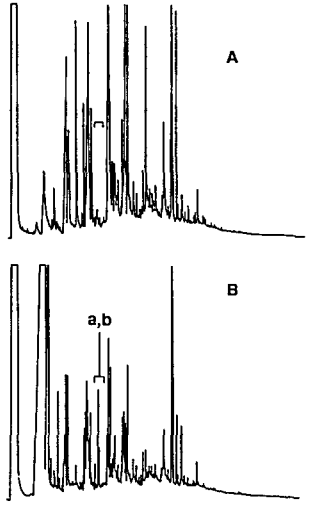

Fig. 2. GC-FID chromatograms from the hydrogenation of: A (blank), sample obtained by extracting 15 mL of skim milk with C18-Si, washing, eluting, evaporating and redissolving in 150 ul of water/2-propanol, 2:1 (prior to hydrogenation); and B, same except the milk was spiked before extraction with 1.5 ug of novobiocin. Hydrogenation conditions: 5 mg Pd/C, 150°C, 60-80 bar, 3 h. Peaks a and b are derived from novobiocin. One ul of a final sample volume of 50 ul was injected.

In Vitro Pancreatic Lipase Hydrolysis of Emulsified Common Fats and Oils by HTGC/FID and HTGC/MS.

Anna J. Sequeira, Experimental Pathology Labs. Inc., c/o Bowman Gray Tech. Ctr., Winston-Salem, NC 27102; Mary S. Uhrig & Bert M. Gordon, R.J. Reynolds Tobacco Co. Winston-Salem, NC 27102; Katherine M. Phillips, TechLab, Blacksburg, VA 24060.

INTRODUCTION

Analytical methods for monitoring lipid enzyme activity are continuously being developed. Many of the present methods are time consuming, cumbersome and involve derivatization. The chromatographic separation of complex Triacylglycerol (TAG) mixtures has been accomplished by TLC, HPLC, GC and SFC. Heretofore, the Free Fatty Acids (FFAs) content has been obtained chromatographically by derivatization to the methyl esters.

In this investigation of lipase metabolism, we describe a simple HTGC method which can simultaneously monitor the disappearance of TAGs and the appearance of Diacylglycerols (DAGs), Monoacylglycerols (MAGs) and long chain FFAs without any chemical derivatization or modification of the extracted emulsions. The characterization of the components was achieved by mass spectroscopy operating in both the EI and CI modes.

EXPERIMENTAL

Cocoa Butter, milk fat, trioleoylglycerol and porcine pancreatic lipase containing 13000 U of lipolytic activity were purchased commercially. Emulsions of these fats were prepared similar to that described by Lindstrom et al, using phosphatidylcholine, sodium taurocholate, sodium taurodeoxycholate, NaCl, $CaCl_2$, NaOH and tris-maleate. Chloroform and methanol were utilized as extraction solvents.

The HTGC system (HP 5890 Series II) was equipped with a temperature/pressure programmable on-column injector and a FID. A 25m x 0.25mm id x 0.1μm film thickness Al-clad methyl 65% phenyl silicone column was used to achieve the separation. For peak identifications the VG 70-VaxSQ system was utilized with NH_3 as the reagent gas for CI. The mass range examined was 50 to 1200u for EI and 300 to 1200 for CI.

RESULTS and DISCUSSION

After emulsion preparation, a single chloroform extraction is performed. A 1μL aliquot of this extract is introduced into the gas chromatograph without any chemical derivatization or modification. The kinetic study was monitored at 0, 2, 5, 10 and 30 minutes (cf Figure 1). Mass spectrometric identifications were made using GC retention times, characteristic fragment ions and the ammonium adduct ion. (T. Murata & S. Takahashi, **Anal Chem**, 45:1816, *1973*).

Quantification of the TAGs, DAGs, MAGs & long chain FFAs was achieved by obtaining the relative response factor ratio (RRF) to Trilauroylglycerol of the saturated TAGs (T6 to T66), C16:0, C18:1, Distearoylglycerol & Trioleoylglycerol. By extrapolation based on Carbon Number (CN), their RRF values and consequently their amounts were calculated at the different time intervals as shown in Table 1 for Cocoa butter.

CONCLUSION

This technique has been successfully utilized to simultaneously monitor (qualitatively and quantitatively) the disappearance of TAGs and the appearance of DAGs, MAGs and long chain FFAs. Sample preparation is a single extraction without subsequent derivatization. Consequently HTGC/MS is a viable technique to characterize complex TAG mixtures and their metabolites. It is believed that this method can be used to monitor any lipase reaction kinetics involving complex TAG mixtures.

Plasma Testosterone by Negative Chemical Ionization GC/MS

Robert L. Fitzgerald and David A. Herold

VA Medical Center, San Diego, CA 92161 and Dept. of Pathology, UCSD, La Jolla, CA 92134

Introduction Testosterone is the primary androgen responsible for development of sexual characteristics in men and is clinically monitored to diagnose a variety of illnesses which cause hyper and hypogonadism. The majority of methods currently used to quantitate testosterone are competitive protein binding assays based on testosterone binding globulin which can crossreact with a variety of structurally related compounds. We have developed a specific method for the analysis of serum testosterone which uses a trideuterated internal standard and gas chromatography/negative chemical ionization mass spectrometry (GC/NCIMS).

Materials Testosterone was obtained from Sigma (lot #50H0345) and the internal standard testosterone-16,16,17-d_3 was from MSD Isotopes (lot #Md-3793). HPLC grade ethyl acetate was from Burdick and Jackson. HPLC grade pyridine was purchased from Aldrich. The derivatizing reagents BSTFA (N,O,-bis(trimethylsilyl)trifluoroacetamide with 1% trimethylchlorosilane) and Florox (O-(pentafluorobenzyl) hydroxylamine 2.5 mg/mL in pyridine) were from Pierce Chemical Company. Commercially prepared testosterone controls were from BIO-RAD (lyphocheck immunoassay control serum level 1, 2 and 3).

Plasma Extraction The internal standard (50 uL of 0.1 ng/uL testosterone-d_3) is added to 1 mL of plasma and briefly vortexed. Three mL of ethyl acetate are added followed by vortexing for 1 min. Samples are centrifuged (2500 rpm for 10 min), the organic layer is pipetted to a clean 100 x 13 mL screw cap test tube and evaporated to dryness at 40°C under a gentle stream of nitrogen. The pentafluorobenzyl oxime derivative is formed by adding 50 uL of pyridine and 50 uL of Florox reagent to the plasma residues and heating for 1 hour at 70°C. The excess derivatizing reagent is evaporated and trimethylsilyl derivatives are formed by adding 50 uL of ethyl acetate and 50 uL of BSTFA and heating at 70°C for 20 min.

Analysis The GC was equipped with a 15 m DB-1 (dimethylpolysiloxane) capillary column and 1 uL samples are injected in the splitless mode. The initial GC temperature was 160°C (one min. hold) which was temperature programed to 280°C at 20°C per min where it was held for 3 min. Injection port temperature was 265°C and the interface oven was 280°C. The mass spectrometer was operated in the electron capture NCI mode using methane as the reagent gas. The ionizer was maintained at a pressure of 0.35 torr and 100°C. The manifold was 100°C, and the high pressure region was 1.3 x 10^{-5} torr. Tuning was optimized on the m/z 414 and 633 ions of perfluorotributylamine (PFTBA). Testosterone was monitored at m/z 535 and the internal standard at m/z 538. Scans were obtained at 2 Hz with dwell times of 200 ms. The structure of the derivatized testosterone is shown on the bottom of the next page.

Results The chromatogram showed well resolved peaks at 7:33 and 7:43 min which are the geometric isomers of pentafluorobenzyl/TMS testosterone derivative. Since the first peak had a larger signal than the second, it was used for quantitative analysis. The derivatization procedure combined with the selectivity of NCI provided clean extracts which contained no interfering substance at the ions monitored. Typical of NCI, the mass spectrum of pentafluorobenzyl/TMS testosterone was fairly simple, consisting primarily of the base peak at m/z 535 $(M-20)^-$ and an ion cluster at m/z 377 $(M-181)^-$ which are probably due to a loss of HF and $C_6F_5CH_2$, respectively. The m/z 535 ion was chosen for quantitations because it had better signal to noise ratio than m/z 377.

The average extraction efficiency of the the method at 1, 5 and 20 ng/mL was 104±15%. The method is linear from 0.25 ng/mL to 20 ng/mL. The error in the analysis, shown in the table, ranged from 6.0% at 1 ng/mL to 1.4% at 20 ng/mL. A comparison of GC/MS with immunoassay values for a commercially prepared control showed that GC/MS is from 2 to 8 times more precise than the immunoassay values listed in the control package insert.

Discussion Immunoassay values for commercially available testosterone controls have coefficients of variation which range from 33% for a low control (target concentration of 1 ng/mL) to 24 % for a high control (target concentration of 13 ng/mL). This wide variation is probably due to the different crossreactivities of the testosterone antibodies with other endogenous steroids and the lack of uniformity between different manufacturers' testosterone antibodies. Using GC/MS with NCI, only testosterone is measured which increases the accuracy of the method. The one step extraction presented here has significant advantages over previously described procedures which required multiple extractions combined with column chromatography prior to GC analysis.

Conclusion The use of a one step liquid extraction, stable isotope labeled internal standard and NCI GC/MS, provided a method for the efficient, accurate and precise measurement of testosterone in serum.

Pentafluorobenzyl/Trimethylsilyl Derivative

Comparision of Electron Impact, Positive and Negative Chemical Ionization Mass Spectrometry of Benzodiazepines

Robert L. Fitzgerald and David A. Herold

VA Medical Center, San Diego, CA 92161 and Dept. of Pathology, UCSD, La Jolla, CA 92037.

Introduction: Benzodiazepines are a group of structurally related drugs prescribed as sedatives, muscle relaxants, anxiolytics and anticonvulsants, which also have the potential for abuse. GC/MS is the standard with which other methods are validated, however the sensitivity of EI GC/MS does not permit the quantitation of low concentrations of the more potent benzodiazepines (and associated metabolites) which have therapeutic concentrations in the low ng/mL range. This lack of sensitivity makes it difficult to detect abuse of these compounds when using EI GC/MS. NCI of benzodiazepines has demonstrated that this technique is very sensitive as compared with EI and PCI, but there are no reports on NCI analysis of some of the newer benzodiazepines or their metabolites. In developing a quantitative GC/MS method for benzodiazepines we compared EI, PCI and NCI to determine which gave optimal sensitivity. These results along with some general rules for interpretation of NCI spectra of benzodiazepines are presented.

Materials: The benzodiazepine standards were all obtained from Sigma Chemical Company except N-1-hydroxy-ethylflurazepam and desalkylflurazepam which were gifts from Hoffman-La Roche (Nutley, NJ) and α-hydroxyalprazolam and α-hydroxytriazolam which were obtained from Radian Corporation. Ethyl acetate was HPLC grade from Burdick and Jackson. N,O-bis(trimethylsilyl) trifluoroacetamide with 1% trimethylchlorosilane (BSTFA with 1% TMCS) was purchased from Pierce.

Methods: Compounds with active hydrogens were silylated by adding 50 uL of ethyl acetate followed by 50 uL of BSTFA containing 1% TMCS and heating at 70°C for 20 minutes. The BSTFA solution was injected into the GC/MS, while compounds which did not require derivatization were injected from a 5 ng/uL methanolic solution. The GC temperature program maintained the initial temperature of 160°C for one minute before increasing at 20°C/minute to 280°C where it was held for 3 minutes. The injection port was maintained at 265°C and the transfer line was 280°C.

Results: The sensitivity of NCI as compared with EI and PCI in the table below shows that the NCI S/N ratio was 4 to several thousand times greater than that of PCI or EI except for medazepam. Medazepam had a EI signal but no NCI signal. Medazepam is also the only compound which did not have a substituent at the 2 position, suggesting that this is important in the electron capture process or stability of the negative ion. Oxazepam, lorazepam, chlordiazepoxide, clonazepam, nitrazepam, oxazolam, lormetazepam, flurazepam, alprazolam and triazolam did not have EI or PCI signals at 5 ng injected; but had NCI S/N greater than 60.

Discussion: Electron capture NCI ionizes compounds with low energy thermal electrons that are formed during the ionization of the reagent gas. The reagent gas also serves a second function by stabilizing the anions formed via a transfer of vibrational energy through collisions. One reason NCI is more sensitive than PCI or EI is that electron capture rate constants can be two orders of magnitude greater than particle ion/molecular reactions. The specificity of NCI is also due to the characteristics of compounds which

capture electrons. Compounds with low electron affinities are not detected by NCI where as compounds with an electronegative functional group such as a halogen are expected to give good signals with NCI. The aromatic rings present in the benzodiazepine structure resonance stabilize the negative charge of these anions, further enhancing the sensitivity for these compounds. The following are a general set of rules which help explain the NCI spectra of benzodiazepines in this study.

Rules for NCI Spectra of Benzodiazepines: Rule 1: Benzodiazepines which form only a molecular ion are characterized by R_7=Cl or NO_2, R_2'=H, 3=CH_2 and N_1 alkyl substituents. This rule applies to alprazolam, flurazepam, diazepam, prazepam, flunitrazepam, estazolam, N-1-hydroxy-ethylflurazepam-TMS, α-hydroxyalprazolam-TMS. **Rule 2:** Benzodiazepines which only form a $(M-162)^-$ ion are di-TMS derivatized with a silyl amine at 1 position and silyl ether at 3 position. This rule applies to oxazepam-diTMS and lorazepam-diTMS. The $(M-162)^-$ ion is probably due to a loss of TMSOTMS. **Rule 3:** Benzodiazepines which only form the $(M-36)^-$ ion have R_7=Cl or NH_2 and R_2'=Cl. This rule applies to triazolam, α-hydroxy-triazolam-TMS, 7-amino-clonazepam-TMS, 7-amino-clonazepam-diTMS, and lormetazepam. The $(M-36)^-$ ion is probably due to a loss of HCl. **Rule 4:** Benzodiazepines which have base peak of $(M-108)^-$ with other major ions at $(M-73)^-$, M^- and $(M-88)^-$ are silylated at the N_1 position with position 3=CH_2 and R_7=Cl. This rule applies to nordiazepam-TMS, desalklyflurazepam-TMS, and delorazepam-TMS. The $(M-108)^-$ ion is probably due to a loss of TMSCl. **Rule 5:** Benzodiazepines which have a base peak at $(M-72)^-$ with major ions at M^- and $(M-88)^-$ are silylated at the N_1 position with position 3=CH_2 and R_7=NO_2.This rule applies to clonazepam and nitrazepam. The $(M-72)^-$ and $(M-88)^-$ ion are probably due to losses of SiC_3H_8 and $SiC_3H_{10}N$ respectively.

Conclusion: NCI provided increased sensitivity when compared to other ionization techniques. Furthermore, the spectra obtained can be readily explained by the structural features of each benzoiazepine.

Compound	NCI S/N	PCI S/N	EI S/N

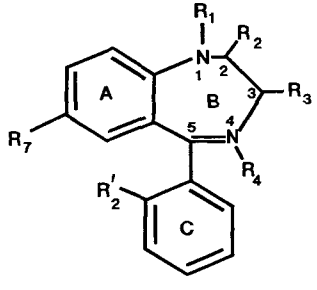
General Structure of Benzodiazepines



CHARACTERIZATION OF LTD_4 ANTAGONIST METABOLIC PROFILES USING CAPILLARY HPLC / CONTINOUS-FLOW LIQUID SIMS,

***J. A. Yergey, D. Nicoll-Griffith, N. Chauret, M. Belley, M. Labelle, R. Zamboni, Merck Frosst Centre for Therapeutic Research, P.O. 1005, Pointe Claire-Dorval, Quebec, Canada H9R 4P8, S. J. Grossman, E. G. Herold, Merck Research Laboratories, West Point, PA 19486**

EXPERIMENTAL:

Liver Microsome Incubations: Incubations of 200 µM MK-0679 or L-699,392 in 0.5 mL were made with 1 mg microsomal protein. All MK-0679 incubations were with ß-napthaflavone induced rat liver microsomes. L-699,392 oxidation incubations were with Rhesus monkey liver microsomes and L-699,392 glucuronidation incubations were with rat liver microsomes. Co-factors included: Oxidation co-factors (2 mM $MgCl_2$, 2 mM NADP, 20 mM glucose-6-phosphate, in 100 mM PO_4 buffer, pH 7.4 + 2 units glucose-6-phosphate dehydrogenase), Glutathione trapping (Oxidation co-factors + 3mM GSH), Glucuronidation (12.5 mM $MgCl_2$, 12.5 mM UDPGA, 20 mM D-saccharic-1,4-lactone, in 50 mM phosphate buffer, pH 6.6). All reactions were for one hour at 37°C, and were quenched with 0.5 mL of CH_3CN.

Solid-Phase Extraction: SPE was used for MK-0679 studies. 1 mL C_{18} columns were conditioned with 2 mL CH_3OH and 2 mL H_2O. Aqueous samples were applied following dilution of incubations to ≤ 5 % CH_3CN, rinsed with 4 mL H_2O, eluted with 3 x 200 µL CH_3OH and dried in a Speed-Evap.

Capillary HPLC / CF-LSIMS: A Waters 600MS HPLC pump supplied 1 mL/min of mobile phase consisting of CH_3OH:20 mM NH_4OAc, pH 5 (1.5 % glycerol in each). The 1.5% glycerol necessary for CF-LSIMS caused no degradation in chromatographic behavior. The main flow was split prior to the injection valve using ~ 5 cm of 50 µm fused silica on a Valco ZDV tee. The split flow of 3 µL/min passed through a 0.5 µL Valco injection valve or a 20 µL injection loop on 6-port electrically actuated Valco valve, then through the KAPPA Spherisorb ODS2 0.3 x 100 mm capillary column (Keystone Scientific) and into the JEOL HX-110A CF-LSIMS mass spectrometer ion source. Injections were of 0.5 µL of SPE or 10 µL of a 10-fold dilution of incubation mixture. CF-LSIMS spectra were acquired from 0-1000 Da every 4 sec.

RESULTS AND DISCUSSION: Initially, solid-phase extraction was used to concentrate samples, in order to observe smaller metabolites using a 0.5 µL injection volume. This was believed necessary in order to approach the optimal injection volume for a 0.3 x 100 mm capillary column of 100 nL or less. More recently, however, we found that simply concentrating sample components at the beginning of the capillary column using a weaker initial mobile phase strength allowed injections of 10-50 µL with no loss in chromtographic performance (See data for L-699,392). Examination of the total-ion-chromatogram often revealed little regarding a metabolic profile, however, plotting mass chromatograms specific for anticipated oxidative products, or class specific fragments, provided evidence of small metabolites. Spectra of parent drug and oxidative metabolites contained protonated molecules and diagnostic fragmentation which allowed the site of oxidation to be pinpointed to a particular substructure of the molecule. The excellent stability of the system permits background subtraction to work extremely well. For example, following background subtraction, the MK-0679 sulfoxide eluting at 19.9 min could be distinguished from the phenol eluting at 20.1 min, based on their distinctive fragmentation patterns (data shown in poster). The overall sensitivity of the system for full-scan spectra was quite good, excellent spectra being obtained when a total of 50 ng (~100 pmol) of material was injected and the metabolites each comprised 2-8 % of the total material. Phase II metabolites (see data for glutathione adduct of MK-0679 and ß-glucuronide of L-699,392) also produced protonated molecules when examined by CF-LSIMS. In addition, fragmentation leading to the parent drug was observed for both conjugates. Analogous data for the ß-glucuronide of MK-0679 were observed, but were not shown. The MK-0679 glutathione adduct required preparative isolation in order to provide enough material for a good spectrum, while the glucuronides were able to be characterized directly from the incubation mixture; about 20 pmol of the L-699,392 ß-glucuronide was injected in the example shown.

CONCLUSIONS: Oxidative *in vitro* metabolism of the potent LTD_4 antagonists MK-0679 and L-699,392 were predominated by sulfoxidation and oxidation at terminal methyl groups. In addition, evidence for epoxidation of the quinoline substructure of MK-0679 was found in incubations with liver microsomes from animals pre-treated with ß-naphthaflavone. Overall, there was less oxidative metabolism and fewer oxidative metabolites observed for L-699,392. Both antagonists also readily formed acid glucuronides *in vitro*, and the epoxide formed for MK-0679 was shown to be trappable by glutathione. Capillary HPLC / CF-LSIMS was capable of providing full-scan mass spectra for all of the metabolites, thereby allowing characterization of the metabolic profiles for these compounds in relatively few experiments.

CAPILLARY HPLC / CF-LSIMS OF L-699,392 OXIDATIVE METABOLITES

FAB Accurate Mass Measurements Using A Rotating Probe On The VG ZAB-2SE Mass Spectrometer

J.L.Occolowitz* and J.M.Gilliam
Lilly Research Laboratories, Indianapolis, Indiana 46285-1513

INTRODUCTION

FAB is arguably the best ionization technique for determining the accurate mass of molecular species because it is a soft ionization technique which generally gives intense, steady analyte signals and introduces no thermal stress. However FAB is not a colligative ionization technique and the addition of internal mass standards can result in suppression of the analyte or alternately suppression of the calibrant. Additionally cationic impurities in the analyte can cationize the calibrant and give rise to complex spectra where considerable care is required to identify the calibration ions. If it is necessary to measure the accurate mass of fragments of relatively low intensity, which correspond to significant peaks in CID spectra, addition of an internal calibrant can cause trouble because of suppression, cationization, or masking of analyte by calibrant.

At the 1992 ASMS conference[1] we demonstrated that we could make accurate (~2ppm) mass measurements by serial introduction of calibrant and analyte. This involved firstly determining a scan of two bracketing calibrant peaks, a scan of the analyte peak, and a further scan of the two calibrant peaks. A drift correction was applied which was calculated by measurement of the second scan of calibrant peaks using the calibration derived from the first scan of calibrant peaks. Subsequently we decided that introduction of calibrant and analyte on a two-faced rotatable probe would improve the method firstly by reducing the time for measurement and comcomitantly by reducing the mass spectrometer drift between calibrant and analyte scans.

PROBE DESIGN AND ION SOURCE MODIFICATIONS

We had previously described[2] a two-faced rotatable probe for a MAT 731 and were able to adapt this design to the VG ZAB-2SE by changing the probe dimensions, the twin target design, and modifying the mass the mass spectrometer ion source. Drawings describing the probe and ion source modifications are available on request. Essentially the probe consists of a fixed outer probe which is inserted through the EI vacuum lock and an inner probe which is retractable and rotatable and guided by bearing surfaces on the interior of the outer probe. When the outer probe is seated the inner probe is extended so that a gold disc 1/8" diameter having cups machined into its opposing surfaces intercepts the ionizing Cs^+ beam.

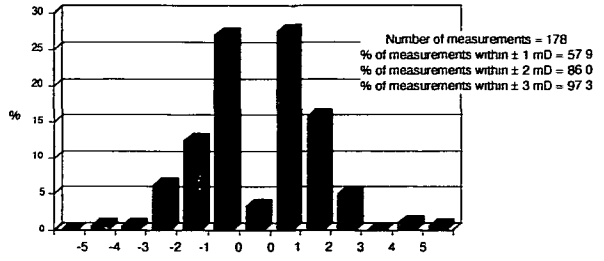
MEASUREMENT TECHNIQUE

The calibrant was either PPG 725, 1200, or 1750 dispersed in "magic bullet" containing lithium iodide. This mixture was placed in one of the gold cups, the other cup contained the analyte usually dispersed in "magic bullet". Data were generated by simultaneously scanning the electric sector and accelerating potentials and recording using the VG OPUS data system in the MCA mode. The magnet prescan initiated by the OPUS was suppressed by operating the mode selector in the MS/MS, V,E, and current modes. The lower calibration mass was brought into focus and the magnet moved 2D lower. The data system was programmed to acquire 10 scans at 1.5s./scan with a 0.05s. interscan period. One minute of scanning was allowed before data accumulation. After the 9th recorded scan of calibrant the probe was rotated 180° and 9 scans of analyte accumulated, after the 9th scan the probe was again rotated 180° and a further 10 scans of calibrant accumulated. The analyte mass was measured as described previously[1].

RESULTS

The histogram shown in Fig.1 shows the frequency of errors resulting from a single measurement of 178 separate samples. For 91% of the samples the error was 5ppm or less,

which is acceptable by JACS[3]. 30% of the measurements were within 1ppm and 50% within 2ppm. Increased accuracy was achieved by using one probe introduction and 10 probe rotations of 180° resulting in 5 bracketed analyte scans obtained in 3 minutes of acquisition time. The results of a measurement of this type is tabulated in Table1.



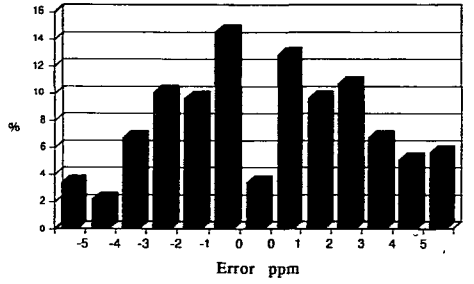


Table 1

Replicate measurements for ion m/z 1662.7651 resulting from a single probe introduction.

Replicate	Uncorrected Mass	Corrected Mass
1	1662.7618	1662.7651
2	1662.7733	1662.7715
3	1662.7646	1662.7663
4	1662.7675	1662.7664
5	1662.7721	1662.7697

Mean mass = 1662.7678, error = 0.0027 D (1.6 ppm)

Structure Determination and Diagnostic Value of Abnormal Bile Acids in Urine from Patients with Generalized Peroxisomal Disease.

*Amit Ghosh, James E. Evans, Jacqueline M. Street, Barbara A. Evans and Marvin R. Natowicz

The E. K. Shriver Center, Mass Spectrometry Facility and Division of Medical Genetics, 200 Trapelo Rd., Waltham, MA 02254.

Detection of taurine conjugates of tri-, tetra- and pentahydroxycholestanoates at m/z 556, 572 and 588 by negative ion FAB-MS analysis of urine extracts is useful for the diagnosis of disorders of bile acid metabolism including generalized peroxisomal disorders (GPD)[1]; other ions have not been reported to be diagnostic. The value of FAB-MS for diagnosis is limited because these ions are not always found in samples from patients with GPD.

We have screened urine samples from normal and diseased controls and from patients diagnosed by other established criteria to have GPD for bile acids by direct injection-continuous flow-negative ion FAB/MS[2]. A number of ions were frequently intense in the spectra from patient samples that were not seen in controls. These included ions m/z 489, and 505, which we postulated correspond to a C29-dihydroxy-monoene-dicarboxylic bile acid and a C29-trihydroxy-monoene-dicarboxylic bile acid respectively. Ions for the glycine and taurine conjugates of the dihydroxy compound were also found at m/z 546 and 596. In addition to these, several patient samples were found that gave high intensity for m/z 625 and 641. These are postulated to be the glucuronides of tri- and tetrahydroxy cholestanoates respectively. Analysis by μHPLC-FAB/MS revealed that several chromatographic peaks are observed for each of these ions presumably corresponding to different positional and/or stereoisomers that are expected to occur for bile acids. B/E product ion CID spectra of these were obtained during μHPLC analyses and are consistent with the proposed structures. Product ion scans were also used to show that an ion at m/z 471 from patient samples lost sodium and is likely to represent the sodium adduct of a trihydroxycholestanoate. The use of m/z 489 and 641 in addition to the previously used m/z 572 significantly increases the sensitivity of FAB-MS for diagnosis of GPD from about 60% to higher than 85%. The table below shows the occurrence of the new ions in spectra from urine samples from normal and diseased controls and from patients diagnosed to have GPD by other criteria.

The Identification of Ketoconazole Metabolites in the Mouse Liver by Liquid SIMS ms/ms.

T.D. Cyr, B. Dawson, A. Menzies and L.W. Whitehouse,
Bureau of Drug Research, Health and Welfare, Ottawa, Canada, K1A OL2.

Ketoconazole is an orally active antimycotic drug often used in immuno-compromised individuals, such as AIDS and transplant patients. Recent research efforts with regard to this drug reflect its potential use for other indications, such as prostate cancer, and problems arising from adverse reactions when used in combination with terfenadine (an antihistamine). Although, this drug is extensively metabolized by the liver, with more than twenty-two metabolites having been detected, only one metabolite, deacetylated ketoconazole, has been identified, to date.

The ketoconazole metabolites were isolated by extracting homogenized mouse livers, then purified by sequential preparative reverse then forward phase HPLC.

The mass spectra were obtained on a VG AutoSpec Q (EBEqQ) tandem mass spectrometer. The samples, in glycerol, were ionized by liquid SIMS using a cesium ion gun (35 kV) and the ms/ms spectra were obtained by programming an increase in the collision energy (Ec = 15 to 25 Ev) as well as admitting argon (7 X 10^{-6} mbar) into the collision cell. The molecular formulae were determined from the high resolution (>5000) accurate mass determinations. Using a combination of techniques (ms/ms, accurate mass ms, and nmr), structures for eight metabolites have been proposed: two of the metabolites result from cleavage and oxidation of the piperazine and the imidazole rings, three metabolites result from transformation of the acetyl group and four metabolites result from oxidation of the piperazine ring and the acetyl group. A proposed metabolic scheme is presented in Figure 1. The CID spectrum for the pseudo-molecular ion as well as the M+2 ion were obtained for each compound. The combination of the two spectra allowed differentiation of the peaks containing the dichlorophenyl group.

The m/z 82 peak was diagnostic for the presence of the imidazole group, and this was generally corroborated by a m/z 255 peak due to scission of the oxygen heterocycle. The m/z 255 fragment also contained the dichlorophenyl group which could be confirmed by the presence of a m/z 257 fragment from the corresponding M+2 CID spectrum.

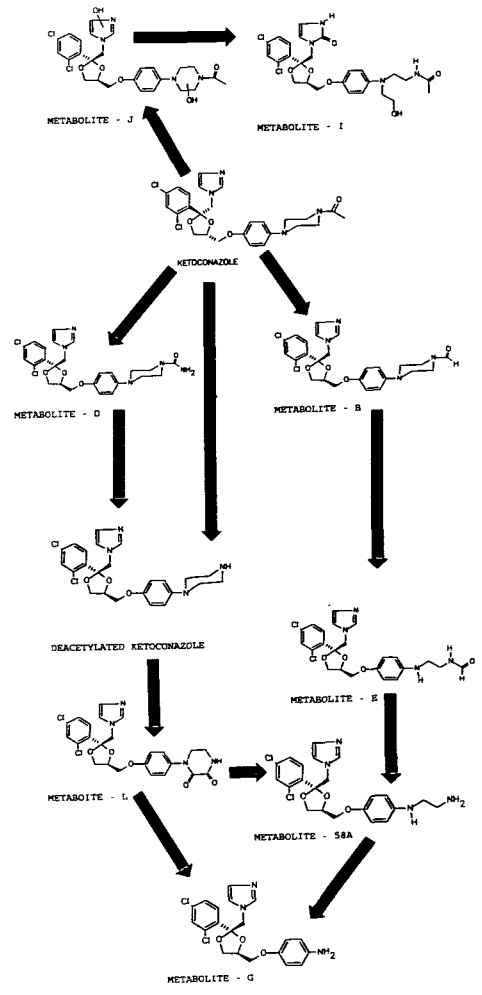

FIGURE 1. Proposed structures and metabolic scheme for ketoconazole.

Complete Mass Spectrometric Structure Elucidation of an Unknown Possible Metabolite

J. P. Kiplinger, L. A. Morehouse, *P.A. Reiche, D.A. Beebe, A. Grodski; Pfizer, Inc., Groton, CT 06340

Mass spectrometry provides useful structural information about unknown compounds, but is usually best combined with other analytical techniques for fast structure elucidation. When the amount of sample is very limited, however, mass spectrometry is often the most convenient tool that can be employed. This poster illustrates the type of structural information that can be obtained using mass spectrometry alone when little other information is available.

A compound being studied as cholesterol lowering agent was tested in African Green monkeys. As part of the study, monkey fecal samples were examined for their bile acid content. Samples were lyophilized and pulverized, then saponified and acidified to deconjugate the bile acids. Bile acids and other lipophilic compounds were extracted with ether and derivatized with p-bromophenacyl bromide.

The derivatized mixture was analysed using HPLC. Many of the bile acids present in the extract may be identified by their retention times, but an unknown peak was observed which comprised more than 50% of the total acidic sterol fraction. The unknown peak was present in the feces of both the control and drug-treated animals, but was more abundant in the drug treated group.

The unknown peak was collected and rechromatographed isocratically to determine it's purity, and was presented purified for mass spectrometric analysis. MS analysis were performed on approximately 2 ug of total sample.

Since the sample was assumed to be related to the other bile acids in the fecal extract, Liquid Secondary Ion Mass Spectrometry (LSIMS) was chosen for the analysis. The spectum shows pairs of peaks at m/z 497/99 and m/z 519/521, the molecular ion species, MH^+ and $(M+Na)^+$, and a pair at m/z 479/81 corresponding to the loss of water. Other Br-containing peaks in the weak spectrum revealed little additonal structural information.

Cholates and deoxycholates have masses in this range, and their bromophenacyl esters exhibit prominent losses of $3H_2O$, and $2H_2O$ respectively. By analogy, the unknown was thought to be a monohydroxy bile acid High resolution analysis of the peak at m/z 497 yielded an exact mass of 497.22878 A formula search of possible elemental compositions (C,H,O, and Br) falling in this range yields only a single formula, $C_{26}H_{42}O_4Br$. This formula contains too many hydrogens to allow the rings of a steroid nucleus; only a saturated monohydroxylated fatty acid ester will fit. Assuming a straight chain, the unknown compound must be a bromphenyl ester of hydroxystearic acid.

To obtain more structural information and identify the position of the hydroxyl group, the remaining sample was analyzed using direct insertion probe EI. No molecular ion is observed; the Br-containing ion pair at m/z 383/85 allowed a tentitive structure to be assigned. This ion, if formed by α-cleavage of the molecular ion and loss of the C_8H_{17} radical, locates the hydroxyl group at the 10 position. High resolution MS confirms the formula assignment.

It is dangerous to base a structural assignment on the appearance of a single peak in a mass spectrum. An available sample of 12-hydroxy oleic acid was analyzed by direct insertion probe EI. The spectrum also shows the α-cleavage fragment at m/z 409/11. This analogy supports the proposed structural assignment of the unknown, and prompted the synthesis of a sample of 10-hydroxy stearic acid for direct comparison.

To confirm the assigned structure, authentic 10-hydroxy stearic acid was synthesised by a known route and derivatized as before. EI and LSIMS spectra of the known material are comperable to the unknown.

Using mass spectrometry alone, a structure has been assigned to an unknown componant from an acidic sterol extract of monkey feces. The early finding that the material was not a bile acid or related compound allowed the study to continue without interruption; the 10-hydroxystearic acid was traced to an oxidized component of the monkeys' diet. The final assignment of the structure was then an academic exercise, and as such illustrates the power of the MS techniques applied to the problem.

STRUCTURE ELUCIDATION OF NOVEL LEUKOTRIENE B_4 METABOLITES FROM CULTURED HUMAN KERATINOCYTES

Pat Wheelan[§], Joseph A. Zirrolli[§], Joseph G. Morelli[‡], and Robert C. Murphy[§]

[§]National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson Street, Denver CO 80206
[‡]University of Colorado School of Medicine
Denver, CO

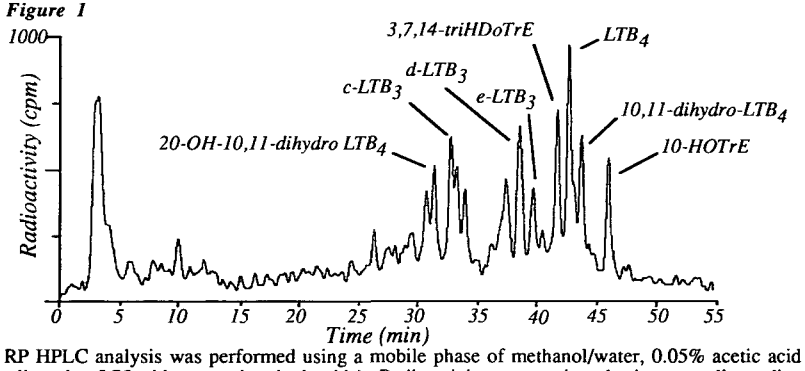
Metabolism of exogenous LTB_4 by cultured human keratinocytes resulted in the formation of several novel products. The structures of these metabolites were determined by a combination of mass spectrometric techniques including the following:

1) CF-FAB/MS was used to identify the molecular weight of metabolites. Additional information on location and type of substituents was obtained by collision induced dissociation and tandem mass spectrometry analyses. FAB spectra were obtained on a Finnigan TSQ 70 triple quadrupole mass spectrometer. The FAB gun was operated at 1 mA with xenon accelerated to 6 kV. For collision induced dissociation and tandem mass spectrometry analyses, argon was used as the collision gas and the collision offset energy (E_{lab}) was 30 eV.

2) ECI GC/MS was employed to gain molecular weight information as well as information on the number of hydroxy substituents of each metabolite from production of the abundant carboxylate anion and ions derived from losses of trimethylsilyl alcohol. For this analysis, metabolites were derivatized as the pentafluorobenzyl ester/trimethyl silyl ether derivatives. The number of double bonds in metabolites was confirmed by ECI GC/MS analysis of the derivatized reduced metabolite (5% Rh/Al_2O_3 in methanol). Spectra were obtained on a Finnigan SSQ 70 with methane as the moderating gas.

3) EI GC/MS analysis of PFB/TMS derivatized metabolites was employed to provide detailed structural information regarding hydroxy substituent position from abundant fragmentations adjacent to trimethylsilyl ether positions. Confirmation of fragmentation assignments and additional fragment ions were obtained by EI GC/MS analysis of the derivatized, reduced metabolites. Spectra were obtained on a Finnigan SSQ 70 using an electron energy of 70 eV.

Figure 1



RP HPLC analysis was performed using a mobile phase of methanol/water, 0.05% acetic acid (pH adjusted to 5.75 with ammonium hydroxide). Radioactivity was monitored using an on-line radioactive detector and UV absorbance monitored from 200 nm to 400 nm.

Results: After a 24 h incubation of LTB_4 (3.5μM) and [$^3H_8$] LTB_4 with human keratinocytes, 73 ± 15% (n = 4) of the added radioactivity was recovered in the extracellular supernatant. **Fig. 1** shows a typical radiochromatogram obtained during RP HPLC analysis. The amount of radioactivity corresponding to nonmetabolized LTB_4 ranged from 0% to 8% of the total radioactivity by HPLC analysis. No major radioactive peak other than recovered LTB_4 retained the chromophore indicative of a conjugated triene.

Metabolism of LTB_4 proceeded by two distinct pathways: 1) reduction of the 10,11 double bond resulting in formation of reduced products and 2) glutathione conjugation. Metabolites identified in the first pathway included 10,11-dihydro-LTB_4, 10-HOTrE (10-hydroxy-4,6,12-octadecatrienoic acid), 3,7,14-triHDoTrE (3,7,14-trihydroxy-8-10-16-docosatrienoic acid), and 20-OH-10,11-dihydro LTB_4. Metabolites formed by the second pathway included c-LTB_3 (5,12-dihydroxy-6-glutathionyl-7,9,14-eicosatrienoic acid), d-LTB_3 (5,12-dihydroxy-6-cysteinylglycyl-7,9,14-eicosatrienoic acid), and e-LTB_3 (5,12-dihydroxy-6-cysteinyl-7,9,14-eicosatrienoic acid).

The CF FAB/MS/MS spectrum of e-LTB_3 is shown in **Fig. 2**. The product ion at m/z 235, which was also observed for LTE_4[1], suggested the cysteine moiety was located at C-6 (**Scheme 1**). The product ion at m/z 229 suggested double bonds were located at C-7,C-9 resulting in a favorable charge remote fragmentation. These positions were confirmed by reaction with hypochlorous acid.[2]

MULTIRESIDUE ANALYSIS OF SULFONAMIDE ANTIBIOTICS IN MILK USING LC/ATMOSPHERIC PRESSURE CHEMICAL IONISATION/MS

D.R. Doerge, National Center for Toxicological Research, Jefferson, AR 72079 USA.
S. Bajic, S. Preece and S. Lowes, Fisons Instruments/VG BioTech, Altrincham, WA14 5RZ, UK.

Introduction

Sulfonamide antibiotics are widely used to prevent bacterial infections in farm animals. Improper use of unprescribed drugs or improper withdrawal times can lead to the presence of illegal residues in milk and meat. It has been estimated that up to 45% of milk and 5% or pork carcasses contain illegal sulfonamide residues[1]. This is of toxicological and regulatory concern because sulfamethazine (SMZ) produces thyroid tumors in rodent bioassays. Current regulatory methods for detection of sulfonamides in milk utilize preparative HPLC followed by derivatization and GC/MS confirmation[1]. The present study explores the use of APcI as a sensitive and selective on-line LC detector for multiresidue analysis of sulfonamides in milk.

Experimental

Mass spectrometry was performed using a VG Platform single quadrupole mass spectrometer (Fisons Instruments/VG BioTech). Samples were introduced into the atmospheric pressure corona discharge source via a heated nebulizer probe (450°C) using nitrogen as the bath and nebulizing gas. The potential difference between the sampling cone and the skimmer was adjustable from 0-100V. LC was performed using a NovaPak RCM cartridge (5x100mm) with a mobile phase of 25% acetonitrile/ aqueous ammonium acetate (25mM, pH6.8) at a flow rate of 1.0mL/min. Commercial milk samples were prepared for analysis using C18 Sep Pak and Cyclobond I (cyclodextrin) solid phase extraction cartridges. Blank milk extracts were fortified with sulfonamides at the indicated levels immediately prior to APcI/MS analysis.

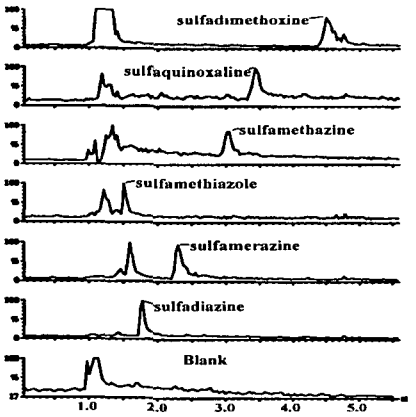

Figure 1. SIR chromatograms for 5ppb of six sulfonamides in a milk extract were obtained by APcI/MS under low cone voltage conditions (30V). The summed ion chromatogram for a milk blank is also shown.

Results

Under conditions of low sampling cone voltage (30V), the mass spectra of all sulfonamides consisted of exclusively $[M+H]^+$ ions. This facilitated high sensitivity by Selected Ion Recording (SIR) of the target sulfonamides. Figure 1 shows the SIR chromatograms produced by 1ng on-column of six sulfonamides along with the corresponding blank summed ion chromatogram. This corresponds to milk containing 5ppb of each component.

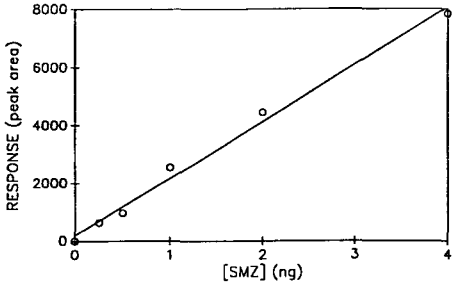

Figure 2. Response curve for sulfamethazine in milk extracts. SMZ was analysed as the [M+H]+ ion formed at low cone voltage (30V) in fortified milk extracts.

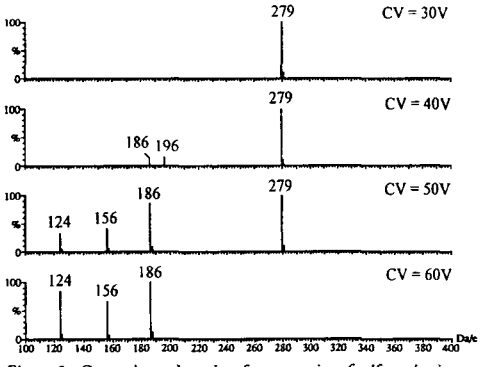

Figure 3. Cone voltage-dependent fragmentation of sulfamethazine. The mass spectrum of SMZ was determined at the indicated cone voltages using flow injection analysis of 100ng injections.

Estimated detection limits for these six sulfonamides in fortified milk extracts ranged from 0.25-2.5ppb. The APcI/MS response curve for a selected analyte, SMZ, was linear (cc = 0.996) over the range corresponding to 1.25-20ppb in milk (see Figure 2). This sensitivity and linearity encompasses the regulatory level of interest for sulfonamides in milk (10ppb).

Another advantage of APcI/MS is the ability to effect collision-induced dissociation by increasing the sampling cone voltage. This can produce information essential for structure elucidation of unknown compounds as well as confirmation of target analytes by using ion intensity ratios from several fragment ions. Figure 3 shows the changes in mass spectrum obtained by increasing the cone voltage. At high cone voltage (80V), only fragment ions were observed from the six sulfonamides tested. Since all sulfonamide antibiotics differ only in the heterocyclic base attached to a constant sulfanilamide portion, the high cone voltage mass spectrum contains a common ion, m/z 156. Selected monitoring of the m/z 156 ion, formed at 80V, permitted class-specific detection of all sulfonamides with minimal loss in sensitivity over that observed for $[M+H]^+$. In addition, the reproducibility of fragment ion intensity ratios from analysis of SMZ in milk at relevant levels (5ppb) suggests that this technique can be used to confirm the presence of sulfonamide residues with a high degree of confidence.

Studies of Secondary Metabolites Newly Identified from *Streptomyces spectabilis* by FABMS, FABMS/MS and LC/FABMS Moving Belt Interface.

*Thompson, A.G.; Sun, F.; Rinehart, K.L.
School of Chemical Sciences, University of Illinois, Urbana, IL 61801

Many metabolites have been previously isolated from *Streptomyces spectabilis*, including the streptovaricins, protostreptovaricins, an acyclic streptovaricin, an atropisostreptovaricin, spectinabilin, tryptophan-dehydrobutyrine diketopiperazine, actinospectacins, deoxymonamycins, and elaiophylin.[1,2] The streptovaricins are the most abundant secondary metabolites and are ansamycin antibiotics. They have strong antibacterial activity, especially against mycobacteria, and inhibit DNA-directed RNA-polymerase (transcriptase) and RNA-dependent DNA-polymerase (reverse transcriptase) of tumor tissues.[1] An extensive mass spectrometric study using positive and negative ion FABMS, FABMS/MS and LC/FABMS with a moving belt interface aided in the identification and structure determination of these known compounds and several newly identified metabolites.[3]

The isolation and characterization began with the detection of molecular ions by LC/FABMS moving-belt experiments which included new signals at *m/z* 1049 and 1065. All subsequent isolation procedures were followed by FABMS. The crude streptovaricin complex was partitioned using 2:3:1 MeOH:H_2O:$CHCl_3$. The methanolic-aqueous layer was purified by amino-silica HPLC and yielded desertomycin A [$(M+H)^+$ *m/z* 1192.7564 ($C_{61}H_{110}NO_{21}$, Δ - 0.6 mDa] and demannosyl desertomycin A , [$(M+H)^+$ *m/z* 1030.7015 ($C_{55}H_{100}NO_{16}$, Δ + 2.7 mDa)].[4] The chloroform layer was purified using a series of C_{18} HPLC solvent systems and yielded oasamycin A [$(M+H)^+$ *m/z* 1027.6585 ($C_{55}H_{95}O_{17}$, Δ - 2.0 mDa)] and oasamycin B [$(M+Na)^+$, *m/z* 1211.6943 ($C_{61}H_{104}O_{22}Na$, Δ -2.6 mDa)] (Figure 1). Other analogs of the oasamycins have been isolated which differ by the number of oxygens, methyl groups, or double bonds.

In positive ion FABMS probe experiments on the oasamycin HPLC fractions, the strong ionophoric capabilities showed almost exclusively $(M+Na)^+$, $(M+K)^+$, $(M+Cs)^+$, and matrix adduct ions. Acidification of the sample yielded more fragment ions, but no $(M+H)^+$. Only the addition of 18-crown-6 to the probe yielded a measurable amount of $(M+H)^+$. Positive and negative ion high resolution FABMS confirmed the molecular formulas of both the oasamycins and desertomycins. Positive ion LRFABMS, HRFABMS and FABMS/MS also showed nine sequential losses of water from the molecular ions, consistent with these polyhydroxy-macrolactone structures. The ^1H and ^{13}C NMR spectra allowed an assignment of oasamycin A,[3] an inhibitor of biosynthesis of cholesterol.[5] A comparison of the FABMS/CID/MS of authentic and isolated desertomycin A also confirmed its identity.

Using FABMS/MS, new fragmentation patterns were also observed for the streptovaricins and deoxymonamycins.[3]

ACKNOWLEDGMENTS

Introduction

Spermatogenesis involves a progressive differenciation of the germ cell toward a terminal stage represented by the mature spermatozoon. During spermatogenesis, histones are replaced by more basics proteins named transition proteins and protamines. These Protamines as well as transition proteins are highly basic proteins, associated with DNA in nuclei (1). They are characterized by a very high arginine or lysine content (more than 50%). Primary structure elucidation of such proteins is therefore particularly difficult when using conventional methods of protein analysis. On purified protamines and/or cleavage peptides, amino acid analysis yields poor information because of the disproportion between the arginines or lysines and the other residues, especially hydrophobic residues. On the other hand serine and threonine, which often appear in the amino acid composition of such polypeptides, are partially destroyed during acid hydrolysis and cannot constitute a reference for the quantitation. Moreover these proteins present an increasing of their heterogeineity by the presence of phosphorylation at different level involved in the modulation of the chromatin decondensation (2). In both case phosphorylation sites can be parttially identified by automatic Edman degradation of the protein after derivatization, but state of these phosphorylation was further demonstrated by electrospray mass spectrometry. Most of the time these proteins are contaminated by phosphate or sulfate buffers and need ionization conditions or non-organic solvent for their mass analysis therefore permitting accurate mass measurement.

Experimental

A VG BioQ triple quadrupole (m/z range of 4000, VG BioTech, Manchester UK) was used to carry out positive ESMS. Extracting cone voltage (Vc) varied from 50 to 100 volts. Samples were dissolved in MeOH or Acetonitrile /water/ 50 / 50 or in pure water at a final concentration of 10 pmol / µl.

Results

Figure 1A shows an ESMS spectrum of the calamar transition protein T1 dissolved in water / MeOH 50/50, containing 1% HCOOH solution recorded at a VC = 50 volts .With the increasing voltage difference between the nozzle and the skimmer of the electrospary interface (figure 1B) an declustering effect of the salt adducts were observed. In those conditions spectrum clearly show the presence of several series identified as multiphosphorylated proteines (+80 Da). Other method such as Edman degradation or method using radioactive elements gave us an average value of phosphorylated sites.

Figure 2 present an human protamine 2 dissolved in water (figure 2A) or in Water / MeOH 50/50 solution (figure 2B). In presence of methanol an important apparition of adduct H3PO4 (+98 Da) was observed and could be due to a local increasing concentration of salt and by stabilization of the protamine charges in presence of organic solvents. Such effect was observed when using other organic solvants such as acetonitrile.

Conclusion

This work has shown that ESMS measurement of molecular masses of hydrophilic proteins such as transition proteins or protamines can be achieved by using water solutions or at higher sampling cone voltage. Nevertheless the biological importance of histones and protamines makes today their analysis by MS an important goal.

Mass Spectrometric Characterization of a Family of Hydrophobic Peptides with Antibiotic Properties Containing Both L- and D-Amino Acids

C. Moore*, D. Tang, D. Medzihradszky, M. Tullius, R. Mandrell and B. Gibson
Department of Pharmaceutical Chemistry, University of California, San Francisco CA 94143

Previously we have reported the isolation and characterization of a family of amphipathic antimicrobial peptides from the skin of *Bombina orientalis* (Asian Toad) [1,2]. After sequencing the cDNA encoding these precursors, a second family of hydro-phobic peptides were found to be likely encoded on the C-terminus of these precursor poly-peptides. To confiurm this possibility, a set of peptides were isolated with the expected masses.

LSIMS analysis of the skin secretions after HPLC separation revealed several pairs of peptides eluting at different HPLC retention times with the same mass and amino acid sequence as determined by both Edman and MS/MS analyses. In an attempt to determine the basis for their structural differences, we embarked on a more extensive sequencing effort using thermolysin, carboxypeptidase Y and amino peptidase M digestions in combination with HPLC and MS/MS analyses. Figure 1 shows two thermolysin-generated peptide fragments from two different members of this peptide family with the same mass, but different HPLC elution positions. The MS/MS spectra our essentially identical, and rule out the possibility of a isoleucine/leucine difference. Edman degradation confirmed this as well. However, one of these two peptides was not susceptible to aminopeptidase M digestion, suggesting that it may contain a D-amino acid at or near the amino terminus. Our studies eventually concluded that these peptides contained N-terminal isoleucine in both the normal L-configuration as well as the unexpected D-configuration. Given that both D- and L-isoleucine containing peptide forms are present in nearly equal abundances, it is likely that a racemase is involved in their biosynthesis. The biological value of such a modification is suggested from the lack of proteolytic action seen in the aminopeptidase M experiment, thus providing a means to stabilize at least half of these peptides. Circular dichroism studies suggest a type II β-turn structure for these hydrophobic peptides, clearly a departure from the usual α-helices found in other amphibian antimicrobial peptides. Biological assays of these peptides, however, showed very little antibiotic or hemolytic activity, and we are currently expanding our investigations to consider anti-fungal, anti-viral or even mastoparan-like cytotoxic activities for this novel class of peptides.

After the C-terminal 15 amino acids the resin was split in half to facilitate manual Leu and Ile coupling and both resins were then split in half again to prepare D- and L- Ile peptides. Peptides were co-injected with amphibian secretion to confirm identity of native peptides.

Comparative CID Study of MHC Class I and II Peptides using ESI versus CF-LSIMS as the Primary Ionization Method

K.L.Johnson, A.J.Tomlinson, L.M.Benson, G.F.Scanlan and S.Naylor

Biomedical Mass Spectrometry Facility, Dept. of Biochemistry and Molecular Biology and Dept of Pharmacology, Mayo Clinic, Rochester, MN.55905, USA

Major histocompatibility complex (MHC) gene products play an essential role in the immune system through their binding of small peptides and subsequent presentation of these peptides to T-lymphocytes. Although the products of two classes of MHC genes, class I and class II, exhibit peptide binding sites that are similar in structure, they present peptides to two different T-lymphocyte subpopulations:

* class I molecules present peptides to cytolytic T-lymphocytes and
* class II molecules present peptides to cytokine-producing helper T-lymphocytes.

Mass Spectrometry has played an important role in estimating the complexity of such self -peptides as well as providing essential sequence information. In this study we compared the efficiency of ionization (ESI v LSIMS) and low energy CID of a series of Class I and II MEIC peptides. A representative series of results are shown in Figures 1-3 obtained on a Finnigan MAT 95Q.

A) CF-LSIMS with CID in the octapole collision cell
B) ESI with CID in the octapole collision cell
C) ESI with CID in the capillary/skimmer region of the ion source

The striking aspect of this data on the singly charged peptide LSPFPFDL-NH_2 is the similarity of the spectra. However, the overall conclusion was that ESI would be the preferred method of generating a precursor ion for CID experiments in the collision cell.

Electrospray Ionization Mass Spectrometry of Peptides and Proteins in the Presence of Detergents

R. R. Ogorzalek Loo, N. Dales, P. C. Andrews

Department of Biological Chemistry, 2552 MSRB II, Ann Arbor, MI 48109

Detergents play a significant role in protein purification with primary applications including solubilization of proteins and disaggregation of complexes. They are employed in applications involving both gel and capillary electrophoresis. Membrane-bound proteins, in particular, require detergent treatment for solubilization prior to chromatography or ultracentrifugation. Unfortunately, some frequently-used detergent solutions perform poorly in bioanalytical mass spectrometry. We undertook a study to evaluate a broad range of commonly used ionic and non-ionic detergents with the goal of finding suitable detergents and conditions for protein applications of electrospray ionization mass spectrometry (ESI-MS). Most of the investigations were performed with detergent concentrations of 0.1% and 1.0% weight:volume (w/v). These are typical concentrations used in biochemical applications.

Except where indicated, mass spectra were acquired on a Vestec 201 mass spectrometer employing the Vestec interface. The solution compositions electrosprayed included 4% acetic acid/50% CH_3CN/46% H_2O and 100% H_2O, selected to reflect conditions frequently used in ESI-MS of proteins. Samples were introduced by injection loop, continuous infusion, and autosampler. Detection was in the positive ion mode.

Horse Heart Myoglobin (M_r 16951) in 4% acetic acid/50% CH_3CN/46% H_2O was continuously infused to evaluate signal suppression at various detergent concentrations. *Severe signal suppression* was observed with the following commonly used detergents at both 0.1% and 1.0% concentrations: *Triton X-100 (Reduced), Nonidet P-40, Taurodeoxycholate, TWEEN-20* and *sodium dodecyl sulfate*. Detergents which yielded better performance in this solvent included: *Octyl Glucoside, Octyl Thioglucoside, n-Dodecyl sucrose, LDAO, CTAB, CHAPS, Thesit, and sodium cholate*. CHAPS, Thesit, and sodium cholate show the least protein signal suppression at the 0.1% detergent concentrations. CHAPS and Thesit are particularly good choices if a 1.0% detergent concentration is used. In continuous infusion studies with other proteins, analyte signal in the presence of 0.1% CHAPS or Thesit was often enhanced by *ca.* 20% over the detergent-free solution. CHAPS is not a particularly good detergent for ESI-MS applications in 100% aqueous solutions, showing significant signal suppression as well as adduct formation. The non-ionic detergent thesit appears to be superior for aqueous applications.

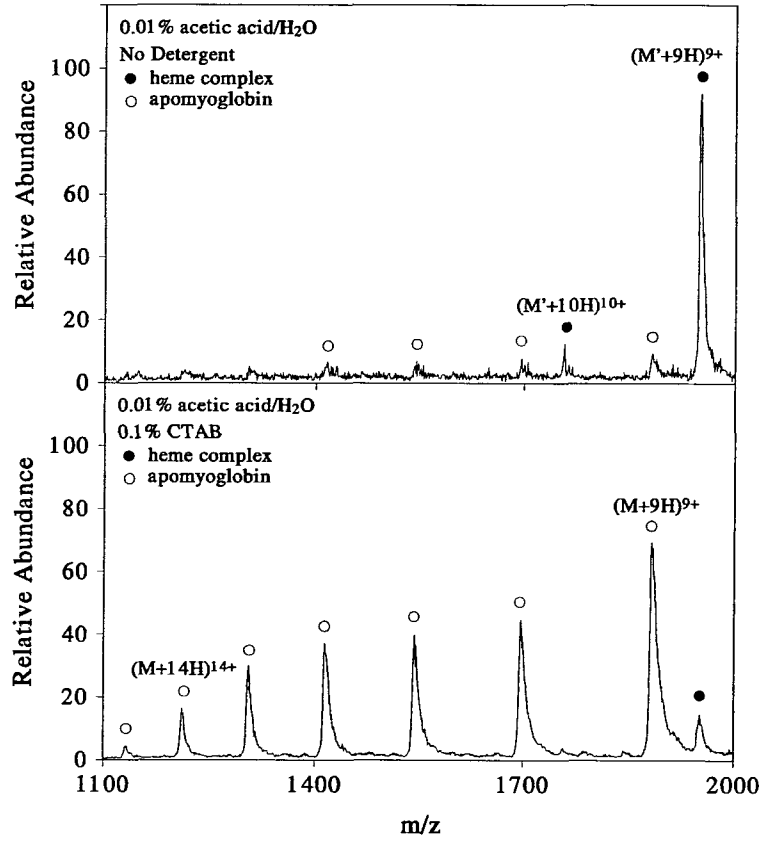
Detergents are well-known for their ability to denature proteins and break up hydrophobic interactions. Figure 1 illustrates mass spectra of myoglobin in 0.01% acetic acid/H_2O without (upper) and with (lower) 0.1% CTAB, a strongly denaturing detergent. The dominant ion in the non-detergent spectrum corresponds to the myoglobin-heme complex, (M_r 17568) while the detergent spectrum shows primarily apo-myoglobin (M_r 16951) in higher charge states; only a small amount of the myoglobin-heme complex is apparent. A similar experiment compared spectra of bovine ubquitin in H_2O with and without 0.1% CTAB; addition of CTAB reduced the intensity of a ubiquitin dimer ion relative to monomer ions. Similarly, the less-denaturing detergent CHAPS has been used to break up protein-protein interactions in noncovalent complexes of concanavalin A.

Significant differences were observed in the ESI-MS charge distributions of cytochrome *c* in water heated off-line with and without 0.1% CHAPS and for lysozyme in 4% acetic acid/50% CH_3CN/46% H_2O boiled off-line with and without 0.1% CHAPS . These differences are attributed to retardation of refolding in the presence of detergent. For unheated solutions of myoglobin in 4% acetic acid/50% CH_3CN/46% H_2O, additions of 1.0% octyl glucoside, octyl thioglucoside, or n-dodecyl sucrose increased charging in comparison to the detergent -free solution. Addition of 1.0% LDAO decreased charging. Higher charging was also observed upon addition of 0.1% cholic acid to myoglobin, ubiquitin, and albumin, but not upon addition of 0.1%

sodium cholate. The mechanism for the apparent increase in charge states observed in the presence of some detergents is not clear. It might arise from better charge separation in more fully-denatured proteins or from effects of the detergents on the dynamics of the electrospray.

Several of the detergents examined in this study should be useful for solubilizing difficult proteins for mass spectrometric analysis, in coupling separations to ESI-MS, and in improving protein recoveries from analytical or purification steps preceeding mass spectometry.

We acknowledge J. A. Loo for the Concanavalin A data acquired on a Finnigan MAT 900.



OPTIMIZATION OF LCMS FLOW RATE FOR MAXIMUM MASS SPECTROMETER DETECTION AND MINIMUM RUN TIME

Ken Stoney[1], Kuldip Mock[2] and Mark Sanders[2]
[1]Michrom BioResources, 5673 W Las Positas Blvd, Pleasanton, CA 94588
[2]Finnigan MAT, 355 River Oaks Pkwy, San Jose, CA 95134

Liquid chromatography (LC) flow rates affect the sensitivity and resolution of peak detection and total chromatographic run time Low flow rates maximize sensitivity and resolution but increase run times, while higher flow rates compromise sensitivity and resolution for decreased run time The purpose of this research is to determine if there is an optimum flow range for achieving maximum sensitivity and resolution while maintaining total run times less than 10 minutes. A commercially available microanalytical LC system designed and optimized for low flow rates was used for this study.

Various LC-MS interfaces are currently available which can accommodate a wide range of flows. We restricted our flow rates to 400ul/min, considered to be on the high end of the range for this project In order to maintain total run times less than 10 minutes, only narrowbore (2.1mm inner diameter (ID)), microbore (1 0mm ID), and capillary (0.5 & 0 3mm ID) were used. The small volumes of these columns combined with the minimum dead volume (<100ul) of the microanalytical LC system, allowed for minimum gradient delays, and therefore very short run times.

To determine an optimum flow rate for maximum mass spectrometer detection, UV absorbance and MS ion current (RIC) peak areas were plotted against various flow rates. UV peak areas (sensitivity) increase exponentially with decreased flow rates while it is hypothesized that MS RIC peaks areas (sensitivity) increase in a linear manner. Where these two plots "intersect" should indicate an optimum flow range. Flow rates below this optimum would result in extended run times and overkill for peak sensitivity and resolution. Flow rates above this optimum would result in lower than maximum sensitivity and resolution.

In order to construct the curves, columns of 4 different inner diameters were chosen which allowed for an overlapping range of flows (Table 1). The test sample used to determine sensitivity and resolution for this study is a mixture containing 5 angiotensins with a concentration of 10ng/ul each (50ng/ul total) quantified by amino acid analysis. Peak B was chosen as the peak to integrate for all chromatographs because it was almost always baseline resolved. The same integration parameters were used for each peak area determination. Except for the inner diameter of the 4 columns, all other variables were constant. (Experimental Parameters)

The figure is the plot of the combined UV and MS sesitivity in terms of total peak area. It is clear that the UV trace follows an exponential increase as the flow rate decreases The MS RIC peak area trace appears to be linear over the range of flows so far investigated. The error in integrating the area of peak B was greater at the lower flow rates Each point represents the average area of peak B of 3 duplicate LCMS runs. It appears from this preliminary data that there may be an "optimum" intersect point in the 10 to 20ul/minute flow range. This is based on extrapolation of the MS RIC peak area curve and would be true only if this curve follows a linear path.

Additional LCMS runs are required to determine if there is an optimum flow rate in the 10-20ul/min range Replicate runs would allow an error to be calculated for the integration of each peak, and therefore help in defining the optimum flow range.

The LC chromatographs shown here illustrate that separations of very similar peptides can be quickly accomplished with high sensitivity and resolution in less than 10 minutes The use of small bore columns with their low volumes coupled with a microanalytical LC optimized for these columns contributes to the rapid separations.

Analysis of Peptides by the Desorption/Ionization Technique K^+IDS, K^+-Ionization of Desorbed Species

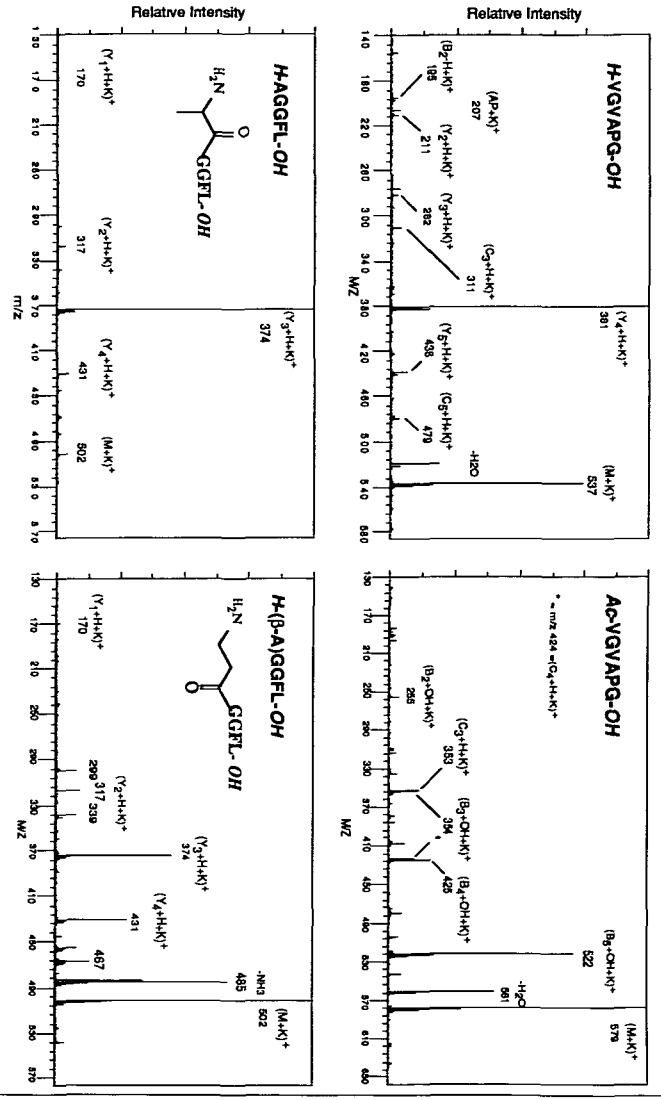
Huaiqin Wu and John Allison
Department of Chemistry, Michigan State University, MI 48824

K^+IDS is a desorption/ionization technique, which is applied here to the analysis of peptides. In the experiment, the analyte molecules are subjected to rapid heating, which leads to desorption of intact analyte molecules (M) and thermal degradation products (D). At the same time, K^+ ions are being generated in the ion source by a thermionic emitter. The K^+ ions attach to the desorbed molecules, yielding mass spectra which contain peaks that represent the $(M+K)^+$ and various $(D+K)^+$ ions. This technique allows us to characterize thermal degradation of peptides, and may be a model for remote-site processes for protonated peptides.

From a typical K^+IDS mass spectrum of *H*-VGVAPG-*OH*, as shown in the attached spectra, K^+IDS spectra show the following features: 1. The dominant ions observed are $(Y_n+H+K)^+$ ions for underivatized peptides. 2. The dominant "fragment" ions observed are $(Y_n+H+K)^+$ ions while their corresponding $(B_n-H+K)^+$ ions are much less abundant even though their corresponding neutral species are formed at the same time and in the same quantities.

In order to understand the dominant cleavages at amide bonds and the dominance of the $(Y_n+H+K)^+$ ions, the thermal degradation mechanism and the K^+ attachment and detachment processes have to be understood. In the study of the thermal degradation mechanism, deuterated peptides, derivatized peptides, and specifically-designed peptides were prepared/synthesized. Our studies on these chemically-modified peptides indicate that thermal degradation of peptides under K^+IDS conditions involves cyclization processes. For example, deuterated peptides show that the shifting hydrogen is not an α hydrogen; For N-terminally acetylated peptides, the characteristic $(Y_n+H+K)^+$ ions are missing in the resulting K^+IDS spectrum and a new $(B_n+OH+K)^+$ ion series dominates the spectrum instead (see the attached spectra). This result clearly indicates that the shifting hydrogen for underivatized peptides is from the N-terminus rather than from internal amide groups. The shift of a hydrogen atom or OH group from a single position in thermal degradation of peptides clearly indicates that the thermal degradation of peptides involves cyclization processes. The differences in the spectra of *H*-AGGFL-*OH* and *H*-(β-A)GGFL-*OH* also confirmed cyclization mechanism. For *H*-AGGFL-*OH*, cyclization generates 3-, 6-, and 9-membered cyclic products and the dominant cleavages occur at the second amide bond from the N-terminus due to the high stability of the 6-membered-ring product formed. For *H*-(β-A)GGFL-*OH*, cyclization generates 4-, 7-,and 10-membered cyclic product. None of these is much more stable than the rest, so the cleavage at the second amide bond is no longer dominant. 2.

The second question is why the $(B_n-H+K)^+$ peaks are so weak in the mass spectra. In our experiments with amino acids, poly-amino acids, cyclic and linear dipeptides, it is found that there exists a response discrimination against small molecules and cyclic molecules. For example, the response of *H*-AA-*OH* is 10 times that of alanine; the response of a linear peptide *H*-GP-*OH* is 6 times that for a cyclic analog, cyclo-(GP). Because the binding energy between K^+ ions and neutral molecules is very small (20 - 40 kcal/mol) and there is no way for nascent K^+ adducts to dissipate the energy released in the binding process other than K^+ detachment or radiative processes, we believe that the relative ion stabilities of the K^+ adducts, thus their lifetimes, are responsible for the dominance of $(Y_n+H+K)^+$ over $(B_n-H+K)^+$ ions.



Fast Atom Bombardment Mass Spectra of 2-Iminothiolane Derivatives

M.G. Bartlett and K.L. Busch
Georgia Institute of Technology, Atlanta, GA 30332-0400

Introduction

2-Iminothiolane, or Traut's reagent, is used as a means of introducing sulfhydryl groups into proteins. These groups could be used to determine the number of exposed lysine groups in a protein. Creaing disulfide bonds within a protein with 2-iminothiolane has been used to study the spatial arrangement of ribosomal proteins. The presence of the sulfhydryl group has the added advantage of allowing further derivatization using fluorophores like N-pyrenyl maleimide (NPM).

In addition to introducing the sulfhydryl group into the protein, 2-iminothiolane also introduces a charged amino moiety. This amino group could be used to improve the response of proteins in fast atom bombardment (FAB) mass spectra. It would also allow for the analysis of proteins that have acid labile functional groups like t-BOC.

Experimental

The mass spectra were acquired on a VG-70SEQ hybrid instrument of EBqQ geometry. Samples were ionized using a Cs^+ ion gun operated at 30 keV. Ions were extracted from the source at 8000 eV. Glycerol was used as the matrix for all samples.

Reactions with 2-iminothiolane were carried out in a pH 8.0 triethanolamine buffer. Reactions were agitated for five minutes and then 2 uL of the sample was added to glycerol and analyzed directly from the probe.

Reactions with N-pyrenyl maleimide were carried out as follows. Prepare a solution of NPM in acetonitrile. Prepare a solution with the protein and 2-iminothiolane in pH 8 buffer. Immediately add the NPM solution to the mixture of 2-iminothiolane and the protein. Allow the mixture to sit overnight (12 hours) at 70 C.

Discussion

2-Iminothiolane reacts rapidly with any protein to yield the addition of a sulfhydryl and a precharged amino group. However, the addition of the precharged amino group causes only a two-fold increase in sensitivity for these compounds. The use of trifluoroacetic acid (TFA) as a modifier for FAB yields more intense molecular species than 2-iminothiolane derivatives. However, if the peptide contains an acid labile functional group like t-BOC, 2-iminothiolane may be beneficial.

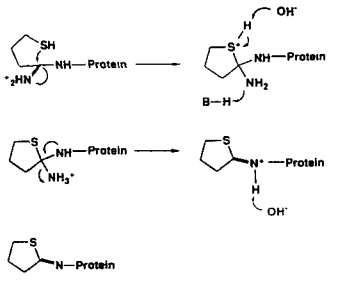
The mass spectrum of the 2-iminothiolane derivatives show a peak 17 daltons lower than the addition of 2-iminothiolane. This peak becomes more intense with time. This increase corresponds to a decrease in signal intensity observed for the derivatized peptide. This loss of 17 daltons has been attributed to the recyclization reaction shown in scheme 1. This recyclization does not seem to be affected by changes in the buffer pH between 8 and 10. This recyclization may be responsible for the unexpected loss of sensitivity of the derivatized products.

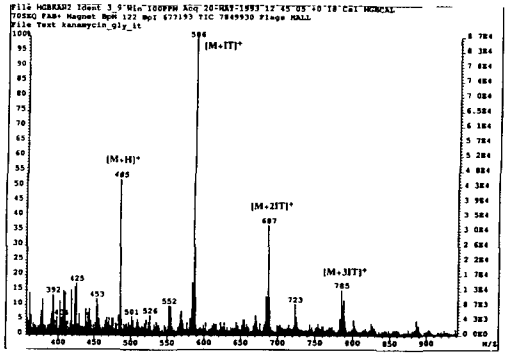
The recyclization side reaction does not affect the ability of 2-iminothiolane to be a linking agent for maleimide fluorophores. The absence of side products, like the recyclization in the reaction of NPM and diphenylalanine and iminothiolane, show that this may be a useful reaction for labeling peptides.

2-Iminothiolane can also be used to derivatize aminoglycosidic antibiotics like kanamycin. Kanamycin A has four amino group. Figure 1 shows kanamycin A 5 minutes after reaction with 2-imnothiolane. After 15 minutes all four amino groups show the addition of iminothiolane.

Conclusions

2-Iminothiolane can be used to introduce both a derivatizable sulfhydryl group and a precharged amino group into peptides. However, because of a recyclization reaction the advantage of the precharged amino group is not recognized. A slight increase in sensitivity over TFA modified sample solutions is observed in the FAB of polyamino oligosacharides. 2-iminothiolane can be used to determine the number of primary amines in a molecule.





Kanamycin-Iminothiolane in Glycerol

Investigations of a One-step Chloroformate Derivatization Procedure for Small Peptides prior to Analysis by FAB-MS

*Jian Wang[1], Zhi-Heng Huang[2], Douglas A.Gage[2], and J. Throck Watson[1,2]
Department of Chemistry[1] and Biochemistry[2]
Michigan State University, East Lansing, MI 48824

Fast atom bombardment mass spectrometry of peptides is often used for molecular weight determination and sometimes for amino acid sequencing. Several experimental factors can prevent successful analysis, such as the poor ionization efficiency of some hydrophilic peptides. This can be overcome by preparing derivatives of the peptides prior to analysis by FAB-MS. Derivatization methods include a variety of peptide modifications, ranging from esterification to the attachment of a single hydrophobic moiety to a specific site on the peptide. None of the reported methods simultaneously derivatizes both amino and carboxyl groups in a single reaction, and most of the methods are time-consuming.

In earlier work, a rapid procedure was developed and refined in this laboratory using various chloroformate reagents to prepare volatile derivatives of amino acids for analysis by GC-FID or GC-MS [1,2,3]. In an aqueous medium, the chloroformate reagent derivatizes both the amino and carboxyl groups as well as most of the side-chain functional groups (amino, carboxyl, thiol, phenolic OH) of amino acids. Carboxyls are converted to esters, while the other functional groups are converyed to N,O and S-alkoxycarbonyl derivatives.

We have investigated the usefulness of this one-step chloroformate derivatization procedure for increasing the detectability of small peptides by FAB-MS. The FAB response of most of the ethyl chloroformate derivatives (forming N(O,S)-ethoxycarbonyl and ethyl esters) of model compounds (di-peptides to penta-peptides) increased five- to fifity-fold relative to that of the underivatized analytes (see Table 1). (The FAB response of the derivatives formed by chloroformate reagents that introduce a larger alkyl group (e.g., iso-butyl) did not show greater enhancement.) However, we have found that peptides are not quantitatively derivatized under conditions that achieved full derivatization of amino acids in a simple one-step reaction. Our preliminary results indicate that derivatization of amino groups (N-terminal and side-chain) is complete, but conversion of carboxyl groups (C-terminal and side-chain) is not complete, regardless of the size of the peptide (from dipeptides to ninemers in our model compounds). Preliminary investigations on the effect of

reaction medium composition, solvent ratio in the reaction medium, reaction time, and extraction efficiency have been carried out. Variation of reaction conditions had little effect on reaction yield, although the ratio of water/ethanol/pyridine in the reaction medium did influence the degree to which the reaction went to completion. The free carboxyl group was determined by MS/MS to be not specifically localized at either the C-terminal or a side-chain carboxyl (see Figure 1). Investigations of modifified chloroformate reaction conditions are continuing to find those that permit efficient and complete reactions of both amino and carboxyl groups on small peptides.

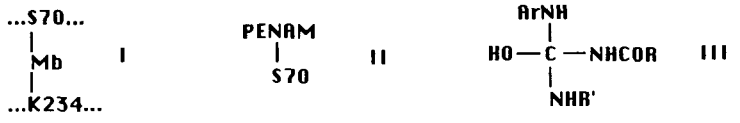
Identification of Novel Chemical Modifications in Proteins: Diamino Formation and Guanidino N-Displacement Product in β-Lactamase and Carbonic Anhydrase

R.A. Day, R. Ahluwalia, Y. Du, A.A. Karagözler and M.A. Roberts
Department of Chemistry, University of Cincinnati, Cincinnati, OH 45221-0172:
K. Jayasimhulu, Department of Environmental Health, College of Medicine, University of Cincinnati, Cincinnati, OH 45221-0056
C.J. Metral, NCI-FCROC, Frederick, MD 21701

Cyanogen (C_2N_2) modification of proteins occurs by condensing salt-bridged functionalities into covalent links (1,2). Only intra-molecular condensations occur with no detectable inter-molecular condensation. With identification of the sites modified the C_2N_2 treatment serves as a salt-bridge probe. The resultant covalent links are acylated amino and guanidino groups. Treatment of the acyl guanidino compound with a good nucleophile as a spectroscopic marker gives a product incorporating the nucleophile moiety covalently attached to the guanidino carbon(III). Structures were assigned through exact mass and fragmentation analysis. β-Lactamases, the principle bacterial defense system against β-lactam antibiotics, are irreversibly inhibited by our novel β-lactams. One of these, a monobactam (MB) with chemical bifunctionality, inhibits thorough a covalent cross-link between active site components SER-70 and LYS-234. The cross-linked, enzymatically inactive β-lactamase protein was stabilized to denaturation as measured by circular dichroism. The assignment (I) was made from FABMS analysis of tryptides. A penam with a 3° amino side chain irreversibly inhibited β-lactamase; FABMS showed it to be covalently attached only to SER-70(II) in the LC isolated tryptide.



EXPERIMENTAL

β-Lactamase Modification with C_2N_2. *B. cereus* Type I β-lactamase (1.6 mg/ml) was mixed with 3 volumes of 0.14 M C_2N_2. After 30 seconds the excess C_2N_2 was entrained in a stream of N_2. The enzymatically inactive enzyme was treated with a 1% solution of p-anisidine (PAN) for 1 hour at room T. After removing excess PAN by alcohol extraction, it was digested with trypsin after further cold alcohol denaturation. The p-anisidine spectroscopically labeled only one peptide which was isolated by C18-RPLC.

β-Lactamase Modification by Active Site-Directed Labels. The procedures of Ahluwalia and Day (4) and of Du and Day (5) were followed. The tryptides and chymotryptides were produced and isolated essentially as described above. Structural assignments (II and III) were made by analysis of data produced from SIMS.

Acylguanidine Modification

(1) Bovine Carbonic Anhydrase (BCA). Cyanogen modified BCA treated with anisidine as described above yielded a peptide with an ARG-111 modified by anisidine.

(2) Acetylguanidine (AG). PAN treatment of AG yielded a displacement product (III). Exact mass and fragmentation analysis confirmed the structural assignment.

DISCUSSION

Mass spectrometric analyses were crucial in assigning the structures of the modified proteins. The determination of the sites of action of C_2N_2 is facilitated by the development of the guanidino moiety specific reagent, PAN itself a spectroscopic probe. The model compound afforded the information necessary to interpret labeling of C_2N_2 modified protein by PAN.

Representative ions were used to assign the position(s) of attachment of our novel irreversible inhibitors. Not unexpectedly, the β-lactamase protein cross-linked between SER70 and LYS234 by the bifunctional monobactam shows both stabilization to denaturation as demonstrated thru circular dichroic studies and altered retention time by C-18 HPLC (4). The monofunctional inhibitor gave a SER-70 acylated product with no attendant stabilization to denaturation or alter retention time (5).

C_2N_2 modification of proteins takes place through conversion of salt-bridged and H-bonded carboxylate pairs to covalent structures (1,2,3,6). Identification of the site(s) modified by C_2N_2 can be done by a combination of molecular modeling and nucleophile labeling (6). Use of an aromatic amine as the nucleophile affords a means to label the ARG guanidino moiety of a carboxylate-guanidino modification product.

The p-anisidine acylguanidino reaction product involves a novel reaction where one of the nitrogens is displaced from the guanidino groups (Structure IIII). Conventional DI spectral analysis afforded the data to assign this structure III.

C_2N_2 modification of β-lactamase leads to ~50% inhibition in 8 minutes with 0.14 M C_2N_2 at 25°. This is attributed to facile conversion of the GLU-166 carboxylate hydrogen bonded to OH of SER-70 to an ester link.

The Characterization of Hydroxyl Radical Oxidized Amino Acids and Peptides by GC/MS

Christa Oberth and A. Daniel Jones
Facility for Advanced Instrumentation
University of California at Davis, Davis CA, 95616

The free radical oxidation of proteins is associated with many degenerative diseases including aging, Alzheimer's', arthritis, immunodeficiencies, and some forms of cancer. Increased oxidative stress can result from exposure to xenobiotic chemicals. The chemistry of protein oxidation, the extent of protein oxidation *in vivo*, and the structural modifications that occur are poorly understood, primarily because previous studies have relied upon indirect methods of analysis.

We have developed a reproducible standardized protocol to investigate the reactions of a model compound, N-acetylphenylalanine, with hydroxyl radical generated by a Fenton system.

Because the products formed by Fenton oxidation have a wide range of physical properties, a single technique is not sufficient to characterize the entire reaction mixture. Several instruments, a quadrupole-GC/MS using electron impact ionization, a magnetic sector instrument using FAB ionization, and a triple-quadrupole instrument using negative electrospray ionization were used to analyze the mixtures. The reaction mixtures were converted to their t-butyldimethylsilyl derivatives prior to analysis by GC/MS. We also analyzed the unfractionated reaction mixture.

The diversity of oxidation products that we have identified by mass spectrometry is the result of the several different modes of hydroxyl radical attack: cleavage of the amide bond, hydroxylation of the side-chain, and products derived from side chain coupling.

An early GC/MS experiment indicated an amide cleavage product, the decarboxylated form of phenylalanine with $M^{+\bullet}$ at m/z 161, as well as products that showed that side chain hydroxylation occurred.

The crude Fenton mixture was placed on a C-18 Bond-Elut cartridge and we analyzed the water fraction directly by GS/MS. Both acetic acid and acetamide, which are two more products of amide bond cleavage were identified.

The mixture was eluted through a strong-anion-exchange cartridge (SAX) to remove the iron in the mixture to improve the yield of TBDMS derivatives. The analyte mixture was eluted with 0.1% aqueous TFA, freeze-dried, and converted to the TBDMS derivatives. The total ion chromatogram (TIC) and the spectra of three major peaks are shown.

The TIC shows three TBDMS-derivatized peaks with scan numbers of 1247, 1277, and 1304, which correspond to the ortho, meta, and para hydroxylated products, respectively. The height of each of these three peaks is important because it gives us an indication of the relative reactivity of each site towards hydroxyl radical in this system. The para isomer was confirmed by comparison with an authentic standard.

Similar reactivity of the *o*- and the *p*- sites, would yield twice as much *o*- isomer to form because there are two ortho positions and only one para. The size of peak 1247 is approximately two times larger than peak 1304 and the meta position is only somewhat less reactive towards hydroxyl radical. This suggests that the hydroxyl radical attacks all aromatic positions in comparable amounts. The spectra of all three isomers have a fragment ion at m/z 221, to yield a benzylic fragment ion. The *o*- and *p*-isomers form this ion to a greater extent because the ortho and para isomers can better stabilize the resultant charge. The relative abundance of this fragment ion in the ortho isomer is lower than that observed for the para isomer presumably due to stabilization of the $[M-57]^+$ ion by neighboring groups.

A unique fragment ion at m/z 147 is present in the spectrum of the *o*-hydroxy isomer. This corresponds to an ion containing two silicon atoms, which forms when silyl derivatives are in close proximity to each other.

For the *m*-hydroxy isomer, one sees fragments that are not seen in the spectra of the other two isomers because the meta isomer generates fragments with few resonance stabilized forms.

Oxidation of N-acetylphenylalanine also yields 1,2-diphenylethane, suggesting formation of benzyl radicals during oxidation.

The FAB spectrum of the SAX-treated-Fenton-oxidized N-acetylphenylalanine verifies the presence of the hydroxyl N-acetyl phenylalanine ($[M+H]^+ = 224$) and the amide cleavage product phenylpyruvic

acid $[M+H]^+ = 165$ was observed. FAB also revealed the dimer product that forms between unreacted N-acetylphenylalanine and hydroxyl N-acetylphenylalanine ($[M+H]^+ = 429$). This product was not seen using GC/MS.

Fenton oxidation products identified by negative ion ES/MS are acetamide, $[M-H]^- = 58$; acetic acid, $[M-H]^- = 59$; phenylalanine, $[M-H]^- = 164$; and hydroxyl N-acetylphenylalanine, $[M-H]^- = 222$.

ESI/MS Detection and Characterization of Novel Thiohydantoin Amino Acid Derivatives

C. Basic, J.M. Bailey, J.E. Shively, T.D. Lee, Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, CA 91010

Automated N-terminal sequencing of peptides and proteins based on Edman degradation methodology is currently limited to the analysis of samples in the low picomole range (1). This limitation is largely imposed by the use of high-performance liquid chromatography, HPLC, to detect the phenylthiohydantoin, PTH, amino acid derivatives produced as the end products of each degradation cycle. There is increased interest in developing new methods to sequence samples in the mid- to low femtomole range. To this end more sensitive fluorometric (2) and electrospray ionization mass spectrometric, ESI/MS, (3,4) detection methods have been utilized, coupled with requisite modifications of the degradation chemistry.

The ESI/MS and MS/MS spectra of a series of novel thiohydantoin amino acid derivatives in which the phenyl functionality of the standard phenylthiohydantoin ,PTH, derivatives is replaced with a tertiary (dimethylaminopropyl thiohydantoin, DMAP-TH) amine are presented. The development and characterization of these derivatives is part of an on-going effort in our laboratory to couple ESI/MS on-line with protein sequencing.

All ESI mass spectra were obtained on a Finnigan MAT TSQ 700 MS fitted with an Analytica of Branford ESI source. Samples were introduced *via* direct infusion through a stainless steel capillary at a flow rate of 2 $\mu l/min$ and a concentration of 10 $pmol/\mu l$, unless otherwise indicated. The source temperature was ≈ 170° C. Pneumatic nebulization was performed using a co-axial flow of N_2 gas. The ESI/MS/MS spectra were obtained at a collision offset of -20 eV with an indicated Ar collision gas pressure of $\approx 3\times10^{-6}$ torr. The DMAP-TH derivatives were synthesized in our laboratory; the PTH derivatives were obtained from Sigma Chemical Co.

The DMAP-TH derivatives characterized to date include: glycine, valine, leucine, isoleucine, phenylalanine, arginine and histidine. A typical ESI/MS spectra of the DMAP-TH -leucine in 50% $MeOH/H_2O$/1% HAc is presented in Figure 1. Each derivative studied gives rise to a $[M+H]^+$ ion as well as a $[M+H-45]^+$ ion. The $[M+H-45]^+$ ions are attributed to loss of $NH(CH_3)_2$ since none of the -R groups studied give rise to a logical loss of 45 mass units. The relative intensities of the $[M+H-45]^+$ ions can be increased by increasing the capillary/skimmer offset. At higher offsets $[M+H-73]^+$ ions attributed to the loss of $(CH_2)_2NH(CH_3)_2$ are also seen (except arginine which shows no 73 loss). Thus, three characteristic ions for each derivative can be monitored in a single stage mass spectrometer.

The ESI/MS/MS spectra of the $[M+H]^+$ ion of DMAP-TH-arginine is presented in Figure 2. Unlike the other derivatives studied, DMAP-TH-arginine shows fragment ions arising from both the DMAP and -R functional groups. The fragment losses indicate that the $[M+H]^+$ ion may be protonated on both the DMAP and -R groups, *e.g.* the $[M+H-17]^+$ may be attributed to loss of NH_3 from the -R group while the $[M+H-45]^+$ ion is attributed to loss of $NH(CH_3)_2$ from DMAP.

The ESI/MS spectrum corresponding to 21 fmoles of the DMAP-TH derivative of phenylalanine is presented in Figure 3. This spectrum demonstrates that the DMAP-TH derivatives can be detected at the tens of femtomole level. The DMAP-TH derivatives for the remaining amino acids have been synthesized and will be characterized by ESI/MS and MS/MS methods. Future work will also involve the interfacing of a dedicated ESI/MS spectrometer to an N-terminal protein sequencer incorporating the requisite modifications of the degradation chemistry.

Synthesis and Mass Spectrometric Characterization of Reference Phosphopeptides.

D. I. Papac, J. E. Oatis Jr., & D. R. Knapp
Medical University of South Carolina, Charleston, SC 29425

Introduction: The need for small quantities (few to tens of micromoles) of multiple peptides, including modified (i.e. phosphorylated) peptides for mass spectrometry standards prompted us to devise a simple manual approach for synthesis of multiple peptides using a relatively inexpensive, commercially available solid-phase extraction apparatus. We report here a description of the peptide synthesis apparatus and its use for preparation of a series of monophosphorylated peptides corresponding to fragments obtained from the C-terminal region of bovine rhodopsin. In addition, we report on the tandem mass spectra obtained for these phosphopeptides using high energy CID conditions.

Methods: The synthesis apparatus shown in figure 1 was assembled from a 12-position solid-phase extraction manifold fitted with empty 1.5 ml polypropylene extraction tubes supplied with polyethylene frits and attached to valved teflon needles. A water aspirator vacuum with trap was used to collect the effluents from the extraction tubes into polypropylene tubes held in a rack within the manifold.

Syntheses were performed on "Wang" resin using standard solid-phase Fmoc chemistry as detailed in figure 2. The sidechain groups were all protected as t-butyl derivatives except for lysine which was protected as the ε-amino BOC derivative.

Serine or threonine residues to be phosphorylated were coupled with the hydroxyl group unprotected. The free hydroxyl groups were phosphitylated by treatment for 1-24 hrs with a 10-40 fold molar excess of N,N-diethyl-di-t-butylphosphoramidite in DMF containing a 40-70 fold molar excess of 1H-tetrazole. The resin was washed with DMF prior to oxidation of the phosphite groups with either a 33-fold molar excess of t-butyl hydroperoxide (3M in 2,2,4-trimethylpentane) or a 30-fold molar excess of m-chloroperbenzoic acid in methylene chloride for 0.5-3 hr.

Separation of synthetic phosphopeptides was achieved on a Vydac C-18 column with a mobile phase of (A) 0.1% aqueous TFA and (B) acetonitrile containing 0.084% TFA. The gradient was 98% A held for 10 min then ramped linearly to 89% A over 50 min.

Mass spectra were obtained on a JEOL HX110/HX110. Samples were dissolved in 10 μl of 1N HCl, applied to the probe on a matrix of 1N HCl/thioglycerol, and ionized with 18 kV cesium ions. MS/MS experiments were performed with the accelerating voltage at 10 kV and a resolution of 1500 for MS1 and 1000 for MS2. The collision cell was operated at 3 kV and filled with enough helium to attenuate the ion current of the C-12 monoisotopic peak by 70%.

Results: Using this peptide synthesis apparatus good yields were obtained for unmodified peptides containing up to 19 residues. Low yields (< 10%) were initially obtained for the incorporation of phosphate; however, sufficient quantities of the monophosphorylated derivatives of ASTTVSKTE were prepared for use as mass spectrometric standards using the published phosphitylation and oxidation conditions[1,2,3]. The low yields were most likely attributed to steric hindrance from the bulky t-butyl protecting groups. In subsequent syntheses of monophosphorylated

derivatives, incorporation of the phosphite group was increased substantially by increasing the reaction time and the amount of N,N-diethyl-t-butyl phosphoramidite and 1H-tetrazole. High energy CID MS/MS of the phosphopeptides displayed the characteristic fragment ions and losses[4]. In addition, a novel side chain cleavage loss was observed for phosphothreonine containing peptides (-125 Da) (Fig. 3). This loss was not observed when the phosphate was located on an N-terminal threonine.

Conclusion: A system for small-scale multiple peptide synthesis built from a commercially available solid-phase extraction apparatus was used to successfully prepare several series of monophosphorylated peptides (ASTTVSKTE & TSQVAPA) on the 10-30 μmol scale.

Tandem Mass Spectral Decompositions of Protonated N-Acyloligoalanines and N-Acyloligoglycines as Models for Those of the Protonated Free Oligopeptides

Daniel G. Morgan and Maurice M. Bursey
The University of North Carolina at Chapel Hill, Department of Chemistry, Chapel Hill, North Carolina 27599

The decompositions of various n-acylated derivatives of tetraalanine and tetraglycine were studied as models for comparison with their corresponding hexa- and octapeptides using fast atom bombardment (FAB) MS/MS The principle purpose of this study was to compare the dependence of the yields of typical backbone cleavages upon structure in these modified and unmodified peptides This comparison was pursued through increasing the aliphatic chain length of the appropriate acylated tetrapeptide to mimic one or two Ala_2 or Gly_2 units through equal mass or through equal degrees of freedom. Thus, nonanoyltetraglycine approximates octaglycine in the number of degrees of freedom while pentadecanoyltetraglycine approximates octaglycine in molecular weight.

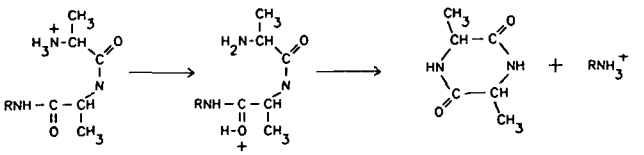
The predominate fragmentation ions noted in the tandem mass spectra for all of the peptides investigated in the study were acylium and ammonium ions, y- and b-type ions as based on the Biemann nomenclature[1] The intensities of these ions in the spectra of the N-acylated oligomers exhibited marked differences when compared with the corresponding free oligomer. Table 1 shows a comparison between Gly_4 and Gly_6 along with the degrees of freedom model for Gly_6, valeroyltetraglycine, and the acylated model of similar mass, heptanoyltetraglycine. Ion, peptides are the fragment ions noted for Gly_4 and Gly_6, while the Ion, models are the labels for the fragments of the acylated peptides For comparison purposes of this study, the b_3 ion of valeroyltetraglycine was considered equivalent to the b_5 ion of Gly_6.

Table 1 Comparison of Gly_4 and Gly_6 with Model Compounds of Similar Mass and Similar Degrees of Freedom (DOF) Based on Total Product Ions

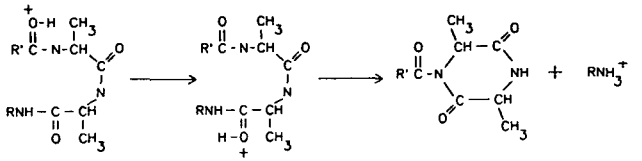
Ion, peptide Ion, models	b_3 b_1	b_4 b_2	b_5 b_3	b_6 b_4	y_2 y_2	y_3 y_3
Tetraglycine	18	21			58	
Hexaglycine		18	40	21		13
Valeroyltetraglycine	1	3	29	10	7	50
Heptanoyltetraglycine	1	4	28	5	6	55

There is a spectacular difference between the spectra of the acylated tetrapeptides and the free tetrapeptides The y_2 ion domination of tetraalanine and tetraglycine is absent and replaced by a domination of the y_3 of the acylated tetraglycine and the b_3 of the acylated tetraalanines Thus the acylation of the terminal amino group prevents the formation of the y_2 ion Yeh et al.[2] argued previously that the intense y_2 ions in the tandem mass spectra of tetraglycine and tetraalanine were due to an especially favorable loss of a diketopiperazine (Scheme 1) This suggests that even though the terminal site of protonation is still favored in the acylated tetrapeptides, as based on proton affinity calculations, the site of protonation has changed from the nitrogen to the oxygen, because of the change of the functional group from an amine to an amide (Scheme 2) Thus the diketopiperazine formation is much less favorable because a transition state ring has increased in size from six to eight Thus, the intensities of the model compounds did not follow statistical or linear free energy relationships as would be expected if they were true homologues.

Diketopiperazine Formation



Scheme 1



Scheme 2

Labeling studies have been performed to study the formation of the intense y_3 ions in the spectra of the acylated tetrapeptides. The five easily exchangeable hydrogens of nonanoyltetraglycine were replaced with deuterium on the FAB probe tip during analysis of the $[M+D]^+$. These hydrogens were the four attached to the nitrogen amides and the one attached to the carboxylic end. An intense ion observed at 196 amu corresponded to the y_3 fragment, deuterated at the exchangeable sites along with two extra deuteriums, one from the matrix and one from the terminal amide nitrogen This is in agreement with the mechanism as proposed by Kenny, et. al.[3] A labeling study of the aliphatic chain was also performed to confirm this pathway d_{17}-Nonanoyltetraglycine was synthesized where all of the hydrogens of the aliphatic chain were replaced by deuterium The results showed that none of the aliphatic hydrogens were involved in the y ion formation.

This work has provided further evidence for the control of ion intensity by the site of protonation in peptides We have adduced evidence for a difference in structure between the conjugate acids of tetrapeptides, acylated tetrapeptides, and of larger oligomers The difference in the availability of the y2 channel between tetrapeptides and acylated tetrapeptides is consistent with the proposition that amides are protonated on the oxygen atom Finally, we have confirmed the mechanism for y ion formation as proposed by Kenny.

Gas Phase Protein Conformations & Folding

*Francis M. Wampler III, Daniel P. Little, Detlev Suckau, Steven C. Beu , Fred W. McLafferty

Chemistry Department, Baker Laboratory, Cornell University, Ithaca, NY 14853-1301

H/D exchange of electrosprayed protein ions in a Fourier transform mass spectrometer (FTMS) has provided extensive evidence of co-existing conformations of such gaseous ions.[1] Improvements over previous work were made possible by an instrument upgrade including the replacement of the old 2.8 T magnet with one of 6.2 T, in conjunction with the addition of two faster (1500L/s) cryogenic pumps. Utilizing these improvements, all spectra are now isotopically resolved, with the resolution of some approaching 10^5. Single or double SWIFT [2] isolations of a desired charge state were used for the H/D exchange studies. All exchange reactions were carried out at 1.1×10^{-7} torr D_2O for 30 minutes, sufficient time for essentially complete exchange of accessible sites.[1]

20 μM equine cytochrome c was electrosprayed from both denaturing and nondenaturing (pure H_2O) solution conditions. 198 protons of this protein are attached to heteroatoms (N, S, O) and are chemically reactive toward H/D exchange with D_2O. In the gas phase, the number of exchanged sites was shown to depend upon the steric accessibility of those sites, and did not necessarily increase with increasing charge state. Three levels of exchange were observed: ~85 exchanges for 6^+ - 8^+, ~130 exchanges for 8^+ - 15^+, and ~110 exchanges for 8^+, 11^+ - 13^+, 15^+ (trace), and 16^+ -18^+. It is not now clear whether the latter exchange levels represent 1, 2, or 3 different conformations. In solution, two hour reactions with D_2O resulted in deuteration of nearly all 198 exchangeable sites in the resulting ions. At several charge states, there was evidence for co-existing stable conformations, resulting in very dramatic bimodal exchange levels. The 8^+ ion, comprised of high and intermediate exchanging conformers, was primarily in a highly denatured state when electrosprayed from CH_3OH solution, and primarily in the intermediate state when sprayed from aqueous solutions.

In attempting to change the gas phase conformations, a charge state of known conformation was SWIFT isolated. Low pressure pulses of butyl amine (proton affinity = 218 kcal/mol) were used to remove protons (strip charge) from the protein. Sufficient time was left for most of the amine to pump away, and then D_2O was admitted through a separate bleed valve. The interconversion among conformers was achieved. (Figures 1 & 2). The 15^+ ion, shown to be mostly denatured (~130 exchanges) was stripped to 7^+. The low exchange (~85) observed for the 7^+ product was consistent with gas phase folding. In a separate experiment, the intermediate exchanging 16^+ (~110 exchanges)

was stripped to 15^+; mostly high exchanging conformer resulted. The similarity in spectra between the 15^+ from charge stripping and that with no amine added are striking, and provide excellent support in the argument for gas phase unfolding.

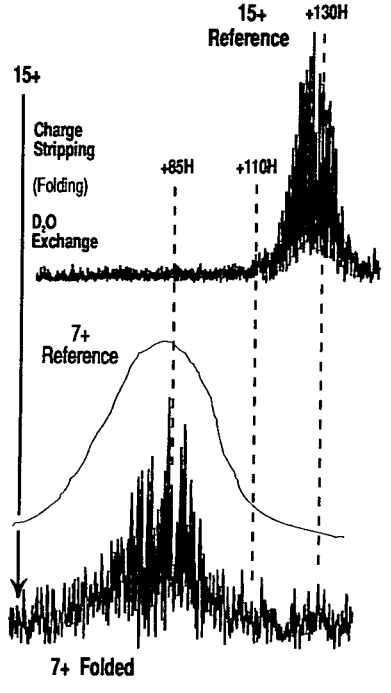

FIGURE 2: "A"-STATE UNFOLDING

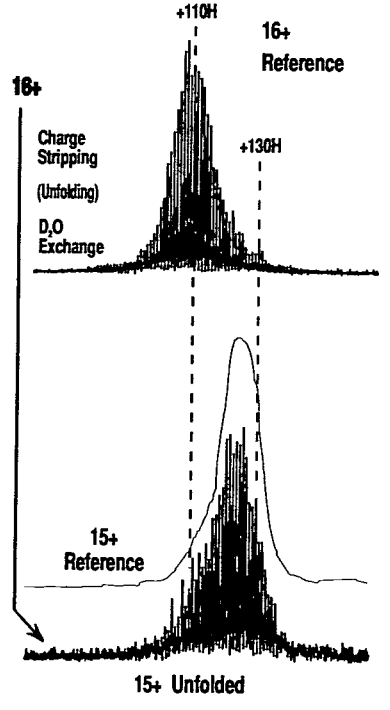

CONFORMATION OF PROTEINS STUDIED BY DEUTERIUM EXCHANGE ESI-MS

D.S. Wagner and R.J. Anderegg, Glaxo Research Institute, RTP NC, 27709

Recently deuterium exchange has been observed with ESI-MS[1,2]; faster exchange being indicative of a more open structure, slower exchange associated with a tightly folded structure or intramolecular hydrogen bonding. Since the experiments performed to date monitor exchange rates for the native and denatured states in different environments (pH, temperature and solvent system), it is not clear whether the variation of the exchange rate is due to the protein's conformational change, to the change in the chemical environment, or to a combination of both. In order to accurately compare the exchange rates for the two different conformations, both the native and denatured states must be analyzed in the same environment. Bovine cytochrome c (MW 12,231) contains 192 labile hydrogens (deuterated molecular weight 12,423). Altering the acid concentration of a solution containing bovine cytochrome c has a dramatic effect on the charge state distribution, CSD, observed in the corresponding ESI mass spectrum: 0% acid (pH=6.0) exhibits 1 CSD ranging between +7 and +11, 2% acetic acid (pH=2.7) displays a "bimodal distribution" one CSD ranging from +7 to +10 charge states and the second CSD ranging between +11 and +18, and 4% acetic acid (pH=2.5) mainly the high CSD. The differences between these spectra have been attributed to changes in the protein conformation, with the tightly folded native states appearing as an CSD at high m/z (low charge) and the denatured state represented by the CSD at lower m/z (high charge). The bimodal charge distribution is interpreted as two conformations in solution, one more tightly folded than the other.

If more than one conformation of a protein exists in the solution, then the more denatured conformation should exhibit a faster rate of deuterium exchange leading to a higher molecular weight at any given time point. Plots of the protein's measured molecular weight versus time for the +8 and +15 charge states in 2% d^4acetic acid (conditions known to produce a bimodal distribution) overlap one another, thus indicating that both charge state distributions have the same rates of H-exchange. Altering the pH and/or organic solvent concentration of the solution changed the observed exchange rate; however, the two charge state distributions always exhibited overlapping curves. This suggests that either the interconversion between the native and denatured states is on a much faster time scale than the exchange reaction, or the protein has only one conformation in solution and the change in the charge state distribution is an artifact of the ESI experiment. Under most conditions the protein's interconversion between conformations is faster than H exchange. Therefore only one overall exchange rate can be observed regardless of the charge state distribution noted in the ESI mass spectrum unless a method for blocking interconversion can be employed.

In order to block the interconversion between the open and closed forms of the protein, samples were partially denatured in an irreversible manner by heating at 95 C for 3 hours[3]. The structural basis for this denaturation probably involves the isomerization of the four proline residues. The mass spectrum of a heat treated sample dissolved in H2O 0% acid (conditions known to produce 1 CSD), displays a bimodal distribution centered around the +9 and +15 charge states. Lyophilized samples of the heat denatured protein were dissolved in D_2O only and the change in m/z as a function of time was monitored. The measured molecular weight versus time for the +8 and +15 charge states clearly shows two unique rates of deuterium exchange for the two charge state distributions (Figure 1). The lower charge state experiences slow exchange representing a tightly folded structure, while the higher charge state undergoes rapid exchange indicating a more denatured structure. This gives unequivocal evidence that two different charge state distributions correspond to two different conformations in solution. A

comparison of the exchange behavior for the native and thermally denatured samples reveals that the high and low CSD of native cytochrome c and the low CSD of the heat denatured protein display similar exchange rates as evidenced by the similarity of their exchange profiles. However, the high CSD of the heat denatured protein displays a markedly faster rate of exchange. Therefore we conclude that there are at least two denatured states of cytochrome c present with approximately the same charge state distribution that have significantly different deuterium exchange rates. The native states that we observe in both experiments are, as far as we can tell, identical.

It is tempting to try to use the ESI-MS exchange data to extract information about the rate of protein unfolding or deuterium exchange. If a uniform first kinetics is assumed, then the observed rate constant $K_{obs}=(k_{unfolding}/k_{folding} * k_{exchange})$ could be obtained for each deuterium exchange experiment. The rate constant for a given experiment can be acquired from a plot of ln[the number remaining of labile hydrogens] versus time. If the protein only contained a single rate constant then the plot would correspond to a straight line, whose slope would be proportional to the exchange rate. However, since each amide has a different first order exchange rate, a curve is obtained instead of a linear plot (Figure 2). The curve can be segmented into groups of amides that exchange with similar rates depicted by linear regions. Although these kinetically isolated sets of protons may have similar exchange rates, this does not indicate they originated from the same structural element.

Deuterium exchange has been shown to be extremely sensitive to protein conformational changes because exchange is irreversible and cumulative. Mass spectrometry can easily monitor the rates of deuterium incorporation by the mass shifts in an experiment. Different conformations do not necessarily have different exchange rates. Data indicates that there are at least two denatured states of cytochrome c which have similar charge state distributions but different rates of deuterium exchange. Therefore the charge state distribution is not a sufficient indicator of the protein's conformation. ESI-deuterium exchange experiments have potential for probing protein folding and obtaining other useful kinetic data. In addition, the stability of proteins upon structural modification, and the effects of ligands, inhibitors or substrates to an enzyme could also be monitored by comparing the appropriate exchange rates obtained by ESI-MS.

Protein Backbone Amide Hydrogen Exchange Determined by HPLC FABMS: Application to Rabbit Muscle Aldolase

Zhongqi Zhang, Carol B. Post and David L. Smith
Department of Medicinal Chemistry and Pharmacognosy, Purdue University
W. Lafayette, IN 47907

Isotopic exchange of protein backbone amide hydrogens has been used extensively as a sensitive probe of protein structure. The principal method for determining rates of hydrogen exchange in small proteins has been one and two-dimensional NMR. However, the use of NMR is restricted to investigations of relatively small and highly soluble proteins.

A new method based on protein fragmentation and HPLC FABMS has been developed in our laboratory to facilitate application of hydrogen exchange to large proteins. We report results obtained when this method was applied to rabbit muscle aldolase and its complex to the N-terminal pentadecapeptide of Band III protein. Aldolase is a protein with four identical subunits and a molecular weight of 157 kDa. Band III protein, a major protein component of erythrocyte membranes, binds to aldolase, thereby inhibiting its enzymatic activity. To better understand the inhibition of aldolase by Band III protein, we are using amide hydrogen exchange to probe conformational changes between bound and free aldolase.

The general procedure used for deuterium exchange-in and analysis is illustrated as follows. The protein was incubated for varying lengths of time in D_2O for deuterium exchange. The exchange was terminated by decreasing the pH of the solution from pH 7.2 to 2.6. The deuterated protein was digested by pepsin for 10 min at 0 °C and analyzed immediately by HPLC FABMS. The extent and location of deuterium exchange-in was determined from the deuterium content of peptides derived from the protein. Conditions used for proteolysis and peptide analysis were selected to minimize hydrogen back exchange (0 °C, pH 2 - 3). The total time required for digestion and analysis was approximately 20-30 minutes, which is substantially less than the half-life for back exchange of amide hydrogens. Since very rapidly exchanging hydrogens (e.g., -OH) undergo back exchange with the HPLC mobile phase, the molecular weights of the peptides are a direct measure of the number of deuteriums located at peptide amide linkages. To correct for exchange occurring during digestion and analysis, nondeuterated and fully deuterated proteins were analyzed by the same procedure. The deuterium levels of the partially deuterated peptides were determined by comparison with the two standards.

Deuterium incorporation into different segments of aldolase was determined as a function of exchange-in time. To investigate the interaction between aldolase and the N-terminal pentadecapeptide of Band III protein, hydrogen exchange into both free aldolase and a mixture of Band III peptide and aldolase were determined. From the rates at which deuterium exchange occurs in different segments of aldolase in free and bound forms, we can see that binding has little effect on the rate of hydrogen exchange in some segments, while increasing the rate of exchange in others (Fig. 1 shows an example for each case). These results suggest that complexation has little effect on intramolecular hydrogen bonding in some regions, while significantly weakens intramolecular hydrogen bonding in others.

Although the present protein fragmentation method is generally limited to determining isotopic exchange rates in segments of proteins, it can be used to obtain more detailed information in some cases. For example, there may be several overlapping peptides from the same region of the protein. Differences in the deuterium contents of such peptides can be used to increase the spatial resolution of the method. For instance, segment 58-64 of aldolase has a significantly increased hydrogen exchange, but segment 58-62 does not change upon binding to Band III peptide. These results show that residues 63 and 64 are responsible for the increased hydrogen exchange of segment 58-64 upon complexation. Fig. 2 shows the difference in the

deuterium levels of segments 58-64 and 58-62, which is a measure of deuterium content in residues 63 and 64. After fitting the curves with an equation of two exponential terms, we found that both exchange rates of the two amide hydrogens increased by approximately a factor of two in the complex (see Fig. 2 insert).

Results described here demonstrate that the amount of deuterium incorporation into a large protein, such as aldolase, can be determined accurately by combining the protein fragmentation method and directly-coupled HPLC-FABMS. Since the rate at which amide hydrogens undergo isotopic exchange is a sensitive probe of the high order structure of proteins, methods described here facilitate use of FABMS in studies of the high order structures of proteins. Although the spatial resolution achieved by this method is not at the single residue level, exchange rates within small segment, sometimes as short as one or two residues, can be determined. Application of this technique to aldolase and its complex to Band III N-terminal peptide have shown that aldolase is locally destablized after binding to the Band III peptide. This may lead to a better understanding of the interaction between aldolase and Band III protein.

Using AMASS to Localize a Modification on a Peptide. *A. G. Craig, C. Hoeger, S. C. Koerber, J. Porter and J. E. Rivier, The Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, P.O. Box 85800, San Diego, CA 92186-5800.

When fragment ions are assigned manually, the 'simplest' explanations are usually arrived at first. Although, these assignments are generally the correct ones, when assignments cannot be made and a computer is used to generate possible rational assignments, criteria are required for the interpretation. From inspecting possible fragment masses generated by AMASS (ref. 1) for 18 di-, tri-, tetra-, penta- and hexa-peptides we found that almost any fragment mass could be rationalized by carrying out two bond cleavages together with up to 2 proton transfers. However, generally the percentage of the most intense fragment ions which were assigned to double bond cleavage was 17 ± 8 %. We propose that the 'simplicity' of assignments (i.e. single versus multiple bond cleavage) be used as a criterion for distinguishing between these rational explanations.

During the synthesis of Azaline A (Ac-DNal-DCpa-DPal-Ser-Lys(Atz)-DLys(Atz)-Leu-ILys-Pro-DAla-NH_2) (where Nal = 2-napthyl alanine, Cpa = 4-chlorophenylalanine and Pal = 3-pyridylalanine, Lys(Atz) = N^{ε}-(3'-amino-1H-1',2',4',-triazol-5'-yl) lysine, Ilys = N^{ε}isopropyl lysine) and that of an homologous series of novel gonadotropin releasing hormone antagonists an impurity (fraction B) could be isolated together with the parent compound (fraction A) and the LSI mass spectra indicated $[M+1]^+$ and $[M+15]^+$ species respectively. We noted that (a) fraction B when tested in an *in vitro* histamine release assay was significantly more potent than the parent compound, (b) the fraction B impurity had a greater propensity to fragment both in the LSI mass spectra and in the high energy CID spectra than fraction A (Figure 1); (c) different types of fragment ions were formed by the fraction B impurity compared to those of fraction A and (d) almost all of the intense fragment ions derived from the fraction B precursor included the addition of ca.14 Da. Based on these results we concluded that the modification was present on the three N-terminal residues Ac-DNal^1-DCpa^2-DPal^3- which were present in azaline A and common to all of the peptides having this impurity. In order to observe fragment ions attributable only to the three N-terminal residues, we selected the m/z 555 fragment ion (derived from fraction B, which was assigned as the 'a3+14' N-terminal fragment) and measured the CID product ion scan.

We constructed three sets of AMASS input structures with the methyl group located on Nal^1, Cpa^2 or Pal^3 and compared the output of one and two bond cleavages generated by AMASS for these structures with the observed fragment ions. We found that if the modification was located on the Nal^1 or Cpa^2 residues, some of the fragment masses could only be explained by three bonds being cleaved and the assignments generally included significantly more multiple bond cleavages (59 and 53 % respectively) than if the methyl group was located on Pal^3 (35 %). Using nuclear magnetic resonance we were able to further localize the methyl group on the aromatic nitrogen of the Pal^3 residue which would

explain observation (a). We propose that during solid phase peptide synthesis, methylene chloride reacts with the pyridinyl nitrogen to form an immonium ion salt (ref. 2). The formation of an immonium ion salt in corollary with quaternary ammonium ion salts (ref. 3) explained the remaining observations (b)-(d).

Interpretation of Peptide CID Spectra using Artificial Neural Networks

R. E. Scarberry, Z. Zhang, K. R. Thornburg, and D. R. Knapp
Medical University of South Carolina, Charleston, SC 29425

A recently reported method for computer interpretation of peptide CID spectra is based upon recognition of patterns of related sequence ions.[1] This algorithm classifies peaks by ion type via recognition (using scoring rules) of patterns of related ions. By mathematically converting all classified ions to the corresponding y ions, the spectrum is transformed into an idealized spectrum of only y type ions, which is then interpreted in a conventional manner. We have extended this approach by use of artificial neural networks to identify ion types.

A prototype algorithm has been developed which utilizes two backpropagation networks to, first, classify peaks as being or not being one of the common ion types (a, b, c, d, v, w, x, y, z+1) and, second, to classify the peaks according to ion type. The classified peaks are then used to generate a transformed spectrum of y ions only which is interpreted in a conventional manner. The members of the family of ion types for a given amide bond cleavage site are related mathematically by the following formulas:

$$a_n = MH - y_m - 27 \qquad x_m = y_m + 26$$
$$b_n = MH - y_m + 1 \qquad z_m + 1 = y_m - 16$$
$$c_n = MH - y_m + 18 \qquad v_{m+1} = y_m + 55$$
$$d_n = MH - y_m + 43 + R_a \qquad w_{m+1} = y_m + 53 + R_a .$$

For each peak in a spectrum, the masses of the corresponding other peaks in the family are calculated from the formulas. Nine families are calculated for the peak in question being due to each of the nine ion types. The peak intensities at these masses are used as the input vector for the neural networks. The complete interpretation algorithm is shown in the flow chart on the next page.

In the prototype algorithm, the networks were trained with a set of high energy CID spectra from the following peptides (containing approximately 650 classified peaks): AA, AAA, AAAAA, VLLS, MGMM, SGAGAG, I I I, LLVY, LGG, MAS, IVV, GLLG, MRF, YKT, GGGG, TKY, VLSEG, and FVQWLMNT. The resulting algorithm was tested with spectra from eleven additional peptides. The correct sequence was either the highest (1) or second highest (2) scoring sequence found for the following peptides: ETTTDK(2), TYSK (1), TSQVAPA(1), DDE(1), AKTE(2), and IFVQK(1). The correct sequence was not among the fifty highest scoring sequences found for the spectra of the following peptides: EDLIAYLK, ASTTVSKTE, LRRASLG, YIPGTK, MIFAGIK. The explanation for this dichotomy of results is not apparent, but the high percentage of correct results is encouraging. Work is underway to further explore this approach by training the networks with larger data sets including larger peptides. The method offers the potential for another approach to peptide CID spectra interpretation which could facilitate peptide sequencing by tandem mass spectrometry.

Rapid Identification of Proteins by Database Matching of Proteolytic Peptide Masses.

D. J. C. Pappin[1], A. J. Bleasby[2], C. W. Sutton[3] and J S Cottrell[3], [1]Imperial Cancer Research Fund, London WC2A 3PX, UK., [2]SERC Daresbury Laboratory, Warrington WA4 4AD, UK., [3]Finnigan MAT Ltd , Hemel Hempstead, HP2 4TG, UK.

Previous investigations have demonstrated the possibility of identifying proteins by (i) proteolysis, (ii) mass spectrometric analysis of the digest, and (iii) matching the set of measured molecular weights against a database generated by applying proteolytic cleavage rules to a collection of known protein sequences [e.g. W. Henzel *et. al.* 3rd Protein Soc. Symp. (1989), J. Yates *et. al.* 5th Protein Soc. Symp. (1991), M. Mann *et. al.* Proc. 40th ASMS, 957-8 (1992)].

We report here on the construction of the MOWSE (MOlecular Weight SEarch) database at SERC Daresbury. MOWSE has been extensively tested with data from plasma desorption, electrospray, and matrix assisted laser desorption (MALD). Experience has shown that proteins can be uniquely identified in a database of >48,000 sequences using only 4 or 5 molecular weight values. The greatest selectivity is provided by peptides in the range 700 to 3000 Da. Mass measurement accuracy is not critical, and even errors of several daltons cause little distortion in the results. The incidence of random matches can be reduced to negligible levels by correlating data from two digests using different enzymes. The MOWSE algorithms have also been implemented as a Microsoft Windows program, MassMap, which runs on a standard PC and uses the NCBI composite sequence database distributed on CD-ROM

Table 1 details results obtained from 37 experimental samples supplied by external laboratories. Searches were conducted either "blind" or "double-blind". Of the 37 samples, 33 were correctly assigned. This included the 27 samples listed, and a further 6 samples that were correctly grouped as unknown because they were later found to have no significant sequence homology with any of the database entries. Three samples were grouped as false negatives, and subsequent investigation revealed that, in two cases, the data sets were dominated by partial cleavage products. The one sample recorded as a false positive, (data not shown), was subsequently found to be a mixture.

MALD is an ideal ionisation technique for this application, since it provides low-picomole sensitivity, tolerance to contaminants such as the digest buffer, and requires no chromatographic separation of the digest products. This approach has enormous potential for rapidly identifying the thousands of proteins resulting from whole cell lysis following separation by SDS-PAGE, blotting, and *in situ* digestion. This further raises the prospect of using peptide mass fingerprint analysis to characterise cellular proteins in conjunction with large scale genomic DNA sequencing. Peptide mass databases could accumulate information faster than any linear sequence databases, and become a primary source of information in their own right. Potential DNA reading frames obtained from large scale DNA sequencing could be translated, digested and searched against such databases to discover whether the reading frame corresponds to a mapped protein.

Molecular Characterization of Surface Topology in Protein Tertiary Structures by Amino-Acylation and Mass Spectrometric Peptide Mapping.

M.O. Glocker, C. Borchers, W. Fiedler, and M. Przybylski
Faculty of Chemistry, University of Konstanz, W-7750 Konstanz, Germany

Understanding the role of structure-function relationships in proteins today is a topic of intense research. Aside from the intrinsic desire to understand the beauty of nature´s architecture, many exceptionally important applications have been proposed. Industrial, clinical, and agricultural developments may be achieved in the coming years by imitation of the interactions between macromolecules that occur naturally in the living cell. We need to know the threedimensional structure before we can begin to understand protein function at the molecular level. Enzyme catalysis, antibody-antigen interactions and receptor-ligand interactions are prime examples. The most commonly used methods for characterizing protein tertiary structures, X-ray crystallography and multidimensional NMR techniques, both have limitations determining chemical reactivities of specific amino acid residues in proteins.

We have developed a new method (1) for the molecular characterization of intact protein structures by combining specific chemical modifications of amino acid residues with peptide mapping of proteolytic mixtures using desorption-ionization mass spectrometry (PD-MS, ESI-MS). ^{252}Cf-plasma desorption (PDMS) has proved to be a powerful tool for these studies especially when *in situ* reactions were applied. The nondestructive nature of PDMS and the protein-binding capacity of the nitrocellulose matrix makes this method suitable for on-target reactions. Acylation reactions of proteins were carried out at pH 6.5 with up to 100,000-fold

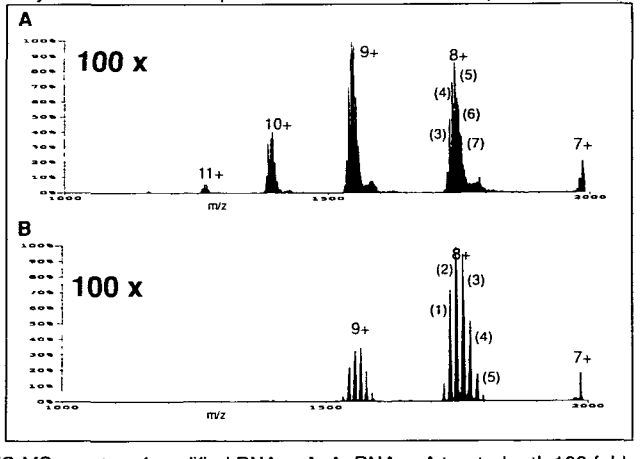

Fig. 1: ES-MS spectra of modified RNAse A. A: RNAse A treated with 100 fold excess acetic anhydride. B: RNAse A treated with 100 fold excess succinic anhydride. The numbers on top of each peak represent the charges. The number of modied residues is given in parantheses.

molar excess anhydride, and the extend of modification was determined by direct PD-MS and ES-MS analyses. A gradual molecular weight increase at increasing reagent concentration was found. Molecular weight determination by ES-MS yielded multiple protonated molecular ion envelopes with varying characteristics. For acetylated protein derivatives the ion envelopes were similar to those of native proteins, indicating a native-like structure for the modified proteins (2). The ES spectra for succinylated RNAse A differ from the acetylated protein spectra. Here, already at a low degree of modification the charge envelope shifts to less charged peaks. Lysines are charged positively at physiological pH (pK≈10.5) and conversion to the amide by acetylation results in charge neutralization, whereas succinylation introduces an additional carboxy function, thereby adding a negative charge to the protein. Peptide mapping analyses of reduced and alkylated protein derivatives were performed by trypsin digestion in solution or on target (3). Molecular ions of most of the relevant tryptic peptides were found. The monitored peptides were assigned and the site of modification in each of the modified derivatives was determined. These results enabled the determination of relative reactivities of the lysine residues in the corresponding protein. The mass spectrometric experiments described here present broad analytical potential in evaluating selectivity of chemical modification agents, the elucidation of reaction pathways, and the analysis of protein surface topology. This new approach may also effectively supplement dynamic methods of surface topology analysis, such as two dimensional NMR techniques and structure simulation approaches.

Thyroxine binding globulin (TBG, an α globulin) is the major circulating transport protein for thyroid hormones, binding 70% of total thyroxine (T4). A number of different TBG assays have been described with potential clinical usefulness in the characterisation of TBG abnormalities. However the widespread use of such assays has been hampered by the lack of an international standard for TBG.

The National Institute for Biological Standards and Control (NIBSC) was invited be the Expert Committee on Biological Standardisation of the World Health Organisation to establish an international reference material for TBG. We report here the characterisation of several preparations of TBG and the formal establishment by WHO of the International Standard for Thyroxine Binding Globulin 88/638.

TBG was isolated from pooled normal human serum provided by the National Blood Transfusion Service. The purification procedure involved four sequential chromatographic steps. The final product was characterised by sodium dodecyl sulphate 12.5% polyacrylamide gel electrophoresis[1], The extinction coefficient, at 280nm of the isolated pure TBG was determined using refractive index measurements to assess the absolute total protein concentration in the samples prior to mass spectrometry.

Electrospray mass spectrometry was performed on a Fisons Instruments/VG BioTech Platform single quadrupole mass spectrometer.

When 30µg of the purified TBG was run on reduced SDS-PAGE and stained with Coomassie blue, only a single band was seen. N-terminal sequencing revealed a unique sequence which was identical to that reported from the cDNA sequence of human TBG[2]. The concentration of the final bulk preparation of pure TBG determined by refractive index measurement was 3.85µg/µl.

Figure1 shows the raw data obtained from one sample of TBG. Several series of multiply charged ions are observed with between 36 and 49 positive charges. The Maximum Entropy processing algorithm was then applied to this data and produced the MaxEnt spectrum shown in Figure 2. This shows a series of peaks grouped in 3 sets. The major component at 52924.8 is observed together with probably one (+38) and then two (+76) potassium adducts. The second component at 53583.7 also has potassium adducts. The mass difference between the first group of peaks is 658Da and that between the second and third groups also 658Da.

The chromatographic procedure used here yielded TBG which was highly purified by all available

criteria.Characterisation of TBG by electrospray mass spectrometry, which has a precision of better than 0.01% for mass measurement of proteins of this size, showed that the only species present were grouped with masses compatible with those expected from the known protein sequence of TBG (44089.7) together with varying degrees of glycosylation.

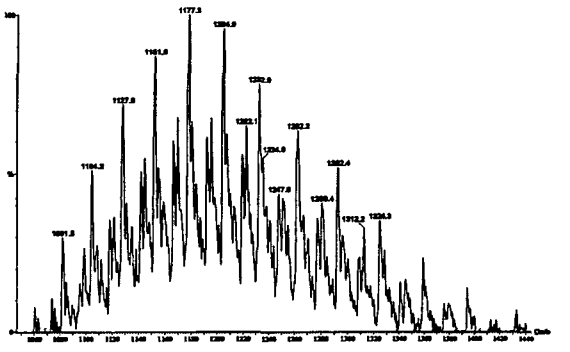

Figure 1. Raw m/z data obtained frim TBG (lot T13). Several ion series observed having between 36 and 49 positive charges.

We cannot exclude the possibility that some of the observed mass heterogeneity may have derived from minor in vitro deglycosylation of TBG, and there is evidence of loss of sialic acid (291Da) from some molecules. However, the mass difference of 658Da between the major sets of peaks corresponds very closely to the calculated mass of a typical chain of GlcNAcGalNeuAc (656Da) such as would form the third arm of a typical complex triantennary N-linked oligosaccharide. It therefore seems likely that there are populations of TBG molecules which are differentially glycosylated with biantennary and triantennary oligosaccharides. Confirmation of this suggestion will require spectrometric and chemical analysis of the structure of the TBG oligosaccharides after cleavage from the protein.

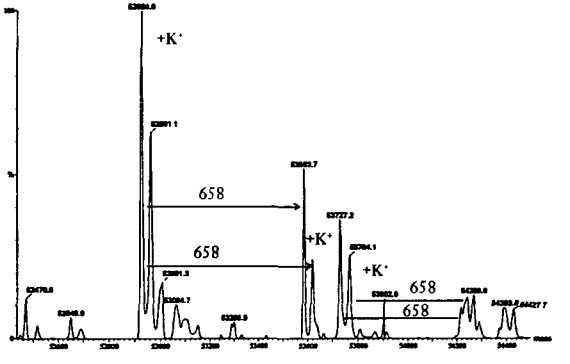

Figure 2. MaxEnt spectrum from human TBG lot 13 probably potassium adducts observed on major component. In addition mass increments of 658 are observed.

PHOSPHORYLATION OF HUMAN AND BOVINE PROTHYMOSIN α In Vivo.

*L.K. Pannell[1], D.M. Sheeley[2], H.M. Fales[2], S.L. Berger[3], A.R. Sburlati[3], A. De La Rosa[3], D.W. Batey[3], G.L. Kurys[3], R.E. Manrow[3] and B.M. Martin[4]; [1]NIDDK, [2]NHLBI, [3]NCI and [4]NIMH, National Institutes of Health, Bethesda, MD 20892.

Introduction: Prothymosin α is a small (12kD), highly acidic polypeptide found in the nuclei of virtually all mammalian cells. The protein is quite abundant in cells and is required for cell growth. All proteins involved in regulating the cell cycle seem to undergo phosphorylation and dephosphorylation, a step which was thought to regulate the cell cycle. Therefore, it was interesting to see if prothymosin α also under went phosphorylation.

When Prothymosin α was incubated in the presence of [^{32}P]orthophosphoric acid, amongst the labelled material was a single labelled protein of 12kD, and this label was alkaline phosphatase sensitive, but was not destroyed under DNA and RNA hydrolysis conditions. Therefore, the phosphate was amino acid linked. Under partial acid hydrolysis, the label was found to be associated with a single amino acid, a serine. There are 4 serines on human prothymosin α (1,7,8,83) and only three on bovine prothymosin α; the question to be answered - To which serine is the label attached?

Isolation: Calf thymus was homogenized in buffer (50mM Tris-HCl at pH 7.5, 25mM KCl, 3mM $MgCl_2$ and 0.4mM phenylmethylsulfonyl fluoride), filtered through cheese cloth and centrifuged. After the addition of 0.1% sodium dodecylsulfate and 1% NP40, the supernatant was phenol extracted. Nucleic acids were digested with 50μg/ml of RNase A and 130U/ml of DNase, and enzymes were removed by additional phenol extractions. Final purification was performed by C18 reverse phase liquid chromotagraphy.

The [^{32}P]-labelled prothymosin α was digested with Lys C and examined by HPLC. The radioactivity was found to be located on a single peptide. An examination of this peak by FAB showed that the labelled peptide was the N-terminal 14 amino acid sequence and that this corresponded to a large peak for the unlabelled material eluting at a later retention time.

Only a small percentage of the protein was labelled and this was consistent with an electrospray examination of the labelled protein sample which did not reveal any modified protein content. However, a peak representing a loss of water from prothymosin α was present and we have observed this before in phosphorylated samples.

Further digestion of the 14-mer was performed with Asp-N. Cuts could occur at Asp2 and Asp6 but, it is doubtful the first cut would occur.

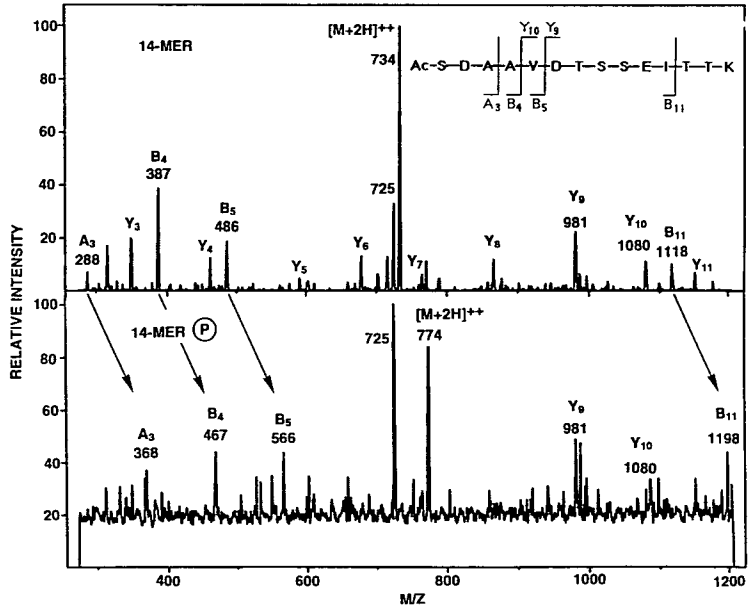
AcS↑DAAV↑DTSSEITTK

As expected a 5-mer and a 9-mer peptide were produced. By comparing the products of labelled and phosphorylated 14-mer, a first peak was found to be consistent

in both phosphorylated and unphosphorylated 14-mer, and did not contain any [^{32}P]-labelling. A second peptide, which eluted earlier, came out even sooner in the phosphorylated sample. When examined by FAB, the first peak represented the 9-mer and the second peak the 5-mer implying the phosphorylation site was on the terminal acetylserine. However, FAB parent ion of the labelled 5-mer was not detected.

To further clarify the location of the phosphorylation site, the electrospray ions representing the doubly charged 14-mer (m/z 734), and doubly charged phosphorylated 14-mer (m/z 774), were examined separately examined under MS/MS conditions using helium as a collision gas. Considerable sequence information from both ends of the chain were observed from the m/z 734 ion. With the phosphorylated m/z 774 ion, shifts in 80 amu (fragments were all of single charge) were observed in fragments containing the N-terminal acetyl serine, but not in any of those ions not containing Ser 1.

LOCALIZATION OF THE PHOSPHORYLATED SERINE RESIDUE BY MASS SPECTROMETRY



Conclusion: Only the N-terminal acetylserine is post-translationally phosphorylated in Prothymosin α.

Characterization of the phosphorylated ribosomal protein S7 from *Tetrahymena*.

*Lisbeth Palm, Jens Andersen, Henrik Rahbek-Nielsen, Karsten Kristiansen and Peter Hojrup, Department of Molecular Biology, Odense University, DK - 5230 Odense M, Denmark.

The basic ribosomal protein S7 is the only r-protein from *Tetrahymena thermophila* which can be phosphorylated *in vivo*. *Tetrahymena* can be multiply phosphorylated upon starvation by a sodium associated kinase. Previously, it was presumed that *Tetrahymena* S7 was homologous with the most prominent phosphoprotein in the ribosomes of higher eucaryotes, S6, where phosphorylation is presumed to essential for enhanced protein synthesis. Surprisingly, sequence determination of *Tetrahymena* S7 showed that it is homologous to r-protein S4 in higher eukaryotes.

The primary structure of *Tetrahymena* ribosomal protein S7 was determined by a combination of two different approaches. First S7 was separated by two-dimensional polyacrylamide gel electrophoresis (2-D PAGE), digested enzymatically *in situ* in the gel. The generated peptides were eluted by diffusion and separated by narrowbore rp-HPLC. Second S7 was purified by three successive rounds of rp-HPLC using three different column supports and elution-buffers. The purification was monitored by 2-D PAGE after the first step, while the following steps were monitored by electrospray mass spectrometry (ESMS). The electrospray mass spectrum of the purified S7 revealed the mass to be 29,458 ± 6 Da (Fig. 1).

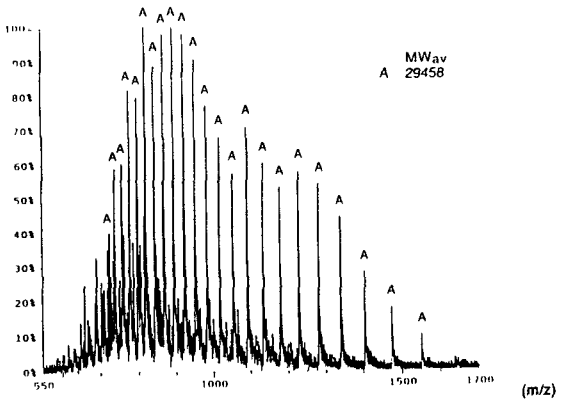


Fig. 1: Electrospray mass spectrum of the column purified *Tetrahymena* ribosomal protein S7.

The *in situ* generated peptides were separated by rp-HPLC and for each peptide the mass was determined by plasma desorption mass spectrometry (PDMS) and the amino acid sequence was determined using automatic pulsed liquid Edman degradation.

The sequence information from the gel purified peptides allowed deduction of 80 % of the *Tetrahymena* S7 sequence. Determination of the remaining sequence was accomplished by sequence determination of the column purified and enzymatically digested protein. A search against the PIR database clearly showed that *Tetrahymena* r-protein S7 is homologous with mammalian r-protein S4 and not to r-protein S6.

In order to determine the phosphorylated sites, starved *Tetrahymena* cell were incorporated with [^{32}P]phosphate and the extracted ribosomal proteins were purified by column chromatography. The molecular mass of the di-phosphorylated S7 was determined by laser desorption mass spectrometry (LDMS) to 29,627 Da, based on the single and double charged molecular ions. This is a derivation of only 0.02% from the calculated mass (29,620 Da) (Fig.2). The laser spectrum is calibrated using a contaminating protein with a known molecular mass of 14467 Da (determined by ESMS).

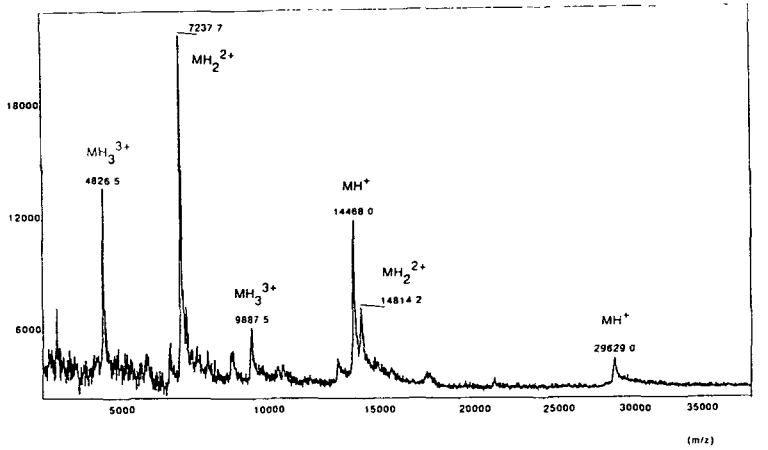

Fig. 2: Laser desorption mass spectrum of the di-phosphorylated *Tetrahymena* ribosomal protein S7.

Phosphorylated peptides were generated by *Staphylococcus aureus* V8 protease digestion and the phosphorylated peptides were monitored using Cerenkov counting. The peptides were analyzed by LDMS and the sequences were determined using Edman degradation. The two phosphorylated residues were located close to the C-terminus.

MASS SPECTROMETRY OF PHOSPHOPEPTIDES ISOLATED BY IMMOBILIZED METAL-ION AFFINITY CHROMATOGRAPHY

Lydia M. Nuwaysir and John T. Stults, Genentech, Inc., South San Francisco, CA

INTRODUCTION

In this study, the feasibility and general applicability of on-line immobilized metal-ion affinity chromatography (IMAC) coupled with electrospray-ionization mass spectrometry (ESI-MS) is investigated for the separation and identification of phosphorylated and non-phosphorylated peptides. The sensitivity and practicality of the technique is demonstrated via the analysis of several synthetic phosphopeptides as well as the phosphoprotein, bovine ß-casein, purified by SDS-PAGE, electroblotted onto a PVDF membrane, and digested in situ with trypsin.

EXPERIMENTAL

SDS-PAGE and electroblotting were performed as described by Wong et. al. [1]. Membranes were digested in 50 μL 0.1 M *N*-ethylmorpholine, 10% acetonitrile, and 0.2 μg of Promega modified trypsin, and incubated for 24 hours at 37°C with the addition of a second aliquot of trypsin after 12 h.

Experiments were performed using a SCIEX (Thornhill, Ontario) API III triple quadrupole mass spectrometer equipped with a pneumatically-assisted electrospray-ionization source (Ionspray). Each scan was acquired over a range of *m/z* 400-2200 using a step of 0.5 u, a dwell time of 1.5 ms, a mass defect of 50 μu , and an 80-V orifice potential.

IMAC was accomplished as follows: A 1.0 mm i.d. x 10 cm long Teflon tube was filled with a 20% ethanol slurry of chelating Sepharose Fast Flow (Pharmacia, Piscataway, NJ). The column was activated by pumping 200 μL of 30 mM $FeCl_3$ solution through the column and excess metal was washed with 2 mL of H_2O. Prior to initial use, two blank runs of all buffers were flowed through the column. Samples were either loaded directly onto the column in acidified (pH 3.5 with acetic acid) digest buffer or in 0.1 M acetic acid. The following buffers were used as eluents to develop the column:

Buffer A: 0.1 M acetic acid
Buffer B: Milli-Q distilled water
Buffer C: 0.1% (w/v) ammonium acetate adjusted to pH 8.0 with 10% NH_4OH
Buffer D: 0.1% (w/v) ammonium acetate adjusted to pH 9.5 with 10% NH_4OH
Buffer E: 2% acetonitrile, 0.1% (w/v) ammonium acetate adjusted to pH 10.5 with 10% NH_4OH.

RESULTS

Figure 1a displays the mass spectrum obtained from a mixture of 10 pmol each of synthetic phosphotyrosine peptides I, II, and III as they eluted together from the IMAC column. The phosphopeptides elute within 15μl of buffer as observed in the TIC (inset).

The application of the IMAC isolation method to a more complex mixture of peptides was studied by analyzing 30 pmol of ß-casein purified by SDS-PAGE, electroblotted onto a PVDF membrane, and digested *in situ* [1]. The peptides that were released from the PVDF membrane upon hydrolysis were loaded onto an IMAC column, washed, and eluted as described earlier. Both the T1-2(4P) and T6(1P) peptides are observed (Figure 1b, and inset: TIC).

CONCLUSION

On-line IMAC separation of the phosphopeptides was found to be crucial in the analysis of low levels of the phosphopeptides. The ability to inject the tryptic digest of an electroblotted protein directly onto the column without buffer exchange and to analyze the eluent directly via on-line IMAC/ESI-MS greatly reduces sample losses incurred through sample handling and provides a convenient method for analyzing phosphopeptides at low levels. With proper optimization of column and solvent conditions, flow rate, and mass spectral scan conditions, better detection limits can be achieved.

An Approach to Characterize Phosphorylation Sites in Phosphopeptides and Phosphoproteins by Combining Enzymatic and Chemical Reactions with MALDI-TOF Mass Spectrometry

*Pao-Chi Liao[1], Joe Leykam[2], Douglas A. Gage[2] and John Allison[1], Department of Chemistry[1] and Biochemistry[2], Michigan State University, East Lansing, MI 48824;

Karen Wang[3], Philip C. Andrews[4] and John Strahler[3], School of Medicine, Department of Pediatrics[3] and Biochemistry[4], University of Michigan, Ann Arbor, MI 48109

The goal: To develop a fast, picomole-scale methodology to localize the phosphorylation sites in phosphopeptides and phosphoproteins.

Advantages of MALDI-based methods: speed, high sensitivity and mixture analysis capability.

Current methods for locating phosphorylation sites: To locate phosphorylation sites in a phosphoprotein, the most common strategy consists of digesting the phosphoprotein into small peptides, followed by analyzing the products. Unfortunately, phosphoserine, the most abundant, naturally-occurring phosphorylated amino acid residue, breaks down to free phosphate in Edman degradation cycles[1]. To overcome this problem, chemically converting phosphoserine into S-ethylcysteine has been proposed, and is becoming an attractive method to biochemists[2]. Another attractive method under development is combining FAB and MS/MS techniques to induce fragmentation of an ionized phosphopeptide to yield sequence information directly [3].

Identify a phosphopeptide: A reagent is required which removes the phosphate moiety from a phosphopeptide, so a phosphopeptide can be identified from the -80 dalton mass shift ($OPO_3H \rightarrow OH$) in MALDI spectra. Enzymatic dephosphorylation by alkaline phosphatase can serve such a function.

Locate phosphorylation sites in a phosphoprotein: Due to the lack of MS/MS capabilitiy when MALDI is used, phosphoproteins must be cleaved into small peptides and phosphopeptides by enzymatic or chemical reactions prior to MS analysis. The digest mixture of peptides and phosphopeptides from a phosphoprotein can be fractionated by RP-HPLC and then subjected to MALDI analysis. When the protein sequence is known, locating phosphorylation sites is achieved by "mass-mapping".

Results: Three synthetic model phosphopeptides, which are phosphorylated at serine, threonine and tyrosine respectively, were studied. The table below shows their detectabilities in MALDI.

peptides	phosphorylated	dephosphorylated
KRP(p)SQRHGSKY-amide	10 fmol	less than 1 fmol
KR(p-)TLRR	10 fmol	less than 1 fmol
LKRA(p-)YLG-amide	100 fmol	less than 1 fmol

Fig. 1 shows the MALDI spectra of the tryptic digestion of a phosphopeptide to locate the phosphorylation site among possible sites. Time-coursed monitoring of the dephosphorylation reaction of a phosphopeptide and locating phosphorylation sites of ß-casein were also discussed. This work has demonstrated that MALDI-TOF mass spectrometry is a fast, easy and sensitive tool for locating phosphorylation site(s) in a phosphoprotein. The phosphorylation sites of Op18, an phosphoprotein expressed in transformed lymphocytes, had been investigated by this method [4].

Limitations and Future work: A major limitation of MALDI-TOF mass spectrometry is that the signal intensities vary considerably between peptides in a mixture. Some peptides do not give a signal. This hampers the proposed method in certain cases. Suppression effects have been observed in a tryptic digest mixture, which makes interpretation of MALDI spectra difficult. Currently, sample consumption of this method is limited by sample handling in the digestion and separation steps. The incorporation of *in situ* digestion on the MALDI probe and microseparation into the proposed method is under investigation.

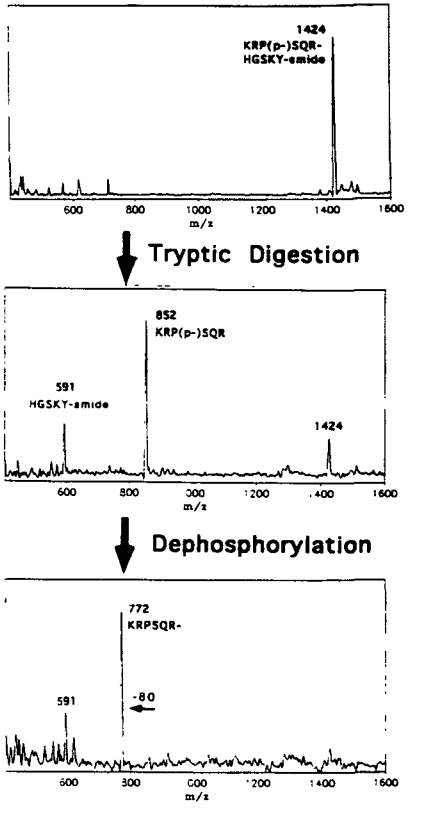

Fig. 1 MALDI spectra of the tryptic digestion of a phosphopeptide to locate the phosphorylation site among possible sites.

Analysis of Amylin and Related Peptides from Biological Fluids Using LC/MS and MS/MS

M.A. Moseley, K.A. Halm, S.E. Unger, Glaxo Inc. Research Institute, 5 Moore Drive, Research Triangle Park, NC 27709

Amyloid deposition in the islets of Langerhans is a major pathological feature of non-insulin dependent (type II) diabetes mellitus (NIDDM). The major protein component of the amyloid is a 37 amino acid, carboxyamide peptide designated islet amyloid polypeptide (IAPP), or diabetes-associated peptide, or amylin (1). Amylin shows high sequence homology with human calcitonin gene-related peptide (CGRP) and has been shown to inhibit glycogen synthesis in rat muscle (2). Amylin and related peptides serve to modulate the effects of insulin and, therefore, may be clinically useful. The sequence of rat and human amylin and their average molecular weights are given below:

Rat Amylin	KCNTATCATQRLANFLVRSSNNLGPVLPPTNVGSNTY	3920.4
Human Amylin	KCNTATCATQRLANFLVHSSNNFGAILSSTNVGSNTY	3903.4

Analytical methodologies capable of measuring amylin or related peptides in biological media or determining their metabolic fate are necessary to better understand their effects. Endogenous plasma levels of amylin are low (0.2-5 pM) in most individuals. However, amylin levels are high (150-400 pM) in certain organs such as the pancreas. To measure these low levels, highly sensitive immunoassays have been used (3).

Electrospray (ESI) LC/MS is capable of detecting low nM levels of amylin or related peptides from serum or plasma (Fig. 1). The $(M+3H)^{3+}$ parent of amylin was monitored and referenced to the $(M+2H)^{2+}$ parent of porcine adrenocorticotropic hormone (ACTH) fragment 18-39 as internal standard. Both the 3+ and 4+ charge states were observed with good intensity. The 2+ and 5+ charge states were also observed, but were less than 10% relative intensity. A standard curve for rat amylin extracted from 0.1 mL of rat plasma is shown in Fig. 2.

Due to their facile adsorption and degradation, protein precipitation with 0.2 mL of an ACN/ 0.1% dimethyloctylamine (DMOA) solution was used. The use of DMOA was found to improve the recovery of amylin and related peptides. At sufficiently high (0.1%) concentrations, DMOA associates with the peptide and minimizes its adsorption to glass or polypropylene surfaces. The association was observed by co-elution of DMOA with analyte and inferred by the improved recovery of peptide. This effect may be due to denaturing the peptide as similar results were observed using sodium dodecylsulfate (SDS) for related peptides. The supernatant was dried under nitrogen and reconstituted in 25 uL of mobile phase before injecting 5 uL onto the LC/MS. A gradient of 20% ACN to 50% ACN over 5 minutes with a 10 minute hold at 50% was used. The mobile phase included 0.1% TFA and 5% i-propanol. A 1 x 50 mm Vydac C4 Protein/Peptide column held at 60°C was used.

This procedure minimized sample losses due to handling and provided analyte of sufficient purity for ESI LC/MS analysis. While these concentrations are significantly higher than endogenous levels, they may be useful for toxicology studies. At nM levels, the highly specific LC/MS method could also be used to validate results from a less specific immunoassay.

Little is known regarding the metabolic fate of amylin, and analytical methods which are capable of identifying amylins or their proteolytic fragments *in vitro* or *in vivo* are essential to better understand its mode of action. Abundant fragmentation is observed in the MS/MS spectra of either the 3+ or 4+ charge states of rat amylin. Over seventy fragments were observed with the majority of assignments (b and a series) arising from charge retention on the more basic N-terminus.

Fig. 3 illustrates the reconstructed chromatograms of amylin exposed to immobilized trypsin. Six tryptic peptides were observed; however, the (1-1), (2-18), and (2-37) fragments were not. The fragments are given below with their average molecular weights and observed charge state:

1-1	K	146.2	*
2-37	CNTATCATQRLANFLVRSSNNLGPVLPPTNVGSNTY	3792.2	*
1-11	KCNTATCATQR	1194.4	1+, 2+
12-37	LANFLVRSSNNLGPVLPPTNVGSNTY	2744.1	2+, 3+
2-11	CNTATCATQR	1066.2	1+
1-18	KCNTATCATQRLANFLVR	2008.4	2+, 3+
19-37	SSNNLGPVLPPTNVGSNTY	1930.1	1+, 2+
2-18	CNTATCATQRLANFLVR	1880.2	*
12-18	LANFLVR	832.0	1+

*not observed.

Proteolytic digests of amylin and related peptides have been useful in determining their presence in serum. Similar (nM) detection sensitivites were noted for the tryptic fragments to amylin.

Characterization of β-Amyloid: A Major Component of Cerebrovascular Amyloid Deposits.

Amina S. Woods and Robert J. Cotter
Johns Hopkins School of Medicine
Baltimore , MD 21205

A.E. Roher
Wayne State University School of Medicine
Detroit, MI 48201.

Alzheimer's disease is a neurodegenerative disorder characterized by global cognitive decline. The lesions are formed by insoluble proteinaceous fibers in the brain: extracellular deposits of amyloid in senile plaques and cerebral blood vessels, and in intracellular neurofibrillary tangles in the cytoplasm of neurons.

The β-Amyloid protein (βA) is composed of 39-42 amino acid residues. It is derived from a larger transmembrane protein precursor (695-700 residues. The putative abnormal processing events leading to amyloid accumulation are unknown. However a small proportion of cases occur in families displaying autosomal dominant inheritance of the disorder.

To find post-translational modifications, parenchymal and cerebrovascular βA solubilized in formic acid were digested with trypsin and the generated fragments separated by reverse phase (RP) HPLC using a C_{18} column. The fractions were analyzed by plasma desorption mass spectrometry (PDMS). The carboxy terminal fragment was not detected in the cerebrovascular βA, so βA was purified using superose-12 size exclusion chromatography in formic acid and digested with pepsin or trypsin. The pellet left after the tissue extraction was resuspended in 80% formic acid and cleaved with CNBr. the various digests were separated by RP HPLC and the fractions analyzed by PDMS. Fraction 5 of the trypsin digest shows MH^+=1086.1 amu, MNa^+ =1106.4 amu and MK^+=1125.3 amu ($GAIIGLMVGGVV_{29-40}$). None of the other fractions showed peptide fragments containing residues 41 and 42. The pepsin digest however showed fragments containing residues 35-40 (MVGGVV), MH^+=561.1 amu and MNa^+ =584.0 amu (fr P_1, Fig. 1a), as well as fragments containing residues 36-42 (VGGVVIA), MH^+=613.3 amu and MNa^+ =636.1 amu (fr P_2, Fig. 1b) and residues 35-42 (MVGGVVIA), MH^+=746.1 amu and MNa^+ =768.1 amu (fr P_2, Fig. 1c). The CNBr digest gave fragments 36-40 (VGGVV), MH^+=431.0 amu and MNa^+ =452.9 amu and 36-42 (VGGVVIA), MH^+=614.2 amu and MNa^+ =637.2 amu.

In conclusion cerebrovascular βA carboxy terminal fragment is made of 42 amino acid residues. however the fragments containing the last two residues are less soluble and therefore less likely to be seen. Roher *et al.*, have shown that the modification occurs endogenously (1). Mass spectrometry was a very effective tool in the study of βA because most fractions contained a mixture of peptides which could not always be easily detected by Edman degradation.

ESMS OF HUMAN SERUM AMYLOID P COMPONENT: CONFIRMATION OF THE STRUCTURE AND ANALYSIS OF THE ROLE OF THE GLYCAN.

M.B. Pepys, G. Noble and J.R. Gallimore, RPMS, Hammersmith Hospital, London, W12 0NN, UK.
S. Amatayakul-Chantler, T.W. Rademacher and R.A. Dwek, Glycobiology Institute, Oxford University, Oxford, OX1 3QU, UK.
T. Hutton and S. Lowes, Fisons Instruments/VG BioTech, Altrincham, WA14 5RZ, UK.

The pentraxins are a family of plasma proteins conserved among all vertebrates. In man the two members are C-reactive protein (CRP) and serum amyloid P component (SAP).

SAP is not an acute phase protein but although it is present at rather stable levels its synthesis is highly regulated. Each molecule consists of 10 glycosylated polypeptide subunits arranged in two pentameric discs interacting face to face. Each subunit bears a single typical complex N-linked bi-antennary oligosaccharide chain, which is uniquely homogenous and invariant. SAP is the precursor of amyloid P component (AP) which is deposited together with amyloid fibrils in all forms of amyloidosis.

The structure of the N-linked glycan at Asn 32 has lately been elucidated following hydrazinolysis, and electrospray mass spectrometry has confirmed the mass of the SAP subunit, 25462Da, corresponding exactly to that of the known amino acid sequence plus the oligosaccharide. This investigation was carried out to establish whether any modifications to SAP are associated with the development of amyloidosis and to confirm the desialylation and degalactosylation procedures used in this study.

SAP and AP were isolated and purified by affinity and gel filtration chromatography. SAP was isolated from pooled normal human serum and malignant effusion fluid. AP was extracted from tissues of individual patients with amyloidosis.However, SAP was desialylated and this asialo SAP was the degalactosylated.

Samples were dialysed extensively against distilled water and lyophilised before reconstitution in aqueous acetonitrile with 0.5% formic acid to a concentration of approximately 20pmol/µl. 10µl. The samples were introduced into the electrospray ionisation source of a Fisons Instruments/VG BioTech Platform single quadrupole mass spectrometer.

Studies of the clearance of ^{125}I labelled normal and asialo-SAP were undertaken in 3 normal healthy volunteer controls (all male, ages 32, 33.4 and 36 years) with more frequent early time points for the asialo protein samples. An imaging study after injection of ^{123}I-asialo-SAP was also conducted on the IGE Starcam gamma camera.

The spectrum shown in Figure 1 is that obtained from SAP isolated from pooled normal human serum. The raw data has been subjected to the Maximum Entropy algorithm to produce this spectrum. The major component of SAP has a measured Mr of 25462.5 within 0.1Da of the calculated Mr 25462.4 for the disialated form of the glycoprotein. Serum amyloid P component isolated from a particular

preparation of malignant effusion fluid SAP differed from other preparations in having only 45% of its oligosaccharide moieties disialated, and 40% monosialated and 15% asialated. These differences were precisely confirmed by high voltage electrophoresis of the oligosaccharides released by hydrazinolysis.

The molecular mass of the major component of the AP isolated from amyloid deposits in tissues from two different patients was also consistent with the disialated form of the glycoprotein.

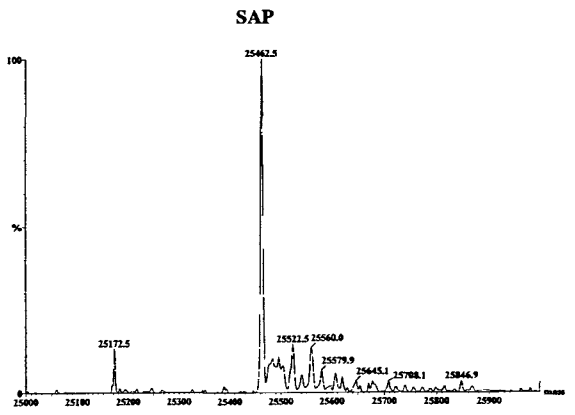

Figure 1

The spectrum obtained in from the neuraminidase preparation confirms that the major component has a Mr of 24882.3Da consistent with the loss of 2 sialic acid (N-acetyl neuraminic acid) groups. Following intravenous injection of ^{125}I labelled asialo SAP there was very rapid clearance from the plasma with 90% of the activity removed by 30 minutes.Whole body scintigraphy after injection of ^{123}I-asialo SAP demonstrated extremely rapid and selective uptake of tracer in the liver which was 'hotter' than the heart blood pool after only 80 seconds. By 40 minutes tracer released from catabolised SAP appeared in the kidneys. Thereafter, radioactivity rapidly appeared in the urine and accounted for 80% of the injected dose by 24 hours and virtually 100% by 3 days. These results contrast sharply with those obtained previously from the same individuals following ^{125}I labelled normal control SAP.

Confirmation of removal of 2 galactose residues from asialic SAP was also demonstrated with the major component molecular mass of 24553.7 consistent with removal of 2 sialic acids and 2 galactose residues from normal control SAP.The clearance rate of this degalactosylated SAP in mice was intermediate between that of asialo and normal SAP.

The results confirm that there is no heterogeneity or polymorphism in either the protein or the glycan moeties of SAP in health and disease, and that AP is unaltered with respect to SAP. Loss of, or deliberate removal of, the terminal sialic acid residues of the SAP oligosaccharide caused SAP to be extremely rapidly cleared from the circulation in vivo, both in experimental animals and in man. Desialated SAP was taken up in the liver by the terminal galactose receptor and catabolised, revealing directly for the first time in man, the carbohydrate-dependent clearance and metabolism of a plasma protein.

Identification of Water Insoluble Human Lens Crystallins by Mass Spectrometry

Laura R. Miesbauer, Jean B. Smith, Zhucheng Yang, Xuanjing Zhou, Yiping Sun†
and David L. Smith
Department of Medicinal Chemistry and Pharmacognosy, Purdue University,
West Lafayette, IN 47907 and
†Procter & Gamble Co., Miami Valley Laboratories, P.O. Box 398707, Cincinnati, OH 45239

In the process of aging or as a factor in disease, the structural proteins in the lens of the eye (the crystallins) become insoluble. Increasing amounts of insoluble crystallins decrease the transparency of the lens by altering the refractive index and scattering light, resulting in cataract. Little is known about the structural changes that occur in the crystallins and the mechanisms that cause them to become insoluble. The goal of our research is to identify the crystallins that are present in the water insoluble portion of the lens and to characterize the post-translational modifications that make these crystallins differ from the water soluble crystallins.

Using ESIMS of intact proteins and FABMS analysis of peptides from tryptic digests, we have identified the major crystallin components in the water insoluble-guanidine soluble portion of human lenses. The amino acid sequences for the primary gene products of α-crystallin, αA and αB, are known, and α-crystallins are thought to be the major constituent in the water insoluble lens. The primary sequences of the human β-crystallins (except βA3, βB2, and part of βB3), are not known, and the γ-crystallin sequences (which include βs, γA, γB, γC, and γD) have not all been confirmed. FABMS analysis of water soluble β- and γ-crystallins allowed a general classification of the water insoluble components that could not be assigned to known crystallin sequences.

Normal human lenses, aged 20-27, were obtained from the National Disease Research Interchange (NDRI) and stored at -70 °C until use. Homogenization of a lens in Tris buffer (pH 7.4, 4 °C) extracted the water soluble portion which could be separated into α- , β- and γ-crystallins by Sephadex G-200 gel filtration The water insoluble pellet was extracted with a Tris buffer containing 6M guanidine hydrochloride, and the guanidine soluble portion was fractionated by gel filtration on Sephacryl S-300 into high molecular weight, dimeric and monomeric species .

The region corresponding to monomers was crudely fractionated into five major fractions (Figure 1) on a C4 HPLC column (0.46 x 15 cm, Vydac, Hesperia, CA) with a gradient of 0.1% TFA in water/acetonitrile. Each fraction was analyzed by ESIMS on a Sciex API III triple quadrupole mass spectrometer. The fractions were also digested with trypsin (1:50 enzyme:protein, 37 °C, 4 hr), separated into peptides on a C18 HPLC column (0.46 x 25 cm, Vydac) and analyzed by FABMS on a Kratos MS-50 mass spectrometer. Peptides were identified by the masses of peptides expected to be generated by trypsin, and by comparison with similar analyses of the water soluble crystallins.

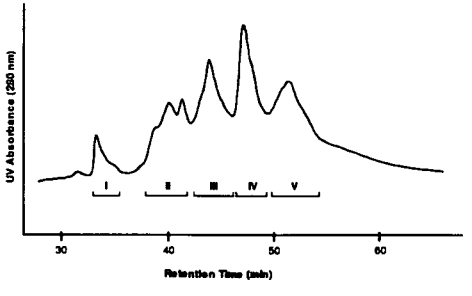

FIGURE 1: C4 HPLC separation of the water insoluble-guanidine soluble portion of human lens.
The five sections collected and analyzed are indicated.

The first water insoluble HPLC section contained βB2 as the major component, as evidenced by ESIMS analysis which gave a molecular weight of 23,290 Da (calculated MW 23,291). The tryptic digest of the second HPLC section identified the complete sequence of βs, portions of γC and γD, and N-terminally degraded αA and αB. The third region contained all of the αB protein with some portions of βs, γC and γD. ESIMS of the third region indicated αB, αB - Lys, αB + PO_4 and αB + $2PO_4$ (Figure 2). The last two HPLC fractions contained αA as a major component, along with some of the βs sequence. The identities of other minor components, possibly β-crystallins whose amino acid sequences are not known, could not be unambiguously assigned. The ESIMS analysis of the fifth section showed the presence of αA at 19,950 (calculated MW 19,952), αA - Ser at 19,865 (calc. 19,865), and αA + PO_4 at 20,030 (calc 20,032).

All major classes of crystallins, α, β and γ were present in the water insoluble-guanidine soluble portion of normal human lenses, with α-crystallin as the most abundant component. Proteins found whose primary sequences are known include αA, αB, βA3, βB2, βB3, βs, γC and γD. Modifications include N-terminal degradation, C-terminal degradation and phosphorylation of αA and αB. Extensive deamidation of Asp and Glu residues, thought to promote insolubilization, was not present, although a small amount of partial deamidation was indicated.

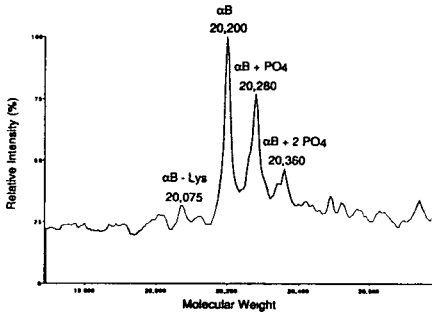

FIGURE 2: ESIMS analysis of Section III from the HPLC separation of water insoluble-guanidine soluble human lens crystallins. The major components of this section are αB (calculated MW 20,201), αB - Lys (20,075), αB + PO_4 (20,081) and αB + 2 PO_4 (20,361)

In spite of denaturing conditions in the chromatographic isolation steps (6M guanidine or 0.1% TFA), it appears that the crystallins still exist, to some extent, as aggregates because some proteins (most notably βs) eluted in nearly all HPLC sections. Since only the monomeric portion of the guanidine soluble extract was analyzed, intermolecular covalent crosslinks were not found but are believed to be the principal components of the higher molecular weight species.

ESIMS was unable to detect the components of sections II and IV, likely because of the large number of components present. Additionally, minor components in the remaining HPLC sections that were indicated by FABMS of the tryptic peptides were not identified by ESIMS. Better separation of the water insoluble proteins will help to identify more of the minor components and modifications that may be present. To this end, we are investigating ion exchange HPLC chromatography in addition to reversed phase HPLC to further purify the guanidine soluble crystallins. The results of this survey of normal human lenses will be used to identify post-translational modifications that may be responsible for insolublization of crystallins in aged and cataractous lenses.

Elucidation of High-order Structure in Lens α-crystallin by Continuous-Flow HPLC FABMS

Yaoqing Liu * and David L. Smith
Department of Medicinal Chemistry
Purdue University, W. Lafayette, IN 47907

α-crystallin consists principally of two gene products, αA and αB. These gene products have molecular weights of approximately 20 kDa, but aggregate to form much larger products with molecular weights of 1,000 kDa. Some of the changes in the eye lens accompanying aging and cataractogenesis have been attributed to changes in the high order structure of α-crystallins. To understand the role of α-crystallin in aging and cataract at the molecular level, it is essential to have analytical methods suitable for detecting and characterizing changes in its high order structure.

We report here a new analytical method based on the rate at which peptide amide hydrogens undergo isotopic exchange as a new probe of the high order structure of α-crystallins. Intramolecular hydrogen bonding, as found in α-helices and β-sheets, dramatically reduces hydrogen exchange rates. Likewise, solvent shielding by hydrophobic residues can decrease the rate of hydrogen exchange. Although the potential of peptide amide hydrogen exchange as a probe of high order structure in proteins has long been recognized, experimental methods for quantifying hydrogen exchange limited applications of the method to relative small proteins. The new method based on protein fragmentation and continuous-flow HPLC FABMS has been applied to α-crystallin. Following a deuterium exchange-in period, isotopic exchange is quenched by decreasing the pH. The partially deuterated protein is fragmented with pepsin into peptides, which are analyzed by HPLC FABMS to determine their deuterium content.

Time course data, as shown in Fig.1, are used to calculate the rate constants for

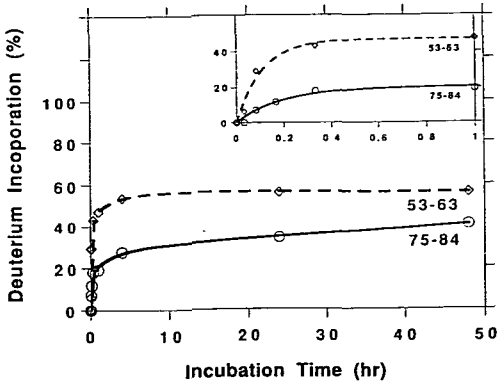

Fig.1

Plot of the deuterium content of 2 segments of αA-crystallin (αA^{53-63} & αA^{75-84}) as a function of the incubation time (2 min. to 48hr). The insertion is a plot of incubation time from 2 min. to 1hr.

hydrogen exchange in specific segments of the protein. Results of this study indicate that many peptide amide hydrogens in α-crystallin exchange rapidly ($k > 10\ hr^{-1}$), while others exchange slowly ($k < 10^{-4}\ hr^{-1}$). As the rates of deuterium exchange into specific segments become available, regions that are either in β-sheet structure, or shielded from the solvent will be identified by their very slow rates of hydrogen exchange. Likewise, regions of random coil and full access to the solvent will be indicated by their high rates of hydrogen exchange.

Since the rate of hydrogen exchange is critically dependent on the hydrogen bonding of the peptide amide hydrogens, it may be used to localize changes in protein structure. The possibility of detecting structural changes has been demonstrated by *determining the rate of hydrogen exchange as a function of the deuterium exchange-in* temperature. The results of some segments (Fig.2) show that hydrogen bonding weakens with increasing temperature, which indicates that this region of the protein is particularly susceptible to thermal destabilization.

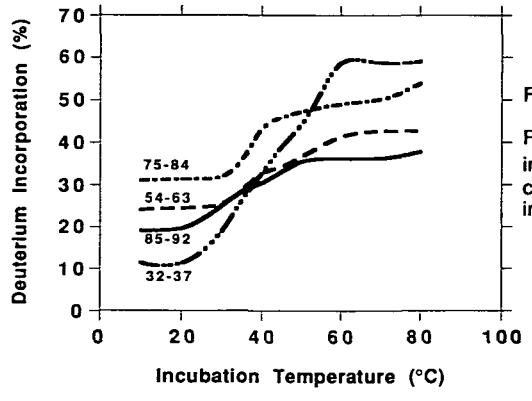

Fig. 2

Plot of deuterium incorporation into specific segments of αA-crystallin as a function of the incubation temperature.

The present results demonstrate that the combination of hydrogen exchange and mass spectrometry may be a useful new tool for investigating the high order structure, and particularly for detecting differences, in various forms of α-crystallin. Hydrogen exchange is a particularly useful probe of high order structure because it may give information about the entire length of the backbone of proteins, rather than a few specific residues.

Disadvantages of the experimental methods described here include: (1) Peptides traceable to all segments of the protein may not be found when pepsin is used to fragment the protein. A possible solution might be to use other acid proteases in addition to pepsin; (2) These measurements are technically very difficult to perform, and require extensive use of a mass spectrometer that is costly to purchase and maintain.

ANALYSIS OF THE BACITRACIN COMPLEX BY LC-IONSPRAY-MS*

M Morris and R K Boyd
Institute for Marine Biosciences, National Research Council, 1411 Oxford Street, Halifax, Nova Scotia B3N 3A8, Canada.

Bacitracin is a mixture of polypeptide antibiotics produced by *Bacillus subtilis* and *Bacillus licheniformis*. The mixture has previously been shown to contain at least ten components, of which only the major component, Bacitracin A, and its oxidized counterpart, Bacitracin F, have been fully structurally evaluated. In a recent study three single substitution sites within Bacitracin A, where Ile has been replaced by Val to form the set of related species known as Bacitracin B, were identified using tandem mass spectrometric methods without any prior separation[1]. Although this type of analysis allowed conclusions to be drawn regarding the sites of substitution, a more definitive method would include separation of the components of the mixture prior to analysis by mass spectrometry. The structure of Bacitracin A with the proposed sites of substitution is shown in Figure 1.

Liquid chromatographic separation of the components of the bacitracin complex has been the subject of study of a number of groups, although the use of buffered solvents was required in these procedures[2,3]. We achieved chromatographic separation using a simple linear gradient elution (acidified acetonitrile water solvent system) that gave reasonable separation of some 18 components of the mixture. Semi-preparative extrapolation of this methodology allowed the eighteen fractions to be collected and concentrated for preliminary MS analysis. Owing to the chromatographic overlap of the components of interest ideal fractionation was probably not achieved, so an on-line coupling of the LC to a mass spectrometer *via* an ESI interface was also attempted.

	Bacitracin			
	A	B_1	B_2	B_3
X	Ile	Val	Ile	Ile
Y	Ile	Ile	Val	Ile
Z	Ile	Ile	Ile	Val

Figure 1 Structure of Bacitracins A and B

LC-MS separation and detection was performed on an Hewlett Packard 1090L high-performance liquid chromatograph coupled to a Perkin-Elmer SCIEX API III triple quadrupole mass spectrometer *via* an ionspray interface.

LC Conditions Gradient elution using a solvent ramp of 10-55% MeCN/0.1% TFA in H_2O/0.1% TFA was used at a flow of 0.2ml.min^{-1} into a Vydac 218TP52 column. The eluent from the column was split to allow 10μl.min^{-1} to flow to the mass spectrometer.

MS Conditions Product ion spectra were obtained by selecting the doubly charged precursor ions for the Bacitracins B (m/z 705) and subjecting them to 20V (40eV in the laboratory frame) collisions in the quadrupole collision cell at a collision gas thickness of 3.5 x 10^{14} atoms.cm^{-2}. The resolution of Q1 was set to pass 1.5 Da FWHM, and Q3 was scanned in 0.5 Da steps with 3 ms dwell over the mass range 800 - 1450 (this range was deemed sufficient to provide the information sought), giving a single scan time of 3.9 sec.

* NRCC # 34852

The reconstructed ion chromatogram for the doubly charged molecular ions of the Bacitracin B molecules is shown in Figure 2, extracted from the LC-MS full scan data. This clearly shows the presence of three major components with the molecular weight of 1408 Da, with the possibility of minor components being eluted both before and after the major components (this is probably attributable to the wide resolution used in MS1 to ensure optimum sensitivity.) The MS/MS spectra acquired for these three peaks are shown in Figure 3. The annotation shows the presence of three components where Ile has been replaced by Val, and the points of substitution are clearly confirmed as being at substitution points X, Y and Z in the structure shown in Figure 1.

Post translational modification of recombinant barley α-amylase 1 expressed in yeast, characterized by mass spectrometry.

J.S.Andersen, P. Roepstorff, M. Søgaard* and B. Svensson*.
Department of Molecular Biology, Odense University, Campusvej 55, DK-5230 Odense M, Denmark and *Department of Chemistry, Carlsberg Laboratory, Gamle Carlsberg Vej 10, DK-2500 Copenhagen Valby, Denmark.

The yeast *Saccharomyces cerevisiae* is widely used as a host for recombinant production of heterologuos proteins because desired post translational modification can be obtained in this organism (1). Even though a large number of heterologous proteins are correctly processed in yeast, non-native modifications have also been reported (2). Consequently, structure verification, purity evaluation and determination of post translational modification are important steps in characterizing recombinant proteins. Here we demonstrate the use of electrospray (ES) and matrix assisted laser desorption ionization (MALDI) MS in combination with protein chemical and genetic methods to rapidly assess the nature of post translational modification in the 45 kDa barley α-amylase 1.

Stains, plasmids, plasmid construction and purification of the enzyme followed the described procedures (3 and 4). ES-mass spectra were acquired on a Vestec model 201 single-quadrupole mass spectrometer (Vestec Corporation Houston, TX, USA). The instrument was independently calibrated using β-lactoglobulin. MALDI-mass spectra were recorded on a LDMS prototype instrument (ABI, Sweden AB, Uppsala) with α-cyano-4-hydroxycinnamic acid as matrix and human insulin as internal calibrant. Reduction and alkylation of cysteines followed standard procedures using dithiotreitol and 2-vinylpyridin. Neutral hexose was determined by the phenol-sulfuric acid method and enzymatic activity by Phadebas Blue Starch (Pharmacia, Uppsala). Alkylated rAMY1-1 was cleaved with CNBr (80% TFA at 20°C for 20h) and rAMY1-4 was digested with endoproteinase Lys-C (0.4M urea, 50mM NH_4HCO_3, pH 7.8 at 37°C for 3h, substrate: enzyme ratio 1:100 (w:w)).

Four forms of recombinant barley α-amylase 1 (rAMY1-1 to rAMY1-4) with different pI and enzymatic activities (3,4) are secreted from yeast cells harboring an AMY1 expression vector. M_r determination of the four forms by ESMS indicated that two forms lack C-terminal Arg-Ser and that two forms have been modified by glutathione leading to misfolding and inactivation of the enzyme. The invariant presence of a minor components 324Da below that of the major species suggested the presence of O-glycosylation in the major product. Taking these modification into account, however, a mass discrepancy of 30Da above that inferred from the cDNA sequence could not be explained.

Lack of C-terminal Arg-Ser was in agreement with previous C-terminal sequence data (3). Genetic removal of Arg-Ser resulted in the production of only two forms (rAMY1-1ΔRS and rAMY1-2ΔRS) as verified by M_r determination. Glutathionylation of a Cys residue was verified by reduction and alkylation followed by M_r determination. Furthermore, rAMY1 mutants were expressed with each of the four Cys residues mutated to Ala (C95A, C106A, C125A and C321A). Mutation of Cys 95 to Ala and truncation of C-terminal Arg-Ser (rAMY1ΔRS, C95A) led to the secretion of a single fully active rAMY1 form.

The O-glycosylation was verified by chemical analysis. From MALDI-mass spectra of the peptide mixture obtained after CNBr cleavage and endo Lys-C digest it was possible to locate the O-glycosylation to Thr_{410} and the mass discrepancy to the region Ala_{283}-Met_{298}. Subsequent Edman degradation of isolated peptides identified by MALDI-MS led to the identification of the sequence error Ala_{284}→Val and verification of the O-glycosylation.

CAPILLARY LIQUID CHROMATOGRAPHY - ELECTROSPRAY TANDEM MASS SPECTROMETRY REVEALS EXPRESSION OF MORE THAN ONE RAT PROOPIOMELANOCORTIN

G.J. Feistner[1], T.D. Lee[1], K.F. Faull[2], P.C. Andrews[3], and P. Roepstorff[4]

[1]Beckman Research Institute of the City of Hope, Duarte, CA 91010, [2]Center for Molecular and Medical Sciences, Mass Spectrometry, University of California, Los Angeles, CA 90024, [3]Department of Biological Chemistry, University of Michigan School of Medicine, Ann Arbor, MI 48109, [4]Department of Molecular Biology, University of Odense, DK-5250 Odense, Denmark.

We have previously suggested the use of peptide charting, i.e. the componential analysis of peptide/protein mixtures in a given tissue (extract), for comparing peptide profiles between different species and/or tissues, as well as to detect responses of the neuroimmunoendocrine system to endogenous regulators, stress, and disease. In the course of exploring the feasibility of peptide charting for experimental models in the rat, we have consistently observed discrepancies between measured and DNA-derived molecular masses for the endorphins (End) and γ-lipotropin (LPH). These discrepancies may be due to pro-opiomelanocortin (pOMC) heterogeneity between different rat strains, to expression of more than one pOMC gene, or to sequencing errors. The DNA data were obtained on Long-Evans rats, whereas we routinely use Sprague-Dawley or Wistar rats for our experiments. Also, the existence of at least two rat pOMC genes was proposed in the original report on the pOMC DNA sequence, but subsequent molecular biological studies suggested that only one gene would be expressed. It is remarkable that no comprehensive analysis of rat pOMC has ever been performed at the protein level. To address this problem, capillary LC-ES-MS and LC-ES-MS/MS studies were performed on Long-Evans rats. No differences to the other two strains were observed.

Summarizing our results, Fig. 1 shows the mass chromatograms for two variants each of joining peptide (JP), γ-LPH, and β-End, in the approximate ratio of 1:7 to 1:10. This ratio was fairly constant between batches and not affected by boiling the extract, thus arguing against artefact generation. Based on molecular mass and LC-ES-MS/MS (Fig. 2) data, the more abundant JP-1 was found to be identical to the one deduced from rat genomic DNA data. The most prominent ion in the LC-ES-MS/MS spectrum of JP-2 was isobaric with Y_5 + of JP-1, whereas the corresponding B_{13} + ion appeared at m/z 1300 in JP-1 but at m/z 1282 in JP-2. Another ion pair, Y_7 + (811)/B_{11} + (1074/1057) confined the sequence difference to the eleven N-terminal amino acids, whereas a series of Y and Z ions (Y_{16} 2+ 842/835; Y_{14} 2+ 713/704, Z_{13} + 1308/1290, Z_{12} + 1236/Y_{12} + 1234, Y_{11} + 1176) further confined the substitution to positions 8-11. A single amino acid substitution of Asp-9 by Pro is likely. The LC-ES-MS/MS spectrum of the pentuply protonated molecular ion of γ-LPH-1 (Fig. 3) shows a series of triply and quadruply charged C-terminal fragments that are consistent with [His12]-γ-LPH. The reported DNA data suggest Gln-12, but we have confirmed His-12 by Edman-type sequencing. The LC-ES-MS/MS spectrum of γ-LP-2 is very similar to that of γ-LP-1 except that many C-terminal Y^{4+}-ions are shifted by about 4 u. Y_{28} 4+ (827/823) and Z_{25} 3+ (979/979) confine the substitution to between residues 25 and 28. No single amino acid substitution can account for the mass difference, but six (fifteen) possibilities for two (three) simultaneous amino acid substitutions exist. With regard to β-End, we find molecular ions that are consistent with the DNA-derived [Val26]-β-End, but more abundant is [Ala26]-β-End as is found in cow and other mammals. Rat Ac-[Ala26]-β-End(1-27) was confirmed by a series of B and Y ions in the LC-ES-MS/MS spectrum of its triply charged molecular ion. Due to low abundance, [Val26]-β-End could not yet be corroborated by a corresponding product ion spectrum.

Characterization of Three Isoforms of Soybean Agglutinin by ESI MS.

D.K. Mandal, G.A. Orr, E. Nieves*, Q Yu, J. Roboz and C.F. Brewer
Albert Einstein College of Medicine; Bronx, NY 10461 and
The Mt. Sinai School of Medicine, New York, NY

Lectins are proteins or glycoproteins that bind to specific carbohydrates and are widely distributed in nature. They are found in plants, microorganism, bacteria and animals and may exist as multiple isoforms. Soybean agglutinin (SBA) which is a plant lectin specific for D-galactose and D-N-acetylgalactosamine is a tetrameric glycoprotein with one Man9 oligomannose type chain per monomer. SBA consist of 4-5 isolectins having similar compositions and binding activities. Despite the widespread use of SBA in biological studies, little information is available on the nature of these isolectins.

Our objective was to use electrospray mass spectrometry to characterize three isoforms of SBA and thus provide insight into the structural relationships and hence possible mechanisms of formation of these various isoforms.

Native SBA was purified from the crude extract of soyfluff by affinity chromatography and chromatofocusing. The materials in each peak was pooled separately and the three isoforms of SBA were subjected to (repeated) rechromatofocusing either on a PBE 94 column or a Mono P column. The isolectins SBA-I, SBA-II and SBA-III were denatured in 6 M guanidine hydrochloride and subjected to RP-HPLC using a Aquapore RP-300 (C-8) column. Electrospray mass spectrometry was performed on the separated HPLC fractions and 10-20 μL aliquots injected directly into the electrospray source. The mobile phase was methanol-water (1:1 v/v) with 1% formic acid; flow rate into the source was 5 μL/min.

The HPLC profiles of SBA-I, SBA-II and SBA-III are shown in Figure 1A, 1B and 1C, respectively. The profiles are similar for all three isolectins with two major peaks (peak 1 and peak 3) of approximately equal intensity and one minor peak (peak 2). However, peak 1 of SBA-II (Figure 1B) showed a doublet labeled as 1a and 1b. Electrospray ionization mass spectrometry was performed for each peak from the HPLC runs of SBA-I, SBA-II and SBA-III. A typical reconstructed mass spectrum for the different peaks obtained from the HPLC of SBA-II is presented in Figure 2. The ESI-MS data for the different peaks obtained from the HPLC run of SBA-I, SBA-II and SBA-III are summarized in Table I.

The calculated mass of the intact lectin monomer from the amino acid sequence of the protein deduced from complementary DNA (cDNA) sequencing of the corresponding gene including a Man9 oligomannose type chain is 29,438 daltons. The complete sequence of the protein representing 253 amino acid residues is shown in Figure 3 and is referred to as the intact subunit α. This intact α subunit was found in HPLC peak 3 of all three isoforms of SBA. The lower masses of the subunits are attributed to the fragmentation from the C-terminus of the protein. The formation of a 240 residue subunit is shown in Figure 3 and is labeled as the β subunit. A 243 residue subunit is shown in Figure 3 and is referred to as the γ subunit.

Characterization of SBA-I. HPLC peak 1 would correspond to a 240 residue β subunit. The component in HPLC peak 2 was not detected in ESI-MS. However, the 2 major peaks (peak 1 and peak 2) were of approximately equal intensity, suggesting that SBA-I consist primarily of α and β subunits and it's composition may be considered as $\alpha_2\beta_2$ in terms of major subunits. Also, the β subunit involves loss of 2 acidic residues (D-243 and E-251) which would account for the highest pI (7.0) for SBA-I.

Characterization of SBA-II. HPLC peak 1 is a doublet of which peak 1a represents the 240 residue β subunit, and peak 1b showed 2 strong peaks in ES-MS for 28,022 daltons (β subunit) and 28,352 daltons representing the 243 residue γ subunit. The 243 and 246 residue subunits show a loss of one acidic residue (E-251) and the β subunit a loss of two

acidic residues. As the intensity of HPLC peaks 1 and 3 were about equal, the compositions of SBA-II may be approx-imately considered as $\alpha_2\beta\gamma$ in terms of major subunits present. The presence of both the β and γ subunits would account for the reason the pI (6.85) for SBA-II is lower than that of SBA-I (pI 7.0).

Characterization of SBA-III. HPLC peak 1 yielded a molecular mass for the 243 residue γ subunit along with 2 minor molecular masses of 28,043 daltons (α subunit) and 27,530 daltons (236 residue subunit). The 243 residue γ subunit involves the loss of one acidic residue (E-251) from the intact subunit, suggesting that the approximate composition of SBA-III may be $\alpha_2\gamma_2$ in terms of major subunits accounting for a lower pI value of 6.7 than that of SBA-II.

The results demonstrate that ESI-MS can be used to characterize the isoforms of SBA. The three isoforms of SBA are primarily due to two similar C-terminal fragmented subunits combined with two intact subunits to form a tetrameric isolectin. The major fragmented subunits are shown to be the 240 and 243 residue subunits, which involves cleavage on an aspartic acid residue, namely D-240 and D-243, respectively.

TABLE 1

Molecular masses of 3 Isoforms of SBA

Isolectin	Peak	Observed mass	Correlated nearest mass and number of AA residues: Average mass	# AA residues
SBA-I	1	28,068	28,001	240 (β)
	2	not detected		
	3	29,437	29,438	253 (α)
SBA-II	1a	28,006	28,001	240 (β)
	1b	28,022 (strong)	28,001	240 (β)
		28,352 (strong)	28,326	243 (γ)
		28,667 (moderate)	28,628	246
	2	29,333	29,324	252
	3	29,448	29,438	253 (α)
SBA-III	1	27,530 (moderate)	27,571	236
		28,043 (weak)	28,001	240 (β)
		28,376 (strong)	28,326	243 (γ)
	2	29,372	29,324	252
	3	29,434	29,438	253 (α)

Profiling Phosphorylation in the High Molecular Weight Rat Neurofilament Protein (NF-H) by ESI-MS

D. M. Sheeley[1], E. Elhanany[2], H. Jaffe[2], W. T. Link[2], H. Gainer[2], H. C. Pant[2], and H. M. Fales[1]

[1]LBC, NHLBI and [2]LNC, NINDS, National Institutes of Health, Bethesda MD 20892

Within the axon, structures essential for maintaining cytoskeletal stability have been identified as neurofilaments, which occur in long straight bundles, and interact with microtubules and other cytoskeletal elements. The neurofilament is composed of three proteins, the light, medium, and heavy neurofilament proteins (NF-L, NF-M, and NF-H), collectively called the "neurofilament triplet". These proteins have head and alpha-helical rod domains which contribute to the neurofilament structure. NF-M and NF-H also have heavily phosphorylated C-terminal tail domains which project outward from the neurofilament body[2]. The phosphorylation of these proteins seems to change during transport and assembly of neurofilaments within the axon. Phosphorylation may regulate the rigidity of the tail domain, and affect its interactions with other structures[1].

In this study, the extent of phosphorylation of the NF-H protein has been partially characterized. The entire NF-H protein has a molecular weight of 200 KDa. The tail domain accounts for approximately 70 KDa, and contains over fifty potential phosphorylation sites. The NF proteins contain a recurring tripeptide motif "Lys-Ser-Pro" (KSP) which appears to be the target for a specific kinase activity. Following digestion with chymotrypsin to remove the head and rod domains, cyanogen bromide digestion breaks the tail domain into three fragments **(Figure 1)**. Peptides obtained by gel filtration following CNBr digestion were analyzed directly by ESI-MS without intervening chromatography in order to evaluate the populations of phosphorylation states present. Phosphorylation at specific sequences has also been evaluated by ESI-MS and Edman degradation.

The C-terminal fragment, CNBr I, contains several serine and threonine residues, but none are in KSP repeats. The molecular weight obtained by ESI -MS for this fragment agrees with the predicted sequence, confiming that it is not phosphorylated. The absence of phosphorylation in this peptide supports the hypothesis that the KSP repeat is a consensus sequence for phosphorylation of the neurofilament proteins and might be the target for specific kinases. The second fragment, CNBr II, contains five KSP repeats. The deconvoluted ESI-MS spectrum for this fragment **(Figure 2a)** shows a mixture of peptides modified with from 3 to 6 phosphates. Because there are only 5 KSP repeats in this fragment, they cannot account for all the phosphorylation observed. There are two sequences in this fragment which are similar to the KSP consensus sequence. One is KTP, and the other is an RSP. One or both of these motifs may be a substrate for phosphorylation. If this fragment is treated with alkaline phosphatase, most of the *phosphate is removed, resulting in a new distribution of peaks in the mass spectrum* **(Figure 2b)**. The molecular weight of the completely dephosphorylated peak corresponds to the anticipated amino acid sequence.

In studies such as this one, MSanalysis provides a particular advantage with repect to mapping and quantification of post-translational modification. By looking at a whole population of peptides, we can get a "snapshot" of phosphorylation. Subsequent characterization of specific peptides can easily assign sites of attachment. Extensive phosphorylation reduces the average charge observed, but not in a one to one relationship, and appears to adversely affect ionization efficiency.

PRIMARY STRUCTURE CHARACTERIZATION OF LEGUME LECTINS; SEQUENCE ASSIGNMENT AND IDENTIFICATION OF POST-TRANSLATIONAL MODIFICATIONS USING LC-MS AND LC-MS-MS+

*P. Thibault[1], D.C. Watson[2], N.M. Young[2]; [1]Institute for Marine Biosciences, National Research Council, 1411 Oxford St., Halifax, Nova Scotia Canada B3H 3Z1; [2]Institute for Biological Sciences, National Research Council, 100 Sussex Dr., Ottawa, Canada, K1A 0R6.

Lectins are a diverse group of proteins of plant and animal origin displaying a high affinity for carbohydrates. These complex proteins were first recognised for their capability to agglutinate a variety of animal cells by binding to cell surface glycoproteins and glycolipids. Considerable interest in these proteins has arisen following the discovery of their important role in cell recognition processes, amongst which are microbial adhesion and adhesion of white blood cells to blood vessels [1].

Most of our current knowledge of the primary structures of lectins has been gathered in the last decade through extensive chemical studies from lectins isolated from leguminous plants. However, such studies are complicated by the diversity in structural features of these complex molecules, and the complete primary sequence is known for only a few. The most well characterized member of the legume lectin family is concanavalin A, a protein isolated from Jackbean. A large number of the legume lectins are single-chain proteins, but sequences deduced from cDNA methods are approximately fourteen residues longer than those obtained from protein sequencing [2], indicating C-terminal trimming. This type of modification was reported recently for the peanut agglutinin (PNA) lectin using ionspray mass spectrometry and indicated that this protein undergoes imprecise C-terminal proteolytic processing resulting in "ragged ends" [3]. In addition to this, many plant lectins are glycosylated which render their complete characterization more difficult.

As an extension to earlier studies on PNA [3], the present investigation evaluated the application of LC-MS and LC-MS-MS with ionspray ionization for the characterization of other leguminous lectins. An example of single-chain lectins examined here is presented in Figures 1 and 2 for a glycoprotein isolated from *Erythrina corallodendron* (ECL). The ionspray mass spectrum (Figure 1) shows an intense series of multiply-protonated ions extending from 15 to 33 charges. The molecular weight of this protein as calculated from the multiply-protonated ion series is 28763 Da, approximately 800 Da more than the mass deduced from the cDNA sequence [4]. Additional components spaced by ≈ 147 Da are also observed in Figure 1 suggesting a pattern of microheterogeneity where different numbers of fucose residues are attached to the ECL glycopeptides. Earlier studies using cDNA cloning and protein analyses [4] have indicated that ECL contains a 26 residue long leader peptide, and the cDNA sequence shows an extra 12 amino acids at the C-terminal end compared to the mature protein. Additional experiments were thus required to answer some of the discrepancies observed between molecular weights determined by ionspray mass spectrometry and those deduced from either protein sequencing or cDNA cloning [4]. The ionspray LC-MS analysis corresponding to the injection of 70 pmols of the tryptic digest of ECL is shown in Figure 2, and permitted identification of most of the predicted peptides. Peptides arising from CNBr cleavage of the ECL lectin were also subjected to LC-MS analyses and provided a complete mapping of the protein sequence. More importantly, these LC-MS analyses permitted identification of glycosylation sites at residues 17 and 113. LC-MS-MS experiments (not shown) confirmed that the carbohydrate attached to residue 113 has the following sequence: GlcNAc-(Fuc)-GlcNAc-$(Hex)_3$ Xyl. The microheterogeneity observed on the ECL lectin is thus likely to arise from the abstraction of fucose on either site of glycosylation.

Similar mass spectrometric analyses were also conducted on a series of more than ten leguminous lectins. In the simplest case, sequence assignments could be made directly by comparing the observed molecular weight with that deduced from published data. This procedure enables a rapid identification of both single chain proteins and other lectins possessing light (α) and heavy (β) chains. However, more complex protein preparations required LC-MS analyses so that overlapping multiply-protonated species could be separated from each other.

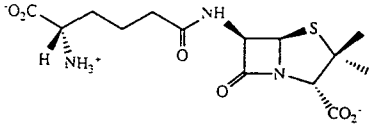
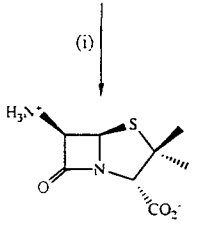
Investigations into the Post-translational Modification and Mechanism of Isopenicillin N:acyl-coenzyme A acyltransferase using Electrospray Ionisation Mass Spectrometry.

R T.Aplin, P.L.Roach,C V Robinson and C J Schofield. The Oxford Centre for Molecular Sciences, The Dyson Perrins Laboratory, Oxford University, Oxford, U K. OX1 3QY

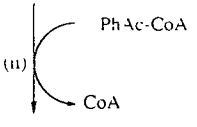
The final step in the production of penicillins with hydrophobic side chains in *Penicillium chrysogenum* is carried out by isopenicillin N acyl-CoA acyltransferase (AT) This enzyme removes the α-aminoadipoyl group of isopenicillin N and replaces it with an acyl group from an acyl CoA (Fig 1)

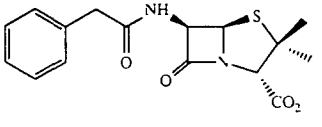


Isopenicillin N (IPN)



6-aminopenicillanic acid (6-APA)





Penicillin G

Figure 1 The biosynthesis of penicillin G from isopenicillin N AT catalyses both steps (i) and (ii)

Post-translational Modifications

The ESI MS of purified AT shows a mixture of four components

A	11497.42 ± 1 01 Da
B	11603 73 ± 1 03 Da.
C	28003 67 ± 1 99 Da
D	28457.35 ± 2 87 Da

The molecular masses of A and D are consistent with the cleavage of a single bond between Gly102 and Cys103 in the preprotein (Calculated masses. A 11498 20, D 28459 67) The mass of component B was consistent with the modification of the α-subunit by the addition of a phenoxyacetate group This was shown to originate from the growth medium by replacement of the phenoxyacetate in the growth medium with phenylacetate or 4-bromophenylacetate.

Acyl Transfer Reactions

A range of acyl CoAs are accepted by AT in the presence of 6-aminopenicillanic acid (6-APA) to yield acylpenicillins ESI MS of AT following incubation with a series of acyl CoAs (hexanoyl, hex-3-enoyl, heptanoyl and phenylacetyl) showed acylation of the β-subunit, both components C and D undergoing acylation That this is a specific process is shown by the addition of the substrate 6-APA to the acylated AT and repeating the electrospray analysis. The species corresponding to the acylated β-subunit are completely absent. Addition of a nonsubstrate amino acid β-alanine has no effect on the abundance of the species corresponding to the acylated β-subunit

In summary, ESI MS has determined the position of the post-translational cleavage of AT and identified the apparent modification by acylation *in vivo* of the α-subunit by exogenously added substituted acetic acids. It has also allowed the direct observation *in vitro* of the specific transfer of an acyl group from a number of acyl CoAs to the β-subunit. Whether this apparent acylation reflects an event in the *in vivo* transformation of isopenicillin N to penicillin G cannot be unequivocally stated at this stage and is the subject of current mechanistic studies

Recombinant Human Neurotrophin-4 (NT-4): Characterization of Protein Folding by Matrix-Assisted Laser Desorption and Electrospray Ionization Mass Spectrometry.

Tanuja Chaudhary, Henryk Cudny, Somesh Nigam, Nancy Tobkes, Candace Seneca and *James E. Labdon,
Regeneron Pharmaceuticals, 777 Old Saw Mill River Road, Tarrytown, NY 10591

Neurotrophic factors are a family of 122-130 residue dimeric proteins which regulate the growth and differentiation of neuronal precursor cells and promote the survival of differentiated neurons in vivo and in vitro. Human NT-4 (also referred to as NT-5) [1-2] is the most recent member of this family, which also includes nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF) and Neurotrophin-3 (NT-3). The neurotrophins exhibit considerable sequence identity and contain six invariant cysteine residues, suggesting similarities in their tertiary structures.

ESI spectra of E. coli derived, human NT-4 (Fig. 1), obtained in unfolded and folded/oxidized forms are in close agreement with their calculated average masses of 13,923 and 13,917 respectively. The deconvoluted spectra differ in mass by 6 amu, reflecting the formation of three disulfide bonds. There are striking differences between the charge envelopes, resulting from a smaller number of sites for protonation in the folded form. Partially-reduced preparations of NT-4 show three peaks by reversed-phase HPLC(Fig.2), resulting from a mixture of the folded, unfolded and partially-folded forms of the protein. ESI-MS analysis of the early-eluting peak 1 (15 min.) was consistent with the native structure while peak 2 had a spectrum with a charge envelope between reduced/unfolded NT-4 (compare to Fig. 1). Fully reduced and unfolded NT-4 (peak 3) had a broad weak ion distribution (not shown) with a charge envelope at low m/z values.

Figure 1. ESI of Unfolded and Folded NT-4

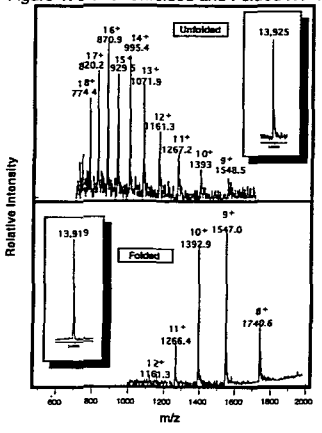


Figure 2. HPLC of Partially Reduced NT4

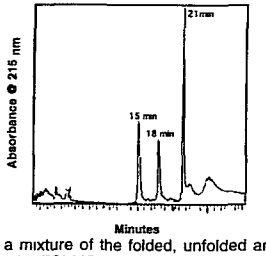

Figure3. ESIMS of HPLC Peaks.

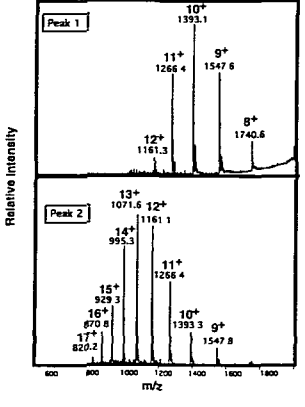

The renaturation of NT-4 requires proper folding, disulfide bond arrangement and non-covalent dimerization. MALDI-MS analysis was performed on a tryptic digest of folded NT-4 to determine disulfide order. The predicted tryptic peptides, in sequence order, are shown in Table 1. Peptide masses confirmed by MS are shown in italics, while the disulfide peptide sequences and masses are shown in bold type. The disulfide arrangement for NGF is 1-4, 2-5 and 3-6, where the numbers refer the order of the cysteine in the sequence.

Samples were prepared using α-cyano 4-hydroxy cinnamic acid as the matrix. With internal calibration, mass accuracy is typically 0.2 %, but order to enhance sensitivity, digest spectra shown here were obtained without using internal calibrant, in order to reduce ion supression effects. Masses of the more intense ions in the digest spectra were confirmed using internal calibration.

MALDI-MS analysis of the unreduced digest revealed ions resulting from cystine (S-S) peptides as a cluster of peaks with m/z values of 2566, 2721, 2782 and 3010 (Fig 3). The first three all result from a Cys 1->Cys 4 disulfide, but include incomplete cleavage products of T-3 with arginine.

Table 1 Tryptic peptides of NT-4.

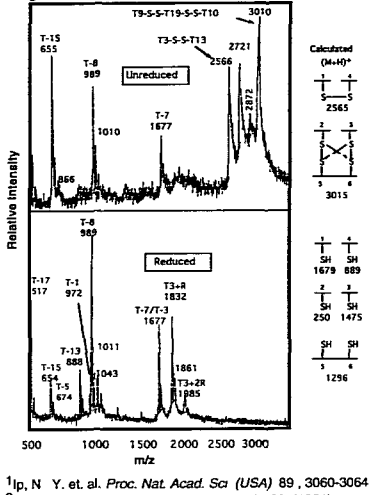
21	89.1	130	130	A		

Figure 3. MALDI-MS of NT-4 Tryptic Digest



Disulfide arrangements are shown to the right with the cysteine residues numbered 1 through 6 in sequence order from the N-terminus The ion at m/z 3010 results from three peptides, T-9 (Cys 2), T-19 (Cys 5 and 6), and T-10 (Cys 3) joined by 2 disulfide bonds. The disulfide diagram shows the NGF pattern in solid lines, but the dashed lines indicate an alternate arrangement for the triplet which cannot be ruled out in this experiment (Cysteines 5 and 6 occur within the sequence Cys-Val-Cys, which is difficult to cleave enzymatically). The experiment does rule out an intramolecular disulfide between cysteines 5 and 6 in T-19. The disulfide peptides disappeared when the sample was reduced on the target with dithiothreitol (lower spectrum)

The masses of the disulfide-linked peptides were consistent with the disulfide pattern inferred from the crystal structure of NGF[3], suggesting that this pattern is conserved throughout the neurotrophin family.

In summary, human NT-4, expressed in E. coli, has been examined by ESI-MS and has been shown to exist in at least four discrete forms: a fully reduced form, an unfolded form from E. coli inclusion bodies, a folded, biologically active form, and an intermediate, unfolded form from partial reduction The forms displayed unique charge envelope patterns in ESI with an increasing number of ions with lower m/z values as the degree of unfolding increased. MALDI-MS analysis of tryptic digests of NT-4 allowed assignment of most of the predicted peptide fragments, including the disulfide-linked peptides.

Effects of Anions on Electrospray Ionization Mass Spectra of Peptides and Proteins

*Urooj A. Mirza and Brian T. Chait
The Rockefeller University, 1230 York Ave, New York, NY. 10021

Introduction Electrospray ionization mass spectra of peptides and proteins are usually obtained from solutions that are acidified and therefore contain relatively high concentrations of anions. The present paper describes a study of the effect of such anions on the electrospray ionization spectra of peptides and proteins and, in particular, on the observed charge distributions.

Experimental Electrospray ionization (ESI) mass spectra were obtained on an instrument constructed at The Rockefeller university and described previously.[1]

Results ESI mass spectra of bovine cytochrome c sprayed from solutions of low pH (2.2 - 1.4) yielded the suprising result that the average charge of the observed ions decreases as the pH of the spray solution is lowered (Fig. 1). Because the spectra taken at the lowest pHs contained trifluoroacetic acid in addition to acetic acid, we hypothesized that the nature of the acid may have effected the charge distribution. In an effort to understand the basis of this phenomenon, electrospray ionization spectra of cytochrome c were obtained from spray solutions containing respectively HCl, acetic, trifluoroacetic, and trichloroacetic acids at a constant pH of 2.2. The distributions of the charge states of ions in the resulting spectra exhibited sharp shifts as a function of the acid used in the spray solution, indicating that the average charge on cytochrome c in the gas phase is effected by the nature of the anion present in the spray solution.

To exclude possible complications from conformational effects, the experiments described above were repeated on small peptides. Thus, for example, the peptide K R Q H P G K R was analyzed from spray solutions maintained at constant pH using respectively acetic, trifluoroacetic, and trichloroacetic acids. The results shown in Fig 2 yielded a similar shift in the charge distribution as a function of the acid used.

These results indicate that the shift in the charge distribution of peptides and proteins is primarily due to the **nature of the anion** present in the spray solution. To further test this hypothesis, ESI spectra of the peptide K R Q H P G K R were obtained in the absence of acid but in the presence of the sodium salts of acetic, trifluoroacetic, and trichloroacetic acid . Again, a similar shift in the charge state is observed suggesting that the anions play a key role in determining the observed charge distribution. We hypothesize that a degree of neutralization was occuring via association of the anion with charge groups on the peptide or protein in solution followed by dissociation of the acid from the peptide or protein in the gas phase. The order of effectiveness of anions to produce such neutralization was **trichloroacetate > trifluoroacetate > acetate chloride.** This series is similar to the electroselectivity series of anions towards anion exchange resins.[2] Association of anions with charge groups were confirmed by comparing the spectra of peptides at relatively low collision-induced desolvation energies with the somewhat higher collision-induced desolvation energies that we normally use to obtain the most intense electrospray ionization mass spectra. At low collision-induced desolvation energies, adducts of the anions with the peptide ions are clearly observed (Fig.3).

Analysis of Biliproteins by Electrospray Ionization Mass Spectrometry

***Shinya HASHIMOTO and Akira OTSUKI**

Department of Marine Science & Technology
Tokyo University of Fisheries
4-5-7 Konan, Minato-ku, Tokyo 108

Electrospray ionization (ESI) mass spectrometry was used for the analyses of biliproteins. The relative molecular masses of α and β subunits obtained by computer deconvolution were 18,185.9 ± 1.0 Da and 19,236.8 ± 2.9 Da for C-phycocyanin and 18,978.0 ± 0.9 Da and 20,325.8 ± 1.0 Da for B-phycoerythrin, respectively.

Most species of cyanobacteria and red algae contain an antenna assembly called the phycobilisome[1]. This particle consists of proteins-pigment complexes (biliprotein), most of which carry covalently attached, open chain tetrapyrrole pigments. The tetrapyrroles are linked to the polypeptide chains through thioether linkages. These biliproteins are made up of two dissimilar polypeptide chains, α and β.

To date, the molecular weights of biliproteins and their subunits have been roughly determined, for example, by the sedimentation equilibrium method[2]. The molecular weight of these subunits described ranged from 18,100 Da to 22,200 Da. However, determination of a more accurate molecular weight may be necessary. We describe here an application of ESI mass spectrometry[3] for the accurate determination of biliprotein and its subunits masses. ESI mass spectrometry was used for the analyses of C-phycocyanin from *Spirulina sp.* (Sigma P-6161) and B-phycoerythrin (Polysciences 18110). The biliprotein samples analyzed were prepared in 2.5 % acetic acid dissolved in 50:50 (v/v) methanol-water solutions at a concentration of 100 pmol/μL. The solution was continuously infused into the ion source with a Harvard Apparatus syringe pump at 1 μL/min. Full-scan mass spectra were acquired from m/z 200-3000 or 700-2700 in 5 seconds and averaged over 1 min. The ESI mass spectral analysis was performed with a Finnigan MAT model TSQ-700 quadrupole mass spectrometer (Finnigan-MAT Corp., San Jose, CA, 4000 m/z range). The ESI mass spectra and deconvoluted mass spectra of C-phycocyanin and B-phycoerythrin are shown in figure 1-4.

The calculation of molecular mass from the observed m/z values of ions indicates that both samples consist of two different proteins (α and β subunits). The relative molecular masses of α and β subunits obtained by computer deconvolution were 18,185.9 ± 1.0 Da and 19,236.8 ± 2.9 Da for C-phycocyanin and 18,978.0 ± 0.9 Da and 20,325.8 ± 1.0 Da for B-phycoerythrin, respectively. The measurement of mass of biliproteins within ± 0.015% can be performed by electrospray ionization. The electrospray technique provides a sensitive and powerful approach to the determination of accurate mass of biliproteins.

Determination Of The Disulfide Bonding Pattern Of Peptide Toxins From The Spider *Agelenopsis Aperta* Using Electrospray Ionization Mass Spectrometry

J.G. Stroh, K.J. Rosnack, N.A. Saccomano, R.A. Volkmann, and D. Phillips
Central Research Division, Pfizer Inc, Groton, CT 06340

Peptide spider toxins are well known Ca^{2+} channel blockers. These peptides contain many disulfide bonds. We reported here on the disulfide bonding pattern of two peptides from the spider *Agelenopsis aperta* Ag-G (Scheme 1) and Ag-H2 (Scheme 2). Both peptides have five disulfide bonds. Trypsinolysis followed by electrospray LC/MS analysis of the partially digested material produced numerous fragments of the proteins (as shown in Figure 1). Based on the molecular weights of the partially fragmented peptides, three of the disulfide bonds could be unambiguously determined in both spider toxins as shown in Table 1.

Mass Spectrometry Characterization of the Phosphorylated Proenkephalin A-Neuropeptides

*Chhabil Dass and P. Mahalakshmi
University of Tennessee, Memphis, TN 38163.

Post-translational processing of bioactive peptides is an area of significant importance and of growing interest. Protein phosphorylation represents one of the most important and ubiquitous post-translational events. Many metabolic and physiological responses of hormones, neurotransmitters, and extracellular signals are manifested through protein phosphorylation. Phosphorylation of Tyr, Ser, and Thr is mediated by substrate- specific protein kinases. Proenkephalin A (PE-A) is a large 263 amino acids long protein, and is the precursor of enkephalin family of opioid peptides. It contains several Tyr, Ser and Thr, residues embedded within the consensus sequences recognizable by the protein kinases. It is important to have a knowledge whether PE-A peptides undergo phosphorylation and what is the biological significance of this covalent modification.

This study was designed to understand the biological significance of phosphorylation of PE-A peptides. As a first step in this direction, the following specific experiments were undertaken: (a) an experimental protocol was developed to synthesize several phosphorylated PE-A peptides. We used Fmoc chemistry and solid-phase peptide synthesis (SPPS) methodology (on an Advanced ChemTech ACT 90 SPP synthesizer) to synthesize phosphorylated leucine enkephalin (LE-PO_4), methionine enkephalin (ME-PO_4), LE-Lys-PO_4, ME-Lys-PO_4, ME-Arg-PO_4, ME-Arg-Phe-PO_4, ME-Arg-Gly-Leu-PO_4 and (b) the conventional magnet scan and MS/MS spectra (in the MIKES mode) of those peptides were acquired with the objective to obtain sequence-specific information. LSIMS (or FAB) is the method of choice for analysis of thermally labile and polar molecules such as peptides. This study used a VG AutoSpec Q mass spectrometer of E_1BE_2-qQ geometry and 30-35 keV Cs^+ ions as the ionizing beam. Glycerol was used as the liquid matrix.

An abundant $(M+H)^+$ ion is obtained in the conventional magnet scan spectrum of those peptides. The signal due to the loss of HPO_3 to yield the $(M+H)^+$ ions of the unphosphorylated peptides is < 10% of the $(M+H)^+$ intensity. The LSIMS data can be used to obtain AA sequence of those peptides. The typical examples are shown in Figs. 1 and 2. As illustrated in Fig. 1, a complete set of b-type N-terminus sequence ions of LE-PO_4 is observed. The AA sequence determination of LE-PO_4 is also feasible from the C-terminus; all of the y-type ions are seen in the LSIMS spectrum.

The MS/MS provides highly structure-specific data because of the link established between the exclusively mass-selected precursor and its product ions. The MS/MS data, acquired in the MIKES mode, is equally information-rich. As shown in Figs. 3-5 for LE-PO_4, ME-PO_4 and LEK-PO_4, respectively, complete sequencing of these peptides is possible from both ends of the peptides.

Thus, LSIMS either alone or in combination with CID can be used to establish the AA sequence of phosphorylated enkephalin peptides.

Acknowledgment: Financial support of the NIH (Grant NS 28025) is highly appreciated.

Identification of Two Sites of Phosphorylation in Bleached Bovine Rhodopsin by Tandem Mass Spectrometry.

D. I. Papac, J. E. Oatis Jr., R. K. Crouch and D. R. Knapp
Medical University of South Carolina, Charleston, SC 29425

Introduction: Deactivation of the visual cascade is achieved at multiple sites in the biochemical pathway. One site of deactivation involves the phosphorylation of activated rhodopsin by rhodopsin kinase[1]. Concentrated between residues 333 to 343 in the C-terminus of rhodopsin are seven hydroxyamino acids, the region thought to contain most of the phosphorylation sites[2]. Using mass spectrometry and synthetic reference standards we have identified the two major sites of phosphorylation, serines 338 and 343, within the 19 amino acid C-terminal segment of bleached bovine rhodopsin.

Methods: Rod outer segments (ROS) were isolated from 50 frozen bovine retinae[3]. Following the isolation, half of the ROS were bleached and half were treated as the bleached ROS, except they were not illuminated. Bleaching was performed on the ROS in 0.1 M sodium phosphate (pH 7.4) containing 1 mM $MgCl_2$ and 4 mM ATP under continuous illumination with white light for 30 min at 37°C[4]. After 30 min, 1M NaF was added to a final concentration of 10 mM to inhibit phosphatase activity[5]. The ROS were then washed with 10 mM Tris-HCl (pH 7.8) containing 50 mM NaF and 10 mM NaPPi and cleaved with endoproteinase Asp-N overnight at 37°C employing an enzyme to substrate ratio of 1:6000 (w/w).

Separation of the enzyme digests was performed on a Vydac C-18 column 4.6 x 250 mm. The mobile phase consisted of 0.1% aqueous TFA (A) and acetonitrile containing 0.084 % TFA (B). The gradient was 98% A held for 10 min then ramped linearly over 80 min to 40% B.

Mass spectra were obtained on a JEOL HX110/HX110 four sector tandem mass spectrometer. Samples were dissolved in 10 μl of 1N HCl, applied to the probe in a matrix of 1 N HCl/ thioglycerol, and ionized with 18 kV cesium ions. Single stage mass analysis was performed with an accelerating voltage of 10 kV and a resolution of 1500. The MS/MS experiments were performed with the collision cell operated at 3 kV and filled with enough helium to attenuate the ion current of the C-12 monoisotopic peak by 70%.

Synthetic Phosphopeptides: Monophosphorylated TSQVAPA, ASTTVSKTE, and DDEASTTVSKTETSQVAPA, were prepared as described[6].

Results: Shown in figure 1 is the chromatogram obtained following endoproteinase Asp-N cleavage of bleached ROS. Peaks 2 & 3 when analyzed by LSIMS produced a MH^+ ion of 2016.8 Da corresponding to the incorporation of one phosphate (+80 Da) into the C-terminal peptide DDEASTTVSKTETSQVAPA (MH^+ = 1936.9 Da). The retention time of peaks 2 and 3 were identical to that for synthetic DDEASTTVSKTETS(p)QVAPA and DDEASTTVS(p)KTETSQVAPA, respectively. Treatment of peaks 1 and 2 with alkaline phosphatase shifted the retention time and MH^+ ion to that for the unmodified C-terminal peptide. Due to difficulty in generating sufficient ion signal peaks 2 and 3 were subdigested with endoproteinase Glu-C. The

digests were separated by HPLC and then analyzed by MS/MS to determine the sites of phosphate attachment. Peak 2 was phosphorylated at serine 343 and peak 3 at serine 338. Using this same approach peak 1 was identified as a diphosphorylated derivative with the phosphates attached at serines 338 and 343. Higher phosphorylation states (tri- & tetra-phosphorylated) of the C-terminal peptide were observed but insufficient material was obtained to identify the sites of phosphate attachment. Analysis of the chromatogram obtained from unbleached ROS revealed only a small amount of phosphorylation at serine 338. When phosphatase inhibitors were omitted during enzymatic cleavage, serine 343 was preferentially dephosphorylated.

Conclusions: *We have identified the major sites of phosphorylation in the C-terminal region of bovine rhodopsin (serines 338 and 343), and the data indicate that this region may be constitutively phosphorylated.* Figure 2 shows the two sites of phosphorylation on the cytoplasmic tail of bovine rhodopsin idicated by shaded spheres. Our observations also suggest the possibility of a site specific order in the phosphorylation and dephosphorylation of bovine rhodopsin.

Mass Spectrometry of Protein Samples Containing Detergents

Ole Vorm, Brian T. Chait*, and Peter Roepstorff, Odense University, DK-5230 Odense M, Denmark. *The Rockefeller University, N.Y., New York 10021

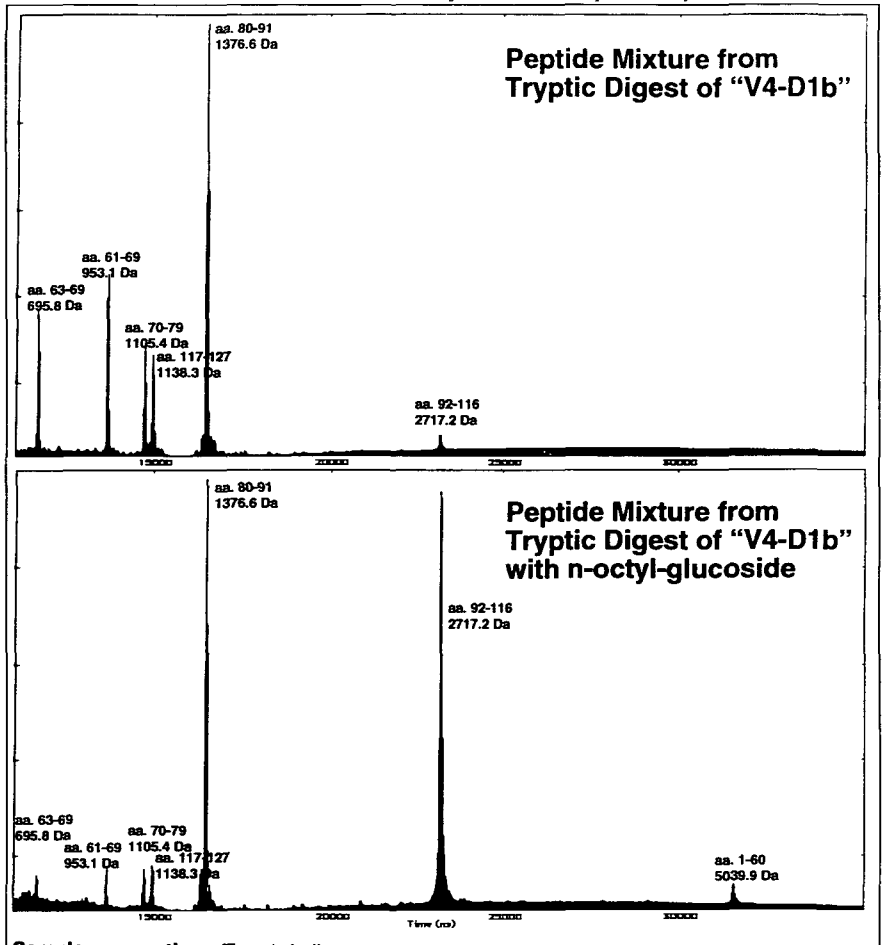
Detergents are widely used in protein chemistry because they greatly increase the solubility of peptides and proteins and facilitate purification and/or separation. However, the presence of detergents in peptide and protein samples usually inhibits mass spectrometric analyses of the "purified" compounds.

We have examined a selection of 16 detergents for their influence on the quality of the spectra of peptides and proteins obtained by ^{252}Cf plasma desorption and matrix assisted laser desorption/ionization mass spectrometry. The detergents are broadly characterized (see the table below) into those that: (i) prohibit the acquisition of useful mass spectrometric data [+++]; (ii) reduce the quality of the spectra [++]; (iii) exert little influence on the quality of the spectra [+]; and (iv) often improve the quality of the spectra [+/+]. In general, the most damaging class of detergents to mass spectrometry are those that are ionic (e.g. SDS) and the least damaging or even beneficial are those that are non-ionic (e.g. n-octyl-glucoside).

Detergent	PD	MALDI
n-Octyl-glucoside	+/+	+/+
n-Dodecyl-glucoside	+/+	+/+
n-Dodecyl-ß-D-maltoside	+/+	+
Octanoyl-N-methylglucamide (MEGA-8)	+/+	+/+
Decanoyl-N-methylglucamide (MEGA-10)	+/+	+/+
Octylphenolpoly(ethyleneglycolether)10 (Triton® X-100)	+++	++
Octylphenolpoly(ethyleneglycolether)7 (Triton® X-114)	+++	++
Dodecylpoly(ethyleneglycolether)9 (Thesit®)	+++	+++
Isotridecylpoly(ethyleneglycolether)8	+++	+++
3-[(3-Cholamidopropyl)dimethyl-ammonio]-1-propanesulphonate (CHAPS)	+++	+++
3-[(3-Cholamidopropyl)dimethyl-ammonio]-2-hydroxy-1-propanesulphonate (CHAPSO)	+++	+++
N-Dodecyl-N,N-dimethyl-3-ammonio-1-propanesulfonate	+++	+++
Polyethylene glycol 2000 (PEG)	+++	++
Sodium dodecylsulphate (SDS)	++	++
Tris(hydroxymethyl)amino-methane hydrochloride (TRIS)	+	+
Ethylenedinitrilo tetraacetic acid, disodium salt dihydrate (EDTA)	+	+

Surprisingly, we have found that the addition of some non-ionic detergents, esp. n-octyl-glucoside, to the matrix or peptide sample solutions prior to the sample preparation often *improves the signal-to-noise ratios of peptide and protein peaks. More importantly, this* procedure reduces the peptide specific suppression effects that are frequently observed in MALDI and ^{252}Cf PD mass analyses of peptide mixtures, thereby greatly increasing the likelihood of actually observing all the components that are present in a sample mixture.

A very pertinent example is, characteristic for the cinnamic acid derivative matrices, that relatively small peptides may suppress larger peptides and proteins, as shown below by two MALDI spectra of the same mixture of tryptic peptides from the locust cuticle protein "V4-D1b" (Mr 12684.8). The upper spectrum is taken without and the lower with n-octyl-glucoside present. The detergent is necessary in order to detect the peptide at Mr 5039.8 (aa seq. 1-60) and also the intensity of the peak of the peptide at Mr 2717.2 (aa seq. 92-116) changes remarkably.



Sample preparation: Two 1µl aliquots of tryptic peptides from V4-D1b (max. 8pmol/µl) in the digest buffer (pH 7.8) were diluted by a factor of five, one of them by water and the other by a 10 mM aqueous solution of n-octyl-glucoside. 0.5 µl of each of these peptide solutions was mixed on a probe tip (of 1.5 mm diam.) with 0.5 µl of matrix solution (saturated solution of α-cyano-4-hydroxy-cinnamic acid in acetonitrile/0.1% TFA 50:50 v/v), i.e. a maximum of 800 fmol of each peptide is applied to the probetip.

Predicting Degratation Products of Environmental Contaminants by On-line Electrochemistry/Mass Spectrometry

Jon A. Jones and Richard A. Yost, Department of Chemistry, University of Florida, Gainesville, FL 32611; Douglas W. Kuehl, U.S.EPA-ERL, Duluth, MN 55804.

Many carcinogenic compounds require metabolic activation to a reactive electrophile before they can alter DNA. The conversion of a procarcinogen into the ultimate carcinogen is generally an enzyme-controlled oxidation-reduction reaction. Many aromatic amines are known to be carcinogenic, and the metabolism of these compounds into reactive electrophiles has been attributed to a variety of enzymes, including cytochrome P-450 [1].

The study of the metabolism of procarcinogens traditionally involves animal studies or lengthy enzymatic digestion followed by solution-phase reactions with DNA. Our interest in this research is to bring the study of procarcinogen metabolism from the solution-phase into the gas-phase. In our laboratory, we have investigated the use of electrochemistry (EC) to activate procarcinogens and mass spectrometry (MS) to analyze the electrochemically generated products. The use of on-line EC/MS to model the enzymatic oxidation of purine compounds has previously been demonstrated, with tandem quadrupole mass spectrometry employed to elucidate the structures of the intermediates involved in the metabolism [2].

In this work, the electrooxidation of some aromatic amines is studied by on-line EC/MS. Of the number of interfaces available for interfacing the solution phase to the mass spectrometer, thermospray (TSP) and particle beam (PB) interfaces were investigated. All EC/TSP/MS experiments were performed using a Vestec Thermospray source on a Finnigan MAT TSQ 45 triple quadrupole mass spectrometer (TQMS) using an Isco LC-2600 syringe pump at a flow rate of 1.0 mL/min. EC/PB/MS experiments were performed with a Finnigan prototype 3-stage PB interface on a modified Finnigan MAT ITS40 quadrupole ion trap mass spectrometer (QITMS) using a Hewlett Packard 1090 liquid chromatograph for sample introduction at a flow rate of 0.15 mL/min. The electrochemistry was conducted using a ESA model 5020 guard cell with a model 173 potentiostat (EG&G Princeton Applied Research). The supporting electrolyte used was ammonium acetate, at a concentration of 0.1 M for TSP and 0.01 M for PB experiments.

EC/MS studies were performed by loop injection of 5-10μL of the sample solution into the electrochemical cell. The electrode potential was held constant for triplicate injections, and the average peak areas for the analyte and any products were calculated at each potential. This procedure was repeated over the potential range of interest by incrementing the electrode potential, thus creating a mass spectrometric hydrodynamic voltammagram (MSHV).

The MSHV obtained for N,N-dimethylaniline (DMA) by TSP/TQMS is shown in Figure 1. The mass spectrum obtained at a potential of +350 mV is shown in Figure 2. The product ion at m/z 241 is thought to be protonated N,N,N',N'-tetramethylbenzidine (TMB). The ion at m/z 227 has previously been attributed to a fragmentation of $(TMB+H)^+$ [3]; however, the mass intensity data for m/z 227 in Figure 1 does not parellel that for m/z 241 as one would expect for a fragment ion. The intensity for the m/z 213 species also does not parallel either of the other two ion intensities, suggesting that this may be a different oxidation product.

The MSHV obtained for benzidine by PB/QITMS is shown in Figure 3. This experiment was performed in a 50/50 methanol/0.01M ammonium acetate solvent system on a new carbon electrode. The ions at m/z 275, 364, and 366, shown in the spectrum in Figure 4, indicate oxidation and further reaction of the benzidine to various products. These products are consistent with those we have observed in on-line EC/MS of p-anisidine. The formation of azo and hydrazo derivatives appears to be the primary reaction pathway for primary aromatic amines at the potentials studied. Repetition of this experiment yielded different results; no products were observed. The absence of EC products for benzidine is thought to be due to adsorption of benzidine or its EC generated products onto the electrode surface. The alteration of the surface appears to have a significant effect on the oxidation of benzidine but does not appear to affect that of DMA or p-anisidine.

A Mass Spectrometer Based Diagnostic to Analyze the Hostile, High Enthalpy Exhaust of a Hypersonic Engine

Albert D. Tomassian and Thomas L. Bunn
Rocketdyne Division, Rockwell International
Canoga Park, CA 91309-7922

A diagnostic application of mass spectrometry has been developed to sample the exhaust of an air breathing supersonic combustion RAMJET engine. This integrated, hydrogen burning engine will power the single-stage-to-orbit, National AeroSpace Plane (X-30). The objective of the gas sampling diagnostic is to analyze the burned and unburned products of combustion emanating from subscale engine components. These engine components (i.e. inlet, combustor and nozzle) are tested in hypersonic, combustion heated wind tunnel facilities. The gas sampling project was undertaken to ascertain the extent of supersonic mixing and combustion as tunnel flow conditions, fuel injection schemes and engine configurations were varied.

Water cooled probes draw gas samples from the test article. Four probes located downstream of the tunnel facility nozzle and eight probes situated in the exit plane of the engine's internal nozzle are mounted on translatable rakes to survey several locations normal to the flow. Each gas sample is transported through the heated, three stage differentially pumped, inlet manifold to a dedicated residual gas analyzer (RGA) for real time analysis. The manifold was designed to prevent water condensation, reduce the pressure and minimize the response time as a gas sample is conveyed from the probe tip to the inlet aperture of the spectrometers. The quadrupole RGA's have independent vacuum systems, utilize open electron impact ionization sources, employ autoranging electrometers and possess a mass range of 1 to 100 amu. The instrumentation is enclosed in an air conditioned and shock isolated cart that is controlled remotely by a data acquisition computer. The computer synchronizes the rake movement with a record of 12 chemical compounds every 1.2 seconds. Spectrometer calibration is achieved for most flow constituents using certified gas mixes and for water vapor by flowing humid nitrogen through the gas sampling diagnostic and a chilled mirror hygrometer simultaneously.

In SCRAMJET tests, fuel is injected through multiple orifices into the engine's parametric (variable geometry) combustor and coerced to mix with the supersonic vitiated air flow by inducing turbulence. The gas sampling

diagnostic is used to analyze the specie concentrations of the vitiated air flow (i.e. O_2 replenished, H_2 combustion heated air flow) at the exit of the facility nozzle and of the combustor exhaust flow at the exit plane of the internal nozzle. Mole fractions, χ_i, are calculated by normalizing the ion signals, which assumes that the diagnostic measured every gaseous component in the flow. An equation for equivalence ratio, ϕ, defined as the ratio of the fuel mass flow rate to the oxidizer mass flow rate, relative to the fuel/oxidizer stoichiometric ratio, is derived in terms of mole fractions. Formulating the "amount of burned hydrogen" term in the ϕ equation as two times the "amount of consumed oxygen" rather than the "amount of water formed" yielded more repeatable and reliable results. Equivalence ratio contours provide data to study fuel penetration as a function of injector location, injection angle and free stream Mach number. Fuel distribution plots also indicate mixing effectiveness as a function of fuel injection schemes and engine configurations. Combustion efficiency, η_c, is also derived in terms of mole fractions and is defined as the percentage of burned fuel in fuel lean locations and as the percentage of consumed oxygen in fuel rich regions.

Using carefully determined calibration sensitivities and background levels, the ion signal versus time data files are reduced to plot contours of specie mole fractions, equivalence ratios and combustion efficiency. N_2 and O_2 mole fraction data for the vitiator (facility) calibration plotted as a function of probe location and H_2, N_2 and O_2 mole fraction contour plots for a SCRAMJET engine test were presented during the poster session. Two equivalence ratio contours were presented in the poster session for different fuel injection schemes. Combustion efficiency contours for these tests were also presented.

The gas sampling diagnostic results are compared with and used to validate computational fluid dynamics codes. Furthermore, combustion efficiency contours are integrated to calculate the overall average (or global) combustion efficiency which is strongly correlated to engine thrust. The global combustion efficiency, $<\eta_c>$, is an important measured property for evaluating performance. Currently, work is under way to understand the vortical mixing process more completely by seeding the fuel with helium through selected injectors and mapping the inert helium to determine the most effective fuel injection scheme.

Identification of Polychlorodibenzothiophenes in Crab Tissues From Raritan/Newark Bay

Zongwei Cai, D. E. Giblin, V. M. S. Ramanujam and M. L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588

Polychlorodibenzo-dioxins and -furans (PCDD/Fs) were found in crab tissues collected from the Raritan/Newark Bay system in New Jersey[1]. Analysis of the samples showed an unknown major component (approximately ten times the level of 2,3,7,8-TCDD) was present in the mass window for TCDD (Figure 1A). The unknown compound has similar chemical and chromatographic properties as PCDD/Fs since it was present in the same sample extract despite many steps of clean-up including three column chromatographic separations. Moreover, the molecular ion clusters of the unknown compound have the same nominal masses and isotopic patterns as those TCDD.

It would be very difficult to determine whether this major peak is an isomer of TCDD or an interference by using the conventional peak top monitoring mode even with GC/high resolution MS at mass resolution of 10,000. The unknown compound has a chromatographic retention time within the window for TCDD isomers. That retention time corresponds to that for at least 16 TCDD isomers.

The mass profile mode provides additional information such as accurate mass about the ions that are being monitored. By using the mass profile mode[2], the unknown compound was not only shown to be an interference but also identified by accurate mass information as a likely isomer of tetrachlorodibenzothiophene (TCDT), a sulphur analogue of TCDF.

Figure 1B shows the profiles of mass peaks of the unknown compound (solid line) and those of 2,3,7,8-TCDD (dashed line). Centroid analysis of the mass profiles for the unknown compound indicates that the accurate masses of the two selected ions are approximately 50 ppm less than those expected for TCDD. The accuracy of masses derived from this analysis have less than 10 ppm deviation. Thus, one can easily determine that the unknown component is not a TCDD isomer. Moreover, the accurate masses (*m/z* 319.8814 and *m/z* 321.8797) match closely those of the molecular ion clusters of TCDT (*m/z* 319.8788 and *m/z* 321.8759) rather than those of TCDD (*m/z* 319.8965 and *m/z* 321.8936). Measurements of the accurate masses along with the isotope distribution pattern suggest that the two ions have atomic compositions of $C_{12}H_4Cl_4S$ and $C_{12}H_4{}^{35}Cl_3{}^{37}ClS$. Similarly, an isomer of P_5CDT was identified in the mass window for P_5CDD.

The mass difference between the molecular ions of polychlorodibenzothiophenes (PCDTs) and PCDDs is 0.0177 mass units, the mass difference between O_2 and S. This small mass difference leads to an interference when resolution of 10,000 in HRMS is used. In fact, a mass resolving power greater than 18,000 is required to separate the PCDTs from the corresponding PCDDs in peak top analysis. Mass Profile, however, can separate an interference from dioxin by the mass difference as low as 0.0032 mass units, for which a resolution greater than 100,000 is needed for the peak top mode.

The identification of the TCDT in the crab samples has been confirmed by using GC/MS (EI) and high resolution peak match combined with GC. The EI mass spectrum of TCDT found in a pancreas sample matched that published in the literature[3]. Exact masses for the three most abundant ions of the molecular ion cluster of TCDT were determined by high resolution peak match performed as the compound came off the gas chromatograph. Mass deviations between experimental and theoretical data in the GC/high resolution peak match analysis were less than 3.0 ppm (Figure 2).

Concentration levels of TCDT and P_5CDT in some pancreas samples are listed in Table 1. The response factors for the PCDTs are unknown owing to a lack of standards. Therefore, we used $^{13}C_{12}$-2,3,7,8-TCDD as internal standard to get preliminary quantitative estimates. The levels of the TCDT are more than 5 times those of 2,3,7,8-TCDD, assuming the relative response factor for TCDT is similar to that for 2,3,7,8-TCDD. In some muscle samples, TCDD/F and P_5CDD/F were not present (detection limits are 1 ppt), whereas TCDT and P_5CDT were easily detected.

PCDTs have been found in other environmental samples[3-5]. The source and potential toxicity of PCDTs remain unknown at this time, but the compounds are expected to be biologically active[3].

PRECURSOR SCANS IN NEUTRAL DISSOCIATIONS

Ming Gu and Frantisek Turecek, Department of Chemistry, BG-10
University of Washington, Seattle WA 98195

Precursor-ion and neutral-loss scans on tandem sector and quadrupole mass spectrometers have been used for ion dissociation studies, as well as for mixture analysis.[1] We have developed a new technique based on monitoring mass-selected neutral fragments formed by ion and neutral dissociations taking place in the tandem quadrupole acceleration deceleration quadrupole mass spectrometer.[2] To obtain a spectrum of precursors fragmenting to form the given marker neutral, ions formed by electron impact in the ion source are transmitted through the first quadrupole mass analyzer operated in the r.f. only mode. The ions are accelerated to 8 keV kinetic energy and neutralized by collisions with a gas (He, Xe, cyclopropane, or CH_3SSCH_3). The neutral products are separated from the residual ions and reionized by collisions with oxygen. The second quadrupole mass analyzer is tuned at unit mass resolution to pass the ions of mass corresponding to that of the marker neutral (m_M), and the deceleration voltage is scanned from zero to the nominal high voltage (i.e. $U_{dec} \approx U_{acc}$). This allows passage of ions formed by reionization of neutrals of increasing kinetic energy as formed by fragmentation of precursor neutrals and ions according to equation 1, where U_{acc} is the constant acceleration voltage. A linear scan

$$U_{dec} = U_{acc} \frac{m_M}{m_p} \qquad (1)$$

of U_{dec} results in a non-linear mass scale with $U_{dec} \rightarrow 0$ corresponding to $m_p \rightarrow \infty$. This is similar to the B^2/E linked scan on a sector instrument. The precursor mass resolution ($m_p/\Delta m_p$) decreases with increasing m_p according to equation 2, where T is the kinetic energy release in the formation of m_M.

$$\frac{m_p}{\Delta m_p} = -\frac{U_{dec}}{\Delta U_{dec}} = \sqrt{\frac{m_M U_{acc}}{16T(m_p - m_M)}} \qquad (m_p > m_M) \qquad (2)$$

This leads to both peak broadening and a compressed mass scale at higher m_p, resulting in less-than-unit precursor-ion mass resolution.

The precursor spectrum of PO from trimethylphosphate (**1**) (Fig. 1a) shows all important ions at *m/z* 140, 109, 95, 79, 65, and represents a fingerprint of neutral dissociations corresponding to the ions in the EI spectrum of **1**. This characteristic precursor pattern is utilized to distinguish oxidized phosphorus compounds in mixtures. For example, the EI spectrum of a mixture of **1** with equal amounts of 1,6-dichlorohexane, methyl benzoate, 1-nonanone, 3-nonanone, 5-nonanone, 1-aminononane, acetophenone, and benzyl amine shows multiple peak overlaps at *m/z* 65, 79, and 109 obscuring the presence of **1** (Fig.1b). By contrast, there is no isobaric overlap at *m/z* 47, so the neutral precursor scan of the mixture (Fig. 1c) displays only PO^+ corresponding to dissociations of **1**. Isobaric overlaps of PO^+ with $CH_3O_2^+$ and $C_2H_7O^+$ in the EI spectrum of the mixture do not result in interferences in the neutral precursor spectrum due to the instability of the $CH_3O_2^{\bullet}$ and $C_2H_7O^{\bullet}$ radicals during the neutralization and reionization processes. Other possible interferences from stable ^{35}ClC and CH_2SH can be deconvoluted based on their unique peaks in the neutral precursor spectra.

RESIDUAL VOLATILES ANALYSIS OF DEACIDIFICATION TREATMENT OF BOOKS USING ON-LINE SFE/GC/MS

Casey C. Grimm[1], Terry J. Braggins[2] and Conrad Kamienski[3]

A combination of gas chomatography/flame ionization/olfactory analysis and on-line supercritical fluid extraction/gas chromatograph/mass spectrometery were utilized to analyize the residual volatiles present in deacidified paper. Paper treated with magnesium alkoxide solvated in freon (Treatment #1), purified magnesium alkoxide solvated in heptane (Treatment #2), and an untreated book were analyized for residual volatiles.

The initial investigation utilized a purge and trap connected to a GC with the effluent split to a conventional flame ionization detector (FID) and to a sniffer port. Offensive odors were eluted at two different locations. To identify the offending compounds, samples of paper taken from the treated books were extracted at 400 atm and 50°C using supercritical CO_2. The split/splitless injecton port of the GC/MS was adapted to accomodate the SFE restrictor (Figure 1). The volatiles were extracted directly from the sample and deposited at the head of a capillary column which was cryofocused at -150°C. The major limitation of the method was the necessity to use the split injector to vent off gaseous CO_2, resulting in decreased sample loading and loss of low boiling compounds.

Using the FID trace, the two offensive odors were related to compounds observed in the total ion chromatogram. The first was associated with the freon solvent and contaminates, and the second related to residual alkoxide impurities. In addition to residual butoxytriglycol three additional compounds; butoxydiglycol, butoxytetraglycol and a compound similar to butoxytriglycol, but containing an extra oxygen were present (Figure 2). These contaminants were also found in the treatment solution and were traced back to the supplier of the butoxytriglycol.

MS/MS CHARACTERIZATION OF PHOSPHATE ESTERS

Paul A. D'Agostino and Lionel R. Provost, Defence Research Establishment Suffield, P.O. Box 4000, Medicine Hat, Alberta, CANADA, T1A 8K6.

The United Nations Chemical Weapons Convention will require sophisticated analytical methods to help ensure compliance by all participating nations. Considerable analytical effort will be directed towards the development and validation of analytical methods for organophosphorus compounds controlled under the Chemical Weapons Convention. For this reason, a homologous series of straight chain C_1 to C_4 phosphate esters, commonly employed as chemical simulants for the organophosphorus chemical warfare agents, was selected for tandem mass spectrometric characterization. These typical organophosphorus compounds, including trimethyl phosphate, triethyl phosphate, tripropyl phosphate and tributyl phosphate, were investigated to ascertain the utility and limitations of tandem mass spectrometry for the detection and identification of phosphate esters.

GC-MS/MS analyses were performed with a VG Autospec-Q mass spectrometer equipped with a H/P 5890 gas chromatograph. A 15 m x 0.32 mm ID DB-1701 J&W capillary column was used with the following program: 40°C (2 min) 10°C/min 280°C (5 min). EI operating conditions were as follows: 3 x 10^{-6} Torr; 200°C; 70 eV; 100 μA and 8 kV. Daughter spectra were obtained for the molecular ion or a higher mass EI fragmentation ion for each phosphate esters with a CAD cell Ar pressure of 8-9 x 10^{-7} Torr and an energy of 25 eV (laboratory scale). This argon pressure reduced the intensity of the PFK ion at m/z 219 to 50% of its original intensity (residual air in CAD cell). The quadrupole was operated at unit resolution and scanned from 250 to 50 u at 1 sec/scan and the sector resolution was set in the 1000 to 3400 range (10% valley definition). RIM data were obtained for tripropyl phosphate by monitoring both the m/z 183 to m/z 141 and m/z 183 to m/z 99 transitions (80 msec with a 40 msec delay). GC-MS/MS specificity was evaluated by spiking the phosphate esters into a complex extract of diesel exhaust emissions (primarily hydrocarbons) collected onto the charcoal bed of a Canadian C2 mask canister.

Daughter spectra were obtained for the principal four to eight EI ions of each phosphate ester with residual air or argon (two different pressures) in the CAD cell by stepping the cell energy from 1 to 100 eV in 1 eV increments (Figure 1 illustrates tripropyl phosphate data). Figure 2 illustrates the GC-MS (EI) chromatogram obtained for the diesel exhaust extract spiked with 2.5 ng of each phosphate ester and the same spiked sample extract during GC-MS/MS analysis. The four phosphate esters were masked by the presence of high levels of chemical interferences and poor quality EI data were obtained for the spiked compounds During the acquisition of daughter spectra for the same spiked extract all the phosphate esters were detected. The increase in specificity afforded by the use of moderate sector resolution was demonstrated during both daughter (Figure 3) and RIM (Figure 4) GC-MS/MS analysis. Reductions in chemical interferences were observed for the daughters of m/z 183.08 ($[M-C_3H_5]^+$ for tripropyl phosphate) by increasing the sector resolution to 2400 (Figure 3). Daughter scanning sensitivity was found to approach typical EI full scanning detection limits (e.g., 100 to 500 pg). Lower levels of phosphate esters were confirmed by multiple RIM (minimum of two transitions). Figure 4 illustrates the RIM chromatograms for the m/z 183 to m/z 141 transition (loss of C_3H_6) with a sector resolution of 1000 and 2400. Chemical interference, due to loss of C_3H_6 from sample components, was reduced with increased resolution and a S/N ratio in excess of 100:1 was observed for 200 pg of tripropyl phosphate at both sector resolutions. GC-MS/MS data obtained for spiked diesel exhaust extracts during parent and constant neutral loss operation were considerably less specific than daughter or RIM operation.

Extraction of Trace Elements in Coal Fly Ash and Subsequent Speciation by High Performance Liquid Chromatography with Inductively Coupled Plasma Mass Spectrometry (HPLC-ICP-MS)

***Jiansheng Wang, Medha Tomlinson and Joseph A. Caruso, Department of Chemistry, University of Cincinnati, ML 172, Cincinnati, OH 45221-0172, USA.**

There is an increasing demand for the trace element speciation of coal fly ash, due to the toxic nature of many of its components. The toxicological profiles of some of the potentially hazardous compounds depend markedly on the oxidation states of the element and/or their chemical forms For example, chromium (III) is an essential element while chromium (VI) has been known to be toxic; vanadium (V) is much more toxic than vanadium (IV); several arsenic compounds such as arsine, arsenite, arsenate, methanearsonic acid and dimethylarsinic acid are known to have various toxicities.

However, the difficulty lies in the successful extraction of these trace elements from coal fly ash, without changing their oxidation states or chemical forms. Most digestion procedures involve harsh conditions, which would change the original form of the element. In this work, attempts to develop procedures for trace element speciation in coal fly ash will be performed utilizing the following order: (a) extraction of coal fly ash with water (pH=1 to 12), (b) extraction of ground coal fly ash (~ 2 to 3 μm)with water, (c) determination of trace elements in solutions of various pH with inductively coupled plasma mass spectrometry (ICP-MS), (d) speciation of trace elements in coal fly ash by high performance liquid chromatography coupled with inductively coupled plasma mass spectrometry (HPLC-ICP-MS)

Preliminary results have shown that most of the trace elements in coal fly ash are released in small amounts in water under normal environmental conditions (pH= 5 to 7). However, when the pH is below 2 or higher than 10, the solubilities of trace elements in coal fly ash are markedly increased. Speciation of vanadium in

the extracted solution by HPLC-ICP-MS indicates that both vanadium (V) and (VI) exist in aqueous solution. Therefore, this extraction method can be applied to the speciation of As, Cr, Ni and other elements.

Determination of Methanol in Water Samples using a Modified EPA Method 8015, Direct Injection GC/MS, and Purge and Trap GC/MS.

*D.W. Berberich, C.K. Trang, B.M. Hughes, J.L. Briscoe, and R.G. Orth, Monsanto Company, 800 North Lindbergh Blvd., St. Louis, MO., 63167, Mailzone S3C.

Two sets of water samples were analyzed by direct injection GC/MS onto a capillary column, purge and trap GC/MS, and a modified EPA method 8015 with direct injection onto a packed column. The data from this analysis is summarized in Table 1. The analysis methods were compared in terms of sensitivity, reproducibilty, and sample turn around times. The mass spectrometers used for this analysis were the VG ZAB 70E double focusing magnetic sector mass spectrometer and the HP MSD quadrupole mass spectrometer. The modified EPA method 8015 was performed by an outside contract laboratory.

The QA/QC data for triplicate injections of the sample indicated reproducibility of 11% for the direct injection method, 25% for the purge and trap method, and the data for the EPA Method 8015 was not available. The laboratory water blank did not have a detectable level of methanol. The direct injection data indicate an 85% recovery for the field effluent spike, 104% recovery for the field distilled water spike, 109% recovery for the effluent lab high spike, and 100% recovery for the effluent lab low spike. The purge and trap data indicate an 86% recovery for the field effluent spike, 96% recovery for the field distilled water spike, 68% recovery for the effluent lab high spike, and 65% recovery for the effluent lab low spike.

The reported water sample concentrations were corrected for % recovery based on the QA/QC spikes. The methanol level in water prior to treatment was 180 ppm and following treatment was approximately 22 ppm, corresponding to an 88% reduction in methanol. The direct injection GC/MS onto a capillary column method had an 18 minute per sample analysis time while the purge and trap GC/MS method had an 1 hour analysis time.

Table 1. Summary of data obtained for methanol analysis.

Sample Description	Concentration (ppm) Direct Injection	Concentration (ppm) Purge and Trao	Concentration (ppm) Modified Method 8015	Predicted Concentration (ppm)
Effluent - 7/21/92	24 ppm	24 ppm	23 ppm	
Effluent - 7/20/92	21 ppm	24 ppm	21 ppm	
Effluent Field Spike - 7/21/92	63 ppm	64 ppm	NA	74 ppm
Water Field Spike - 7/21/92	52 ppm	48 ppm	39 ppm	50 ppm
Effluent Lab High Spike - 7/21/92	98 ppm	NA	NA	90 ppm

Chemical Ionization of Pesticides Using a GC/MS Ion Trap Detector

Y. A. Ranasinghe[1], G. A. Loraine[1], G. L. Glish[2] and M. J. Charles[1]

[1]Department of Environmental Science and Engineering and [2]Department of Chemistry, University of North Carolina, Chapel Hill, NC 27599.

Guidelines to pesticide usage in agriculture and the potential short and long term health risks to biota and humans is a principal topic in environmental science. The major concerns are the detection, control and environmental monitoring of pesticides in ground water, streams and in consumables such as fruits and vegetables.

The use of CI in concert with ion trap mass spectrometry for the analysis of pesticides offers the advantage of providing the needed sensitivity while collecting full-scan spectra to assist in confirming the identity of the compounds. The nature of the ion trap CI experiment results in electron ionization of analyte molecules in the interval that is devised to ionize reagent molecules. Consequently EI ions can occur in the mass spectra that are produced[1]. Difficulties arising due to the "hybrid" spectra can be prevented by using a very low rf trapping level during ionization[2]. Decreasing the rf amplitude during ionization can cause high mass ions to be lost from the trap. In this study experiments were performed to determine the effect of the rf amplitude (cut-off mass) during the electron pulse on the chemical ionization mass spectra of specific pesticides, and comparing these spectra to the electron ionization spectra in the ion trap, and chemical ionization mass spectra obtained on a beam instrument.

A Varian Saturn II GC/MS ion trap detector was used to create a methane CI library for propazine, propanil, prometryne, atrazine, dacthal, dichlobenil, difolotan, dinoseb, vegadex, lindane, DDE and methoxychlor, pesticides recieved from Polyscience Corporation (at > 90% purity). The samples were diluted in either hexane or methylene chloride. Separations were performed on a 30 m, DB-5, .25 um fused silica capillary column, at a He carrier gas pressure of 13 psi. The optimum conditions for the CI spectra were obtained with an electron pulse of 1000-2000 usec for concentrations of ~ 10-50 ng/ul sample, at an emission current of 5 uA, run under automatic reaction control (ARC). The methane was maintained at a constant pressure that yielded equal ion abundances of CH_5^+ and $C_2H_5^+$. Methane pressures giving a similar $CH_5^+/C_2H_5^+$ ratio were used to generate CI spectra for the same pesticides on the Finnigan 4000 quadrupole instrument for comparison.

The effect of varying the cut-off masses from 10, 5, 3 & 2 on the appearance of the chemical ionization mass spectra is exemplified by comparing the electron ionization and the chemical ionization mass spectra for propazine obtained in the ion trap (Table 1). The electron ionization mass spectrum is characterized by the presence of a molecular ion at m/z 229 (Figure 1). The major fragment ions appear at m/z 214 (100%) due to the loss of a CH_3 moiety; at m/z 172 (65%) and at m/z 58 (60%) due to $((CH_3)_2CHNH)^+$. The abundance of m/z 58 decrease in the CI spectrum with a decrease in the rf amplitude and completely disappears at a cut off mass of 2 (Table 1). However this adversely affects the performance of the ion trap by reducing the total ion current (TIC). This could be due to the repulsion of methane ions by He^+ which is trapped at this value.

In general, similar CI mass spectra were obtained on an ion trap and on the quadrupole instrument (Figure 1). Major differences occurred for methoxychlor and difolotan. For methoxychlor the ion trap spectra yielded protonated molecule and fragment ions due to losses of HCl. In contrast the quadrupole spectra contained primarily m/z 227, which is also the the primary ion $(M\text{-}CCl_3)^+$ in

the EI spectrum. For difolotan, the ion trap spectra show $(MH\text{-}HCl)^+$ as the major ion at m/z 314 (100%) and M^+ (8%) at a lower intensity. The quadrupole mass spectrum exhibits ions at m/z 152 (100%) and m/z 79 (60%). The m/z 79 (100%) is also the major fragment in the EI spectrum.

Other investigators are devising changes to scan functions that need both hardware and software modifications to eliminate the EI artifacts[1]. Here data is presented to show that these ions could be eliminated by changing the rf amplitude on the ring electrode. The CI mass spectra obtained under these specific conditions were similar to those using a quadrupole mass spectrometer.

Low PPB Detection Limits for the Analysis of Atmospheric Contaminants in Ultrapure InertGases

Charlene Long, Jeremiah D. Hogan,
Texas Instruments Inc., Dallas, TX 75265

A Hewlett Packard 5988A GC/MS with a Teknivent Vector Two data system is used to detect atmospheric contaminants in several ultra high purity (UHP) and very large scale integration (VLSI) grade inert cylinder gases.

With the aid of a custom-made gas blending system for calibration, five-point calibration curves over several orders of magnitude of concentrations are generated, allowing for ppm to low ppb level detection limits for contaminants such as carbon monoxide, carbon dioxide, methane, argon, neon, and oxygen. A porous layer, open tubular (PLOT) column in series with a mole sieve (MS) column provide baseline separation for all concerned species at ambient temperatures. A single, ten-port injection valve with a 200 mL injection volume provides adequate sample for S/N ratios of approximately ten for concentrations as low as 50 ppb. Figure 1 shows the injection valve scheme in both the inject and load modes. Valve switching permits a reversal of column order to permit the elution of CO_2 prior to the other components. The novel feature of this injection scheme is that the direction of flow is never reversed. Utilizing this sampling scheme allows turnaround times of about half an hour per cylinder, including a purge-down time of approximately five minutes, a standard injection to verify calibration, and a total GC run time of fifteen minutes per sample,

Shown below are: 2A) a reconstructed chromatogram of a calibration standard in helium which contains 2.5 ppm of CO_2, Ne, Ar, N_2, CH_4, and CO 2B) the same run at a concentration of 50 ppb.

Enhancement of Molecular Ion Detection by Variation of Mass Analyzer Thermal Energy for C_{10}-C_{28} Alkanes by Ion Trap Mass Spectrometry

by **Curtis S. Phinney**, Water Resources Division,
U.S. Geological Survey, 431 National Center, Reston, VA 22092

The qualitative determination of low molecular weight alkanes in natural waters is important in investigations of contaminant geochemistry, fate and transport studies, and aquatic particle-organic chemical interactions. Our efforts to analyze this class of compounds by gas chromatography/ion trap mass spectrometry (GC/ITMS) were hampered by the virtual absence of molecular ions (M+) and excessive fragmentation. This study investigated the effectiveness of varying the thermal energy imparted to the analyte molecules in the Finnigan MAT Ion Trap Device (ITD) mass analyzer manifold as a means of reducing the fragmentation of C_{10}-C_{28} alkanes and enhancing the production of molecular ions.

In this investigation, the thermal energy imparted to ions stored in the ion trap was systematically varied. This was achieved by incremental variation of the mass analyzer manifold temperature. The production of molecular ions (expressed as % of base peak), efficiency of mass transfer, and the degree of similarity to classical electron impact mass spectra were evaluated.

Ionization is achieved in this device by electron impact within the mass analyzer region itself. Ionization times range from .078 to 25.0 milliseconds (mS). Ions in the potential field below the specific threshold mass (20 amu at the initial RF voltage) become unstable and leave the trapping field region. An additional time, on the order of .100 mS, lapses prior to the start of the analytical scan function. It is hypothesized that these residence times in a highly energetic environment can lead to rearrangement decompositions of saturated aliphatic hydrocarbon ions. Hence, experiments were conducted in an effort to reduce the thermal energy imparted to these analyte molecules during storage.

A Finnigan MAT model 800A quadrupole ion trap, directly interfaced to a capillary gas chromatograph by way of the standard flexible transfer line was used for this study. The manifold temperature was initially set to 70°C., and then returned to the standard operating temperature of 200°C. in 6-8°C. increments. The production of molecular ions for a range of n-C_{10} through n-C_{28} alkanes and a branched C_{19} compound (pristane) was measured at each temperature. The effectiveness of the data system at correctly matching the resultant mass spectra with classical electron impact mass spectra was investigated. The reported purity (the resemblance to the library entry for the authentic compound) was measured for each compound as the temperature was varied. The efficiency of mass transfer through the GC/ITD interface region was determined by calculation of total ion current (TIC) relative response factors (RRF), normalized to n-C_{10}, as the mass analyzer manifold temperature was varied. Although independently heated, the interface temperature is influenced by the large thermal mass of the manifold, and was found to be subject to "cold spots" at low manifold temperatures.

The use of brand, firm, or trade names does not constitute endorsement by the U.S.G.S.

Results of this study indicate that the production and subsequent detection of molecular ions is enhanced at reduced manifold temperatures (figure 1). For example, M+ production for n-C_{17} varied from zero at manifold temperatures above 150°C. to above 16% of the base peak at temperatures below 90°C. The production of molecular ions was highest for all of the compounds at a manifold temperature of 101°C. This high production of M+ did not produce adequate additional fragmentation to allow library matching with classical electron impact mass spectra. However, operation in this temperature range may be useful for determination of molecular weights of unknowns, or for analysis of compounds that are not typically analyzed by electron impact ionization due to excessive fragmentation. The ability of the Finnigan MAT ITDS v. 4.10 data system to match the resultant mass spectra with those in the mass spectral library was greatest at low to intermediate manifold temperatures, e.g. 115-140°C, with the highest purity match values being achieved at 123°C. TIC relative response factors for the higher molecular weight compounds generally increased with manifold temperature, with n-C_{24} showing the highest TIC RRF at 184°C. Optimal mass transfer, as defined by a leveling off of response relative to n-C_{10}, was observed for all compounds through n-C_{24} at temperatures of 123°C. and above (figure 2). Mass transfer was low for n-C_{28} at temperatures below 146°C., and some peak tailing was evident at temperatures below 160°C. Hence, the optimal manifold temperature selected is dependant on the type of information desired from a given experiment, i.e. maximization of M+ production or optimal matching of classical electron impact mass spectra. An additional constraint on selection of an optimal manifold temperature is the minimum temperature at which a given analyte demonstrates acceptable mass transfer across the GC/ITD interface.

M+ Production vs. Temperature

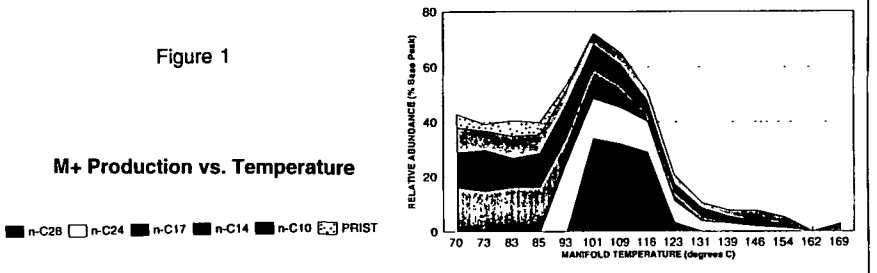

Figure 2

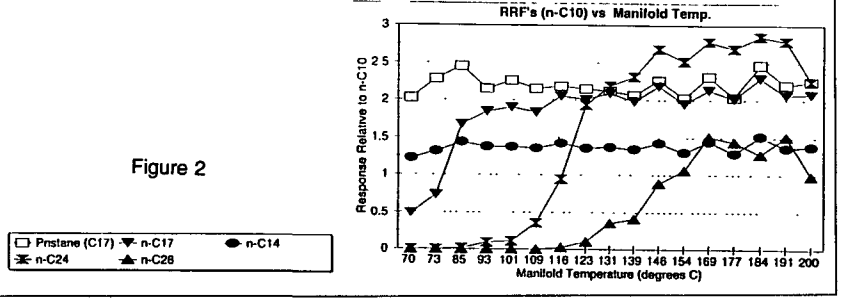

Survey of Volatile Organic Chemical Emissions from Waste Composting Facilities. Brian D. Eitzer, The Connecticut Agricultural Experiment Station, P. O. Box 1106, New Haven, CT 06504.

The proper disposal of solid waste materials is a problem facing many communities and industries. A disposal option for much of the solid waste stream is composting, which is actually a recycling option, taking wastes and generating a usable soil amendment. There are, however, several community concerns which must be addressed before this form of waste recycling can be utilized to its full potential. Some of these concerns relate to potential volatile organic chemical (VOCs) emissions from large composting facilities. In an attempt to answer these concerns we have recently completed a survey on VOCs at eight waste composting facilities.

The facilities span a size range from 5-10 tons/day design capacity to 660 tons/day. Facility types range from in-vessel systems with forced aeration to open windrows with no aeration other than weekly turning. Some facilities only use source separated waste, while others have extensive waste separating on site, and another co-composts sewage sludge. Several of the facilities use biofilters to try to reduce the odorous (and VOCs) emissions. Thus, this set of eight facilities represents a survey of the many possible approaches to MSW composting and provides a first estimate of the types and quantities of VOCs that should concern MSW composting facilities.

At each facility several sampling locations were selected. Where possible these included: the tipping floor, biofilters, different areas of active composting (differing in age of the compost), air near shredders, and curing compost piles. In addition, a field blank was taken at every facility

Samples were taken by using small portable sampling pumps to draw air at a rate of 0.6 liters per minute through sampling tubes containing Tenax-TA or Carbotrap-300. The sampling tubes were placed in the side of a bottomless plastic carboy which was set into the area to be sampled. Thus, the air sampled was isolated so that the sample was correlated to the specific location within the compost pile rather than ambient air in the vicinity of the pile.

In the laboratory these tubes were analyzed by thermal desorption GC/MS utilizing a thermal desorber accessory to a Tekmar LSC-2000 purge and trap, interfaced to a Perkin-Elmer 8500 Series GC/MS (ion trap). After a 2 min dry purge to remove excess water the tubes are thermally desorbed at 250°C for 4 min, and VOCs are transferred to the GC/MS system where they were cryogenically focused in the GC at -10°C. The GC/MS is operated using a J&W 30 meter DB-624, 0.53 mm ID capillary column. The GC oven was temperature programmed as follows; -10°C for 2 min, 5°C/min to 180°C, 10°C/min to 220°C hold for 4 min. The ion trap is operated with automatic gain control on, background 39 amu, scanning from 40-400 daltons at one scan per second.

A set of target compounds was developed which included most of the compounds from EPA method 8240 as well as several other VOCs for which standards were readily available. Standards of all target

compounds were analyzed to determine retention times, and, response factors based on the most intense and/or most distinctive ion for each compound. All target compounds were screened for in every sample with identification based on single ion chromatographic peaks at the proper retention time as indicated by the standards. Compounds were quantified using the external response factors developed with the standards.

The group of compounds producing the largest total ion chromatographic peaks were identified by computer searching of the complete mass spectra. These "largest peak" compounds are classified as terpenes. Due to the large number of structural isomers, similarities in spectra and unavailability of standards these compounds were not specifically identified but quantified as a class using a set of five terpene standards to develop an average response factor.

Two trends were observed in the results. First, though the facilities spanned a range of sizes and composting styles, a consistent pattern of VOCs at similar concentrations were seen at all of the composting facilities. These great similarities also allowed averaging of the data from all of the facilities for comparisons of concentrations within the different areas of a facility. When this was done the second trend was observed, VOCs concentrations were much higher on the tipping floors, by the shredders and at the early composting stages than in older, more mature compost. This indicates that the VOCs are rapidly emitted from the material as the pile comes to its 150 ^{o}C operating temperature. Finally, it should be noted that the observed concentrations remained well below permissible exposure limits for workplace air as defined in the ACGIH handbook (1).

The results from this study indicate that municipal waste feed used for composting has VOCs emissions, but, knowledge of the location of those emissions allows for planning in the design of new facilities

DIRECT DETECTION OF TRIBUTYL PHOSPHATE ADSORBED ON SURFACES OF ENVIRONMENTAL INTEREST BY STATIC SIMS

G. S. Groenewold, J. C. Ingram, A. D. Appelhans, J. E. Delmore, D. A. Dahl, Idaho National Engineering Laboratory, P. O. Box 1625, Idaho Falls, ID 83415-2208

Tributyl phosphate (TBP) was widely used in the DOE complex to recover U, Pu, Th, Np and Am. The compound is not toxic by itself, but it may be useful as an indicator for the presence of Pu, U and other contaminants at DOE burial sites. TBP can be analyzed by extraction/GC/MS, but this analysis is time consuming. Further, the compound can adsorb strongly onto mineral surfaces, thereby making extraction difficult.

The Idaho National Engineering Laboratory (INEL) and Hanford have sites that are contaminated with TBP. The predominant mineral in both areas is basalt, which is a black aluminosilicate material stutted with Fe and other transition metals. The basalt is very porous, and wet chemical extraction can be difficult.

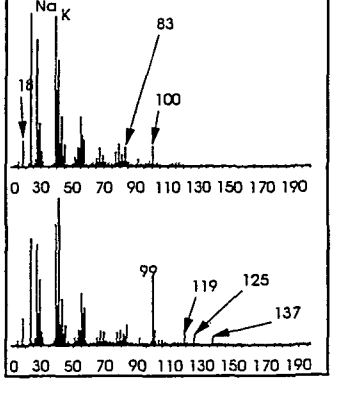
The objective of the present research is to develop rapid methods and instrumentation for the analysis of TBP on minerals and other refractory materials. Ideally, the technology should be fieldable, and should require minimal sample preparation, thereby avoiding the generation of laboratory waste. Clearly, the ability to directly analyze amorphous, irregular materials like basalt is desirable.

Static secondary ion mass spectrometry (SIMS) instrumentation which employs ***pulsed extraction*** and a ***perrhenate ion gun*** was used for the direct analysis of TBP on basalt. Sample preparation consists of attaching a basalt chip to a target planchette using double-sided tape. Using pulsed extraction, anions and cations are alternately drawn from the sample surface, which prevents charge buildup on the basalt, and also allows for the simultaneous acquisition of anion and cation spectra. The perrhenate ion gun produces a massive, high energy (10 KeV), anionic, molecular particle (ReO_4^-, ca. 250 da), which is very efficient for producing abundant secondary particles at low primary ion currents (typically 100 picoamps).

When basalt is spiked with TBP, or immersed in an aqueous TBP solution, no molecular ion species are observed in the SIM spectrum, but abundant ions are observed at m/z 137^+, 125^+, 119^+, 99^+, 79^-, and 63^- (fig. 1, lower, fig. 2). The analysis can be performed in about 5 minutes with no sample preparation. It is of interest that small quantities of TBP on the surface of basalt do not rapidly pump away, which indicates that the TBP must be strongly bound to the surface of the basalt.

Excellent signal to noise was observed when basalt was exposed to low concentrations of TBP in H_2O (10 ng/ul). In addition, TBP could be easily observed on basalt that had been exposed only to gas-phase TBP.

Figure 1. Cation SIM spectra of unspiked basalt (upper), basalt exposed to TBP solution (lower)



m/z 99^+ is the most abundant ion in the spectrum, and accordingly is the most sensitive ion for low level TBP detections. The abundance of this ion was used to estimate the minimum detectable quantity of TBP on basalt at 1 to 10 ng. Generally, lower quantities of TBP are observable on basalt surfaces which are smoother. The use of m/z 99^+ for low level TBP detections has limitations, because there is a m/z 99^+ ion in the background spectrum of the unspiked basalt, and the uncertainty for any abundance measurement in these experiments was ca. 30% (1 standard deviation).

Abundant cations not derived from TBP are also observed in the SIM spectrum of basalt (fig. 1, upper). Hydrocarbon cations could be observed at odd masses corresponding to C_2, C_3, C_4, C_5, C_6, and C_7. The abundances of the hydrocarbon cations decrease above m/z 100^+. Background ions at m/z 100^+, 83^+, 56^+, 30^+, and 18^+ originate from cyclohexyl amine, which is an atmospheric contaminant in our laboratory that adsorbs to basalt and other minerals. The other abundant cations in observed on the basalt surface correspond to Na^+ and K^+. Significant anions observed in the SIM spectrum originate from the mineral itself, and are are attributed to O^-, OH^-, C_2H^-, SiO_2^-, and SiO_3^-.

Figure 2. TBP fragmentation observed in SIMS analysis.

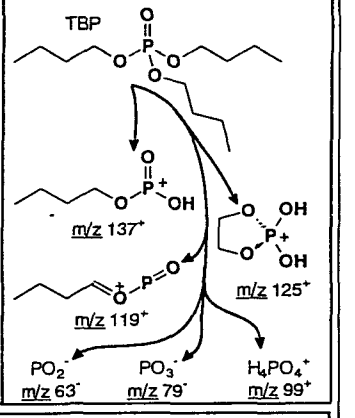


Figure 3. General structure proposed for basalt

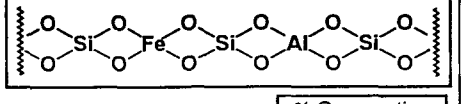

Basalt was analyzed using scanning electron microscopy (SEM) and X-ray powder diffraction to identify surface moieties that might be responsible for interaction with TBP. SEM images revealed a very irregular surface, with significant amounts of Si, Al, Fe, and Ca. An aluminosilicate structure stutted with Fe is proposed (fig. 3), where Ca is the predominant counter ion. We hypothesize that the efficacy of SIMS for analysis of TBP on basalt stems from interaction of the phosphoryl group with Fe in the basalt structure, which immobilizes TBP on the surface, and catalyzes the formation of ions. Alternatively, TBP may be bound on the basalt surface through interaction with silanol groups. We prefer the former hypothesis at this time, because no deuterium uptake could be observed in the TBP ions when the basalt was treated with D_2O. Further, TBP appears to adhere less strongly to quartz (SiO_2) than to basalt.

A NEW ANALYSIS TECHNIQUE FOR ENVIRONMENTAL LEVELS OF MERCURY USING ICP-MS

J.E. Halverson and D.M. Beals
Savannah River Technology Center
Westinghouse Savannah River Company
Aiken, SC 29808 USA

Introduction

Mercury is an extremely toxic metal, thus it is important to monitor its concentration in the environment at ppt levels. The speciation of Hg in the environment can affect its toxicity and mobility A procedure has been developed at the Savannah River Technology Center (SRTC) to determine the concentration and speciation of Hg in environmental samples.

Methods

Mercury in its elemental form is quite volatile and will diffuse through membranes. These principles were used by Braman (1971) to develop a membrane probe to detect Hg. At the SRTC, we built a membrane probe based on Braman's 1971 design. The probe is lowered into an aqueous solution so that the membrane is in contact with the sample solution to be analyzed.

A Turner Scientific Sola ICP-MS (now Finnigan MAT Sola) is used for the detection of Hg. We are currently using Au as an internal standard, which is aspirated into a CETAC Technologies U-5000 AT ultrasonic nebulizer. Argon gas incorporates the Au and then flows past the SRTC membrane probe (MP). Elemental Hg diffusing through the membrane is carried to the ICP torch by the argon, along with the Au. The mass/charge (m/z) range of 197 to 202 is scanned for the Au and Hg peaks.

Each sample analysis requires four measurements on the ICP-MS. The elemental Hg in the sample is first determined. After the addition of $SnCl_2$ the inorganic Hg concentration is measured. This is followed by the addition of $NaBH_4$ which gives a measure of the organic Hg. Lastly, a Hg standard is added to the sample. The absolute concentration of Hg in each form may then be calculated by standard addition equations.

To determine the Hg concentration in an aqueous sample 40 mL of sample solution are poured into a 50 mL glass breaker. The sample is typically preserved prior to analysis by the addition of nitric acid (Seastar Chemicals, Seattle WA). Soil or sediment samples are weighed into a 50 mL glass beaker. Distilled water or 2M nitric acid (Seastar) is added to the beaker to a total volume of approximately 40 mL. The SRTC MP is placed in the solution, which is continuously stirred during the analysis.

Results

Analysis of Standards. Standard solutions were prepared by the sequential dilution of a 1000 ug/mL Hg ICP standard (Specpure, Johnson Matthey) with 2% HNO_3. The SRTC MP was lowered into the solution and the Hg concentration measured by standard addition. The results are shown in Table 1

Table 1. Calculated vs. Expected Hg Concentrations in Standard Solutions

Expected (ppb Hg)	Calculated (ppb Hg, 2 sigma)
0.063	0.054 ± 0.018
0.25	0.26 ± 0.15
2.50	2.54 ± 0.78

Soil and sediment samples from NIST and the Canadian Bureau of Standards having certified Hg concentrations were analyzed using the SRTC MP. The results are shown in Table 2.

Table 2. Calculated vs. Expected Hg Concentrations in Standard Soils and Sediments

STD	Expected (ppb Hg)	Calculated (ppb Hg, 2 sigma)
NIST 1806	60	25 ± 7
SO-1	22	11 ± 1.4
SO-2	82	27 ± 3

Comparison with Other Methods. Well samples were collected and then split for analysis. One aliquot was analyzed using the SRTC MP, the other aliquot by cold vapor atomic adsorption (CVAA). A comparison of the results is shown in Table 3.

Table 3. Hg concentration in ppb measured in well water by the SRTC MP and by CVAA

Sample ID	Hg form	SRTC MP	CVAA
TGB-FB	metal	<0.03	
	inorganic	0.03 ± 0.004	
	+ organic	0.055 ± 0.006	<0.5
TGB-4-1	metal	<0.05	
	inorganic	4.6 ± 0.6	
	+ organic	4.1 ± 1.3	5.8
TGB-4-2	metal	<0.04	
	inorganic + organic	1.7 ± 0.6	5.6

Conclusions

The SRTC MP technique for detection of Hg in aqueous samples appears to give accurate results when analyzing standard solutions and compared to the EPA approved method of CVAA. At this time we are uncertain as to the inaccuracy of the technique when analyzing standard soil samples. We are continuing to examine this technique as an alternative to the EPA soil method of sample digestion followed by dilution and CVAA analysis.

INTRODUCTION

Organometallics containing toxic levels of pentavalent antimony have received extensive use as parasiticides or drugs for treatment of leishmaniasis infected cattle and human beings. The parasiticides, meglumine antimonate and sodium stibogluconate are susceptible to thermal degradation and readily transform to involatile salts. This has precluded their study using electron impact ionization, and hampered the elucidation of mechanistic pathways.

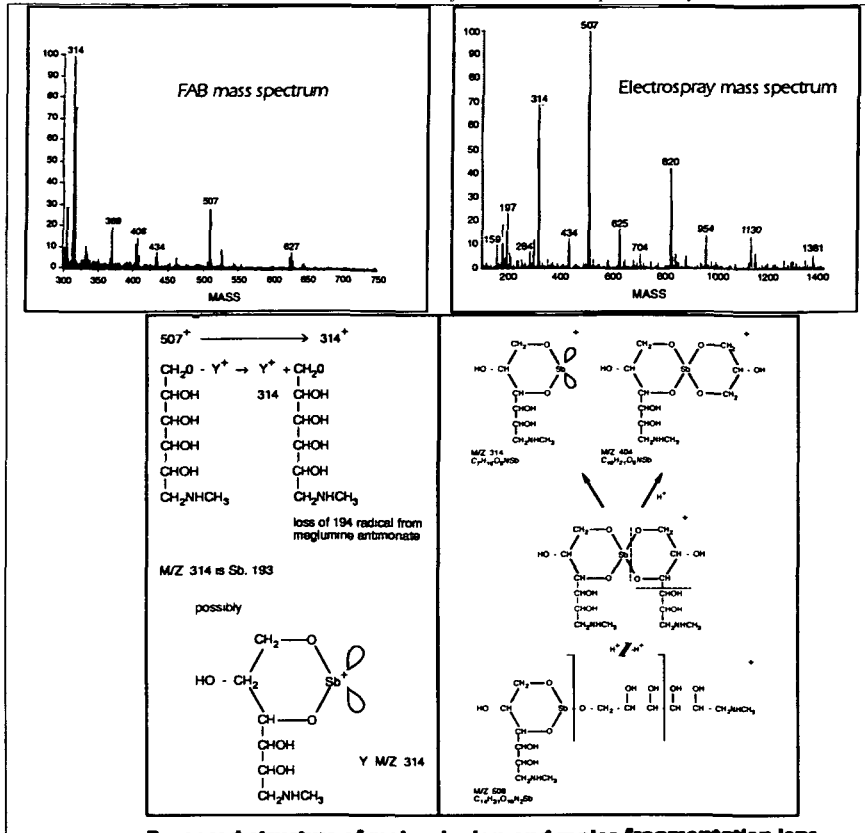
In this work, these parasiticides were studied using electrospray and fast atom bombardment, as part of an on-going program to develop mass spectrometry tools for broad spectrum analysis (BSA) of pesticides. BSA is used in the context of optimizing the information obtainable from analyses of environmental samples.

EXPERIMENTAL

Studies were conducted using a VG AUTOSPEC-Q and a VG 70S-Q mass spectrometers. For the FAB experiments, suspensions of the antimonials in glycerol were deposited on the target of a FAB probe using a pasteur pipette and the target bombarded using argon atoms (6Kv energy). Studies were also conducted using samples acidified with HCl, employing constant neutral loss scan of 121 (atomic weight of Sb 121), parent-ion scans and daughter-ion scans in the mass range 50 - 1500 amu. Similar experiments were performed using electrospray, with loop injection and a mobile phase of 50/50 methanol/water acidified with 1% acetic acid.

RESULTS AND DISCUSSION

Both the electrospray and FAB experiments resulted in diagnostic mass spectral data for meglumine antimonate. No diagnostic ions, however, were observed for sodium stibogluconate. Discussion is thus limited to the results obtained for meglumine antimonate. As shown in Figure 1-2, the positive ion mass spectrum of meglumine antimonate contained ions with characteristic antimony isotope ratios (57:43) at m/z 627, 507, 406, 314. There was also evidence of ion clusters containing antimony atoms (Sb_{1-3}), which revert to Sb_1 under acid pH conditions. The linked scan data was consistent with a molecular weight of 507, for which the Sb_1 pentavalent antimony was oriented predominantly in a coplanar configuration, suspected to be important for efficacy of the parasiticide and transformation products (Scheme 1-2).



Proposed structure of molecular-ion and major fragmentation-ions

CONCLUSION

The electrospray and FAB techniques provided complementary data for the mass spectral characterization of one of two parasiticides investigated. Further work is required to develop techniques amenable to mass spectrometry studies of sodium stibogluconate and similar compounds for BSA of environmental samples.

DETERMINATION OF ACID AND BASE-NEUTRAL PESTICIDES IN WATER BY LC-MS WITH A NEW MICRO PARTICLE BEAM INTERFACE

A. Cappiello, G. Famiglini, P. Palma, A. Berloni and F. Bruner
Istituto di Scienze Chimiche, Università di Urbino
P. Rinascimento 6, 61029 Urbino, Italy

SUMMARY

A new method for the determination of 32 base neutral and 13 acid pesticides in water, which is proved as particularly amenable with High Performance Liquid Chromatography (HPLC), is presented.
A liquid-solid extraction procedure for the isolation of pesticides from acqueous samples is employed.
The LC-MS analysis is carried out with a LC-18 reversed-phase packed capillary column coupled with a Hewlett-Packard 5989A quadrupole mass spectrometer using a new micro Particle Beam interface. Mobile phase flow rates, ranging between 1-5 uL/min, are allowed into the Electron Impact (EI) ion source of the mass spectrometer.

EQUIPMENT

A Kontron HPLC PUMP 420 binary system (Kontron Instruments, Milano Italy) is coupled with a HP 5989A quadrupole mass spectrometer (Hewlett & Packard, Palo Alto, CA, USA) via a modified HP 59980B Particle Beam unit. For UV detection a Jasco UVDEC-100-V, UV-Vis detector (Jasco, Tokyo, Japan) is connected to the column outlet by a 50 μm ID fused silica tubing which is also used as micro-flow cell.

INTRODUCTION

The use of HPLC methods for the analysis of pesticides in various matrices has become imperative after the introduction of a very large series of polar compounds of high efficiency and easily degradable. However, The lack of specificity of the usual HPLC detectors and the large number of compounds to be identified and quantitatively analyzed, push to the use of LC-MS techniques for better analytical results in order to avoid misleading interpretations.
Particle Beam interface provide the variety of structurally significant fragment ions characteristic of conventional electron ionization (EI) mass spectrometry. Furthermore, detection limits were generally in the range of required for enviromental analyses (0.1-30 ppb).
Recently, in our group a modification of the Particle Beam interface has been realized which allows the use of packed capillary columns with a mobile phase flow rates of the order of magnitude of 1 uL/min (1). Improved sensitivity, better response with high water content mobile phases for a greater chromatographic performance during gradient analysis and negligeable instrument contamination are peculiar characteristics of the new device.

EXPERIMENTAL

Figure 1 shows the chromatographic separation of a standard mixture of 32 base-neutral pesticides recorded with the mass spectrometer in the

TIC mode. Figure 2 shows the TIC profile for a mixture of 13 acid pesticides. A 250 um ID C18 packed capillary column (2,3) was employed for both separation. The flow rate was costantly kept at 2 uL/min. It can clearly noticed that no peak broadening is introduced by the the micro interface. The evident peak tailing of most acid pesticides is mainly due to extra chromatographic processes and in particular to thermal decomposition phenomena activated by the electron impact source enviroment. A more extented discussion is reported in reference 4. The performance of micro Particle Beam interface has been improved by adding ammonium acetate in the mobile phase employed for the separation of base-neutral pesticides. As discussed by Bellar et al. (5), the enhancements are attributed to both improved chromatographic efficiency and Particle Beam carrier process.
These beneficial effects can be also found in a enhanced linearity of the calibration concentration plots. Similar effects are obtained by adding a proper amount of TFA in the mobile phase used for acid pesticides separation.
A liquid-solid extraction procedure for the isolation of pesticides from acqueous samples is employed (6). A polyethilene cartridge is filled with a 250 mg of graphitized carbon black (Carbopack B) and is used to sample up 2L of water. By taking advantage of the presence of positively charged active centers on the Carbopack B surface, a stepwise elution system allowed the complete separation of base-neutral pesticides from the acidic ones. After a partial solvent removal the two sample were analyzed by HPLC-PB-MS.

Analysis of Pesticide Residues in Food using GC/MS/MS with an Ion Trap Mass Spectrometer

Steve Schachterle and Robert D. Brittain
Varian Chromatography Systems, 2700 Mitchell Drive, Walnut Creek, CA 94598

Introduction:

Gas chromatography coupled to tandem mass spectrometry (MS/MS) can be used to achieve selective detection of target pesticide components, even in the presence of a complex matrix. Two recent developments in ion trap technology, resonant ejection to remove unwanted ions during the isolation step and modulation of the RF field during CID excitation, make using the ion trap a good choice for MS/MS. These techniques use MS/MS control parameters which are virtually independent of sample or matrix concentration and may be calculated rather than optimized experimentally.

Data are presented showing the linearity and detectivity for malathion by GC/MS/MS. Matrix interferences for malathion-spiked orange extract samples are compared for standard full-scan EI-GC/MS, CI-GC/MS, Selected Ion Storage (SIS), and for this GC/MS/MS approach.

Methods:

A standard Saturn 3 equipped with a Wave-Board was used for all work. Breadboard MS/MS Software was used to insert intermediate segments in between ionization and mass analysis (1). These segments were applied to both the AGC prescan and the analytical scan. A Selected Ion Storage (SIS) waveform was applied during ionization to eject unwanted ions above and below the parent ion and to selectively store a narrow range of ions around the parent ion (2). Off-resonance excitation of 173^+ ion with modulation of the RF trapping voltage was used to provide energy for CID.

Results:

GC/MS/MS was compared to three other GC/MS techniques for the analysis of malathion in orange extract. The techniques differ in the amount of the chemical background that they reject. MS/MS is the most selective technique, virtually eliminating the background. It also gives the best detection limit for malathion.

Using resonant ejection during the isolation step and modulation of the RF during CID excitation, the spectra remain constant across the chromatographic peak.

Calibration curves for malathion standards were also run. Using the major ion of the MS/MS spectrum (127^+) gave a linear response from 2.2 pg/μl to 22 ng/μl.

Conclusions:

Using resonant methods of ion isolation and modulated ion excitation, GC/MS/MS is reliable and easy to automate, offering a convenient way to analyze target compounds in a complex sample matrix.

Ion Trap GC/MS Analysis of Pesticides Using Chemical Ionization with Selective Ion Ejection

Robert D. Brittain and Charles K. Huston, Varian Chromatography Systems

Determination by GC/MS of trace level target compounds in complex matrices can be impeded by the interference of matrix components. Chemical ionization (CI) reduces matrix interference without excessive sample cleanup. CI is a "softer" ionization approach, so analyte ions generally fragment to a lesser degree than in EI. CI spectra are often concentrated in a higher mass range than in EI, thus reducing matrix interferences. Also, saturated molecules including hydrocarbons (typical matrix interferences), are poor proton acceptors and respond poorly to CI. We choose the determination of pesticides in food extracts for illustration.

Three steps occur sequentially in ion trap CI: Ionization, Reaction, and Detection First, electrons enter the ion trap to ionize the CI reagent gas (methane for our study). Primary reagent gas ions (CH_3^+ and CH_4^+) react with neutral CH_4 to produce more stable CH_5^+, $C_2H_5^+$, and $C_3H_5^+$. Electron ionization of analyte and interfering matrix can also occur at this time. The EI artifact ions can be ejected during reagent gas ionization by a Selective Ejection wave form applied to the endcap electrodes of the ion trap so that only reagent ions are stored. The maximum m/z for ion storage is set by adjusting the amplitude of the wave form. The elimination of EI artifacts in the CI mass spectrum of Heptachlor is shown in Figure 1. Reagent gas ions then react with GC column effluent for a time determined by an Automatic Reaction Control prescan. High mass product ions are now stored in the ion trap Several classes of reactions can occur between reagent gas ions and analytes during the reaction period. **Proton transfer** produces characteristic M+1 ions which can also undergo fragmentation processes. Although ion traps utilize a low pressure of CI reagent gas, **adduct ions** at M+17, M+29 and M+41 may be observed in good proton acceptors such as Simazine. **Charge transfer** reactions can produce EI-like ions during the reaction period. Figure 2 compares the EI and methane CI chromatograms of a bell pepper extract. The total ion count for the most intense EI peak is over 1,300,000; the mass spectrum at the apex (Scan 1075) is characteristic of hydrocarbon interference from the matrix. The ion count for this peak is reduced to about 40,000 in the CI chromatogram, a reduction of matrix interference at this point in the chromatogram of over 95%.

CI can improve S/N and detectivity in complex matrix samples. Figure 3 shows the extracted ion chromatograms for characteristic ions of methoxychlor in EI and CI The S/N values calculated for each peak demonstrate the advantage gained by shifting ion intensity of the target compound to higher mass. Although the peak heights in CI are reduced from those in EI for this compound, S/N values increase in CI because higher mass ions have less background interference.

Chemical ionization is an option of ion trap mass spectrometer operation which is easy to use; alternating EI/CI segments may be programmed in the same acquisition using programmed acquisition tune events in the Saturn 3 GC/MS. Selective Ejection CI in the Saturn 3 system uses a non-resonant ejection wave form to remove EI artifact ions during the reagent gas ionization process so that a pure CI mass spectrum is acquired Chemical ionization spectra of complex matrices such as food extracts exhibit much less interference than corresponding EI spectra. The reduction of interference can lead to improvements in detectivity, particularly for compounds which are good proton acceptors

COMPOSITIONAL ANALYSIS OF SUBMICRON PARTICLES IN AIR BY TIME-OF-FLIGHT MASS SPECTROMETRY

W. D. Reents, Jr., A. Swanson, S. Downey, A. M. Mujsce, A. J. Muller, B. Emerson, D. J. Siconolfi, and J. D. Sinclair
AT&T Bell Laboratories, Murray Hill, New Jersey 07974

Particles are a major contamination problem in the electronics industry. From plasma processing to clean room conditions, particle formation continues to cause semiconductor device failures. Currently, particle sizes ≥0.05 micron are of concern. As linewidths in devices shrink, particles of even smaller size will create problems. There is no effective way to detect and analyze small particles so as to identify and eliminate their source in clean rooms.

We have built a prototype instrument fo rdetection and chemical analysis of individual airborne particles. A schemiatic of the instrument is shown in Figure 1. Particles are introduced via a 0.53 mm ID x 500 mm long tube and two stages of differential pumping separaaated by 1.0 mm ID orifices. The particles travel 15 cm to the ion source of a time-of-flight mass spectrometer where they are struck by the focused output of a pulsed excimer laser (308 nm, 1-2 x 10^8 W/cm^2). The ions are then accelerated to 4kV and mass analyzed. Teh output of the electron multiplier is digitized with an oscilloscope.

Mass spectra of individual particles have been obtained with the compositions of $(NH_4)_2SO_4$ (Figure 2), SiO_2, $RbNO_3$, and $CsNO_3$. Detection of SiO_2 particles deomonstrates the ability to analyze refractory materials with high ionization potentials. Molecular ion are observed for both $(NH_4)_2SO_4$ and SiO_2 particles. In contrast, $RbNO_3$ and $CsNO_3$ particles produce only the metal cations, Rb^+ and Cs^+, respectively.

We have also obtained mass spectra of particles as small as 0.02 micron. Both $(NH_4)_2SO_4$ and $RbNO_3$ give readily identifiable mass spectra. The ion intensity is proportional to particle diameter for 0.02 to 0.1 micron diameter particles (Figure 3).

In summary, we have demonstrated the ability to detect individual airborne particles as small as 0.02 micron. In addition, we can identify a particle's composition from its characteristic mass spectrum.

MATCHING PROBABILITY OF LIBRARY SEARCH IN SCREENING ENVIRONMENTAL SAMPLES BY GC/MS

Hsia Yung Hur, John R. Oppenheimer and Qingmei Zha
Center for Environmental Science, College of Staten Island
City University of New York, Staten Island, NY 10301

Great concern has been focused on the air pollution. The volatile organic compounds (VOCs) have been detected in ambient atmosphere at certain levels. Some of those compounds have been proven to be toxic, mutagenic and possibly carcinogenic in laboratory studies and have been linked to respiratory cancer in certain occupational settings. In late eighties, Staten Island Air Pollution and Respiratory Disease Study was initiated at our center, which involved a lung cancer case-control study and an air monitoring program. Staten Island, as an urban region of metropolitan New York, is a river apart from New Jersey industrial complex. The world's largest landfill is located in Staten Island. As a consequence, Staten Island has a complex air matrix.

The sampling and analysis of ambient air have been reported previously [1]. Over 24 hours period, air were pumped through the sample traps filled with Tenax at a rate of 8 ml/min (low flow) and 16 ml/min (high flow), respectively. The sample traps were then sealed and send to laboratory for analysis. Sample screening was performed on a thermal desorption-GC/MS system. The volatile compounds trapped in Tenax were released by a thermal desorption unit (Perkin-Elmer ATD-50) and transferred to a GC/MS (Hewlett Packard 5970B) for mass spectral analysis. The capillary column was DB-5, 60m x 0.25mm, 1.0 um thick film. The column was cryo-focused and gradually heated to 225°C over 40 min period for a sample run.

The numbers of chromatographic peaks between summer sample and winter sample were slightly different. The average number of peaks is 264 for summer and 272 for winter. The summer samples showed not only less peaks, but also lower concentrations of VOCs. This behavior probably related to the seasonality of ozone concentration in atmosphere [2]. Among those peaks, 228 compounds were mass spectrally identified and verified. According to their characteristic functional groups, the 228 compounds were placed into 6 classes: alkanes (51), alkenes (37), cycloparaffins (35), aromatics (52), halocarbons (22) and oxygenated compounds (30). In addition, there was one sulfur containing compound.

The first step in screening ambient air samples was computer library search. For every chromatographic peak, library search can narrow down the possible candidates to a reasonable small number in a short period. All the possible candidates suggested by the library search were listed by their percentage matching probabilities. To find the right structure of the unknown, all the candidates need to be carefully considered by their physical properties, and finally verified by the injection of the pure form chemical of the potential candidate. However, a candidate with a high percentage matching probability would most probably be the right structure of the unknown.

The NBS library gave a low overall mean match probability of 56.5%. Among the 6 different classes, aromatics had the highest average matching probability of 70.3%, while the alkenes had the lowest average probability of 41.2%. The average matching probability was 69.6% for halocarbons, 59.1% for alkanes, 50.8% for oxygenated compounds and 44.2% for cycloparaffins. The number of compounds that had high matching probability was very limited. Only 17 compounds (7.5% of the total identified compounds) had the matching probability greater that 90%. Most of them were aromatics (9) and halocarbons (5). Furthermore, there were 24 compounds (10.5% of the total identified compounds) that were indicated by NBS library as "no match".

Oxygenated compounds had the highest percentage 23.3% of "no match" (7 out of 30). Aromatics and cycloparaffins had low "no match" percentage of 0% (0 out of 52) and 2.9% (1 out of 35), respectively.

It was understood that a candidate with a high percentage matching probability may not always be the right structure of the unknown. However, 56.5% of overall mean matching probability turned out too low. In order to assess this valve, the matching probabilities of the compounds in real samples were compared with that from pure chemicals. For the randomly selected 28 compounds, the mean matching probability was 63.9% for real sample while it was 67.4% for the pure chemicals. Although some compounds from pure form chemicals had the higher matching probabilities than that from the real sample, and vice versa, there seemed to be no significant differences in mean matching probability between the real sample and the pure chemicals.

Comparison of NBS library search probablity between samples and pure compounds

Identification of Surfactants in Formulated Detergents By Using FAB and FD on the AutoSpec-Q Mass Spectrometer

J. G. Nowlin, I. Dzidic, L. A. Spino and L. Kravetz

Shell Dev. Company, Westhollow Res. Center, Houston, TX 77082

Introduction

Surfactant characterization in formulated detergents has long been dependent on a combination of both classical chemistry methods and chromatographic techniques. The analytical procedure starts with the extraction of surfactants followed by cleanup steps using a series of ion exchange columns, titrations and analyses by GC and LC.

Instead of using these lengthy procedures, one can rapidly identify surfactants in detergents directly using the combination of positive and negative ion FAB and FD mass spectra. The nonionic surfactants, such as alkyl ethoxylates, R-(OCH2CH2)nOH and polyethylene glycols, H-(OCH2OCH2)nOH can be identified from the positive FAB and FD ions, MH+ and MNa+. These spectra provide the (OCH2CH2)n distribution up to n = 40 as compared to LC, which can determine the distribution up to about n=18.

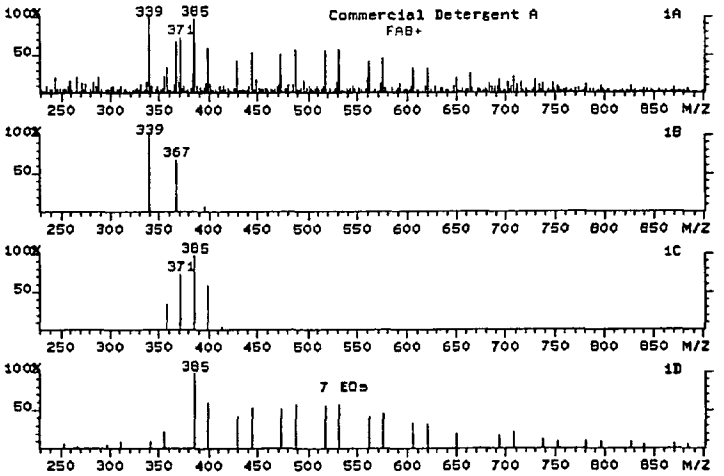

Figure 1

Results and Discussion

Positive ion FAB spectrum of a typical liquid detergent is shown in Figure 1A. This "total" positive ion spectrum indicates that several different surfactants are present in this detergent. By using the data processing "filter", the composite "total" spectrum is sorted out into the spectra B, C, and D, which indicate that at least three distinct surfactant types are present in the sample.

Note that the positive ion spectra shown in Figure 1C and 1D exhibit the same nominal mass ions at m/z 385 and 399. In order to prove that these two ions belong to different molecular formulas, the spectra were acquired again at a higher mass spec resolution, which produced two well resolved peaks at m/z 385.2929 and 385.4988 from which the molecular formulas, C20H42O5Na (spectrum D) and C19H31SO3Na2 (spectrum C) were obtained. From the molecular formulas it was concluded that compounds in the spectrum D belong to the nonionic C12/C13 alcohol ethoxylates and in the spectrum C to the C11, C12, C13, etc., alkyl benzene sulfonates.

Figure 2 compares positive ion FAB and FD mass spectra of a C11 alcohol ethoxylate sample. The FD spectrum (bottom) does not exhibit any fragment ions and is now used routinely for screening high molecular weight surfactants. While the FD spectrum exhibits the higher intensities for the potassium aduct ions, MK+, the FAB spectrum (top) exhibits more intense MH+ ions. The (CH2CH2O) distribution obtained from intensities of MH+ ions is in agreement with the data obtained from the GC/LC analysis.

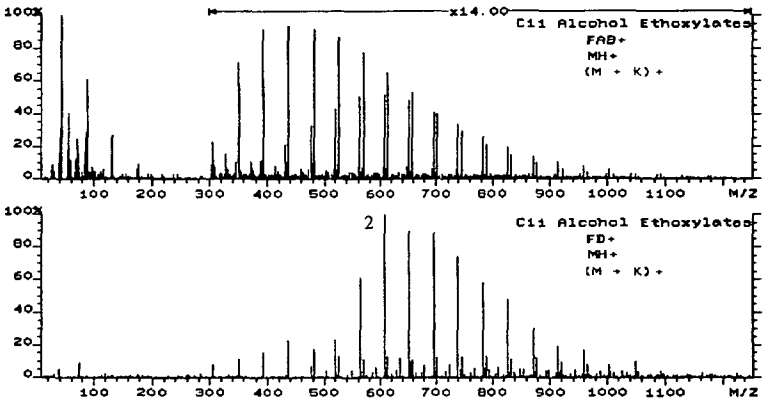

Figure 2

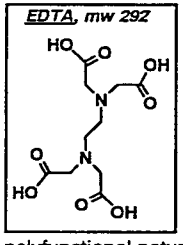
DETECTION OF METAL COMPLEXING AGENTS ON MINERAL SURFACES BY STATIC SIMS

G. S. Groenewold, J. C. Ingram, A. D. Appelhans, J. E. Delmore, D. A. Dahl, Idaho National Engineering Laboratory, P. O. Box 1625, Idaho Falls, ID 83415-2208



Ethylenediaminetetraacetic acid (EDTA) and related compounds [nitriloacetic acid (NTA) and diethylenetriaminepentaacetic acid (DTPA)] have been widely used at Department of Energy facilities for complexing radionuclides, and have been disposed of together with radionuclides. EDTA is not toxic by itself, but decreases the ability of minerals to adsorb radionuclides, and enhances the mobility of radionuclides in the environment. Additional motivation for studying EDTA is related to its implication in the generation of H_2 in the Hanford nuclear waste storage tanks. EDTA analyses have been effectively performed using derivatization/GC/MS, and electrospray MS. However, due to the polyfunctional nature of the molecule, screening for EDTA on surfaces, and determination of EDTA speciation can be time consuming and difficult.

The objective of the INEL research effort is to develop rapid methods and instrumentation for analysis of EDTA on minerals and other refractory materials, and also having the potential for determining EDTA speciation. Ideally, minimal sample preparationwould be required, and little or no lab waste would be generated.

Static secondary ion mass spectrometry (SIMS) instrumentation which employs ***pulsed extraction*** and a ***perrhenate ion gun*** was used for the direct analysis of EDTA on basalt. Sample preparation consists of attaching a basalt chip to a target planchette using double-sided tape. Using pulsed extraction, anions and cations are alternately drawn from the sample surface, which prevents charge buildup on the basalt, and also allows for the simultaneous acquisition of anion and cation spectra. The perrhenate ion gun produces a massive, high energy (10 KeV), anionic, molecular particle (ReO_4^-, ca. 250 da), which is very efficient for producing abundant secondary particles at low primary ion currents (typically 100 picoamps).

Ionic species of EDTA in solution versus pH	
pH range	predominant species
<0.0	H_6Y^{+2}
0.0 - 1.5	H_5Y^+
1.5 - 2.0	H_4Y
2.0 - 2.7	H_3Y^-
2.7 - 6.6	H_2Y^{-2}
6.6 - 10.2	HY^{-3}
> 10.2	Y^{-4}

EDTA can exist as a variety of species in solution, with the dominant species varying as a function of pH. If the solution-phase ions are preserved on the dry surface of the basalt, then the SIM spectrum will likely be affected. Basalt chips were exposed to EDTA solutions having pH values ranging from 1.4 to 11.5 in order to assess this factor. The pH of the unmodified Na_2EDTA solution (4.7) was adjusted using HCl or NaOH in order to generate solutions of different EDTA species.

When basalt was exposed to EDTA solutions having low pH (2.2 or less), no $[M + H]^+$ or $[M - H]^-$ were observed; instead, m/z 235^+ was observed(fig.1), which corresponds to the loss of one of the CH_2CO_2 moieties. This ion has been interpreted in terms of *a* (fig. 2). Presumably, formation of this ion requires the

presence of excess protons on the surface for the protonation of the carboxyl moieties, because EDTA exists predominantly as a zwitterion with a -1 charge in a pH 2.2 solution.

When basalt was exposed to EDTA solutions having a pH of 4.7, the ion corresponding to the loss of a single methyl carboxyl moiety is observed at m/z 233^+. The formation of an ion having fewer hydrogen atoms is consistent with the idea that there are fewer protons available on the surface for protonation of the carboxyl and amine moieties of EDTA, and with the fact that the predominant species of EDTA in a pH 4.7 solution is H_2Y^{-2}. A cyclic structure *b* is proposed in order to account for the unsaturation dictated by this mass.

When basalt was exposed to EDTA solutions having a pH close to neutral (6.0 - 7.0), the ion corresponding to the loss of a single methyl carboxyl moiety is nearly evenly partitioned between m/z 233^+ and m/z 231^+. The conclusion for this experiment is the same as for the pH 4.7 experiment: fewer protons are available on the surface for protonation of EDTA, and the predominant species in a pH 7 solution is even further deprotonated, HY^{-3}. M/z 231^+ is interpreted in terms of a bicyclic structure *c*, in order to account for the unsaturation dictated by this mass. In both the pH 4.7 and 7.0 experiments, no $[M + H]^+$ or $[M - H]^-$ were observed.

The decrease in mass of the $[M-CH_2CO_2]$ ion from m/z 235^+ ion to m/z 233^+, and then to 231^+ as the pH of the spiking solution increases is interpreted in terms of increasingly deprotonated EDTA species present on the surface. The surface species which give rise to these ions reflect the predominant species originally present in the EDTA spiking solution. We conclude that different EDTA surface species are distinguishable in the SIM spectra of exposed basalt, although we note that intact EDTA is difficult to sputter off a mineral surface because it strongly binds to minerals.

INFRARED PYROLYSIS OF POLYMERS FOR GCMS ANALYSIS

B. Wiezorek[1,2], *G. Baykut[1], and K. P. Wanczek[2]
1) Bruker-Franzen Analytik GmbH Fahrenheitstr. 4, 2800 Bremen 33, Germany; 2) Department of Chemistry, University of Bremen, NW2, 2800 Bremen 33, Germany

The analysis of solid samples by mass spectrometry requires special sample introduction techniques. In the on-site environmental mass spectrometry, one prefers to use simple methods, that produce results of high information content. Membrane inlets used in the mobile mass spectrometry, make it necessary use special devices for handling solid or liquid samples. A fast gas chromatographic separation simplifies the mass spectrometric identification of the components in the sample.

The infrared pyrolyzer[1,2], the application of which we present in this paper, is recently developed to use with the environmental mass spectrometry. This device helps to prepare solid samples for the mass spectrometric analysis. It is also used for detemining GCMS contaminants in solid matrices. Soil samples containing environmental pollutants.

In the infrared pyrolyzer (Fig. 1), the sample is heated remotely by an infrared lamp (Osram, Halotherm 500). This rod shaped IR-source and the reaction chamber are mounted along the two focal axes of an elliptic cylinder. The reflecting inner surfaces are covered with aluminum (reflection coeff. 94% for the used IR radiation). The sample is

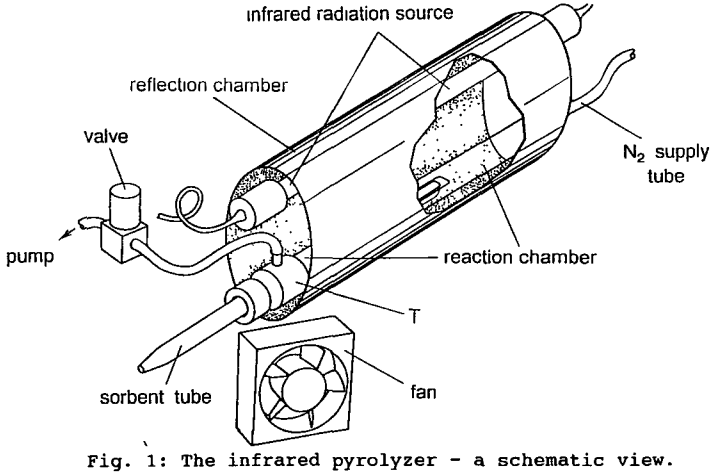

Fig. 1: The infrared pyrolyzer - a schematic view.

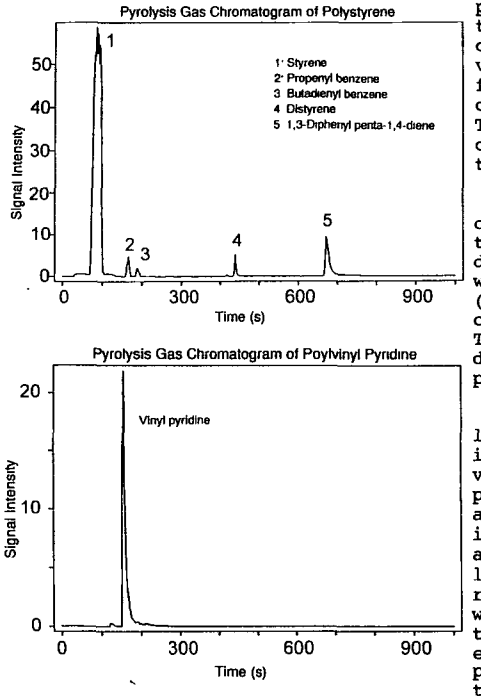

Fig. 2: Two examples of IR pyrolysis chromatograms of polymers

placed in the center of the reaction chamber into a boat-shaped container made of aluminum or Invar. The infrared radiation is focused onto a solid sample placed in a quartz reaction chamber. The programmable heating rate is controlled by pulse modulation of the infrared lamp.

During the experiments a carrier gas flow (9l/h) was maintained in the reaction chamber during pyrolysis. The products were collected in the sorbent (Tenax) tube, which is placed at one end of the reaction chamber. The sorbent tube was kept cool during trapping of the pyrolysis products.

Polyethylene, polypropylene, polystyrene, polyvinyl pyridine, polyvinyl chloride, polyvinyl acetate, polyvinyl alcohol, polyvinyl phenol, polyvinyl carbazole, polyvinyl benzoyl chloride, poly-hydroxyethyl methacrylate and poly ethylene terephtalate have been studied by infrared pyrolysis. Gaseous products were transferred into a sorbent tube filled with Tenax by an inert carrier gas (N_2). Collected products were then desorbed in the desorption oven of the gas chromatograph (4.5m fused silica capillary, stat. phase: RTX 200) and detected after GC separation by quadrupole mass spectrometry.

Most of the studied polymers were relatively easy to identify, since the infrared pyrolysis has led to the corresponding monomers with a high yield. Other polymers like polyethylene terephtalate yield to a multitude of products, which in turn form the characteristic pyrolysis GC pattern for the corresponding compound.

MODULAR INLET SYSTEMS AND SAMPLING DEVICES FOR MOBILE ENVIRONMENTAL MASS SPECTROMETRY

***G. Baykut, G. Weiss, A. Brekenfeld, H.-P. Vetters, G. Heinen, and J. Franzen**
Bruker-Franzen Analytik GmbH, Fahrenheitstr. 4,
2800 Bremen 33, Germany

Environmental mass spectrometry with on-site sampling and analysis capability requires special inlet and sampling systems for various types of natural samples. Most of the analytical investigations in the environmental science are aimed to determine anthropogenic, as well as biogenic contaminants. Studies of contamination dynamics help determine protection and decontamination strategies. In order to avoid losses and possible changes of samples during their transport from sampling site to the laboratory, a large number of analytical determinations can be performed using on-site analysis instruments. In order to obtain a high throughput, these sampling systems must operate very quickly.

A series of inlet and sampling systems (MS peripherals) have been developed in our laboratories to be used in mobile mass spectrometry. These devices are developed in a modular concept. This allows them to be quickly installed and easily operated. A task-oriented combination of different modules is possible. Two examples for the sampling modules are the injector/desorber module and the air sampling module.

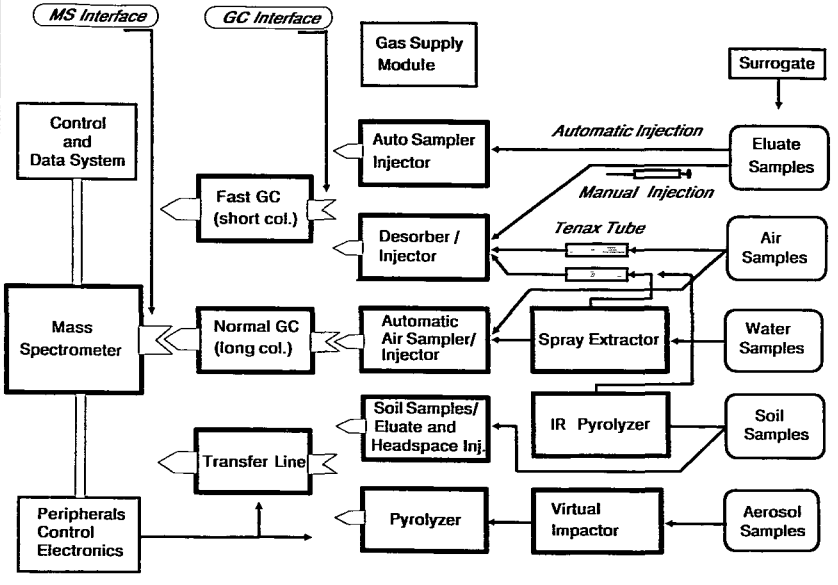
A primary peripheral module of the mass spectrometer is the gas chromatographic separator. The GC is mounted on top of the mass spectrometer and has a special quick connection system to the mass spectrometric inlet membrane port. On its other end, a similar quick connector helps to combine it with the secondary peripherals. Injector and desorber units are considered as the secondary periphery. Two versions of the GC is developed. One of them is equipped with a short (3.5m) capillary and is used for semi and low volatile compounds. The other GC has contains a longer capillary (20m) and is developed for volatile compounds. However, volatile compounds can also be run through the short GC, since a special peak separation algorithm in the post-processing software helps resolve overlapping GC signals. The gas chromatographic separator is interfaced to the membrane inlet of the mass spectrometer. This is a heated hollow fiber membrane made of polysiloxane. The GC-separated compounds flow through the hollow fiber and diffuse through its walls into the mass spectrometric vacuum system.

The *injector/desorber module* can be used as a liquids injector for the GC as well as a desorber for sampling tubes filled with sorbents. Sorbent tubes with gaseous contaminants from air or from *spray-and-trap* gas sampling in aqueous samples can be inserted into the desorption port of the module. The automatic gas sampling module *"air sampler"* can be used as an alternative secondary periphery. This module consists of a computer controlled preconcentration system. Here, a sorbent tube filled with Tenax is used to adsorb and desorb compounds in the sample and inject them into the GC. The sorbent tube of the air sampler can be reused several hundred times. In order to sample volatile organic compounds in water, a *spray extractor* is used. The water sample is sprayed in a chamber in form of small droplets, where the VOCs are easily extracted into

the gas phase. The sampled compounds are preconcentrated in the *air sampler*, before the GCMS analysis is performed.

The soil sampler and the *infrared pyrolyzer* are two of the other secondary peripherals. The soil sampler has a heated sampling head with a polysiloxane membrane. The sampler head heats the soil sample on contact and desorbs the volatile organics. They diffuse through the sampler membrane, and will be transferred through a short GC capillary to the mass spectrometric inlet membrane port. The IR pyrolyzer is used for solid samples, contaminated soil and polymer pyrolysis. The soil sample is heated by an infrared lamp and the pyrolysis products are transferred into a sorbent tube by an inert carrier gas.

The following scheme shows the overall view of the sampling and inlet devices in the modular concept of mass spectrometric accessories:



The major difference between these sampling and inlet systems and conventional GC or GC/MS equipment is their modularity. Unlike in the conventional systems, the injector/desorber module can easily be separated from the GC module and replaced with a different injection module, in a very short time just by simple hand operations. Being able to perform fast GC runs of 4-5 minutes with the 3.5 m-capillary GC module, decreases the sample througput time enormously, which is important for on-site measurements.

AUTOMATED ANALYSIS OF SELECTED ORGANIC COMPOUNDS IN URBAN AIR BY AN ISOTOPIC DILUTION GC/MS METHOD

***E. Davoli, L. Cappellini, O. Rossi, S. Ferrari[1], U. Delprato[2] and R. Fanelli, Istituto di Ricerche Farmacologiche Mario Negri, Via Eritrea 62, 20157, Milano, ([1]) RIAL Vacuum S.p.A., Via Novara 6/A, 43100 Parma, Italy and ([2]) ELECOS S.p.A.,Viale degli Eroi di Cefalonia 123, 00128 Roma, ITALY.**

A new technique is presented that allows fast, direct, automated analysis of environmental air enriched with isotopic labelled internal standards. The method is based on a cryofocussing GC/MS technique with a fixed loop 6-way sampling valve and an on-line permeation tube device.

The instrument is based on a modified residual gas analyzer (RGA) (RIAL QM 130) coupled to a DANI 86.10 gas chromatograph equipped with a cryofocussing device (TCT, Chrompack, The Netherlands) and with a 6 way sampling valve with a 100 ml fixed loop(1). A custom made thermostated permeation tube, filled with an isotopic labelled standard, is placed on the sampling line in order to continuously enrich the sample with known amounts of internal standard.

Benzene and toluene were chosen as the target compounds because of regulatory interests and their toxicity. In order to achieve an analytical cycle as short as possible the chromatographic column, a 10 m CP Sil 5, 150 µm ID, 1 µm film thickness has been kept isothermally at 110 °C. The carrier gas was nitrogen.

In fig 1. a chromatogram of air enriched with the internal standard (benzene-d_6) is shown. The instrumental response (5537 ± 1.2 %, mean ± RSD) during the period of the experiments was very good. The amount injected was correspondent, for the permeation tube used during this experiment, to 266 µg/m^3 (with an air sample of 100 cc and a sampling speed of 500 ml/min). We have not observed major interference peaks, even with such a short cycle, in the sample or internal standard time window.

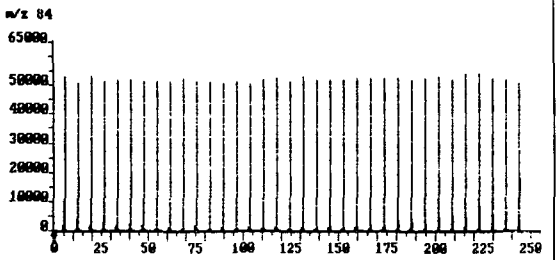


Fig. 1

A calibration curve of benzene/benzene-d_6 and toluene/benzene-d_6 was prepared, with splitless injections of 1 µl of solutions containing 10 ng/µl of internal standard, in the range 50-5000 pg. Quantitation was performed on the

basis of this calibration curve, and of the internal standard peak area. The internal standard added was deuterated benzene at a concentration of 26.6 µg/m^3. Sensitivity was high enough to monitor benzene concentrations in urban air. A 10 pg benzene splitless injection gives a S/N higher than 3, therefore if we assume a 100% adsorption and desorption efficiency of the trap, the lowest detection limit under the same experimental setup, should be 0.1 µg/m^3.

In fig. 2. benzene and toluene concentrations of a 5 days urban air monitoring experiment are reported. The analytical cycle time was 14 minutes.

The monitoring system here described is the first application, at our best knowledge, that takes advantage of an "on line" isotopic dilution technique. The use of an "on line" isotopic dilution technique, in air monitoring, gives not only the accuracy advantages of isotopic dilution, but also a continuous check of the trapping efficiency of the cold trap.

It is interesting to note that a "low end" mass spectrometer, like RGAs are considered from the most of us, might have a role also in solving some analytical chemistry everyday problems, like the one discussed before. We believe that in cases like this, when the technical performances are sufficient, it is even preferable to use RGAs over conventional organic mass spectrometers not only for the lower price, but for a more reliability that comes from a more general mechanical simplicity.

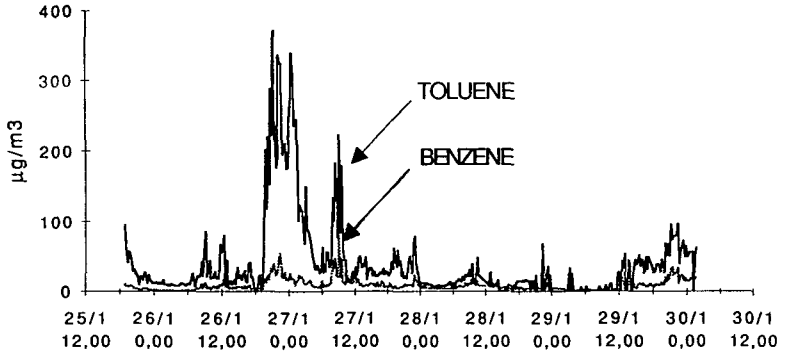

Fig. 2. Urban air benzene and toluene concentrations. Results of five days monitoring.

This study has been supported by the CNR-ENEL project-interactions of energy system with human health and environment. Rome-Italy.

A NOVEL HIGH RESOLUTION MASS SPECTROMETER FOR AUTOMATED TARGET COMPOUND ANALYSIS

Schubert R., Pfaff H., Huels W., Pesch R.
Finnigan MAT GmbH, Barkhausenstr. 2, 28197 Bremen, Germany

INTRODUCTION

The analysis of target compounds as halogenated dibenzo-dioxins and -furans is well regulated and standardized. A growing number of samples has to be evaluated for ever lower concentrations of these species. As this trend escalates, analytical instrumentation is required to accommodate greater sample loads with improved efficiency through automation, better sensitivity, and increased stability and reliability.
The QUANTUM is a fully microprocessor controlled high resolution mass spectrometer that incorporates a novel mouse oriented user interface TACO (TArget COmpound Analysis Software) (Fig. 1). This gives the unique advantage to customize complete methods like USEPA 1613 and 8290 including routine MS-setup, automatic data evaluation, reporting and quality assurance. Instrument feedback control from TACO guarantees that only data are acquired which are within user specified tolerances. To validate the QUANTUM a sensitivity and stability test was performed.

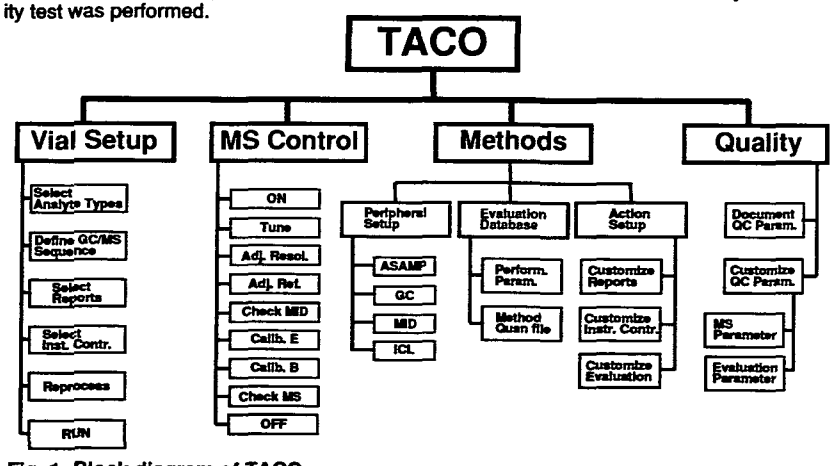

Fig. 1: Block diagram of TACO

SENSITIVITY TEST

The QUANTUM was autotuned via TACO - MS-Control -Tune. In the VIAL SETUP a batch was defined containing solutions from 3 fg/µl to 1000 fg/µl of native 2378-TCDD together with 5 pg/µl $^{13}C_{12}$-2378-TCDD standard as carrier. Triple injections onto a 25m DB 5 capillary column were performed from each vial containing 10 µl. The MID descriptor acquired the M^+

and the $(M+2)^+$ ion for each congener and two reference ions. Cycle time was 500 ms. Each run took about 20 min and the total batch (including blanks 26 injections) was processed unattended over night. The resolution was written into a QC-chart inbetween the different concentrations. Since it was within the specified limits no retuning of the system was necessary. Sensitivity specifications of 30 fg with S/N > 10 : 1 are easily achieved and the response indicates good linearity over the complete concentration range.

STABILITY and REPRODUCIBILITY TEST

An initial calibration was performed as required by USEPA method 1613. This calibration was verified twice a day for one week. The batch for the initial calibration included the window-test GC performance-test and the calibration solutions CS 1 to CS 5. GC and MID setup was performed via TACO as required by USEPA method 1613. MID peak jumping accuracy and resolution at full and reduced accelerating voltage were checked against the limits and documented automatically via TACO inbetween injections. Automatic data evaluation included checks for the isotope ratio, the retention time stability and the reference mass stability. Quantification was performed in respect to USEPA method 1613. TACO also performed reports for individual runs as well as the summary report for the calibration. Batches for verification included the window-test, GC performance-test, and the verification solution CS 3. Instrument parameter and data evaluation limits were specified within TACO in correspondence to USEPA method 1613. There was no need for any retuning of the QUATUM during this week.

LC/MS Analysis of Mutagenic/Carcinogenic Heterocyclic Aromatic Amines in Food Products

B.P-Y. Lau, D. Lewis, B. Starvic and R. Klassen
Food Research Division, Health & Welfare Canada,
Ross Ave., Tunney's Pasture, Ottawa, Ont. CANADA. K1A 0L2

INTRODUCTION : It is well known that mutagenic and potentially carcinogenic aromatic amines (HAAs) are formed in protein-rich foods during typical cooking procedures. The formation of HAAs depends on the cooking temperature and duration as well as the presence of other food constituents. Precursors are believed to be creatine or creatinine, amino acids (such as phenylalanine, threonine and alanine) and sugars. In order to assess the human risk and to ensure the safety of the consumer, a sensitive and specific analytical method is required to routinely monitor this type of mutagenic/carcinogenic food contaminant. The objective of the present work is to investigate the use of an electrospray (ESI) or a heated nebulizer interface (HNI) coupled to an atmospheric pressure chemical ionization (APCI) mass spectrometer for the analysis of eight HAAs (IQ; MeIQ, MeIQx; 7,8-DiMeIQx; 3,4,7,8-TetraMeIQx; Trp-P-2, PhIP and Trp-P-1) in cooked meat and food flavors. The complete method involves solvent extraction, simple cation-exchange cartridge cleanup followed by on-line HPLC/MS analysis.

EXPERIMENTAL : Acidified food flavor or food homogenate was continuously extracted with CH_2Cl_2 for 48 hrs. The aqueous layer was made basic and extracted again with fresh CH_2Cl_2. The extract was then back extracted into 0.2N HCl and the above extraction scheme was repeated The final extract was evaporated down to dryness and redissolved in 20% CH_3CN and 0.06% HCOOH. It was then transferred onto a HEMA-SB (sulphobutyl) cation-exchange cartridge (Alltech) and subsequently washed with 0.1N HCl; 20% MeOH in 0.1N HCl and H_2O. HAAs were eluted with 40% acetonitrile in 0.5M NH_4Ac/NH_4OH (pH=9.4). Twenty microliters of the final sample dissolved in mobile phase were injected onto a polymer based PLRP-S column (Polymer Lab , 25 cm x 4 6 mm ID, 5µm) which was connected to a UV detector (254 nm) and the electrospray or heated nebulizer interface in series. A TAGA 6000E (SCIEX, Toronto, CANADA) mass spectrometer equipped with an atmospheric pressure chemical ionization ion source was operated in SIM mode to monitor the protonated molecular ions of 8 HAAs in two groups. The electrospray interface was fabricated in-house but fashioned after the commercial version. A splitter with a split ratio of *ca.* 30:1 was used to reduce the LC flow rate of 0.7 mL/min to 20-30 µL/min. A commercial heated nebulizer interface was also used using the following parameters : probe temperature = 480 °C, nebulizer gas (N_2) = 80 psi, aux. gas flow rate = 1 L/min

RESULTS : Both electrospray and heated nebulizer interfaces produce strong protonated molecular ions for all 8 HAAs under investigation. Fig. 1 shows the responses from a 50 ng injection of 8 HAAs using a heated nebulizer interface. The separation of IQ and MeIQ, the two most mutagenic compounds of the isolated HAAs, are highly susceptible to mobile phase composition and column packing. Very fine particles from the cation-exchange cartridge often enter the chromatographic system. Frequent changing of the protective on-line filter and the guard column is required to maintain the peak shape and sensitivity of

these two compounds. Detection limits for the 8 HAAs range from sub-nanograms to low ng per injection which is equivalent to low ppb (ng/g) in samples. Fig. 2 clearly demonstrates that these compounds can be easily detected in a bouillon blank sample spiked with 2.5 ppb each of the eight HAAs. This figure also shows that the simple cation-exchange cleanup method can effectively remove most of the interferences to allow the detection by LC/MS at this low level. The recoveries of the cleanup method range from 105-90% for MeIQ, IQ and MeIQx and 84-67% for Trp-P-1, Trp-P-2, 7,8-DiMeIQx, TetraMeIQx and PhIP.

CONCLUSION : Although both electrospray and heated nebulizer interfaces have been successfully applied to the HAA analyses in cooked meat and food flavors, the latter offers the following advantages :

1) *It accepts the entire flow from a standard 4.6 mm ID analytical HPLC column without* the complexity of using a splitter.
2) It can accommodate a higher concentration of buffer which is present in the sample as a result of the cation-exchange cleanup method.
3) Its rugged design makes the day-to-day operation easier and maintains a more stable and reproducible performance

Indirect Measurement of Spatial Spread and Initial Velocity Spread of Ions Produced in MALDI.

A.A. Makarov, S.C.Davis and R.J.Greathead
Kratos Analytical, Barton Dock Road, Manchester M31 2LD, UK

Introduction

Recent studies of ion energy distributions[1-3] from matrix assisted laser desorption ionisation (MALDI) have suggested that the process involves ablation of the matrix/analyte mixture with the formation of a fast and collisional gas jet. The objectives of this work were to further explore the origin of time-of-flight spread in the MALDI process using ion-optical measurements, and elaborate a model of the physical processes to account for the findings.

Experimental

The experimental work involved measurement of resolution in linear mode on a Kratos Kompact time-of-flight mass spectrometer as a function of voltage, V, in the ion source (see Figure 1). The ion-optical arrangement consists of two acceleration regions and a drift region. Grids were used to create linear field gradients. Measurements were made on three compounds: gramicidin S, bovine insulin and lysozyme. The matrix used in all cases was sinapinic acid. The measured resolutions as a function of the extraction voltage V are shown in Figure 2. An accelerating voltage of 8kV was used for these particular experiments.

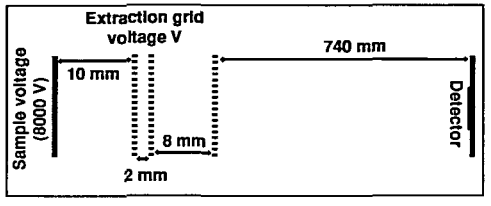

Figure 1: Ion optical arrangement

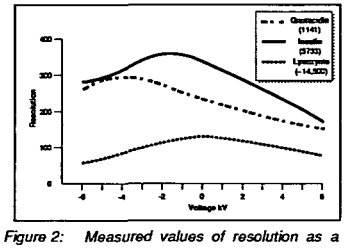

Figure 2: Measured values of resolution as a function of extraction voltage V.

The Model

Models used to try and explain the measured results considered the following possibilities:

(i) Jet-induced initial velocities
(ii) Debye shielding because of space charge
(iii) Spatial spread caused by space charge, length of ion formation and geometrical non-uniformity of the cloud
(iv) Mass-dependent energy losses during expansion because of collisions
(v) Drift of ions in the cloud under the influence of electric field.
(vi) Scattering on grids.

The main factors which need to be involved to obtain a reasonable fit (Figure 3) with the experimental results are (i) and (iv); Jet-induced initial velocities and mass dependent energy losses during expansion because of collisions. The model is illustrated in Figure 4.

Laser irradiation is absorbed by the matrix producing a shock wave in the solid state and a dense ablation jet. Absorbed energy is transformed into jet velocity. Multiple collisions activate proton transfer reactions so that $(M+H)^+$ ions are formed during the initial stage of expansion. At this stage the electric field can't accelerate ions efficiently due to space charge and collisional dissipation of energy. Rapid expansion provides rarification of the cloud (after the first 10 - 15 µm) and more effective extraction of ions by the field. Ions move in the cloud, undergoing multiple collisions and dissipation of energy. This rarified region has an effective length d.

As laser power is increased values of various parameters increase giving reduced resolution. Conversely, laser powers closer to the threshold produce higher resolutions than those shown in Figure 2.

Conclusions

Experimental values are adequately explained by the jet mechanism (velocity ~ 800 ms^{-1}), and a rarified region resulting in a spatial spread and velocity spread (determined primarily from dissipation of the jet velocity). The length d of the rarified region increases with mass since the collisional cross section is larger and energy dissipation will continue to occur in more rarified regions. Lengths used were: d = 15 µm for gramicidin S, d = 20 µm for insulin and d = 30 µm for lysozyme. A higher value for initial velocities (1500 ms^{-1}) is needed to explain the resolution values obtained from gramicidin S. This is feasible since lighter masses have a higher mobility than more massive ions.

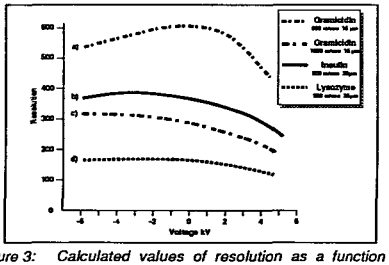

Figure 3: Calculated values of resolution as a function of extraction voltage V
(a) gramicidin: d = 15 µm, v = 800 ms^{-1}
(b) gramicidin: d = 15 µm, v = 1500 ms^{-1}
(c) insulin: d = 20 µmm, v = 800 ms^{-1}
(d) lysozyme: d = 30 µm, v = 800 ms^{-1}

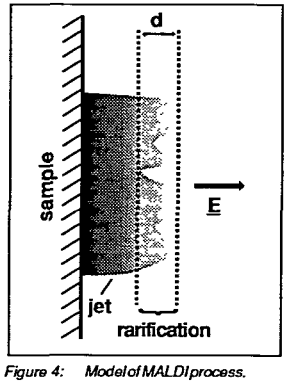

Figure 4: Model of MALDI process.

High Mass Resolving Power for High-Mass Ions in LD FT/ICR/MS: Quadrupolar Axialization and Ion Cooling

Shenheng Guan, Markus C. Wahl†, Troy D. Wood, Hyun Sik Kim, and Alan G. Marshall†

Departments of Chemistry (and Biochemistry)†, The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

The high kinetic and internal energies of ions formed by laser desorption may be effectively cooled by collisions of the ions with argon buffer gas atoms at 10^{-6} - 10^{-7} Torr. The collisions expand the magnetron radius. However, magnetron motion may be converted into cyclotron motion by azimuthal quadrupolar excitation; collisions then collapse the cyclotron radius, leaving ions on-axis in the center of the trap where they may be efficiently transferred from the high-pressure source to the low-pressure analyzer of a dual-trap for high-resolution detection [1].

Here we report highly promising initial applications of the quadrupolar excitation/ion cooling technique to Nd:YAG (1.06 μ) laser-desorbed ions [2]. First, ions may be stored for lengthy periods (several minutes or more). Second, high FT/ICR/MS resolution is easily achieved for laser desorbed ions. For example, rhodamine 6G $(M+H)^+$ ions initially detected in the source trap are resolution-enhanced simply by addition of a cooling gas, presumably because the z-distribution of ions is more uniform after cooling so that the pre- and post-excitation cyclotron radius distributions are similar (i.e., all of the ions reside in the same magnetic field environment during detection). On azimuthal quadrupolar excitation in the presence of ion-neutral collisions, ions may be efficiently transferred to the analyzer trap for high resolution detection ($m/\Delta m \approx 144{,}000$ at m/z 443). Third, dramatically improved sensitivity results from the improved trapping efficiency.

Unfortunately, trapping can be so efficient that the resulting high space charge produces a noticeable downward drift in ion cyclotron frequency during the detection period, severely degrading mass resolving power. Although the time-domain signal for laser-desorbed axialized $(M+K)^+$ ions from leucine enkephalin persists for almost 1 min (Fig. 1, top), its corresponding ICR mass spectrum is quite broad (Fig. 1, middle). The observed (and theoretically explainable) ICR frequency drift during detection may be eliminated by a digital quadrature heterodyne technique [3] to yield an ultrahigh-resolution ($m/\Delta m = 1{,}300{,}000$ at m/z 594) mass spectrum (Fig. 1, bottom).

A fourth advantage of this technique is its high ion selectivity. For example, we have isolated ions of a single isotopic mass (e.g. the all-^{12}C isotope of C_{84}^-) [2]. The selectivity advantage may be exploited for MS/MS. For example, single cluster ions, C_{94}^+, may be isolated from a fullerene mixture and transferred to the analyzer trap for high-resolution CID to generate fullerenes which lose either C_2 or C_4, as shown in Fig. 2 [4]. MALDI Fourier Transform Mass Spectrometry

Joel P. Covey, James Haas, Long-Sheng Sheng, Donald Weigt and Joseph E Campana
Extrel FTMS, Millipore Corporation, 6416 Schroeder Road, Madison, Wi 53711-2424

Introduction

Obtaining sequence and molecular weight information on peptides and other biological molecules is a topic of considerable interest to the mass spectrometry community. By performing a combination of MALDI, SWIFT, CID and MS^n experiments on a Extrel Fourier transform mass spectrometer equipped with a 3 tesla magnet and three lasers -- CO_2, Nd:YAG and N_2 -- we have developed techniques that can provide significant and, in many cases, total sequence information on medium to high weight (>2000 Da) peptides.

Small Peptides

The $[M+H]^+$ and the $[M+Na]^+$ species of a synthetic peptide (MW 933 Da) were analyzed in several MS^n experiments and ions that could provide the complete sequence of the peptide were observed. In the spectrum shown in Figure 1(a). the N-terminus (b_1, b_2, b_3) and C-terminus ions (y_4, y_5, y_6, y_7) provide sequence information on the lysine and the triple proline amino acid residues.

In Figure 1(b) the Na-attached y_6 ion of the molecular ion was isolated and underwent CID. Two sets of ions, $[b_6+ Na+ OH]^+$, $[y_4+ Na]^+$ and $[b_5+ Na+ OH]^+$, $[y_5+ Na]^+$ provide sequence information about both the valine residue and its neighboring proline residue. The most abundant species [b7 + Na + OH] +of the first doublet represents a loss of a valine residue (99 Da) from the C-terminus while the satellite peak $[y_5+Na]+$ represents the lost of the proline residue (97 Da) from the other end of the peptide fragment. The second set of ions represent the additional loss of the proline residue next to the C-terminus valine. The b_5 and c_5 ions indicate that the fifth residue is either a leucine or isoleucine.

To obtain further information, the Pro-Pro-Trp-Ile fragment of the Na-attached peptide, i.e. the middle four residues of the peptide, was isolated and underwent CID in a MS^n experiment. The N-terminus ions, $[b_5+Na]^+$ through $[b_4]^+$, shown in Figure 1(c) provide information about the tryptophan residue. In addition, the ion 28 Da below the main peak of the fragment is characteristic for isoleucine (the equivalent ion from leucine would be 42 Da below) and is caused by the loss of part of its side chain. In all these experiments an Nd:YAG laser was used, argon was the collision gas and the collision energy was 25 eV nominally.

By using a N_2 laser, other peptides such as Substance P, (1348 Da), α-Melanocyte Stimulating Hormone (1664 Da) and Ribonuclease S-peptide (2166 Da) were also analyzed with MS/MS techniques. In all cases significant structual information was obtained.

Large Peptides

A modification to allow the trap plates to be raised to 40 volts in less than 2 µs, combined with the use of a cooling gas or a mixed matrix of frucrose and DHBA[1] allowed for efficient trapping of ions to 9000 Da. We have observed the molecular ions of proteins such as bovine insulin (5734 Da) and ubiquitin (8565 Da).

Heavy Atom Effects on Matrices for Matrix Assisted Laser Desorption Ionization Mass Spectrometry

Lisa M. Preston, Kermit K. Murray and David H. Russell
Department of Chemistry
Texas A&M University
College Station, Texas 77843

Ion formation in MALDI can be described as an excited state proton transfer process between an acidic (or basic) matrix molecule and a basic (or acidic) analyte molecule.[1] For ionization to take place in this manner, the proton transfer reaction must occur on timescales similar to other competitive excited state decay processes such as fluorescence. Heavy atom substituents such as bromine and iodine tend to alter the excited state relaxation dynamics of organic molecules either by quenching the state or by promoting triplet transfer.

In this study, we use bromine and iodine substitution to change the excited state relaxation dynamic of MALDI matrices. Absorption spectra (245-600 nm) and fluorescence emission spectra from thin films are acquired, as well as MALDI mass spectra, using absorbing and non-absorbing analytes. The results are analyzed for the correlation observed between fluorescence quantum yields with analyte ion yields of $[M+H]^+$ ions.

Table 1 contains results from spectra of vitamin B_{12} acquired using various heavy atom substituted matrices and their non-substituted counterparts. Note that the relative abudance of the "intact" analyte ion is markedly increased when a heavy atom matrix is used. This increase relative to the fragment ions observed, suggests that the addition of the heavy atom substituent has changed the ionization process, allowing the production of intact ions from compounds with highly labile bonds (the -CN of vitamin B_{12}). The mechanism of ionization may be "colder" due to changes in the relaxation dynamics of the matrices.

Table 2 contains results from fluorescence emission spectra, taken using a SLM Aminco 8000 fluorometer. Comparison of the results shows a consistent decrease observed in the fluorescence quantum yield for iodine and bromine substituted matrices relative to their non-substituted counterparts. It is suggested that the decrease in fluorescence is linked to the observed increase in $[M+H]^+$ observed from the MALDI experiments.

Heavy atom matrices improve the relative $[M+H]^+$ ion yield for peptides as well as UV-absorbing compounds. Figure 1 contains two mass spectra of leu-enkephalin acquired using 4-hydroxy-3-iodo-5-nitrobenzoic acid and 4-hydroxy-3-nitrobenzoic acid. The increase in $[M+H]^+$ ion signal observed when the iodo substituted matrix is used, supports the hypothesis that decrease of fluorescence may enhance the mechanism of proton transfer, perhaps by promoting triplet transfer.

Table 1.

Comparison of Ion Signal Observed for Vitamin B_{12}

Matrix	Total Analyte Ion Signal Ampl.	Rel. Abundance Fragment Ions	Rel. Abundance "Intact" Ion
4-hydroxy-3-nitro-benzoic acid	9 mV	96 %	3 %
4-hydroxy-3-iodo-5-nitrobenzoic acid	13 mV	40 %	60 %
salicylic acid	22 mV	100 %	0 %
5-iodosalicylic acid	22 mV	71 %	29 %
2,4-dinitro-aniline	53 mV	100 %	0 %
2-bromo-4,6-dinitroaniline	21 mV	83 %	17 %
2,4-dihydroxy benzoic acid	3 mV	100 %	0 %
5-bromo-2,4-dihy-droxy benzoic acid	38 mV	95 %	5 %

Table 2.

Comparison of Fluorescence Emission Quantum Yields

(Excitation wavelength = 337 nm)

Matrix	λ_{max}	Fluorescence Em. Quantum Yield	% Q.Y. Decrease with H-atom Subs.
4-hydroxy-3-nitro-benzoic acid	392 nm	2860	
4-hydroxy-3-iodo-5-nitrobenzoic acid	392 nm	2400	16 %
salicylic acid	393 nm	9030	
5-iodosalicylic acid	393 nm	4350	27 %

Fragment ions are often observed in direct laser desorption/ ionization (DLDI) mass spectra. Lower molecular weight analytes may also show fragment ion formation during matrix assisted laser desorption/ionization (MALDI) under appropriate conditions. However, the types and abundances of MALDI fragment ions may be significantly different than DLDI fragment ions and prompts the question: "What mechanism(s) of energy transfer leads to fragment ion formation during MALDI?"

A systematic investigation of matrix/analyte ratio and desorbing laser intensity has been performed for several matrices with several smaller DNP substituted peptides and Vitamin B12 as model analytes. Figure 1 contains spectra of vitamin B_{12} by DLDI and MALDI. DLDI yields extensive unresolved fragmentation in the TOFMS. MALDI using α cyano-4-hydroxy cinnamic acid as a matrix, gives the M-CN fragment ion as the most abundant analyte ion, and weaker signal from additional assignable fragments.

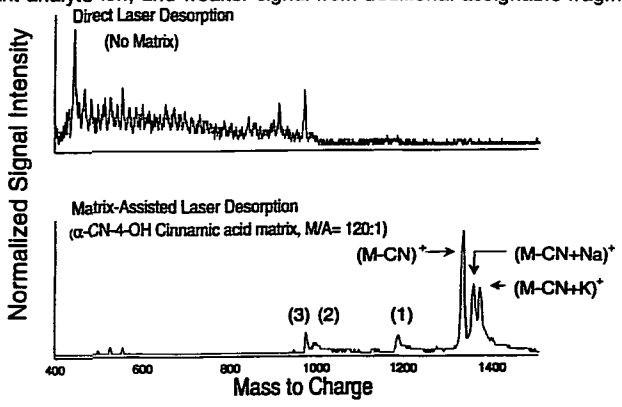

Figure 1. DLDI and MALDI mass spectra of vitamin B_{12}.

Three mechanisms must be considered as potential sources for the fragment ions observed for vitamin B_{12}.

(1) Substrate laser heating with subsequent thermal energy transfer to vitamin B_{12}.

(2) Direct photodissociation of the vitamin B_{12} by the desorbing laser.

(3) Photoactivation of the matrix with subsequent matrix mediated energy transfer to the vitamin B_{12} analyte.

A study of matrix/analyte (M/A) ratio with vitamin B_{12} and α-cyano-4-hydroxy cinnamic acid shows a clear transition from the DLDI type fragmentation to MALDI type fragmentationat M/A of 60:1 or greater. Once this ratio is exceeded little change in either the extent or type of fragmentation is observed at threshold desorbing laser intensities. This behavior suggests that substrate mediated thermal energy transfer is of little significance at M/A of 60:1 or greater.

Comparison of the vitamin B_{12} spectra resulting from use of lasers with different pulse widths (600 ps vs. 3 ns) indicates little change in the extent or type of fragmentation observed. This suggests that the second mechanism of gas phase photodissociation is unlikely. Furthermore, a matrix has been identified (4-hydroxy-3-iodo-5-nitrobenzoic acid) which not only yields an intact parent ion of vitamin B_{12}, but little fragmentation other than the M-CN ion (Figure 2). This result supports the conclusion that fragmentation of vitamin B_{12} is not a result of direct photodissociation. Energy transfer from the photoactivated matrix to the analyte molecule dominates at ratio of 60:1 or greater.

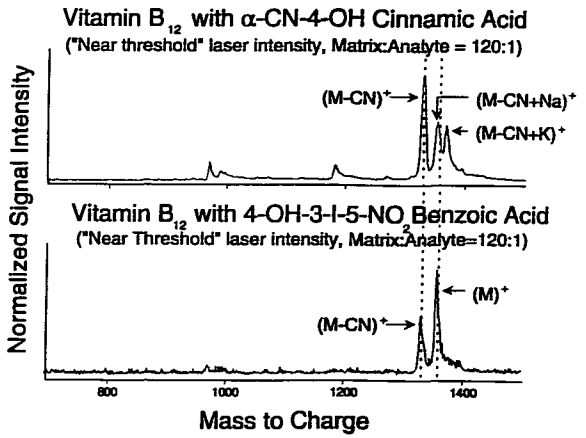

Figure 2. MALDI mass spectra of vitamin B_{12} acquired using two different matrices.

Matrix-assisted Laser Desorption Ionization of Hydrophobic Peptides and Proteins

Kevin L. Schey[1] and Jeff W. Finch[2]
[1]Department of Pharmacology, 171 Ashley Ave
Medical University of South Carolina, Charleston, SC 29425
[2]JEOL USA, Inc., 11 Dearborn Rd, Peabody, MA 01960

Hydrophobic proteins represent an important class of proteins having diverse functions such as ion/molecule transport and signal transduction. The hydrophobic nature of these proteins makes them insoluble in solvents used in standard methods of analysis. The versatility of MALDI makes it an attractive method for molecular weight analysis of hydrophobic peptides and proteins. Two experimental protocols are presented for the analysis of hydrophobic proteins by MALDI. First, formic acid (FA) in combination with hexafluoroisopropanol (HFIP) is used to dissolve hydrophobic proteins present as precipitates, in their native membranes, or even in their native tissues. Second, non-ionic detergents are used to solubilize hydrophobic proteins prior to mixing with the standard MALDI matrix solutions.

Hydrophobic proteins were solubilized by mixing the protein with FA and HFIP in the ratio of 3:7:2. Precipitated proteins can be solubilized using the same ratio of FA to HFIP. Sonication for 5-10 minutes is required for solubilization. The protein solution is then mixed 1:3 with sinapinic acid (50 mM, 70% FA) and spotted on the sample probe tip. Due to deleterious effects of formic acid (discussed below), isopropanol was substituted for FA in the above protocol in several experiments. The second method of sample preparation involved concentrating hydrophobic proteins in non-ionic detergents such as Lubrol-PX and Thesit at concentrations of 0.1%.

Photography of the spotted probe tips indicates drastic differences in crystal formation between the standard MALDI preparation and the preparations described above for hydrophobic proteins. The use of formic acid and HFIP generates a crystalline ring which is lipid coated for solubilized membrane preparations. When isopropanol was substituted for formic acid, a surface of widely dispersed matrix crystals was observed.

Molecular weights were determined for a variety of integral membrane proteins including native and recombinant bacteriorhodopsins; bovine, gecko, and salamander rhodopsins; and the human platelet thromboxane receptor using the FA protocol. A MALDI spectrum of salamander rhodopsin desorbed from solubilized intact retina tissue is shown in Figure 1.

Peptide and protein formylation of serine and threonine residues as well as cleavage of acid labile Asp-Pro bonds are observed in the presence of formic acid. HFIP enhances MALDI signals in this protocol; however, formylation is increased in the presence of HFIP. Substitution of isopropanol for formic acid results in dispersed crystals and oscillatory MALDI signals. Figure 2 shows a MALDI spectrum of bacteriorhodopsin solubilized with isopropanol/HFIP and spotted with sinapinic acid (7:3 isopropanol:HFIP).

A mixture of GTP binding proteins prepared in cholate or CHAPS detergent

micelles produced no MALDI signals. Exchange into non-ionic Lubrol-PX or Thesit provided strong MALDI signals for the gamma subunits of of these proteins.

In conclusion, two protocols have been successfully implemented for the generation of MALDI signals for hydrophobic proteins. Substitution of isopropanol for formic acid was only partially successful. Continued investigation of non-reactive solvents should provide improved MALDI performance for this important class of proteins.

MONITORING BIOMOLECULAR REACTIONS USING MALD MASS SPECTROMETRY

Lee Q. Huang, Robert Tilton, Bart Haigh, and Bill Knowles,
Miles Research Center, Miles Inc., 400 Morgan Lane, West Haven, CT 06516
M. Kimber, A. D. Hoffman, S. C. Davis, C. Moore, D. C. Dingley
Kratos Analytical Inc., 535 East Crescent Ave., Ramsey, NJ 07446

Mass spectrometry has traditionally been reserved for elucidation and confirmation of low molecular weight compounds. However, in recent years mass spectrometry has joined the revolution in the biological sciences, due mainly to the discovery and development of matrix assisted laser desorption (MALD) and electrospray ionization of biological molecules. In this presentation, we report the successful use of MALD mass spectrometry to monitor the biomolecular reactions.

The instrument used in this study is a desktop matrix assisted laser desorption time-of-flight mass spectrometer (Krotos Kompact Maldi III). It comprises both liner and reflectron facilities. The linear facility provides high mass performance as well as highly accurate assignments. Increased resolution is achieved by use of the integral reflection. The system has a 300 Mhz transient recorder for high bandwidth data acquisition. The disposable sample substrate accommodates up to 20 samples and standards. With the MALDI technique only Pico-mol quantities of sample are required. The sample is mounted on a probe that is drawn into the vacuum system under full software control. Interlocked turbo vacuum pump systems provide rapid pump down and a contamination free environment.

The first example is the reaction of a cysteine containing peptide antigen with the protein carrier, BSA. This bioconjugation was monitored by the MALD-MS (Figure 1), and the efficiency of the multiple coupling as determined by mass spectrometry agrees well with independent chemical analysis.

In the second example, MALD-MS was used to monitor the chemical synthesis of peptides containing phosphotyrosine. Analysis of the multiple peaks obtained following HPLC separation allowed us to readily identify the fully deprotected and unmodified phosphopeptide. The kinetics of dephosphorylation by specific phosphotyrosine phosphatases was also examined by MALD-MS. The results demonstrate that MALD-MS has sufficient mass resolution and mass assignment accuracy for monitoring the phosphorylation.

Geometric Signal Averaging Applied to Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry

Randall W. Nelson and Marvin L. Vestal
Vestec Corporation, 9299 Kirby Dr. Houston TX 77054

INTRODUCTION

For some time the matrix-assisted laser desorption/ionization technique has been recognized for its ability to generate time-of-flight mass spectra exhibiting impressive signal to noise ratios (S/N). In numerous examples, spectra resulting from a single laser shot have shown S/N > 10, and in themselves were quite adequate for nominal molecular weight determination. Typically though, spectra are produced by averaging signal from multiple laser shots, either in a computer after single shot acquistition, or during acquisition using a transient recorder capable of fast mathematical operations. The most common signal averaging techniques generally use some form of arithmetic average where the spectra from individual laser shots are added together and the cumulative spectrum divided by the number of spectra used, i.e.

$$[(y)_1 + (y)_2 + (y)_3 + \ldots (y)_n] / n . \qquad \text{Eq. 1}$$

This presentation addresses a new approach to signal averaging, one in which the product of the individual laser shots is used rather than the sum. In this approach, the individual laser shots are multiplied together and the nth root of the product taken (n being the number of spectra used), i.e.

$$[(y)_1 (y)_2 (y)_3 \ldots (y)_n]^{1/n} . \qquad \text{Eq. 2}$$

In principle this approach, termed geometric averaging, offers a variable degree of signal enhancement. Like the arithmetic approach, the signal enhancement for the geometric approach is dependent on the S/N of the individual shots and the number of individual shots taken. Another factor for which the arithmetic approach is independent does however influence the degree of signal enhancement during geometric averaging. This is the absolute offset, above zero, of the individual spectra. At the limits of the absolute offset, zero and infinity, the geometrically averaged spectra approach signal to noise ratios of infinity (for a baseline of zero) and that of the arithmetic average (at a baseline offset of infinity). Practically, the limits of enhancement are reached before either of these extremes, with a significant improvement in S/N, over the arithmetic average, being achieved under proper conditions.

EXPERIMENTAL / RESULTS

Data sets comprised of single laser shot time-of-flight spectra exhibiting similar qualities were generated from samples prepared using sinapinic acid as a matrix, and irradiated at a laser wavelength of 355 nm (frequency-tripled Nd:YAG). Fig. 1 shows five single laser shot time-of-flight spectra of bovine insulin. Each spectrum exhibits a S/N, insulin to baseline noise, of between 5 and 15, with a noticeable amount of single-ion noise. The spectra have been normalized to the insulin signal, giving it a value of 1, and have been given a very small positive baseline offset (~0.01). Adding the five spectra and dividing the summed spectrum by 5 results in Fig. 2, the arithmetic average. As can be seen, an insulin signal to baseline noise enhancement is observed, relative to the individual spectra, and also a significant, but not complete, reduction in the single-ion noise. Because of the nature of the arithmetic average, the characteristics of this spectrum are independent of linear mathmatical operations performed on the individual spectra prior to averaging, i.e., multiplication of, or addition to, the individual spectra before averaging does not affect the cumulative spectra. When geometric averaging (Eq. 2) is applied to the

same data sub-set used in Fig. 2, Fig. 3 results. An almost complete reduction of the single-ion noise is observed.

DISCUSSION

An approach alternate to straight arithmetic signal averaging has been presented. As opposed to using the sum of individual spectral events, the product is used (the approach is termed geometric averaging). In principle, the S/N enhancement of the geometric averaging technique has no limit. The reason for this is that the product of baseline noise crossing through zero, is zero, yielding no noise whatsoever. The product of non-zero coherent signal, on the other hand, yields a signal of something other than zero. Under such conditions a S/N of infinity is expected. In practice, the geometric signal averaging technique mandates an offset of the baseline. A dependence on the absolute value of the baseline, and the single-shot signal to noise ratio, is observed. In general, as the baseline approaches zero, for any data set, increasing signal to noise ratios are observed suring geometric signal averaging. Practical limits at which the geometric S/N equals the arithmetic S/N, and at which a maximum geometric S/N enhancement is obtained, are observed.

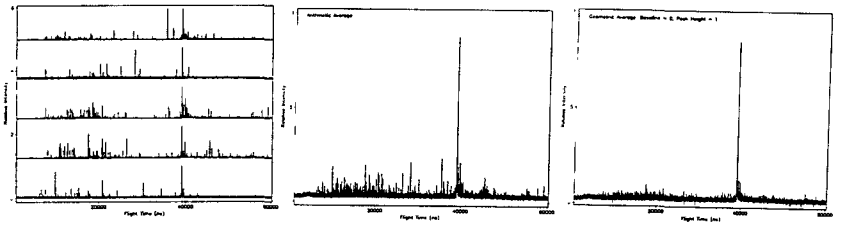

Fig. 1 (left) Five single laser shot time-of-flight spectra of bovine insulin. Sinapinic acid was used as a matrix with 355 nm radiation (frequency-tripled Nd:YAG). **Fig. 2 (center)** Arithmetic average, summed and divided, of the five single shots presented in Fig. 1. The spectra were intensity normalized to the insulin signal (value of 1) and given a slight baseline offset (~0.01). An increase in the insulin signal-to-noise ratio is observed, as well as a reduction in the singl-ion noise contribution. **Fig. 3 (right)** Geometric average of the data set in Fig.1. Again an increase in the insulin signal-to-noise ratio is observed, and an almost complete elimination of the singl-ion noise contribution.

Matrix-Assisted Laser Desorption/Ionization of Oligonucleotides

Kai Tang, Steve L. Allman and Chung H. Chen
Oak Ridge National Lab Oak Ridge, TN 37831-6378

Matrix-assisted laser desorption/ionization (MALDI) has been quite successful in detecting very large protein molecules However, the progress of using MALDI to analyze oligodeoxyribonucleotides is somewhat limited In this work, we report our recent results on this topic for detecting larger homo-oligomeric deoxynucleotides as well as those containing four different bases.

A Nd YAG laser with frequency tripled output of 355nm in wavelength is used for desorption/ionization A linear time-of-flight mass spectrometer was used to analyze the ions produced by MALDI. The typical laser fluence was between 40mJ/cm^2 and 400mJ/cm^2 depending on the absorption coefficient of the matrix used. The typical quantity of the oligonucleotides loaded for analysis was about 2 to 30 picomoles with matrix to analyte ratio of 5000:1 to 10000:1.

Experimental results of poly(dA)$_{12-18}$, poly(dC)$_{12-18}$ and poly(dG)$_{12}$ with ferulic acid (FA), 3-hydroxypicolinic acid (3-HPA) and 2,5-dihydroxybenzoic acid (2,5-DHB) as matrices are shown in Fig 1, Fig.2 and Fig 3 respectively For poly(dA), FA and 3-HPA were better matrices than 2,5-DHB in which one base was cleaved for each nucleotide For poly(dC), base cleavage was observed for both FA and 2,5-DHB matrices, and 3-HPA was obviously a better choice For poly(dG), serious fragmentations due to depurination were observed for both FA and 2,5-DHB as matrices and fragmentations due to the broken of the DNA backbone were also observed in the 2,5-DHB case. Again, 3-HPA was shown to be a better matrix

With 3-HPA as matrix, we have succeeded in detecting oligonucleotides with size up to 60 mer for poly(dA), 30 mer for poly(dC) and poly (dG), and 100 mer for deoxynucleotides containing mixed bases, as shown in Fig 4, Fig 5, Fig 6, and Fig 7 Larger oligomers might be detected if high quality synthetic deoxynucleotides are available. For poly(dT), however, 2,5-DHB continues to be the best matrix when mixed with 10% 5-methoxysalicylic acid as up to 130 mer could be easily detected (shown in Fig.8), although up to 100 mer could also be seen when 3-HPA or FA is used as matrix. These results indicate that deoxynucleotide-matrix interaction is the most critical factor for the success of DNA analysis by MALDI

In conclusion, MALDI has been demonstrated successfully for detection of medium sized deoxynucleotides. We expect it can be used to detect even larger sizes in the near future With further improvement in resolution and sensitivity, DNA sequencing using MALDI-TOF mass spectrometer could become a reality

[3]Memorial University of Newfoundland, Canada A1B 3X7

INTRODUCTION

The inability to directly identify, locate, and quantify post-translational modifications of proteins is a major shortcoming of the standard Edman sequencing methods,(1,2).

We have recently developed a rapid, highly efficient method for sequencing polypeptides: Protein Ladder Sequencing. In this method, a controlled stepwise chemical degradation is performed on one terminus of a polypeptide. The reactions yield a set of sequence-defining peptides, each differing from the next by a single amino acid. This protein sequencing ladder is read out rapidly in a one-step operation by matrix-assisted laser desorption mass spectrometry. Each amino acid is identified from the mass difference between successive peaks, and the sequence is determined by the position in the data set.

Three peptides with different types of post-translational modifications (serine phosphorylation, tyrosine phosphorylation, and N-glycosylation) were subjected to protein ladder sequencing. The experimental results show that all of these three modifications can be identified and that the sites of modification can be determined. Our experimental results demonstrate that the ladder sequencing method can be used to determine the sites and masses of modified amino acids within peptides and proteins.

In this presentation, we also report the automation of the ladder generating chemistry. In addition, results are presented of using short degradation times to generate the sequencing ladder in the absence of a blocking agent and for parallel degradation of multiple peptide samples

EXPERIMENTAL

I. Generating of protein sequencing ladder. The N-terminal degradation reaction of peptides was performed in the presence of a small amount of terminating agent, phenylisocyanate (PIC). The ratio of PIC to phenylisothiocyanate (PITC) is 1:20.

II. Automation of ladder generating chemistry. The automation of this method was carried out by using the chemical delivery device on an ABI-471A protein sequencer.

III. Ladder sequence read-out. Matrix-assisted laser desorption mass spectrometric analysis was carried out on a device constructed at The Rockefeller University. α-cyano-4-hydroxy-cinnamic acid was used as matrix.

RESULTS AND DISCUSSION

An additional advantage of the ladder sequencing method over conventional Edman sequencing is its ability to determine the sites and masses of modified amino acids within peptides and proteins. To assess the potential of ladder sequencing for the elucidation of post-translational modifications, we have applied the method to an analysis of a 16-residue serine-containing peptide that is a substrate for cAMP-dependent protein kinase. Both the phosphorylated and unphosphorylated forms of the peptide were subjected to protein ladder sequence analysis. The ladder sequencing of the 16 residue synthetic peptide: SWI-57A, L-R-R-A-S^5-G-L-L-Y-N^{10}-N-P-L-M-A^{15}-R-NH_2. are shown in Figure 1, (A) Phosphorylated peptide, (B) Unphosphorylated peptide. Each peptide sample was subjected to ten cycles of ladder-generating chemistry, after which the sequence-defining set of fragments was read out in a single operation by laser desorption mass spectrometry. Data defining the N-terminal 11 amino acid residues is shown. The Ser(P_i) residue was characterized by a mass difference of 166.7 daltons (Ser, calculated residue mass 87.1; Ser(P_i) calculated residue mass 167.1) observed in position five. There is no evidence of loss of phosphate.

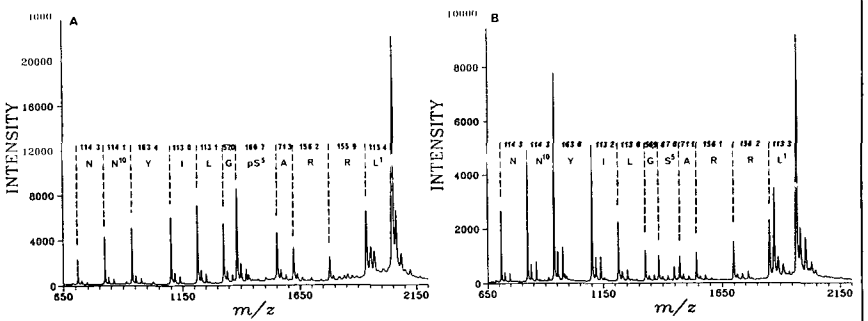

Figure 1. Ladder sequencing of Ser-phosphorylated peptide. (A) phosphorylated peptide; (B) unphosphorylated peptide.

CONCLUSION

The ladder sequencing method has general applicability to the direct identification of post-translational modifications.

LASER ABLATION OF PROTEINS USING NANOSECOND PULSES OF TUNABLE MID-IR RADIATION

David M. Schieltz, David Dogruel and Peter Williams
Department of Chemistry and Biochemistry
Arizona State University
Tempe, AZ 85287-1604

Previously we demonstrated that massive DNA molecules can be ablated intact from thin frozen films of aqueous solution by nanosecond pulses from a visible laser. The angular distribution of the ablated DNA is strongly forward-peaked, consistent with the idea that the ablated water vapor plume undergoes a supersonic jet expansion which can efficiently cool the entrained biomolecules. Although ionization in this process is highly irreproducible, when a mass spectrum is obtained, the peaks show no evidence of fragmentation, which is consistent with the idea that efficient cooling occurs in the expanding vapor plume. A difficulty with reproducibility in this approach is that, because heating follows energy deposition in the substrate, each laser shot completely ablates the entire sample film in the irradiated area, so that the sample must be moved for each successive shot. In contrast, mass spectra of DNA ablated using UV radiation from a UV chromophore matrix show extensive fragmentation, suggesting that cooling in the vapor plume is far less efficient. Because only a shallow depth is ablated on each shot, multiple shot averages can be obtained from an appropriate region and sample uniformity becomes far less important. However, the small amount of vapor produced on each shot appears not to develop a full supersonic expansion which can cool the ablated biomolecules efficiently.

It would be desirable to combine the best properties of both ablation approaches. If the ice matrix could be heated directly, using ~ 2.9 μm radiation, thick targets could be used and spectra from multiple laser shots could be obtained from a given region of the sample. The relatively large extinction depth of 2.9 μm radiation in ice should result in ablation of a few μm thick water layer, which should evolve into a supersonic jet capable of effectively cooling entrained biomolecules. Recent publications have indicated that ions are formed reproducibly at this wavelength. To date, ablation experiments in the mid-IR have used 150-200 ns long pulses, and we were concerned that the continued irradiation of the vapor plume by the tail of the laser pulse might cause heating which would negate the cooling effects of the expansion. We have now evaluated the effectiveness of ablation of frozen DNA and protein solutions using 2.9 μm radiation from an optical parametric oscillator (OPO). The OPO (STI Optronics Inc., Mirage 3000) is pumped by 1064 and 532 nm pulses from a Q-switched Nd-YAG laser, and produces 1-2 mJ pulses a few nanoseconds wide. In principle the OPO is tunable over a wavelength range from ~ 1.5 - 4 μm, but all our experiments were conducted at 2.9 μm.

We reached the following conclusions about this approach:

a) The OPO is a more complex laser system than is desirable for a robust analytical technique, but with care it delivered 2.9 μm pulses reproducibly over a one-month evaluation period.

b) Ablation depths for aqueous targets at 2.9 μm are certainly far greater than for UV chromophores in the UV; it was estimated from the single pulse ablation of thin frost layers that ablation depths were on

the order of several micrometers.

c) Time-of-flight mass spectra were *not* obtained reproducibly using this approach. For most experiments we used small proteins rather than DNA analytes, and shot-to-shot reproducibility, although significantly better than for our visible laser approach was far worse than in the UV, and was unacceptable for analytical purposes.

d) The most reproducible spectra were obtained using solid matrices such as 2,5-dihydroxybenzoic acid. Even here, reproducibility was worse than in the UV. The mass spectrum of bovine albumin, ablated from succinic acid is shown in Fig. 1. The spectrum contains molecular ions in charge states extending up to at least +7. Disappointingly, the high background signal and the broad peaks suggest that extensive fragmentation is occurring, so that the anticipated greater cooling and reduced post-ablation heating appear not to have the desired effect of producing cool, unfragmented molecular ions. The difference between these spectra and those obtained for DNA from ice using an indirect heating approach may result from coupling a significantly greater amount of energy into the sample volume by direct heating with 2.0 μm radiation.

Structural Characterization of Oligonucleotides by Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry

*Bing H. Wang and Klaus Biemann
Department of Chemistry, MIT, Cambridge, MA 02139

Structural characterization of small oligonucleotides (3-50mer) by mass spectrometry has many applications. For example, the assessment of the homogeneity and correctness of the sequence of a synthetic oligonucleotide is very difficult by conventional methods. We have found that some of these problems can be conveniently solved by measuring the molecular weights of the samples by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOFMS). Subjecting the samples to Maxam-Gilbert reactions prior to MALDI-TOFMS analysis yields additional structural information.

Maxam-Gilbert Reactions[1] For "C+T" base-modification reactions in this study, a few microliters of oligonucleotides (50 pmol/μL) was combined with 60 μL of hydrazine. The mixture was incubated in a thermal bath for a selected length of time. For "T" base-modification reactions, 1 μL of pyridine was combined with 1 μL of 5% aqueous solution of OsO_4 and a few microliters of oligonucleotide (50 pmol/μL). The mixture was incubated at 30 °C for 15 minutes. For strand-scission reaction, based-modified oligonucleotide mixture was dissolved in 100 μL of 1 M piperidine and incubated at 90 °C for 30 minutes.

MALDI-TOFMS Analysis Typically, 0.5 μL of oligonucleotide solution ($1\text{-}5\times10^{-5}$ M) was co-deposited with 2 μL of matrix consisting of 1:1 (weight) mixture of anthranilic acid and nicotinic acid in aqueous 30% acetonitrile solution (12 g /L). Ion exchange resin (100-200 mesh) was added to reduce the formation of alkaline-metal adduct. [2] All spectra were obtained with a linear time-of-flight mass spectrometer (VESTEC-2000) equipped with a nitrogen laser (337 nm) in the negative ion mode. Typically 10 laser shots were summed to yield one mass spectrum.

We have been able to observe $(M\text{-}H)^-$ ions up to $d(T)_{40}$, for which a mass resolution (FWHM) up to 500 has been obtained.

The utility of direct molecular weight measurements of oligonucleotides is illustrated by an example involving a 16mer-synthetic oligoribonucleotide, in which one phosphate-diester group has been succesively replaced by a phosphorothioate group. MALDI-TOF analysis revealed that, as the synthesis progressed from 3'-end toward the 5'-end, the sulfur atom was gradually lost, *i.e.* replaced by an oxygen atom (Figure 1).

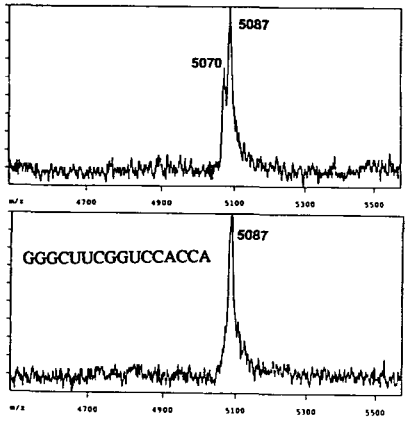

Figure 1. MALDI-TOFMS Spectra of 16mer Oligoribonucleotides. Phosphorothioate Substitution Occurred at the Positions between C11 and C12 (Top); and between G1 and G2 (Bottom).

Combining chemical reactions with molecular-weight data provides additional structural information. An example illustrating this approach concerns a 25mer-synthetic oligodeoxynucleotide, in which one G was replaced by its O^6-n-butyl guanine derivative to study the mutagenic effect of alkylation at the site of modification. The mass spectrum revealed the presence of two products differing by 72 u due to incomplete removal of the protecting butyryl group. This extra component had eluded the detection by gel electrophoresis. "T" cleavage confirmed that the modification site is in the correct region. However, the butyryl group has been lost during the cleavage reactions.

When a synthetic 12mer deoxynucleotide (5'-TCTGGUACCTCT-3') was subjected to "C+T" reactions, U was removed much faster than C or T, leaving TCTGGp (*m/z* 1573) and pACCTCT (*m/z* 1806) as two major products (Figure 2). In contrast, when an oligodeoxynucleotide does not contain a U, "C+T" cleavage occurs much more uniformly at all positions of T and C.

In conclusion, MALDI-TOFMS is a sensitive and convenient technique for the detection of oligonucleotides. Mass resolution up to 500 (FWHM) obtainable by this technique allows the identification of small changes in the structure of an oligonucleotide, which may elude the detection by conventional techniques. Structural information can be obtained by combining Maxam-Gilbert reactions with MALDI-TOFMS.

COLLECTOR STUDIES OF ANGULAR DISTRIBUTION AND FRAGMENTATION OF PROTEINS ABLATED FROM ICE AND UV-ABSORBING MATRICES

Congwen Luo and Peter Williams
Department of Chemistry and Biochemistry
Arizona State University
Tempe, AZ 85287-1604

Despite the dramatic successes of matrix-assisted laser ablation in generating intact molecular ions of extremely large biomolecules, there still exists no concensus on the mechanism by which the matrix apparently protects analyte molecules from destruction by the intense laser radiation. Suggested mechanisms include a "bottleneck" for energy transfer from matrix to analyte (Vertes), cooling by evaporation of a matrix molecule solvation shell (Hillenkamp) and cooling in a supersonic free jet expansion (Nelson *et al*). There is little experimental evidence concerning the first two models, but evidence does exist that some degree of supersonic expansion occurs. Nelson *et al* showed that angular distributions of radiolabelled DNA ablated from an ice matrix were very strongly forward-peaked. Cooling by a factor of 3-5 could result from such expansions. Velocity measurements have shown that UV-ablated matrix and analyte molecules have similar mean velocities, again suggestive of a jet, although the velocity *spread* is broad, suggesting that cooling may not be strong. Early successes with UV ablation of intact proteins are proving difficult to reproduce with DNA molecules; UV-ablated DNA mass spectra show extensive fragmentation, suggesting that the process produces very hot molecules. We have used a collector approach to determine angular distributions of lysozyme and matrix molecules ablated from 2,4-dihydroxybenzoic acid (DHB) and from ice, and gel electrophoresis to determine the state of fragmentation of the ablated protein. We have also revisited earlier collector measurements of DNA ablated from ice.

UV-ablation samples were prepared as films (~ 1 cm^2) on a stainless steel sample holder, using DHB/lysozyme ratios typical of those used for mass spectrometry. Because a relatively large amount of ablated material is required, the sample was moved mechanically under the laser beam to irradiate an area of approximately 1 cm^2. Frozen solution films were prepared by spreading ~ 20 µL over a 1-2 cm^2 area on a copper block cooled to ~-20 °C and subliming to a few µm thickness in a rough-pumped vacuum system. The samples were then plunged into liquid nitrogen and transferred when cold to the liquid nitrogen-cooled sample stage of a time-of-flight mass spectrometer. The DHB samples were ablated using the tripled output of a Q-switched Nd-YAG laser at 355 nm. Power densities were in the range 10^7 to 10^8 W/cm^2. Ice samples were ablated using 578 nm pulses from a dye laser; power density was ~ 10^9 W/cm^2. Ablated material was collected on a Whatman No. 2 filter paper suspended 2 cm from the sample. The angular distribution of DHB was visualized using UV-induced fluorescence and recorded photographically. The protein was stained with Coumassie Blue and photographed. Photographs were digitized using a slow-scan CCD camera and digital line scans were obtained across the distributions.

A typical angular distribution of lysozyme UV-ablated from DHB is shown in Fig. 1. The data are compared with a power cosine function, $I(\Theta) = I(0)\cos^n\Theta$, for various values of n. The best fit to the UV data was obtained for n = 4-5. The distribution of the lysozyme was slightly narrower than that of the DHB at lower power, but the two distributions became identical at the highest power used. These data may be compared with the angular distribution of lysozyme ablated from a thin ice film (Fig. 2) This

distribution was much more strongly forward-peaked (n = 35 ± 5), consistent with our earlier results for DNA ablated from ice (n ~ 40). Gel electrophoresis of the collected lysozyme showed that fragmentation had occurred, but that the extent of fragmentation decreased as the laser power density increased. This too is consistent with our earlier work.

These data suggest that the cooling effect accompanying the expansion of UV-ablated DHB is quite small. The fact that the supersonic jet expansion is poorly-developed probably is due to the shallow ablation depth resulting from the high extinction coefficient of the UV chromophore. In a true supersonic jet, expansion can only occur in the forward direction. When only a few tens of monolayers of material are ablated, however, expansion can also occur in the reverse direction after the plume detaches from the surface. The asymmetry introduced by the surface imposes a net forward velocity on the system which is typically hyperthermal, but the cooling of translational velocities is much less effective than in a full supersonic expansion. In the frozen samples, typically the entire film in the irradiation area is removed in a single pulse -- a thickness of several µm -- giving a gas pulse that has more of the characteristics of a true supersonic jet.

This work was supported by the US Department of Energy Grant DE-FG02-91ER61127.

Effects of Desorption Technique and Post-Ionizing Laser Pulse Width on Molecular Fragmentation

*C. R. Ayre,[a] L. Moro[b] and C. H. Becker[a]

[a]Molecular Physics Laboratory, SRI International, Menlo Park, CA 94025
[b]Instituo per la Ricerca Scientifica e Tecnologica, Divisione di Scienza dei Materiali, I-38050 Povo-Trento, Italy

The influence of desorption technique and post-ionizing laser wavelength on the fragmentation of *l*-tryptophan and serotonin, two biologically important molecules, has been investigated using time-of-flight mass spectrometry (TOF-MS) and the results compared with positive, static secondary ion mass spectrometry (SIMS) data obtained with the same apparatus. While ion-stimulated desorption using 7 keV Ar^+ was employed exclusively in the SIMS experiments, both ion-stimulated and thermal desorption were used in conjunction with laser post-ionization. Furthermore, laser wavelengths of 118 (10.5 eV) and 266 nm (4.66 eV) were employed to compare the photofragmentation patterns arising from single photon and multiphoton laser post-ionization. Finally, in the 266 nm experiments, the effects of post-ionizing laser energy density were explored by making independent measurements using the fourth harmonic of 5 ns and 35 ps Nd:YAG lasers.

All experiments were conducted in a stainless steel UHV chamber with a typical base pressure of ca. 5×10^{-9} torr which has been described elsewhere [1,2]. Briefly, in laser post-ionization experiments, neutrals desorbed from a sample were photoionized by a focused laser beam passing approximately 1 mm above and parallel to the sample surface. The photoions were analyzed by a reflecting time-of-flight mass spectrometer, which electrostatically rejects secondary ions, and detected by a dual microchannel plate assembly [1]. Alternatively, time-of-flight positive SIMS spectra were recorded after minor adjustments of the mass spectrometer voltages [3]. In ion-stimulated desorption experiments, a pulsed (10μs), 7 keV Ar^+ beam was employed. A typical Ar^+ current of 0.1 μA in a 160μ diameter spot was obtained at the target for a continuous beam. Post-ionizing laser radiation from two different lasers was used. For experiments involving 266 nm post-ionization, the frequency quadrupled output of 5 ns and 35 ps Nd:YAG lasers was used independently. VUV radiation (118 nm; 10.5 eV) was obtained by third harmonic generation of the 355 nm output of the 35 ps Nd:YAG laser in Xe phase-matched with Ar. Samples were prepared by laser post-ionization experiments by pressing *l*-tryptophan or serotonin powder onto indium or tantalum foil. In SIMS experiments, silver foils etched with nitric acid and rinsed in deionized water were dipped in sample solutions of serotonin or *l*-tryptophan (concentration: *ca.* 10 μg/μL), the excess solution was shaken off, and the sample was allowed to dry in air.

The effects of ion-stimulated and thermal desorption on fragmentation pattern were probed by comparing the spectra obtained for *l*-tryptophan and serotonin when each of these techniques was followed by photo-ionization at a particular laser wavelength and

energy density. For *l*-tryptophan *m/z* 130 $(M-74)^+$, which arises from C_α-C_β cleavage of the amino acid side chain, was among the most intense peaks in all spectra. By contrast, for serotonin, the most abundant mass fragments varied as a function of both desorption method and laser wavelength. For positive SIMS, for example, loss of both the hydroxyl (-OH) and amine ($-CH_2CH_2NH_2$) substituents to yield *m/z* 115 $(M-61)^+$ and loss of water and the amine side chain to produce *m/z* 114 $(M-62)^+$ occurred. These peaks were several times more intense than *m/z* 146 $(M-30)^+$ due to α-cleavage of the amine, *m/z* 160 $(M-16)^+$ due to radical loss of $-NH_2$, and the molecular ion M^+ (*m/z* 176). However, the *m/z* 114 and 115 peaks are absent from both the 118 and 266 nm laser post-ionization spectra recorded following ion-stimulated desorption, and the *m/z* 146 $(M-30)^+$ peak is of greater intensity. Yet, in single photon (118 nm) post-ionization following the thermal desorption of serotonin at 200 °C, *m/z* 112 and 113 due to the loss of the amine and hydroxyl substituents plus 2-3 additional hydrogens were stronger than *m/z* 146 $(M-30)^+$. Finally, the *m/z* 112-115 peaks were absent from the 266 nm thermal desorption spectra at all laser energy densities employed.

In general, the use of a pulsed 7 keV Ar^+ beam for desorption was found to cause extensive fragmentation of both *l*-tryptophan and serotonin relative to thermal desorption. The molecular ion (M^+) for *l*-tryptophan (*m/z* 204) was absent from all spectra in which ion-stimulated desorption was employed. A weak M^+ (*m/z* 176) signal was observed in the positive SIMS spectrum of serotonin, but no M^+ peak appeared when either 118 or 266 nm post-ionization of sputtered neutrals was employed following ion-stimulated desorption.

Finally, increased fragmentation of both molecules occurred when the intensity of the 266 nm post-ionizing laser energy density was increased. For example, for both serotonin and *l*-tryptophan, an increase in post-ionizing laser energy from *ca.* 2.5×10^3 mJ cm^{-2} to 8×10^3 mJ cm^{-2} resulted in an increase of an order of magnitude in the ratio of the total yield of fragment ions to the molecular ion yield.

Laser Desorption and High Temperature Methods for Vaporization and Ionization in Particle Beam LC / MS Interfacing

J. Chris Richardson and Richard F. Browner, School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, Georgia 30332-0400

INTRODUCTION

Particle beam LC/MS is unique in using an aerosol based interface that is solely a "transport" interface. After aerosol generation, the analyte is desolvated and transported to the mass spectrometer as solid crystals or solvent-free drops. Consequently, the technique does not exclusively favor any one ionization technique over another, and a wide variety of vaporization / ionization techniques may be used. Up to this point, the ion formation has been a two step process of vaporization by collision with a resistively heated source block followed by electron impact or chemical ionization. However, many compounds are too involatile or thermally labile to be vaporized and ionized effectively by these techniques. Some have demonstrated decreased thermal degradation with the use of an extremely hot target, consisting of electrically heated nichrome ribbon. Also, softer ionization methods such as FAB and SIMS have been used with varied success in this laboratory. More recently, we have been successful in obtaining laser desorption / ionization (LDI) and matrix assisted laser desorption (MALD) spectra on a quadrupole mass spectrometer using flow injection introduction.

The purpose of this research is threefold: 1) Directly compare laser vaporization / electron ionization to other forms of high temperature vaporization, 2) Test the feasibility of surface ionization (ionization caused by contact with a surface held at temperatures in excess of 1500C), and 3) Explore and improve on current techniques for producing laser desorption ionization spectra with the particle beam interface.

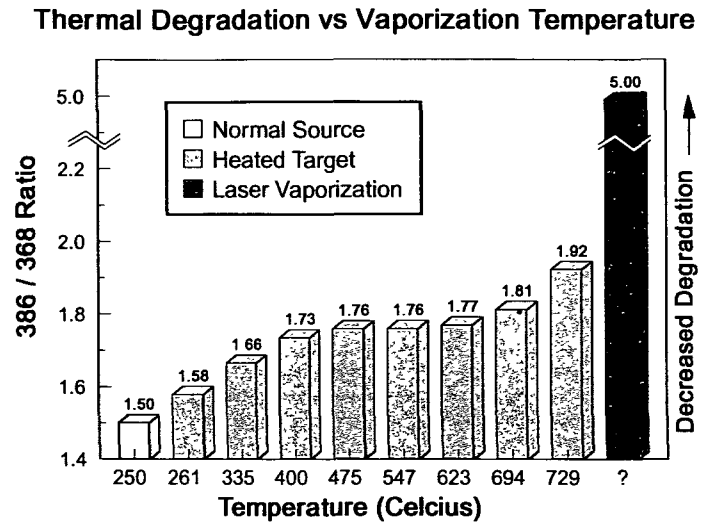
EXPERIMENTAL

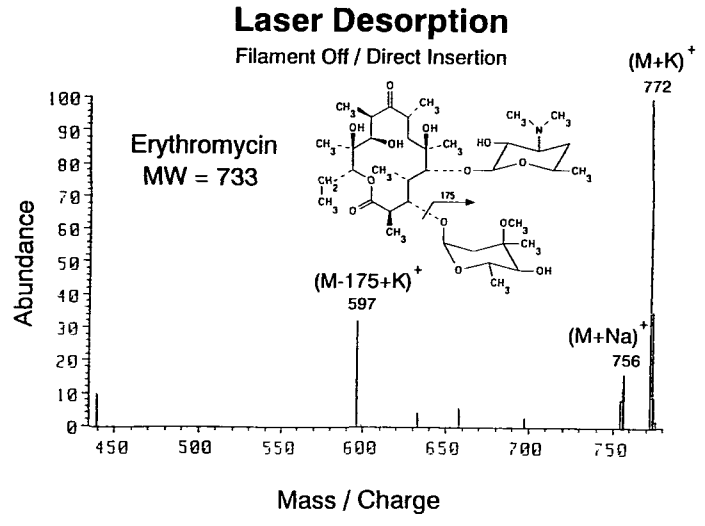
Experiments were performed on an HP 5988 quadrupole mass spectrometer. The laser in use is a continuous wave, 3W Argon ion laser, operated in the multi-line mode at 457.9-514.5nm, focused to a power density of ~10^3 W/cm^2. Flow injection experiments were performed using an HP 1090 HPLC pump at 0.4mL/min with a 5 µL injection volume.

RESULTS AND CONCLUSIONS

The loss of water by cholesterol is often used as a measure of the thermal degradation caused by a system. Figure 1 shows the results of a comparison between laser vaporization and other forms of vaporization. Decreased degradation is observed with increasing temperature, with the laser vaporized cholesterol showing at least a three fold decrease in degradation. These results suggest that the coupling of laser vaporization to a softer ionization technique such as chemical ionization, could make the analysis of very thermally labile compounds by particle beam a routine process.

Next, LDI experiments were performed using the argon ion laser. The ion source was completely removed to accommodate the laser. The particles exiting the PB transport tube were directed onto a blackened ceramic probe, where LDI takes place. Thus far, flow injected LDI spectra have been obtained for methyl red, naloxone caffeine, aerosurf, sucrose, and cholesterol. All spectra show little or no fragmentation, with a potassium adduct ion $(M+K)^+$ as the base peak. Several direct insertion spectra have been obtained using the argon laser, including aldicarb, ampicillin, and erythromycin, which is shown in figure 2. These spectra demonstrate the potential of this technique to broaden the scope of compounds amenable to PB-LC/MS.





POWER-DEPENDENT CALIBRATION SHIFTS IN LASER ABLATION TIME-OF-FLIGHT MASS SPECTROMETRY

Chau-Wen Chou and Peter Williams
Department of Chemistry and Biochemistry
Arizona State University
Tempe, AZ 85287-1604

Laser ablation time-of-flight mass spectrometry is becoming widely used for molecular weight determination of massive proteins and other biomolecules, and impressive accuracies have been claimed for such mass determinations. Although mass reference standards are often incorporated into the analytical sample, it may often more convenient to attempt to establish an instrument calibration curve using an external standard and to assume, or hope, that this curve is universally applicable. We have recently identified a circumstance where this hope may not always be justified.

A fullerene mixture provides a useful time-of-flight calibration sample at relatively low masses because the mass distribution of unseparated fullerenes is dominated by the C_{60} and C_{70} peaks at masses 720 and 840 Da respectively. In using such a fullerene mixture to calibrate a time-of-flight mass spectrometer, we noticed that the C_{60} and C_{70} peaks could be shifted to significantly longer flight times if the laser power was increased to the point where intense signals from the copper substrate were present at low mass. Figure 1a shows a typical time of flight mass spectrum of an unseparated fullerene mixture. 10-20 µL of a dilute solution of the fullerenes were pipetted onto a copper sample block and allowed to evaporate, forming a thin deposit over an area of 1-2 cm^2. The sample was ablated using 532 nm pulses from the frequency-doubled output of a Nd-YAG laser. Pulse energies were ~ 0.8 mJ/pulse and the beam was focussed to an elliptical spot ~ 100 x 200 µm across, giving an energy density ~ 4 J/cm^2. The C_{60} and C_{70} peaks form a distinctive doublet at 15.2 and 16.3 µs. The position of these peaks is within < 1% of the calculated flight time for these ions through the mass spectrometer. When the laser power was increased to ~ 2 mJ/pulse (10 J/cm^2), a strong signal was generated at low mass from the copper substrate. Accompanying this low mass signal, we saw a significant increase in the C_{60} and C_{70} flight times as seen in Figure 1b. Again, the distinctive signature of the two peaks ensures that we are not seeing the appearance of some new heavier species. These shifts vary with the intensity of the low-mass signal, which depends on the laser power.

Examination of peak shifts at varying laser power revealed the following:

a) Both the C_{60} and C_{70} peaks shift together: the time difference between the peaks is constant to better than 100 ns while the peaks shift by several microseconds.

b) At higher power a mass 1 peak can be seen; the flight time for these H^+ ions is consistent with the flight time calculated from a fullerene calibration *at low power*, i.e. there is no detectable shift in the mass 1 peak at times when the fullerene peaks are shifted by several µs.

c) There is a rough correlation between the duration of the intense low mass signal and the fullerene shift, i.e. the time difference between the upper time limit of the low mass peak and the fullerene peaks is roughly constant.

The mechanism we feel is most consistent with our data is as follows. At high power, the pulse of low-mass ions is sufficiently intense to result in a strong space charge above the sample surface; if we assume that the low-mass ions are distributed over a 100 µm deep region above the sample surface, the ion density in this volume is estimated to be ~ 10^{18} ions/m^3. Because the heavier fullerene ions move away from the surface more slowly, the effect of this charge will be to screen the fullerenes from the acceleration field for a short period until the low mass ions are accelerated away. From the width of the low mass peak it may be estimated that extraction of the ions from the space-charge cloud can take up to ~ 5 µs. Only when this space charge has been dissipated can heavier ions trapped below the cloud be extracted. These ions then see the normal acceleration field, and their *relative* flight times are characteristic of the relative masses accelerated in the full field. However, the arrival times are delayed by the dissipation time of the low-mass pulse. Also consistent with this picture is the fact that the arrival time of the mass 1 peak does not vary significantly in the different spectra.

This space charge effect has serious implications for mass calibration accuracy in any situation where there is an intense low-mass ion flux, which can often be the case in matrix-assisted laser desorption. In such a case, the calibration curve for a set of protein masses will not go through zero time at zero mass but will be offset. If several calibration masses are available, a valid calibration curve may still be obtained. However, if only a single calibration mass is used, with the assumption that the curve passes through the origin, errors will result. Additionally, external calibrations at different laser power settings may be erroneous. In systems where the low-mass ions are suppressed by a deflector pulse after acceleration, the operator may not be aware of the possibility of space charge effects. Finally, if shot-to-shot fluctuations in laser power occur, the effect of varying space charge will be to degrade mass resolution in an averaged spectrum due to the shifting peak positions.

HYPERTHERMAL SURFACE IONIZATION MASS SPECTROMETRY IN SUPERSONIC MOLECULAR BEAMS

Aviv Amirav, Albert Danon and Shai Dagan

School of Chemistry, Tel Aviv University, Tel Aviv 69978, Israel, Fax 972-3-6409293

Organic molecules acquired with hyperthermal (1-20 eV) kinetic energy in a supersonic molecular beam (SMB) undergo efficient surface ionization. The molecular kinetic energy increase the surface ionization yield by several orders of magnitude and thus hyperthermal surface ionization (HSI) can serve as a universal ion source for organic mass spectrometry with tunable selectivity.

Five main types of HSI processes were observed:
(a) Molecule-surface electron transfer, (b) Surface-molecule electron transfer, (c) Hyperthermal surface induced dissociative ionization, (d) Chemically induced hyperthermal surface ionization and (e) local hot spot HSI.
These processes will be described with several examples.

We have found that HSI may lead to extensive ion dissociation and non-statistical negative and positive fragment ion formation. This fragmentation occurs near the surface in small molecules and is affected by it while in large polyatomic molecules such as cholesterol, it is unimolecular far away from the surface. HSI serves as a very efficient mass spectrometry ion source with total ionization efficiency of over 10 percent. This and the lack of vacuum background ionization result in sub-femtogram minimum detected amount. HSI in SMB is also uniquely supplemented by a fast GC-MS inlet and a fly through electron impact ion source. This combination results in a new approach of mass spectrometry in supersonic molecular beams. The electron impact ion source results in EI mass spectra with total fragmentation tunability and enhanced relative abundance of the molecular weight peak. In addition, the in line combination of EI ion source and HSI surface, allow the surface induced dissociation (SID) of EI produced ions on the HSI surface. We have found that rhenium oxide surface is a very good surface for both HSI and SID with 70 times enhanced SID yield in comparison with stainless steel.
Hyperthermal surface ionization is also characterized by a tunable degree of ionization selectivity which is controlled by the surface used (work-function) and molecular kinetic energy. The selective detection of aromatic compounds in gasoline with fast GC-HSI-MS will be demonstrated.

pH EFFECTS AND INSULIN CLEAVAGE IN MATRIX-ASSISTED LASER DESORPTION MASS SPECTROMETRY

X. Tang[a], R. Donaldson[b], A.Vertes[a*]
[a] Department of Chemistry, [b] Department of Biological Sciences
The George Washington University, Washington, DC 20052

The effect of pH on matrix assisted laser desorption mass spectrum (MALD-MS) of insulin has been studied to uncover the influence of matrix acidity. UV optical absorption spectra of insulin and four different matrix solutions (sinapinic acid: SA; 2,5-dihydroxy-benzoic acid: DHB, α-cyano-4-hydroxycinnamic acid: CHCA; 2-(4'-hydroxyazobenzene)-benzoic acid: HABA) were investigated while gradually replacing their solvents with NaOH solution. Minor shifts in the absorption maximum were observed. Melting point and pH measurements supplemented the investigations. Characteristic values for melting points, UV absorption maxima, molar absorptivity at nitrogen laser wavelength (337 nm), pH, and pK_a are shown in Table 1 for the matrices and for the corresponding sodium salts.

Table 1. Characteristics of matrices and their sodium salts:

	Matrices					Sodium salts of matrices			
	MP (°C)	λ_{max} (nm)	ϵ_{337nm} ($M^{-1}cm^{-1}$)	pH	pK_a	MP (°C)	λ_{max} (nm)	ϵ_{337nm} ($M^{-1}cm^{-1}$)	pH
SA	203	320	14,000	3.75	6.20	>290	310	7,200	8.60
CHCA	206	335	28,000	2.70	4.08	>300	325	14,800	6.08
DHB	252	330	5,600	2.52	3.76	>290	322	1,940	4.50
HABA	211	359	28,000	3.63	5.96	>300	349	16,800	7.10

MP: melting point; pH was measured at 0.05 M concentration

Matrix sodium salts show significantly increased melting points, elevated pH and somewhat lower molar absorptivity at 337 nm. Insulin absorption maxima were found at λ_{max}=277 nm in 0.1% trifluoroacetic acid solution (ϵ_{337nm} =92,000 $M^{-1}cm^{-1}$) and λ_{max}=295 nm in 0.02 M sodium hydroxide (ϵ_{337nm} =9,000 $M^{-1}cm^{-1}$).

MALD-MS of insulin in the four matrices and in their sodium salts were recorded on a Comstock Model TOF-101 time-of-flight mass spectrometer. The instrument was modified to accommodate laser desorption and 30 kV accelerating voltage. A Laser Science VSL-337ND nitrogen laser was used for ion generation. Spectra were obtained close to threshold irradiance for ion formation. Good protein molecular ion signal was found for neat SA, DHB, and CHCA matrices. Partial or total neutralization of the matrix solutions with NaOH led to declining total ion yields. Diminishing of both insulin related *and* matrix molecular ion signals were observed in the MALD spectra. We could not compensate spectrum deterioration by increasing laser irradiance.

The cool plume model of MALD [1] predicts that minor increase in melting point and/or lowering of the molar absorptivity can be compensated for by elevating the laser irradiance. In fact, model calculations showed that SA and SA sodium salt matrix produced plumes of similar *neutral*

particle densities at 2×10^6 W/cm^2 and 10^7 W/cm^2 irradiances, respectively.

There are several possible explanations of the lack of matrix and protein molecular ions in the salt based MALD-MS. Significantly lower acidity of the matrix salts may explain the lack of protonated insulin ions. Sodiated quasi-molecular ions, however, could be present in these spectra. Another possible explanation is the thermal degradation of the salt matrix. Neat matrices produce plumes by strong sublimation, whereas the salt matrices may decompose before they reach their phase transition temperature. The existence of this process is supported by the presence of low molecular weight non-matrix specific ions in the mass spectrum.

Similar MALD-MS measurements were carried out using neat matrices and insulin dissolved in 0.05 M NaOH. Standard quality spectra were observed showing the kinetics of insulin cleavage. Figure 1 shows a series of MALD spectra of insulin incubated in 0.05 M NaOH for (a) 10 min, (b) 35 min, (c) 60 min, (d) 75 min, (e) 420 min, respectively. The peaks labelled A, B, I correspond to chain A, chain B and to intact molecular ions of insulin, respectively.

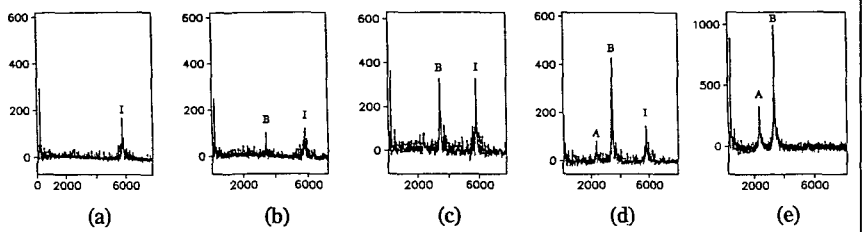

Figure 1.

At 10 min after dissolving the insulin in 0.05 M NaOH only the intact insulin molecular ion peak appeared. After 30 min, both reduced chain B and intact molecular ion peaks were abundant, but no chain A was observed. The domination of chain B in positive-ion spectra was also mentioned by other authors [2]. The intensity of chain B peak increases with increasing reaction time. After 7 hrs, only chain A and chain B species were observed. To study the effect of base concentration 0.004 M NaOH solvent was also used. MALD-MS at 10 min, 30 min, 1 day and 1 month showed no sign of insulin cleavage, only intact molecular ion peak appeared.

To verify that the cleavage is a liquid phase process (i.e. to rule out photochemical effects) gel filtration was used to detect the cleavage products before laser irradiation. Sephadex G-25 gel filtration of insulin (10 mg/ml) dissolved in pH 10.5 phosphate buffer showed no cleavage in the eluent. Complete cleavage was observed in the presence of β-mercaptoethanol (0.02 ml/ml). UV absorption detection after the column indicated three components in insulin incubated in 0.05 M NaOH for 1 hr. Thus, we concluded that the formation of chain A and B in mild base is a liquid phase process. MALD-MS proved to be an appropriate tool to follow the cleavage process.

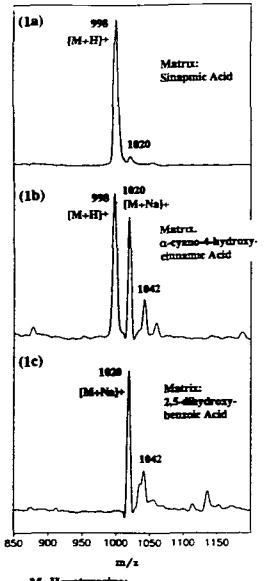
Investigating the Ionization Step in MALDI: Matrix-Dependent Formation of [M+H]+ *vs.* [M+Na]+ Ions of Small Peptides

*Pao-Chi Liao and John Allison
Department of Chemistry, Michigan State University, East Lansing, MI 48824;

Matrix-assisted laser desorption/ionization, MALDI, has one feature that links it to other desorption/ionization techniques such as FAB and SIMS - its development and commercial availability preceded our understanding of the chemical and physical processes that are involved. To generate ions in MALDI, analytes must be desorbed and, at some point, ionized. Models to describe the desorption of large, intact molecules from an energized matrix have been pursued, and appear to accurately describe the desorption step[1]. The chemical step, leading to ionization, is still a matter of considerable debate. Data are presented here concerning our pursuits in defining the ionization step in MALDI. We concentrate our efforts here on positive ion formation, using UV laser excitation.

Our initial goal was to attempt to understand why some matrices seem to generate [M+H]+ ions for peptide analytes, M, while other matrices generate predominantly [M+Na]+ ions for the same analytes. An example is given in the three spectra shown. In all three, hexatyrosine is the analyte. In Figure 1a, when sinapinic acid is the matrix, the pseudo-molecular ion is the [M+H]+ ion. In Figure 1b, where α-cyano-4-hydroxy-cinnamic acid is the matrix, both an [M+H]+ and an [M+Na]+ peak is present. In Figure 1c, where 2,5-dihydroxybenzoic acid is the matrix, only an [M+Na]+ peak is present. For a hexatyrosine/α-cyano-4-hydroxycinnamic acid (molar ratio, analyte/matrix = 1:150) system, it is found that [M+Na]+ ion yield increases dramatically when NaCl/α-cyano-4-hydroxycinnamic acid is ~ 1/3 (molar ratio).



M=Hexatyrosine;
Analyte:Matrix = 1:50 (molar ratio);
NaCl was added to samples to give
NaCl:Matrix = 2.5:1 (molar ratio)

Possible mechanisms for the formation of [M+H]+ *vs.* [M+Na]+ ions in MALDI were considered. Possible mechanisms for protonation are: excited state acid-base chemistry[2], chemistry following matrix photoionization and chemistry following analyte photoionization. Possible mechanisms for the formation of [M+Na]+ ions are: excited state "salt" chemistry, protonation of the sodium salt of the analyte and gas phase capture of Na+ ions by the analyte.

It is known that MALDI spectra cannot be used for quantitation of mixtures. The signal intensity for each peptide of a mixture reflects the efficiencies of both the desorption and the protonation steps. The response seems to correlate with the basicity of the peptides. To investigate this further, MALDI spectra of small molecules with known PA's were obtained. The results indicated that there is a PA requirement for a successful MALDI analysis. The analyte must have a PA that lies above some value, X kcal/mol, where 208 < X < 223.

Triphenylphosphonium(TPP)-derivatives of the peptide *H*-VGVAPG-*OH* were made to investigate the formation of gas phase ion from "preionized" species in MALDI(figure 2). There is no detectable signal for this peptide before derivatization. However, very strong signals were observed for the TPP-derivatives. From this experiment, it was demonstrated that the formation of gas phase ion from "preionized" species in MALDI is possible.

Data are consistent with a model that involves acid/base chemistry for excited matrix molecules in the condensed phase leading to protonation. While some matrices seem to generate predominantly [M+Na]+ forms of the analyte, instead of protonated molecules, these matrices seem to be available with a high salt content. However, it is unclear why the addition of NaCl to MALDI matrices does not <u>always</u> lead to predominant of [M+Na]+ ions over protonated molecules.

A Postacceleration Detector For Time-of-flight Mass Spectrometry Utilizing Ion To Photon Conversion

*Robert S. Brown, Scott S. Hermsen, John J. Lennon, Department of Chemistry, Colorado State University, Ft. Collins, CO 80523

Three detector designs for time-of-flight mass spectrometry based upon the use of a fast (2.3 ns decay half-life) plastic scintillator (polyvinyltoluene) coupled to a fast response photomultiplier tube (Burle model S83062E) were evaluated in terms of obtainable mass resolution, sensitivity, response vs. mass and the degree of signal perturbation induced by significant (5-20 kV) amounts of postacceleration. All of the designs involved primary ion to secondary electron conversion, followed by secondary electron to photon conversion at the scintillator. The photons were then detected by the photomultiplier tube. Designs 1 and 2 (figure 1) utilized a conventional conversion dynode, either a 3 mm thick CuBe venetian blind dynode or a 1 mm thick CuBe focused mesh (Beckton-Dickinson) dynode. The latter should offer a smaller flight path perturbation due to its thinner size, but in practice gave identical performance to the venetian blind style dynode in terms of mass resolution and sensitivity. In fact, both designs produced limiting mass resolutions of ≈500 (fwhm) for the protonated molecular ion of porcine insulin. Mass resolution is probably being limited by the initial kinetic energy distributions of the ions in the linear TOF-MS utilized (25 kV accelerating potential) rather than the ion detector. Representative spectra for cytochrome C obtained with the venetian blind style conversion dynode in place is shown in figure 2 at various dynode bias up to -15 kV. Unlike what is observed when similar conversion dynodes are coupled to electron multipliers, little signal distortion is observed with the scintillator-PMT design. This signal distortion is thought to be due to the sputtering of secondary ion species off the dynode surface by primary ion impact. These secondary ion species are not uniformly extracted out of the conversion dynode, resulting in significant signal tailing. The improvement in response with the scintillator is believed to be due to the fact that the scintillator requires very fast particles to induce a response, therefor effectively discriminating against secondary ions and preferentially responding to secondary electrons. Some signal distortion is observed at high extraction fields, but it is significantly less than what we have observed with other postacceleration schemes. Increased signal at higher postacceleration is offset by increased noise, believed to be due to random field ionization events caused by high localized electric fields at the thin dynode edges.

The third design evaluated is depicted in figure 3. It utilizes a flat, optically transparent dynode (currently a sapphire window - Al_2O_3) instead of the previous dynodes. It makes use of the fact that the primary ion beam is tightly focused by a wire ion guide (-100 V). An optically reflective 5 mm aperture at the exit of the wire guide is coated with a 0.5 mm thick scintillator film. Secondary electrons sputtered from the dynode surface are accelerated back towards the scintillator and produce photons which the PMT detects. The angular

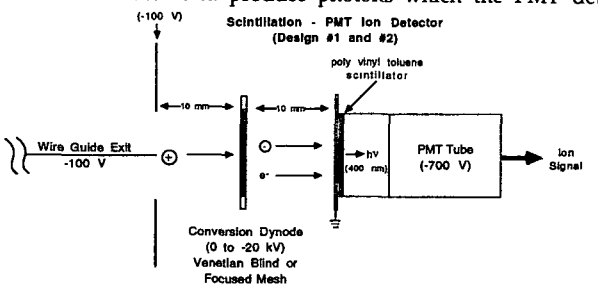

Figure 1

distribution of the emitted secondary electrons is such that the majority miss the small wire guide exit aperture. A typical MALD TOF mass spectrum for porcine insulin with this design is shown as figure 4 (-18 kV dynode bias). Sensitivity and mass resolution are comparable to the previous designs, although some signal tailing and fronting is apparent due to the high postacceleration. Interestingly, the smooth surface of the dynode eliminates field ionization induced noise. This design will be explored more in terms of the effect of coating the dynode with thin films of various materials (such as Cu, Au) to try and enhance secondary electron sputtering. It may also be possible to enhance the response for larger m/z ions by utilizing materials, such as LiF, as the dynode and optimizing the detector for effective sputtering of small secondary ion species.

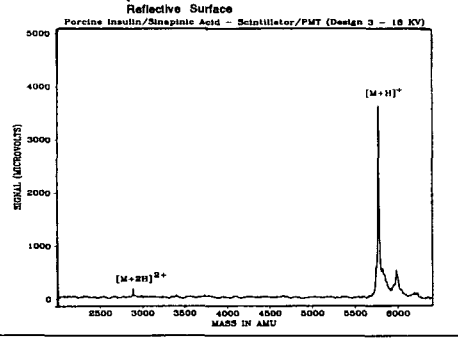

Figure 4

High Mass Resolution and High Mass Accuracy MALD/I Spectra with a Triple Electrostatic Analyzer Time-of-Flight Mass Spectrometer

*J.A. Chakel, E.P Marsh and R.W. Odom, Charles Evans & Associates, 301 Chesapeake Drive, Redwood City, CA 94063

High mass resolution and high mass accuracy analysis of biomolecules using matrix assisted laser desorption/ionization (MALDI) is possible on an innovative time-of-flight mass spectrometer (TOF-MS). A schematic of this TOF-MS is shown in Figure 1. This instrument was originally designed for TOF secondary ion mass spectrometry (TOF-SIMS) applications [1]. It features specialized stigmatic ion optics which transport an image of ions formed at the sample surface through the mass analysis section of the instrument and high precision, fast digital detection circuitry. The three 90° quasi-hemispherical ESAs provide complete first order energy focusing for both ion flight times and ion imaging with very small residual second order aberrations. The ESAs are fitted with field termination plates (Herzog shunts) and Matsuda plates for electrostatic field shaping.

This design is both strongly energy and position focusing having a large spectrometer energy acceptance (~340eV, FWHM) and angular acceptance (±90 mrad) [2]. In addition, an energy slit (between the first and second ESAs) can be used to define the energy spread of transmitted ions. The transmitted ion beam traverses various image points and image planes along the ~2 M flight path. Unlike a reflectron based TOF-MS, the ions are maintained at full acceleration energy throughout their flight path and thus, space charge broadening and ion/neutral collisions are minimal in this instrument. Metastable ions formed before the third ESA are not transmitted to the detector thus minimizing peak broadening or spurious metastable peak detection. The overall transmission efficiency of this instrument is higher than 50%.

A frequency tripled Nd YAG (355 nm) laser was used. The laser beam was attenuated primarily with a variable beam attenuator and by software control of the Q-switch delay The pulsed laser output (4-5 ns FWHM) was focused and transmitted onto the sample Analysis of selected individual matrix crystals was achieved with a tightly focused laser beam (6-7 μm diameter) Ion detection was accomplished with a DMCP detector coupled with a 200 MSample/s (5 ns channels) transient recorder.

A single shot spectrum for gramicidin S obtained with use of the energy slit is presented in Figure 2. The mass resolution (>8000) is difficult to measure with a single channel peak and illustrates the need for faster transient recorders. Accurate mass measurements require accurate determinations of the peak centroids. Fast transient recorders are thus desirable, especially in the peptide mass range. Timing inaccuracies produced primarily by trigger jitter could shift the centroid of higher mass peaks by a few tenths of a mass unit. Mass measurements of the molecular ion of angiotensin produced from a mixture of gramicidin S, angiotensin and substance P in sinapinic acid revealed mass measurement accuracies of 2 to 63 ppm. The absolute mass error in all of these analyses was <0.1 Da which is on the order of a single 5 ns timing channel (0.13 to 0 14 Da at these masses).

High mass resolution and high mass accuracy are desirable in extending the utility of MALD in direct digest mixture analysis. The spectrum from 10 laser shots of a single location of a 3.2 pmole deposit of a hemoglobin α & β chain tryptic digest mixture in dihydroxybenzoic acid is illustrated in Figure 3 The expanded mass range plot in the lower panel shows the β-chain T-5 fragment at mass 2059 The mass resolution for the monoisotopic peak of this fragment is ~12,000 FWHM. Mass accuracies for this digest mixture range from 22 to 108 ppm for the observed fragments and the absolute mass error is less than 0.12 Da. The width of a single 5 ns channel varies from 0 08 to 0.18 Da over the range from 451 to 2226 Da.

Initial Kinetic Energies of Peptide Ions Formed by MALDI

Dieter Kirsch, Bernhard Spengler, Raimund Kaufmann,
Inst. of Laser Medicine, University of Düsseldorf, Moorenstr. 5, D-4000 Düsseldorf, Germany

Recent results on desorption kinetics of MALDI ions obtained by several groups, suggest the formation of a supersonic jet of matrix ions carrying larger analyte ions with almost mass independent velocities [1-3]. Knowledge of jet velocities, as well as of ion start time profiles will give important information about the mechanism of ion formation and desorption, and will, on the other hand, help to optimize instrumental design with respect to high mass accuracy, mass resolution and sensitivity.

Employing different matrices such as 2,5-dihydroxybenzoic acid (DHB), α-cyano-4-hydroxycinnamic acid (4HCCA) and sinapinic acid, positive and negative ions of matrix, proteins and oligonucleotides have been investigated with respect to initial kinetic energies and mean virtual ion start times. This was done by monitoring the drift time of the ions in a spatially and electrically well defined field free region s_1 of variable length between sample surface and acceleration field (Figure 1). The field terminating grid was specially designed to avoid field penetration from the acceleration region into the field free drift region. By varying the length of the drift region a mean virtual desorption time (relative to the laser pulse event) could be extrapolated precisely.

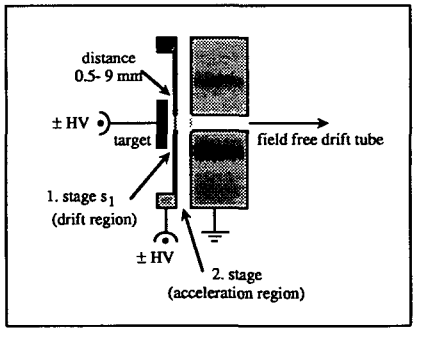

Figure 1: Ion acceleration region of the linear TOF instrument. The electric field of the first acceleration region could precisely be set to zero.

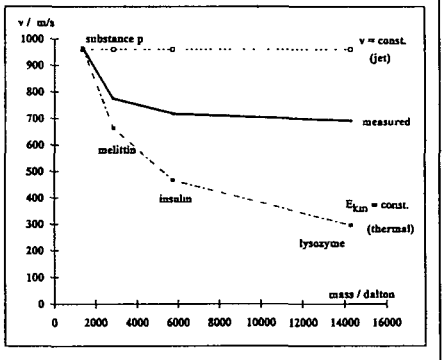

Figure 2: Dependence of analyte ion velocities on their mass, indicating an expansion process with combined thermal and supersonic-jet characteristics.

Initial velocities of analyte ions have been found to significantly depend on analyte mass, irradiance and matrix used. Figure 2 demonstrates the dependence of analyte ion velocities on mass. It shows a behavior characterized by a combination of supersonic jet expansion (v=const.) and thermal desorption (E_{kin}=const.).

Mean virtual desorption times have been found to be non-zero in most cases (Figure 3), imaging probably collision- and acceleration-effects of (slower) analyte ions with (faster) matrix molecules and ions, rather than real ion start time delays (Figure 4). Virtual desorption times are typically 200 to 400 ns at threshold irradiance and approach zero at high irradiance. Evaluating the fastest analyte ions of the velocity distribution leads to zero virtual desorption times at threshold irradiance (Figure 3).

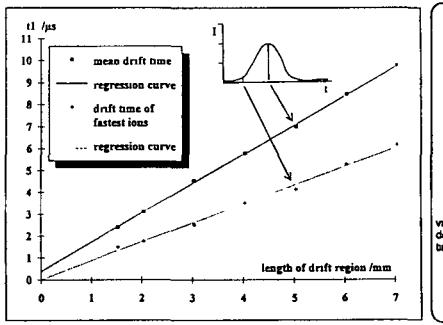

Figure 3: Drift time of the most abundant and of the fastest negative ions of oligonucleotide TTGAC in the field free drift region s_1 at various lengths of s_1.

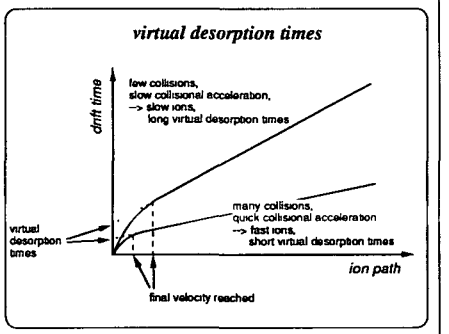

Figure 4 Modell for explaining non-zero virtual desorption times. Collisional ion acceleration extending over different distances leads to different extrapolated flight time values.

DESIGN OF A NEW FLOW PROBE FOR CONTINUOUS-FLOW MATRIX-ASSISTED LASER DESORPTION IONIZATION

Davinder S. Nagra and Liang Li*
Department of Chemistry, University of Alberta
Edmonton, Alberta, Canada T6G 2G2

Matrix-assisted laser desorption (MALD) is a very powerful technique for the generation of ions from large biochemicals. Currently, MALD is usually performed from a solid insertion probe. A desired feature of this technique would be to desorb and ionize molecules directly from a solution. This would permit MALD to be interfaced with various solution-based separation methods for on-line detection and quantitation. Recently, we demonstrated the feasibility of using a continuous flow (CF) probe with a liquid matrix, namely 3-nitrobenzyl alcohol (3-NBA) to introduce solution samples directly into a linear time-of-flight (TOF) mass spectrometer [1]. In this present work we report a much improved design over the previous flow probe for CF-MALD and show that (1) it is now possible to perform flow injection analysis of large peptides with molecular weights above 10,000 with CF-MALD and (2) flow injection ion profiles of these biochemicals in the subpicomole region can readily be obtained.

Figure 1 shows the new design of the continuous flow probe. A capillary tube is inserted into a stainless steel tube and extends from the sample injector to the probe tip. A piece of Kapton (2.8-mm diameter), with a small hole pierced through the center, is mounted at the tip. The capillary tube punctures through the hole in the Kapton and is placed no more than 1 mm above the surface. A piece of filter paper is wrapped around the probe tip to absorb the excess liquid. The flow probe is inserted into the TOF mass spectrometer between the repeller and extraction plates. The sample molecules are carried by a solvent mixture (aqueous trifluoroacetic acid, ethanol, ethylene glycol, and 3-NBA) through the capillary tube and onto the Kapton surface. The resulting MALD ions are recorded on an oscilloscope and the data is transferred in real time to a PC via GPIB. The data transfer and data analysis software are developed in house. After storing all the mass spectra in the PC a selective ion profile can be established.

Figure 2 shows a representative single-shot CF-MALD mass spectrum of cytochrome c (MW ~ 12,360) with a total sample injection of 3 picomoles. Trypsinogen (MW ~ 24,000) aids in the initial optimization of the flow conditions by continuously flowing onto the probe surface. Since more than 500 mass spectra can be obtained and only a portion of the sample flowing onto the probe surface are actually being desorbed, the total amount of sample consumed for generating such a mass spectrum is less than 6 femtomoles. A flow injection ion profile can be obtained by calculating and plotting the peak area of the molecular ion as a function of the elution time. Figure 3 shows the ion profiles of 5 repeat injections of different amounts of cytochrome c. Note that there are some variations in peak heights and areas with repeat injections. We are currently in the process of better optimizing the flow conditions. Figure 4 shows a sensitivity curve for cytochrome c (±1 std deviation). A linear response of one order of magnitude in the low picomole region can be obtained. While the precision still needs to be improved, quantitative CF-MALD shows much promise.

OPTIMIZATION OF ION EXTRACTION AND ION DETECTION FOR CONTINUOUS-FLOW MATRIX-ASSISTED LASER DESORPTION

Randy M. Whittal, Davinder S. Nagra and Liang Li*
Department of Chemistry, University of Alberta
Edmonton, Alberta, Canada, T6G 2G2.

Matrix-assisted laser desorption (MALD) has become an established technique for the analysis of large biomolecules. Recently, we extended this technique by using a continuous flow (CF) probe with the liquid matrix 3-nitrobenzyl alcohol (3-NBA), to introduce solution samples directly into a linear time-of-flight (TOF) mass spectrometer [1]. However, mass resolution was relatively poor due, in part, to the ion extraction geometry. Static MALD spectra are normally generated with the ions extracted in parallel to the direction of ion expansion. This geometry minimizes the initial ion spatial distribution. However, with this geometry, the sample probe is usually floated at a high voltage. In order to avoid possible electric breakdown in the CF probe, we grounded the probe and placed it in between the repeller and extraction grids. Thus, ion extraction is performed orthogonally to the ion expansion direction.

In this report we demonstrate that it is now possible to perform CF-MALD in the parallel ion extraction configuration. The objective of this work is to evaluate the performance of the parallel CF-MALD method in terms of sensitivity, signal stability and mass resolution, with emphasis on comparison to the orthogonal method.

We recently constructed a linear TOF mass spectrometer which can accomodate both the parallel and orthogonal ion extraction geometries. A frequency quadrupled Nd:YAG laser (266 nm) is used to perform MALD. The resulting mass spectra are recorded on a digital oscilloscope and transferred in real time to a PC via a GPIB. The data transfer and data analysis software is developed in house. The design of the flow probe for CF-MALD is described elsewhere [2]. In brief, a solution containing an internal standard in a mixture of 3-NBA, aqueous trifluoroacetic acid, ethanol and ethylene glycol is introduced continuously through the flow probe. A sample injector allows for on-line injection of protein samples.

We first present results with static MALD in order to assess the performance between the different ion extraction geometries. The sample and matrix are mixed together on a probe tip and inserted into the vacuum chamber. Figures 1A and 1B illustrate the static MALD spectra for bovine insulin ß-chain (MW 3496) mixed with 3-NBA for the orthogonal and parallel configurations, respectively. Parallel MALD produces a sharper peak, resulting in a resolution enhancement of approximately 3.5. Sensitivity improves by approximately an order of magnitude in parallel MALD.

Figure 2A shows the orthogonal CF-MALD spectrum produced from an injection of 5 pmol of chicken egg lysozyme (MW~14400). Figure 2B represents the corresponding parallel MALD spectrum. In both cases reproducible ion profiles can be obtained with repeat injections. The ion profile (not shown) shows that 500 spectra can be produced from one injection. Thus, Figure 2 actually represents a spectrum for a few femtomoles of sample. The sensitivity of CF-MALD improves 5 to 10 times in the parallel ion extraction configuration. We are currently in the process of studying the degree of resolution enhancement.

Basic Matrices for the Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry of Proteins and Nucleic Acids

Michael C. Fitzgerald, Gary R. Parr, and Lloyd Smith
Department of Chemistry, University of Wisconsin, Madison, WI 53706

Matrix-assisted laser desorption/ionization (MALDI) mass spectrometry has emerged as a powerful new analytical technique that permits the mass analysis of high molecular biopolymers (up to 300,000 Dalton). The matrix, a small organic molecule, is a key part of the desorption and ionization process in this mass spectral method. By irradiating the sample with a high intensity, pulsed laser beam it is possible to generate intact, gas phase molecular ions of the analyte. Several matrix materials including nicotinic acid, sinapinic acid, and 2,5-dihydroxybenzoic acid have proven to be effective for the MALDI analysis of a wide variety of proteins. However, these acidic matrices have not been found to be generally applicable to the analysis of nucleic acids. The goal of this study was to determine if pH is an important factor in the MALDI analysis of nucleic acids and proteins.

All mass spectra were recorded using a Vestec Model VT 2000 laser desorption, linear time-of-flight mass spectrometer. The flight tube has been modified with a nickel wire, 0.012 mm in diameter, that spans the length of the 2 m flight path and is biased at 120 volts so ions are efficiently transported along the center axis of tube. Desorption and ionization of samples was accomplished with a Lumonics Model HY 400 Nd:YAG laser. Ions were accelerated in two stages through a total of 30 keV. All spectra were summed over 50 laser shots.

A total of 37 highly substituted pyrimidine, pyridine, and benzene derivatives containing basic amino groups were screened as potential matrices. Several of these compounds were useful for the preparation and analysis of samples under neutral and basic pH conditions. The matrix, 2-amino-4-methyl-5-nitropyridine (matrix solution pH=7.1), gave good results with small proteins (up to about 12,000 Dalton). The best results with nucleic acids were obtained with 2-amino-5-nitropyridine (matrix solution pH=7.3), which was a useful matrix for the analysis of mixed base oligonucleotides smaller than 20 nucleotides in length and homopolymers of thymidine. It is also noteworthy that at neutral and basic pH the prevalence of sodium and potassium salts is high with nucleic acids. However, treatment with an ion exchange resin removes these alkali cations and yields a single molecular ion peak [1]. The resin's effectiveness is illustrated in Figure 1.

Protein analysis using basic matrices is apparently limited to relatively low molecular weight samples (<12,000 Da); oligonucleotide analysis using basic matrices was found to be subject to the same constraints of size and base composition that hold when acidic matrices are used. However, a major advantage of these newly discovered matrices is that they extend the utility of MALDI to the analysis of acid sensitive species. The MALDI analysis of a short oligonucleotide containing an acid labile dimethoxytrityl group at it's 5' terminus is shown in Figure 2 and provides a dramatic illustration of the utility of basic matrices.

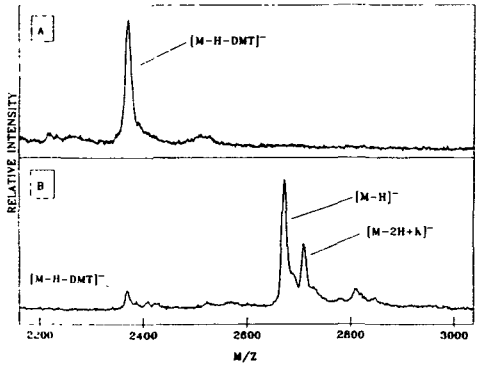
The resolution (FWHM) of the major peaks in (A) and (B) was 191 and 226, respectively.



Influence of Amino Acid Gas Phase Proton Affinities on Ion Yield from Matrix Assisted Laser Desorption Ionization (MALDI) by D.R. Phillips, M. Karas, H. Ehring, and F. Hillenkamp, Institute for Medical Physics and Biophysics, University of Muenster, 4400 Muenster, FR Germany.

INTRODUCTION The lack of understanding concerning the mechanism of matrix assisted laser desorption ionization (MALDI) along with the methods increasing popularity for studying mixtures has prompted this study.

If the analyte was closely associated with matrix molecules (ions) and competing for the proton of ionization during the MALDI process, then the gas phase proton affinity of the analyte would partially determine the efficiency of analyte ionization. The idea was tested by measuring the MH^+ ion abundance of 12 amino acids. Each amino acid (a.a.) MH^+ ion abundance was measured and no correlation with gas phase proton affinities was observed. Studies were extended to investigate the presence or absence of ion suppression in a.a. mixtures. When a correlation was observed for a.a. mixtures, several peptides and proteins were selected to test for suppression in protein mixtures.

METHODS All spectra were acquired by a LAMMA 1000 time-of-flight mass spectrometer equipped to visually direct laser shots. The samples were prepared by adding 0.5 µL of each equimolar analyte (a.a., 5.7 mM; peptides, 1.0 mM; proteins 58.0 µM) to 2.5 µL of 10 g/L 2,5-dihydroxybenzoic acid (DHB) matrix. Upon drying, the sample formed a crystallin rim and an amorphous center.

In all cases, 50 spectra were averaged together which were acquired from a minimum of 5 different sights from either the crystalline rim or the amorphous center. The MH^+ ion peak height was measured from the averaged spectrum.

RESULTS Values in TABLES 1-3 correspond to molecular ion peak height in the mixture referenced as a percentage to the peak height of MH^+ when desorbed alone. E.g., the MH^+ ion signal from gln in DHB is 33.9 mV and that of arg in DHB is 80.3 mV. However, in a mixture of gln and arg the MH^+ ion signal from gln is 5.0 mV or (5.0 mV/33.9 mV)*100=15% of the expected value if MH^+ is unsuppressed and arg is (62.7 mv/80.3 mV)*100=78% as intense as when gln is absent (Table 1, bolded). The a.a.s are placed in the order of descending gas phase proton affinity[1] going from left to right and top to bottom. The upper number in each box corresponds to the amino acid listed above it and the bottom number to the amino acid to the left. With few exceptions, the smaller percentage value in the individual boxes results from the amino acid with the lower gas phase proton affinity. In all tables, the upper right portion of the table contains values obtained by sampling the DHB rim and the lower left is by sampling the center of DHB.

TABLE 1 MH^+ Ion Intensities of A.A s Compared to MH^+ Ion Intensities from A.A. Mixtures Obtained by MALDI of DHB

A.A.	Arg	His	Lys	Gln	Pro	Ala
Arg		166 128	0 84	**15** **78**	48 119	0 75
His	134 19		0 184	22 430	55 253	0 177
Lys	126 0	36 0		same mass	110 60	1 29
Gln	56 3	111 13	same mass		76 70	16 129
Pro	20 5	78 3	85 105	93 44		16 134
Ala	35 0	167 0	18 4	95 0	84 0	

Arg, arginine; his, histidine; lys, lysine; gln, glutamine; pro, proline; ala, alanine.

The peptides and proteins TABLES 2-3 were chosen for the ion suppression studies based on their differing arginine content (ß-Lipotropin fragment 1-10 (ß-lip), 0 arg/10 a.a.; neuromedin B (neur), 0 arg/10 a.a.; substance P (sub. P), 1 arg/11 a.a; dynorphin fragment 1-10 (dyn), 3 arg/10 a.a.; insulin 1 arg/51 a.a. = 2% total composition; ubiquitin 4 arg/76 a.a. = 5%; aprotonin 6 arg/58 a.a. = 10%). In each case shown, except one, the relative MH^+ ion current from the protein with the smaller percentage of arg was suppressed more than the other protein in the mixture. These results were as predicted by a simplistic model.

TABLE 2 MH^+ Ion Intensities of Peptides Compared to MH^+ Ion Intensities from Peptide Mixtures Obtained by MALDI of DHB

Peptide	Dyn	Sub. P	Neur	ß-Lip
Dyn		5 52	5 85	0 99
Sub. P	44 7		20 36	0 40
Neur	67 12	100 55		0 78
ß-Lip	55 0	43 0	63 0	

The model makes the assumption that the proton of ionization (H^+) is associated with the most basic a.a. residue (usually arg) in a protein.[2] If a protein contains multiple arg residues, then each arg has an equal chance of obtaining H^+. When two proteins are associated during the MALDI process there is a competition between them for H^+. The protein with the fewer number of arginines has the lowest probability of obtaining H^+ and hence, ion suppression is observed. Note for the mixture neuromedin B and ß-lipotropin, neuromedin contains the more basic a.a., his.

CONCLUSIONS This study shows that there is a suppression effect when using MALDI. Suppression is observed when two a.a.s are present in a sample and it correlates with the a.a.s' gas phase proton affinities. In the case of the protein mixtures, ion suppression relates to the lack of a.a.s with high gas phase proton affinities. Suppression effects are observed in both the crystalline rim and amorphous center of the droplet. Ion suppression correlating to analyte gas phase proton affinity indicates the probability of the analytes being associated at some time during the MALDI process.

TABLE 3 MH^+ Ion Intensities of Proteins Compared to MH^+ Ion Intensities from Protein Mixtures Obtained by MALDI of DHB Droplet

Protein	Aprotonin	Ubiquitin	Insulin
Aprotonin		35 70	48 88
Ubiquitin	58 105		5 69
Insulin	82 45	152 9	

Exceptions to the proposed model in the RESULTS section are expected due to variables not accounted for such as gas phase ion structure of the protein and protein solubility in matrix.

A New Matrix for MALDI Analysis of Water Insoluble Organic Molecules

M.P. Lacey and T. Keough
The Procter and Gamble Co., Miami Valley Laboratories
P.O. Box 398707, Cincinnati, OH 45239-8707

Matrix-assisted laser desorption/ionization has been used by several laboratories to analyze synthetic polymers[1-4]. Most of these polymers (PEG, PPG, PMMA) have been soluble in water, ethanol or acetone, and have been analyzed out of matrices typically used for protein analyses. Unfortunately, a number of important classes of organic molecules are water insoluble and cannot be analyzed from conventional matrices. Here we report the use of a new matrix, 5-chlorosalicylic acid, for high sensitivity MALDI analyses of water insoluble organic molecules.

We have previously been unsuccessful in analyzing water insoluble polymers from aqueous matrix solutions. A typical spectrum of PDMS 3000 analyzed from DHB is shown in Figure 1 (upper trace). The PDMS was diluted in water and mixed with an equal volume of DHB. A total of 10 picomoles was loaded onto the end of the probe, and the sample was run without washing the probe tip. When analyzed from a chloroform solution and 5-CSA, the results improve dramatically (lower trace).

We analyzed a series of PDMS standards from 5-CSA as shown in Figure 2. The measured molecular masses of these standards are about a factor of two lower than those quoted by the supplier (Table 1). Similar results were obtained with vapor phase osmometry, NMR, desorption chemical ionization mass spectrometry, supercritical fluid chromatography and electrospray ionization mass spectrometry.

Mass calibration can be somewhat more difficult than for water soluble analytes. However, small peptides and proteins can be used as internal calibrants for this application by first loading the peptide or protein from an aqueous solution containing a water soluble matrix like sinapinic acid. After that solution is thoroughly dried, an overlayer of analyte plus 5-CSA in chloroform is loaded onto the probe tip. It is possible to find regions of the tip that contain both analyte and standard. Unfortunately, this approach is somewhat irreproducible. An alternative strategy involves the use of high-mass, chloroform soluble compounds that can be mixed directly with the analyte and the matrix. We use various olestras[5], which have molecular masses greater than 1000 Da and have been well-characterized.

The role of the matrix is uncertain in the MALDI characterization of small synthetic polymers. Sensitivity for low-mass PDMS standards is somewhat enhanced relative to laser desorption without a matrix. The spectra obtained in the presence of 5-CSA show mainly MNa^+ molecular ions, while the spectra obtained without matrix show comparable levels of Na^+ and K^+ attachment. Very little fragmentation is evident. In our hands, small water soluble polymers like PEG 3300 also show similar spectra when analyzed with a matrix like DHB or without a matrix (Figure 3).

Studies of oligonucleotides by matrix-assisted laser desorption time-of-flight mass spectrometry

*Kuang Jen Wu, Anna Steding and Christopher H. Becker
Molecular Physics Laboratory, SRI International, Menlo Park, CA 94025

Matrix-assisted laser desorption time-of-flight mass spectrometry has been used to produce quasimolecular ion signals from underivatized mixed-base single-stranded DNA oligomers ranging from 10 to 67 nucleotides in length with the matrix material, 3-hydroxypicolinic acid (HPA). The desorption and simultaneous ionization was by 5-ns pulsed laser at 10 to 50 mJ/cm^2, studied at 266, 308, and 355 nm. HPA is found to be very effective as a matrix material at all three wavelengths examined and demonstrates to be less destructive to the analyte molecules. An examination of the direct positive and negative mass spectra reveals three major mass peaks directly related to HPA: parent, and two features associated with the loss of stable neutrals (H_2O and HCOOH). Unlike some other matrices, HPA is not sensitive to the variation of the base components of oligonucleotides, a property desirable for this application.

Both reflecting and linear TOF-MS operating in positive and negative ion detection modes has been used. A study comparing positive and negative ions signal intensities measured by reflecting and linear TOF-MS under the same desorption condition by 355 nm laser has been performed. The results are summarized as follow.

- Strong and comparable single intensity for positive and negative ions measured by linear TOF-MS.
- Moderate negative ion signal measured by reflectron TOF-MS.
- Weak (or no) positive ion signal measured by reflectron TOF-MS.
- Linear mode demonstrates higher signal intensity and better mass resolution.

We attribute such results to the strong metastable decay of the oligonucleotide ions during the flight path. Such effect causes mass peak broadening and significant loss of signal intensity. Since both positive and negative ion signals in linear mode appear fairly comparable in strength, it thus appears that the formation of positive and negative ions is equally effective, whereas the decay of positive ions is possibly much stronger and become almost unobservable by the detector after reflected. With the advantages of better sensitivity and mass resolution, we therefore conclude that a linear TOF-MS system is better suited for the studying of DNA oligomers.

Measurements of 355 nm laser threshold energy density for desorption as a function of oligomer length has been performed by using reflecting TOF-MS. A trend of increasing threshold energy density as the size of molecules increases is observed.

CLEAVAGE OF INTERCHAIN DISULFIDE BONDS FOLLOWING MATRIX-ASSISTED LASER DESORPTION

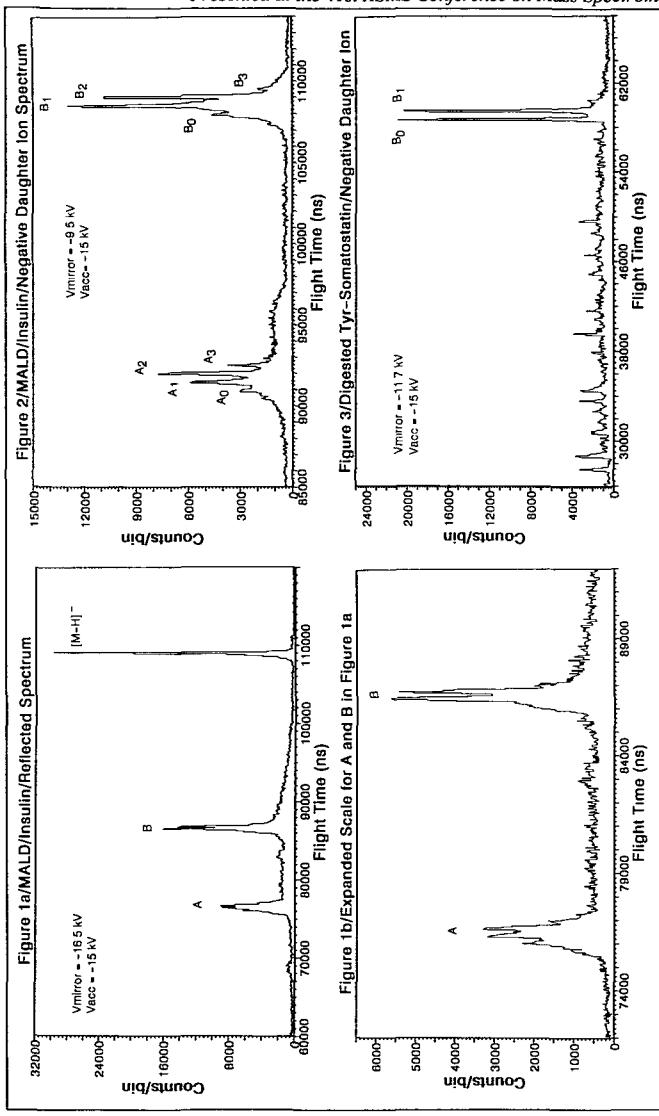
J. Zhou[1], W. Ens[1], N. Poppe-Schriemer[1,2], K. G. Standing[1] and J. B. Westmore[2]
[1]Physics and [2]Chemistry Departments, University of Manitoba, Winnipeg, Manitoba,Canada R3T 2N2

The assignment of the positions of disulfide bonds in a protein is an important part of the determination of its primary structure. Recently, Bean and Carr examined a number of peptides of masses up to ~2000 u containing single interchain disulfide bridges [1] with tandem mass spectrometry. They observed cleavage at the bridges with retention of zero, one or two sulfurs on the charged fragment. With matrix-assisted laser desorption, we have investigated the cleavage of interchain disulfide bridges of insulin and a digest of tyr-somatostatin, containing two and one disulfide bond(s) respectively.

Targets were prepared from bovine insulin or from a tryptic digest of tyr-somatostatin (Sigma) in matrices of sinapinic acid or α-cyano-4-hydroxycinnamic acid (4HCCA). The digestion of tyr-somatostatin was performed at room temperature for a few minutes. No purification was made of the digestion products. A few μL of sample solution (~0.4 g/L insulin in 0.1% TFA or ~0.5 g/L digested tyr-somatostatin in solution) were mixed with 10-20 μL matrix solution (10g/L in 1:3 water:acetonitrile) and dropped onto a 1 cm diameter etched silver foil, then dried in air.

The measurements were carried out in our reflecting time-of-flight spectrometer (TOF II) [2]. Ions were desorbed from the target by a nitrogen laser (Laser Science ND337) at a wavelength of 337 nm and a power density (~10^6 W/cm^2) slightly above threshold. In the reflecting mode, the mirror V_m is set at higher potential than the target. Undissociated ions as well as charged daughters are reflected by the mirror. A convenient method of measuring the mass of a daughter ion is to reduce the mirror voltage to a value V_m^* such that the flight time of the daughter is the same as that observed for its parent with mirror voltage V_m. The ratio of daughter ion mass m* to parent ion mass m is then given directly by the ratio of the measured voltages, i.e. $m^*/m=V^*/V$ [2].

Figure 1a shows the reflected spectrum of negative ions for insulin. A- and B-chain daughter ions are observed in the spectrum. Some structure is apparent in the peaks and is seen clearly on an expanded scale in figure 1b. The negative daughter ion spectrum, as shown in figure 2, was then measured with a reduced mirror voltage; a considerable improvement in resolution is obtained. Masses of the individual components were determined by varying the mirror voltage as described above. Results are clearly consistent with decay into A- and B- chain daughter ions with retention of zero, one, two or three sulfurs from the interchain bridges, as represented by A_0, A_1, A_2 and A_3 for A- chain daughters, B_0, B_1, B_2 and B_3 for B- chain daughters. There is one intrachain disulfide bridge in tyr-somatostatin (M.W.=1801.1 u) between Cys_4 and Cys_{15}. A tryptic digestion is expected to cleave at Lys_5 and Lys_{10}, but only the latter is observed, yielding a peptide with two chains (1261.6 u and 556.2 u) linked by a single disulfide bond. Figure 3 shows the negative daughter ion spectrum of digested tyr-somatostatin. Calibration results correspond to zero or one sulfur on a B-chain daughter.



The cleavage of interchain disulfide bridges of insulin and digested tyr-somatostatin has been observed in the negative daughter ion spectra from matrix-assisted laser desorption. The $[M-H]^-$ molecular ion decays into negative A and B chain, or only B chain, daughters with various numbers of sulfurs attached. The observation may provide a simple analytical method for determining interchain disulfide bridges in peptides or proteins.

B-2610 Wilrijk, Belgium

The three most toxic components of *Amanita Phalloides* (green death cap) are usually analyzed by high performance liquid chromatography or radioimmunoassay [1]. Recently, electrokinetic capillary chromatography was used to accurately identify other mycotoxins [2]. Matrix-assisted laser desorption mass spectrometry (MALD-MS) has made the rapid and accurate determination of small peptides feasible [3].

Three cyclic peptides, α-amanitin (inhibitor of RNA polymerase II), β-amanitin and phalloidin (inhibitor of cytoskeletal function) were measured using MALD-MS. 337 nm nitrogen laser excitation of five matrices (sinapinic acid: SA; α-cyano-4-hydroxycinnamic acid: CHCA; 2,5-dihydroxybenzoic acid: DHB; 2-(4'-hydroxyazobenzene)-benzoic acid: HABA; 6-aza-2-thiothymine: ATT) provided molecular ions of all three toxins. MALD spectra were simple and straightforward to interpret. α-amanitin showed peaks at $[M+H]^+$ (m/z 920), $[M - OH]^+$ (m/z 903), and $[M+Na]^+$ (m/z 942). Molecular adduct ions $[M+M' - OH]^+$ (M': matrix molecule) (m/z 1046) also were observed. DHB, CHCA and ATT usually produced good quality spectra.

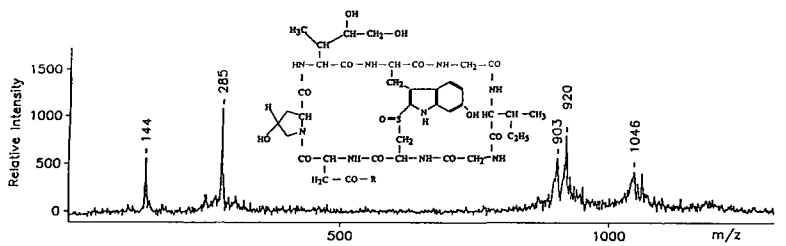

Figure 1. MALD-MS of α-amanitin in ATT matrix and its structural formula. $R=NH_2$ for α-amanitin; R=OH for β-amanitin.

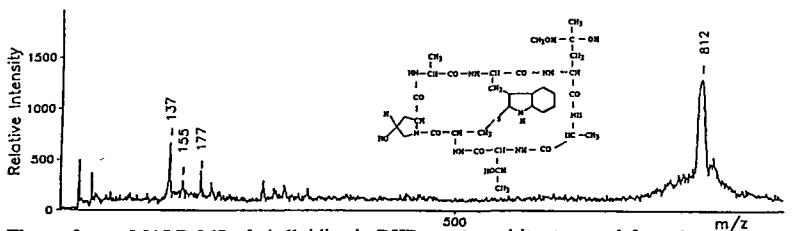

Figure 2. MALD-MS of phalloidine in DHB matrix and its structural formula.

Both protonated and sodiated peptide ions were present in spectra taken in ATT and DHB matrices (Figs. 1 and 2). It is interesting to note that MALD-MS *did* produce fragment ions in some cases. The m/z 903 ion in Figure 1 corresponds to a protonated molecular ion after the loss of an OH group. Similar loss of small functional groups (NO_2, Dns) in MALD was reported earlier [4]. Table 1 summarizes the most abundant ions of the three toxins in ATT and in DHB.

Toxins	Analyte ions m/z	
	ATT matrix	DHB matrix
α-amanitin	903: $MH-OH^+$; 920: MH^+; 942: MNa^+; 1046: $MM'-OH^+$	885: $MH-2OH^+$ (?); 903: $MH-OH^+$; 920: MH^+;
β-amanitin	888: $MH-OH^+$; 905: MH^+; 927: MNa^+	905: MH^+
phalloidin	773: $MH-OH^+$; 790: MH^+; 812: MNa^+	812: MNa^+

Table 1.

Preliminary experiments were carried out to detect α-amanitin in human serum. The major serum protein components like albumin and different globulins were removed from the α-amanitin spiked serum by centrifugal ultrafiltration (Millipore, Ultrafree-MC, 30,000 NMWL). Salts and other low-molecular-weight components (MW < 30,000 Da) accumulated in the filtrate collection tube. The 1μL filtrate, 1μL 1M HCl and 5μL 0.05M DHB matrix solutions were directly applied to the probe tip. The dried deposit was washed by immersing the probe tip into distilled water to remove any water-soluble contaminants, particularly Na^+ ions. α-amanitin ions were detected but the spectrum quality was poor. The sample preparation technique needs further refinement.

Although the specificity of the mass spectrometric determination is better than that of other methods, detection limits are generally higher and quantitation remains difficult.

ANTISENSE DNA OLIGONUCLEOTIDES II: THE USE OF MATRIX-ASSISTED LASER DESORPTION IONIZATION MASS SPECTROMETRY FOR THE COMPLETE SEQUENCE VERIFICATION OF METHYLPHOSPHONATE OLIGODEOXYRIBONUCLEOTIDES

Thomas Keough, Timothy R. Baker, Roy L.M. Dobson and Martin P. Lacey, The Procter and Gamble Co., Miami Valley Laboratories, PO Box 398707, Cincinnati, OH 45239-8707.
Timothy A. Riley, Jody A. Hasselfield and P. Eric Hesselberth, JBL Scientific, Inc., 277 Granada Drive, San Luis Obisbo, CA 93401-5809.

Antisense therapy uses modified oligonucleotides, like methylphosphonate oligodeoxyribonucleotides, to bind to messenger RNA, thereby inhibiting the synthesis of specific proteins. The specificity needed to inhibit a particular protein synthesis is thought to require an oligonucleotide 12 to 18 bases in length. Of course, the exact oligonucleotide sequence affects the highly specific binding of these materials, and sequence verification is needed prior to biological testing. A novel matrix-assisted laser desorption ionization (MALDI) approach for complete sequence verification of synthetic methylphosphonate oligodeoxyribonucleotides is reported.

The UV-MALDI mass spectrum obtained from 5 pmols of a representative methylphosphonate oligonucleotide is given in figure 1 (Vestec VT 2000 mass spectrometer, frequency tripled Nd:YAG (355 nm), sinapinic acid matrix, positive ions). Methylphosphonate oligonucleotide MALDI spectra are dominated by the MH+ molecular ions. Mass measurement accuracy of +/- 1 Da is typically achieved, and the mass resolution is >200 (FWHM). The spectra are all quite simple; no fragmentation is observed. Unlike phosphodiester oligonucleotides, the quality of these spectra appears to be independent of base composition. All of the methylphosphonate oligonucleotides examined to date have given spectra of comparable quality to the spectrum given in Fig. 1.

Obviously, the MALDI mass spectra of purified methylphosphonate oligonucleotides exhibit no fragmentation and no structural information. However, detailed structural information can be obtained by direct analysis of the crude synthetic products formed in these solid-phase syntheses. This results because the coupling yield for each added nucleotide is only 96 to 99%. The remaining 1 to 4% that has not undergone coupling in each cycle, the failure sequence, is capped with acetic anhydride to simplify final product purification. Capping also prevents subsequent reaction to produce "mixed" sequences, which would preclude the use of MALDI for this application. After the final cycle, the desired product and the failure sequence mixture are cleaved from the resin. This cleavage procedure also removes the 5'-protecting group from the final product, and the acetate capping groups from each failure sequence that has been formed.

The first step in the MALDI sequence verification involves direct analysis of the crude synthetic mixture. The spectrum obtained from analysis of a crude synthetic 15-mer is given in Fig. 2. An intense molecular ion is observed for the desired final product (1-15)+, where nucleotide 1 is defined as the 3'-end of the molecule. The spectrum also exhibits several abundant series of ions. The most intense corresponds to the failure sequences (1-14)+, (1-13)+, etc. The oligonucleotide sequence is simply established by measuring the mass differences between adjacent members in this series, and comparing these values with the known masses of the four methylphosphonate nucleotides used in the synthesis. If one measures from the (1-15)+ molecular ion toward lower mass, the reading direction is from the 5'-end to the 3'-end as determined by the synthetic procedure. In this particular example, 11 of the 15 nucleotides were easily established. However, the 4 nucleotides near the 3'-end were not observed.

The strategy for obtaining the remaining portion of the sequence can be understood by re-examination of the MALDI spectrum obtained from the crude synthetic mixture. An expanded view of a portion of that spectrum is given in Fig. 3. Each failure sequence molecular ion, the top series of ions, is accompanied by a satellite peak weighing about 78 Da more. These peaks, indicated with asterisks, could be formed by non-specific base-catalyzed hydrolysis during the resin cleavage step. If this interpretation is correct, a

WP 149
Code

complementary set of products containing the 5'-end of the molecule should also be produced. In total, four products should be produced for each hydrolyzed phosphonate group. Re-examination of the MALDI spectrum given in Fig. 3 reveals that indeed, there are many clusters of four ions evident in the spectrum. The failure sequence ions provide information about the 5'-end of the molecule. The complementary set of hydrolysis products, lower series, provide information about the 3'-end of the molecule.

Complete sequence verification is possible by combined use of the failure sequence ions and hydrolysis product ions. However, some crude synthetic mixtures have shown relatively low levels of the complementary hydrolysis product ions. Fortunately, they can be produced rather easily when needed. This is illustrated by the spectrum in Fig. 4, which was obtained by intentionally hydrolyzing a purified methylphosphonate 15-mer in 3% ammonium hydroxide at 50C for 1 hr. The starting 15-mer was highly purified. It did not contain either hydrolysis product ions or failure sequence molecular ions. After hydrolysis, the resulting spectrum reveals all of the complementary information needed to complete the sequence assignment.

Angular- and Time-resolved Intensity Profiles of Ejected MALDI Ions

V. Bökelmann, R. Kaufmann, *B. Spengler
Inst. of Laser Medicine, University of Düsseldorf, Moorenstr. 5, D-4000 Düsseldorf, Germany

A new time-of-flight instrument was developed for the investigation of spatial and temporal characteristics of the ejected ion jet [1-3] in matrix-assisted laser desorption ionization (MALDI). It consists of a cylindrical vacuum chamber with a fixed laser beam path, focused on to a tiltable sample holder which is located in the center of the apparatus (Figure 1). Two individual Wiley-McLaren-type TOF systems equipped with post-accelerating detectors are placed in the vacuum chamber, one in a fixed reference position and the other rotatable around the sample. TOF system and sample holder are positioned by stepper motors. All surfaces outside the TOF systems are electrically grounded in order to allow field-free ion propagation.

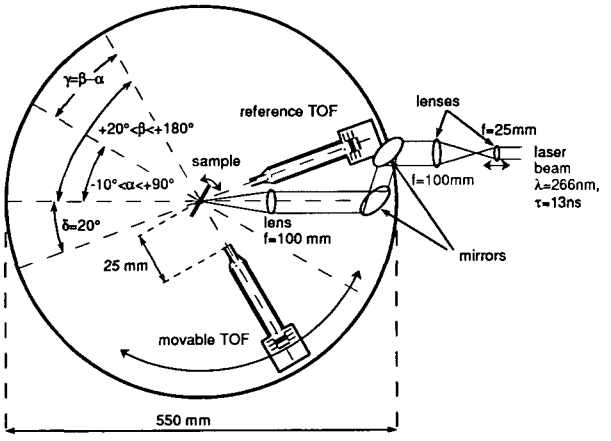

Figure 1: Scheme of the time-of-flight instrument for angular- and time-resolved ion intensity measurements.

In order to investigate the characteristics of the ion jet, the kinetics and spatial distributions of the predominant matrix ions have been analysed. Due to the special construction of the time-of-flight analysers initial velocity distributions of both, the total ion pulse (acceleration voltages turned off) and of mass separated ions (acceleration voltages turned on) could be monitored. Single crystals (size up to 3*5*15 mm) were used as samples in order to provide a topologically well-defined surface.

In the case of 2,5-dihydroxybenzoic acid (DHB) used as a matrix, the most intense ion of the dehydrated parent molecule at M=137 shows an angular dependent intensity distribution $I \sim \cos^{2.39}$ at a focus diameter of 150 µm under threshold conditions (Figure 2). The angle of the laser beam with respect to the surface normal was fixed at 20°. Ion velocities of the dehydrated parent molecule have been measured in the range of 1700 m/s (ion ejection angle 0° to surface normal) to 1300 m/s (ion ejection angle 70° to surface normal). Corresponding kinetic energies were in the range of 2.4 eV to 1.25 eV (Figure 3). Kinetic energies of the dimer ion M=273 were considerably lower in the forward direction, suggesting that the ion jet is mainly energized by the (most abundant) monomer ion (M=137).

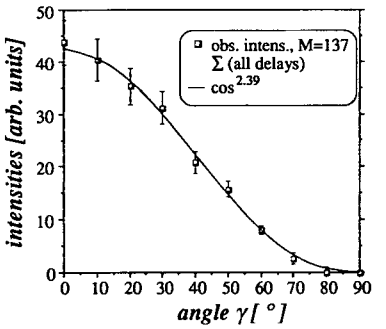

Figure 2: Angular intensity distribution of the dehydrated parent ion of DHB obtained fron a single crystal.

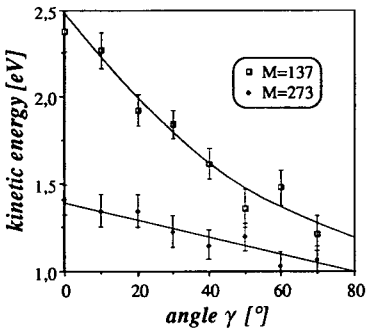

Figure 3: Mean kinetic energies of ions from a DHB single crystal as a function of the angle γ between sample surface normal and TOF axis

It has been observed that both, velocity distributions and angular distributions are strongly dependent on laser irradiance and size of the laser focus. Under focused conditions (focus diameter ≈80 µm) velocities of the dehydrated parent molecular ion range from 2700 m/s (threshold irradiance) to 7400 m/s (5.6 times threshold irradiance). At high irradiances angular distributions are significantly narrower compared to threshold conditions The obtained results support the idea that a nozzle-beam-like supersonic jet is formed by laser irradiation, rather than an effusive one. The spatial and temporal characteristics which are determined by source pressure and size of the nozzle in classical molecular beam systems, seem to be determined by laser irradiance and focus diameter in MALDI systems.

An External Ion Source FTMS for the Analysis of High Molecular Weight Biomolecules

*Brian E. Winger, Bruce L. Becker, Richard E. Hein, James A. Haas and Joseph E. Campana
Extrel FTMS, Millipore Corporation, 6416 Schroeder Rd., Madison, WI 53711-2424.

Ion formation external to the superconducting magnet with subsequent injection through the fringing magnetic field, first demonstrated by McIver et. al., allows for the use of a variety of ionization sources without degrading the high-performance characteristics, i.e., ultra-high resolution and accurate mass measurement, of Fourier transform mass spectrometry (FTMS). Recent demonstrations of coupling FTMS with ionization sources such as electrospray (ESI), continuous-flow fast atom bombardment (FAB), glow discharge and matrix-assisted laser desorption (MALDI) have increased the acceptance of FTMS. Specifically with regards to ESI, the detection of the bovine albumin dimer (M_r 132,532) and resolving powers in excess of 1.0 x 10^6 for bovine ubiquitin have demonstrated the potential of ESI-FTMS for the analysis and subsequent sequencing of biological molecules.

Figure 1 is an illustration of the external source FT/MS system. The design of the ionization source chamber allows for easy interchangeability between EI/CI, FAB and ESI and other ionization sources. The ion injection optics are based upon an acceleration/deceleration electrostatic injection system. An acceleration potential of ~ 2 kV, although voltages in the range of 50 to 2500 have been used succesfully, is used to guide the externally-generated ion beam into the magnetic field. The FT/MS is a commercially available Extrel FTMS Model 2001 based on a 3 Tesla superconducting magnet. All instrument control and data acquisition is accomplished with the Odyssey Data Station.

Polymers are easily ionized by using ESI. Figure 2 is the ESI mass spectrum of a 20 mM solution (MeOH and 0.1% NaBr) of poly(propylene glycol) (PPG) whose weight average molecular weight was listed as 725. The distribution shown here is the sodiated form of PPG. By using a feature of the Odyssey data analysis software, the calculated weight average molecular weight of the sodiated polymer is 709.467 and 686.972 for the nascent polymer.

The data illustrated in Figure 3 of angiotensin II represents our first result of ESI for peptides. The peptide concentration was10 mM and was dissolved in 1:1 MeOH:H_2O with 5% HOAc. The ESI mass spectrum of angiotensin II exhibits an intense monoisotopic $[M+H]^+$ ion at 1046.550, where the calculated value is 1046.542, resulting in an error of 7.6 ppm without using an internal mass reference.

These preliminary results indicate the feasibility of our external source FTMS design, and further developments to optimize sensitivity and speed of acquisition are currently underway.

Storage Tandem MS — Nucleophilic Substitutions in the Gas Phase

M. Stöckli, S. König, H. Reinhard, M. Sägesser, P. Kofel and U. P. Schlunegger
Institute of Organic Chemistry, University of Bern, Freiestr. 3, CH-3012 Bern, Switzerland

A purpose built quadrupole, quistor, quadrupole tandem mass spectrometer [1], enhanced by a personal computer equipped with a data acquisition board [2] was used for the experiments. Primary ions were generated in the differentially pumped external ion source under EI, resp. self-CI conditions, mass selected by a first quadrupole mass filter and injected into a quistor. After a variable storage period in the quistor for reaction the product ions were extracted and analysed by a second quadrupole mass filter. For the QRE-experiments (quistor resonant excitation) a supplementary ac voltage of low amplitude (app. 1 V) was applied to one end-cap electrode of the quistor.

The reaction of CH_4^+ with methane was studied for calibration of the gas pressure inside the quistor volume and subsequently for the investigation of the influence of the kinetic ion energy on product ion distribution [3]. A pressure differential of 35 between quistor volume and quistor housing was determined by comparison of the observed rate constant to the literature value of $1.13\ 10^{-9}\ cm^3 mol.^{-1} s^{-1}$. Unselective increase in the kinetic ion energy by increasing the trapping potential as well as selective increase of kinetic energy using the QRE-technique results in the opening of endothermic reaction channels. The kinetic ion energies in the range of 1-2 eV were monitored as a function of the ratio $I_{m/z\ 27} / I_{m/z\ 29}$ [4].

In an H/D exchange study of the ion / molecule reaction between protonated acetaldehyde and methanol the origin of the protons in the reaction products was determined. Besides the adduct ion and formation of methanol cluster ions [5], methylated acetaldehyde ions could be detected, resulting from water cleavage of the protonated acetaldehyde - methanol adduct [6]. The provenience of the hydrogen atoms in the cleaved water molecule could be established in ion / molecule reactions of labelled reagents (d_1-, d_3-, d_4-methanol and d_4-acetaldehyde) with undeuterated counterparts. A reaction rate constant of $1.0\ 10^{-10}\ cm^3 mol.^{-1} s^{-1}$ for the formation of the methylated acetaldehyde ion and a H/D transfer rate constant of $4\ 10^{-10}\ cm^3 mol.^{-1} s^{-1}$ for the hydrogen directly bound to the C1 atom of the carbonyl group could be determined. The hydrogen atoms cleaved with the water molecule were found to be those that are directly bound to oxygen atoms in the intermediate protonated acetaldehyde - methanol adduct (see figure).

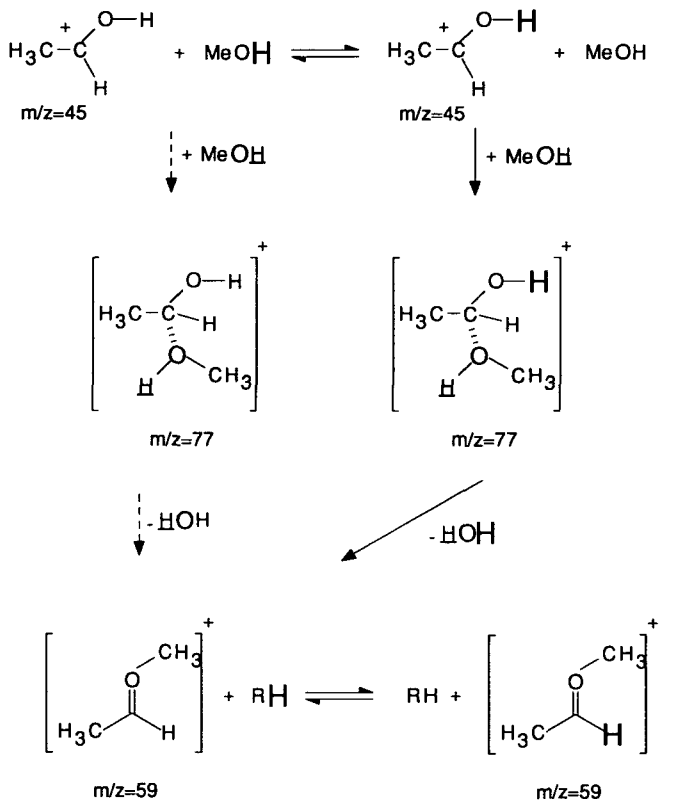
Reaction scheme for production of methylated acetaldehyde



THE EFFECT OF Z-DIRECTION STRETCHED GEOMETRY ON ION INJECTION INTO A QUADRUPOLE ION TRAP MASS SPECTROMETER. Habibi-Goudarzi, S. and McLuckey, S.A., Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6365.

Precise electrode spacing is one of the criteria for producing a pure quadrupole potential field in a Paul type ion trap. Symmetrical alterations in the end cap spacing introduces fourth-order distortions (e.g. octapole), and asymmetrical alteration, third-order distortions (e.g hexapole).[1] It has been shown that these higher-order fields may be controlled advantageously.[2] The theoretical and experimental treatments of non-linear fields have not addressed their effects (if any) on the injection of ions into an ion trap. We have performed some preliminary experiments with a "quadrupole" ion-trap mass spectrometer (Finnigan ITMS) in which the trap geometry has been changed via symmetrical stretching in the z-direction This is accomplished by simply changing the length of the spacers which separate the ring electrode from the end caps. Three geometries are reported here and they are: (1) "Pure" quadrupole geometry z_o=0.7071 cm, (2) Finnigan geometry z_o=0.7884 cm, (3) S62 geometry z_o=0 8697. Note that the end cap electrode surfaces were not altered. Therefore, geometries two and three should have strong fourth-order distortions. Ions are formed and injected into the ion trap via the atmospheric sampling glow discharge ionization source (ASGDI) as described previously [3] A series of mass spectra were recorded using DNT and TNT as model compounds. An obvious observation was the mass shift in the spectra which was predicted using Knight's equation[4]: $q_z = -8eV/m(r_o^2 + 2z_o^2)\Omega^2$ In terms of observed mass, m_1, which is proportional to the rf amplitude (V) needed to eject that ion at q_{eject}=0 91 in the mass selective instability mode (a=0), a simple expression $m_2=m_1(d_2/d_1)$ is derived where $d_i=(r_o^2 + 2z_o^2)$ corresponds to the appropriate geometry. For example, TNT with m/z 227 is observed at 201,226, and 257 in geometries 1-3 respectively. Note: Axial modulation is not used and the calculated m/z values could have an error of about 3 u. Injection efficiencies are affected in an m/z dependent fashion The relatively limited set of results reported here indicate that the pure quadrupole trap has a higher injection efficiency for the TNT molecular anion than the Finnigan trap (by a factor of about four; Fig.1). Separate experiments illustrated nearly the same injection efficiency for the DNT molecular anion. The S62 geometry has consistently lower injection efficiency, by at least one order of magnitude, as compared to that in the pure trap. These studies indicate that further stretching of the already stretched Finnigan geometry will provide no benefit in ion injection efficiency and that there appears to be no benefit of the present stretched geometry over the "pure" ion trap in this regard

Since the overall performance of a given geometry is needed to determine whether one should be selected over another, characteristics other than injection efficiency were studied. In the case of MS^n experiments, the larger the fraction of fragment-ions collected leads to higher values of n. MS/MS efficiencies were recorded for the three geometries and the values varied significantly from one geometry to another. In the case of TNT, an efficiency in the range of 50 to 80% was observed in the Finnigan geometry (Fig. 2). This performance was at least a factor of two better than the pure trap and about the same as that in the S62 geometry. All three ion trap configurations had higher MS/MS efficiencies for the DNT molecular ion (m/z 182) than that for TNT. But the "pure" trap geometry again had lower MS/MS efficiency than that of the other two geometries. Another factor considered was mass resolution: $R=m/\Delta m$ where Δm is the full width at half maximum (FWHM). The DNT molecular anion peak was arbitrarily chosen for this purpose which had R values of 250, 320, and 310 for geometries 1-3, respectively. Axial modulation improves the resolution and peak intensity up to a factor of two in the case of the two stretched geometries, however, in the pure quadrupole trap, both

"The submitted manuscript has been authored by a contractor of the U.S. Government under contract No. DE-AC05-84OR21400. Accordingly, the U.S. Government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so for U.S. Government purposes."

R and peak intensity are reduced by about 10 to 15 percent. Present experiments indicate that the trade-off between injection and MS/MS efficiencies and resolution need to be examined for geometries in between cases 1 and 2, specially with ions of larger molecules.

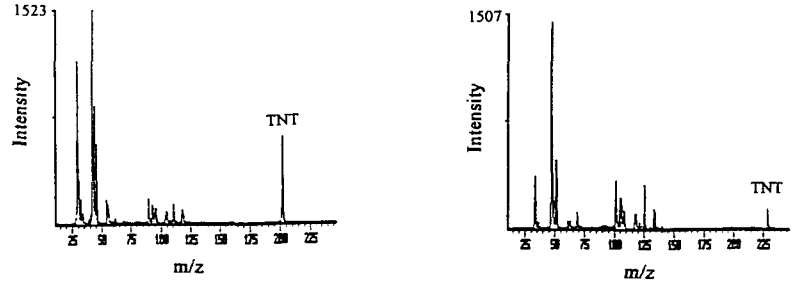


Figure 1. Atmospheric-sampling glow discharge mass spectra of TNT (5 ms injection time) recorded using (from left to right) the "pure" and the Finnigan traps.

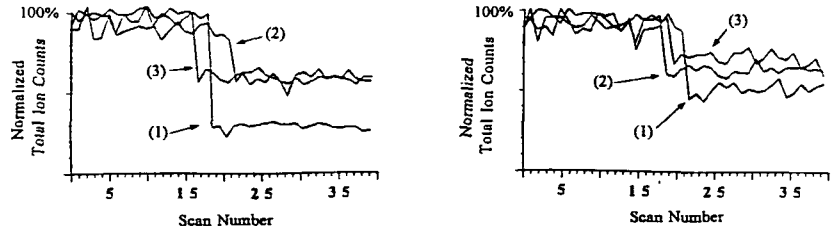

Figure 2. Normalized total ion counts recorded before and after collision-induced dissociation of the TNT anion (left diagram) using (1) the "pure" trap with 30% MS/MS efficiency, (2) the Finnigan trap 67%, and (3) the S62 trap 62% compared with the counts recorded for the DNT anion in (1) 56%, (2) 69%, and (3) 74%.

Deflection of Laser-Produced Ions in Laser-Desorption/FTMS

Nick A. Thornburg, Ihab M. Abdelrehim, Steven H. Pullins, and *Donald P. Land,
Department of Chemistry, University of California, Davis, CA 95616.

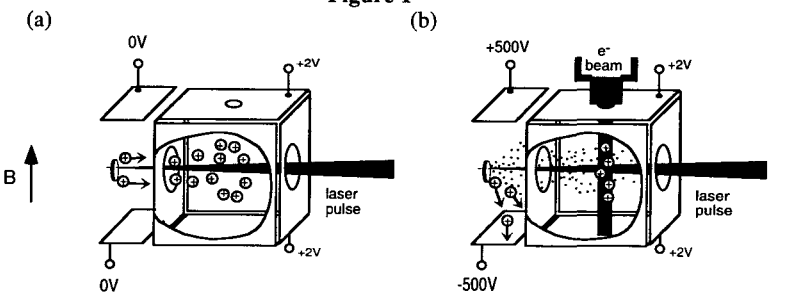
The presence of even small quantities of alkali metals can prevent LD/FTMS studies of monolayer organic adsorbates and surface chemistry. This is because alkalis have low heats of vaporization as well as low heats of ionization. Thus, vast quantities of ions are produced directly by the laser during desorption, thereby filling the cell and making detection of post-ionized organics impossible. However, alkali promotion in catalysis is an important industrial technique which is poorly understood, and one which we would very much like to study using LITD/FTMS. Results are presented here for laser-induced thermal desorption from oxidized Ti foils using a new method for deflection of the laser-produced ions using a static electric potential outside the cell. Desorbed material must pass through this potential on the way (1 cm) to an aperture (1 cm diameter) into the FTMS analyzer cell, as depicted in Fig. 1. Deflected ions do not pass through the aperture into the cell, but neutrals are unaffected and can be postionized (with an electron beam inside the cell) and analyzed, even with significant amounts of K present on the surface.

Fig. 2 compares two laser-desorption spectra from Ti foil surfaces with less than 1% of a monolayer of K plus approximately one monolayer of carbonaceous material. The first spectrum uses no deflection voltage and shows only laser ionized K^+ (m/z 39) and K^{++}. The second spectrum utilizes a 600V deflection potential and does not show K^+, but does exhibit the ions due to adsorbed organics, such as benzene (m/z 78, 77, 52, 51, 50), ethylene (m/z 28, 27, 26), and other, as yet unidentified species. The peak at mass 39 in spectrum (b) is not due to K+ (m/z 38.96) but occurs at m/z 39.02, correct for $C_3H_3^+$ (a common fragment for virtually all hydrocarbons). This uses the high resolution capabilities of the FTMS to obtain information about elemental composition of unknown peaks.

To further characterize the deflection of laser-produced ions, the Ti sample was deliberately ablated to provide a renewable, consistent source of directly formed ions. Three variables are manipulated during these experiments: deflection voltage, laser energy, and sample-to-aperture distance. Deflection plate voltages were varied from 0 to +500 V on one plate and 0 to -500 V on the second. For a sample-to-aperture distance of 1 cm and laser power density 5% above threshhold for Ti ablation, laser produced ions were completely deflected using a minimum of 500V (±250V). When the laser energy was increased an additional 6% above the threshold for ablation, the voltages placed on the ion deflection plates had to be increased from ± 50 V to ± 200 V for complete ion deflection at a distance of 1.5 cm. Thus, as expected, lower ion deflection plate voltages were necessary to deflect ions when the sample was moved away from the cell aperture.

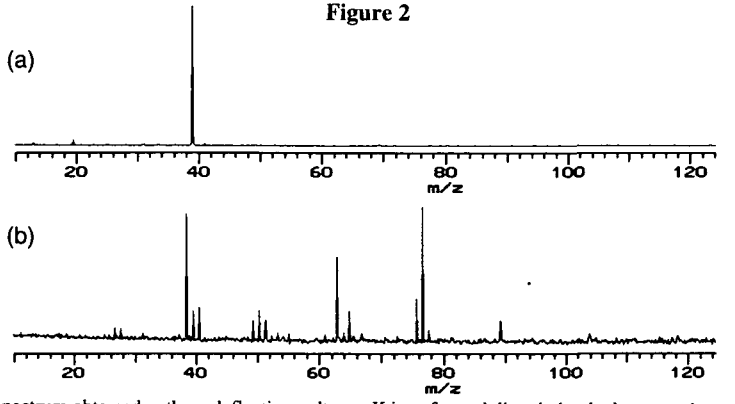
This technique, therefore, allows the detection of postionized species in the presence of easily ionized coadsorbates by deflecting ions formed externally to the cell so that they do not pass through an aperture. This is important for studies of alkali promoted catalysts, as well as environmental samples or samples exposed to biological fluids.

Figure 1



Above is a depiction of the cubic (5 cm) ICR cell with ion deflection plates. (a) Ions formed directly during desorption flood the analyzer cell, preventing detection of postionized neutrals desorbed. (b) Deflection of the laser-formed ions by a DC voltage on external deflection plates allows postionization and detection of desorbed neutrals

Figure 2



(a) Spectrum obtained with no deflection voltage. K ions formed directly by the laser are the only observable species. (b) With 600V applied to one plate the K ions are completely deflected and the organics are postionized and detected.

Determination of Relative Dissociation Energies in an Ion Trap Mass Spectrometer

K.J. Hart, S. Habibi-Goudarzi and S.A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6120

The minimum energy required for the fragmentation of a polyatomic ion is of fundamental importance in mass spectrometry. Recently, March and Todd have recognized that collision-induced dissociation as it is typically effected in the quadrupole ion trap can be characterized by the kinetics of parent ion decomposition under various experimental conditions. We were intrigued by this approach for its potential for allowing for quantitative measurements of critical energies of decomposition for the wide variety of ions that can be stored in an ion trap. Such a capability would significantly enhance the value of the ion trap as a tool for fundamental research in gaseous ion chemistry and might also prove useful analytically in isomer differentiation. To investigate the possibility of measuring critical energies, or some parameter that can be related to critical energies, we have studied a number of parent ions with critical energies measured by other means.

The method used to measure relative dissociation energies in the ion trap is: 1) form the molecular ion by EI and isolate, 2) apply an optimized ac signal to the endcap electrodes at several different amplitudes, 3) monitor loss of parent ion versus the duration of the ac pulse, 4) plot $\ln([P]_t / [P]_0)$ versus time and record the slope of a linear regression fit, 5) convert the slope to a dissociation rate constant using the number density of helium, 6) plot dissociation rate constants versus resonant excitation amplitude and 7) extrapolate the resulting curve to $k_v = 0$ to determine the "threshold resonant excitation amplitude" (TREA). The resonant excitation frequency was optimized at each amplitude and a shift of 200-400 Hz over a 200-300 mV range was routinely observed in these experiments. A helium buffer gas pressure of 1.1 mTorr and a trap temperature of 100 °C were maintained for all determinations. The effect of the q stability parameter was studied using n-butylbenzene and only a 4.5% relative standard deviation was observed in the TREA's obtained with a range of q's from 0.2 to 0.4.

A summary of the TREA results obtained for several model systems is provided in Table 1 with the corresponding literature critical energies. Comparison of these thresholds with literature critical energies indicate that the experimentally derived minimum resonance excitation amplitude is indeed related to kinetic stability of the ion as shown in Figure 1. Two hypothetical $P(\varepsilon)$ vs. ε curves, both Boltzmann internal distributions, are shown in Figure 2 reflecting parent ions before resonant excitation and during collisional activation once a steady state condition is reached. Our interpretation of the threshold resonant excitation measurement is that it reflects a parent ion "temperature" at which a negligible number of parent ions have sufficient internal energy to fragment but one in which a slight increase in temperature would dissociate. The k_v values reflect the rate at which parent ions achieve sufficient energy to fragment. If the internal energy distributions can be characterized by temperatures, the TREA is a measure of ΔT. Provided all parent ions start at the same temperature, there is a correlation between ΔT and critical energy because they are proportional. This work constitutes an important first step in developing a means for quantifying ion stability with a quadrupole ion trap. The authors wish to acknowledge the support of the Office of Basic Energy Sciences, U.S. DOE.

TABLE 1

CID of $M^{+\cdot}$

System (dissociation)	E0 lit. (eV)	TREA (mV)
tetraethylsilane (loss of $\cdot C_2H_5$)	0.5 [1]	0*
nitromethane (loss of $\cdot CH_3O$)	0.71 ± 0.03 [2]	52.5 ± 7.9
allyl chloride (loss of ·Cl)	1.01 ± 0.05 [3]	88.40 ± 2.9
n-butylbenzene (loss of C_3H_6)	1.10 ± 0.10 [4]	105.3 ± 9.4
ethylbenzene (loss of $\cdot CH_3$)	1.30 ± 0.02 [5]	137.5 ± 8.7
toluene (loss of ·H)	1.70 ± 0.06 [6]	159.7 ± 6.4
styrene (loss of C_2H_2)	2.43 ± 0.05 [7] (2.7 ± 0.6) [8]	180.6 ± 10.2

Trajectory Modeling of Electrosprayed Protein Ions in a FT/ICR

Peter B. O'Connor*, Mike W. Senko, Steven C. Beu, and Fred W. McLafferty; Chemistry Department, Baker Laboratory, Cornell University, Ithaca, NY 14853-1301

Ion trajectory simulations are an attractive method for investigation of space charge effects in a fourier transform mass spectrometer. Several analytical approaches have been used successfully in the past. The models by Marshall [1] and Comisarow [2,3] have been very successful at describing frequency shifts and line broadening, and the model by Beu and Laude [4] describes some peak shape distortions very well. However, it is more satisfying to allow full inclusion of coulombic forces. Recently, Dunbar's group has done so numerically [5], and showed some interesting results, but they had trajectory stability problems. Our Multiple Ion Trajectory Simulator (MITS) uses Runge Kutta fourth order numerical integration with adaptive timestep correction to solve the stability problems and a KSR1 parallel supercomputer to allow the calculation of many ions simultaneously.

MITS has been applied to several problems. Investigations of radial and axial ejection of fragment ions formed in the ICR cell by splitting of multiply charged ions showed that the energies of the repulsion alone should not eject the ions (figure 1). Although the ions are specified to fragment in the axial direction, the two ions here represent a "best case" scenario with respect to the magnitude of the repulsion because the parent ion is assumed linear with evenly distributed charges which minimizes effective charge. The effective charge is calculated by a $1/r^2$ weighted average. Fragmentation of higher charge states or from conformations that are more compact initially will increase the chance of axial coulombic ion ejection, but loss of ions should be easily prevented by raising the trap potentials.

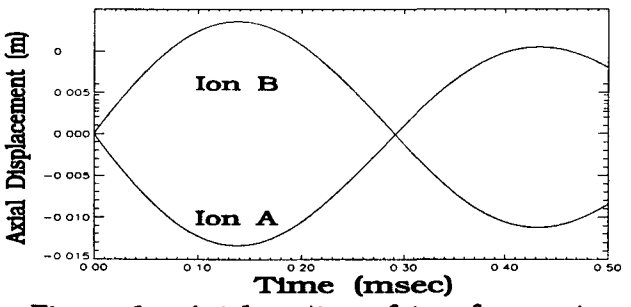

Figure 1: Axial motion of two fragments.

A new trapping mechanism is proposed. If an ion moves axially through a cell that contains trapped ions, the ions will interact coulombically, and the trapped ions can absorb some of the axial energy of the "hot" ion thus trapping it. This mechanism was modeled with MITS, and the "hot" ion was indeed trapped (figure 2).

The effects of increasing mass and cross sectional area at constant m/z was modeled. As mass increases, the effect of collisions with background gas diminishes, and the ions have better resolution. As cross sectional area increases, the number of collisions increases and resolution decreases. However, increasing mass usually implies increasing cross sectional area. Therefore, assuming that volume is proportional to mass, we increasec cross sectional area proportional to mass$^{2/3}$, and resolution still increased at high mass. Therefore, the solution of the problem of achieving high resolution at high mass must concern other line broadening mechanisms such as space charge and field inhomogeneities.

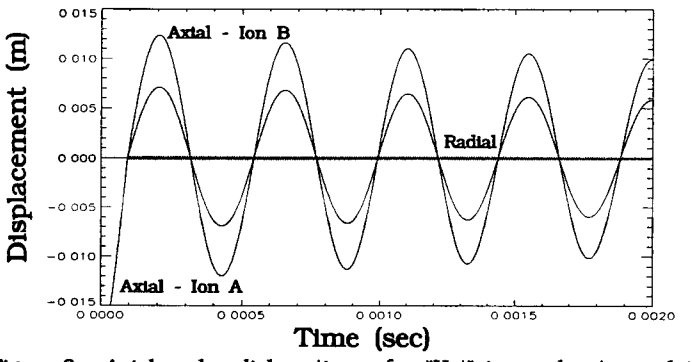

Figure 2: Axial and radial motions of a "Hot" ion and a trapped ion

Equilibrium Distribution of Space Charge in a Quadrupole Ion Trap

Shenheng Guan and Alan G. Marshall†

Departments. of Chemistry (and Biochemistry†),The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

Quadrupole (Paul) ion trap mass spectrometry has developed into a powerful technique for mass analysis, with demonstrated high mass range, multi-stage MS, and potentially high mass resolving power. However, poor mass measurement accuracy can result from space charge effects which are difficult to model theoretically and evaluate experimentally. Here, we propose a simple model for ion space charge distribution based on the pseudopotential or Dehmelt approximation.

In a Paul ion trap, the high-frequency, high-amplitude rf voltage applied between the ring and end-cap electrodes forms a three-dimensional pseudopotential that may be approximated as a quadrupolar electrostatic potential, $\Phi_0(r)$ Ion motion in such a potential may be modeled as a harmonic oscillator when $q_z = (4qV_{rf}/mr_0^2\Omega^2) < 0.4$). Unlike the three-dimensional electrostatic potential in free space bounded by closed-surface boundary electrodes, the three-dimensional pseudopotential has a "true" energy minimum at the center of the trap.

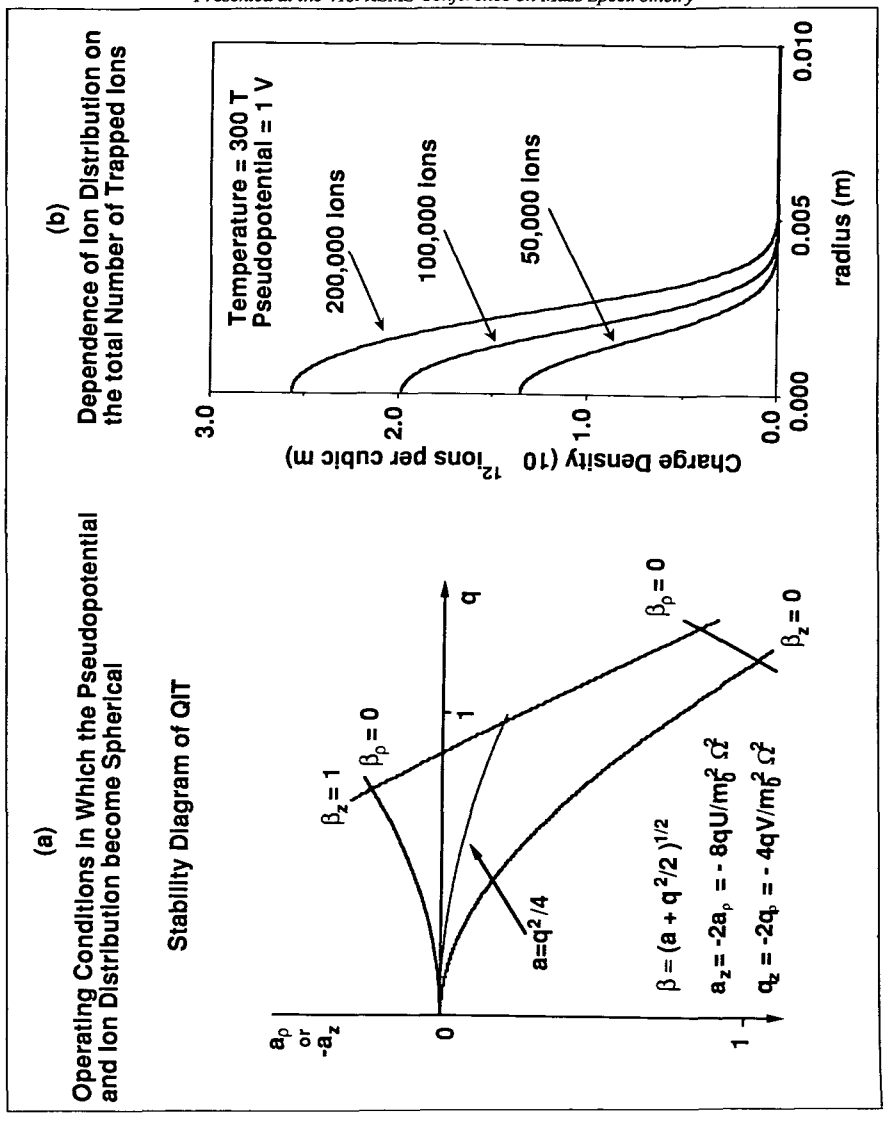
At millitorr He buffer gas pressure, ions collide with He atoms several tens of thousands times per second, and those collisions tend to thermalize the ion motions. After a long (several-seconds) ion storage period, one can approximate the ion velocity distribution as a Boltzmann thermal distribution, particularly at small q_z-value for ions located near the center of trap. At thermal equilibrium, the charge distribution depends only on the total number of charges, the pseudopotential, and the temperature), and is independent of the choice of collision gas. As a further simplification, we consider only operating conditions under which the pseudopotential (and thus the ion distribution) is spherically symmetric (see Figure 1a). The potential generated by the space charge must satisfy the one-dimensional Poisson equation

$$\nabla^2\Phi_s(r) = \frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{d\Phi_S(r)}{dr}\right) = -q\,n(r)/\varepsilon_0 \qquad (1)$$

in which r is the position, $\Phi_S(r)$ is the space charge potential, and n(r) is the ion number distribution which should also satisfy the Boltzmann distribution with the respect to the pseudopotential

$$n(r) = N\frac{\exp\left(-q[\Phi_0(r) + \Phi_S(r)]/kT\right)}{4\pi\int \exp\left(-q[\Phi_0(r) + \Phi_S(r)]/kT\right) r^2\,dr} \qquad (2)$$

in which $\Phi_0(r)$ (proportional to r^2) is the pseudopotential. We solve the above problem self-consistently. First, an arbitrary ion distribution is generated and subjected to Eq. 1; the space charge potential is then solved and substituted into Eq. 2. This process is repeated until the solutions agree with each other. A detailed description of the method will be given in an upcoming manuscript. This work was supported by NSF (CHE-9021058), and The Ohio State University.



Chemical Ionization in Ion Trap GC-MS Using Selective Ion Ejection Techniques.

Charles Huston, Barbara Bolton, Mingda Wang, and Greg Wells,
Varian Chromatography Systems, WC-14
2700 Mitchell Drive, Walnut Creek, CA 94598 U S A

Introduction

The electron ionization (EI) process used to internally create chemical ionization (CI) reagent gas ions in a quadrupole ion trap mass spectrometer can also produce EI products from the analyte and any contaminants The mass instability CI scan function can use a low ionization rf level to minimize (but not completely eliminate) the storage of EI fragments at higher m/z Complete elimination of unwanted EI products prior to mass analysis can be accomplished by using selective ion ejection techniques

Methods

Wave-Board electronics were added to a Varian Saturn II GC/MS System to provide the flexibility to implement three simultaneous ion ejection techniques Resonant Ejection, Non-Resonant Dipole Ejection, and dc Isolation These techniques caused the reagent ions and their lower mass precursors to be stored, following ionization and prior to CI reaction, while all ions at higher m/z were ejected For **Resonant Ejection**, a complex waveform (containing the resonance frequencies for the ions to be ejected) was applied to the endcap electrodes **Non-Resonant Dipole Ejection** utilized a simple square wave (500Hz) whose amplitude could be characterized in terms of a desired lower m/z cutoff point The **dc Isolation** method applied -2V dc to the ring electrode of the ion trap during the ejection period

Results

The *Ejection Comparison* chart shows that, depending on the compound, the ejection methods gave an apparent 50-65% reduction of selected EI fragments when compared to Mass Instability CI None of the three ejection methods produced significantly different results relative to each other.

Comparison of *EI Spectrum of Methoxychlor* with *Mass Instability CI* illustrates the presence of EI products (i e., the ion at m/z=227) in CI spectra. All of the simultaneous ejection CI methods produced methoxychlor spectra that were similar to that shown for *Non-Resonant Dipole Ejection CI* This CI method reduced the abundance of m/z 227 by more than 50% (relative to mass instability CI), however, its continued presence indicated that it was also produced by a non-EI pathway Confirmation that the remaining fragments at m/z 227 were produced by a CI charge transfer reaction was obtained by observing isobutane CI spectra in *Non-Resonant CI Using Isobutane* The use of a softer CI reagent gas produced a spectrum that was very similar to those produced by simultaneous ejection CI using methane The use of different CI techniques to examine the spectra of other compounds allowed similar qualitative ion chemistry information to be obtained

Finally, CI signals from the three simultaneous ejection CI methods ranged from 8-30% higher than comparable Mass Instability CI results

Numerical Computation of Trapping and Excitation Electric Fields and Ion Trajectory Simulations in an ICR Ion Trap

Xinzhen Xiang, Shenheng Guan, Alan G. Marshall†, L. A. Southern, and D. Knight

Departments. of Chemistry (and Biochemistry†),The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

A numerical method has been developed for computation of trapping and excitation electrical fields in a rectangular/cubic ICR ion trap and for simulation of ion trajectories. Theoretically, the problem of solving for the potential, $\Phi(x,y,z,t)$, inside a rectangular or cubic trap with arbitrary boundary conditions at any given time, t, may be simplified to superposition of "eigen" potentials, $\Phi_0(x,y,z)$

$$\Phi(x,y,z,t) = V_{x+}(t)\,\Phi_0(x,y,z) + V_{x-}(t)\,\Phi_0(-x,y,z) + V_{y+}(t)\,\Phi_0(y,x,z) + V_{y-}(t)\,\Phi_0(-y,x,z) + V_{z+}(t)\,\Phi_0(z,y,x) + V_{z-}(t)\,\Phi_0(-z,y,x)$$

in which the eigenpotential is the solution for the special boundary condition that one trap electrode is set to 1 V and the other electrodes are at groundl; $V_{x+}(t)$ etc. denote potential applied to the electrode (i.e., at $x = +a/2$, a is the trap edge length). Our program also contains routines to generate arbitrary excitation waveforms, including SWIFT algorithms. Ion trajectories for a variety of excitation modes (see Table) and in the presence of collisional frictional force may be simulated. The time-domain ion signal derived from the image current induced on the detection electrodes and its frequency-domain spectrum may also be generated.

The programs are written in Fortran 77 and compiled and executed on a CRAY Y-MP8/864 computer with 8 processors and 512 megabytes of high-speed memory at the Ohio Supercomputer Center. The Supercomputer provides both computational speed and high accuracy. In order to visualize the desired potential, the data are transfered to a SUN SPARC station and converted to a Felix data file format. Both contour and stack plots may be generated within the Felix program. Trajectory data are then transferred to a Macintosh IIsi, where they are displayed and printed from a BASIC program. 3D videos from apE have also been generated.

To produce the "eigen" potential data with high precision, an array of 101X51X51 dimensions is reserved. By symmetry, only one fourth of the eigen potential data need be generated, reducing computation time and storage space. The potential is computed by a simple relaxation method. Over 10,000 iterations (6,300 s of CPU time) were excuted until the maximum deviation of data points between the last two consecutive iterations is less than 10^{-8}. The large computing effort is warranted, since the "eigen" potential need be generated only once, from which the electrical field anywhere in the trap may then be calculated. During the trajectory simulation, the "eigen" potential was extrapolated to double the spatial resolution for the electric field data. The Lorentz equation of ion motion is solved by a 4th-order Runge-Kutta method at 100 ns time increments.

Our simulations have already revealed some interesting nonlinear effects of a real ICR trap and details will be reported in an upcoming manuscript [1]. In future work, we shall investigate the effects of space charge on the temporal evolution of an ion distribution. Supported by NSF (CHE-9021058) and Ohio State University.

Azimuthal quadrupolar $2\omega_-$ excitation	$V_x\sin2\omega_-t$	$V_x\sin2\omega_-t$	$-V_x\sin2\omega_-t$	$-V_x\sin2\omega_-t$	V_T	V_T

Non-linear Resonance Conditions and their Relationships to Higher Multipole Fields in Quadrupole Mass Filters and Non-linear Ion Traps

Y. Wang and J. Franzen

Bruker-Franzen Analytik GmbH, 2800 Bremen 33, Germany

It is non-linear resonances, caused by higher multipole fields, which change the stability and instability of ion motion based on the pure quadrupole field. The resonace can be termed as the "internal" resonance.

With theoretical analysis, a general non-linear resonance conditions for three-dimensional non-linear quadrupole systems can be derived:

$$n_x\beta_x + n_y\beta_y + n_z\beta_z = 2\nu \qquad (0 \le \beta_x, \beta_y, \beta_z \le 1) \tag{1}$$

where $\beta_x, \beta_y, \beta_z$ are secular frequency parameters in x, y, z direction and n_x, n_y, n_z, ν are $0, \pm1, \pm2, \pm3, \cdots$ all integers. The resonance conditions (1) can be applied in non-linear ion traps with three-dimensional distortions; and quadrupole mass filters with distortions and/or fringe fields. Distortions mean, for example, any twists, and so on.

Some kind of symmetry of electrode shapes results in the corresponding symmetry of the electric field in the quadrupole system. Therefore, resonance conditions are reduced and some resonances are not produced due to the symmetry. For the ion trap with the rotational symmetry, reduced non-linear resonance conditions are

$$n_r\beta_r + n_z\beta_z = 2\nu \tag{2}$$

with $n_z, \nu = 0, \pm1, \pm2, \cdots$ all integers and $n_r, \nu = 0, \pm2, \pm4, \cdots$ even integers. Specially for the superposition with higher "odd" rotationally symmetric multipoles, there are additional restrictions for resonance conditions (2): n_z are odd integers; and for the superposition with higher "even" rotationally symmetric multipoles, n_z are even integers. In non-linear quadrupole mass filters, reduced non-linear resonance conditions are

$$n_x\beta_x + n_y\beta_y = 2\nu \tag{3}$$

with $n_x, n_y, \nu = 0, \pm1, \pm2, \pm3 \cdots$ all integers. In general, there are no additional restrictions in this case.

There are different types of resonances as following: Type (I): One-dimensional resonances (uncoupling resonances), which fulfil resonance conditions:

$$n_\xi\beta_\xi = 2\nu \qquad (n_\xi, \nu : \text{integers}) \tag{4}$$

where ξ means x or y or z in general three-dimensional cases, r or z in ion traps with rotational symmetry, and x or y in quadrupole mass filters. On this type of resonance, the ion takes up energy in ξ direction only. One-dimensional resonances are strong. Type (II): Sum-resonances (coupling resonances). In Eq. (2) and (3), ν and n are positive integers. On this type of resonance, the ion takes up energy in each direction at the same time. Sum-resonance are strong, too. Type (III): Difference resonances (coupling resonances). In Eq. (1) (2) and (3), there are positive and negative integers for n numbers, respectively. On this type of resonance, energy is exchanged mainly between different directions of ion motion. Difference resonances are weak.

In practice, z direction resonances are dominant in ion traps because ions are damped by buffer gas to the center of the trap, then often excited in z axis. Sum-resonances should be paid more attention in quadrupole mass filters, because they locate within the up-corner of the first stability diagram, which is used to analyse the ion mass. In general, difference resonances will be not easily observed in experiments.

Concentrated on the non-linear resonance conditions, each order of multipoles generates a few resonances which fulfil different group of resonance conditions. However, different orders of multipoles generate resonances which fulfil different and/or same group of resonance conditions. In mass spectrum, a group of mass picks caused by non-linear resonances may be generated by different multipoles or mixtures of them. Therefore, orders N of resonance conditions are defined as

$$|n_r| + |n_z| = N \quad \text{(ion trap)} \quad \text{or} \quad |n_x| + |n_y| = N \quad \text{(quadrupole mass filters)}$$

$N = 2$: $2nd$ order of resonance conditions; $N = 3$: $3rd$ order; $N = 4$: $4th$ order; $\cdots$.

If weight factors of a whole set of higher multipoles decrease with multipole order n asymptotically, resonances with a few lower orders N are stronger. Furthermore, resonances with lower orders, for example, the 3rd and/or the 4th order are always observed even if weight facters of a few more higher multipoles are larger. There exist restraining or encouraging functions for resonances if superimpose two or more than two main higher multipoles.

Each order N of resonance conditions consists of several resonance lines. In non-linear ion traps with rotational symmetry, resonance lines for the hexapole superposition(the 3rd order is main) are $\beta_z = \frac{2}{3}$ and $\frac{1}{2}\beta_z + \beta_r = 1$; and for the octopole superposition(the 4th order is main) are $\beta_r = \frac{1}{2}, \beta_z = \frac{1}{2}, \beta_r + \beta_z = 1$. In non-linear quadrupole mass filters, resonance lines for hexapole superposition are $\beta_x = \frac{2}{3}, \beta_y = \frac{2}{3}, \frac{1}{2}\beta_x + \beta_y = 1$, and $\beta_x + \frac{1}{2}\beta_y = 1$; and for octopole superposition are $\beta_x = \frac{1}{2}, \beta_y = \frac{1}{2}, \beta_x + \beta_y = 1, \frac{1}{2}\beta_x + \frac{3}{2}\beta_y = 1$, and $\frac{3}{2}\beta_x + \frac{1}{2}\beta_y = 1$.

Oscillating frequencies of a ion trapped in the pure quadrupole field are

$$\omega_\xi^m = (m_\xi + \frac{\beta_\xi}{2})\Omega \tag{5}$$

where Ω is frequency of the driving voltage, m_ξ means m_x, or m_y or m_z, which are integers. The main resonance frequency($\omega_\xi^0 = \frac{\beta_\xi}{2}$) conditions are

$$n_x\frac{\beta_x}{2}\Omega + n_y\frac{\beta_y}{2}\Omega + n_z\frac{\beta_z}{2}\Omega = \nu\Omega \tag{6}$$

If main resonance frequencies fulfil resonance conditions (6), all side-bands(ω_ξ^m with $|m_\xi| \ge 1$) also fulfil resonance conditions. Therefore, the non-linear resonance is a kind of resonance of a group of resonance frequencies.

Presented at the 41st ASMS Conference on Mass Spectrometry

Electric Trap Fields and High Mass Ions in FTMS: Peak Ratios

C. L. Holliman, D. L. Rempel, M. L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304, USA.

The effect of the electric trap field increases with mass and can adversely affect resolution and sensitivity at high mass. Peak ratios may also be affected. Pre-detection mechanisms to which inaccurate abundances of low mass can be attributed are: z-excitation [1], chirp amplitude [2], and coulombic interactions [3]. DeLong and coworkers [4] present a damping model for post-excitation isotopic fractionation.

While all of the above may play a role in the analysis of high mass ions, the effect of the electric trapping field must also be considered. The effect of the trapping fields on ions approximately 10% of the cell's critical mass can be investigated with the C60 buckminsterfullerene molecular ion (m/z 720) in a 0.0254 cm cubic cell at 1.2 tesla field (m_c = 8100) and scaling the results. For example, *m/z* 720 at 1.2 T scales to *m/z* 24,500 at 7 T. Because tools like the RF-only-mode event and cell compensation produce quality signals at high mass [5], it becomes worthwhile to turn to more subtle high mass problems.

All experiments are performed with a 2.54 cm. cubic molybdenum cell. The trap plates are divided into disc and ring sections and electrically isolated so that different voltages may be applied. The disc is held at 1 V and compensation is achieved by raising the voltage as indicated on the outer ring. Benzene is introduced to a pressure of $1x10^{-7}$ torr (uncorrected). Default parameters are; ionization at 70eV and 35 nA emission current for 15 msec. The fragment ions of *m/z* 50, 51, and 52 are excited by consecutive rf bursts (high to low mass) for 700 usec at 0.74 V_{p-p}. The outer trap electrode is at 1.7 V. C60 buckminsterfullerene is introduced to the cell by a heated solids probe. Default parameters are; ionization at 70eV and 80 nAmp emission current for 500 msec. The molecular and isotope ions of *m/z* 720, 721, 722 are excited by a single rf burst centered on *m/z* 720 for 300 usec at 1.27 V_{p-p}. The outer trap electrode is at 2.3 V.

Discrimination due to chirp/sweep excitation is avoided by exciting the molecular ion and isotopes with a single rf-burst. The frequencies of *m/z*'s 720 at 25042 Hz to 722 at 24973 Hz differ by only 69 Hz. The bandwidth of the rf-burst is sufficiently wide to excite simultaneously ions 720-722 with retention of their relative abundances. Only by going out 5 mass units *m/z* 727 at 24797 Hz is a modest change observed.

Fractionation due to dampening of the signal is circumvented through the use of complex area measurement [6]. Complex areas, sample the initial envelope of the transient before dampening processes have an effect.

The role of space charge is determined by increasing the beam time and plotting the ratio of areas 720/721. Although there is curvature due to space charge, the coulombic interactions reported by Dunbar do not play a major role under these experimental conditions. Space charge effects during detection are increased by reducing the detection orbit by one third. A lack of significant change in the ratio behavior indicates that space charge during detection is not playing a major role in our measurements.

The role of mass and the electric trapping field can be evaluated by comparing the performance of C60 ions with benzene ions. The excited ion orbit is scanned to observe the the effects of the trapping field. Ions sample different areas of the cell during detection by increasing the excitaion time. The ratios of the benzene fragment peaks 50/51 and 50/52 vary by approximately 40% over a 2-fold increase in excite time. A similar increase in excite time for C60 ions results in a 150% change in the ion ratios indicating that the high mass is more sensitve to changes in the electric field.

The shape of the trapping field is changed with compensation voltage and its effect on detection is observed. The ratios of benzene ions remain relatively constant over a change of 0.8 V on the ring electrode whereas the C60 ratios vary as much as 150%. The dependence of high mass relative abundance measurements on trapping field is further demonstrated by a measure of the deviation from the theoretical C60 isotope ratio Figures A-C. As the compensation voltage is increased, the isotpic abundances can be "tuned" to the proper value.

Evidence suggests a previously unreported mechanism exists that effects the detected isotope ratios of high mass ions. The mechanism is not dependent on the details during the excitation time and coulombic interactions do not play a significant role. Electric trap inhomogeneity plays a strong role in accurate isotope ratios at high mass and its effects can be moderated by cell compensation.

SIMULATION OF EXCITATION PROFILES GENERATED BY EXTERNAL SOURCE FTICR ION DISTRIBUTIONS

F. Hadjarab, D. Riegner, C. J. Harper, T. L. Williams, D. A. Laude, Jr.; Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712

The use of Fourier transform ion cyclotron resonance mass spectrometry (FTICR) to examine externally generated ions. Unfortunately, the injection of externally-formed ions increases the likelihood that the trapped ion population is not well-behaved, either in terms of its spatial or kinetic energy distribution. Whereas ideally a low amplitude ensemble of ions will be captured along the z-axis centerline of the cell, it is more realistic to consider for example that laser desorbed ions formed in a region adjacent to the cell might assume a much broader spatial distribution in the cell.

We are interested in understanding the appropriate excitation conditions for an ensemble of ions that enter the cell under non-ideal conditions. Toward that goal a simulation program was written that determines the predicted FTICR signal for an initial ion packet that is subjected to excitation events of increasing magnitude. What distinguishes this simulation from others is the accommodation of statistical ion populations applied to model external ion injection. This increases the reliability of modeled excitation profiles in predicting appropriate excite events for well-characterized but non-ideal ion populations.

In order to simulate the motion of ion clouds under the effect of resonant electric fields inside the ICR trap, we first solve analytically the equation of motion for a single particle, and then write a FORTRAN program that applies this solution to an ensemble of ions. The equation of motion of an ion moving inside the ICR cell under the effect of a single cyclotron excite voltage is known to be :

$$\frac{d^2u}{dt^2} - i\omega_c \frac{du}{dt} - \frac{\omega_z^2}{2}u = F(t)$$

Where $F(t) = F_0 \sin(w_c + q)$ and where $u = x - i\,y$, x and y being the usual Cartesian coordinates describing that component of the ion's motion that is transverse to the magnetic field. The homogeneous solution of this second order differential equation is readily found to be:

$$Z = Z_c + Z_m = r_c e^{(\omega_c t + \delta)} + r_m e^{(\omega_m t + \varphi)}$$

where r_c, r_m, d and j are the cyclotron and the magnetron radii and phases respectively.

In order to find the inhomogeneous solution due to F(t), we use the known mathematical formula:

$$Z_{sol}(t) = Z_c(t)\int_0^t \frac{Z_m(x)F(x)}{W}dx - Z_m(t)\int_0^t \frac{Z_c(x)F(x)}{W}dx$$

This is the inhomogeneous solution for a forced oscillator second order differential equation (like the one above) in which $Z_c(t)$ and $Z_m(t)$ are two independent solutions of the homogeneous problem, F(t) is the electric force, and W is the Wronskian:

$$W(Z_c, Z_m) = Z_c \frac{dZ_m}{dt} - Z_m \frac{dZ_c}{dt}$$

Hence, the time dependent solution under the cyclotron excitation electric field is given by:

$$Z = Z_c + Z_m + A[(\frac{1}{\omega_c - \omega_m} + \frac{e^{-2i\theta}}{\omega_c + \omega_m})e^{i(\omega_m t + \theta)} -$$

$$-(\frac{1}{\omega_c - \omega_m} - it + \frac{e^{-2i\theta}}{2\omega_c})e^{i(\omega_c t + \theta)} - (\frac{1}{\omega_c + \omega_m} - \frac{1}{2\omega_c})e^{-i(\omega_c t + \theta)}] \text{ where : } A = \frac{-iqB\beta}{2m(\omega_c - \omega_m)}$$

q,B,b, m,w_c and w_m are the ion charge, the magnetic field , a coefficient characteristic of ICR cell geometry, and the effective cyclotron and magnetron frequencies respectively.

For the simulation program, the above solution is the basic entity describing the behavior of each ion. The program first starts by setting all the parameters relevant to a typical ICR experiment such as the magnetic field strength, the excite signal voltage, the temperature etc.... It then builds the ion cloud itself taking into account the spatial ion density distribution as well the Maxwell-Boltzmann distribution for the random velocities. It also is capable of handling an initial macroscopic velocity of the ion cloud as a whole. Once this is done, the program calls a subroutine to bring the ion cloud to some desired excited state (through excitation of the cyclotron resonance). Finally a detection subroutine is called to calculate the current induced by the ion cloud on the detection plates, taking into account the gradual disappearance of the ions as they hit the plates. In this initial set of simulation to test the veracity of the simulation, several simplifying assumption were made. First a collision and Coulomb-free environment is assumed. It is also assumed that a uniform distribution of ions is initially formed. Several examples are considered. One is presented here:

Presented in Figure1 is excitation profiles for an ion beam injected on axis but with a spatial distribution extending over the entire cell. This might correspond experimentally to a laser desorption experiment in which the desorbed ions are formed at increasing distance from the trapped ion cell. For this case, the range of r_m increases steadily but the radial kinetic energy remains negligible and r_c ---> 0. Presented in Figure 2 is the predicted optimum excite for each initial ion spatially distributed on-axis. It is observed that a general skewing of the excitation profile to lower optimum excite voltages occurs. This is expected since an increasing fraction of the ions possess a substantial off-axis component The generation of an excitation profile for this uniform distribution verifies that with the application of an excitation event, an asymmetric ion population is generated for detection. of the optimum excite voltage for each of the distributions. The wide range of different optimum excites argues strongly that an understanding of the injected ion population distribution be known to avoid inappropnate application of an rf excitation event that does not generate an FTICR signal. In future work this simulation program will be used to consider the case of ions injected with a substantial kinetic energy distribution. In addition, it will be possible to determine which ions in a particular distribution of injected ions actually participate in generating the detected signal.

Probing Ion Frequencies in a Quadrupole Ion Trap

Donald M. Eades*, Jodie V. Johnson, and Richard A. Yost
Department of Chemistry, Univeristy of Florida, Gainesville, Fl 32611

Introduction and Experimental

Ion motion in a quadrupole ion trap has been described as a harmonic oscillator in both the axial direction (center-to-endcap electrode) with frequency ω_z and in the radial direction (center-to-ring electrode) with secular frequency ω_r. However, other frequency components, comprised of combinations of ω_z, ω_r, and the drive frequency (Ω), contribute to the total ion motion. The magnitude of each component depends on the location within the Mathieu stability diagram and on the contribution of higher-order fields to both the quadrupolar trapping field and to the dipolar excitation signal. Vedel et al. [1] have reported frequency components of ion motion corresponding to ω_z, $\omega_z/2$, $2\omega_z$, ω_r, $2\omega_r$ and other linear combinations while storing N^+ ions at q_z=0.5, a_z=0 (DC=0V). Franzen has reported [2] calculations of the magnitudes of frequency components in a quadrupole ion trap with superimposed higher-order fields.

The work presented here investigates ion frequency components at points on the Mathieu stability diagram corresponding to regions employed during either mass-isolation (i.e. RF/DC) or resonance excitation (for CID). Specifically, the points chosen for this work were near 1) the apex (q_z=0.78, a_z=0.118), 2) the β_z=1 edge (q_z=0.85, a_z=0.05), 3) the β_z=0 edge (q_z=0.70, a_z=-0.19) and 4) q_z=0.3, a_z=0. At each point, m/z 40 ions of argon were subjected to dipolar resonant excitation of varying frequency. When the excitation frequency corresponded to a component of the ion motion in the axial direction, power was absorbed by the ion resulting in ion ejection. A Finnigan MAT ion trap mass spectrometer, controlled by the ICMS Ion Trap Software v. 2.2 [3], was used for all experiments. The RF drive frequency (Ω) was 1.1 MHz.

Probing Ion Frequencies

The absorption spectrum obtained while storing ions near the apex (q_z=0.78, a_z=0.118) is shown in **Figure 1**. The excitation amplitude and time were purposely increased in order to observe the low magnitude frequency components. The Ω-ω_z component absorbs approximately 84% as much as ω_z. Although the $\Omega+\omega_z$ component does not appear to significantly contribute to the ion motion, it should be noted that the ability to probe frequency components above 1.5 MHz is hindered due to attenuation of the excitation signal by the ITMS frequency synthesizer. Consequently, frequency components in this region contribute more than what is observed. The two small absorption bands between ω_z and Ω-ω_z have not been attributed to any combination of ω_z, ω_r and Ω as of yet, but are currently being investigated. The absorption spectrum obtained near the β_z=1 stability edge (q_z=0.85, a_z=0.051) was similar to the that near the apex. Probing frequency components along the β_z=1 edge in the lower portion of the stability diagram (i.e. a_z < 0) will be the subject of future studies.

The absorption spectrum obtained while storing m/z 40 ions of argon near the β_z=0 edge (q_z=0.7, a_z=-0.186) is shown in **Figure 2**. The frequency components corresponding to the secular frequency (ω_z=126 kHz), $3\omega_z$, Ω-$3\omega_z$, Ω-ω_z, and $\Omega+\omega_z$ are observed to contribute to the total ion motion. Additional spectra obtained in this region verify the identity of the components involving $3\omega_z$. Interestingly, components due to $\omega_z/2$ and $2\omega_z$ are not observed. These components may be hidden in the absorption band due to the strong excitation signal.

The absorption spectrum obtained for q_z=0.3, a_z=0 is shown in **Figure 3**. The observed frequency components can be attributed to $\omega_z/2$, ω_z, and $2\omega_z$, all of which were verified by other absorption spectra acquired in the region. Although not shown, frequency components corresponding to Ω-ω_z and $\Omega+\omega_z$ were also present and of greater magnitude. Absorption due to a $3\omega_z$ component was also present, but required excitation of 10 V_{p-p} from an external waveform generator to be observed. The sharp spikes observed at a slightly higher frequency than the $2\omega_z$ and $3\omega_z$ absorption bands (**Figure 2 & 3**) are believed to be evidence of the collective behavior of the ion cloud [1]. This was further investigated by varying the ion population while storing m/z 40 ions at q_z=0.3, a_z=0. Shown in **Figure 4** is a comparison of absorption bands corresponding to $2\omega_z$. Note that the observed effect increases with increasing ion population (space charge effects) which might be expected to promote the collective behavior of the ion cloud. Inspection of the absorption band shape indicates that the band is not shifting, but is simply splitting as evidenced by the width of the band and by the position of the spike.

Optimization of simple open cylindrical trapping geometry for FT/ICR

L Schweikhard, M. Lindinger, H. Hartmann, Inst. f. Physik, P.O. Box 3980, 55029 Mainz, Germany

Ion cyclotron resonance (ICR) traps consist of homogeneous magnetic fields allowing mass-to-charge analysis of the trapped charged particles by their cyclotron frequency, and of electric fields providing the trapping in the axial direction (i e. along the direction of the magnetic field, z-direction). The electric field is produced by application of voltages to the trap electrodes A broad range of electrode geometries has been introduced [Mar92]. Whereas the main purpose of the electric field remains the same (axial trapping) these different electrode arrangements differ in the details of the field. The axial electric trapping field implies radial components which lead to a shift in the cyclotron frequency. In most cases (e g. the traditional cubic or cylindrical ion cells for Fourier Transform/ICR, FT/ICR) this shift is position dependent. It is position independent only for a pure axial quadruple potential (i.e. an ideal Penning trap). Such a potential can be approximated by hyperbolical trap electrodes (a ring and two endcaps). However, even for these traps, deviations from the ideal geometry (e.g. truncation of ideally infinite electrodes, entrance and exit holes for the ions, machining imperfections) lead to perturbations of the ideal ion motions and position-dependent frequency shifts. To minimalize the imperfections of the potential, compensation electrodes can be placed between the ring and endcaps (Van76) and additional correction electrodes may adjust the perturbations of the axial holes [Bol90].

Traditionally, emphasis has been on the creation of the best possible quadrupole approximation for the trap center. This is the appropriate approach for experiments with small amplitudes of the ion motion In FT/ICR however, the ions are excited deliberately to relatively large cyclotron radii (on the order of magnitude of the trap radius itself). In order to improve the potential for the purpose of FT/ICR investigations it seems appropriate to fine-tune the trap regions that the ions experience after they are excited

As a first example for a detailed analysis of trapping field optimization at finite cyclotron radius, the "simple open cylindrical geometry" was chosen. By "simple" we mean restriction to the minimum number of electrodes to create a trapping potential, namely three (in general; in special cases two electrodes may do [Sch90]). "Open" traps allow free optical and ion optical access to all trap regions Since the ions are guided by the magnetic field lines this access is accomplished best via the trap axis. There is a long tradition of use of open geometries for the storage of charged particles [Byr65]. Special multi-electrode designs have been developed to allow a shimming of the central trap potential without effecting the trapping frequency [Gab89], and open geometries have recently been introduced to FT-ICR [Beu92] Recent investigations lead to a cylindrical trap design which offers an almost perfect quadrupolar trapping potential not only in the very center of the trap, but also in a rather large region [Har93] The programs developed for the latter studies have been employed for the investigations described below

The simple open cylindrical design investigated by us consists of a center tube (center electrode) and on each side an infinitely long tube (trapping electrodes) of the same diameter The aspect ratio R = L/D (length-over-diameter, Fig. 1) of the center trap was varied for numerical calculations of the trapping potential These calculations give, e g , the potential along the z-axis and as a function of distance r from the trap center in the symmetry plane (z = 0) for several aspect ratios. A byproduct is, e g., the depth of the trapping potential as a function of the aspect ratio (Fig. 2).

The electric trapping field leads to a shift $\Delta\nu = \nu_c - \nu_+$ of the reduced cyclotron frequency ν_+ as compared to the pure cyclotron frequency $\nu_c = qB/2\pi m$ in the absence of the electric trapping field. From the potential (for each given aspect ratio) we can calculate the frequency shift as a function of the ion position in the trap. For a first analysis we chose a pure cyclotron motion (no magnetron motion) in the symmetry plane (z = 0) of the trap (no axial motion). The calculation was performed for a magnetic field

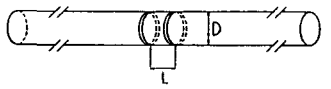

Figure 1: Geometry of 'simple open cylindrical trap'. The aspect ratio is defined as R = L/D.

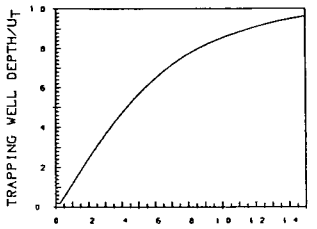

Figure 2: Depth of the trapping potential in units of the voltage difference UT between the trapping electrodes and the centerelectrode as a function of the aspect ratio R.

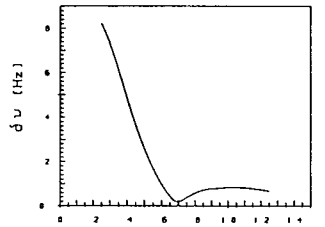

Figure 3: Root-mean-square frequency deviation for a cyclotron radius range of D/6 > r > D/3 as a function of aspect ratio R. For details see text.

of B = 5 T, trap diameter D = 80 mm, and a trapping potential on the trapping electrodes of U_T = 1 V (with the center electrode on ground potential) For a given range of cyclotron radii r of interest (in this example D/6 < r < D/3) we can now calculate the respective range of frequency shifts, or the root-mean-square deviation $\delta\nu$ from the respective average frequency. Figure 3 shows a plot of this measure of the frequency deviations versus the aspect ratio of the trap While the deviations are small in general (a few tenth of a Hertz as compared to cyclotron frequencies from 15 MHz to 15 kHz for ion m/q = 5 to 5000 amu/e) we find a minimum at the aspect ratio R = 0 7 For ultimate mass resolution this is the aspect ratio of choice for this electrode configuration (and the range of radii used), since it minimalizes the frequency deviations of ions that are excited to different cyclotron radii.

This study has dealt with the trapping potential only For FT-ICR the electrodes have to be segmented further to allow for excitation fields and pick-up of image charge signals (again, there are special cases that can do without [Mar92]) 120° seems to be the angle of choice for the pick-up electrodes since it minimalizes the third harmonics components of the signal in the standard (dipole) detection scheme. On the other hand, 60° segments maximize the third harmonics and therefore allow for ion cyclotron radius determinations based on the third-to-first harmonic ion signal [Gro92]. Further segmentation may be needed for special excitation [Sch93] or detection modes [Mar92]. Finally, the electrode segmentation for excitation/detection can be extended to the trapping tubes as well As has been pointed out [Beu92], this avoids z-ejection by the excitation field. It has two further advantages: No dependence of the ICR signal on the amplitude of the trapping motion and an excitation amplitude that is independent of the cyclotron radius.

DETERMINATION OF PHOSPHORYLATION SITES ON THE SENDAI VIRUS P PROTEIN BY MALD-ITMS AND MALD-TOF

K.R. Jonscher and J.R. Yates, III, Dept. of Molecular Biotechnology,

University of Washington, Seattle, WA 98195

INTRODUCTION

Protein modifications by phosphorylation are ubiquitous in nature and are often important factors in biomolecular functions such as synaptic vesicle transport, cell cycle progression and signal transduction. Phosphorylation may also play a role in maintaining the structural integrity of the phosphoproteins of *Paramyxoviridae*. Viruses belonging to this family include human parainfluenza viruses, mumps, measles, canine distemper and the Sendai virus. The amino acid sequence of the P protein of the Sendai virus has been deduced from the nucleotide sequence and is rich in serine and threonine residues (~25%), providing ample sites for phosphorylation [1]. The purpose of the present work is to determine the phosphorylation sites on the P protein of the Sendai virus using a combined approach of quadrupole ion trap (ITMS) and time-of-flight (TOF) mass spectrometry. A modified quadrupole ion trap, capable of high resolution and resonant excitation/ejection, provides sequence information for the determination of peptide structure. Mixtures of species with a wide range of *m/z* are analyzed by matrix-assisted laser desorption (MALD) TOF mass spectrometry. The combination of these instruments provides a strong methodology for the investigation of biological problems.

APPARATUS

Quadrupole Ion Trap: Components from an ITMS and TSQ70 (Finnigan MAT) were used in the construction of an instrument employing a quadrupole ion trap as a mass analyzer, a 20 kV collision dynode/electron multiplier detection system and a differentially pumped vacuum housing to provide for the addition of external ionization sources [2]. The trap was filled with a mixture of 10:1 He:Ar at a nominal pressure of 1 mtorr. A supplementary rf voltage placed across the endcaps of the ion trap allows extension of the mass range by resonant ejection of the ions and collision-induced dissociation by resonant excitation and collisions with the He bath gas. A MALD source consisting of a nitrogen laser coupled to an optical fiber was interfaced to the mass spectrometer [2]. Sample was applied to a probe tip then the position of the probe with respect to the fiber was optimized.

Time-of-Flight: A Lasermat (Finnigan MAT) linear time of flight mass spectrometer was employed to supplement information obtained on the quadrupole ion trap. Light from a laser is focused through a rotating stage onto a plate containing the sample. Ions are accelerated by a 20 kV grid then drift through a field-free region and are detected by a 20 kV collision dynode/electron multiplier detection system [3].

SAMPLE PREPARATION

~ 250 pmol of sample was subjected to S-carboxymethylation and proteolytic digestion with trypsin. An aliquot of the digested protein was separated with an ABI 140A reverse phase HPLC equipped with a 2.1 mm x 3 cm C_{18} packed capillary column using a 75 minute gradient of 0 - 55% solvent B (80% acetonitrile/20% 0.1% TFA). Fractions of the eluent were collected and analyzed by MALD - ITMS and MALD - TOF mass spectrometry. The matrix used was a super-saturated solution of α–Cyano-4-hydroxycinnamic acid.

RESULTS AND DISCUSSION

Peptide masses representing 55% of the amino acid sequence of the P protein of Sendai virus have been observed. Approximately 0.1 mtorr Ar was added to the bath gas, allowing some fragmentation to occur during ion injection. Figure 1 illustrates the identification of predicted fragment ions corresponding to *m/z* 2909, confirming the structure of this peptide. Preliminary data indicates the presence of one phosphopeptide, residues 255-282. The mass spectrum is shown in Figure 2 [a) MALD-ITMS and b) MALD-TOF]. The molecular ion was observed at *m/z* 2912 and the phosphorylated moiety (indicated by an asterisk) at *m/z* 2993. The signal of the phosphorylated peptide on the ion trap is reduced by a factor of ~15 compared with that obtained on the TOF. The peak at ~18-19 below the ion at *m/z* 2912 may be loss of water from *m/z* 2912 and/or loss of HPO_4 from *m/z* 2993. Loss of phosphoric acid from the phosphorylated peptide due to energetic injection conditions in the ion trap may explain the reduced signal intensity.

CONCLUSIONS

A modified quadrupole ion trap was employed in conjunction with a TOF mass spectrometer to determine the sites of post-translational modification in the amino acid sequence of the P protein of Sendai virus. Peptide masses representing 55% of the protein sequence have been observed. Preliminary data reported here indicates the presence of one phosphorylation site in residues 255-282. This peptide contains four serines, thus further analysis is required to find the position of the phosphorylated amino acid.

Investigation of Saccharide Anion Fragmentation using Fourier Transform Mass Spectrometry and Semiempirical Calculations (AM1)

James A. Carroll and Carlito B. Lebrilla
Department of Chemistry, University of California
Davis, CA 95616 USA

There is current interest in developing reliable methods for saccharide analysis using mass spectrometry. Several research groups have used fast atom bombardment (FAB) for saccharide ionization, and this has proven to be a powerful technique for their analysis. An area in which significant progress has been made is in the discrimination of the five possible linkage types present between adjacent monosaccharide units in an oligomer, i.e. a 1→4 type linkage versus a 1→6 type linkage. It has been shown that high energy collisionally activated dissociation (CAD) of saccharide anions is useful for distinguishing linkage types using sector mass spectrometers.[1,2] Our results have shown that the external source Fourier transform instrument is useful for saccharide analysis. In the negative ion mode, di- and trisaccharide linkage isomers can be distinguished in a single-step analysis, without the need for CAD.[3] The negative ion spectra of two trisaccharide linkage isomers, isomaltotriose (glcα[1→6]glcα[1→6]glc) and panose (glcα[1→6]glcα[1→4]glc) are shown in figure 1. The two spectra are easily distinguishable due to the different linkages present in the molecules.

We are currently investigating the mechanism of saccharide fragmentation reactions using model oligosaccharides and isotope labeling experiments. It has been proposed that cross-ring fragmentation, which is necessary for linkage discrimination, occurs via a retro-aldol mechanism initiated by ring-opening.[4] Evidence for this is that non reducing saccharides, in which ring-opening cannot occur, show no ring cleavage from the reducing ring. Once the ring has opened, a hydroxyl group beta to the aldehyde can initiate the retro-aldol reaction, leading to the loss of a neutral fragment. The size of the neutral lost depends on the position of the glycosidic linkage between the two saccharide monomers. All of the possible linkage types have different characteristic neutral losses. Analysis of a ^{13}C-lactose compound verifies that it is the anomeric carbon that is lost in the ring fragmentation of lactose, which supports this mechanism.

Using β-glucose as a model, the relative stabilities of the possible intermediate and transition state structures were determined using semi-empirical calculations (AM1).[5] The heat of formation of the fully optimized structure of deprotonated glucose was found to be -309.6 kcal. The barrier to ring opening was determined by increasing the C-O bond distance, as indicated in figure 2, incrementally, and fully optimizing every other parameter at each increment. The gradient was then calculated, and the transition state verified using a force calculation. The barrier can therefore be calculated as 14.8 kcal. The same method was used to calculate the barrier for loss of the neutral as 18.6 kcal. The results are summarized in figure 2.

FACTORS WHICH AFFECT THE ACCURACY OF MASS MEASUREMENT OBTAINED WITH THE QUADRUPOLE ION TRAP MASS SPECTROMETER

J D Williams, K A. Cox, C.D. Cleven, R G. Cooks
Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393

Recently, a peak matching technique has been developed to calibrate higher-resolution mass spectra and tandem mass spectra obtained with a quadrupole ion trap mass spectrometer (ITMS).[1] This technique allows both calibrant and analyte ions of differing masses to be brought to the identical point in the stability diagram. Typically, the accuracy of mass measurement is $\leq \pm 0$ 008%, when this method is performed with internal calibration. The goal of these studies was to further determine the underlying factors which affect mass measurement accuracy when higher-resolution mass spectra are acquired with the quadrupole ion trap

All spectra were recorded using a digital storage oscilloscope (Tektronix TDS 540) to monitor the signal produced by the pre-amplifier in the ITMS electronics. The first parameter studied was the change in the ejection time (i e. mass shift) of $Cs_3I_2^+$ (m/z 912.3) and $Cs_3Br_2^+$ (m/z 768 4, 770 4, 772.4, 774.4) ions as a function of ionization time when they were resonantly ejected from the trap. The scan rate was slowed to 1,100 and 628 Da/s, respectively, by using the offset-DAC method [2] Figure 1 shows that the ejection of the isotopes of $Cs_3Br_2^+$ was delayed with increasing ionization time However, this delay varied for each isotopic species. These independent shifts are caused by space-charging of the trap.[2] In the mass-selective instability scan, ions of increasing mass are sequentially ejected from the trap. Thus, space-charging is reduced for ions of higher mass since fewer ions are present when they are ejected from the trap. A reverse RF resonance ejection scan (i e decreasing the amplitude of the RF voltage for ion ejection) was done to invert the order of ion ejection Figure 2 shows the results recorded for this experiment. Mass resolution was much poorer for the reverse scan experiment The cause for this loss in resolution is unclear, but it is suspected that the higher-order field components in the trapping field may be responsible for this effect.[3] Variations in the ejection time of all the isotopes (i.e. mass shifts) in this experiment were small until the ionization time was increased above 300 ms.

In a another set of experiments, it was demonstrated that space-charging affects the ejection time of specific isotopic peaks from one scan to the next Figure 3 shows that the ejection time for m/z 770.4, shifted from scan to scan, while the signal that represented m/z 772 4 remained fixed when the forward scan rate was 103 Da/s and the ionization time was 120 ms When the ionization time (i e the number of trapped ions) was reduced, this shift in peak position was minimized

Figure 4 shows the results obtained when the ionization time was held constant and the pressure of the helium buffer gas was varied These results show that the position of the peaks shifted, most likely due to the increased number of ions that were trapped during the injection period. Mass resolution also decreased as the pressure of the buffer gas was increased.

These studies show that the ionic environment plays an important role in determing how accurately masses are measured with the quadrupole ion trap mass spectrometer The accuracy of mass measurement is improved when internal calibration is performed since the trapping conditions are the same for both analyte and calibrant ions. Reduction of ion-ion interactions along with the use of internal calibrants should allow the accuracy of mass measurement obtained with the quadrupole ion trap to be improved further.

Uni-Directional Ion Ejection in Ion Trap

*Edward Marquette & * Mingda Wang*
Varian Chromatography Systems, 2700 Mitchell Dr., Walnut Creek, CA 94598

In current ion trap mass spectrometry, the symmetry of the electric field causes ions to be ejected towards both end caps so that only half of the ions are collected by the electron multiplier. Since the maximum number of ions stored in an ion trap without degrading mass resolution is limited, the detection limit is reduced by not using the other half of the ions. Franzen [1] showed in his trajectory simulation that ions could exit from one end cap by adding a hexapole term, which was achieved by changing the shape of the trap electrodes.

We have developed a novel and practical unidirectional ion ejection method without any geometric modification of the trap electrodes. In the method, **an RF (not DC) dipole and/or monopole field**, which has the same frequency as that of the trapping field, is applied to the two end caps. The superimposed dipole field shifts the ion packet towards one of the end caps (see Figure 1) and forces ions to exit preferably towards that end cap. This is achieved by minor electronic circuit modifications of the Varian Saturn II GC/MS mass spectrometer. Since it does not rely on the non-linear resonance ejection, this new method places **no constraints on the axial modulation frequency**. For example, in our experiments, the standard 485 KHz was used as the axial modulation frequency. By contrast, the method of reference [1] requires the axial modulation frequency to be 1/3 of the trapping field frequency - the non linear resonance frequency as reported in reference [1]. Figure 2 shows the PFTBA spectra acquired with/without superimposed rf dipole field. The ion signal is doubled when an appropriate dipole field is applied. A computer simulation with the SIMION program also confirms that with a 3% of dipole field, the ratio of ion exiting two end caps is about 4 to 1. With our new approach to ion ejection, **the non-linear field can be switched on and off and the exit direction of the ions is changeable**.

In an ion trap, negative and positive ions are able to be confined simultaneously. With our new method, negative and positive ions are forced to exit in the opposite directions due to their opposite electric polarity. Therefore, **negative and positive ions may be detected simultaneously and separately** by this new method.

A new method for the generation of ions has been developed for use with FT/ICR mass spectrometry. Low-mass (high ion cyclotron frequency) ions may be excited to high kinetic energy in the form of projectiles to ionize and fragment neutrals species in an ICR ion trap [1,2]. Projectile ions (e.g. H_2O^+, N_2^+, Al^+) are formed inside the trap by standard ionization methods (e.g. electron impact, laser desorption) and are excited to large ion cyclotron orbital radius. High-energy impact of the ion with neutrals in the trap serves to ionize the neutrals, after which standard FT/ICR excitation/detection is employed. Because the projectile ions are themselves trapped within the ICR trap, we denote this MS/MS procedure as *Internal Ion Impact Ionization (IIII, or I^4)*. The primary motivation for these experiments is the availability of high collision energy in the center-of-mass frame, leading to considerable fragmentation of the neutral species.

The first experimental applications of this technique are shown. Figure 1 shows one such demonstration: ions from both N_2 and perfluorotributylamine (PFTBA) are generated by EI in an ICR trap (top); all ions with ion cyclotron frequencies below that of N_2^+ are ejected from the trap (middle); the remaining N_2^+ ions are then excited to larger ICR radius to serve as projectiles for ion impact ionization with neutral PFTBA (bottom). Figure 2 is a plot of FT/ICR magnitude-mode signal peak area as a function of duration of excitation of N_2^+ projectiles; the signal for PFTBA fragment ions clearly increases with the duration of resonant excitation of the projectile ion until the projectiles gain sufficient kinetic energy to be ejected from the trap. Ionization is not achieved merely by menas of thermal gas-phase reactions between N_2^+ and PFTBA, as evidenced by the absence of PFTBA fragment ions even after several tens of milliseconds in the absence of excitation of projectile ion cyclotron motion. Ionization is therefore achieved only by impact of projectile ions on neutrals. Ion impact ionization is effective even with off-resonance cyclotron excitation of the projectile ions. We have also produced ion impact ionization with N_2^+ projectiles onto acetophenone, as well as with other projectiles formed by electron impact (e.g. H_2O^+).

Finally, ions formed by laser desorption may also be employed as projectiles. For example, Al^+ generated by laser desorption from aluminum foil for ion impact ionization of acetophenone produces acetophenone fragment ions as well as $Al(acetophenone)_n^+$ (n = 1,2) ions. Off-resonance excitation of the Al^+ projectile ions seems to be particularly effective in producing acetophenone fragment ions. Work supported by NSF (CHE-9021058) and The Ohio State University.

Mass-selective Ion Accumulation in the Ion Trap: Ion Injection using Filtered-Noise Fields

Keiji G. Asano, Douglas E. Goeringer, Scott A. McLuckey
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6365

Don Hoekman, Teledyne MEC, Mountain View, CA 94039

The quadrupole ion trap has become a very versatile analytical instrument due in part to its adaptability to various ionization methods as well as its sensitivity and tandem mass spectrometry capabilities. Another characteristic of the ion trap that can be exploited for chemical analysis is the ability to accumulate ions. Specifically, the sample dynamic range can be extended beyond the working range of stored ion number densities by controlling the duration of ion formation or introduction. This method, which allows accumulation times to be maximized for low sample concentrations and limited at high sample concentrations, is most effective in systems such as GC/MS where the analyte ions are the most abundant species in the mass spectrum. However, the degree of dynamic range enhancement is minimal when analyte ions comprise only a small fraction of the total ion signal, the sample dynamic range then being limited by the matrix ion number density. This is the case for our instrument, a Finnigan-MAT ion trap mass spectrometer (ITMS) modified with an atmospheric sampling glow discharge ionization (ASGDI) source, which is used for analysis of trace organics in air. Nevertheless, even in such cases further improvements can be realized if ion accumulation is performed in a selective manner. One such method is a wideband resonance excitation technique using filtered-noise field (FNF) technology recently developed by Teledyne-Hitachi.

In the FNF, a signal having evenly spaced frequency components (250, 500, or 1000 Hz) and spanning the secular frequency spectrum (10-500 kHz) for the entire ion trap mass/charge range is digitally synthesized by the Teledyne-Hitachi HST-1000 module. Subsequent digital processing allows the signal to be notch-filtered to effect mass-selective ion accumulation. In addition to mass-selective accumulation, mass selective ion isolation (single m/z, multiple discrete m/z values, continuous m/z range, and discontinuous m/z ranges), selected reagent CI, and tandem mass spectrometry (ThP 106) are possible with the FNF. This paper reports on our experiments using the FNF during the ion injection process. The mass spectra were taken with a 1 s injection period with trinitrotoluene (TNT) and sulfur as our analyte. The mass spectrum in Figure 1 was taken without applying the FNF and shows very little signal from the molecular anion (m/z 227) of TNT and from sulfur clusters at m/z 64, 96, and 128. Figure 2 shows the same mass spectrum with the FNF signal applied during ion injection. The signal for the molecular anion of TNT is approximately ten times greater. Figure 3 is a magnified view of Figure 1 in the mass/charge range where sulfur cluster ions should appear. The S_4^- ion (m/z 128) can be identified, but ions from S_2^- (m/z 64) and S_3^- (m/z 96) are obscured by the matrix ions. Figure 4 shows the same region when the FNF signal is applied and demonstrates both multiple, discrete ion accumulation as well as improved signal intensity.

SELF_CI IN THE ION TRAP

Krishnaswany Nagarajan1, Henry M. Fales2, and Lewis K. Pannell3,
1. Armed Forces Institute of Pathology, Washington, DC 20306, 2. NHLBI, NIH, and 3. NIDDK, NIH, Bethesda, MD 20892

The many advanteges of the ion trap mass (high mass range, high resolution, msn capability, sensitivity, etc.) are not bought without certain concurrent disadvantages including susceptibility to space charge effects, ion-molecule reactions ("self-CI"), and difficult mass assignment at high mass. The first problem is overcome with the Finnigan automatic electron gating system ("AGC") while the second requires careful attention to limit the amount of sample admitted to the trap, In practice this is not always convenient, and when a second analyte is present in overwhelming amounts, not always possible.

We have examined self-CI in the trap with a variety of compounds including trimethylsilyl derivatibes of short chain acids of the Krebs cycle, aliphatic and cycloaliphatic amines, esters and various halogenated species to determine the relative concentrations required to cause self-CI. The types of ion-molecule reactions that result are themselves interesting (e.g., M+73 an M+147 in TMS derivatives) and, as in classical CI, occasionally reveal the molecular weight when a molecular ion is not present. In addition, use of the tickling facility provided with the ITMD (Finnigan) version of the ion trap allows selective removal of the adducting ion.

In the accompanying spectra we show the effects of lactic acid trimethylsilyl ether under heavily overloaded conditions compared with the normal spectrum. Space charging has diminished the intensities of the normal ions below 219 and the ions at 73 (TMS) and 147 (TMSIODMS) have adducted to the normal molecule of mass 234. Interestingly, the most intense ion at m/z 117 (COOTMSI) does not adduct under these conditions probably because it is a weaker Lewis acid due to the charge being distributed into the carbonyl. Within the small class of compound types examined here, we were not able to predict the type of reaction that would occur. Thus simple dimerization was seen with bromonaphthalene, M+(M-1) with others, and 2M+H in some cases. The only clear correlation found is that for self-CI to be prominant the molecule needed to be a good Lewis base since, by definition, the cation is a good Lewis acid.

COMBINED RF AND MAGNETIC TRAPPING IN A HIGH PRESSURE FOURIER TRANSFORM MASS SPECTROMETER

C. L. Hendrickson, E. G. Schmidt and D. A. Laude, Jr.; Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712

Fourier transform ion cyclotron resonance mass spectrometry (FTICR) traditionally employs collinear static electric and magnetic fields for the purpose of ion trapping. The magnetic field confines ions in the plane perpendicular to the magnetic field axis while the electric field traps the ions along this axis (normally referred to as the z-axis). This type of trapping has proven adequate for successful operation at relatively low pressure. However, the performance of the instrument deteriorates as the cell pressure is increased. This is due to the radial electric field associated with the static z-axis electric field which, in conjunction with collisions, causes rapid ion loss through expansion of their magnetron orbit. Situations in which high pressure is desirable include ion-molecule reactions, ion stabilization and ion cooling. Therefore, methods must be developed for high pressure ion trapping and relaxation.

One high pressure trapping technique which has shown great promise is the "RF-only" event currently employed by Gross and coworkers [1]. This method involves the use of high voltage RF trapping, similar to that of a quadrupole ion trap, during any event which exposes the trapped-ion cell to high pressure. Traps involving both a static magnetic field and an oscillating electric field were developed in the 1950's [2] and are known in the physics community as "combined traps". These traps, which have been investigated for use in laser and microwave spectroscopy, collisional studies and mass determination, have been shown to operate successfully at high pressure [3]. However, relatively little has been done to exploit the analytical utility of such a trap (for one example, see [4]). In this work, efforts to investigate and optimize this method of ion confinement are presented. An FTICR spectrometer which has been designed and constructed specifically for high pressure studies is described. FTICR spectra are presented comparing conventional static electric field trapping, RF electric field trapping and a combination of static and RF electric fields. Evidence for high pressure ion cooling is presented as well as an RF optimization study.

All experiments were performed on an electromagnet system consisting of a 4.1 cm cubic cell mounted within an ultra-high vacuum chamber which is pumped by a 1500 l/s diffusion pump to a base pressure in the mid 10^{-8} torr range. The cell electrodes are made of 80% transmissive hexagonal mesh to maximize conductance. Ionization is accomplished using a laboratory-built electron gun which is mounted on the cell flange. The vacuum chamber is mounted in 90 mm gap between the pole faces of a 1 Tesla electromagnet. The cell flange is equipped with two MHV electrical feedthroughs which allow up to 5 kV to be applied to the trap electrodes. Two leak valves and one set of pulse valves allow for the introduction of analytes and collision gases in both static and pulsed modes. Instrument control and data collection, which are shown in Figure 1, were accomplished using an Odyssey data station which was equipped with an Extended Trap Control Module*. The module allows RF voltage to be gated onto the trap plates from either an internal or an external source. In the internal mode the RF signal is taken from the cell controller and amplified by the module to a maximum of 80 V_{p-p}.

In preliminary experiments with the high pressure trap evidence was obtained which indicates that RF confinement can improve high pressure trapping performance. In these experiments naphthalene was used as the analyte of interest and helium served as the buffer gas. Helium was chosen in order to minimize ion scattering (and potential loss) through collisions with the buffer gas. Because of its high ionization potential it is also easy to exclusively ionize the analyte in the presence of this gas. To collect the data, naphthalene was leaked into the vacuum chamber at a pressure of 2 x 10^{-6} torr and ionized by a 12 eV, 500 nA, 8 ms electron beam

event. Helium was admitted through a second leak valve at a steady pressure of 2 x 10^{-5} torr (readings uncorrected). A 400 ms delay was inserted before excitation as a stringent test of trapping efficiency. Despite the high pressure a clean signal of adequate resolution is obtained.

Successful RF trapping generated spectra similar to the RF-off experiment suggesting similar trapping efficiency and cooling for the two trapping methods. The RF amplitude and frequency values were chosen after an optimization experiment using the previously stated conditions. Since 80 V is the upper limit of the internal RF, it is reasonable to think that higher voltages will improve performance.

The result of a third type of trapping were obtained. Here the combination of a 3 V DC potential and an 80 Vp-p, 600 kHz RF potential is applied during the 400 ms delay. This spectrum shows a significant increase in signal abundance, implying an improvement (~ a factor of three) in trapping efficiency and ion cooling.

As further evidence of ion retention and cooling, excite profiles were acquired in which ions are excited to a moderate cell radius followed by a cooling delay and subsequent excite to detect. The results of RF trapping are shown in Figure 2. As can be seen in the figure, the optimum cooling delay was 600 ms (as opposed to 50 ms for DC trapping) for these experimental conditions. Although the RF cooling is superior at long delays it appears to be less effective for shorter times. No explanation can be given for this anomaly at this time. However, these results are preliminary. In the future the experiment will be repeated while varying the first excite amplitude. This will reveal information about the efficiency of the cooling at different radii in the cell.

ELECTRON BEAM DEPRESSION AS AN ION TRAP IN FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY

C.L. Hendrickson, F. Hadjarab and D. A. Laude, Jr., Department of CHemistry and Biochemistry, University of Texas at Austin, Austin ,TX, 78712

Electron beams are commonly used in Fourier transform ion cyclotron resonance (FTICR) experiments as ionization sources. Since the beam is terminated prior to any ion manipulation, excitation or detection, its affect on ion motion is rarely considered. It is known, however, that the space charge of the electron beam creates a potential well and that ions can be trapped for a relatively long period of time in such a well. The electron beam has been used extensively to ionize, trap and excite positive ions in order to measure a variety of properties such as ioization cross-sections and potentials. Recent emphasis has been placed on spectroscopic studies of highly-charged ions in instruments known as electron beam ion traps (EBIT). EBIT experiments are performed using a high magnetic field for radial electron beam compression and a static electric field for axial confinement of any generated ions. Since these conditions are identical to those employed in a typical FTICR experiment, it seems reasonable that ions formed by electron ionization may be trapped in the electron beam until its termination. In this work electron beam ion trapping is demonstrated to occur during the FTICR experiment and a model describing the confinement process is presented. Conditions for ion trapping and escape are demonstrated through the use of resistive-wall destabilization of the magnetron motion of ions in the FTICR cell. Plots of ion retention time versus ion number are consistent with a model in which ions are initially trapped in the electron beam but eventually "fill" the cell and escape into a magnetron orbit. The model predicts a potential well dependent on electron beam current, energy and dimension which is capable of holding a finite number of low energy ions. The model is compared to experimental results in both a qualitative and quantitative manner and good agreement is found. Several analytical applications of the technique are discussed.

An electron beam of energy V_e, current I_e, and diameter a will produce a radial potential depression V_t given by equation 1

$$V_t = \frac{I_e}{4\pi\varepsilon_0 V_e^{1/2}(2\eta)^{1/2}}$$

where η is the electron charge-to-mass ratio and ε_0 is the permittivity of vacuum. If the parameters used in the majority of this work (70 eV, 50μA) are substituted into equation 1, a potential well of about 0.1 V is obtained. This well depth is capable of trapping a substantial number of thermal energy ions. A graphical depiction of the well is shown in Figure 1 for a 70 eV, 50μA, 1 mm diameter beam.

Consider a case in which ions are formed by an electron beam away from the central axis of an FTICR trap. If the ions are not influenced by the electron beam they will start on a magnetron orbit as soon as they are formed and an annulus of ions will result. Therefore, only a small image current will be detected (that which is due to any asymmetry in the annulus). . However, if the ions are trapped in the beam they will be precluded from starting their magnetron orbit until after the beam is terminated. Now the ions are released in a coherent cloud and the image current in the detection circuitry is much greater. This causes resistive damping to occur much more quickly and the ion retention time to decrease. As ionization continues the well will "fill up" and ions will begin to leak into their magnetron orbit. This leakage will degrade the coherence of the cloud, thereby reducing image current and increasing retention time. Eventually, however, there are so many ions in the annulus that the density outside the well is greater than inside the well. Now the ions opposite the well are the source of a monopole which grows with ion number and brings the retention time to a minimum.

The results of experiments in which on- and off-axis electron ionization and subsequent detection of coherent magnetron motion were performed were presented. In Figure 1 ion number was altered by varying the electron beam event time. The on-axis data shows the expected exponential decay in retention time as ion number is increased. The off-axis data reflects the more interesting result expected from the previous discussion. The curve shows an initially rapid decrease in retention time due to efficient ion trapping and subsequent coherence of the magnetron motion. As ion number is increased the well "fills up" and ions leak into their magnetron orbit. This destroys the coherence of the motion and retention time increases. Eventually the retention time reaches a minimum.

Further evidence for electron beam ion trapping came in the form of ion transfer data from two similar dual cell experiments. The results are shown in Figure 2. In the "beam off" experiment ions were formed by electron ionization along the z-axis on the source side of the dual cell with 2 V trapping potentials on the trap plates and conductance limit. After termination of the electron beam the conductance limit was grounded during a variable ion transfer period. After transfer the conductance limit was raised and excitation and detection occurred in the analyzer cell. The data reflects rapid signal loss as the ions are forced to pass between cells more times. A logical explanation for this is that immediately after ionization the ions begin their magnetron orbit which, if not perfectly aligned with the conductance limit, takes many of them on a trajectory that strikes the conductance limit instead of passing through. It is obvious upon inspection of the "beam on" data that this does not occur during this experiment. This experiment differs from the "beam off" experiment in that the conductance limit is grounded throughout the ionization period which continues to occur dunng the transfer period. This data shows that ion abundance grows linearly with time which implies that no ion loss occurs during ion passage through the conductance limit. This observation can be explained by noting that the ions can be trapped in the electron beam. Therefore, if the electrons make it through the conductance limit, the ions will too.

Ion/Molecule Reactions and Electron Detachment of O_2^- in a Quadrupole Ion Trap Mass Spectrometer

J. Murrell†, M.L.Langford†, J.F.J.Todd† and P.Watts‡
†The Chemical Laboratory, University of Kent, Canterbury, Kent, CT2 7NH, U.K.; ‡Chemical and Biological Defence Establishment, Porton Down, Salisbury, Wiltshire, SP4 0JQ, U.K.

Molecular oxygen anions have been the focus of much research as they play an important part in negative ion chemical ionisation, in ion mobility spectrometry and the negative ion processes of the atmosphere. To date there has been relatively little work published on the behaviour of O_2^- ions in the ion trap mass spectrometer, and this presentation reports on preliminary results on the trapped ion chemistry of this species.

The oxygen anions were created in an external DC glow discharge in 'zero grade' air and injected into the quadrupole ion trap (a modified Finnigan ITMS™); following a variable reaction period (utilising the method of 'dynamically programmed scans') the ions were analysed by ramping the amplitude of the RF drive potential. Typically the discharge chamber was maintained at 800 mTorr and the glow discharge current was *ca.* 7.0 mA; the helium buffer gas pressure in the trap was *ca.* 10^{-4} Torr.

There are essentially four major collisional means of increasing the internal energy of an ion in a quadrupole ion trap. These are by altering the q_z value at which the ion is stored, by applying an on-resonant tickle voltage, by boundary excitation and by varying the pressure and the composition of the buffer gas. All these methods can be used to excite ions to either dissociate or to react with a substrate where there is a need to overcome activation energies in order to form products.

The reactions were performed by setting the initial conditions and then incrementing the reaction time. The four types of experiment which were investigated were: (1) holding the O_2^- at constant q_z over a range of values; (2) holding the O_2^- at q_z values of 0.3 or 0.5 with a small on-resonant tickle voltage applied; (3) holding the O_2^- at a q_z value of 0.3 and setting various values of a_z; (4) the effect of removing the helium buffer gas from experiment 1.

For the Type (1) experiment storing O_2^- at a q_z value of 0.4 produces the plot shown in Figure 1. The only observed product of this reaction is NO_2^- which is thought to be formed by the charge-exchange reaction:

$$O_2^- + NO_2 \rightarrow O_2 + NO_2^-$$

involving NO_2 molecules formed in the discharge. The remaining loss of O_2^- is considered to be by electron detachment as the electron affinity of O_2^- is low (0.44eV). The logarithmic plots of O_2^- ion intensity *versus* time show excellent linearity, and Figure 2 shows how the plots depend upon the value of q_z during storage. Similar experiments in which either a low amplitude on-resonant tickle or in which the (a_z,q_z) value for the ion was held near to a stability boundary gave similar graphs. On the assumption that similar rate coefficients for O_2^- ion intensity reflect similar ion kinetic energies it is possible to superimpose the data on the same plot, and thus draw conclusions about the comparable degrees of ion excitation under different conditions (Figure 3). With the removal of helium from the trap and storing the ions at a q_z of 0.3 there is a greater rate of loss of O_2^- and less formation of NO_2. This demonstrates the cooling effect of the helium, indicating a possible competition between electron detachment from the O_2^- and electron transfer to NO_2.

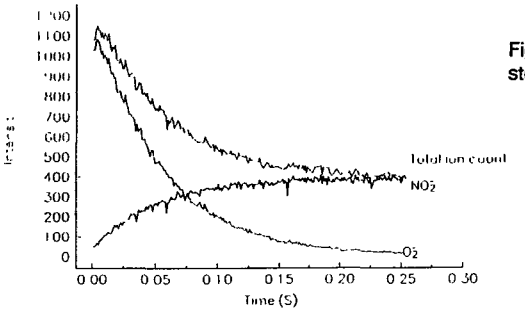

Figure 1: Reactions of O_2^- stored at q_z = 0.4

Negative-ion fragmentation pathways of four isomers of dinitrotoluene (DNT)

M L Langford and J F J Todd

The Chemical Laboratory, University of Kent, Canterbury, Kent CT6 7NH, UK.

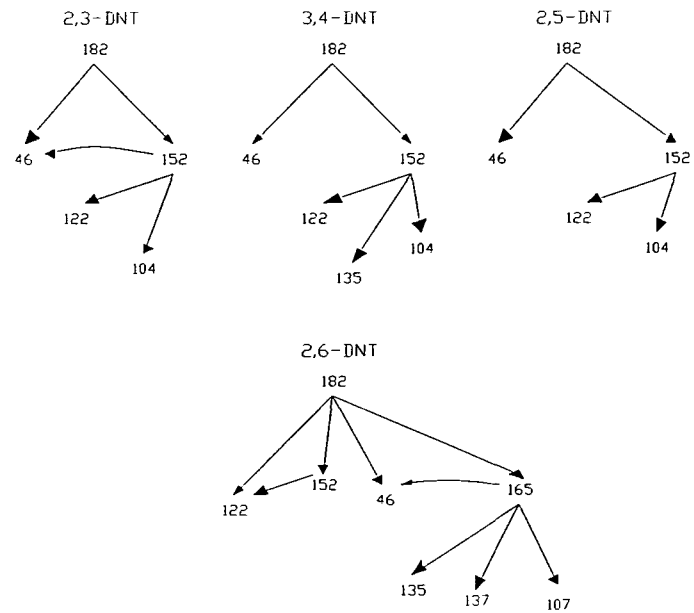
The present study examines the mass spectra and fragmentation routes generated by the dissociation of negatively charged isomers of DNT.

All experiments were carried out on a Finnigan MAT. Ion Trap Mass Spectrometer (ITMS) coupled to an Air Sampling Glow Discharge Ionisation (ASGDI) source. A few grains of either 2,3-, 3,4-, 2,5- or 2,6-DNT were placed inside an unheated sampling chamber and air was drawn over the sample into the glow disharge ionisation source. Collision induced dissociation reactions between energetic electrons and sample molecules gives rise to the production of neutral fragments. These fragments, and sample molecules, may form negative ions by the capture of low energy electrons. Negative ions produced in the glow discharge were directed into a quadrupole ion trap by a series of lenses. The application and manipulation of the RF and DC voltages applied to the ion trap is controlled by the construction of a scan function. This was defined using ITMS software to enable MS/MS/MS experiments to be performed in the ion trap enabling the examination of fragmentation routes down to the 3rd generation.

The negative-ion mass spectra of 2,5- and 2,3-DNT are very similar with base peaks at m/z 182, a strong peak at m/z 46, weak peaks at m/z 152 and 104 and a vanishingly small peak at 122 u. The mass spectrum generated by 3,4-DNT produced a weaker mass spectrum with additional peaks at m/z 135 and 137. The negative-ion mass spectrum of 2,6-DNT shows a base peak at m/z 182 with a

strong peak at m/z 46 and very weak peaks at m/z 122, 152 and 165. The negative-ion fragmentation pathways of 2,3-, 3,4-, 2,5- and 2,6-DNT observed in this investigation are shown the Figure.

It can be seen that the isomers 2,3-, and 2,5-DNT have straightforward fragmentation routes producing four daughter/granddaughter ions. The fragmentation pathways of 3,4-DNT are similar but with an additional fragment with m/z 135. The fragmentation pathways of 2,6-DNT are more complex with an additional fragmentation route initiated by the loss of OH. This additional fragmentation route may be due to the proximity of the two *ortho* NO_2 groups to the methyl group which increases the probability of a rearrangement leading to the loss of OH and the formation of the fragment seen at m/z 165.



Extended Mass-to-Charge Range Operation of a Non-Linear Quadrupole Ion Trap

Kenneth Morand[1], Michael Schubert[2], Jochen Franzen[2] and Matthias Mann[1]
[1]Protein and Peptide Group, European Molecular Biology Laboratory, Heidelberg, Germany
[2]Bruker-Franzen Analytik GmbH, Fahrenheitstrasse 4, 2800 Bremen 33, Germany

Following the introduction of the Quadrupole Ion Trap Mass Spectrometer in the early 1980's there have been numerous advances. High mass, high resolution and external introduction of ions in particular have enhanced the applicability of the quadrupole ion trap to the analysis of biological compounds, paving the way for the introduction of the ion trap into the molecular biology laboratory.

Unfortunately, while mass spectrometry in general has made great advances in biological analysis and such instruments are now routine in these laboratories, the quadrupole ion trap has seen only limited use in this areas. Therefore, it is a goal of this research group to begin a program for implementing the ion trap and many of the developed methods into mainstream molecular biology analysis, emphasizing practical problem solving.

Figure 1 depicts the cesium ion desorption mass spectrum for the $[M+H]^+$ ion of substance P (Mr 1347.6). The mass spectrum was acquired for 5 pmole of the peptide mixed with 1 μL of the matrix solution on the tip of the direct-insertion probe. Ions were injected into the ion trap for 2 msec in the presence of 1 mTorr of helium bath gas. The scan rate was reduced by a factor of 16X with the results of a measured resolution of > 3000 (M/ΔM, FWHM).

Figure 2 shows the mass spectrum for the $[M+H]^+$ ion of substance P in the presence of 0.5 mTorr of laboratory air. A comparison of this data with the spectrum in Figure 2 reveals some loss of resolution (M/ΔM > 2000, FWHM). However, the loss is offset by an increase in the signal intensity of approximately 25% due to increased trapping efficiency [6]. In addition, the use of laboratory air as a buffer is beneficial for both increased energy deposition during MS/MS experiments[6] and when the ion trap is coupled with electrospray ionization.

Non-linear traps are characterized by a sharp octopole resonance, therefore, analysis utilizing this resonance point is associated with high mass accuracy. For this reason, extension of the m/z range was effected by a reduction of the RF drive frequency[5], instead of the standard method of resonance ejection, and allowed us to maintain mass analysis with the strong octopole resonance. Mass accuracy data is presented in Table 2 for the mass measurements of five peptides covering a period of six consecutive days.

Previous work in which the RF drive frequency was reduced to effect an increase in the mass range, undesirable effects were observed that included poor resolution even when the scan rate was significantly reduced. The results presented in this work suggest that high resolution may be maintained even at a significantly reduced drive frequency.

Pulse Sequences for the Study of Simultaneously Trapped Positive and Negative Ions with ICR-Spectrometry

M.Paul, R. Malek, Y. Wang* and K.P. Wanczek,
Inorganic Chemistry, Universtity Bremen, D-28 Bremen 33
*Bruker Franzen Analytik GmbH D-28 Bremen 33

The ICR-Cell constructed by Y. Wang [1] is an effective new device for the study of positive and negative ion interaction. Positive and negative ions are stored simultaneously. Storage is possible for several seconds. Even generation and storage of double positve ions together with negative ions was achieved. Quantitative data on ion abundance can be acquiered. The properties of Xe and SF_6 are studied, with focus on the ions SF_6^- , $SF_5^{+/-}$, Xe^+ and Xe^{++}.

Experiments are carried out using a CMS-47 mass spectrometer with a 7 T superconducting magnet. The system is controlled by an Aspect 3000 microcomputer, and a personal computer.

A new cell parameter control program allows changes of the trapping conditions during the experiment. By this means charge selective axial ejection and thus determination of ion polarity is possible. In Figure 1 is a a broad band spectrum of simultaneously stored positive and negative ions of Xenon and SF_6 shown. ($Xe^{++}$and Xe^+-Isotopes, SF_6^-, $SF_5^{+/-}$, SF_4^+, SF_2^+, SF^+; SF_3^+ is ejected by double resonance). Having quenched positive ions, only SF_6^- and SF_5^- remain.

High resolution spectra can be acquired where positive and negative ions of identical atomic composition are resolved (resolution for SF_5^+/ SF_5^- is >100000). Figure 2 contains a high resolution spectrum of SF_5^+ and SF_5^-.

Combination of a pulsed valve inlet system and storage mode switches (e. g. from a mode storing one charge polarity only to a mode storing both charge polarities) during experiments allows charge selektive ion generation from several neutral species and study of their interaction. Electron ejection using trapping frequency resonance is employed for some experiments. These new features allow even storage of Xe^{++} together with negative ions.

Multiparticle Simulations of Operating Modes of the Quadrupole Ion Trap Mass Spectrometer

R.K Julian, Jr., H.-P Reiser, R G Cooks, Department of Chemistry,
Purdue University, West Lafayette, IN, 47907

Small scale multi-particle simulations are used to characterize the ion motion of ensembles of ions under various kinetically excited conditions These conditions include (i) ejection via the $\beta_z = 1$ boundary, the so-called mass selective instability scan [1], (ii) resonant ejection and resonant excitation via an auxiliary (AC) field [2] The spatial and temporal relationships between ions of the same mass-to-charge ratio (m/z) under kinetically excited conditions is important because of the consequences for the mass resolution of the ejected ions. The random nature of the ion secular phase is introduced via an preliminary ionization simulation The key to mapping ion behavior is an accurate description of the motion of the ions within the ion trap under the influence of collisions, and higher order electric fields This study uses Poincaré sections to evaluate the role of buffer collisions during ion storage and resonant excitation. Higher order fields are evaluated via harmonic analysis Simulations of mass spectra collected from octopole field containing traps is also presented

The small scale simulation (ITSIM) is primarily used to visualize ion trajectories, in space as a function of time, and as phase space plots Phase space plots can be plotted directly or simplified by constructing Poincaré sections Figure 1 gives an example of three types of information available from a collection of stable ions of m/z 202 at $q_z = 0\ 4$ The top trace shows the x position, the second trace shows the z position and the third shows the total kinetic energy The fourth plot is a axial (z) phase space plot and the last is a Poincaré section of the phase space taken at the RF drive frequency of 1.1 MHz, sampled at a zero phase angle It has been observed that the mass resolution of the mass selective instability scan can be greatly improved by performing resonant ejection either near the stability limit or much below the stability limit [3] Some explanations for the difference in resolution can be observed by comparing Figures 1 and 2. In Figure 1 a single ion of m/z 202 is just brought to the instability point (q_z=0 908) by applying ~2520 V_{0-p} to the ring electrode. In the presence of a buffer gas, the motion is stabilized within the electrode structure, despite mathematical instability. The trajectory plots for the x and z directions shows that the motion is erratic. The kinetic energy plot (KE) reflects the random nature of the motion The scattered Poincaré section indicates the stable attractor has been replaced with a chaotic attractor, which indicates that ions of the same m/z value with only slightly different initial conditions will have extremely different trajectories leading to a wide range of ejection times and hence to the low mass resolution

The chaotic situation in Figure 1 is to be contrasted by the stable condition shown in Figure 2 for the resonant ejection case Here ions at a $q_z = 0\ 4$ are resonantly excited with a 2 5 V_{0-p} field at a frequency of 160.911 kHz The trajectory plot indicates that in the presence of the buffer gas the motion is being dampened, however in the z direction that dampening is being balanced by the resonant excitation signal As shown in the Poincaré section, a limit cycle is created which all ions are driven

towards. In phase space, once two trajectories fall on the same limit, they are phase locked. This limit cycle forces the ions to become a coherent ion cloud with a very narrow range of maximum amplitudes and phase shifts. As the ion absorbs energy from the auxiliary field, the limit cycle will increase in diameter until the electrode dimension is reached and the ions are ejected. If the ions are given time to adjust to changes in the RF amplitude, the limit cycle will remain elliptical. When the RF ramp is slow, ions are allowed to equilibrate and to maintain their phase coherence, resulting in the high mass resolution observed when slow RF ramps are used

We have reported the mapping of ion distributions in the axial direction of the ion trap using laser photodissociation of trapped ions.[1] These studies have shown the effects of other molecules and ions on the distribution and the effects of resonant excitation on the distribution. They provide insight into the collisional damping process and provide data from which collision frequencies (300/sec at 10^{-3} Torr) can be obtained. By phase-locking the laser probe with the supplementary AC field, we have also determined experimentally the velocity and kinetic energies of ions subjected to resonant excitation.[2] We present new data that describes ion trajectories in the radial direction. These data are obtained by measurement of photodissociation product ion yield ($C_6H_3Cl_3^{+\bullet} \rightarrow C_6H_3Cl_2^+$) as a function of the radial position of the laser beam, i.e., the laser beam enters the ion trap through the *endcap* electrode. Because the ion trap can operate at relatively high pressures, the spectroscopy of collisionally excited and collisionally relaxed ions can be studied. Fig. 1 shows the photodissociation spectra at 10^{-4} Torr He and 10^{-5} Torr He. Transitions to excited vibrational states observed in the high pressure spectrum are washed out, presumably due to the greater number of excited vibrational and rotational states at lower pressures. The radial distributions of $C_6H_3Cl_3^{+\bullet}$ at $q_r = 0.1$ and 0.3 are shown in Fig. 2. As expected, the distribution at the higher q_r is narrower because the ions reside in a deeper potential well. Fig. 3 shows that ions are collisionally relaxed in the radial direction, just as they are axially. Resonant excitation at ω_z would not be expected to perturb ion motion in the radial direction. Although these motions would be independent in an ideal trap, they could be coupled through collisions with the helium buffer gas or by higher-order fields in the ITMS. Distributions measured at 10^{-4} Torr of helium with resonant excitation are broader than those with no AC voltage applied (Fig. 4). At lower helium pressures (10^{-5} Torr), no (or less) broadening would be observed if the motion in *r* and *z* were coupled solely through collisions. These experiments suggest that higher-order fields do contribute to the coupling of motion. This effect is difficult to quantitatively assess because the product ion abundance decreases at lower pressures.

Computer Simulations of Ions in an Electrostatic Ion Guide for FT/ICR Mass Spectrometry

Michael A. May, Patrick A. Limbach, and Alan G. Marshall†

Departments of Chemistry (and Biochemistry†), The Ohio State University, 120 West 18th Avenue, Columbus, Ohio 43210

An electrostatic ion guide (EIG) consists of a conductive outer cylinder and a rigid central wire to which a dc potential difference is applied. Such an EIG can transport ions from an external glow discharge ion source through the strong magnetic field gradient of a 3T superconducting magnet, and ultimately into an ICR trap.[1] Here, we report the use of SIMION[2] to calculate initial conditions (ion mass, ion position, ion entry angle, ion kinetic energy, and EIG cylinder/wire voltage difference) under which low energy ions can enter the ion guide, traverse a strong magnetic field gradient, and exit the guide at the entrance to an ICR ion trap.

Figure 1 shows the geometry of the target, central wire, outer cylinder, and ICR trap electrodes. The nominal dimensions (in mm) of this EIG system correspond to a secondary ion FT/ICR mass spectrometer recently constructed in our laboratory.[3] Figure 3 shows the magnetic field map as a function of axial position (in both the z- and xy-directions) which was input to SIMION. Ion trajectory simulations under various initial conditions demonstate that low kinetic energy ions (1-10 eV) formed near the EIG entrance may be accelerated, transferred through the guide, and decelerated upon exit.

Figure 2 shows an ion trajectory in the xy- and xz-planes under the following initial ion conditions: m/z 1000, KE = 5 eV, entry angle = 10°, z_0 = 1012 mm, and r_0 =3 mm. For this trajectory, the wire was biased at -15 V and the cylinder at -10 V. The xy-plot shows that the ion ends up 7 mm off-axis; ergo an open-ended ICR trap would be experimentally desirable in this case.

At suitable EIG voltage difference, ions of various kinetic energy and entry angle may be efficiently captured in the guide cylinder. Figure 5, for example, shows that a 5 eV ion of m/z 1000 may enter the guide at a maximum angle of 15°–60°, depending upon the EIG voltage difference. The trajectory simulations also suggest that ion transport efficiency through the EIG depends strongly on ion initial position, velocity, mass, and entry angle. Figure 6 shows that 1000 u ions are transported through the EIG at entry angles of 10°–15° under specified conditions. Further simulations indicate that high-mass ions (of sufficient kinetic energy) should be efficiently transported through the EIG. This work was supported by NIH (GM-31683), NSF (CHE-9021058), and The Ohio State University.

Investigations in Resonance Excitation in the Quadrupole Ion Trap Mass Spectrometer

*Randall E. Pedder[†], Jodie V. Johnson[‡], and Richard A. Yost[‡].
[†]Millipore Corporation, Extrel Mass Spectrometry, Pittsburgh, PA 15238
[‡]Department of Chemistry, University of Florida, Gainesville, FL 32611

Introduction. It has been observed that the effective collision energy in a collision-induced dissociation experiment in a quadrupole ion trap increases with RF trapping potential (the Mathieu parameter q). It has been observed that for small RF trapping potentials (low parent ion q) collision-induced dissociation fragmentation efficiency is poor. March et al.[1] have observed that for a given mass at a given RF trapping potential, the fluence (i.e. the product of resonance excitation voltage and excitation time) is constant to achieve either ion ejection or some degree of collision-induced dissociation. The objective of this work is to identify the dependencies of the resonance excitation experiment on acceptance aperture and pseudopotential well depth (maximum ion kinetic energy), to assist understanding of some of these observations.

Mathematical modeling of ion trap physics was performed using the BASIC computer program Hyperion[2]. Hyperion uses a fourth-order Runge-Kutta algorithm to numerically integrate the Mathieu equation with a dipolar field perturbation term.

Estimation of Maximum Ion Kinetic Energy. The energetics of a resonance excitation experiment are dependent upon the maximum amount of kinetic energy which an ion can have and remain in a stable trajectory within the ion trap cell. The maximum kinetic energy for a given ion increases with increases in the Mathieu parameter q as shown in Figure 1. For low trapping RF voltages (low q's) ions are resonance ejected prior to collision-induced dissociation because the ion collision energy is limited. As RF voltage is increased, the range of ion collision energies increases, resulting in more energetic reaction products.

Acceptance Aperture of a Quadrupole Device. The acceptance aperture of an RF quadrupole device is defined by the superposition of a family of acceptance ellipses calculated from an ion's trajectory. That area in phase space which is common to all phases of RF is identified as the acceptance aperture. For an RF-only quadrupole device, the relative acceptance (acceptance radius divided by inscribed radius) decreases with increasing q, as shown in Figure 2.

Fluence. The fluence required for resonance ejection of m/z 134 at various values of q is shown in Figure 3. The dramatic dropoff at q>0.8 of the fluence curve is attributed to the reduction in the size of the acceptance aperture of the quadrupole ion trap with increasing q. The curve shown in Figure 4 was calculated by scaling the maximum energy curve in Figure 1 by the relative acceptance curve in Figure 2.

For resonance ejection (axial modulation), maximum resolution is predicted to coincide with the maximum of the curve of relative acceptance aperture scaled by maximum kinetic energy a function of q (coinciding with maximum fluence) (q 0.6 to 0.8).

HIGH-MASS ANALYSIS ON THE QUADRUPOLE ION TRAP MASS SPECTROMETER

J.V. Johnson, M.M. Booth, J.L. Stephenson, Jr., R.R. Vargas, and R.A. Yost
Chemistry Department, University of Florida, Gainesville, FL 32611

The Finnigan MAT ITMS was introduced with a maximum mass range of m/z 650 using the mass-selective instability scan.[1] Subsequently, in an excellent paper, Kaiser *et al.* demonstrated that **axial modulation** provides the most straightforward and efficient method to increase the mass range of the ITMS[2]. Rearrangement of the definition of the Mathieu q_z parameter shows that the maximum m/z of a quadrupole ion trap can be determined by:

$$(m/z)_{max} = \frac{-8\ e\ V}{(r_0^2 + 2z_0^2)\ \Omega^2\ q_{z,eject}}$$

where, V = RF trapping voltage, m/z = mass-to-charge ratio of ion, Ω = frequency of RF trapping voltage, r_0 = ion trap ring electrode radius, e = charge on an electron, and $q_{z,eject}$ is the q_z value where ejection of ions occurs during the RF scan. **Mass range extension** is achieved by resonantly exciting and ejecting ions during the mass-selective instability RF scan, i.e. axial modulation. By reducing the frequency of the resonance voltage applied across the endcaps, the point on the stability diagram where ions are ejected occurs at a lower $q_{z,eject}$ and the mass range is extended.

The **objectives** for this research are to (1) characterize the mass range extension capabilities of the "standard" ITMS with respect to m/z range, mass resolution and sensitivity, (2) characterize the effect of the resonant excitation voltage on ion ejection, and (3) investigate the implications of resonant excitation for CID of high-m/z ions.

Experimental. The "standard" (unmodified) Finnigan MAT ITMS electronics were utilized for axial modulation. Internal electron ionization (EI) of perfluorotri-N-butylamine (FC43) and a perfluoropolyether (UltraMark 3200F) were utilized for the characterization studies. However, the low intensities of the higher m/z Ultramark EI ions and the contamination of the ITMS by this relatively non-volatile compound precluded its use and results from it are not reported here.

Effect of mass range extension on resolution. As the $q_{z,eject}$ is lowered and the mass range extended, there is a reduction in mass resolution. For example, for the m/z 614 EI ion of FC43, the peak width at 1/2 peak maximum increases from 1 to 5 to 30 mass units with mass range extension factors of 1, 10, and 30, respectively. This is the result of two major factors: increased scan rate and reduced resolution of resonant excitation. The scan rate of the RF voltage and ion signal sampling and integration response rate and times were designed for a m/z 650 mass range and is constant at ≈5550 u/s. With mass range extension, a greater range of m/z is scanned in the same time interval thus reducing the resolution. Below a q_z = 0.2, the effective frequency bandwidth that elicits resonant excitation begins to widen and the difference in secular frequencies of adjacent m/z ions decreases with decreasing q_z, i.e. mass resolution of resonant excitation is reduced with decreasing q_z. The

combination of high resolution techniques (axial modulation at slower scan rates) in conjunction with mass range extension may compensate for the instrumental limitations. However, further characterization of the ion physics is required to overcome (if possible) the limitations of the latter.

Effect of mass range extension on sensitivity. For $q_{z,eject}$ between 0.45 and 0.908, the sensitivity remains fairly constant. However, below a $q_{z,eject}$ of 0.45, the sensitivity decreases dramatically until at $q_{z,eject}$ of 0.1, the ion signal is often less than 1/100 of that at $q_{z,eject}$ > 0.45. It was observed that the sensitivity for higher m/z ions decreased first. This behavior suggests that the lower resonant excitation frequencies may act like a DC voltage resulting in a high m/z cutoff with low $q_{z,eject}$. Although multiple or longer duration ionization events can compensate for this, further characterization is necessary in order to determine the source of this phenomenon.

Effect of resonant excitation voltage on mass range extension. Either resonant ejection does not occur or collision-induced dissociation (CID) does occur at low resonant excitation voltages; both are undesirable. With increasing resonant excitation voltages, the "apparent m/z" of the ions decreases as they are ejected earlier. For example, as the resonant excitation voltage was varied from 1 to 6 volts, the m/z 219 EI ion of FC43 was ejected at an RF voltage level corresponding to low m/z cutoff levels decreasing sequentially from m/z 76 to m/z 71 while it's predicted ejection should have been at m/z 72.5. The resonant excitation voltage for optimum ejection increases with the m/z of the ejected ion. Further characterization is required to delineate the exact relationship between the resonant excitation voltage and the "apparent" m/z such that the m/z of an ion can be accurately assigned.

Resonant excitation CID of high-mass ions. Conventional MS/MS in the ITMS relies upon resonant excitation to increase an ion's axial kinetic energy sufficiently such that upon collisions with the buffer gas, collision-induced dissociation occurs. The efficiency of resonant excitation CID falls off dramatically below q_z (parent ion) of 0.20 for low m/z ions. This is due to the shallow potential well-depth at low q_z values resulting in ejection of parent ions instead of their CID. From the Dehmelt pseudopotential well model, the maximum center-of-mass (COM) collision energies can be estimated for a range of high m/z ions held at the maximum RF voltage (low m/z cutoff ≈650) possible on the ITMS. Even with collision gases more massive than helium, the available COM collision energies are minimal (with Xe, maximum kinetic energies (COM) < 10 eV for m/z < 3000). We have begun to characterize the use of **photo-induced dissociation (PID)** as an alternate means of performing MS/MS in the ITMS (see Stephenson *et al.* TP 155, ASMS, 1993). It offers a number of advantages over CID including being largely independent of an ion's secular frequency and q_z and being most efficient when ions are near the center of the ion trap where the optimum trapping of parent and daughter ions also occurs.

EVALUATION OF A LOW COST, LOW HOMOGENEITY, VERTICAL BORE 7-T MAGNET FOR FTICR

J.S. Anderson, E. G. Schmidt, V. H. Vartanian, and D. A. Laude, Jr., Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX, 78712

INTRODUCTION

The adaptation of superconducting magnets for Fourier transform ion cyclotron resonance (FTICR) mass spectrometry has produced both higher magnetic field strengths and simplified external ion injection compared to conventional electromagnets. In addition, higher field strengths have the analytical advantages of extended mass range, extended mass resolution, and improved mass accuracy. Such utility is theoretically possible due to the increased magnetic flux present in the trapped ion cell at higher field strengths. As a result, coherent ion clouds can be constrained radially to a smaller volume and the detected cyclotron frequency is better defined.

Superconducting high field magnets specifically designed for FTICR have high magnetic field homogeneity and wide, horizontal bores for ready installation of FTICR vacuum chamber and cell. One disadvantage of such magnets is the rather large capital investment. We decided to evaluate a possible solution to such an expense: a vertical bore NMR-type magnet which costs a fraction of the horizontal bore FTICR magnet.

We have constructed an FTICR mass spectrometer based on an inexpensive vertical bore magnet of field strength 7.2 Tesla. Issues of concern in evaluating this magnet for FTICR performance include its narrow 86 mm bore and the poor magnetic field homogeneity of about 1000 ppm.

To be presented here are pilot studies of FTICR performance in our high field magnet. Initial efforts were directed at placement of the trapped ion cell within a homogeneous region of the magnet solenoid to optimize signal detection. A probe-mounted translatable cell was useful for this study.

EXPERIMENTAL

The FTICR instrument constructed around the vertical bore magnet is shown in Figure 1. The magnet was a 7.2 Tesla vertical 86 mm bore superconducting magnet designed and built by American Magnetics, Inc. (Nashville, Tennessee). To maximize bore diameter, a UHV flange was welded directly to the magnet warm bore. The cell flange assembly, electron beam assembly, laser desorption probe, and 1.50 inch cubic trapped ion cell constructed of OFHC copper fit easily inside the restricted bore The vacuum system was pumped by a diffusion pump which due to geometric constraints was located approximately 2 meters from the trapped ion cell. Consequently, overall pumping performance in this system was often inadequate and difficulty existed in reaching the low 10^{-8} Torr region

Of great concern was the placement of the trapped ion cell in the proper region of the superconducting solenoid. Due to large magnetic field inhomogeneities within the solenoid, 1000ppm over 1 cm diameter spherical volume (DSV), misplacement of the cell by a few mm could have deleterious effects with respect to signal detection and mass resolution. Taking this into account we have designed our cell to be translatable over a 12 mm z-axis region of the solenoid.

Using field mapping values obtained from the manufacturer, a plot of axial displacement versus field strength is shown in Figure 2. The optimum cell placement is also shown to illustrate the possible magnetic fields experienced by an ion in the cell at a point away from the suggested solenoid center.

RESULTS A study on the detected frequency of benzene at different axial cell positions shows a distinct change in Δf as the cell is displaced. As illustrated in Figure 3, the frequency change is much more pronounced in the 0-3mm and 8-12mm regions. This would indicate a greater inhomogeneity in these regions and a basis for the more severe frequency change.

Using this information, excite profiles of benzene were performed in two different regions of Figure 4, 4mm and 12mm displacement. Shown in Figures 4a and b are excite profiles which indicate an increase in ion loss at 12mm displacement. Besides the collisional loss mechanism which is also prevalent in the 4mm case, a very promenent reason for the loss of ion signal would seem to be the lack of magnetic field homogeneity as the cell is displaced from the center region of the solenoid.

The ability to better define the magnetic field effects on performance were hampered by the difficulty in achieving a good vacuum. Pressures in the cell typically ranged from high 10^{-8} Torr to mid 10^{-7} Torr. Consequently, the inability to obtain high resolution data at this point cannot necessarily be assigned to problems with the magnet, since every spectrum obtained exhibited a pressure-limited transient. We believe the pressure problem likely rests with an inadequate pumping scheme for our vacuum chamber design. Even if homogeneity is found to limit mass resolution performance for low mass ions, the effects will be less severe for the high mass applications intended with the mass spectrometer, specifically the MALDI experiment.

Short term future concerns will be focused on reducing the system pressure. Probe displacement experiments will then be repeated at sufficiently low pressure to better define performance. Given a magnet cost that is one-tenth the price of a standard 7T, wide bore horizontal magnet, there is a compelling argument for pursuing the performanace capabilities for high mass applications.

MATRIX-ASSISTED LASER DESORPTION/IONIZATION IN THE QUADRUPOLE ION TRAP: A NEW METHOD FOR TRAPPING ENERGETIC IONS USING CONTROLLED GATING OF THE TRAPPING FIELD

Vladimir M. Doroshenko and Robert J. Cotter
The Johns Hopkins University, Baltimore, MD

The ability of the ion trap to perform $(MS)^n$ experiments suggests broad opportunities for utilizing ion traps in biochemistry, protein chemistry and molecular biology, for elucidating the structures and sequences of biomolecules. MALDI has undoubtably become one of the most promising techniques for the desorption of biomolecule ions. The major problem during an introduction of ions formed external to the ion trap into the trapping field is that the ion kinetic energy needed to overcome the RF field also prevents trapping the ions. So far there has been only one approach to this problem which is to accelerate the ions to kinetic energies sufficient to penetrate inside the active RF field, and subsequently reduce their kinetic energies through collisions with a buffer gas. An additional approach has been discussed in the literature but never realized which involves phase-synchronized gating of the trapping RF voltage during the introduction of ions to the trapping field.

In this work we have developed a novel method for trapping ions formed by MALDI which involves gradual ramping of the RF field amplitude from zero to trapping values during the flight of ions into the center of the cell. The desorbed ions easily penetrate the weak electric field at the initial stage of RF ramping, and are trapped with high efficiency during the last ramping stage, when they reached the center of the trap. It does not require phase synchronization with the trapping field, or use collisions with helium atoms as primary method for reducing ion kinetic energy

A Finnigan MAT series 700 ITD has been modified for MALDI inside the trap using the fourth harmonic (266 nm) laser pulse from a Quantel International Nd:YAG laser. The 0.04" diameter probe tip was inserted inside the ion trap through the existing ~0.05" hole in the upper *end-cap* electrode normally used for introduction of the electron beam. The sample on the probe tip was illuminated by the focussed laser beam through the gap between the *ring* and bottom *end-cap* electrodes. In order to operate beyond the standard 650 u, *resonant ejection* of ions was used. Mass resolution was improved by slowing the RF voltage scan rate. In operation, the firing of the laser and onset of the gated fundamental RF voltage was followed by a 10-20 ms storage period. The rise time of the RF amplitude in response to switching on the control voltage was 20-30 μs. The settling value of the RF voltage at the storage period corresponded to the mass level of 450-520 u. Single-shot laser MALDI spectra were acquired by a digital oscilloscope using TOFWARE, a WINDOWS-based data acquisition system.

Spectra of several peptides obtained at different mass scan rates are shown in Figures 1 and 2. The buffer gas pressure of 10^{-3} torr was typical for normal trap operation and is several times less than that used in previous experiments. Using *Gramicidin S* as a test compound, we were able to observe spectra by our method at buffer gas pressure of $\sim 2\times10^{-4}$ torr. Highest resolution is achieved in a single-shot experiments (Figure 2b) and approached one in 12,000.

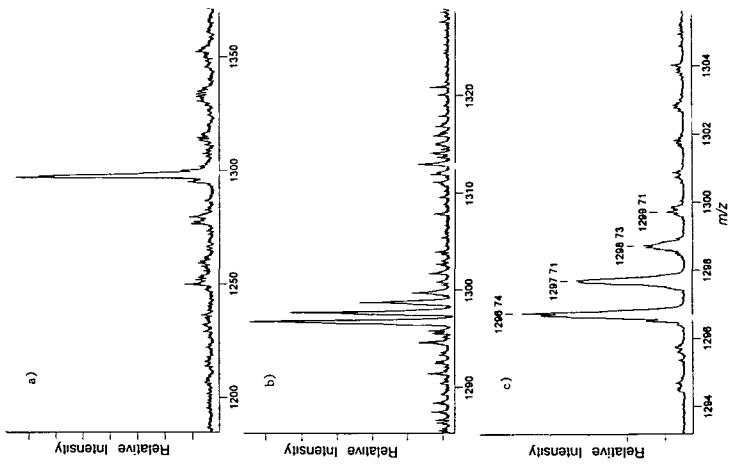

Fig. 1. The MALDI spectra of *Angiotensin I* obtained at the different mass scan rates. (a) 5555 Da/s, 12 laser shots are averaged, mass resolution R=880; (b) 1291 Da/s, 32 shots, R=3,800; (c) 373.3 Da/s, 49 shots, R=7,600.

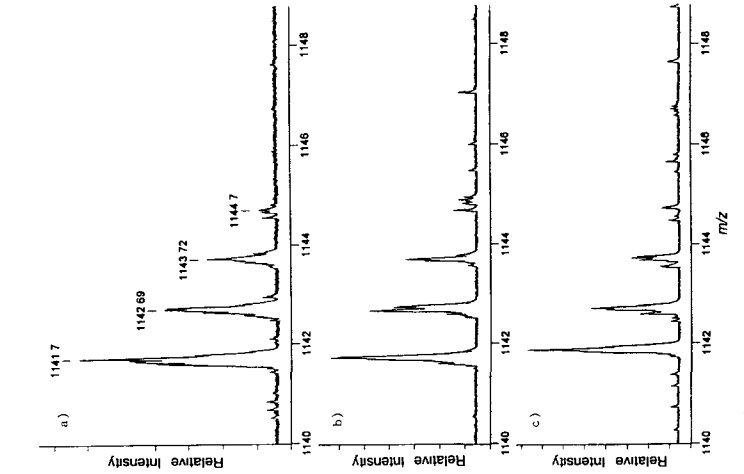

Fig. 2. The MALDI spectra of *Gramicidin S* obtained at the mass scan rate 330.6 Da/s: (a) 16 laser shots are averaged, mass resolution R=7,600; (b) single shot experiment, R=12,000; (c) space charge effect, single shot experiment.

The Development of Mass-selected Automatic Gain Control on a Quadrupole Ion Trap Mass Spectrometer

*Timothy P. Griffin, Nathan A. Yates, Richard A. Yost
Chemistry Department, University of Florida
Gainesville, FL 32611-2046

The quadrupole ion trap is a high performance mass spectrometer that exhibits high sensitivity, low limits of detection, and a large linear dynamic range (LDR). Increasing the ionization time to increase the number of ions can result in space charge effects (poor resolution, incorrect mass assignment) due to the high abundance of ions. To limit the effects of space charge while maintaining high sensitivity, Finnigan MAT developed automatic gain control (AGC)[1]. AGC automatically adjusts the ionization time dependent upon the total number of ions detected. AGC is limited, however, when two or more compounds of widely varying concentrations are present in the trap simultaneously. Since AGC detects the total number of ions in the trap, the ionization time is controlled by the major component, resulting in discrimination against compounds present at lower concentrations.

We are developing mass-selected automatic gain control (MSAGC) specifically for co-eluting compounds and complex mixtures. The scan function for MSAGC (shown in **Figure 1**) can be applied to: 1) co-eluting peaks of widely varying concentrations, 2) complex mixture analysis, and 3) GC/MS/MS. During the AGC pre-scan, two-step isolation was used[2,3]. The factors used to calculate the ionization time were optimized to give the best resolution and response while preventing space charge.

To characterize the MSAGC technique, the signal response for co-eluting compounds was investigated. For example, **Figure 2** shows two spectra for a mixture containing 4 ng of an M+8 analyte (m/z 199) and 525 ng of an M+4 internal standard (m/z 195) using AGC (**Figure 2a**) and MSAGC (**Figure 2b**). The ionization time for MSAGC was 100 times that used for AGC; the increase in ionization time produced more ions and thus, the m/z 199 peak is still easily detected.

To demonstrate the effect of MSAGC on calibration curves, mixtures composed of 525 ng of an M+4 internal standard (m/z 195) and varying amounts of the M+8 analyte (m/z 199) were used to generate the log-log calibration curve for AGC and MSAGC (**Figure 3**); all injections were performed in triplicate. Note that the slope of the MSAGC calibration curve (**Figure 3b**) is 1.0, which is the expected slope for a log-log calibration curve; this is a marked improvement over the slope for the AGC calibration curve (**Figure 3a**). Also, when using MSAGC, data were obtained for all three injections at the 1 ng level, whereas data were obtained for only one out of three injections for AGC.

In summary, mass-selected automatic gain control shows the possibility of automatically adjusting the ionization time dependent upon only the ion of interest. The calibration curves which result are linear (i.e., slope = 1.0 for log-log plot) even when the analyte is not the most abundant ion in the ion trap.

Gas Chromatography/Ion Trap Mass Spectrometry Using an External Ion Source

Matthew M. Booth, James L. Stephenson, Jr., Richard A. Yost
Chemistry Department, University of Florida, Gainesville, FL 32611

INTRODUCTION

When an ion trap is used as a GC detector (**Figure 1**), mass spectral peaks due to ion-molecule reactions are commonly observed for compounds containing oxygen or nitrogen (1) The fragment ions for these types of compounds have relatively high gas-phase acidities, and both proton transfer (creating excessive M+1 abundances) and alkyl group transfer (creating adduct peaks) can occur (see **Figure 5**) In this work, an external ion source is used to limit the number of neutral molecules (either analyte, solvent, or contaminants) present in the ion trap during storage and scanning in an attempt to minimize ion-molecule reactions that may occur during GC/ITMS analyses

EXPERIMENTAL

A schematic of the external ionization system is shown in **Figure 2**. For this work, a Finnigan 4500 ion source was directly coupled to a Finnigan ITMS-style ion trap The only modification to this system was that a tube lens was mounted onto lens L3 of the 4500 source. The Finnigan 4500 ion source, ITMS ion trap, and electron multiplier were mounted inside of a cradle-style vacuum manifold A Varian 3400 GC was interfaced to the vacuum system using a transfer line adapted from a solids probe A Finnigan 4000 quadrupole electronics module (QEM) was used to control the ion source (filament, collector, and lens potentials), and Finnigan ITS40 electronics were used to control the ion trap. Injection of ions was accomplished by grounding the ion source and floating both the endcap and ring electrodes of the ion trap by a variable potential. A standard ITMS electron gate was used as the ion gate for this system. The electron gate TTL signal produced by the ITS40 electronics was inverted and amplified using a custom circuit and a Kepco model 400B variable power supply to produce the ion gate voltage

RESULTS

Since benzophenone forms both protonated molecule (m/z 183) and adduct ions (m/z 216, 231 and 259), it was chosen to evaluate the GC/MS performance of this system. **Figure 3** shows the total ion chromatogram and mass spectrum for 1 ng of benzophenone analyzed on the GC/ITMS external ion source system **Figure 4** compares the M+1/M ratio for the analysis of benzophenone using both internal and external ionization systems The theoretical ratio for this value is 14 6% if only ^{13}C contributes to M+1 As can be seen from this figure, the M+1/M ratio remains constant and very close to the theoretical value for the GC/ITMS system using external ionization The data for the internal ionization system, though, shows that even at 0 5 ng, the proper M+1/M ratio for benzophenone is never obtained

Figure 5 shows the mass spectrum for 100 ng of benzophenone analyzed on the GC/ITMS system using internal ionization At this concentration, both protonated benzophenone molecule and adduct ions can be seen. **Figure 6** shows the mass spectrum for 500 ng of benzophenone analyzed on the GC/ITMS system using external ionization. Even at this high concentration, the proper M+1/M ratio is obtained, and no adduct ions are observed in this spectrum.

FUTURE WORK

Future work will include improving the limit of detection for this system by making ion optic and ion trap changes and by increasing the ion injection time. GC/ITMS using negative ion chemical ionization (NICI) will also be attempted (NICI cannot be performed on an ion trap system using internal ionization due to the lack of thermalized electrons inside the ion trap)

A New Model for the Estimation of Ion Kinetic Energy in a Quadrupole Ion Trap

*Randall E. Pedder[†], Richard A. Yost[‡]
[†]Millipore Corporation, Extrel Mass Spectrometry, Pittsburgh, PA 15238
[‡]Department of Chemistry, University of Florida, Gainesville, FL 32611

The Dehmelt pseudopotential well model for the estimation of maximum kinetic energies of ions stored in a quadrupole ion trap is known to be inaccurate for values of the Mathieu parameter q>0.3[1]. The Dehmelt pseudopotential well model is essentially based on a single-term truncation of the analytical solution of the Mathieu equation. A new model, derived from a four-term truncation of the analytical solution of the Mathieu equation, has been proposed for the estimation of maximum ion kinetic energy. This new model, the Expanded Analytical Solution Model, is compared with results calculated using the computer simulation program developed in our lab called Hyperion[2].

Ion motion in a quadrupolar field can be described using the Mathieu equation:

$$\frac{d^2u}{dt^2}=\frac{eu}{mz_0^2}(U+V\cos\Omega_0 t)$$

The analytical solution of this equation can be used to identify position at time t (assuming zero initial velocity):

$$u(t)=A[C_0\cos(\omega_0 t)+C_{-2}\cos(\omega_{-1}t)+C_{+2}\cos(\omega_{+1}t)+C_{-4}\cos(\omega_{-2}t)+...]$$

where the coefficients (C_{2n}) can be calculated as a function of the Mathieu parameters a and q, and the frequencies can be calculated as a function of β and the RF drive frequency Ω_0:

$$\omega_n=(\frac{\beta}{2}\pm n)\Omega_0 \quad \text{where} \quad n=0,\pm1,\pm2...$$

Note that the ripple seen in the classic photomicrograph of Wuerker et al.[3], and in simulated ion trajectories, is not the drive frequency applied to the trapping electrodes, as often identified in the literature. Rather, that ripple is the result of the first and second harmonics (ω_{-1}, and ω_{-2}) beating upon each other.

Ion velocity can be calculated as the first derivative of the Mathieu equation Analytical solution.

$$\frac{du}{dt}=\dot{u}(t)=-A(C_0\omega_0\sin(\omega_0 t)+C_{-2}\omega_{-1}\sin(\omega_{-1}t)+C_{+2}\omega_{+1}\sin(\omega_{+1}t)+C_{-4}\omega_{-2}\sin(\omega_{-2}t)+...)$$

Since the maximum of a sine function is one, maximum ion velocity can be calculated from:

$$\dot{u}(t)_{max}=A(|C_0\omega_0|+|C_{-2}\omega_{-1}|+|C_{+2}\omega_{+1}|+|C_{-4}\omega_{-2}|+...)$$

In the Dehmelt pseudopotential well model, the ion velocity equations are truncated to a single term (C_0=1, $C_{n\neq0}$ =0):

$$\dot{u}(t)=AC_0\omega_0\sin(\omega_0 t)$$
$$\dot{u}(t)_{max}=A|C_0\omega_0|$$

Kinetic energy, calculated as shown below, reduces to Dehmelt's:

$$E_{kinetic,max}=\frac{1}{2}m\dot{u}(t)^2=\frac{mA^2\omega_0^2}{2}=\frac{qV_{RF}}{8}$$

In the Expanded Analytical Solution Model proposed here, the maximum ion velocity equation is truncated to four terms:

$$\dot{u}(t)_{max}=A(|C_0\omega_0|+|C_{-2}\omega_{-1}|+|C_{+2}\omega_{+1}|+|C_{-4}\omega_{-2}|)$$

Kinetic energy can be calculated as: $E_{kinetic,max}=\frac{1}{2}m\dot{u}(t)^2_{max}$

Inclusion of these three additional terms results in a doubling of velocity with a five-fold increase in estimated ion kinetic energy. Although the higher harmonics tend to be small in amplitude, their large frequencies cause them to have significant contributions to velocity and kinetic energy. Indeed, the velocity contribution of the first harmonic frequency, ω_{-1}, is always greater than that of the fundamental frequency.

Conclusions. The harmonic frequencies of ion motion evident in the Wuerker photograph and in simulations contribute significantly to ion velocity and kinetic energy: low amplitudes at high frequencies yield large contributions to ion velocity. The proposed Expanded Analytical Solution Model yields calculated ion kinetic energies five-fold larger than the Dehmelt pseudopotential well model for all values of q. Hyperion numerical integration results yield an additional factor of two increase in estimated kinetic energy, for a total ten-fold increase over the Dehmelt model. While the Hyperion numerical integration results are presumed more accurate, calculations using the Expanded Analytical Solution Model are much simpler to implement.

FTMS External Ion Source for Ion-Molecule Reactions

C.R. Chris Wang, Anthony M. DeSantolo, Mary L. Mandich and William D. Reents, Jr.
AT&T Bell Laboratories, Murray Hill, New Jersey 07974

Reactivity studies of gas phase semiconductor clusters have provided new insights into the chemistry of nanosize semiconductor surfaces and the chemistry of gas phase semiconductor precursor species which arise during semiconductor processing. The size and stoichiometric dependent reactivities of gas phase semiconductor clusters are under study using powerful trapped ion cell technique of Fourier transform ion cyclotron resonance (FTICR) mass spectrometry in conjunction with an external cluster source and ion guide.

Using an external cluster source and a differential pumping of an ion guide allows for operation of the FTICR at requisite low pressure conditions while extracting clusters generated in a high pressure environment. A fast atom bombardment (FAB) sputtering source was chosen in our early investigations due to its simplicity in construction and capability of producing continuous cluster beams, containing both neutrals and ions, with broad range of cluster sizes. The FAB gun (Phrasor Scientific), capable of delivering a maximum 25 kV and 250 $\mu A/cm^2$ continuous primary Xe/Xe^+ beam, is operated typically at 10 kV and 25 $\mu A/cm^2$. It is aligned with an angle of 70° to the surface normal of the sample target to obtain the maximal secondary ion fluent. Fig. 1 shows the schematic of our external cluster source and ion transfer system. A 6.4 mm diameter target is mounted on a sample holder that can be floated at a source voltage (Vs). The sputtered cluster ions are transferred through the magnet fringing fields into the ICR cell by a newly designed ion guide which permits a high transfer efficiency. The ion guide consists of ion extraction/ acceleration, X&Y deflection (Z defined as the direction of the central magnetic field line), field-free (1 kV) regions, ion focusing elements (Einzel lens), and deceleration region. Most of ion optical lenses are made of 2.3125" (diameter) x 0.125" (thickness) copper discs with a 0.75" diameter central opening on each one. Einzel lens L1 focuses the ions through the differential pumping aperture A2 and Einzel lens L2 refocuses the ion which are then decelerated to their original kinetic energies before entering the ICR cell. A smooth ion deceleration is achieved using an assembly of exponential deceleration lenses connected through a resistive voltage divider.

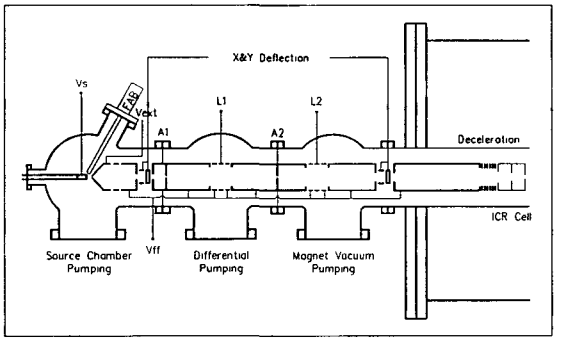

Figure 1. Schematic diagram of the external cluster source and ion transfer system.

Cluster ions from the ion guide are trapped in the ion cell and then specific cluster ions are isolated from the total ion population for reactivity studies. Fig. 2 shows the required pulse sequence for ion loading, trapping, isolation, reaction and detection. Briefly, prior to ion collection in the cell, all ambient ions are quenched from the cell. Since ions are streaming continuously from the source towards the cell, they must be prevented from entering the cell during this quench pulse. This is accomplished by pulsing one of the ion guide deceleration lenses near the ion cell entrance to a large positive voltage (typically +260 V). During ion collection, the ion blocking pulse is removed which allows ions to re-enter the cell. A collection time of 20 ms is found to be sufficient to "fill" the ion cell. Once the cell is loaded, ions are again blocked from reaching the cell until the next experimental cycle. The ion cell is operated with a constant +1.0 V trapping voltage on both the near and far trapping plates except for during the ion collection period. While ions are loading into the cell, the far trapping plate is pulsed to a higher voltage (1-10 V) which is found to assist the trapping process. An isolation pulse is employed in ion-molecule reaction studies to selectively isolate a single size or stoichiometry of cluster ion by strongly irradiating the other cluster ions at their cyclotron frequencies.

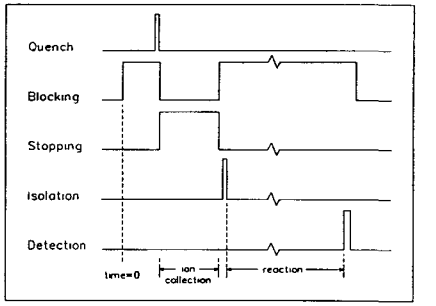

Figure 2. Timing Sequence required for an experimental cycle.

Indium phosphide cluster ions, $In_xP_y^+$ ($x<9$, $y=0,1,2,3$), have been successfully generated, transferred and detected, as shown in Fig. 3. The retarding potential analysis on the total $In_xP_y^+$ ion beam indicates that the kinetic energy distribution is very broad. However, 80% of the cluster ions have kinetic energies less than 20 V. The dis-tribution of the kinetic energies of the remaining 20% of the cluster ions tails out to more than 100 V. Highly selective reactions of these indium phosphide cluster ions are observed with ammonia and trimethylamine. Of all of the $In_xP_y^+$ cluster sizes and stoichiometries studied, only In_2^+ reacts with ammonia. Trimethylamine is much more reactive. However, the reaction probability decreases to zero as the clusters become larger.

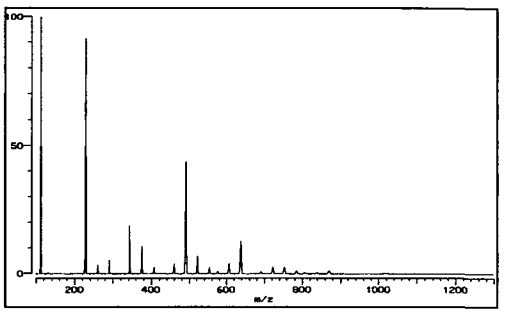

Figure 3. Measured mass spectrum of indium phosphide clsuter cations, denoted as (x,y).

Characterization of an FT/ICR Mass Spectrometer Based on a 0.4 T Permanent Magnet

*Loreen C. Zeller,[1] James M. Kennady,[1] Diane T. Leeck,[1]
Lori M. Castro,[1] Joseph E. Campana,[2] and Hilkka I. Kenttämaa[1]

[1]Department of Chemistry, Purdue University, West Lafayette, Indiana 47907-1393
[2]Extrel FTMS, Millipore Corp., 6416 Schroeder Rd., Madison, Wisconsin 53711-2424

The performance of a Fourier transform ion cyclotron resonance mass spectrometer based on a 0.4 T permanent magnet has been explored. In this mass spectrometer the cell is 3.0 cm along the z-axis and 3.2 cm along each of the x- and y-axes. Several screened cells[1] were constructed and their performance was compared. SIMION calculations were performed to study the effect of the grounded screens on the electrostatic field inside the ICR cell. The mass range, the dynamic range and ion isolation were examined.

SIMION calculations show that the electrostatic field inside the cell is significantly reduced by the introduction of a grounded screen inside the trapping plates (Figure 1). The performance of a screened cell (3 wires/cm placed 2 mm inside the trapping plates) and an unscreened cell was compared by performing electron ionization of perfluorotributylamine (PFTBA) (Figure 2). For similar ionization and trapping conditions, the signal in the screened cell was significantly greater than the signal in the unscreened cell, suggesting that more ions are trapped in the screened cell. The data obtained in the screened cell compares favorably to that obtained in a commercial Extrel Model 2001 FTMS system (4.76 cm cubic dual cells, 2.4 T).

The upper portion of the mass range was examined by using 2,4,6-(perfluorononyl)-1,3,5-triazine (MW 1485) and 2,4,6-(perfluoroheptyl)-1,3,5-triazine (MW 1185). Electron ionization of these compounds produced abundant fragment ions of m/z 1466, 1066 and 866 (Figure 3). A cell in which the wires of the screen were spaced 2 wires/cm proved to have the best performance in this portion of the mass range. Unit mass resolution is achievable at m/z 1466.

The dynamic range of the instrument was studied by measuring the mass spectrum of air in a screened cell in which the wires were spaced 3 wires/cm. Argon was detectable in the presence of nitrogen. In an additional experiment, SWIFT was used to selectively excite the lower abundance components.[2,3] By using this method of detection it was possible to detect CO_2, which is present in air at 0.0033%, thus demonstrating an extended dynamic range in excess of 10^4.

A wide variety of ion chemistries can be studied in this instrument. Of interest to gas-phase ion chemists is the ability to isolate and study highly reactive species, such as organic radical cations. This is demonstrated here for ionized propanal. Propanal was pulsed into the mass spectrometer and the radical cation was isolated by using a SWIFT waveform (Figure 4). The isolated ion was reacted with both dimethyl disulfide and cyclopentanone. Very little interference occurs from ion-molecule reactions with trace levels of the neutral precursor.

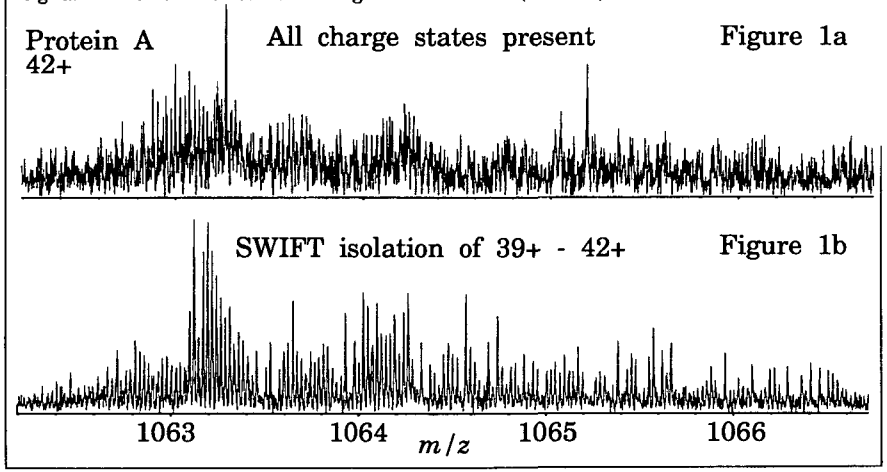
High-Resolution Fourier-Transform Mass Spectrometry of Large Biomolecules

*Michael W. Senko, Peter B. O'Connor, Steven C. Beu, John P. Quinn, and Fred W. McLafferty, Cornell University, Department of Chemistry, Ithaca, NY 14853-1301

Fourier-transform mass spectrometry (FTMS) has features that are appealing for the analysis of large biomolecules: ultrahigh resolution, high mass accuracy, and simultaneous ion detection over a wide m/z range. The benefits of high resolution include mass determination uneffected by unresolved adducts and the unambiguous determination of charge from isotopic peak spacing. The initial coupling of an electrospray ionization (ESI) source to FTMS demonstrated high resolution analysis of multiply charged biomolecules of greater than 15 kDa [1]. Improvements to the instrument have increased resolving power, sensitivity and mass accuracy by an order of magnitude [2]. Resolving powers of $2x10^6$ for ubiquitin (8.6 kDa) and $5x10^6$ for carbonic anhydrase (29.0 kDa) have recently been demonstrated [3].

Performance for molecules larger than 30 kDa has been unexpectedly poor. Potential problems at high mass are the increased charge carried by each molecule, larger collisional cross sections, and increased heterogeneity. Each of these has been investigated in an attempt to extend the range of compounds amenable to high-performance ESI-FTMS analysis.

Optimum resolution is obtained with the FTMS using small ion populations. Larger biomolecules have more isotopic peaks, carry more adducts, and have more charge states, causing a decrease in signal levels for the same number of ions. Ion populations large enough to produce acceptable signal levels degrade resolution. By initially overloading the cell (Figure 1a), then using SWIFT [4] to remove all but a few charge states (Figure 1b), high resolution can be maintained with acceptable signal levels for molecules as large as Protein A (45 kDa).



Microheterogeneities for large molecules can arise from various sources including adducts and structural modifications [5]. To minimize the effect of non-covalent adducts, the nozzle-skimmer bias is set high enough to induce some covalent bond fragmentation. Even under these conditions, the molecular weight distribution for porcine albumin (67 kDa) is 1000 Da wide (Figure 2).

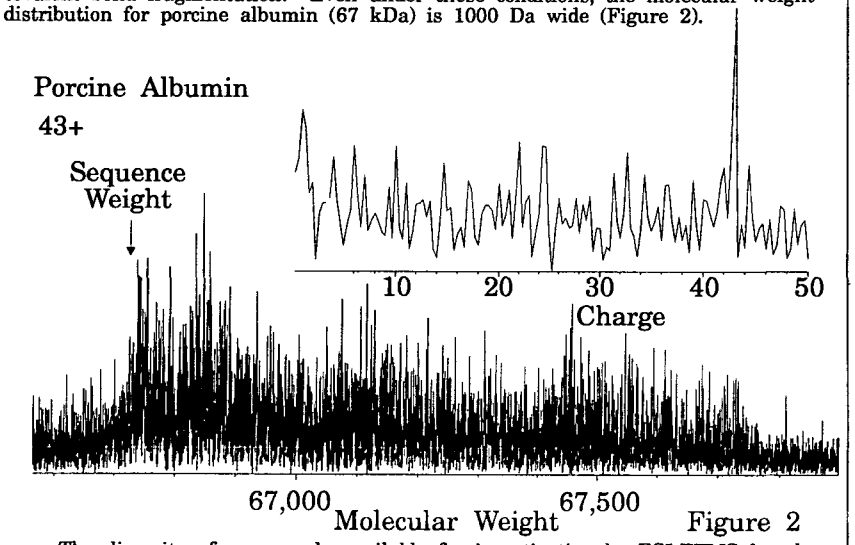


Figure 2

The diversity of compounds available for investigation by ESI-FTMS has been increased by extending the mass limit amenable to high-performance analysis. The main cause of poor performance has been determined to be a combination of space charge effects and microheterogeneities. Larger molecules are more heterogeneous, with wider isotopic distributions and more charge states, and therefore require larger ion populations to produce acceptable signal-to-noise ratios. Larger ion populations have a negative effect on resolution, and it is therefore necessary to remove the majority of charge states before analysis to maintain high resolution. By removing all but one charge state, unit resolution is obtained for molecules as large as porcine albumin (67 kDa).

Martin Marietta Energy Systems, Inc.
Oak Ridge, Tennessee 37831-8189

Previous Work

The purpose of this work is to improve quantitative elemental analyses by glow discharge mass spectrometry (GDMS) by predicting the individual sensitivities of the elements. The results reported on this poster reinforce recently published work (JASMS 1993, 4, 278-285). Relative ion yields (RIYs), defined in that work, were experimentally measured for 19 elements in NIST steel reference materials (#661-665) using both pure argon and argon containing 1 vol % H_2. RIYs were also theoretically calculated using the following equation:

$$RIY_s = \frac{(Mass\ factor)_s\ (Ionization\ factor)_s\ (Atomic\ weight)_{Fe}}{(Mass\ factor)_{Fe}\ (Ionization\ factor)_{Fe}\ (Atomic\ weight)_s}$$

The mass factor, taken to be $1 - e^{-0.04\,AW}$, was believed to result mostly from the mass dependence of analog detection. The predicted use of ion counting to eliminate the need for this factor is one of the interesting aspects of the present paper.

The thermodynamic ionization factor, $1/[1 + e^{+(EA+IP-\mu)/kT}]$, involves the electron affinity and the first ionization potential for each element, as well as a chemical potential (μ = 9. ev), the Boltzman constant k, and a temperature (T = 14000 K). The atomic-weight factors are necessary to convert atom % to wt %.

When the theoretical RIYs were plotted versus the experimental RIYs, the correlation was found to be strong when the measurements were made using argon that contained 1 vol % H_2.

Present Results

The following results were obtained using a Concept S32 high-resolution glow discharge mass spectrometer (manufactured by Kratos Analytical, Ltd.):

1. When ion counting was used, theoretical RIYs without a mass-dependent factor correlated well to experimental RIYs when argon was used that contained 1 vol % H_2.

2. When Inconel-steel reference materials (4.5 to 46 wt % Fe) were measured using argon containing 1 vol % H_2, the theoretical RIYs (previously used for low-alloy steels) correlated well. This indicated that the same RIYs apply to a wide variety of steels.

3. When a steel standard was measured using argon containing 5 vol % helium, the results were nearly the same as the results obtained when pure argon was used. This indicated that the physical effect of thermal conductivity (which is similarly high for both H_2 and He compared to argon) does not account for the improved correlation observed for argon containing 1 vol % H_2.

Development of a Pulsed-Gas Glow Discharge Ion Source for High Mass Resolution on a Fourier Transform Ion Cyclotron Resonance Mass Spectrometer

Clifford H. Watson,[1] John Wronka,[1] Frank H. Laukien,[1] Christopher M. Barshick,[2] and John R. Eyler[3]; [1]Bruker Instruments, Inc., Manning Park, Billerica, MA 01821; [2]Oak Ridge National Laboratory, Oak Ridge, TN 37831-6375; [3]Department of Chemistry, University of Florida, Gainesville, FL 32611-2046.

ABSTRACT

A new pulsed-gas glow discharge (GD) source has been developed for use with a commercial external ion source Fourier transform ion cyclotron resonance (FTICR) mass spectrometer. Since the gas load in the mass analyzer region was greatly reduced an improvement in mass resolution was observed. Mass resolutions, $m/\Delta m_{\frac{1}{2}} > 1{,}000{,}000$ were achieved for Cu in a brass sample. The pulsed-gas glow discharge source shows promising analytical usefulness for high resolution detection in FTICR mass spectrometry.

INTRODUCTION

The FTICR mass spectrometer requires extremely low pressure in the analyzer region ($< 10^{-8}$ torr) to obtain ultra-high mass resolution. For most FTICR instruments the 1 torr background of argon present in the GD source can severely limit the base pressure in the FTICR analyzer region and degrade the mass resolution. The method most commonly used in FTICR mass spectrometry to eliminate the gas load associated with GD or other high pressure sources is to separate physically the ionization and detection regions[1]. Watson et al.[2], have successfully used a commercial FTICR instrument that utilized 3 kV electrostatic ion focussing to transfer ions from a continuous glow discharge source into the ICR analyzer cell while maintaining a pressure differential of 10^8. Since the FTICR is inherently a pulsed technique a pulsed-gas glow discharge source was developed to further lower the gas load on the system in order to improve the mass resolution and conserve both gas and sample.

EXPERIMENTAL

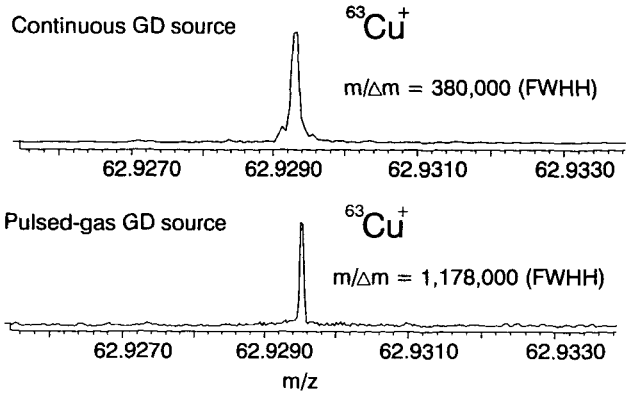
The glow discharge source was mounted in the normal source housing of a Bruker APEX 47e external ion source FTICR mass spectrometer. The instrument was pumped by cryopumps with separate pumps for the source region (800 l/s,N_2), ion optics and transfer region (400 l/s,N_2), and analyzer region (400 l/s,N_2). The pulsed-gas glow discharge source was mounted on a standard source flange that mates with the external ion source housing. The glow discharge was formed within an enclosed high pressure compartment, much like a chemical ionization (CI) source housing, maintained at a 1 torr pressure of argon that was introduced through a piezoelectric pulsed valve. Ions extracted from a 1 mm ion exit orifice, located 6 mm from the standard external source lens stack, were accelerated toward the analyzer cell by a -3 kilovolt potential.

The samples, usually consisting of metallic rods 1 to 3 mm in diameter and 10 to 15 mm long, were held at a potential of -1000 to -1500 volts at a distance of 5-10 mm from the (grounded) ion exit orifice plate and sputter/ionized in the argon atmosphere. The experimental sequence was as follows. A quench pulse is applied to the ICR cell to remove any ions stored in the trap. The pulsed valve was opened allowing argon to enter

the GD source. Ions were allowed to exit the source once a stable discharge was established. A delay of 0 to 9s allowed time for the background argon to be pumped away before ion excitation/detection.

RESULTS AND DISCUSSION

At higher mass resolutions the ion image current signal is attenuated as collisions with background gas dephase the coherent ion motion resulting in a loss of signal. For the continuous GD source the signal has faded away to noise after ca. 0.75s. By pulsing in the argon gas and waiting 3s prior to detection, the reduction in the gas load allows the signal to last for more than 2s. The mass spectra obtained from a standard continuous-gas and pulsed-gas source are shown below. Since the coherent ion signal for the pulsed-gas source is longer lasting the mass resolution is improved from 380,000 to 1,178,000 (FWHH). The improvement is resolution observed with the pulsed-gas operation is directly proportional to the reduction in the background pressure[3]. The background pressure can be lowered by an order of magnitude with a pump-out time delay of 9s between ion accumulation and detection.



CONCLUSION

Coupling a pulsed-gas glow discharge ion source with an external ion source FTICR mass spectrometer offers a technique that provides ultra high mass resolution to separate closely spaced isotopic peaks. Additional benefits include a reduction in the gas load on the pumping system, and a reduction in the rate of sample consumption.

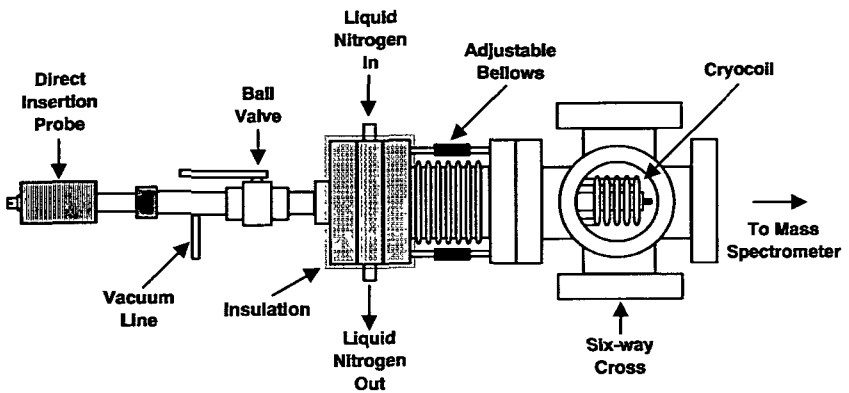
THE EFFECT OF CRYOGENIC COOLING ON THE GASEOUS IMPURITY AND ANALYTE ION SIGNALS IN GDMS

*S. K. Ohorodnik and W. W. Harrison
Department of Chemistry
University of Florida
Gainesville, Florida 32611

Glow discharge mass spectrometry (GDMS) is an elemental analysis technique in which atomization, excitation, and ionization of the solid sample occur independently in the discharge. A common problem encountered with a glow discharge ion source is the presence of gaseous impurities, particularly water vapor and air (N_2, O_2, CO_2), that can reduce the amount of sample sputtering as well as quench excitation and ionization reactions. The main source of contamination in the glow discharge is water vapor, which can be introduced into the GD chamber from the following sources: sample cathode, discharge gas, vacuum leaks, and desorption from the ion source surfaces. Elimination of water vapor and other gaseous impurities from the ion source is essential to obtaining reliable quantitative results and has been attempted using one or more of the following methods: (1) high purity discharge gases, (2) gettering reagents in the gas lines, (3) maintenance of high vacuum conditions, (4) frequent baking of the glow discharge system, and (5) cryogenic cooling of the ion source.

This poster described a cryogenic cooling coil that is inserted directly into the glow discharge ion source, resulting in a cooling sink adjacent to the plasma, permitting removal of impurities from the discharge gas by their physical freezing onto the coil surfaces. The coil is a simple and effective design for cryogenic cooling of the glow discharge chamber, which can be adapted to many different types of ion source configurations.



Since the greatest interferences from water and other impurities occur in the m/z range between 10 - 40, an aluminum cathode was chosen for analysis. The mass spectrum of the alloy after sputter cleaning the cathode for 30 minutes included water impurity species at 17, 18, and 19 Da as well as other impurities at 3, 12, 14, and 29 Da corresponding to H_3^+, C^+, N^+, COH^+, and N_2H^+. The major species in the spectrum are H_3^+ and ArH^+, both a result of residual water vapor. A mass spectrum of the sample taken after 30 minutes of cooling with liquid nitrogen is devoid of any of the impurity species except N^+, which is not removed by cryogenic cooling.

The relative sensitivity factor (RSF) values were calculated for a standard low-alloy steel sample (NIST SRM #1264) with and without cryogenic cooling. RSF values calculated for the cryogenic cooled sample had between a 50-95% increase in precision (determined by their %RSD) as compared to the noncooled values (Table I). In addition to the increase in precision, the magnitude of the RSF values also differed between the cooled and noncooled analyses. By controlling the liquid N_2 flow rate through the coil, it was possible to control the temperature of the coil and degree of impurity removal. The effect of the liquid N_2 flow rate on the RSF values of Al, Ti, and Cu was determined. The RSF of Al^+ decreased with increasing flow rate because of the removal of interferences at m/z = 27, while the RSF value of Ti^+ increased probably because of the reduction of TiO^+ production. Copper, a relatively unreactive element toward oxygen, shows a small decrease in RSF value with increasing flow rate, at present unexplained. The effect of liquid N_2 flow rate on the gaseous species was also determined. The ArH^+ and H_3^+ species decreased with increasing flow rate, while the Ar^+ increases.

The cryogenic cooling coil, as expected, is effective at removing water vapor and other gaseous impurities from the glow discharge plasma. The cryogenic coil provides a mean of manipulating the gaseous impurities in the plasma making it possible to investigate the effect the impurities have on the plasma chemistry. Elimination of these impurities results in RSF values of greater precision that should, as a consequence, produce more precise quantitative analyses. The RSF values also varied as the flow rate of liquid nitrogen through the coil and the amount of impurities in the discharge varied. Therefore, accurate and reproducible quantitative analyses also require that the water vapor and other impurities be controlled at a known and reproducible value.

Table I. Relative Sensitivity Factor Values for Low-Alloy Steel NIST SRM #1264 (*n = 3)

CHARACTERISTICS OF RADIO FREQUENCY POWERED GLOW DISCHARGE CELL FOR THE ANALYSIS OF FLAT SAMPLES

Charles R. Shick, Jr. and R. Kenneth Marcus
Department of Chemistry, H.L. Hunter Laboratory, Clemson University,
Clemson, SC 29634

INTRODUCTION: The research interests of this group have focused on the development of radio frequency (rf) powered glow discharge sources which can directly sputter and atomize nonconductive materials such as glasses and ceramics. In addition to the expanded sampling scope, rf sources have proven to be advantageous in the analysis of metals and alloys which tend to form oxide layers, such as Al.

The VG GloQuad (Fisons) quadrupole mass spectrometer is currently equipped with a dc GD source. Recently, we have begun work in the interfacing of an rf GD source to this mass spectrometer system. This report describes the preliminary development and characterization of a direct insertion rf probe (DIP)-flat sample introduction assembly for use with the VG GloQuad. The goals of this research were:

1. To develop an rf-GD DIP flat sample holder for the VG GloQuad.
2. To demonstrate the figures of merit for the rf source through exemplary spectra, pre-sputter time, internal stability, and external reproducibility.
3. To show that rf-GDMS warrants further evaluation for the analysis of both conductive and nonconductive flat sample types.

EXPERIMENTAL: The GloQuad is a quadrupole-based instrument with two detectors installed: a Faraday cup for high ion currents typical of matrix species and an electron multiplier for trace measurements. A novel flat sample holder (Figure 1) was designed to mount onto the end of the DIP allowing for the analysis of flat samples with only slight modifications of the GloQuad ion volume. Preliminary studies were conducted with this rf source to determine pre-sputter times, internal stability, and external reproducibility. Since the sputtering region is defined by a grounded limiting orifice, the use of a 5mm and a 10mm orifice was used for this presentation

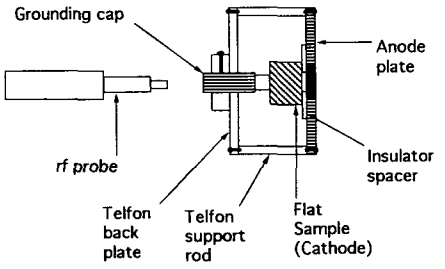

Figure 1. Flat sample holder for rf-GDMS

RESULTS AND DISCUSSION

Conductive sample: An NIST 1243 Waspaloy standard was used with the rf flat sample holder. 5mm and 10mm anode orifice plates were used, with the maximum signal for $^{58}Ni^+$ being 3.5E8 and 4.2E9 counts per second, respectively. For both orifice plates, The temporal profile was collected for 20 minutes while scanning the $^{60}Ni^+$ peak. The internal stability data was obtained by peak jumping the selected elements for 45 minutes. The external reproducibility data was obtained by five different runs whereby the sample was exposed to the atmosphere between each run, and the concentration values calculated with the GloQuad RSF software package. Results show that with both orifice sizes, the analyte signal stabilizes within 4 minutes of the plasma ignition. The 5 mm cell yielded slightly better precision than the 10 mm cell, both internally (4% vs. 7% RSD) and externally (9% vs. 12% RSD).

Nonconductive sample: For this study, an NIST 1412 multicomponent glass standard was used with the rf flat sample holder. Again, the 5mm and 10mm anode orifice plates were used with the maximum signal for $^{28}Si^+$ being 1.4E8 and 3.5E8 counts per second respectively (spectrum from 10 mm plate is shown in Figure 2). These optimized intensities and plasma parameters were used throughout this study. Temporal stability and external precision for nonconductive sample are hindered because the sample surface is prone to contaminated upon exposure to the atmosphere. All oxide-base sample types have a propensity for spectral interferences. For the 5mm orifice plate, the $^{28}Si^+$ isotopic abundance after 20 minutes is 89.5% (accepted value=92.18%), whereas the 10mm orifice plate has an abundance of 91.8% after 20 minutes, indicating that it stabilizes faster after exposure to atmosphere.

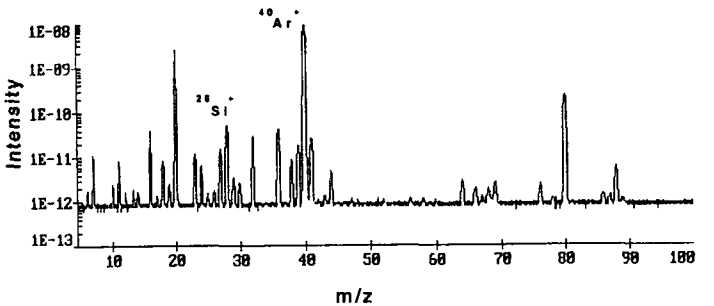

Figure 2 Mass spectrum of an NIST 1412 multicomponent glass using a 10 mm plate.

SUMMARY: An rf source for flat samples has been adapted to a commercial quadrupole mass spectrometer, the VG GloQuad. Preliminary results for both conductive and nonconductive samples indicate that the new source is promising in terms of beam intensity, internal stability, and external reproducibility. These results also support previous observations that the anode orifice plate is a factor in optimizing the plasma conditions.

ANALYSIS OF ELECTRODEPOSITED METAL IONS BY GLOW DISCHRAGE MASS SPECTROMETRY

Charles R. Shick, Jr., Paula R. Cable, Ashley Torrence, and R. Kenneth Marcus,
Department of Chemistry, Clemson University, Clemson, SC 29634

INTRODUCTION: Glow discharge techniques continue to grow in both scope and application; however, the method has thus far been primarily limited to the analysis of bulk solids and thin films. Solution samples may be analyzed as residues which have been dried onto a conductive host matrix. For the latter case, sample preparation is labor intensive, and sample atomization of the resultant oxide material does not necessarily provide a steady state atomic population. Electrodeposition of metal ions onto a cathode forms a more homogeneous thin film of non-oxidized material that produces an abundance of atoms and ions when analyzed by GD methods. We have investigated a technique for electrodepositing thin films of metallic material from solution onto vitreous carbon electrodes. Metal ions are stripped out of solution and are introduced directly into the GD ion source where they are sputter atomized.

EXPERIMENTAL: For this study, five molar concentrations (i.e. 0.01 - 0.5 M) of aqueous $Co(NO_3)_2$, $BaCl_2 \cdot 2H_2O$, and $Pb(NO_3)_2$ solutions were electrodeposited onto vitreous carbon electrodes. The 3 mm x 12 mm electrodes were partially submerged in 5 ml of test solution, which was magnetically agitated during the procedure. Each electrode was electroplated for 5 minutes with an applied voltage of -5 V, oven dryed for 10 minutes, then affixed to a direct insertion probe (DIP) for subsequent analysis by rf-GDMS. A representation of the electrodeposition apparatus is shown in Figure 1. The thin films were analyzed using a VG GloQuad which is a quadrupole-based instrument with a differentially pumped vacuum system. Two turbo pumps produce a final stage vacuum of 10E-7 mbar. A Faraday cup was used for detection.

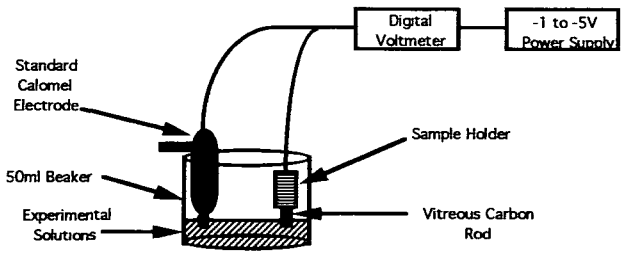

Figure 1. Electrodeposition Apparatus

RESULTS AND DISCUSSION: Deposition of metal ions to form a thin film suitable for GDMS analysis was readily achieved. The films appeared, for the most part, to be homogeneous and metallic in character. Surprisingly, the analyte signals, as measured with a Faraday cup, for the solutions of 0.5 M produced ion beam currents equivalent (>10^{-10} A) to those obtained for sputtering bulk metals. The signals display the anticipated transient nature as shown in Figure 2, though not all of the analyte films are removed at the same rates. At this point, no sort of electrolyte species is employed, and thus nonlinearities in terms of plating efficiencies would be expected. As such, the quality of the generated calibration curves is not as good as hoped.

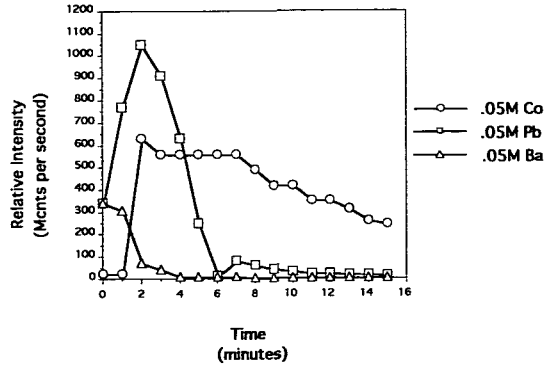

Figure 2. Temporal profiles of analytes sputtered by the rf-GDMS source.

The analyte intensities observed after a 5 minute sputter time are quite encouraging in terms of the beam currents. As these signals are measured on the Faraday cup detector to be on the order of 10^{-11} A, the ability to detect minute beam intensities on the electron multiplier detector (~10^{-17} A) would suggest that this method could be very sensitive. An added benefit of the technique itself is that it is multielement in nature.

SUMMARY: A technique of electrodepositing aqueous metal ions onto a glassy carbon electrode for rf-GDMS analysis seems to be a viable alternative to the current methods of solution residue analysis. Future studies will first focus on improving the deposition methodologies, and then look at the relevant figures of merit. It is hoped the the electrodeposition, rf-GDMS approach may find use in the simultaneous, multielement analysis of volume-limited samples.

ACKNOWLEDGEMENTS: Financial and instrumentation support from the National Science Foundation and VG Elemental is gratefully acknowledged.

AN IMPROVED DOUBLE QUADRUPOLE MASS SPECTROMETER FOR VERSATILE RADIO FREQUENCY GLOW DISCHARGE STUDIES

Yuan Mei and R. Kenneth Marcus
Chemistry Department, Clemson University, Clemson, SC 29634l

INTRODUCTION: The use of rf-GD double quadrupole mass spectrometer in our laboratory has been successful for conducting studies that entail both the application and fundamental aspects of the rf-GD plasma. The original laboratory-constructed mass spectrometer suffered from low ion transmission efficiency. Recently, a new ion optics assembly has been constructed that improves both the ion throughput and the energy defining properties of the instrument, with which collision induced dissociation (CID) studies were carried out using Ar, Xe, and N_2 as target gases to eliminate polyatomic interferences generated in the rf plasma. Studies were also conducted to assess the role of charge exchange in the CID process.

EXPERIMENTAL: The modified double quadrupole mass spectrometer is shown in Figure 1. The old three-element lens stack has been replaced by an ion optics system that combines an accel/decel design and an offset lens insert. The offset lens acts as a photon/neutral stop such that the original ion deflecting unit (ESA) situated in front of the detector has been removed to allow coaxial installation of the detector with respect to the ion beam.

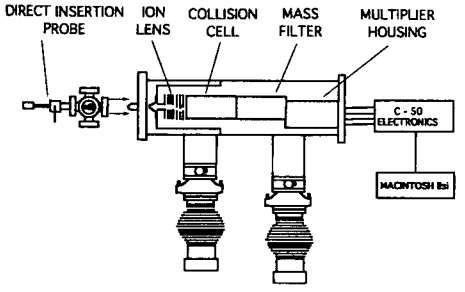

Figure 1. Double quadrupole rf glow discharge mass spectrometer

RESULTS AND DISCUSSION:

I. Ion transmission and energy definition of the new lens: Previous studies have shown that the high negative voltage (-1100 V) applied on the acceleration lens (skimmer cone), combined with the on-axis detector arrangement, improved the ion throughput by a factor of 5. This is especially favorable for the detection of low concentration species such as metal argides and dimers that are of interest in CID experiments. In addition, comparison of the kinetic energy values of several ions measured with both the old and the new lens systems indicate that the new lens system transmits a better defined (5-6 eV narrower) energy range. This property helps optimize a better defined collision energy in the collision quadrupole.

II. Collision energy optimization for target gases: A primary factor affecting the efficiency of CID is the collision energy, related as the center-of-mass energy which is experimentally determined by the dc bias voltage applied on the collision (first) quadrupole (Q1). To select the best Q1 bias for different target gases, the CID efficiency for several ions was studied as a function of the Q1 bias. The best CID results (maximum dissociation of the

molecular species with minimum loss of elemental ions) are obtained when Q1= -8V for Ar, 1V for Xe, and -10V for N_2, corresponding to E_{cm} values in the neighborhood of 4eV.

III. Effect of target gas pressure on CID efficiency: For each of the target gases used, Ion signal intensities were collected across a certain pressure range which is predicted to be on the order of 1 mTorr based on the third stage vacuum gauge reading on the mass spectrometer. Shown in Figure 2 is the CID efficiency of Ar, expressed by the signal attenuation factor $\ln(I_0/I)$, as a function of the indirect collision gas pressure. Ar^+ demonstrated the highest loss which was probably caused by symmetric charge exchange reactions with the target Ar atoms. It is important to note that the analyte ion, Cu^+, is lost to the least degree as compared with the unwanted species, i.e., ArH^+, Ar_2^+, $CuAr^+$, and Cu_2^+. Similar studies with Xe and N_2 as the target gas indicate that the degrees of signal attenuation are comparable between Ar and N_2. The signal attenuation factors obtained with Xe at 1/10 of Ar and N_2's pressure are as high as those of the latter, probably a result of the increased scattering by the heavier Xe atoms.

IV. The role of charge exchange reactions to the ion loss processes: The double quadrupole mass spectrometer used here allowed for further probing of the charge exchange process occurring in Q1 , which can be expressed by the following equations:

$$A_1^+ + A_2 = A_1 + A_2^+ \text{ (symmetric)}, \quad \text{and} \quad A_1^+ + B_1 = A_1 + B_1^+ \text{ (asymmetric)}.$$

The involvement of charge exchange in the total ion loss process of Ar^+, ArH^+, and Cu^+ was studied by monitoring the signal attenuation factors of the three ions while changing the pole bias on the second quadrupole to pass through ions with selective energy ranges. As the Q2 pole bias is decreased (Figure 3), ions resulting from the charge exchange reaction (that posses lower kinetic energies) are more readily passed through the mass analyzer. These ions make up for part of the lost primary ions, resulting in a smaller I_0/I This trend is most obvious with Ar^+, observable with ArH^+, and least apparent with Cu^+, indicating that symmetric charge exchange reactions (Ar^+) occur to a higher degree than the asymmetric ones (ArH^+) in Q1, whereas little charge exchange is involved with the loss of Cu^+ ions.

GLOW DISCHARGE - ISOTOPE DILUTION MASS SPECTROMETRY

***C.M. Barshick and D.H. Smith**
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6375, USA

After developing a glow discharge mass spectrometric (GDMS) method to analyze microliter volumes of solutions as dried residues, we turned our efforts to glow discharge isotope dilution mass spectrometry (IDMS). IDMS is a powerful technique for determining the concentration of a target species in a given unknown, with the crucial step being the establishment of an isotopic equilibrium between the spike and the analyte of interest. With gases and most liquid samples, this step is easy and rapid; all that is needed is to mix the two species prior to analysis. When the analyte is present in solid form, as is typically the case for GDMS, spark source mass spectrometry, or SIMS, equilibration during sample preparation is believed to be impossible. Because glow discharge cathodic sputtering affords a certain degree of mixing during sampling, however, equilibration of the spike and sample, even if both are present as solids, might be possible.

Although our long range goal is to use isotope dilution to determine directly the elemental concentrations of analytes in the solid, in all studies performed to date both the spike and the analyte of interest have been present in an acidic aqueous medium; under these conditions, equilibration is considered to be rapid and complete. Table 1 compares the results obtained using GDMS and inductively coupled plasma optical emission spectroscopy (ICP-OES) in the analysis of lead in three oil leachate samples. Solutions were prepared using EPA Method 3050. Both GDMS calibration curve and GDMS isotope dilution results compare well with those obtained by ICP-OES (EPA Method 6010). IDMS internal precision was found to be better than 5%, even when the concentration was just above the detection limit (LOD ~ 0.3 ppm for GDMS solution residues). External precision was about 2%, better than the precision obtained when using calibration curves or relative sensitivity factors (RSFs).

Table 1. Elemental Lead Concentration in Three Aqueous Leachates Prepared from Contaminated Waste Oils by EPA Method 3050

Contaminated Oil Leachate	ICP-OES Calibration Curve Concentration (ppm)	GDMS Calibration Curve Concentration (ppm)	GDMS Isotope Dilution Concentration (ppm)
†A	2.65	2.68	2.69
†B	3.52	3.97	3.54
†C	81.56	86.68	81.97

†Aqueous Samples

Simultaneous with the isotope dilution investigations of aqueous solutions, we have been evaluating the glow discharge solution residue sampling methodology for analyzing

organic solutions. Early results showed that cathode formation could not be achieved simply by drying and pressing, and an additional step (low temperature ashing) was incorporated. The LFE low temperature ashing system that we are using enables the dry removal of organic materials from a sample, while retaining the inorganic elements. Atomic oxygen produced in an r.f. discharge chemically reacts with the sample material to produce H_2O, CO, CO_2, etc., which is continuously exhausted by a mechanical vacuum pump. The sample temperature never exceeds 120° C, ensuring nearly 100% recovery of trace residual elements. For the initial work reported here, we compared two NIST aqueous reference solutions with two SPEX standard reference oils. After drying and ashing the oil, only small differences in relative ion yields (less than 10% average) were observed between the two types of samples; this is well within experimental error. Table 2 illustrates the results obtained when a second NIST 3172 cathode was used to develop RSFs (1 / RIY) specific for lead (RSF_{Pb} = 1.25, RSF_{Ag} = 1.00). Good accuracy (better than 5% average error) indicates a minimal matrix effect, although it is still too early to speculate about the degree with which the matrix will influence the analysis of other types of solutions (high brines, volatile organic compounds, etc.,). Not shown in Table 2 but also observed, was good agreement between these results and the EPA approved ICP-OES calibration curve methodology.

Table 2. Elemental Lead Concentration in Four Reference Materials Prepared by Drying and Low Temperature Ashing

Sample	Reference Lead Concentration (ppm)	GDMS Measured Lead Concentration (ppm)	Percent Error
*SPEX SPPB8 - 2Y	109.6 ± 2.2	102.0 ± 1.7	7.2
*SPEX MIO - 12B	109.9 ± 2.2	106.2 ± 2.5	3.5
†NIST 3128	100.0 ± 2.0	98.3 ± 8.8	1.7
†NIST 3172	100.0 ± 2.0	104.5 ± 0.7	4.5

*Organic Sample, †Aqueous Sample

Research in this area will continue as we develop a ^{204}Pb isotopically enriched organic spike to improve further the accuracy of GD elemental analysis in organic media. We will also continue to look for ways of delivering small amounts of solid (< 1 mg) spike material directly into the bulk, to extend IDMS's role in GDMS.

Isotopic Analyses by Glow Discharge Mass Spectrometry

Lee R. Riciputi, Douglas C. Duckworth, Christopher M. Barshick, David H. Smith

Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831

Glow discharge mass spectrometry (GDMS) has enjoyed considerable success as an elemental analysis technique, but its potential for the measurement of isotope ratios is relatively unexplored. Analysis of isotope ratios by GDMS offers a number of potential advantages, including limited sample preparation, direct analysis of solids, and relatively high sample throughput. In this paper we evaluate the internal and external precision achievable in the measurement of isotope ratios using a glow discharge, double-focusing mass spectrometer (VG9000). The effects of various instrument operating conditions and sample form on precision will be addressed, as will possible variation in mass biases.

The VG9000 was operated at relatively low mass resolution (~500) to provide flat-topped peaks. Secondary ion signals were measured using either a Faraday cup or Daly detector, peak jumping the magnet to shift masses. Counting times were 1.28 seconds on the Faraday cup, and 2 to 4 seconds on the Daly. One hundred sets of ratios were measured in each analysis, split into 10 blocks of 10 ratios each. Internal precision (discussed below) were calculated on the basis of 10 blocks. Samples were prepared as pins 1.8 cm long, and ranged in diameter between 2 and 5 mm. Isotope ratios, measured using NIST standards when available, include those for B (NIST 951), Cu (variety of samples), Sr (NIST 987), Ag (NIST 978), Re (NIST 989), and Pb (NIST 981). When conductive, analyses were done on solid pins (Cu and Pb as pins, Re wrapped on Pt). Otherwise, samples were prepared as 0.75 to 10 wt% standard mixed with either Cu or Ag powder and pressed into pin shape at high pressure. Most analyses were conducted with the glow discharge in DC mode, although the use of RF power was also investigated.

Cu was used to investigate the influence of pin material and instrument parameters on precision of isotope measurements. The best results on a single sample were obtained in DC mode using a solid Cu pin, with an external precision of 0.035% after correction for linear drift. Results using a single pin of pressed Cu powder were similar (0.046%). Using either constant voltage or constant current in DC mode yielded similar isotope ratios and external precision, although internal precision was slightly better with constant current. Isotope measurements made in RF mode had internal precision (ave 0.19%) that were an order of magnitude worse than those made using DC power (ave 0.026%). The poor internal precision probably results from the poor peak shape associated with RF mode. However, external precision obtained using RF power are only a factor of 2 worse (0.057%, n=5) than those using DC power on the same sample (0.030%, n=7). With improved filtering, both internal and external precision obtained using RF mode should improve. True external reproducibility was evaluated by making four pressed Cu powder pins, and loading and analyzing each one several times. External precision (0.29%) is ten times worse than that achieved using a single pin. These results may be improved by developing a different, more reproducible, sample geometry (flat cell), and by allowing a longer pre-sputter period before starting the analysis. Average daily $^{65}Cu/^{63}Cu$ ratios

ranged between 0.4534 and 0.4466.

Results for a number of NIST standards are summarized in the table below. External precision (single pin) ranged between 0.025% and 0.28%, and generally correspond to the concentration of the element in the matrix. There is no apparent matrix effect on measured Sr isotope ratios using Ag and Cu matrix powder (data not shown). In general, biases are low (<1%), and there is no correspondence between bias and mass or ionization potential. This result is not surprising, since atomization (cathodic sputtering) and ionization take place in two separate steps in GDMS. In fact, the variation in isotopic bias between different elements is similar to the daily changes in the measured isotope ratio for a single element.

GDMS holds promise for the relatively precise measurement (<0.1%) of isotope ratios on solids with a minimum of sample preparation. Current performance may be improved by optimizing sample and cell geometries, improving the stability of the discharge, and by optimizing the detection system. Accurate analyses will require daily calibration of the instrument.

SUMMARY OF SELECTED ISOTOPE ANALYSES USING GDMS

Element (detector)	Material	Ratio	N	Ave.	%External Precision	Accepted Value	Bias

Design of an Array - Detector Mattauch - Herzog Mass Spectrometer for Atomic Mass Spectrometry

Thomas W. Burgoyne, Gary M. Hieftje, and Ronald A. Hites
Department of Chemistry and School of Public and Environmental Affairs,
Indiana University, Bloomington, IN 47405.

Introduction. The quadrupole is the most common device for mass analysis in plasma source mass spectrometry. However, a major drawback of the quadrupole is that masses are detected one at a time; it is a scanning instrument. For example, 99.6 % of the analyte material is wasted from a continuously operating ion source (e.g. ICP or glow discharge) (not including quadrupole transmission efficiency) if a complete atomic mass spectrum (from mass 7 to 238) is required. This tremendous waste of sample reduces sensitivity and sample throughput. In addition, scanning results in each mass experiencing different conditions due to small fluctuations in the ion source (plasma). This produces a poorer S/N ratio in an isotope - ratioing mode. Scanning also limits precision. Furuta (1) found that with an increase in the mass scanning rate, the precision of lead isotope ratio measurements improved due to the elimination of the effects of drift in the plasma source.

An improvement to the plasma source mass spectrometer would therefore be a mass spectrometer capable of detecting all (or most) of the masses simultaneously; a direct reading mass spectrograph. This improvement could be accomplished by using a mass spectrometer with an array detector that will simultaneously detect ions as they undergo mass analysis by a magnetic field (a sector). Such an instrument should provide better sensitivity, speed, precision, and throughput compared to the commonly used quadrupole mass analyzer.

Methods. A 3 - inch array detector will be used in our instrument, so the mass spectrum will be detected in segments that we call mass windows. We situated our mass windows around argon, an abundant element in the ICP that could blind the detector. Skipping mass 40 (±1) leads to a mass ratio of 5.4 : 1 (analyzing masses 7 to 38) for the first mass window. That window corresponds to a high - mass trajectory radius of 9.5 cm and is the size of our mass spectrometer. We will measure the remainder of the mass spectrum in two additional mass windows containing masses 42 to 224 and 225 to 238 respectively.

The electric sector cancels second - order angular aberrations at the high mass trajectory (9.5 cm). The pertinent calculations, performed by Johnson and Nier (2), specify a ratio of 1.68 between the radii of the electric and magnetic sectors. The electric sector is equipped with shims, sometimes called Rose corrections (3), to correct for a drop in the electric field near the edge of the pole pieces. The electric sector is located between two electrodes called diaphragms or Herzog shunts (4), which produce field-free regions before and after the electric sector.

The mass spectrometer will require a three - stage sampling interface in order to be coupled to an ICP. To accelerate the ions into the spectrometer, the ICP source will float to the appropriate potential by applying a voltage to the sampling cone which sits in the plasma. Electrostatic lenses focus and accelerate the ions to a slit after the sampling process. The source slit should provide adequate resolution yet not reduce throughput excessively. The theoretical resolving power for a Mattauch - Herzog mass spectrometer is (5):

$$R = r_e/2S$$

where R is the theoretical resolving power, r_e is the radius of the electric sector, and S is the slit width. The design criterion for this instrument is a resolution of 500. MacSIMION (Montech, Australia) was used to simulate the ion optics of the ICPMS interface.

Design. All materials are stainless steel except for Macor spacers that separate the electrodes from the instrument body (see Figure 1). The apertures in both the sampler and skimmer cones are 1 mm. An electrically isolated lens tunnel follows the skimmer which acts as a lens and a barrier between the second and third stages. A series of six lenses follows the lens tunnel; three cylindrical lenses and three aperture lenses. The lenses focus the ions onto a slit 0.15 mm by 6.35 mm, producing a theoretical resolution of 533. After the slit, the ions travel through a channel 11.32 cm long to the electric sector. The electric

sector is between shunts 1.14 mm from the electric sector face to reduce fringing fields. The electric sector has a gap width of 1.52 cm and pole face of width 3.81 cm. An electromagnet with a gap width of 8.64 mm and capable of a 8 kilogauss field will be used for the magnetic sector.

Conclusion. A Mattauch - Herzog mass spectrograph has been designed for the inductively coupled plasma. Construction is underway at the Indiana University Mechanical Instruments Services.

Optimization of an ICP/High Resolution Mass Spectrometer System for Elemental Analysis

Otsuka, K., Kubota, E., JEOL Ltd., Akishima, Tokyo, Japan 196, and Musselman, B.D., JEOL USA, Inc., 11 Dearborn Road, Peabody, MA, USA 01960

The development of a new ICP/High Resolution Mass Spectrometer system has been undertaken. Prior reports have focused on the use of high resolution mass analysis to resolve various atomic ion species in order to obtain more reliable quantitative results through elimination of interferring ion species. This work describes improvements in the instrument control circuitry which have been added to permit more routine analysis of ICP-MS samples while operation in high resolution mode is being utilized.

Experiments describing the use of both magnetic field and acceleration voltage scanning to permit multi-element analysis at low solvent flow rates is also described. Low resolution quadrupole-based ICP-mass spectrometers typically utilize ion counting-based detectors for signal determination. This type of detection system is appropriate with low resolution mass filter systems where peak profile information is not required. The use of scanning methods in quadrupole-based instrument would in effect lead to oversampling of the peak of interest. Magnetic sector instruments with their higher resolution have the capability to resolve the signal from different isobaric ions. The information derived from peak shapes is useful in identification of possible interfering ion species since peak shapes as well as relative ion abundance can be determined from the raw data.

The use of magnetic field scanning desirable for survey scans where a variety of elements are being determined and wide dynamic range for ion detection is desired. The instrument

is operated with the acceleration voltage fixed to 5kV for this experiment. Ions enter the mass analyzer and by applcation of an increasing current through the coil of the electro-magnet the mass of the ions being passed to the detector is changed. By using this scanning method it is possible to detect all of the ions in the desired mass range less than a second. Repetitive scanning over the same mass range is used to effect signal averaging. This method is useful for qualitative analysis but not particularily effective for quantitative analysis.

The reproducibility of the ion current from a specific ion is a function of the ion statistics involved in the formation of that ion, the time period of its detection and the detector response to transitent signals. Using a magnetic field scan severely limits the interval of time that an ions derived from a specific ion specie strike the detector. In the case of a 2 second scan of the mass range 20 to 220 for example, the time period that the maximum ion ion current from an ion with m/z 50 would strike the detector is less than 1 millisecond.

In order to extend the time period for more accurate relative ion abundance determinations, it is necessary to use a different scan function. The control function required for this experiment requires that adjusting the magnetic field to pass the ion of interest, and then completeing an acceleration voltage sweep be effected for each ion abundance being measured. The net result of this action is that all of the ions of a small mass window are passed to the detector. The ion current from the ions is then integrated. In cases where interferring ion species have been observed, the integration of signal from only one of the ion packets in the prescribed mass window can be completed. Changing the time interval of the sweep, and adjusting the mass range passed to the detector yield more quantitative results as shown. The time interval of the sweep, or dwell time, can be set to any time period desired to improve the ion statistics.

ICP/TOFMS SYSTEM FOR USE IN ELEMENTAL ANALYSIS

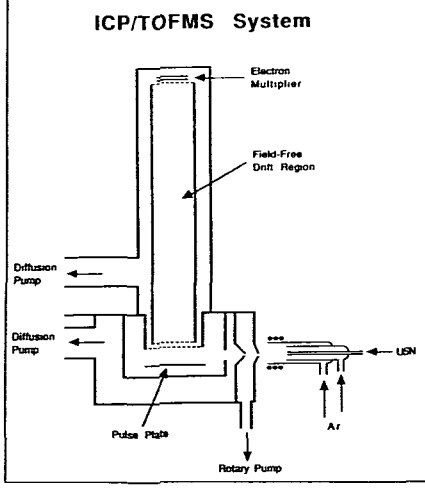
Mingin Wu, Paul B. Farnsworth, and Milton L. Lee
Department of Chemistry, Brigham Young University, Provo, UT 84602, USA

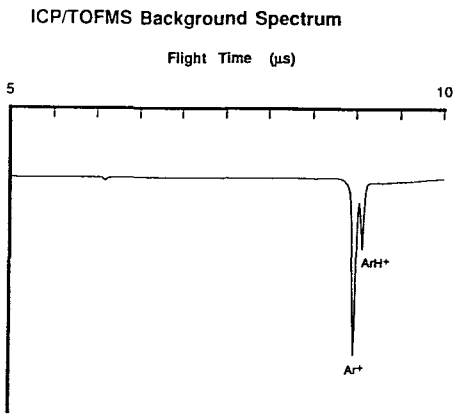
Chung Hang Sin and Edgar D. Lee
Sensar Corporation, 479 West Universal circle, Sandy, UT 84070, USA

The use of a time-of flight mass spectrometer (TOFMS) with inductively coupled plasma (ICP) ion source offers significant advantages over conventional ICP/MS systems with quadrupole mass analyzers. The attractive features of TOFMS include simplicity, high speed, high transmission efficiency, and instantaneous recording of the full mass spectrum. However, a TOFMS with an on-axis pulsing geometry suffers the shortcomings of low duty cycle and limited resolution.

The problem encountered with on-axis acceleration TOFMS can be overcome utilizing an orthogonal acceleration configuration. The unique right angle pulsing geometry allows the pulsing region to be refilled with extracted ions while a full spectrum is being recorded; this raises the duty cycle significantly. Also the resolution can be improved by accelerating the ions in a direction perpendicular to the ion beam.

In this paper, we describe an ICP/TOFMS system that has been developed based on an orthogonal acceleration configuration. The background spectra obtained with an Ar plasma indicates the current instrument has a mass resolution of 100 at 40 amu. Future work will center on ion focusing schemes and the use of a high speed data acquisition and processing system.





Elemental IonSpray-Mass Spectrometry: Analysis of Solutions of Metal Salts

J.J. Corr and D.J. Douglas, SCIEX, 55 Glen Cameron Rd., Thornhill, Ontario, Canada, L3T 1P2

Recent studies, by Kebarle and co-workers [1] and Agnes and Horlick [2] for example, have indicated that electrospray ionization-mass spectrometry (ESI-MS) has application to the study of the gas-phase chemistry of metal ions. Most recent work has involved spectra typically dominated by ion solvent clusters such as hydrated clusters of the metal ion or methanol/water metal ion clusters. These metal-solvent adducts ions complicate the spectra and increase detection limits by diluting the analyte ions over a number of ionic species. Agnes and Horlick [2] have succeeded in observing a number of spectra where bare metal ions (M^+) were the predominant ions and have demonstrated their ability to control the degree of clustering for a number of different ions.

In the present work some 45 elements ranging in mass from Na at 23 amu to U at 238 amu have been studied by IonSpray-mass spectrometry, the pnuematically assisted version of ESI-MS. Solutions were prepared by dissolving salts in water or from commercially available standards. Dilutions were with water, or methanol, or a water/methanol mixture. A differentially pumped interface was utilized on the front end of a MS-MS system. The N_2 curtain gas and the declustering potential (the voltage difference between the orifice through which the free jet expansion occurs and the skimmer in the differentialy pumped region) were chosen with other operating parameters to allow desired degrees of declustering. Seeking maximum declustering of multiply charged ions promoted charge reduction [1] and hence the observation of bare metal singly-charged ions.

In addition to bare metal ions, metal hydroxides or tightly bound metal oxides and their solvent adducts were easily obtainable and sometimes unavoidable. In many cases spectra such as those in Fig 1 were obtainable by varying the declustering in the interface In most cases the sensitivities obtained for the singly-charged bare metal ions or their oxides were within an order of magnitude of those attainable with inductively coupled plasma-mass spectrometry (ICP-MS). Detection limits of a few ppt to 0.5 ppb were measured for a range of elements. Since this technique does not have the same interferences as ICP-MS, it offers advantages in detection of certain elements, particularly in negative ion mode. Calibration curves (log-log) were linear over a range of four orders of magnitude in solution concentration and did not "roll over" before data accumulation was limited by detector saturation at a few million cps per ppm. The acid content of typical commercial standards increased the conductivity of diluted solutions causing a detrimental effect on analyte sensitivity.

Real world applications of such a technology should be plentiful An example of interest in the nuclear industry is the detection of ^{137}Cs in the presence of Ba, which has isotopes which interfere with Cs detection. To test such a possibilty, solutions containing ^{133}Cs and Ba were sprayed. Taking advantage of the variable declustering available it was possible to "shift" Ba up by 17 amu by detecting $BaOH^+$ while leaving much of the $^{133}Cs^+$ in the bare metal state.

The speciation capabilities of the technique have been demonstrated by selectively detecting selenite and selenate in the negative ion mode.

In this preliminary study the sensitivities and detection limits obtained, the ability to observe bare elemental ions in uncomplicated spectra, and the speciation capabilities indicate that the IonSpray-MS method has great promise as a complementary technique to ICP-MS for elemental analysis.

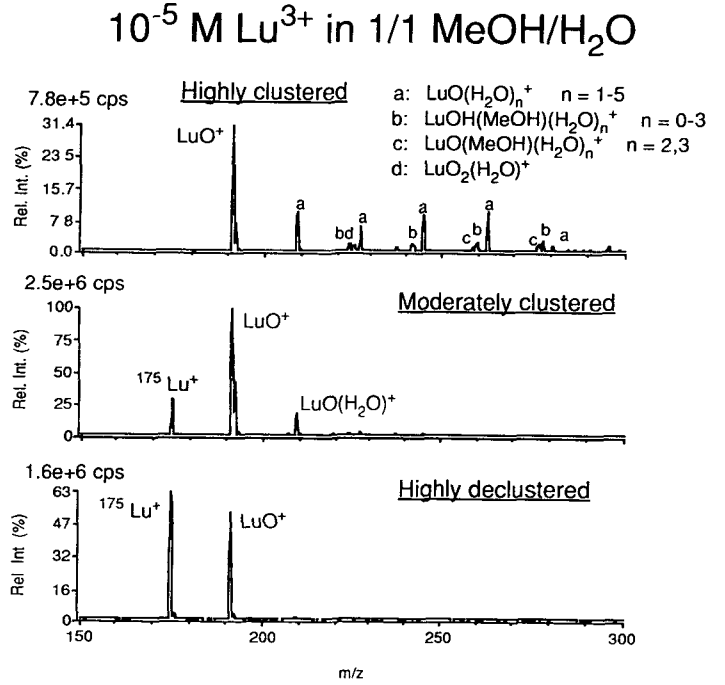
[4] Agnes, G.R. and Horlick, G. *Appl. Spectrosc.* **1992**, 46, 401



Spectra from 10^{-5} M $LuCl_3$ show that various degrees of declustering are possible. In this case LuO^+ could not be completely dissociated. Other rare earth elements show similar behaviour.

METAL ISOTOPE RATIO DETERMINATION WITH LASER DESORPTION TIME-OF-FLIGHT MASS SPECTROMETRY.

Iphigenia L. Koumenis[1], T. William Hutchens[2*] and Marvin L. Vestal[1]

[1]Vestec Corp., 9299 Kirby Dr, Houston, TX 77054 and [2]Protein Structure Laboratory, USDA/ARS Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, 1100 Bates, Houston, TX 77030, USA.

INTRODUCTION: Laser desorption time-of-flight mass spectrometry (LD/TOF-MS), a technique mainly used for the accurate molecular weight determination of intact macromolecules, is for the first time evaluated for the determination of stable metal isotopic ratios.

The need to eliminate the use of radiotracers for mineral bioavailability studies resulted in the development of several techniques that quantify stable isotope ratios. Current techniques for analysis, such as thermal ionization mass spectrometry (TIMS), inductively coupled plasma mass spectrometry (ICP/MS), fast atom bombardment mass spectrometry (FAB/MS) and resonance ionization mass spectrometry (RIMS), are either inadequate or extremely expensive and time consuming. Because of these limitations and the high cost of tracers, only a limited number of such studies are possible at the present time.

In this work, metal isotope ratios are determined using a LD/TOF mass spectrometer and emphasis is given to the high measurement precision required to permit accurate measurements. The factors that might affect the precision are systematically studied and the results are discussed in this presentation. The five metal ions studied were: Cu, Zn, Mg, Ca and Fe.

RESULTS: With the existing LD/TOF-MS instrument, we show that the technique can overcome the difficulties that the existing methods have: 1) all metals seem to be ionizable, thus overcoming the major drawback of thermal ionization 2) biological matrix components do not seem to cause any interference thus overcoming the major disadvantage of FAB/MS, and 3) accuracy and precision required for tracer work is feasible. Most importantly, the TOF-MS instrument permits all masses to be monitored simultaneously. This permits excellent precision on small quantities of materials, since small changes in isotope ratios can be detected. A substantial reduction in cost can result from using less tracer material.

The two limiting factors for the precision, as determined in these studies, are the digitizer statistics (when not operating in the ion limiting region of the EM gain) and the inadvertent saturation of the signal which distorts the ratio of the peaks.

The RSD is 0.2-0.5% for the higher abundance isotopes and 0.8-2.3% for the lower abundance isotopes. Those values can easily be improved if a 12-bit digitizer is used. The digitizer statistics can be further improved by averaging a higher number of laser shots. We have shown that there is no depletion of sample as a function of analysis time, thus a higher repetition laser can be employed to decrease the analysis time.

A computer-controlled electronic gate can also be incorporated in the digitizer to prevent signal distortion from inadvertent saturation. With this computer-controlled gate a desired window of the signal intensity is preset and any spectra outside the desired window are rejected.

Finally, the technique allows the detection of mixtures of two or more metals to be monitored simultaneously. This is extremely important because two or more metals can be studied at the same time within the same sample. Studies are underway to quantify the ratios of various free and peptide-bound metal ions to establish new approaches for the determination of complex equilibria constants.

DETERMINATION OF SUBPICOGRAM QUANTITIES OF TECHNETIUM-99 IN ENVIRONMENTAL SAMPLES BY POSITIVE THERMAL IONIZATION MASS SPECTROMETRY

J.M. Pochkowski and D.M. Beals
Environmental Technology Section
Savannah River Technology Center
Westinghouse Savannah River Company
Aiken, SC 29808 USA

Introduction

The Savannah River Technology Center's (SRTC) Environmental Technology Section (ETS) has developed a new isotope dilution method to measure ^{99}Tc concentrations in environmental samples. The instrumental detection limit is calculated to be 10 fg (0.17 fCi). The method uses a boric acid/silica gel ion enhancer coupled with positive thermal ionization mass spectrometry (PTI-MS).

Technetium-99 is a by-product of the Savannah River Site (SRS) operations. Technetium, as Tc_2O_7, is extremely volatile. Once in the environment, it readily forms the pertechnetate ion, TcO_4^-, which can be easily transported in hydrologic systems. The long-lived (2.15×10^5 yr) radionuclide is of concern because technetium has been shown to concentrate in the thyroid and GI tract of animals

In the past, most ^{99}Tc measurements have been made by radiochemical separation followed by low-level beta spectrometry. This method is neither specific nor sensitive enough for environmental sample analysis. Other mass spectrometry techniques suffer from hydrocarbon interferences, as well as, isobaric interferences caused by molybdenum and ruthenium not removed during sample preparation. The method developed by the ETS employs a "Delmore" style filament to reduce filament contributions, a rigorous chemical separation and cleanup procedure to reduce chemical blank, and a boric acid/silica gel slurry to allow the sample to be run at a lower temperature with increased ionization efficiency.

Methods

Aqueous samples to be analyzed for ^{99}Tc are spiked with 1.2 ng of ^{97}Tc After equilibration of the tracer, the technetium is separated using a chromatographic resin (TEVA-Spec) method developed by the ETS.[1] Samples are initially screened by isotope dilution/inductively coupled plasma-mass spectrometry (ID/ICP-MS). Five samples per hour can be analyzed with a procedure detection limit of 0.5 pCi/L. Approximately one-half of the concentrated sample is used for the ID/ICP-MS screening

The remaining sample may be further purified and concentrated using a microdistillation technique[2] and analyzed by PTI-MS to confirm a positive result or to decrease the effective detection limit. The microdistillation is performed in a precleaned Teflon vial. After the microdistillation, the technetium is in 4 µL of 0.1 M NH_4OH. The sample is then loaded onto a 0.007" deep "V" dimpled Delmore style zone refined rhenium filament using a camera driven microloader. The technetium is loaded in a 2 µL boric acid/silica gel (1:4) slurry sandwich. The microloader permits consistent point loading of 1 µL solutions onto the filament. The benefit of point loading is that it controls and limits sample contamination and increases sample ionization. This loading procedure gave better reproducibility than previously obtained by other techniques tried by the ETS.

Results

The isolated technetium is analyzed on a National Institute of Standards and Technology (NIST) designed and ETS modified 30.5 cm, 90° deflection, single sector mass spectrometer. We found the maximum stable intensity of the Tc^+ thermal ion signal to occur at a temperature of 1510 ± 50° C using this instrument and

loading procedure. At this temperature, Ru^+ and Mo^+ ions are not formed from the filament This lower temperature also minimizes the time and temperature dependent effects of isotopic fractionation.

Despite rigorous steps to clean the silica gel, organic species were still a minor problem. We found that by heating the sample filament at a temperature of 1100° C for 15 minutes prior to analysis, this interference was significantly reduced.

An average lower limit of detection for ^{99}Tc on this instrument was calculated to be 10 fg (6.1×10^7 atoms, 0 17 fCi) based on the analysis of the ^{97}Tc spike. Several standards containing 10 pg of ^{99}Tc were analyzed using the conditions described above and produced ion count rates of 6000 to 8000 counts per second for over an hour.

The ETS is responsible for performing low level analyses of ^{99}Tc in support of the SRS monitoring programs Air filter samples collected near the administrative area (3/700), the reprocessing areas (200 F, 200 H), and the burial grounds were analyzed for ^{99}Tc using the described technique. As shown in Table 1, the reprocessing areas have as much as 14 times greater ^{99}Tc activity than the site administration area.

Table 1

Location	^{99}Tc Activity (fCi±2σ)
3/700	0.67 ± 0.03
200 F	3.38 ± 0.04
200 H	9.59 ± 0.23
Burial Ground	0.91 ± 0.03

Conclusions

The success of these measurements demonstrates that the use of a highly selective chromatographic resin coupled with a PTI-MS boric acid/silica gel ion enhancer can yield ^{99}Tc measurements as low as 0.67 fCi. This sensitivity approaches that of negative thermal ionization without the need for additional filament preparation and instrument modification. Measurements of SRS environmental samples show that the movement of ^{99}Tc is limited to the SRS plant boundary. Future work includes detailed ^{99}Tc measurements of SRS waters, vegetation, soil, and air filters to study the migration of ^{99}Tc in the Savannah River Site environment.

Simultaneous Observation of UO^+ and U^+ Ion Ratios via Total Evaporation Thermal Ionization Mass Spectrometry

Douglas D. Jenson
Westinghouse Idaho Nuclear Company, Inc.
Idaho Falls, ID, 83403

Production of UO^+ ions was studied concurrently with isotopic analysis of uranium. A MAT 262V thermal ionization mass spectrometer was used; Faraday cups were positioned to collect data simultaneously at masses 233, 235, 238, 249, and 251. Sample material was NBS U-750 spiked with high purity ^{233}U. The ^{233}U allowed for isobaric corrections to the data. The technique of total sample evaporation and signal integration was used. Filament and sample-handling conditions were varied with an interest toward minimizing the UO^+/U^+ ratio during isotopic analysis.

A "worst-case" situation for UO^+ production is shown in Fig. 1. Oxide ions typically appear at slightly higher filament currents than the metal ions, but they grow rapidly and often dwarf the desired specie. If sample lifetime is sufficient, two U^+ peaks are observed, with corresponding UO^+ peaks.

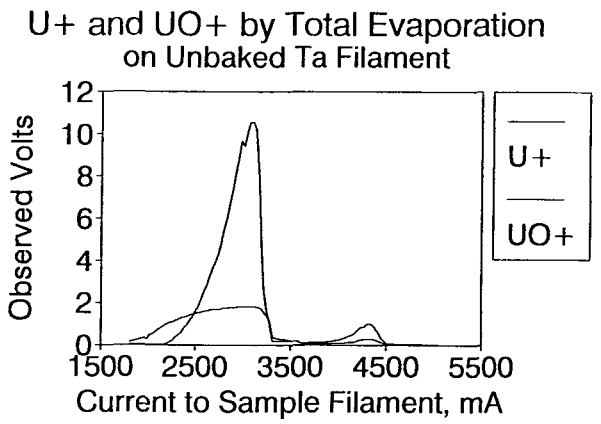

Figure 1. Evolution of U^+ and UO^+ ion beams as a function of current applied to sample filament.

The effects of various experimental conditions on the final integrated UO^+/U^+ ratio are shown in Table 1.

Filament	Condition	Relative Final UO^+/U^+
Ionizing	2250 °C	2
Ionizing	prebake in atmosphere	71
Ionizing	prebake in vacuum	100
Sample	baked Ta	2
Sample	baked Re	16
Sample	unbaked Re	33

Table 1. Relative final integrated UO^+/U^+ ratio compared to reference condition: unbaked ionizing filament at 2100 °C; sample loaded on unbaked Ta sample filament. Reference condition=100.

Small sample size improves the UO^+/U^+ ratio. Fig. 2 demonstrates this effect. Typically, 100 ng total U produces a good U^+ ion current while minimizing the UO^+.

As a "best case" combination, 100 ng U analyzed on a baked Re sample filament produces a final integrated UO^+/U^+ of 0.0002. However, the signal from baked Re tends to tail off gradually.[1]

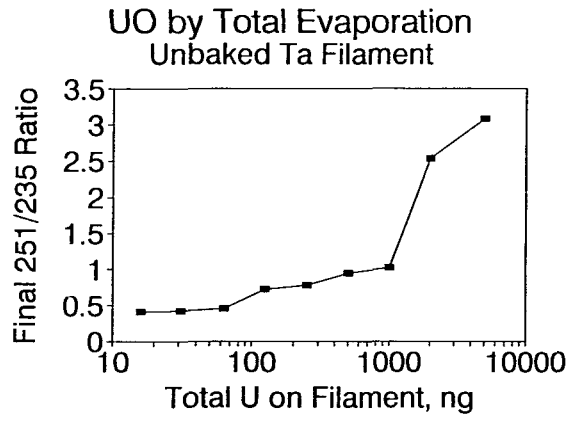

Fig. 2. Effect of sample size loaded on filament.

and Dept. of Pathology, University of California-San Diego, La Jolla, CA 92134

Introduction

Studies have shown that Pb may have adverse long term effects on cognitive and motor function at blood concentrations that are significantly below the level that gives rise to clinical symptoms. The potential for long term learning disabilities in several million American children caused by Pb toxicity has prompted the Centers for Disease Control to lower the "threshold of concern" for children from 250 ug/L to 100 ug/L of Pb in whole blood. At this concentration several million children are considered to have poisoning and to be at risk of irreversible mental and physical damage. In order to monitor lead exposure, assays for determining lead concentrations in biological samples are needed. Previously we have used diethyldithiocarbamate for chelating and extracting Pb from biological samples. We found that further reaction with 4-fluorophenyl magnesium bromide (4-FPMB) produced stable derivatives which can be measured with good precision and accuracy as well as very little memory effect when analyzed by GC/MS. Our initial studies were done with a magnetic sector MS instrument using on column GC injections. In the present study, we used a quadrupole GC/MS equipped with an autosampler to study para-substituted aryl lead compounds under EI, PCI and NCI.

Experimental

Reagents: Lead atomic absorption standard solution was from Aldrich. Lead nitrate (70.94 atom% ^{204}Pb, Oak Ridge National Laboratory), the enriched isotope used in memory effect studies was dissolved in deionized water with the addition of a few drops of concentrated HNO_3. Phenylmagnesium bromide (3.0 M), 4-fluorophenyl magnesium bromide (2.0 M), 4-chlorophenyl magnesium bromide (1.0 M), sodium diethyldithiocarbamate, Na(DEDTC), CF_3-phenyl bromide and anhydrous tetrahydrofuran were purchased from Aldrich. Ethyl ether and toluene were purchased from Baxter. Glacial acetic acid was obtained from Fisher, and sodium acetate was obtained from Mallinckrodt.

Grignard Preparation: CF_3-phenyl magnesium bromide was prepared to be a 1.0 M solution in 10 mL of THF. After the glassware was assembled, a stir bar and 0.242 g (0.01 M) Mg turnings were added to the round bottom flask. Under argon, 5 mL of toluene was added and boiled through the system to remove any residual water. After cooling, THF was added through the septum. The CF_3-phenyl bromide (0.01 M) was added dropwise, with stirring and refluxing, until a reaction was visible. After the reaction appeared complete, i.e. the magnesium appeared mostly gone, the solution was removed with a syringe and stored in a dry, argon-filled plastic tube fitted with a rubber septum.

Derivitization: The sample was buffered to pH 4 with acetate buffer and reacted with a 20 mM solution of Na(DEDTC). The $Pb(DEDTC)_2$ chelate was extracted into 1 mL of toluene and evaporated to dryness

under nitrogen at 40°C. The samples were then reconstituted with 100 µL of THF, and 5 to 10 drops of Grignard were added. Excess Grignard was destroyed with 100 µL of 10% isopropyl alcohol in toluene, followed by addition of 1mL of 1N HNO_3. The organic layer was extracted into 1mL of toluene, then dried under nitrogen at 40°C. Samples were reconstituted in 200 µL of toluene.

Instrument Conditions: Samples were analyzed using splitless injection onto a 10m x 0.32mm DB-1 bonded phase fused silica capillary column. The GC was temperature programmed from 160°C (one minute hold), to 280°C degrees at 20°C/min where it was kept for 3 minutes. Total chromatography time was 10 minutes. Approximate retention times for phenyl, 4-Cl-phenyl, 4-F-phenyl and 4-CF_3-phenyl Pb compounds were 5.0, 9.0, 4.8 and 4.3 minutes respectively. For comparison of EI, PCI and NCI, equal amounts of the lead derivatives were injected. EI tuning was optimized at m/z 100 and 502 of perfluorotributylamine (PFTBA) ions. Methane was used as the reagent gas for PCI and NCI. PFTBA was also used to optimize tuning for chemical ionizations; PCI tuning was optimized at m/z 219 and 414 while NCI tuning was optimized at m/z 414 and 633. Studies using NCI for memory, accuracy and precision studies were done by injecting 5 ng of natural Pb or 8 ng of ^{204}Pb as the 4-FP derivative and measuring the $[M-L]^-$ cluster (m/z 489, 491, 492 and 493). Isotope ratios were determined by integrating peak areas.

Results and Discussion

Precision: The precision obtained for $(4\text{-F-phenyl})_4Pb$ in the NCI mode when determining the more abundant isotopes in naturally occurring Pb at the 5 ng level was a C.V. of 0.51% or less.

Memory Effect: The slight memory effect observed from analysis of lead chelates with 330-fold differences in the ratios of m/z 493 to m/z 489, corresponding to ^{208}Pb and ^{204}Pb. Since this limiting case would practically never be encountered, memory effect does not limit this method.

Signal-to-noise Ratio: Using chromatographic peak areas and a base noise level of 10 area units, the signal-to-noise ratios can be calculated. These results for the different Pb compounds are compared according to ionization mode. The $(4\text{-F-phenyl})_4Pb$ compound using NCI conditions gave the most intense S/N ratio. NCI analysis of a sample of natural lead (5 ng Pb on column) in aqueous solution gave a signal to noise ratio of 1089:1 for the weakest signal, ^{204}Pb. This suggests that a sample in the low pg range would give an acceptable signal-to-noise ratio of 10.

Conclusion

Stable isotope dilution NCI GC-MS using 4FMB derivatization of the DEDTC chelate eliminated memory effect. This method enhances the sensitivity by a factor of 75 and increases the precision by a factor of 4. The increased sensitivity and minimal memory effect using an autosampler equipped quadrupole instrument in the NCI mode increases the utility of the GC/MS analysis of Pb in medical and environmental applications.

A STUDY OF MESO-SUBSTITUTED ZINC TETRABENZPORPHYRINS BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY

J.B. Carlson, P. Vouros

Department of Chemistry and Barnett Institute for Chemical Analysis
Northeastern University, Boston, MA 02115

Metallotetrabenzporphyrins are being extensively investigated because of their large and rapid nonlinear optical response[1]. The nonlinear response has applications in the fields of optical communications and optical data processing. The nonlinear optical response is enhanced by the synthesis of metallobenzporphyrins with substituted phenyl rings in the meso position[2].

The structure for zinc tetrabenzporphyrin is shown in Figure 1, where "R" represents the meso position. Nine different meso-substituted zinc tetrabenzporphyrins with a broad range of electron donating or electron withdrawing characteristics were evaluated where R = p-dimethylaminophenyl-, p-hydroxyphenyl-, p-decyloxyphenyl-, p-methoxyphenyl-, phenyl-, p-chlorophenyl-, m-fluorophenyl-, p-trifluoromethylphenyl-, and perfluorophenyl-.

A VG Quattro triple quadrupole mass spectrometer with a cesium ion Fast Atom Bombardment source was used for the analysis. The meso-substituted zinc tetrabenzporphyrins were dissolved in 3-nitrobenzyl alcohol and placed on a static probe for analysis.

FAB/MS provides a rapid technique for structural confirmation of the meso-substituted zinc tetrabenzporphyrins. In addition to molecular weight information, the mass envelope of naturally occurring isotopes is a source of information for the elemental composition of these compounds. The distinctive isotopic abundance pattern unique to each of these compounds compares favorably with theoretically calculated isotopic abundances.

The loss of successive meso-substituents is the primary fragmentation pathway for the zinc tetrabenzporphyrins. The fragmentation is dependent upon the electron withdrawing or electron donating characteristics of the meso-substituent. No fragmentation is observed for zinc meso-tetra-(p-dimethylaminophenyl)tetrabenzporphyrin while the fragment representing the loss of a single meso-substituent is the predominant ion observed in the mass spectrum of zinc meso-tetraperfluorophenyltetrabenzporphyrin. The susceptibility of the zinc tetrabenzporphyrins to fragmentation is related to the nonlinear optical properties of these compounds.

As a representative example, the FAB/MS spectrum of zinc meso-tetraphenyltetrabenzporphyrin is shown in Figure 2. The mass envelope starting at m/z 876 represents the molecular ion and the fragment at m/z 800 represents the loss of a single meso-substituent (R).

Figure 1: The structure of zinc tetrabenzporphyrin where "R" is the meso position.

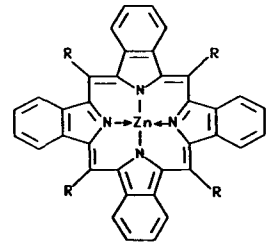

Figure 2: The FAB mass spectrum of zinc meso-tetraphenyltetrabenzporphyrin.

Gas Chromatography-Combustion Isotope Ratio Mass Spectrometry (GCC-IRMS) at Femtomole Carbon Levels and High Enrichments

Keith J. Goodman & J. Thomas Brenna
Division of Nutritional Sciences
Cornell University
Ithaca, New York

Introduction

Since its introduction in 1978, GCC-IRMS (Goodman & Brenna, 1992, Analyt. Chem. 64, 1088) has been employed almost exclusively in studies of $^{13}C/^{12}C$ fractionation due to natural processes. High precision is required in these studies since natural processes usually result in subtle changes in isotope composition. Minimum sample loads of 10ng can be determined to delta (PDB) <0.3°/oo. Terrestrial isotope segregation rarely results in ratios beyond the narrow range of -60°/oo<delta(PDB)<30°/oo.

Recently, we and others have reported application of GCC-IRMS to biomedical tracer experiments using artifically enriched precursors. Such experiments may result in samples with orders of magnitude greater enrichment than natural variation. Therefore, lower precision is often tolerable for investigation of small highly enriched samples. We have characterized the precision and accuracy for enriched samples ≥14°/oo and quantities on column below 250 picomoles carbon

Experimental

The first high sensitivity GCC-IRMS system, a Finnigan 252 interfaced to a Varian 3400 GC, was operated with splitless injection, using the temperature profile 60 °C(1min) to 190 °C(10 min) ramping at 50 °C/min, and a 30 J+W DB Wax 0.25um 0.32mm 30 meter column.

The instrument was operated exclusively in high sensitivity mode with the ion source window closed completely. Methyl stearate (Me18:0) of 36% 13C content was diluted serially with natural abundance Me18:0 to generate a series of eight standards with defined isotope ratio to 14°/oo. Each standard was injected in triplicate at total quantity on-column ranging from about 250 picomoles to 50 femtomoles carbon (minimum sample of less than 1 picogram). Standard deviations and delta-PDB values were generated using vendor-supplied software.

Results and Discussion

"Apparent" delta-PDBs and standard deviations were plotted versus quantity on-column for enrichment levels approximately 14, 50, 100, 500, 1000, 8200, 27000, 37700 °/oo. Typical plots are shown in figures 1 & 2 for the 500°/oo level. Enrichment levels for 1000 °/oo and below plateau above about 1 pmole.

Precision for these levels is usually well within 1°/oo standard deviations, with all data considered and no outliers thrown out. Below this value systematic error is observed. For 100°/oo and below, apparent isotope ratios increase, and for 500°/oo and above apparent isotope ratios decrease. At the highest levels investigated, about 100 pmoles, isotope ratios are offset slightly and in the same direction as is observed at lower levels, which appears to be related to an increasing mismatch between sample and standard CO2 total levels. Below 1 pmole, isotope ratios are a strong function of sample size.

For 8200°/oo and above, isotope ratios do not plateau at any sample size on column. This appears to be due to the limited dynamic range of the detection/electronics, which allow only about 1000. For highly enriched compounds, the mass 45 signal is at very high levels while the mass 44 detector is simultaneously at very low levels.

These data indicate that $^{13}C/^{12}C$ isotope ratios can accurately and precisely be measured for samples sizes above 1 picomole carbon, below 1000°/oo for samples which do not substantially exceed the level of the standard CO_2 Outside these limits measurements can be made with great attention to sample standard matching, dilution of high enrichment samples with natural abundance material to reduce enrichment, and the use of calibrated standards internal to the sample.

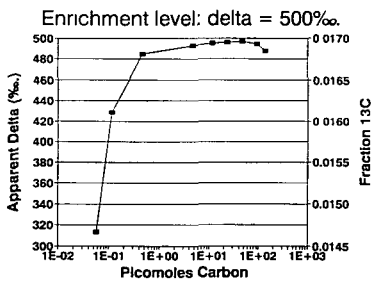

Figure 2

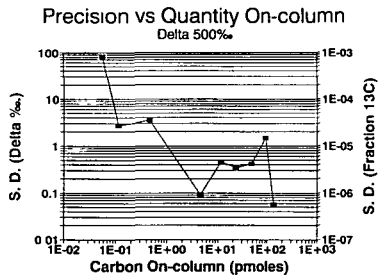

Comparison of Polymer Additives Analysis by High Temperature GC/MS vs. Particle Beam LC/MS

*R.A. Ludicky, G.B. Kenion, D.E. Doster and P.D. Souchek
Morton International, 1275 Lake Avenue, Woodstock, IL 60098

Polymer additives include many compound classes and a variety of molecular weights. Ultraviolet stabilizers and antioxidants include small compounds such as Tinuvin 326 (MW = 315), hindered phenolics such as Ethanox 330 (MW = 774) and phosphite esters such as tris(nonylphenyl) phosphite (MW = 688). The smaller species are on the low end of what can be analyzed using a particle beam LC/MS interface while the largest species are not gas chromatographable. With the advent of high temperature capillary GC columns, the area of common ground between GC/MS and LC/MS has been significantly increased. A comprehensive comparison of quantitative (precision and sensitivity) and qualitative (quality of mass spectra and chromatography) will be presented to facilitate the best choice for analysis of most of the more common antioxidants and UV stabilizers.

All the work described here was performed on an Extrel ELQ 400 GC/LC/MS system. The GC separations were performed on a J&W DB-5 high temperature capillary GC column while LC/MS was performed on a two column set consisting of a Phenomenex 250 cm by 4.6 cm W-Porex 5 phenyl 300 Angstrom column and a 250 cm by 4.6 cm Spherex 5 phenyl 80 Angstrom column. The LC flow rate was 0.5 ml per minute. Fourteen Antioxidants and UV stabilizers were chosen for this study. These additives were Ethanox 330, Irganox 1024, Irganox 1035, Irganox 1076, Irganox 3114, Naugard 445, Naugard 524, Tinuvin 144, Tinuvin 326, Tinuvin 327, Tinuvin 328, Tinuvin 770, Tinuvin 900 and Wytox 312.

Both GC/MS and LC/MS gave nearly identical spectra for the same additives. These two methods, however, gave far different detection limits. The detection limits of the seven compounds which could be analyzed by both techniques are:

Additive	GC/MS Detection Limit	LC/MS Detection Limit
Tinuvin 326	10 nanograms	500 nanograms
Tinuvin 327	5 nanograms	600 nanograms
Tinuvin 328	5 nanograms	600 nanograms
Naugard 445	6 nanograms	300 nanograms
Naugard 524	5 nanograms	600 nanograms
Tinuvin 900	5 nanograms	600 nanograms
Irganox 1076	6 nanograms	1000 nanograms

GC/MS is more sensitive than LC/MS. LC/MS, however, is more universal. Of the fourteen compounds chosen for this study only eight could be analyzed by GC/MS. Twelve of the compounds, on the other hand could be analyzed by LC/MS. The only two compounds which could not be analyzed by LC/MS, Tinuvins 144 and 770, probably could be analyzed if different LC/MS conditions were chosen.

LC/MS was far more precise than GC/MS. Precision data is given below for the seven compounds which could be analyzed by both techniques.

Additive	Relative Standard Deviation GC/MS	Relative Standard Deviation LC/MS
Tinuvin 326	35 %	18 %
Tinuvin 327	36 %	11 %
Tinuvin 328	36 %	11 %
Naugard 445	50 %	11 %
Naugard 524	42 %	22 %
Tinuvin 900	46 %	11 %
Irganox 1076	75 %	14 %

Relative standard deviation for GC/MS was determined by six replicate injections while relative standard deviation for LC/MS was determined by five replicate injections.

Fourteen polymer additives were analyzed by LC and GC/MS. GC/MS is more sensitive but LC/MS is more precise and universal. The data presented here tends to indicate that particle beam LC/MS polymer additive analyses should be done as quickly as possible to give the sharpest peaks. Sharp peaks give better detection limits. The data also indicates that quantitative GC/MS analysis is difficult using standard GC and GC/MS hardware. GC/MS analysis of polymer additives may be improved by use of cold on column injectors which have recently become available. Quick analyses and less thermal stress should improve LC/MS and GC/MS polymer additive analyses.

BASICITY AND SOLVATION EFFECTS IN ELECTROSPRAY MASS SPECTROMETRY

M. Shahgholi and K.D. Cook, Chemistry Department, The University of Tennessee, Knoxville, TN 37996-1600, and M.V. Buchanan, Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120

Several factors have been reported to affect the response of electrospray (ES) MS. For example, hydration energies have been considered in deriving a quantitative model for predicting the response of amino acids[1] and tripeptides[2]. Correlation has also been reported between the pK_b of some thirty amines and their ES response[3]. Furthermore, a role for gas phase chemistry has been suggested in reporting the occurrence of gas phase proton transfer reactions in the drift space between the needle and the mass spectrometer inlet[2]. The present investigation seeks to determine whether thermochemical measures of solvation and basicity are useful in predicting ES response for compounds of varying chemical functionality. Towards this end, two classes of compounds with known thermochemistry, n-alkyl amines and amino acids, were tested for correlation of their ES response with solution phase acidity, pK_a, gas phase basicity, polarizability, and heats of solvation. In this latter case, the heat of solvation, $\Delta H_s^0(BH^+)$, is comprised of a neutral term, $\Delta H_s^0(B)$, and an electrostatic term, $\Delta H_s^0(BH^+)^{el}$[4].

Amines were dissolved in methanol at a concentration of 100 μM. Amino acids were prepared in 50:50 (v/v) methanol:water at a concentration of 100 μM. An ES source similar to Chait's was constructed and interfaced to an Extrel (Model 065-2) quadrupole mass spectrometer. Samples were electrosprayed at 4 μL/min with a needle potential of +3.0 to 3.5 kV. The capillary and skimmer potentials were +90-130 V and 45-65 V, respectively. The inlet capillary was heated to 100-120°C for desolvation of the sampled spray.

The n-alkyl amines used in these correlation studies were propyl- and butylamine (1°); diethyl-, dipropyl-, and dibutylamine (2°); triethyl-, tripropyl-, and tributylamine (3°). The amino acids examined were alanine, isoleucine, phenylalanine, proline, threonine, valine, and glycine. The ES response of the amines and amino acids were tested for correlation with pK_a, gas phase basicity, solvation energies, and polarizability, as estimated from the r^2 "goodness of fit" parameter for a quadratic least squares fit of the data ($r^2=1.0$ for perfect correlation, $r^2=0$ for no correlation). Among the parameters tested, polarizability, pK_a, and the neutral heat of solvation, $\Delta H_s^0(B)$, correlate well ($r^2>0.7$) with the observed ES response of the alkylamines. In considering gas phase basicities and solvation energies of the alkylammonium ions, $\Delta H_s^0(BH^+)$ and $\Delta H_s^0(BH^+)^{el}$, correlation is also observed, and in fact a distinction can be made among 1°, 2° and 3° amines (e.g., Figure 1). The strong correlations observed reflect the general similarity of the various members of this homologous series of compounds.

The amino acids studied, on the other hand, represent a diverse group of compounds. The correlation of the various parameters with the ES response of the amino acids was less well-defined. Only poor correlations ($r^2<0.5$) with pK_a, gas phase basicities, and the electrostatic solvation energies, $\Delta H_s^0(BH^+)^{el}$, were observed (e.g., Figure 2). The only strong correlation observed was with polarizability ($r^2=0.9$).

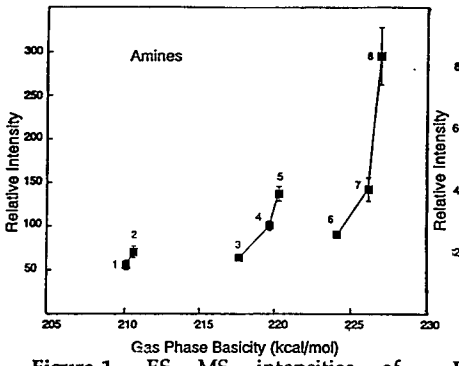

Figure 1. ES MS intensities of alkylamines versus gas phase basicity. (1) propylamine; (2) butylamine; (3) diethylamine; (4) dipropylamine; (5) dibutylamine; (6) triethylamine; (7) tripropylamine; (8) tributylamine

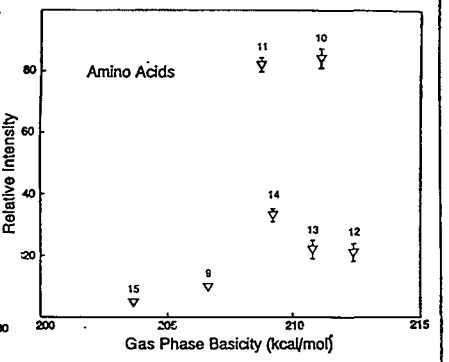

Figure 2. ES MS intensities of amino acids versus gas phase basicity. (9) Ala; (10) Ile; (11) Phe; (12) Pro; (13) Thr; (14) Val; (15) Gly

Thermochemical data utilized for correlations were obtained from J.E. Bartmess[5].

Sensitivity, Dynamic Range and Solvent Effects in Electrospray (Ionspray) Ionization

° R. Kostiainen and * A.P. Bruins, University Centre for Pharmacy, A Deusinglaan 2, 9713 AW Groningen, The Netherlands

In spite of the growing number of publications describing the applications of electrospray, there is a lack of understanding of the details of the ionization process. Fenn and Kebarle and their coworkers have studied aspects of the fundamental limitations of the electrospray process Concerning the dynamic range of electrospray and ionspray, the upper limit of the sample ion signal observed after mass analysis is reached at approximately 10^{-5}M sample concentration[1], both for proteins and for small molecules.

We have used the ionspray version of electrospray in a home built atmospheric pressure ionization source on a NERMAG 3010 mass spectrometer Other equipment: Jasco Familic 100N syringe pump and Brownlee syringe pump operating at 5 or 10 μL/min; Rheodyne injectors with 20μL loops to generate broad and reproducible sample bands, so that peak height is not affected by dead volume or tailing. Sample solutions: tetrabutylammonium bromide in 95% acetonitrile + 5% methanol. The amount of charge on droplets leaving the nebulizer is measured as depicted in Fig. 1.

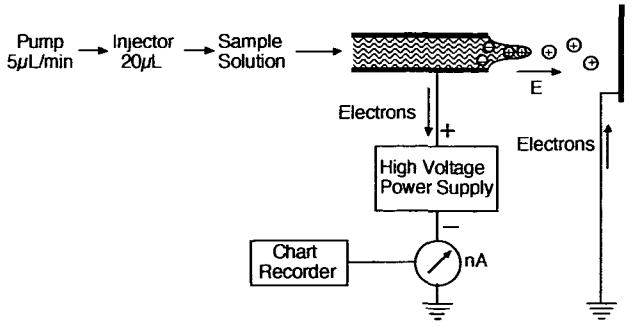

Figure 1 Measurement of spray current

Kebarle et al. have described electrospray as a special case of an electrolysis cell[2]. Positive charge on droplets is the result of removal of negative ions (charge separation). Since the number of available negative ions is proportional to sample concentration, charge separation and spray current are a function of sample concentration. Theory has predicted and experiments have shown that the spray current is proportional to c^n (c: concentration; n= 0.2 – 0.4). Figure 2 shows that the ion signal reaches a plateau at 10^{-5}M, while the spray current (charge on droplets) keeps rising. Insufficient charge on droplets thus does not appear to be the major cause of signal saturation.

The upper limit to the ion signal may also be due to an upper limit on the number of ions

that can be taken from the source into the vacuum of the mass analyzer. By repositioning the sprayer to a longer distance from the ion sampling orifice, the total number of ions transported into the mass analyzer is reduced. Figure 2 also shows that ion signal limitation still exists when the sprayer is placed far away. Thus, limitation in the transport of ions is ruled out as a cause of ion signal limitation.

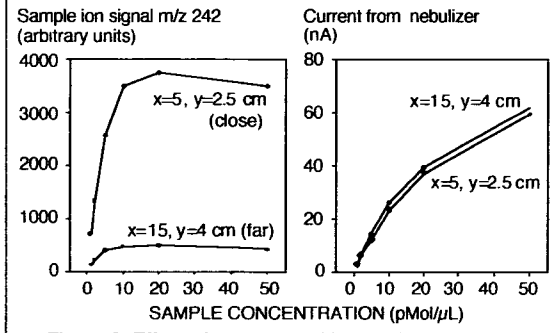

Figure 2. Effect of sprayer position on dynamic range

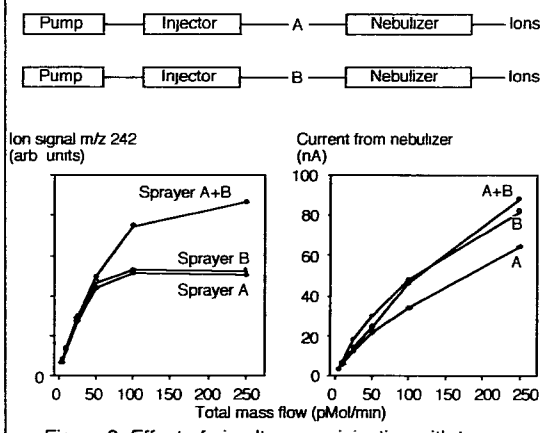

Figure 3 Effect of simultaneous injection with two injectors and two sprayers, after twofold dilution (A+B)

Next, the limitation could be inherent in the nebulization (droplet formation) process By splitting the flow into two sprayers operating in parallel, one could generate more droplets, or spread droplets in order to reduce interaction between droplets. No improvement was obtained in such a simple split into two nebulizers

If on the other hand the sample concentration is halved, and two simultaneous injections are made, a shown in figure 3, so that the total sample mass via two sprayers is equal to the total sample mass injected into one sprayer, at the original concentration, then the dynamic range is extended.

Thus, the dynamic range is not limited by the total amount of sample introduced into the source, but related to concentration *per se*.

For the time being, we conclude that the sample ion signal limitation is due to a concentration dependent limitation in the liberation of ions from charged droplets. The details are still unclear to us.

Investigation of Metal-Ligand Aqueous Solution Chemistry using Electrospray Mass Spectrometry

Roger Guevremont, K.W.M. Siu, J.C.Y. Le Blanc[a], and Z.L. Cheng, Institute for Environmental Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6

The ions observed in electrospray (ES) mass spectrometry appear to originate from preformed ions in aqueous solution. In recent work we have investigated the speciation of metals in aqueous solution, and have considered the role of droplet evaporation in electrospray mass spectrometry. Preliminary results suggest that the ions are formed early in the ES process, and therefore the composition of the aqueous phase from which the ions are evolved more closely resembles that of the bulk solution than previously thought possible. The characteristic profile of multiply charged ions observed in the electrospray spectrum of proteins appears to originate from an array of pre-formed multiply charged protein ions in aqueous solution. An aqueous solution equilibrium model based on the pKa's of acidic and basic sites on proteins can be used to compare the distribution of ions in solution to the shape of the ion abundance profile in the electrospray mass spectrum[1]. We will now consider the extension of this work to the speciation of labile metal-ligand complexes in solution.

Electrospray measurements were performed using a TAGA 6000E (SCIEX Inc., Thornhill, Ont. Canada) triple quadrupole mass spectrometer. To ensure reliable measurement of relative ion abundance data, the mass resolution was decreased from unit mass resolution to the extent that two or more measurements were taken near the apex of every peak. Samples were continuously infused at a rate of 20µL/min through a 100µm ID stainless steel capillary held about 3kV. Stable operation of electrospray was achieved with the needle approximately 1.5 cm from the instrument orifice, and with a measured stable current of between 70 and 120 nA (positive ion mode).

The aqueous solution acid-base chemistry of Deferoxamine (DFA) MW=561 was studied using positive ion electrospray of a series of solutions of various pH (adjusted with piperidine). Simplex calculations were used determine the formation constant which best matched the variation in species concentration as a function of pH. The species concentrations were calculated using COMICS [2]. The pKa for the protonation of DFA (H_3L to H_4L^+) appears in Table I.

Complexation of DFA with La, Yb and Y were investigated since these metals each provided several positively charged electrospray ions. Samples were prepared with 1 or 2 mM of metal ion and 1 mM of DFA and pH adjusted with piperidine (pKa=11.1). Formation constants of species were calculated by Simplex optimization of the constants to achieve the best match between the ES ion abundance and the calculated species concentration as a function of pH. The aqueous solution model included protonation of the DFA (pKa_2=9.7, pKa_3=9.03, pKa_4=8.39 where the fully protonated ligand is taken to be H_4L^+) and several known metal-ligand complexes

and metal-hydroxide complexes (since the samples were between pH 3 and pH 10). Typical species included ML, MHL, MH_2L, MH_3L, and hydroxide species. Table I includes formation constants of several complexes.

Table I. Stability Constants of DFA Complexes.

Complex	DFA	Yb:DFA (1:1)	La:DFA (1:1)	La:DFA (2:1)	Y:DFA (1:1)
H4L/H3L	8.5(8.39)*				
MHL/M.HL		17.1(16.0)	13.6(10.9)	13.3(10.9)	18.5
MH2L/MHL.H		5.4(4.7)	6.0(6.4)	6.3(6.4)	5.8
MH3L/MH2L.H		2.5(4.4)	5.8(6.0)		4.2

Using a coaxial sheath flow electrospray probe [1] which is stable over several hours of operation, peptides with differing acidities have been investigated by Flow Injection Analysis (FIA) and by capillary electrophoresis (CE) ESMS on aminopropylsilane-treated capillaries [2] The sensitivities of the most abundant mono- or doubly-protonated molecules have been compared. For acidic peptides one order of magnitude less sensitivity than for the basic peptides has been found, both in FIA and CE ESMS. In contrast with peptide mixture analysis by ^{252}Cf-plasma desorption mass spectrometry, where suppression effects of basic, hydrophobic peptides on the ion intensities of acidic, hydrophilic peptides have been observed [3], these effects were not found in the mixture analysis by ESMS.

Coaxial sheath flow ESMS was further applied to proteins (Cytochrome c and Lysozyme), injected in solutions with pH's from 2 to 10 with a constant sheath flow composition (50:50, MeOH 3% acetic acid, pH 2), and with SDS addition in the sample solution. Using basic sample-solutions, a shift in the envelope of mass-to-charge ratios to higher masses is observed. Although the resulting pH at the probe tip is about 3 5 - when measuring the mixture of basic sample-solvent (pH 10) and sheath-flow (pH 2) directly at the needle-tip without spraying - the resulting charge distribution suggests that the conformation is more like that from the pure sample-solution and is not influenced by the sheath flow solvent.

For ES mass spectra aquisition of SDS- or high amounts of salt-containing protein-solutions (10 mM NaOH), higher repeller voltages were used on a Vestec 201A-quadrupole mass spectrometer Repeller voltages of 40 to 80 V can be used for CID-fragmentation of peptides, even higher repeller voltages (100 to 150 V) applied to a mixture of lysozyme and SDS (10:1 / w:w) can lead to dissociation of protein-dodecylsulfate complexes (Fig. 1 a,b) resulting in easily interpretable mass spectra (Fig 1 c,d) and may be advantageous in the analysis of biological samples

THE USE OF MULTIPLE SPRAYER SYSTEM IN THE ELECTROSPRAY MASS SPECTROMETRY

R. Kostiainen[1,2] and A.P. Bruins[1]

2. Environmental Laboratory of Helsinki, Helsinginkatu 24, 00530 Helsinki, Finland

A limited usable flow rate (2-10 µl/min) in the electrospray mass spectrometry (ESMS) is a well known phenomenon, which is reported to be due to droplet coarsening at high flow rates. In this study we present the use of two and four sprayers instead of one in ESMS and in ionspray (pneumatically assisted electrospray) mass spectrometry (ISMS). In our experiments the flow from a liquid chromatograph (LC) was divided to the sprayers with Valco minimum dead volume T-pieces and fused silica capillaries (Fig. 1). The flow rate in the individual sprayer was decreased with the number of sprayers, while the flow rate from the LC was not decreased Tetrabutylammonium bromide (TBABr, 2 pmol/µl) was used as a reference compound. The measurements were made in MeCN/MeOH 95/5%. The injection volume was 20 µl causing flat topped peaks, which were broad enough to check the stability of the ion current m/z 242 (TBA^+) The instrument was Nermag R 3010 triple quadrupole mass spectrometer equipped with a custom-made atmospheric pressure ionization (API) source.

The dependence of abundance of the ion current m/z 242 (TBA^+) on the flow rate measured with one, two, and four sprayers in ES and IS has been presented in Figs. 2 and 3 Fig. 2 clearly shows that the usable flow rate can be increased in ES by increasing the number of sprayers. This is because the flow rate in the individual sprayer and thus the size of the initial droplet is decreased with the number of sprayers In our experiments it was possible to see the spray against an intense light during the acquisition. We recognized that at the flow rate, where the ion current decreased, also the shape of the spray changed due to sudden coarsening of the droplets The usable flow rates from the LC for one, two, and four sprayers are 4-10, 4-50, and 10-75 µl/min, respectively The flow rate of 4-10 µl/min from the LC (1-2.5 µl/min in the individual sprayer) in the four sprayer system is too low for an efficient dispersion of the liquid

The measurements with one, two, and four sprayers in ISMS (Fig. 3) at fixed position (x=7, y=2.5 cm; x=axial distance, y=off axis distance) resulted in very similar curves in contrast to curves obtained with ES (Fig. 2). The droplet size distribution is less dependent on the flow rate in IS than in ES due to pneumatic nebulization in IS We recognized visually that at high flow rates the size of the droplets in IS are significantly smaller than in ES. The smaller droplet size in IS leads correspondingly to better sensitivity in IS than in ES at high flow rates as shown in Figs. 2 and 3.

Although a reasonably good sensitivity was obtained in ISMS even at a flow rate of 1000 µl/min, the signal becomes very unstable above 200 µl/min leading to noisy background. However, the stability of the signal is highly dependent on the positioning of the sprayer. To keep good stability at high flow rates the sprayer must be removed to more off axis and to a larger distance from the sampling orifice. The positioning of the sprayer is more critical in ES than IS.

The dependence of the ion signal on the flow rate in IS was measured with one, two, and four sprayers and by repositioning the sprayers to achieve the best possible combination of high intensity and good stability for each flow rate (Fig.4). To maintain good stability the sprayer was moved to a longer distance from the sampling orifice, when the flow rate was increased. The operation at a long distance leads to decreased sensitivity. However, we recognized that the four sprayer system can be operated closer the sampling orifice than the one or two sprayer systems This means that the usable flow rate can be enhanced by using several sprayers instead of one.

Characterization of a New Atmospheric Pressure Ionization Interface for Liquid Chromatography/Mass Spectrometry

Mark Hail, Iain Mylchreest, Finnigan MAT, San Jose, CA 95134.

In the past few years, the atmospheric pressure ionization (API) interface has emerged as the interface of choice for high-sensitivity LC/MS. Recently, we have designed a new API interface which may be operated in either electrospray (ESI) or atmospheric pressure chemical ionization (APCI) mode with liquid flow rates of up to 2 mL/min. In this interface, ions created via ESI or APCI are desolvated and transported from atmosphere to vacuum through a heated metal capillary tube. The ions exiting the capillary region at 0.7 Torr are focused by a tube lens through a skimmer orifice into the differentially-pumped vacuum manifold of a single quadrupole or triple quadrupole mass spectrometer.

An rf-only octapole, which transports the ions from the skimmer exit to the quadrupole entrance, has replaced the 3 electrostatic lenses used in our previous ESI source. The octapole, which exerts a lateral restoring force on the ions, can efficiently contain ions through this 1 mTorr region with minimal losses due to scattering. This is particularly significant for the detection of low mass ions, which are more susceptible to these collisional scattering losses. For example, the spectra in Figure 1 show that signal response for the tetrapeptide Met-Arg-Phe-Ala increased 70-fold, while that of myoglobin increased 5-fold when the octapole was used in place of the 3-lens system.

The capability to operate in ESI mode over a wide range of liquid flow rates (1μL/min - 1 mL/min) is due to the ability to achieve excellent control of the desolvation process with the heated capillary. By varying the temperature of the heated capillary, one can achieve optimum results at virtually any flow rate, obviating the need for post-column splitting. For example, a capillary temperature of 200 C is typically used for flows of 50 μL/min, while temperatures of 250-275 C are used at 1 mL/min. Higher capillary temperatures dramatically reduce solvent background at high liquid flow rates, as shown in Figure 2. As shown by the chromatograms in Figure 4, the signal intensity actually increases when the entire column flow of 1 mL/min is introduced into the ESI interface as compared to splitting the flow down to 200 μL/min or 50 μL/min. This seems to indicate that the electrospray response may not be purely concentration dependent, particularly in these high flow applications.

Another aspect of the interface that has improved high flow operation is the use of a misaligned capillary-skimmer arrangement which has no line-of-sight from the capillary exit through the skimmer. This dramatically improves the signal-to-noise ratio by preventing aerosol particles which are not desolvated in the capillary from reaching the detector. This is demonstrated in Figure 3 which shows data for the on-axis versus the off-axis capillary-skimmer arrangement for 3 loop injections of 500 pg of reserpine. In the on-axis mode the analyte is completely obscured by the aerosol noise events, while excellent signal-to-noise is obtained in the off-axis configuration.

Fundamental Energy Studies of Electrospray Ions Entrained in a Free Jet Expansion

***Erol E. Gulcicek, Craig M. Whitehouse and James G. Boyle**
Analytica of Branford, Inc. Branford, CT 06405

Energy and energy distribution of electrospray ions were studied using a two pumping stage electrospray ion source interfaced to a high vacuum apparatus which may utilize various types of mass analyzers.

Electrospray ions are formed at atmospheric pressure and are entrained in a free jet expansion through several pumping stages before they reach the TOF mass analyzer. In order to increase the transmission of ions, "unconventional" electrostatic fields are utilized in the earlier viscous flow and transition flow pumping regimes. As a result, the final energy and the energy spread of the ions retain components from both the free jet expansion and the electrostatic fields. Although the free jet energy of the ions can be estimated, the electrostatic components are hard to determine since they depend on the voltage gradient around the region where ions attain a collision free path to the mass analyzer. This study determines both of these energy components and their energy spreads experimentally over a wide range of molecular weights. The energies of the ions have been determined as a function of different electrostatic conditions at the transition pressure flow and the free molecular flow interface.

The set-up for the stopping potential experiment is shown in Figure 1. Electrospray ion currents were measured with the conductive plate at the end of the optical lens stack as a function of the plate voltage with respect to the grounded mesh in front of it. The experiments were conducted for gramicidin S (MW 1141 Da), cytochrome C (MW 12,361 Da), and bovine albumin (MW 66,267 Da) at 1 pmole/µl concentrations.

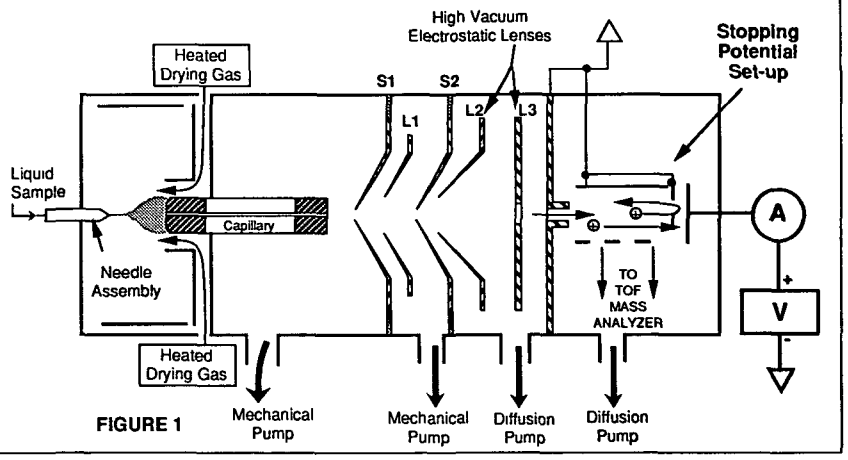

FIGURE 1

A typical plot of the measured current vs stopping potential voltage in the absence of electrostatic fields (all lenses at ground potential) is shown on the top trace of Figure 2; the bottom trace shows the first derivative of this plot for easy observation of the energy spread of the ions.

Figure 3 shows the stopping potential distribution for the gramicidin S ions with all the ion optical lens voltage settings optimized for maximum ion signal. Of the total of 12.7 V required to stop the gramicidin S ions in the mass analyzer, only 0.6 V comes from the free expansion as measured in Figure 2.

By measuring the stopping potential of the ions, one can approximate the location of the ions theoretically where they become collisionally free. The results show that in most cases, the energy of the ions are established approximately within a mm of the orifice of the second skimmer (S2). Furthermore, the correlation between the voltage difference applied to S2 and L1 lenses and the electrostatic field lines created by them near S2 can be used to control the total energy of the ions.

Application of Orifice Potential Stepping for the Sequence Identification of Phosphorylated Proteins

*J.-M. Ding, W. Burkhart, and D.B. Kassel, Glaxo Research Institute, 5 Moore Dr., Research Triangle Park, NC 27709

INTRODUCTION

A number of groups have begun to evaluate non-biochemical methods for identifying sites of phosphorylation (in the absence of radio labeled ^{32}P-ATP). and the majority of these studies have involved mass spectrometric analysis.(1-3) We have investigated an alternative method for identifying the phosphorylation of proteins and sequencing phosphorylated peptides. The method is similar to that described by Carr et al. (4) for the identification of glycoprotein digests. By ramping the orifice potential as a function of m/z ratio, Carr et al showed that it was possible to produce both molecular weight information and fragmentation characteristic of common glycoforms to aid in the rapid identification of glycopeptides. In an analogous manner, we have investigated the utility of orifice potential scanning for the identification of phosphopeptides. Orifice potential "stepping" rather than "ramping" in the negative ion mode was used for the identification of phosphorylation. Results are presented within for a model mixture of non-, mono- and (bis)-phosphorylated peptides, a known phosphorylated protein β-casein and a novel tyrosine kinase.

EXPERIMENTAL

Tyrosine, threonine and serine phosphorylated peptides were synthesized "in-house" (M. Rodriguez, Glaxo Research Institute) following the procedure of Andrews et al.(5). Peptides were dissolved in H_2O containing 0.1% TFA.

β-casein was purchased from Sigma Chemical Company (St. Louis, MO). The tyrosine kinase, SH3-SH2-TK, was expressed in baculovirus and purified "in-house" (M.A. Luther et al., Glaxo Research Institute).

A one nmol protein of SH3-SH2-TK was digested in-situ with subtilisin (Boehringer-Mannheim) following the procedure of Burkhart (6), and a 13 KD fragment was then digested with Staph V8 at pH=8.5. The eluant was speed-vac lyophilized and reconstituted in100 µl of aqueous 0.1% TFA .

A Hewlett-Packard HP1090 microbore HPLC was used for all analyses and operated at a flow rate of 250 µl/min. A 30mm x 320µm packed capillary Vydac reverse phase C18 column (LC Packings, USA, San Francisco, CA) was used for all peptide separations. The column flow rate was adjusted to 5µL/min by aid of a 40:1 pre-column split. A piece of fused silica tubing (75 µm i.d. x 150 µm o.d.) was connected directly to the end of the column and terminated at the ionspray needle assembly. An ABI 785A absorbance detector was used "in-line" between the column oulet and the mass spectrometer, and the peptides were detected at a wavelength 205 nm. A Sciex API-III IonSpray Triple Quadrupole Mass Spectrometer (PE-Sciex, Thornhill, ON, Canada) was used for all analyses.

RESULTS AND DISCUSSION:

A mixture containing 3 mono-, 2 di-, and one non-phosphorylated peptides was readily analyzed in the negative ion mode with orifice potential stepping and the phosphorylation could be identified. The orifice potential (OR) was set to -160 V in the mass range of m/z 74 to 574 and to -120 V in the mass range of m/z 574 to 1074. The low mass fragments generated at high orifice potentials could be used as a diagnostic for phosphorylation. We chose an OR value of -120 V to permit observation of both the $[M-H]^-$ ion and fragments in the molecular ion mass region which are characteristic of phosphorylation (e.g., $[M-H3PO4]^-$). Figure 1 shows a simple extraction of the m/z 79 ion (PO 3) from a TIC trace of a 6-peptide mixture. Five phosphopeptides were selectively identified. In addition, extraction of m/z 159 (HPO3: PO 3)$^-$ from the TIC trace enabled the (bis)-phosphorylated peptides to be identified.

β-casein with known phosphorylated serines was evaluated as a model protein to determine the utility of the orifice potential stepping method for identifying the phosphorylated peptides from a complex enzymatic digest. The phosphorylation was identified readily by negative ion mode LC/ESI/MS with orifice potential stepping method. A reconstructed mass chromatogram of m/z 79 ion produced only the two phosphorylated peptides.

A novel protein which contains non-phosphorylated and phosphorylated proteins was digested in-situ (6) using subtilisin to produce a 13 KD fragment which was determined to be phosphorylated from positive ion mode LC/ESI/MS analysis. This 13 KD protein was isolated and digested using Staph V8 at pH=8.5. Both positive LC/MS and negative LC/MS with orifice potential stepping were performed.

Figure 2 shows the TIC of the Staph V8 digestion acquired in positive LC/MS mode. Two peptides were observed whose masses differed by 80 Da and were suspected to be the phosphorylated and non-phosphorylated peptides. An LC/MS analysis in the negative ion mode with orifice potential stepping enabled the charge state of these peptides to be determined based on the formation of the TFA adduct (ΔMS=57 for a -2 charged ion), Phosphorylation was confirmed by extracting the ion at m/z 79 in Figure 3.

CONCLUSION:

We have demonstrated that negative ion orifice potential stepping provides a rapid way for identifying phosphorylated peptides from protein digests. For small molecular weight peptides, mono- and di-phosphorylated peptides were differentiated by the extraction the characteristic ions at m/z 79 and 159, respectively. For phosphorylated proteins, we demonstrated that the 79 ion could be used to identify the relevant peptides for a model protein, β-casein and a novel protein , SH3-SH2-TK. Additionally, TFA adducts in the negative ion mode were used to establish charge states for peaks in the negative ion LC/MS spectra.

Capillary LC/MS and LC/MS/MS Analysis of Peptides Using a New Capillary LC/MS Interface and a Redesigned Collision Cell

Bruce Thomson, Tom Covey, Bori Shushan, Mark Allen and Takeo Sakuma
Perkin Elmer Sciex Instruments, Thornhill, Ontario, Canada L3T 1P2

There is a strong need for obtaining amino acid sequence information from a small amount of tryptic digest sample (low picomoles or less) by LC/MS and LC/MS/MS. In order to facilitate the sensitive LC/MS/MS data acquisition it is important to generate reproducible chromatographic elution profiles from a small bore column, preferably packed capillary columns for routine analysis.

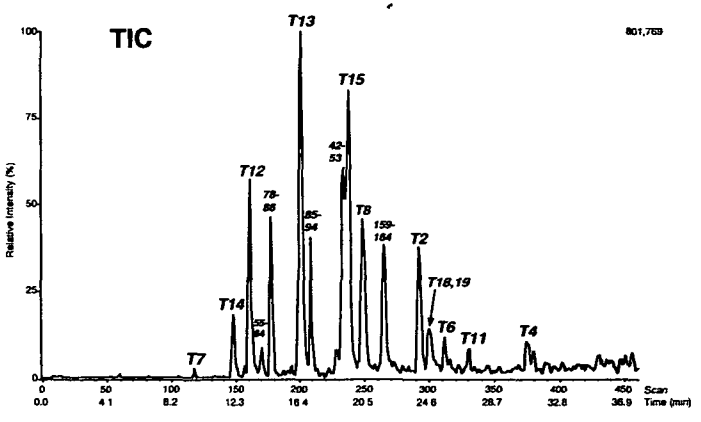
We developed a low dead volume interface assembly coupling a packed capillary LC column to an API *III* triple quadrupole system using an IonSpray. This interface assembly is mounted on the IonSpray Source Housing. Details of the construction will be shown in the poster.

Capillary columns of 180, 320 and 500 μm ID, 5 to 15 cm in length, were packed with Applied Biosystems Aquapore OD-300 material, 7 μm particle size, 300Å pore size, in our laboratory. Peptide analysis columns of similar sizes but different packing materials were also procured from LC Packings and Keystone Scientific.

An ABI Model 140 B Dual Solvent Delivery System equipped with 2 x 10 mL syringes was used with a 10 μL Lee Visco Mixer for efficient mixing of the two mobile phases. A = H_2O(0.1% TFA), B = 75/25 CH_3CH/H_2O (0.1% TFA). Gradient 20% B (5 min) to 80 %B (60 min). A typical flow rate for a 170 μm ID column was 80 to 100 μL/min with 2 to 3 μL/min going into the capillary column.

Figure 1 is a typical TIC trace obtained from 1 picomole of hGH tryptic digest using a 180 μm ID Vydac C18 column. Figure 2 is an LC/MS/MS spectrum obtained from 1 picomole of T2. A series of Y ions as well as A and B ions were observed.

Figure 1



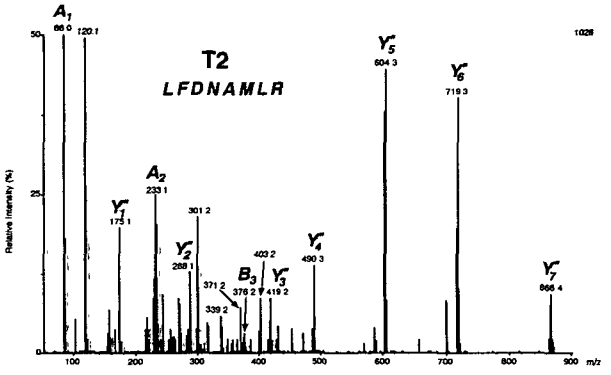


Figure 2

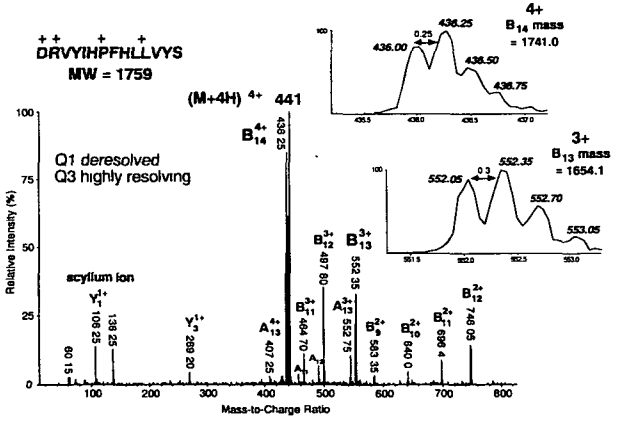
In the past, daughter ion resolution was generally low due to a broad ion energy distribution from the energy release upon fragmentation, thus making unequivocal mass assignment difficult. The collision cell of an API *III* and the surrounding ion optics were redesigned to minimize the ion energy spread, ion scattering loss, and focusing artifacts. A diagram will be shown in the poster. The new ion optics produce unit mass resolution across the entire mass range with up to 20 times greater MS/MS sensitivity over the conventional collision cell.

The daughter ion spectrum of renin substrate shown in Figure 3 was obtained by lowering the Q1 resolution to allow the C13 isotope peak of the quadruply charged parent ion into the new collision cell. The charge state of multiply charged fragmentation with up to 4 charges could be assigned on the basis of the isotope spacing.

Figure 3



COMBINING CAPILLARY ELECTROPHORESIS WITH ELECTROSPRAY IONIZATION/ION TRAP MASS SPECTROMETRY FOR BIOPOLYMER ANALYSIS

R.S. Ramsey, K.G. Asano, K.J. Hart, D.E. Goeringer
G.J. Van Berkel, and S.A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

Capillary electrophoresis (CE) when combined with mass spectrometry holds considerable potential for the analysis of complex mixtures of biomolecules. CE offers extraordinary resolving power and speed of analysis as compared to more conventional approaches for separations while MS provides the selectivity required for compound identification. Some of the features which make CE attractive for separations, however, impose stringent requirements for MS detection. Small injection volumes require high sensitivity for analysis and the narrow peaks (ca. few seconds at FWHM) given the high column efficiencies demand rapid scan speeds. We have used an electrospray interface with a coaxial sheath to couple CE to an ion trap mass spectrometer (ITMS) for on-line analysis. As compared to other analyzers the ITMS offers enhanced sensitivity and broader capabilities for obtaining structural information (1,2). Full utilization of these capabilities, especially with regard to multiple stages of mass spectrometry, however, are limited in on-line applications when operating the trap under normal modes. Collisional activation (CA) which forms the basis for MS/MS and MS^n experiments is generally effected by applying a single rf frequency, corresponding to the fundamental secular frequency of the ion selected to undergo dissociation, to the end-caps (3). This secular frequency is dependent upon the mass/charge ratio of the ion as well as operating conditions and physical parameters of the trap. To optimize CA several parameters must be "tuned", including selection of the optimum excitation frequency, amplitude, and duration. The implications for on-line analysis are that the mass/charge ratio of the parent must be known for each peak and that tuning has to be performed rapidly during elution. An alternative which we have recently explored is using random noise applied to the end-caps which enables trapped ions to be collisionally activated independent of their mass/charge ratios (4). This approach yields structurally informative MS/MS spectra in on-line CE as demonstrated below.

We have also determined that signal/noise ratios in total ion current (TIC) profiles may be improved by applying low amplitude noise to the end-caps. Chemical noise and background in on-line CE derive primarily from ionic buffer components and clusters, as well as solvent clusters. Buffer ions that consistently appear in the background may be ejected from the trap, reducing overall background, but the application of noise results in further improvements. Figure 1 shows a comparison of the total ion current electropherograms for three peptides, bradykinin, xenopsin, and neurotensin, obtained with and without the application of noise. These results were obtained using a tris-phosphate buffer (pH 7.6) for separation, scanning the mass range from 100 to 1300, and ejecting the predominant background ions at mass/charge 122 and 243, corresponding to protonated tris and its proton-bound dimer. Under the conditions employed, the increase in signal to noise is ca. a factor of three using noise CA. The quantity of material injected was 180, 200, and 220 fmoles for the three peptides, respectively.

To obtain structural information by broad-band CA the noise was applied at higher amplitudes (ca. 2 to 5 fold). Figure 2 shows an example of the structural information obtained for

neurotensin, injecting 0.9 pmoles of material. Some of the product ions that were identified are labeled. The spectrum was found to be similar to that obtained by single frequency CA with continuous electromigration of the peptide. The major differences in the spectra were in the relative abundance of some of the major product ions and the absence of some lower mass/charge ions. Overall, the noise CA spectrum contains a great deal of structural information and is easily obtained in on-line CE. Mass spectral scans where the amplitude of the noise is alternatively turned off and on or varied from low to high during peak elution may also be used to obtain molecular weight and structural data in a single analysis as reported for on-line HPLC (5).

High Mass Accuracy Electrospray/Fourier Transform Ion Cyclotron Resonance Mass Spectrometer.

CH Watson, GH Kruppa, FH Laukien, J Wronka, M Knobeler[1], K-P Wanczek[1], Bruker Instruments, Inc., Billerica, MA; [1]University of Bremen, Bremen, Germany

Introduction

In addition to being able to ionize a variety of high molecular weight molecules via multiple charging, electrospray ionization (ESI) also provides an efficient means to dissociate high molecular weight ions. Using a commercially available ion source with a Bruker BioAPEX™ 47e external ion source Fourier transform ion cyclotron resonance (FTICR) mass spectrometer both parent ions (with multiple charge states) and fragment ions obtained by increasing the capillary/skimmer voltage difference have been measured for a series of peptide samples. Mass resolved isotopic peaks for multiply charges parent and fragment ions are obtained for ions with up to 20 charges. The charge state of an unknown peak can be determined unambiguously from the mass difference between adjacent isotopic peaks. Mass measurements made on both the parent and fragment ions are extremely accurate. Errors in the mass assignments range from very low ppm (> 5ppm) to ppb using external calibration. An additional advantage of the ESI/FTICR technique is that the calibration procedure is straight-forward and provides reproducible mass assignments with error less than 5 ppm for weeks after calibration.

Experimental

All experiments were carried out using a Bruker Bio-APEX™ 47e mass spectrometer equipped with a 4.7 T superconducting magnet, an external ion source operating at ground potential, and the newly developed RF-shimmed Infinity™ analyzer cell. The external ion source has two stages of differential pumping with one 800 L/sec cryopump for the source, one 400 L/sec cryopump for the electrostatic ion transfer region, and a 400 L/sec cryopump for the mass analyzer region. The pressure between the capillary exit and the first skimmer, where CID ocuurs, was ca. 1 torr. The needle was maintained at ground potential and 4.6-5.0 kV was applied to the capillary entrance. Collision induced dissociation spectra were obtained by increasing the voltage difference between the capillary exit and the first skimmer. A syringe pump supplied a steady 0.8 um/min flow of a 49.5:49.5:1 H_2O, methanol, acetic acid solution to the source. Samples were injected into the flow stream using a standard HPLC injection valve with a 10 ul loop.

Results and Discussion

For all of the peptide and protein samples analyzed to date (up to myoglobin) a capillary/skimmer voltage difference of 200 volts was sufficient to achieve extensive fragmentation. An exact mass analysis was preformed on the parent and fragment ions from samples of Substance P, bombesin, melittin, ubiquitin, and cytochrome C. As an example of the exact mass analysis capability afforded by ESI/FTMS, the most abundant primary sequence fragments from melittin are listed in Table 1. Similar results with average mass error of 2 ppm were obtained for all of the samples.

In addition to the stable and accurate mass calibration the ESI/FTICR technique provides high mass resolution such that the charge state of multiply charged fragment ions

can be readily determined from the spacing of isotopic peaks. Figure 1 shows a typical source CID spectrum of ubiquitin (average molecular weight 8564). The fragments ions generated from the multiple charged parent species have a distribution of charge states ranging from +1 to +8. Without the high resolution capability of FTICR the correct assignment of masses for each fragment ion would be difficult. As an example, Figure 2, shows a portion of the ubiquitin CID spectrum at m/z 1050 showing the presence of several different charge states. The insert shows that at a resolution of 30k, a very moderate resolution by FTICR standards, overlapping charge states of +2 and +8 can be readily resolved and identified.

Table 1. Melittin Exact Mass Analysis

Ion	Formula	Meas. Mass	Charge	Theo. Mass	Error
M^{+2}	$C_{131}H_{230}N_{39}O_{31}$	1423.3873	+2	1423.3873	1.89
y_{19}	$C_{101}H_{176}N_{31}O_{24}$	1104.1811	+2	1104.1789	2.00

FTICR CHARACTERIZATION OF BEAM DYNAMICS AND ELECTROSTATIC CONTRIBUTIONS TO THE ELCTROSPRAY ION KINETIC ENERGY

V. Campbell, Z. Guan, D. A. Laude, JR.; Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712

The kinetic energy distribution of ions exiting the electrospray ion source depends upon the contribution of electric fields experienced by ions in the source and upon the velocity assumed by the ions as a consequence of the flow dynamics in the spray. Understanding and controlling the kinetic energy of electrospray ions is essential for obtaining optimum performance of Fourier transform ion cyclotron resonance (FTICR) mass spectrometry, since the ions have to be captured in a trapped ion cell prior to detection. In the work to be presented, the electrospray ion kinetic energies were evaluated under a variety of experimental conditions by using both variable trapping in the FTICR and retarding grid measurements at a collector behind the trap. Experiments were also performed to determine the effect of ion conformation on kinetic energy achieved in the source.

All experiments were performed with a 3.0T FTICR mass spectrometer coupled to an electrospray ionization source. The spectrometer included a 6" diameter bore into which the vacuum chamber was inserted. The essential components of the vacuum chamber and interface consist of four concentric vacuum chambers of increasing diameter which extend into the high-field region of the magnet.

Two separate pumping arrangements were used to acquire the data in this experiment. Electrospray system 1, a Chait-type electrospray interface, featured a 500μm i.d. resistively heated desolvation capillary and a skimmer with a 400μm orifice. The capillary-skimmer region of this arrangement was pumped to 8 torr. Electrospray system 2 featured a reduced skimmer orifice of 200μm and a increased pressure of 14 torr in the roughing region. These interfaces will be referred as large and small orifice skimmers, respectively.

The primary contributions to the kinetic components to the energy are the velocity component achieved in the supersonic expansion and the electric field component derived from the potential on the skimmer. These are expressed as the first and second terms, respectively, in Equation 1 which predicts the optimum trapping potential for injected ions.

$$V_{trap}=K_{slip}(v^2/2Ae)(m/z)+K_{eff}V_{skim} \qquad \text{eq 1}$$

K_{slip}: correction factor for velocity slip in the expansion

K_{eff} : correction factor for the effective field experienced by the ions

Changing the skimmer orifice size can cause significant differences in ion kinetic energies. This is illustrated by the retarding grid profiles in Figure 1, in which electrospray ions from the larger skimmer exhibit an average kinetic energy that is 1/3 the skimmer potential. In contrast, ions traversing from the smaller skimmer exhibit a kinetic energy that is 60% of the skimmer potential.

Presented in Figure 2 is a plot of optimum m/z trap potential and retarding grid measurement of kinetic energy for the two interfaces shown in Figure 2. The data is fit to eq1 to obtain velocity and effective field data. In general, the larger orifice skimmer promotes an improved expansion and consequently a larger velocity contribution from the flow dynamics. This is reflected in the larger velocity of 900m/s. In contrast, for the smallest skimmer, the reduced slope indicates a weaker expansion and lower electrospray ion velocity 250 m/s achieved from gas dynamics. Instead, the effective electric field is much larger and contributes the preponderance of ion kinetic energy. This is reflected by the large y-intercept.

Kinetic energies for the smaller skimmer is now examined. Retarding grid and FTICR variable trapping profiles indicate that the variable trapping technique yields data that reflect the kinetic energy of trapped ions. Profiles acquired for increasing skimmer potential at a skimmer-capillary distance of 4.5 mm suggest a uniform narrowing of the kinetic energy distribution as the skimmer potential decreases; the contribution to kinetic energy from flow dynamics is apparently small at this close distance and high post skimmer pressure.

One key feature of the instrument is that by placing the electrospray source in the magnetic field, radial motion is confined. Consequently only one focusing potential is employed--the potential applied to the skimmer. Very narrow distributions can then be collected in the cell at small skimmer potentials. For example, using a 3.0V skimmer, a trapping profile for horse heart myoglobin exhibits a trapping bandwidth of only 0.02 V. Signal intensities for ESI spectra are of the same magnitude as for broader kinetic energy profiles.

It is possible that identical molecules that possess different structure would achieve different kinetic energy during the supersonic expansion process. Shown in Figure 3 are variable trapping profiles for the +10 charge state lysozyme of the closed (native) and the open form(denatured, i.e after reduction of the disulfide linkages with dithiothritol). The profiles indicate that the closed form is preferentially trapped at about 0.4 V lower potential than the open form. Velocities were calculated to be 288m/s and 359m/s for the open and closed forms respectively.

Increasing the capillary voltage promotes fragmentation of exiting electrospray ions to yield dissociation products that are detected by FTICR. It was desirable to determine whether a distinction in kinetic energy distributions existed for precursor and dissociation product ions. This difference in kinetic energy would introduce mass discrimination into the resulting spectra and further complicate analysis. The retarding grid and variable trapping profiles were examined for assorted mellitin ions at low and high voltages. Increased fragmentation was observed at 500V as expected. What is important is that the variable trapping profiles for each ion at 500V were identical. This is likely because a 3 mm skimmer-capillary distance was used to sample a subsonic, or higher pressure, region of the spray. The identical profile shapes indicate mass discrimination is avoided.

A Direct Injection Electrospray Source for Fourier Transform Ion Cyclotron Resonance Mass Spectrometry

R. Ramanathan, J. A. Shalosky and J. R. Eyler
Department of Chemistry, University of Florida
Gainesville, FL 32611-2046

The multiple charging phenomenon in electrospray ionization allows conventional mass spectrometers with limited mass-to-charge (m/z) range to detect ions having masses in excess of 1,000,000 Da. However, coupling ESI sources with double sector or Fourier transform ion cyclotron resonance (FTICR) mass spectrometers can lead to further benefits from the high mass resolution and mass accuracy of these instruments. Initially, Henry and McLafferty coupled an ESI source externally to a FTICR mass spectrometer and demonstrated its capabilities (1). However, inefficient transfer of ions from the source to the cell limited the use of this instrument for routine experiments. In 1992, Hofstadler and Laude interfaced an ESI source within the strong magnetic field of a FTICR mass spectrometer and showed that this interface can transfer ions from the source to the cell efficiently (2). The ESI source that has been developed in our laboratory is similar to Laude's ESI source.

Figure 1a is a schematic illustration of the ESI source developed in our laboratory. Ionization takes place in the Delrin/MACOR spray cavity. The ESI source is inserted inside a 3/4" stainless steel probe and a vacuum seal is made with a Viton O-ring. When the probe is inserted into the strong magnetic field, the electrospray ionization process occurs 24 cm from the FTICR cell. All experiments were performed using a 2 Tesla FTICR mass spectrometer equipped with a Nicolet FTMS 1000 data station. All the other operating parameters used in these experiments are shown Figure 1b. All the samples were $1x10^{-5}$ M in 50/50 $MeOH/H_2O$ solution (with 1-2 drops of acetic acid for Bradykinin).

It was necessary to measure the ion current along the z-axis to determine where most of the ions are lost during the transfer from the source to the cell. A 50/50 methanol/water solution of Rhodamine 6G perchlorate (1.0×10^{-5} M) was electrosprayed and the total ion current was measured at each component. In addition to ion current information, molecular weight and structural information of Rhodamine 6G ($[M-CH_3]^+$ @ m/z 428) were obtained using the ESI source. The potential difference between the skimmer and the capillary, ΔV, causes the ions exiting from the capillary to undergo energetic collisions with the gases (from the atmosphere) present in the capillary/skimmer region. The primary collisionally induced dissociation product observed was $[M-4CH_3-3CH_2]^+$ (m/z 326).

Recently we have been involved in studies of photodissociation of solvated ions (3). Solvated ions in these studies were produced as products of ion/molecule reactions. ESI could be used as an alternative method to produce solvated ions. As shown in Figure 1c, when the capillary was maintained at 150 °C $[Ru(bpy)_2H_2O]^+$ was observed as the predominant peak following electrospray ionization of a solution of $Ru(bpy)_3(PF_6)_2$. However, when the capillary temperature was dropped to 100 °C peaks due to $[Ru(bpy)_2H_2O]^+$, $[Ru(bpy)_2CH_2O]^+$ (?) and $[Ru(bpy)_2H_2OCH_3OH]^+$ were observed. These preliminary results indicate that ESI can be used to produce solvated ions for further reactivity and dissociation studies. In addition to solvated ions, we were able to produce the doubly protonated molecular ion $[M+2H]^{2+}$ and the porotonated molecular ion $[M+H]^+$ of Bradykinin (Figure 1d). Our future plans include studies of a number of multiply charged organometallic and biological species.

In conclusion, we have demonstrated the potential of electrospray ionization as an ion source for our FTICR mass spectrometer. Our source is still in the early stages of development The following modifications will be implemented before the ESI source can be used for routine experiments : (1) mounting a shutter on z-axis to open only during the ion injection period and (2) reducing the 1st and 2nd conductance limits to ~2mm diameter. This will lead to pressure in the low 10^{-6} Torr range in the cell region and improve mass resolution.

High Energy CID of Multiply Charged Polypeptides and Polynucleotides Produced by Electrospray

D. Fabris*, M. Kelly, C. Murphy, Z. Wu and C. Fenselau
Structural Biochemistry Center
University of Maryland Baltimore County, Baltimore MD 21228

The recent implementation of an electrospray source on a four sector instrument has allowed the present study of high and low energy CID of multiply charged ions[1]. The objectives of the present work are to show a scan scheme allowing the use of kilovolt potentials in both MS-1 and MS-2; to devise an algorithm to accomodate multiple charges in assigning sequence ions; to evaluate structural information obtainable from high molecular weight precursors; to evaluate sites of charge localization in multiply charged ions.

Collisional induced dissociation (CID) mass spectra were obtained on a JEOL (Tokyo, Japan) HX110/HX110 four sector mass spectrometer ($E_1B_1E_2B_2$), under control of DA5000 or DA7000 data systems and equipped with an Analytica of Branford (Branford, CT) electrospray ionization source. Positive multiply charged ions were collided with Xe in the third field-free region within a **grounded** or **floated collision cell**, using 75% primary ion beam attenuation. The resolution was experimentally determined to be 1100 (50% valley). B/E linked scans were performed according to the following **scan scheme**, allowing all the possible fragments produced in a floated collision cell to pass through MS-2 and be detected: $ze(V_a-V_c) = V_2-V_c$ where z is the charge state of the precursor ion, V_a is the acceleration voltage, V_c is the voltage of the collision cell and V_2 is the initial voltage of MS-2. The use of the floating cell on one hand improves both transmission and sensitivity, on the other hand allows to perform different experiments with both high and low collision energy.

The **interpretation** of the spectra is based on the nomenclature presented by Biemann[2], which has been adapted to accommodate multiple charging. In the CID spectrum of a singly charged cation, c, d, v, w and y series ions originate by loss of neutral molecules and the charge is still conferred by the proton added in the original ionization process. For a multiply charged fragment of one of these series, all of the charges are due to additional protons, and the mass of the fragment (m_f) can be calculated as $m_f = m/z * y - y$ where m/z is the position of the peak in the spectrum and y is the charge state of the fragment ion. Singly charged ions in the a, b, x and z series do not retain an extra proton. In a multiply charged fragment of these series all the charges but one are carried by additional protons and the mass is $m_f = m/z * y - (y-1)$ The additional complexity of fragment ions detected with variable charge states strongly recommends computer supported prediction of fragments and interpretation of spectra.

Nine polypeptides were studied in the mass range 2000-5000 daltons, molecular weights that fall across the mass range of most proteolytic peptides. As shown in **Figures 1-2**, both backbone and side chain cleavages occur, immonium ions are formed, and some internal fragments are observed: fragmentation processes are qualitatively similar to those observed in high energy CID spectra of singly charged precursor ions. Fragment ions are detected with all charge states up to that of the precursor.

The general pattern of the spectra (**Figures 1-2**), showing no intense peaks with high mass to charge ratios (large fragments with low charge states) and a only few fragments with low mass and high charge states, suggests that as a precursor loses residues, it also loses charges. In this way, the m/z ratios of the resulting fragments tend to remain close to a constant number and the peaks occur with striking frequency close to that of the precursor ion. If we assume that transmission effects do not overwhelmingly shape the spectra, one feasible explanation is that charges tend to be distributed at rather even spatial intervals across the precursor ions.

Analysis of charge patterns suggests that charges are accommodated as far apart as possible. There is a general correlation with chain length and the number of protonable residues. The position of strongly basic residues influences which fragment ions are detected.

The general features of the low energy spectra are similar to those reported in triple quadrupole instruments[3]: mostly b and y series ions have been assigned in low energy studies. A much richer selection of ions were detected with high energy activation of melittin 4+ and 3+ and of human parathyroid hormone [1-44] 5+ than has

been observed with lower energy activation in either triple quadrupole[3,4] and four sector instruments[1].

Differences noted between low energy experiments in sector and in triple quadrupole[3] instruments are perhaps due not only to the use of different target gas, Xe instead of N_2, but also, most probably, to different numbers of collisions and different time domains.

High Flow Electrospray LCMS on a High Performance Magnetic Sector Mass Spectrometer

R.H. Bateman, P.A. Bott, A. Phillips, A.R. Woolfitt and D. Peake

Fisons Plc., VG Analytical, Floats Road, Wythenshawe, Manchester, M23 9LE, U.K.

An electrospray/Atmospheric Pressure Chemical Ionisation interface for a VG AutoSpec double focussing mass spectrometer has already been described. The standard electrospray ion source exhibits maximum sensitivity at a flow rate of around 1µl/minute, although is capable of operating at solvent flows of upto 150-200µl/minute. This presentation details the operating characteristics of a modified interface designed to accept solvent flows from 1 to 1000µl/minute.

The key changes that facilitate reproducible, reliable, high-flow or 'Megaflow' electrospray include the following. Firstly, the electrospray is pneumatically assisted using nitrogen at 5-6 bar (earlier studies had typically utilised 2 bar nebulising gas pressure). Secondly, certain of the gas flow passages in the atmospheric pressure region of the interface were enlarged, both to permit a higher gas loading and to expedite the removal of any condensed solvents. Thirdly, the source was heated to 90-100°C, compared to a usual temperature of 50-60°C for low-flow electrospray analysis with the standard version.

Figure 1 shows part of a TIC trace obtained from a magnet scanning experiment in which repeat injections of gramicidin S were made at various flows between 10 and 1000µl/minute. The trace has not been smoothed, so that a true comparison of relative peak heights can be made. Figure 2 clearly demonstrates that the response in terms of injection peak area with increasing flow rate is close to the theoretical value based on the assumption that no loss of performance occurs. Furthermore, no degradation was observed even after several days' continuous operation at 500µl/minute, and the vacuum pressures were unchanged.

Figure 3 shows the UV trace from the repeated gradient separation of a mixture of myoglobin and cytochrome C carried out at a flow rate of 200µl/minute. An Aquapore RP-300 column was used, with a gradient of 30-50% acetonitrile in water + 0.05% TFA. By using the same protein mixture for mass calibration (thus excluding any possible error arising from a discrepancy between the theoretical masses and the actual masses of these protein samples), an RMS error of 32ppm was obtained. This is comparable to the accuracy achieved in low-flow continuous infusion experiments involving similar acquisition parameters. Surprisingly, the required cleaning interval appeared to be independent of solvent flow rate in this study, perhaps because the higher-velocity gas flows tended to keep the sampling cone clean.

Capillary Electrophoresis with Electrospray Ionization Time-of-Flight Mass Spectrometry

L. Fang, R. Zhang and R.N. Zare; Department of Chemistry, Stanford University, Stanford, CA 94305

Capillary electrophoresis (CE) has demonstrated the capability for separating mixtures of large biomolecules (>10,000 Da) with nanoliter samples, but detection and characterization of these components remains a challenge. Mass spectrometry (MS and tandem MS), well known for its high sensitivity, has been used extensively for obtaining molecular weight and structural information from femtomole quantities of biologically important compounds. By combining MS with CE, it may be hoped that analytes could be differentiated not only by their elution time but also by their masses and structures. We are using a time-of-flight MS as the detector because TOF has a fast sweeping speed and a high repetition rate with the ability of measuring a full mass spectrum on every injection pulse. In addition, the TOF device is relatively simple, inexpensive and can achieve a resolution of 1000 or greater by using a reflectron configuration. All these superiorities should make TOF-MS an ideal detector for CE.

To use MS as an on-line detector for CE separations, the exit of the CE column must be removed from the buffer reservoir and have a well defined electric potential.[1] In our preliminary interface arrangement, which is shown in Fig. 1, the fused silica capillary of the CE column was used to replace the original inner stainless steel needle in an electrospray needle assembly. By inserting a gold electrode (25 μm, one end connected to the needle assembly) into the outlet of the CE column (75 or 100 μm ID), the electrical contact for the CE capillary exit was established to that of the needle. Stable electrospray current is generated by maintaining the spray needle at ground while counter-electrodes inside the ES source are maintained at a negative 3 to 4 kV. Effluent from a CZE column is introduced into an electrospray ionization (ESI) source which generates a fine mist of highly charged droplets from the solution. Subsequent solvent evaporation and electrostatic repulsion produces multiply-charged molecular ions. Ion current entering the vacuum through the capillary and two skimmers from atmospheric pressure is essentially continuous. A TOF mass analyzer, conversely, is an inherently pulsed technique requiring spatially and temporally resolved ion packets to conduct mass analyses. To combine ESI with TOF, ions are extracted perpendicular to the axis of the electrospray interface with a pulsed electric voltage applied to the repeller plate, which takes the advantage of the low

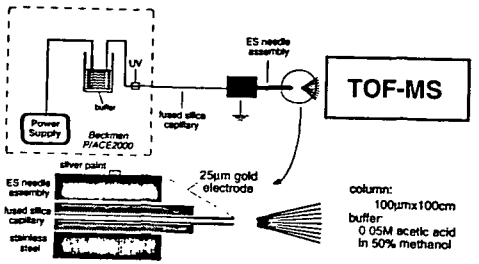

Fig. 1 Schematic diagram for interfacing capillary electrophoresis to electrospray ionization TOF-MS apparatus.

translational energy spread in this dimension. This 0 - 400 V pulsar has a specified rise and fall time of 10 ns, which defines the ion packet.

We have demonstrated that a mixture of peptides can be separated by CE and detected on-line with our TOF-MS. Fig. 2 illustrates a 3-D plot of 15 TOF-MS spectra collected at different elution times during a single CE separation. Lys-bradykinin (B^{3+}, m/z 397; B^{2+}, m/z 595) elutes first from 26.0 to 26.5 minutes. Gramicidin S (G^{2+}, m/z 571; G^{+}, m/z 1142) appears next from 31.0 to 32.5 minutes, and crystal violet (C^{+}, m/z 371) appears from 33.4 to 35.9 minutes. Leu-enkaphalin (E^{+}, m/z 556) elutes finally from 40.5 to 41.0 minutes. Note both gramicidin S (G^{2+}) and crystal violet (C^{+}), which are poorly separated by CE, are resolved simultaneously, a distinct advantage of the CE/MS detection system.

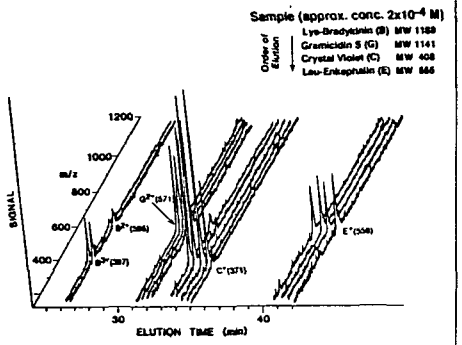

Fig. 2 3-D plot of 15 TOF-MS spectra for peptide mixture by CE-ESI-TOF-MS.

We have found out that by reducing the surface tension interaction between the solution and the outlet of the capillary, the ionization efficiency from the electrospray process can be improved, which is consistent with previous results by others.[2,3] Two ways exist to reduce the surface tension: 1) sharpening the silica capillary tip (decreasing the o.d. of capillary to less than 200 μm), so that the emerging liquid surface area is greatly lessened; and 2) eliminating the coating on outside of the silica capillary tip so that the surface is altered. The ESI-TOF-MS signal for crystal violet has been increased by a factor of 4 to 5. A stable electrospray current has been generated from solvent with a 90% water content, which enables ESI-MS to analyze samples in conditions that are optimal for CE separation. Normally, a 50% water + 50% methanol solvent is needed for operating ESI-MS.

To improve further the sensitivity of our apparatus, our current efforts are focused on modifying the ion optics to increase the ion transmission efficiency. In addition, a reflectron will be incorporated into the system to achieve higher resolution.

Electrospray Ionization Collisionally Activated Dissociation on a Bench-Top Mass Spectrometer

*William H. Cusworth, III, and Frantisek Turecek, Department of Chemistry, BG-10, University of Washington, Seattle, WA 98195

A Hewlett-Packard 5971A benchtop mass spectrometer has been modified and furnished with an interface for electrospray ionization as described previously. The overall layout of the instrument, along with the flow-injection sampling system, is shown in (Figure 1). The flow-injection system consists of a linear syringe pump and a 6-port manual switching valve. The electrospray interface consists of a spray chamber containing a 110 μm i.d. syringe needle charged to +4-5.5 kV, an interchangeable stainless-steel capillary (0.4 or 0.5 mm i.d.), which is embedded in an alumina tube resistively heated to 80-120°C and charged to +100-500 V, a skimmer with a 0.5 mm orifice at +20-40 V, and electrostatic lenses. The expansion space between the capillary and the skimmer is pumped to 0.9-1.8 Torr, while the mass spectrometer is pumped differentially to 10^{-4} (skimmer region) and ~10^{-5} Torr (quadrupole analyzer and detector region). Recent modifications have been made to the spray needle and the electrostatic lenses which have resulted in an increase in total signal.

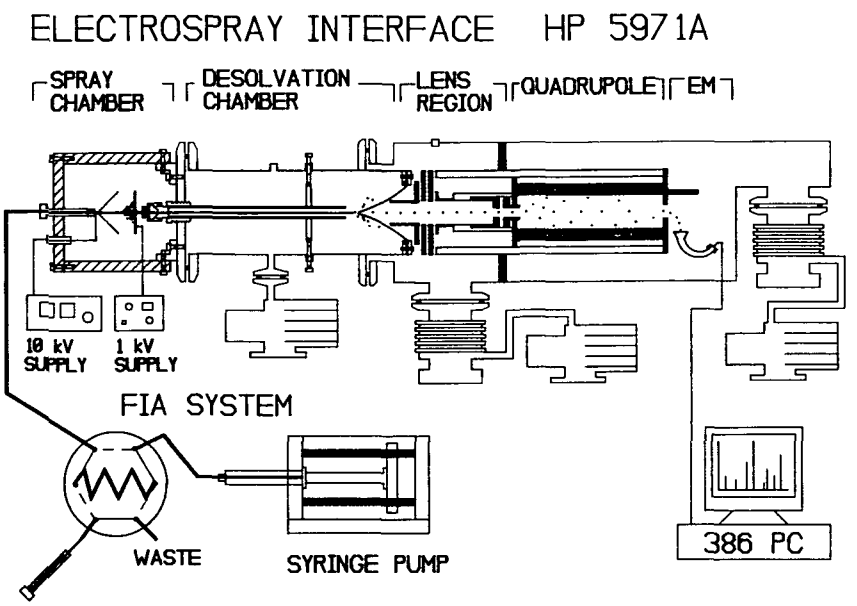

Figure 1. Overall layout of bench-top instrument.

Flow-injection experiments have been carried out and standards of crystal violet have been run. The instrument showed a linear concentration response from 5 μM (present limit of detection) to 100 μM. Above 200 μM, the signal becomes saturated and the response levels off.

We now report an efficient collisionally activated dissociation of the stable cation of crystal violet, $C_{25}H_{30}N_3^+$, *m/z* 372, upon applying bias ($\Delta V = V_{cap} - V_{skimmer}$) between the capillary and the skimmer in the high-pressure region. Spectra taken at increasing bias with a 0.4 mm i.d. capillary are shown in (Figure 2). No dissociation is observed up to ΔV = +85 V, corresponding to E_{CM} = 6.1 eV. Above this voltage elimination of CH_4 is observed (ion **a**, *m/z* 356) which peaks at ΔV = +130 V (E_{CM} = 9.4 eV), where the fragment **a** represents >90% of the total ion current. Elimination of a second CH_4 molecule sets on at ΔV > +130 V and peaks at ΔV = +180 V (E_{CM} = 13 eV) with the ion at *m/z* 340 (**b**) representing >90% of the total ion current. At higher ΔV competitive and consecutive eliminations of CH_4, CH_3N, C_2H_5N, and of an aromatic ring take place to give *m/z* 311, 268, 239, 191, and eventually the fluorenyl ion at *m/z* 165.

The surprisingly step-wise character of the methane eliminations is probably due to their relatively high endothermicities (~1 eV), the absence of competing dissociations, and slow translational heating under multiple-collision conditions. Experiments aimed at utilizing the high pressure CAD for mixture analysis are in progress.

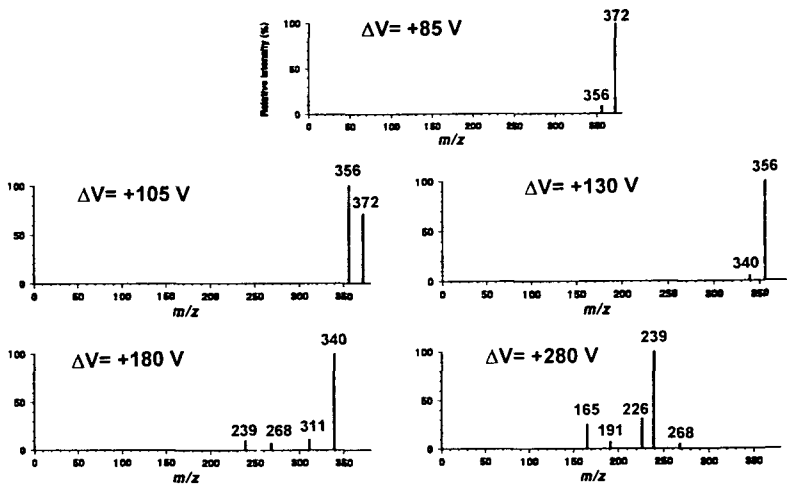

Figure 2. Collisionally-activated dissociation spectra for crystal violet ion taken at increasing capillary-skimmer bias.

Secondary Electron Resolved Mass Spectrometry

Jan Axelsson, Curt T. Reimann, Per Håkansson, Plamen Demirev and B.U.R. Sundqvist
Department of Radiation Sciences, Div. of Ion Physics, Uppsala University, Box 535, S-751 21 Uppsala, SWEDEN

Introduction

In conventional mass spectrometry, all the ions impacting the conversion dynode or the detector are counted irrespective of mass and charge state. Especially with electrospray mass spectrometry of mixed solutions, many ions of different charge states are present. Therefore several masses are likely to fall into the same mass-over-charge (M/Z) channel so that peaks of different masses will overlap in the M/Z spectrum.

In this report we demonstrate a method to resolve such overlapping peaks using the secondary electron yields, i.e. the number of electrons emitted from a single ion impacting the conversion dynode. Using the mass dependence of the secondary electron yield features in the M/Z spectrum can be emphasized for a desired mass region and hidden peaks can be raised from the noise. The method of Secondary Electron Resolved Mass Spectrometry will be referred to as SERMS. Furthermore, a method has been developed where the direct measurement of the secondary electron distribution is employed to give mass information through the mass dependence of the electron yield. This method which has proved useful to probe fragmentation and dimerization will be referred to as 'Direct SERMS'

Method

Secondary electrons emitted from the impact of a positive electrospray ion at the -20 kV conversion dynode are accelerated towards ground potential. The electrons are deflected magnetically into an energy-sensitive silicon surface-barrier detector, where the total energy deposited is proportional to the number of secondary electrons. 'Direct SERMS' is performed collecting electron yields from a large number of impacts with a multi-channel analyzer so that information about the most probable yield and hence the mass of the ion can be deduced.

Feeding the output of the amplified detector signal into a discriminator (or a single-channel analyzer - SCA) and counting the number of pulses per unit time within a certain energy (i.e. electron multiplicity) window allows to measure the number of ions with a mass corresponding to that electron multiplicity. Scanning the M/Z setting of the mass spectrometer and simultaneously registering the pulse rate from the SCA results in a M/Z spectrum in which the masses corresponding to the electron multiplicity window is enhanced. The SCA window can easily be correlated with the secondary electron distribution so that any interesting feature appearing in an electron distribution can be selected for enhancement.

Results

Using the direct SERMS with Cytochrome-C, a distribution of a main peak and a lower intensity peak at higher electron multiplicity is observed. Fitting the distribution to two summed Gaussian distributions gives the position of the two peaks. Applying the empirical dependence found for constant velocity (constant accelerating potential and M/Z) for an Al_2O_3 dynode

$$[\text{electron yield}] \propto [\text{Mass}]^{0.63}$$

on the peak positions yields that the second peak has twice the mass of the main peak, thus the second peak is the dimer peak.

Direct SERMS has also been employed to show that the higher mass poly-ethylene glycols (PEG) do not survive either the process of electrospray, or the transport through the vacuum system (of our experimental set-up). A direct SERMS distribution of PEG 35 000 u shows a main peak at the expected location, whereas a PEG of mass 100 000 u shows low-mass fragments and a main fragment peak at about mass 35 000 u (Fig.1). The same fragment peak has been observed for PEG of mass 300 000 u.

A mixture of myoglobin and insulin (1: 60 molar) in a solution is used to illustrate the possibility to enhance specific masses in an electrospray mass spectrum of a mixture. Setting the discriminator level far above the main peak corresponding to insulin, allows to enhance the myoglobin peaks compared to a conventional electrospray mass-spectrum of the same mixture (Fig. 2).

Similarly, a discriminator level corresponding to the second peak in the Cytochrome-C electron distribution enhances the dimer peaks of odd charges, M/Z=2M/(2N+1), which are residing between the composite peaks of the monomer and the even charged dimer.

Switching to a Myoglobin solution after running Valinomycin (strong peak at M/Z=1131), the Apo-myoglobin peak (M/Z=1134) could not be distinguished from the much stronger traces of Valinomycin. Setting a high discriminator level results in a complete suppression of the Valinomycin peak (Fig.3,4).

An electrospray solution of myoglobin contains three high mass components: native myoglobin (17 567 u), Apo-myoglobin without the 'heme' group (16 951 u) and Apo-myoglobin dimer (33 902 u). In the electrospray spectrum the myoglobin and the Apo-myoglobin dimer peaks are very close in M/Z, so that they will be unresolved. With SERMS a shift in the composite peak towards the M/Z-value of the Apo-myoglobin dimer has been demonstrated when the discriminator level was set to higher masses.

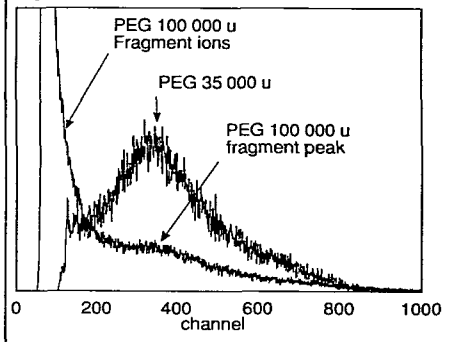

Fig.1. Fragmentation of mass 100 000 u poly-ethylene glycol by 'direct SERMS'.

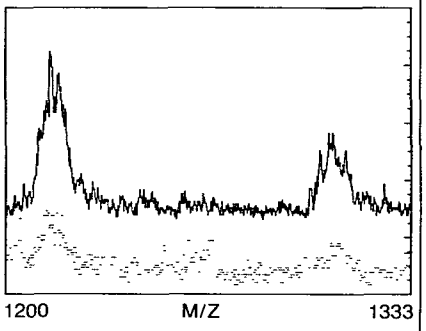

Fig. 2. Low concentration of myoglobin in insulin solution (bottom). Apo-myoglobin peaks are 'lifted' up by SERMS (top).

THE USE OF A FAST SCANNING FOCAL PLANE DETECTOR IN LC-ESI/MS

R. Pesch, E. Schroeder, H. Muenster
Finnigan MAT GmbH, Barkhausenstr. 2, 28197 Bremen, Germany

Focal plane detectors are a suitable means to increase the sensitivity of magnetic sector mass spectrometers. This is particularly true for applications where detection limits are determined by the absolute number of ions transmitted rather than by the ratio of signal to chemical noise.

Electrospray ionization (ESI) produces less chemical noise than many other ionization techniques. Therefore, the use of focal plane detectors is advantageous in many ESI applications.

Since ESI is commonly used in conjunction with on-line separation techniques like liquid chromatography (LC) and capillary zone electrophoresis (CZE), a usable focal plane detector must conform to the time and mass range constraints imposed by the separation technique, i.e. be capable to acquire wide mass range scans with short cycle times.

The focal plane detector used in the experiments is an ion counting device with spatial resolution (PATRIC = Position And Time resolved Ion Counting). The key feature is its capability to be used in rapid wide mass range scans while maintaining mass resolution (> 5,000 FWHM) and the full gain in sensitivity (> 100 over a point detector).

Because the mass scale calibration for the PATRIC detector and the point detector is identical and selection of detectors is electrical with the mass spectrometer used (Finnigan MAT 900), change of detectors takes only about 0.2 sec and can be initiated between scans or within a scan.

Although low chemical noise is produced in ESI, it turned out that for small peptides chemical noise again is the limiting factor in achieving lowest limits of detection. This is especially true with static focal plane detection. The detection limit of 2 fmole bradykinin could not be improved for this reason.

In fast scanning focal plane detection mode, typical detection limits are in the low fmole range for small and medium size peptides (Fig. 1, 3). Because the PATRIC scan cycles of about two seconds compare well to LC and CZE peak widths (Fig. 2), the full sensitivity advantage of focal plane detection can be utilized without restrictions to the liquid separation.

It is expected that ongoing development with the ESI interface, leading to lower noise and higher overall sensitivity, will improve routine detection limits in fast scanning mode into the attomole range.

Quantitative Analysis of Pharmaceutical Targets using a CCD Array Detector and Electrospray Mass Spectrometry

S. Kennerley, H. Wight, D. Little, M. Kimber, C. Moore
Kratos Analytical, Barton Dock Road, Manchester M31 2LD, UK

Introduction

Conventional array detectors have had limited use for on-line LC-MS experiments because of their slow acquisition times. In the past it has been necessary to take snap-shots of limited sections of the mass range and then "piece" these together to form a full spectrum. Since the chromatographic peaks may only be a few seconds in duration the time taken to reconstruct a spectra has prohibited the use of these detectors for quantitative analysis.

As most pharmaceutical companies strive to reduce the amount of active compound administered on a per patient basis, the required detection limits fall far below those currently achieved with point detectors .

A new scanning array detector has been developed which achieves the necessary scan speeds and the detection limits required.

How the detector works

Ions strike a microchannel plate multiplier which is one inch long and detects a minimum of ±2% about the m/z value focused at its centre. The microchannel plates are connected by a phosphor and fibre optic link to a charge-coupled device (ccd) array. The ccd has 1152 elements in the dispersive plane. As the analysers are scanned, the ions at each m/z value are electronically tracked across the array so that the resulting signal is integrated 1152 times. The integrated data is continuously transferred to the computer system where it is treated as a normal spectrum and can be processed in an identical manner to data from a conventional detector.

Experimental

The sulphonamide mixtures were analysed by on-line LC-MS using an electrospray interface and a CONCEPT mass spectrometer. Chromatographic separation was achieved using a 15 cm x 2 mm Spherisorb ODS HPLC column operated isocratically with a mobile phase of 70% (1% acetic acid) water and 30% acetonitrile at a flow rate of 100µl per minute.

A post column splitter device was employed to reduce the flow rate to 5 µl per minute before its introduction into the electrospray source. The mass spectrometer was operated with an acceleration voltage of 4 kV. Acquisition was performed over the mass range 100 u to 500 u scanning at 5 seconds per decade with a resolution of 1000 (10% valley definition).

A dilution series was prepared with a mixture of 4 sulphonamides. For the purposes of quantitation, an internal standard (SDM) was added to each of these dilutions. Mass chromatograms were obtained for each of these dilutions using both the point detector and the array detector. Relative response factors were calculated for each compound using peak area measurement.

Results

Examples from the analysis of the sulphonamide dilution series are shown in Figures 1 to 3. The HPLC trace is shown in Figure 1 with the corresponding ion chromatograms from the LC-ESI-MS analysis in Figure 2. An example spectrum of one of the components, sulphamethazine, is illustrated in Figure 3. This is taken from the 2 pmol/µl concentration level.

Conclusions

The CCD array detector enables sufficient scans to be acquired to achieve positive identification and good quantitative analysis on trace level components separated by liquid chromatography. The relative response factors for the experiment illustrate this in Table 1 and Figure 4 shows a calibration curve plotted for one of the components, in this case sulphadiazine (SDZ).

NOTES ON THE COUNTER ELECTRODE. The initial design of the electrode had three considerations. Open pumping holes to allow pumping of the nozzle tip and prevent accumulation of material that cause shorts. Make the electrode's exit hole coaxial with the nozzle tip to collimate the ion beam. Make the distance to the nozzle tip adjustable to physically control field strength. Only the latter considerations proved critical.

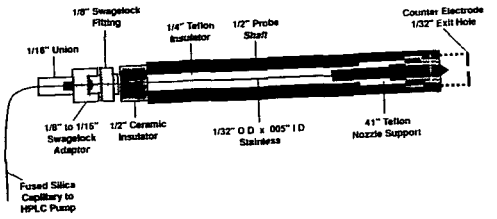

FIGURE 1

Later designs performed well even when pumping holes were omitted This electrode can be made from 1/4"- 3/8" o.d. 1/8" i.d. stainless force fitted into the probe shaft.

DISCUSSION The probe shown was designed as a result of the presentations on ESI, and the related workshop at the 40th ASMS Conference (1992). ESI requires a solvent evaporation system, an electric point source, and a strong electric field. The atmospheric pressure conditions, the long desolvation zones, and the additional lensing present in ESI are brought about by droplet size at the onset of ion formation. The Coulomb explosion seemed governed by physical parameters that could also be correlated to the inital droplet size. Therefore, it was paramount to reduce this initial droplet size and shorten the desolvation zone requirements of ESI. The difficulty in producing multi charged ions may be due to the fast removal of the solvent that seems to favor larger m/z ratios more characteristic of LSIMS. Smaller droplet size brings about two improvements over ESI, namely, a reduced load on the pumping system, and elimination of optics between the probe and the quads As expected, typical operating conditions for FALDI are within those of ESI (<2ul/m flow, 1-3KV). Initial comparisons with ESI have shown FALDI to be 100x more sensitive than our ESI unit for small peptides, CsI, etc. However, for myoglobin and other proteins our ESI unit had no trouble producing spectra while our probe failed A closer look must be taken of intermediate compounds such as medium sized polypeptides to try to find conditions for multi charged ion formation. Compared to LSIMS (i.e., a Cs gun), however, the sensitivity is not as good and the spectrum quality inferior. The peak shape of FALDI spectra is intriguing, it maybe reasoned that without the atmospheric pressure conditions of ESI the only way to thermalize the ions is the removal of excess kinetic energy by evaporation of solvent, and the peak shape is a reflection of the energy spread of the ions entering the quads. However, the observed base line should be extremely high, and peak tops should not be so sharp above the 10% intensity level (high base line and wide peak profiles are observed during small pressure bursts but they disappear completely when the stable conditions return).

CONCLUSIONS. At the present the only conclusion we can make is that the system can be used as an alternative to LSIMS perhaps extending the mass range for polar molecules by a factor of 3 or 4 but not the more striking 20 to 60 of ESI The final word on this technique, maybe its very survival, hinges on finding multi charged ions or an explanationn for their absence. As it stands now, the technique is useful as an interface to an HPLC or CE and as a substitute to CF-FAB but not as a replacement to ESI.

A PROCESS FOR THE DIRECT GENERATION OF IONS FROM POLAR LIQUID SOLUTIONS.

Dr. Climaco J. Metral, PRI-NCI-FCRDC/Dyncorp P.O.Box B. Frederick, MD 21702

INTRODUCTION. Protonated and polymeric molecular ions form directly from polar liquid solutions when the liquid is forced to exit a small nozzle (<100 μm aperture) into high vacuum (<3x10^{-5} torr) in the presence of a field below 5 KV/cm. Larger nozzle apertures are possible by controlling the liquid viscosity with LSIMS matrices such as glycerol, etc.; however, the preferred nozzle apertures are below 50 μm. The ions formed are protonated molecular and polymeric ions characteristic of the compound(s) in solution The higher viscosity solutions allow flow rates of up to 1-2 ul/min. Although field and flow conditions are similar to electrospray ionization (ESI) it takes place in a vacuum without auxiliary pumping, pneumatic gases, desolvation zones or additional lensing [3] The requirements for the process described here are: a) An efficient evaporation of the excess solvent b) A strong electric field in the region immediate to the entrance of the liquid into the high vacuum c) A high viscosity polar liquid solution to control liquid flow. d) A conducting nozzle with apertures below 100μ in diameter. e) A high voltage point electrode A 1/8" i.d. tubing is coupled externally to a 50μm i.d. glass capillary which supplies the pressure from a syringe pump. The spectra observed are almost identical to LSIMS This process is suited for HPLC/MS, CZE/MS, and CF-FAB Although the ion formation process resembles ESI, it is not clear why it could not generate the +17, and higher multiple charged ions for myoglobin observed by ESI[3] The presence of doubly and triply charged ions for angiotensin II suggests that it is possible to generate multicharged ions but we have not found the proper conditions. Several attempts to observe the multicharged ions of myoglobin even under extreme acidic conditions have failed

EXPERIMENTAL Experiments were carried out with the direct probe shown in the inset. Several stock solutions were prepared ranging from 5% to 30% glycerol in acidified methanol. After filling the solvent bottle of a syringe pump with a stock solution, the probe was purged and flow stabilized below at 2 ul/min. The probe assembly was introduced to within 2 cm of the extraction plate of the mass spectrometer adjusting this distance to vary the temperature of the nozzle tip With the probe secured and insulated, power was applied limiting current to <40 μamps and voltage to<2.4KV Once conditions stabilize, analytes are introduced directly into the liquid flow by various methods A practical approach employed for the purpose of this paper was to put the pump in negative flow conditions, load several microliters of the analyte solution into the micropump syringe barrel, and reestablish flow conditions This procedure increases the loading capacity of the system and permits observation of spectrua for a longer time A better approach is to use HPLC injector The spectrum shown in Figure 2 using the first method. The resulting spectrum is similar to the corresponding LSIMS or FAB spectrum, except for a significant difference is the wide base of the peak profile below 10% intensity The effect of this shape on the centroiding algorithms of our 4600 Finnigan quadrupole instrument , at unit resolution, is to produce a noisy base line that obscures and at times deletes the ^{13}C isotope peak.

NOTES ON NOZZLE CONSTRUCTION. It is important to note that there is no need for capillary tubing anywhere in the probe, what is important is a conducting nozzle with apertures below 100 microns. Apertures below 50 microns are difficult to manufacture from conventional tubing, however, 25μ nozzles are commercially available. Nevertheless, it is possible to obtain nozzle apertures <50μ using stainless steel tubing (.004", 003") by grinding the tip of the nozzle with an emery cutting wheel causing it to seal the nozzle and subsequently reopen it with 12000 emery paper under pressure. Alternatively, purposely clogging larger nozzles using a saturated solution of CsI/H_2O also produces smaller nozzles. This approach tends to unclog unpredictably causing severe flash overs

THERMAL SURFACE IONIZATION IN THE PARTICLE-BEAM MASS SPECTROMETRY ANALYSIS OF (ANTI)-CHOLINERGIC DRUGS AND HERBICIDES

A.P. Tinke, R.A.M. van der Hoeven, W M.A. Niessen, U R. Tjaden and J. van der Greef

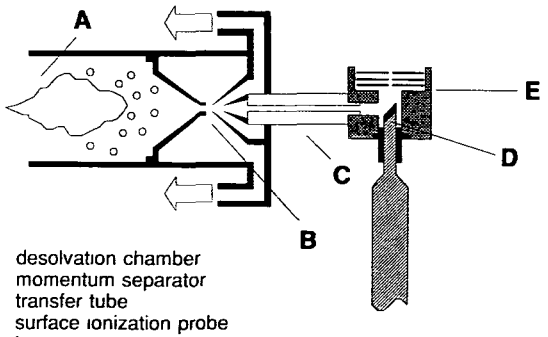
Division of Analytical Chemistry, Center for Bio-Pharmaceutical Sciences, P.O. Box 9502, 2300 RA Leiden, The Netherlands.

Considering the high ionization efficiencies reported for Surface Ionization (SI), we are investigating whether SI can be achieved by colliding molecules from a (supersonic) molecular beam onto a suitable heated surface [1,2]. This would allow the application of SI in LC-MS interfacing, e.g., via a particle beam interface, as depicted in the schematic representation. In former experiments three types of surface ionization phenoma have been observed [2]:

* hyperthermal surface ionization, resulting in radical cations
* thermal surface ionization, e.g., of quaternary ammonium compounds
* alkali addition

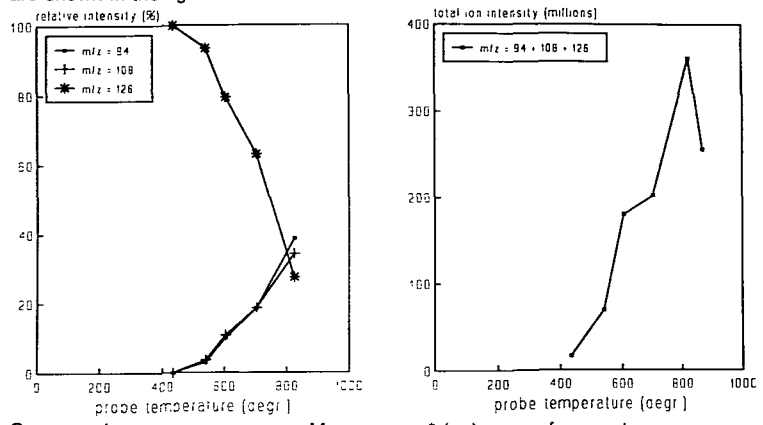
In this presentation, the thermal surface ionization of (anti)-cholinergic drugs and some herbicides (paraquad and diquad) is further investigated. For the experiments a Finnigan MAT TSQ 70 mass spectrometer is equipped with a Hewlett Packard HP 59980 particle-beam interface. An EI ion source is used, operated in filament-off mode. A laboratory-built heatable probe is used with a platinum tip in such a way, that the particle beam collides with the surface at an angle of 45°. A small bias potential (0-5V) is applied to the probe tip. Column-bypass injections (20 µl) into a 0.5 ml.min acetonitrile stream are applied for sample introduction.

Schematic Representation



A = desolvation chamber
B = momentum separator
C = transfer tube
D = surface ionization probe
E = ion source

Effects on the response are observed from various surface treatment procedures. Introduction of oxygen into the ion source is believed to clean the probe surface by the rapid oxidation of contaminants. An optimum probe temperature is observed at 600-700 °C after stabilization for 1 hr. Injection of strong acids results in a 2-3x improvement of the signal. The mechanism of thermal surface ionization is assumed to be based on the simple dissociation of ion pairs (salts) by collision with the hot surface. However, in practice the response in negative-ion mode appears to be poor. These observations indicate that the mechanism of thermal surface ionization is more complex. The Surface Ionization spectra of most (anti)-cholinergic drugs do not only contain molecular cations, but give thermally-induced fragmentation. Probe-temperature effects on the mass spectrum of the pipenzolate cation (M_r 354) are shown in the figure



Compound	M_r	* (pg)	fragments
tetrabutylammonium	242	2	242
acetylcholine	146	10	58,72,104,146
isopropamide	353	100	114,264
pipenzolate	354	150	95,108,126
valethamate	306	150	100,114,163,306
diquad	184	10	169,183

The Application of Low Flow Techniques to Particle Beam Liquid Chromatography / Mass Spectrometry

J. Chris Richardson, [†]Matthew A. Tarr, and Richard F. Browner, School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, Georgia 30332-0400

[†] Present Address: USEPA, 960 College Station Road, Athens, GA 30613-7799

INTRODUCTION

Low flow rate chromatography, such as capillary LC, microbore LC, and capillary electrophoresis (CE), has many advantages for the separation of various classes of compounds, including biomolecules. Although very high resolution and low absolute detection limits can be achieved, the major drawback lies in the difficulty of detection. While absorption, fluorescence, and electrochemical detection have been developed extensively for CE, the advantage of more structural information has made mass spectrometry an attractive alternative. Aside from the recent use of FAB, electrospray ionization (ESI) has been the primary method for CE-MS and capillary LC/MS interfacing. ESI provides good detection limits; however, ESI spectra are often difficult to interpret and contain mostly singly and multiply charged molecular ions, with little fragmentation.

In our current study, we have succeeded in directly nebulizing liquid flows as low as 5 µL/min through the use of an ultrasonic nebulizer (USN), and 1 µL/min using a concentric nebulizer. No splitting of streams or addition of makeup solvent is necessary. This method of nebulization results in a neutral aerosol, which can be sampled by the mass spectrometer with the use of a particle beam interface. In this manner, any method of ionization can be utilized, including EI, CI, and others.

EXPERIMENTAL

Experiments were performed on an HP 5988 quadrupole mass spectrometer.The ultrasonic nebulizer used was built in house, and operates at 1.35MHz. Chromatography was carried out on an HP 1090 HPLC, which has the capability of producing liquid flows as low as 1 µL/min. The column used in this study is a 250 x 0.5mm column (purchased from Keystone Scientific) with a 5µm C18 packing. Optimun flow rate for this column is 12 µL/min.

RESULTS

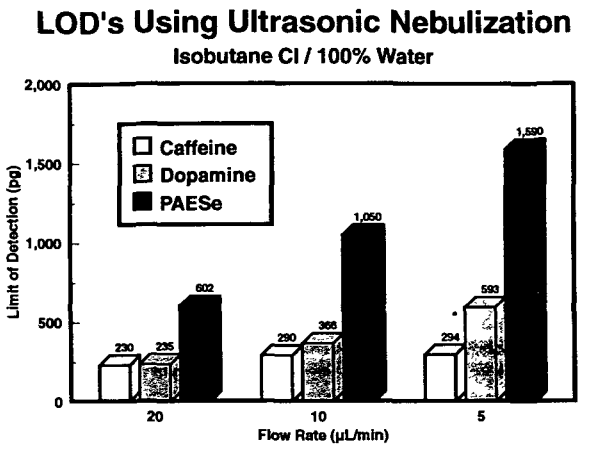
The USN produced very stable aerosols down to 10 µL/min with a slight loss of stability at 5µL/min. The limits of detection for the USN are shown in figure 1. These LOD's are quite good, and are comparable to LOD's at high flow rates.

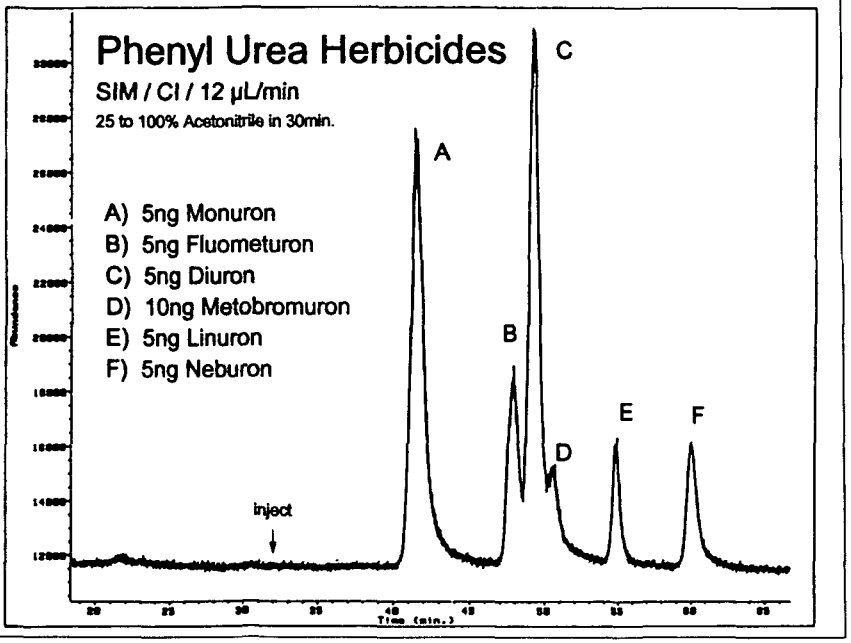
Similar experiments were carried out using the standard concentric nebulizer. Nebulization at lower flows proved to be very unstable, until the 100 µm capillary was replaced with a 25 µm capillary. After this modification, flows as low as 1 µL/min (the lower limit of the HPLC) could be nebulized. The separation of six phenyl urea herbicides is shown in figure 2.

CONCLUSIONS

The coupling of capillary LC to mass spectrometry using the particle beam interface is a simple process, requiring only the use of a smaller capillary. Sensitivity is comparable, and in some cases better than sensitivity at high flow rates.

The less intrusive nature of the USN may make it more compatible with CE, however, flows lower than 5 µL/min and high buffer concentrations may cause problems in the future.





Antisense DNA Oligonucleotides I: The Use of Ionspray Tandem Mass Spectrometry for the Sequence Verification of Methylphosphonate Oligodeoxyribonucleotides

Timothy R. Baker*, Thomas Keough, and Roy L. M. Dobson; The Procter & Gamble Company, Miami Valley Laboratories, Cincinnati, OH, 45239-8707
Timothy A. Riley, Jody A. Hasselfield, and P. Eric Hesselberth; JBL Scientific, Inc., 277 Granada Drive, San Luis Obisbo, CA 93401-5809

Interest in a new pharmaceutical therapy known as Antisense has recently become widespread. This technology utilizes molecules known as oligodeoxyribonucleotides to bind to messenger-ribonucleic acid (m-RNA), thereby inhibiting the synthesis of specific proteins. This highly specific binding to m-RNA is affected by the base content and the exact sequence of the oligomer. Any therapeutic investigations involving these compounds will require verification of the sequences of the synthetically prepared oligonucleotides. Our current interest lies in the use of oligodeoxyribonucleotides having a methylphosphonate backbone, which provides resistance to cleavage by nucleases. Unfortunately, the stability of these molecules precludes sequencing by the Sanger procedure [1].

A variety of mass spectrometric techniques have been utilized to obtain masses of oligonucleotides [2-7]. Recent work using ion trap [8] and fast atom bombardment [9-10] has demonstrated the ability to obtain limited sequence information with small oligonucleotides, but there has been a general paucity of data on larger oligomers. This work demonstates the utility of ionspray mass spectrometry to verify the sequences of these compounds (12-18 mers). Experiments (positive ion) were conducted using a PE-Sciex API III (flow injection).

Initial attempts to generate product ion spectra from multiply charged oligonucleotide precursors focused on maximizing the intensity of product ions. Experiments were conducted using doubly and triply protonated precursors so product spectra would contain ions with fewer possible charge states, facilitating their interpretation. Disadvantages of these constraints were that precursor ions were usually of lower relative abundance and production of fragment ions from doubly and triply charged precursors required collision conditions (high energy and gas thickness) that contributed to the formation of ions of limited diagnostic value. However, these initial experiments did produce a limited series of singly charged ions that were diagnostic of the original oligodeoxyribonucleotide sequence. These ions corresponded to m/z values resulting from simple heterolytic cleavages at the phosphonate-sugar bond with charge retention at the 3'-end of the molecule (defined as y-series fragments). Subsequent experiments proved that these ions could be enhanced relative to nondiagnostic ions by use of milder collision conditions (lower energy and gas thickness). Moreover, these y-series ions could be more readily produced from precursor ions having higher charge states. The product ion spectrum of the $[M+5H]^{5+}$ precursor of d(GGAACTTACCCGACAAGG), not shown, illustrated this point. Although the mild collision conditions resulted in much lower product ion production (<5% of precursor intensity), there was a predominance of diagnostic y-series ions produced. The inefficient yet gentle collision conditions resulted in product ions of all possible charge states.

Visualizing how this MS/MS spectrum relates to sequence becomes more obvious if the diagnostic ions detected in that spectrum are tabulated (see table). There are 17 possible y-ions for this 18-mer. The calculated m/z of the possible multiply charged y-ions are shown in alternating columns, up to the 5^+ state (parent ion charge state). Ions detected in the

spectrum are in bold, in columns for singly, doubly, triply charged, and so on. For this particular oligomer, verification of the sequence was nearly complete. Although there was no sequence information obtained for the y_{11} and y_{12} fragments, there was also no evidence to suggest that these bases were switched (i.e., no peaks at inappropriate m/z values).

Similar results were obtained with other methylphosphonate oligomers and tabulations of results showed the trend of product ion charge state increasing size. The trend is logical since the physically smaller ions prefer to support a single charge (y1-y3), while larger ions that comprise most of the molecule can easily support 3 or 4 charges. Thus far, we have been unable to find convincing evidence of the presence of additional ion series that are indicative of oligomer sequence.

EFFECTS OF SURFACE TENSION AND SURFACE ACTIVITY ON ELECTROSPRAY RESPONSE

M.V. Buchanan, Analytical Chemsitry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831; *M. Shahgholi and K.D. Cook, Chemistry Department, The University of Tennessee, Knoxville, TN 37996

The effect of surface tension on the formation of a stable electrospray (ES) has been studied extensively[1]. However, the impact of this parameter on the sensitivity of ES MS has not been characterized. The present study seeks to assess the effect of surface tension, as well as surface activity, on the mass spectrometric response of electrosprayed ions.

Electrospray experiments were performed with a source designed after that of Chait, interfaced to an Extrel (Model 065-2) quadrupole mass spectrometer. Samples containing 50 μM ($C_6H_{13}N^+(CH_3)_3$) bromide, HTMA, and varying amounts of surfactants were prepared in 50:50 water:methanol or methanol. Each sample was electrosprayed at approximately 4 μL/min through a needle held at +3.2 - 3.5 kV. The drying capillary (heated to 100-120°C) and the skimmer were biased to +90 - 130 V and +45 - 65 V, respectively.

In order to study the effects of surface tension, cationic, anionic, and non-ionic surfactants were added to samples of HTMA. Figure 1 shows the response of HTMA upon addition of varying amounts of the cationic surfactant, ($C_{18}H_{37}N^+(CH_3)_3$) bromide, ODTMA. Up to a concentration of ≈ 30 μM, addition of ODTMA bromide was observed to enhance the signal due to 50 μM HTMA in 50:50 (v/v) water:methanol. The added ODTMA lowers surface tension, presumably resulting in formation of smaller droplets which evaporate more efficiently. At high concentration, the more surface active ODTMA apparently competes with HTMA for surface sites on the droplets, reducing the efficiency of HTMA sampling. Furthermore, the increasing ionic strength may also contribute to the observed decrease in signal for HTMA. When analogous solutions were prepared with 100% methanol, the initial HTMA response enhancement by added ODTMA was not observed, suggesting that ODTMA has a negligible effect on the inherently low surface tension of methanol solutions.

The above experiment was repeated with SHS ($C_{16}H_{33}OSO_2^-Na^+$), an anionic surfactant. This compound should not be transmitted into the positively-charged electrospray and thus compete with the HTMA signal as observed with the cationic surfactant. At concentrations and surface tensions comparable to those in the previously studied cationic solutions, the HTMA signal does not improve. Furthermore, the SHS data reflected instabilities due to clogging of the ES needle, which could have been caused by the oxidation of SHS in the needle or its inherent lower solubility.

To avoid the problem of increasing the ionic strength of the solution, as in the case of the anionic and cationic surfactants, varying amounts of Triton X-100 were added to 50 μM solutions of HTMA in 50:50 (v/v) water:methanol. As shown in Figure 2, the response to 50 μM HTMA is enhanced by the addition of the non-ionic Triton X-100, up to roughly 0.3 mM surfactant. This behavior is attributed to surface tension lowering as also observed with the cationic surfactant, ODTMA. The decline in intensity observed at concentrations of Triton X-100 exceeding 0.3 mM is believed to

result from the onset of micellization (the critical micelle concentration for Triton X-100 is 0.3 mM[2]), which may strip the analyte from the droplet surface. Alternatively, high concentrations of Triton X-100 may interfere with droplet evaporation.

As a test of the role of competition for surface sites (described above), solutions containing equimolar amounts of $C_nH_{2n+1}N^+(CH_3)_3Br^-$ (n=6, 10, 12, 14, 16, 18) were electrosprayed at varying concentrations. When the concentration of each component was less than 2 μM, the responses of the various components were equal. At higher concentrations, the intensity observed for a given member of this series was dependent on its surface activity. This suggests that competition for surface sites induces sampling bias only at high concentrations.

These studies have several important analytical implications. Although it was not generally possible with our instrument to obtain ES mass spectra from aqueous solutions without methanol, this restriction was generally relieved by addition of Triton X-100. Further, these studies suggest that the reported enhancement of ES response resulting from protein denaturation[3] may arise from enhancements in surface activity because denaturation exposes the hydrophobic interior of the protein. Finally, this data shows that caution must be exercised in the quantitative analysis of multi-component mixtures by ES.

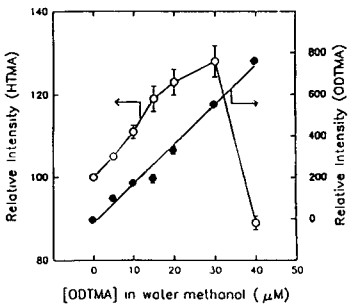

Figure 1. Dependence of the ES response of HTMA and ODTMA on [ODTMA] in 50:50 (v/v) water: methanol.

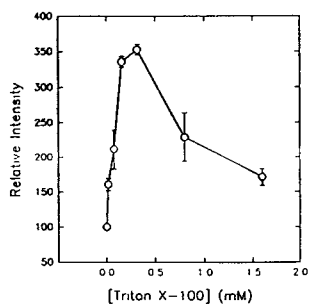

Figure 2. Dependence of the ES response of HTMA on [Triton X-100] in 50:50 (v/v) water:methanol.

Studies of the Physical Processes of Electrospray

Ross Willoughby, Ed Sheehan, Andy Jarrell,
Randy Peddar, Tom Marecic, and Steve Penn
Millipore/Extrel Mass Spectrometry
575 Epsion Drive, Pittsburgh, PA 15238

Introduction:

An energy balance model is proposed to explain the behavior of the liquid in the electrospray process of aerosol generation and ion formation. Consider that the energy flow on the axis of the electrospray needle and cone is conserved. The system is divided into section a, the needle; section b, the cone; section c, the jet; and section d, the droplets. This condition would be valid for the following assumptions.

Assumptions:

1. The liquid is incompressible, at constant temperature, and in a steady-state geometry.
2. No current flows due to gas discharge, therefore:

   $i_a = i_b = i_c = i_d$ where i = needle current

3. Mass is conserved in the z-axis, flow is constant:

   $dm_a/dt = dm_b/dt = dm_c/dt = dm_d/dt$ where dm/dt = mass flow

4. Energy flux is conserved on the z-axis:

   $dE_a/dt = dE_b/dt = dE_c/dt = dE_d/dt$ where dE/dt = energy flux

5. Energy flux partitions into kinetic, surface, and electrostatic components;

   $dE/dt = dK/dt + dS/dt + d\varepsilon/dt$, where

dK/dt = Kinetic Energy Flux; dS/dt = Surface Energy Flux; and $d\varepsilon/dt$ = Electrostatic Energy Flux

Nebulization Parameters

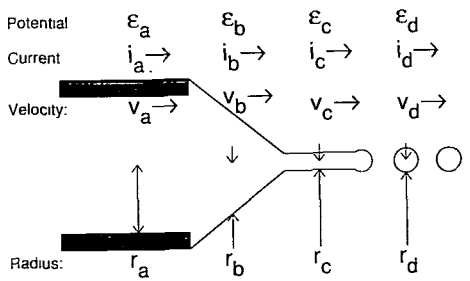

Table I: Partitioning of Energy in Cone

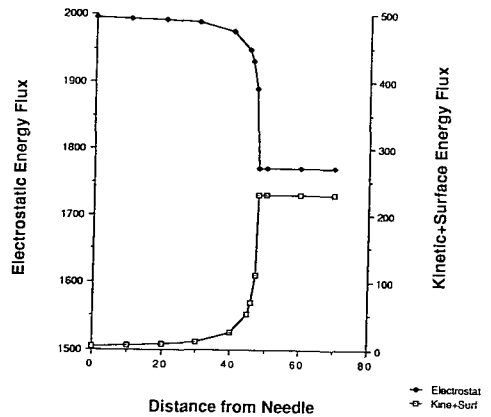
Region	dK/dt	dS/dt	dε/dt
A	$\pi r_a^2 \rho v_a^3/2$	0	$i\varepsilon_a$
B	$\pi r_b^2 \rho v_b^3/2$	$2\pi r_b v_b \gamma$	$i\varepsilon_b$
C	$\pi r_c^2 \rho v_c^3/2$	$2\pi r_c v_c \gamma$	$i\varepsilon_c$
D	$(4\pi r_d^3 \rho v_d^2/6)(dn/dt)$	$0.69(2\pi r_c v_c \gamma)$	$i\varepsilon_d$

Partitioning of Energy with Stable Cone



Conclusions:

1 Primary aerosol generation in electrospray can be explained using the Energy Balance Model for a steady state cone .
2. The model predicts that the Rayleigh Limit for surface instability occurs at the point where the liquid jet emerges from the cone. This is an important point in that primary droplets in electrospray are born at (or near) the Rayleigh Limit and consequently little or evaporation is required before subsequent breakup occurs.
3. Secondary droplet formation and geometry is also explained with this model to explain cone formation on the surface of the droplet.
4 The model predicts the observed increase in jet diameter with increased liquid flow rate.

Optimization of the Ionspray Mass Spectrometer as an LC Detector.*

R.K. Boyd, M.A. Quilliam and S. Pleasance[a], *National Research Council, Halifax, Canada B3H 3Z1*; S.J. Vanslyke and P.D. Wentzell, *Chemistry Dept., Dalhousie University, Halifax, Canada B3H 4J3.*
[a] *Present address: Wellcome Research Laboratories, Beckenham, UK BR3 3BS.*

Ionspray (IS, pneumatically assisted electrospray, ES) is an invaluable LC-MS interface for both proteins and small molecules [1]. The pneumatic assistance permits separation of nebulization from droplet charging, and thus greater flexibility. The mechanistic relationships between ES and IS have been clarified [2]. Recently [3] some empirical considerations of the interplay between the sometimes competing demands for chromatographic and mass spectrometric optimization of IS, were presented. The present work expands on this theme by examining the optimization of an ionspray LC/MS interface for both sensitivity and signal/noise ratio, with respect to parameters including needle position and angle, needle voltage, flowrates of nebulizing gas and of nitrogen curtain gas, mobile phase composition and flowrate (including post-column split ratios), *etc.*

Complex interactions of the position parameters were investigated systematically using a central composite design. Figure 1 shows the dependence of both analyte signal (m/z 571.5, $(M+2H)^{2+}$ ion from gramicidin S) and chemical background (cluster ions from aqueous acetonitrile) on the radial distance of the needle tip from the central axis; the signal maximised at about 5mm, but the signal/noise at about 7 mm. This optimum radial position (and also the optimum axial position, not shown) were essentially independent of solvent composition, a finding of significance for gradient elution operation.

Following optimization of the needle position, the dependence of analyte signal on mobile phase flowrate was investigated using the same flow-injection technique (no split). The response maximized at 3-10 µL/min, but dropped off in a quasi-exponential fashion (not shown) to a value about 10% of the maximum at 200 µL/min. Such behaviour of the ionization efficiency has been commonly observed. However, the results shown in Figure 2 were obtained using a full LC/MS method for Diltiazem (m/z 415), with a post-column split controlling the fraction of mobile phase (and thus of the analyte) delivered to the IS interface. At low values of this fraction the signal increases with increasing split ratio, reflecting the increasing fraction of analyte delivered to the mass spectrometer. However this trend is reversed at higher values, where the ionization efficiency effect becomes the dominant factor. There is a fairly broad range where the performance is close to optimal, so this adjustment is not critical. The appropriate choices of column i.d. (and thus of mobile phase flowrate) and of post-column split ratio, are inter-related and complex; the best choice will depend on the analytical problem at hand, *e.g.* how much sample is available, how concentrated is the analyte and its co-extractives, and thus how small an injection volume can be used, *etc.* Simple considerations of ionization efficiency alone do not suffice to optimize LC/MS analyses.

Other parameters investigated included mobile phase acidity (effect on both analyte signal and background), per cent organic content of mobile phase (acetonitrile gives a fairly broad plateau in which response is almost independent of composition), analyte type (*e.g.* small molecules yielding singly-charged ions *vs.* proteins yielding a distribution of charge states). The interactions of all of these parameters with one another have been considered in the context of optimizing LC/MS performance for both chromatographic resolution and overall sensitivity.

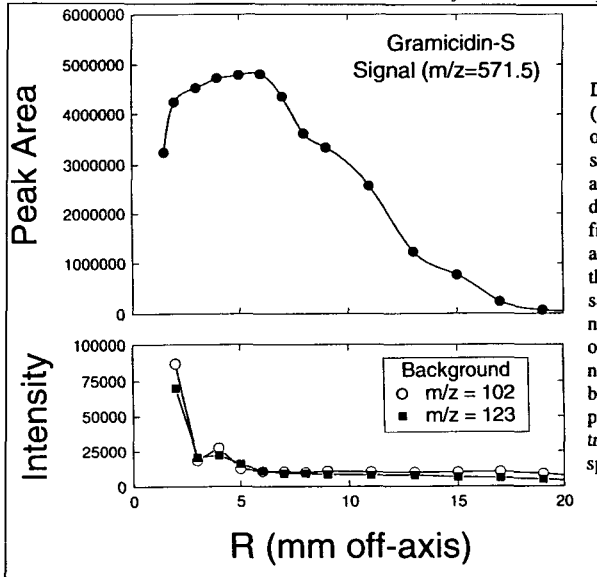

FIGURE 1.

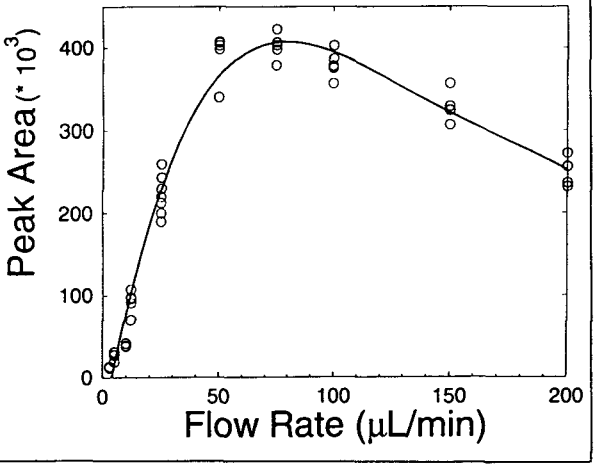
Dependence of the analyte signal (gramicidin S, $(M+2H)^{2+}$ ion), and of the most intense background signals (cluster ions from acidified aqueous acetonitrile) on radial distance of the ionspray needle from the central axis. Both the axial distance of the needle from the interface plate (containing the sampling orifice), and the needle/main-axis angle, were optimized. A sample size of 20 ng in 2 µL was used, introduced by flow injection into a mobile phase flowrate of 50 µL/min transmitted directly to the mass spectrometer with no split.

FIGURE 2.

Dependence of the analyte signal (m/z 415, protonated Diltiezam) on post-column split ratio. A fixed sample size of 100 ng in 2 µL was injected on-column, using a fixed flowrate of 200 µL/min of aqueous acetonitrile (isocratic). The flowrate delivered to the ionspray mass spectrometer was varied *via* a simple post-column split device.



CHEMICAL DERIVATIZATION FOR ELECTROSPRAY IONIZATION-MASS SPECTROMETRY

Gary J. Van Berkel[1] and J. Martin E. Quirke[2]
[1]Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge TN 37831-6365
[2]Department of Chemistry, Florida International University, Miami, FL 33199

The presence of analyte ions in solution appears to be central to the observation of analyte ions in the gas-phase using ES-MS. Therefore, derivatization of neutral analytes to form ionic species should benefit their analysis as has been previously demonstrated for FAB and SIMS.[1] Derivatization along with manipulation of solution chemistry to ionize (or neutralize) a particular analyte has the potential to not only improve the detectability of a particular analyte in ES-MS, but also to add a degree of analyte selectivity to an analysis. In fact, this derivatization approach to the analysis of certain analytes by ES-MS has recently been reported by several groups.[2-6] In this paper, derivatization strategies and specific derivatization reactions for conversion of mono-functional organics to ionic or solution-ionizable derivatives, i.e., "electrospray active" forms of the analyte, are presented. The derivatizations discussed here are not only applicable to the simple, mostly mono-functional molecules used as examples. Rather, these reactions might be used to ionize or transform the selected functionality as part of a larger, more complex molecule. In such a way the ES behavior of these more complex molecules might be enhanced or otherwise altered. The ES-MS instrumentation used in these studies was a modified version of a Finnigan-MAT ion trap mass spectrometer (ITMS) adapted to sample ambient air.[7] Detailed procedures for the derivatizations presented can be found in the papers cited and in most organic chemistry texts.

Three general chemical approaches, collectively referred to as chemical derivatization, are available to effect the solution-phase ionization of analytes. The most straightforward and most often used method takes advantage of the Brønsted or Lewis acid/base properties many molecules possess. Acid/base methods of solution-phase ionization have as their major advantage simplicity, but they are not generally applicable. Another means to ionize analytes in solution is via electron-transfer reactions. For example, chemical oxidants including Brønsted acids, charge-transfer reagents, and Lewis acids can be used to form radical cations of highly conjugated, aromatic, and heteroaromatic compounds. A third approach to generating an ionic form of the analyte is to chemically transform a functional group on the molecule to a solution-ionizable moiety. This transformation might be to a salt (**Figure 1**), to a group that is ionizable via acid/base chemistry (**Figure 2**), or to a group that is ionizable via an electron-transfer reaction (**Figure 3**). Rather than attempt to list possible derivatives, the general synthetic strategies for transformation of a particular functional group to an electrospray active moiety are presented. To aid this discussion, the common functionalities have been placed in groups based on their propensity to undergo similar types of organic reactions.

Hydrocarbons. Alkanes, because of their unreactive nature pose the most ***difficult*** problem for derivatization. In contrast, alkenes and alkynes can be transformed by making use of the propensity of the π-bonded system to undergo ***addition reactions***. In addition, the alkyne carbanion that can be generated from terminal alkynes in strong base is nucleophilic and may take part in ***addition or substitution reactions***. Aromatics are readily amenable to ***electrophilic substitution reactions***, but as a compound class they are relatively easy to oxidize and/or reduce. Therefore, chemical ***electron-transfer reactions*** can be used to form cations/anions of certain aromatics in solution.

R-X Type Compounds. The presence of an electronegative group in RX-type compounds, i.e., a halogen, -OH, -SH, $-NR_2$, and NO_2, provides for a wide range of strategies for generating ionic species for ES-MS. In general, however, the most obvious route to ionic derivatives is to employ

nucleophilic substitution. Some compounds of this type, ***amines and phenols*** in particular, can also be charged by simple ***acid/base chemistry***. Additionally, it is possible to ***transform the "X" group*** of R-X type compounds into an ionic or solution ionizable moiety in a variety of ways.[1]

Aldehydes and Ketones. ***Addition reactions*** across the double bond of these functional groups can be used to form an R-X type compound which can then be transformed to an electrospray active species as outlined above. A second and probably more promising route to a suitable derivative is via ***condensation reactions***. An alternative route for ***aldehydes*** is to take advantage of their facile ***oxidation to carboxylic acids*** which are electrospray active species.

Acyl halides, amides, anhydrides, nitriles, and esters are derived from carboxylic acids and are most easily converted to electrospray active species by ***hydrolysis to the parent acid***. While identification of the carboxylic acid is facile, a second step is required to identify the nature of the "X" group. For example, only one half of an ester can be detected using this approach. An alternative for ***amides*** is ***reduction to the amine*** in which case the product may be further derivatized to an electrospray active species using one of the techniques discussed for R-X type compounds.

High Resolution Precision Mass Measurements of Noncovalently Bound Protein Aggregates Using Electrospray Ionization Fourier Transform Ion Cyclotron Resonance Mass Spectrometry

Steven A. Hofstadler, James E. Bruce, Brian E. Winger, and Richard D. Smith
Chemical Sciences Laboratory, Pacific Northwest Laboratory Richland, WA 99352

Since its introduction as a viable ionization technique for mass spectrometry of large molecules by Fenn and coworkers, electrospray ionization (ESI) has become a key tool for the analysis of bioanalytically relevant compounds including proteins, peptides, and nucleotides. Aside from the fact that ESI typically generates multiply charged ions, thus lowering the m/z range necessary for detection, the "softness" of the ionization technique allows analysis of large intact biopolymers and potentially provides a direct link between solution chemistry and gas phase conformations. Recently, we have constructed an external source electrospray ionization Fourier transform ion cyclotron resonance (FTICR) mass spectrometer capable of high precision mass measurements and ultra-high resolving power (*i.e.* >> 2 x 10^6 at m/z 1434). The high resolution capabilities of the spectrometer allow simple charge state determination based on the isotopic spacing of molecular ion peaks of a single charge state, thus making it an ideal platform on which to study the abundance and stability of protein aggregates (*i.e.* monomers, dimers, trimers, etc.) based on the observed isotope distribution of aggregate peaks.

Under favorable solution conditions and "gentle" electrospray source conditions, which include minimal capillary heating and low capillary-skimmer potential difference, protein aggregation is often observed. These aggregate peaks correspond to multiply charged noncovalently bound species with molecular weights equal to **n** x $\mathbf{M_r}$, where **n** is the order of the aggregate (eg. **n**=2 corresponds to the dimer species) and $\mathbf{M_r}$ is the molecular weight of the monomeric species. Given that different multimeric species can occupy different charge state distributions, it is often the case that multiple aggregated species are observed at the same nominal m/z. For example, shown in Figure 1 is a mass spectrum of bovine insulin (M_r = 5734) acquired under "gentle" ionization conditions. Even at low resolution it is apparent that additional peaks corresponding to higher order aggregates are evident. A closer look at these peaks reveals that they contain contributions from several multimeric species. It is evident at higher resolution that the peak at m/z 1912 has contributions from the 3+ monomer (***M***), 6+ dimer (***D***), and 12+ tetramer (***T***). Figure 2 demonstrates Bovine cytochrome c (M_r = 12,223) aggregation in the presence of a low concentration of sodium. Under harsher interface conditions less aggregation is observed as is a precipitous decline in the abundance of the monomeric sodiated species. Such aggregates constitute only one example of a broad range of noncovalent associations which should be amenable to study using these methods, including many associations of importance in physiological processes.

This research was supported by internal PNL exploratory research through the U.S. Department of Energy. Pacific Northwest Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy through contract DE-AC06-76RLO 1830.

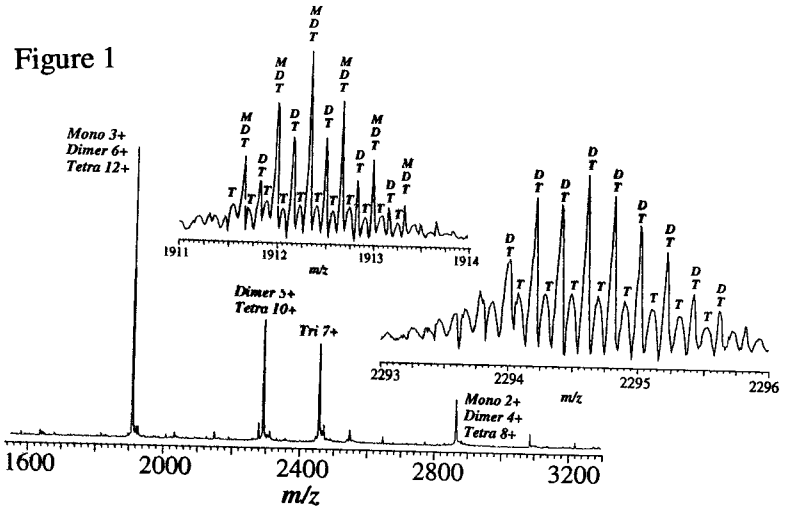

Figure 2

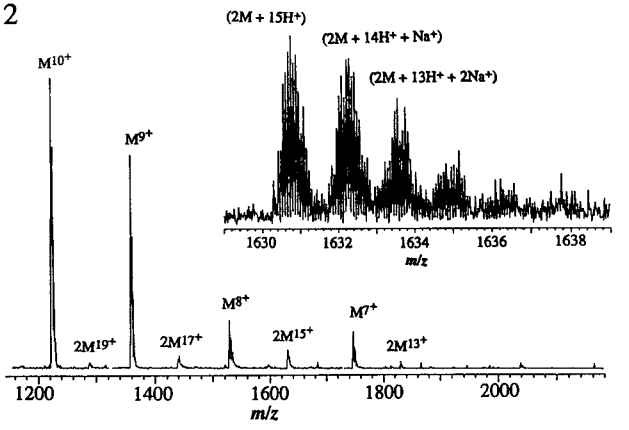


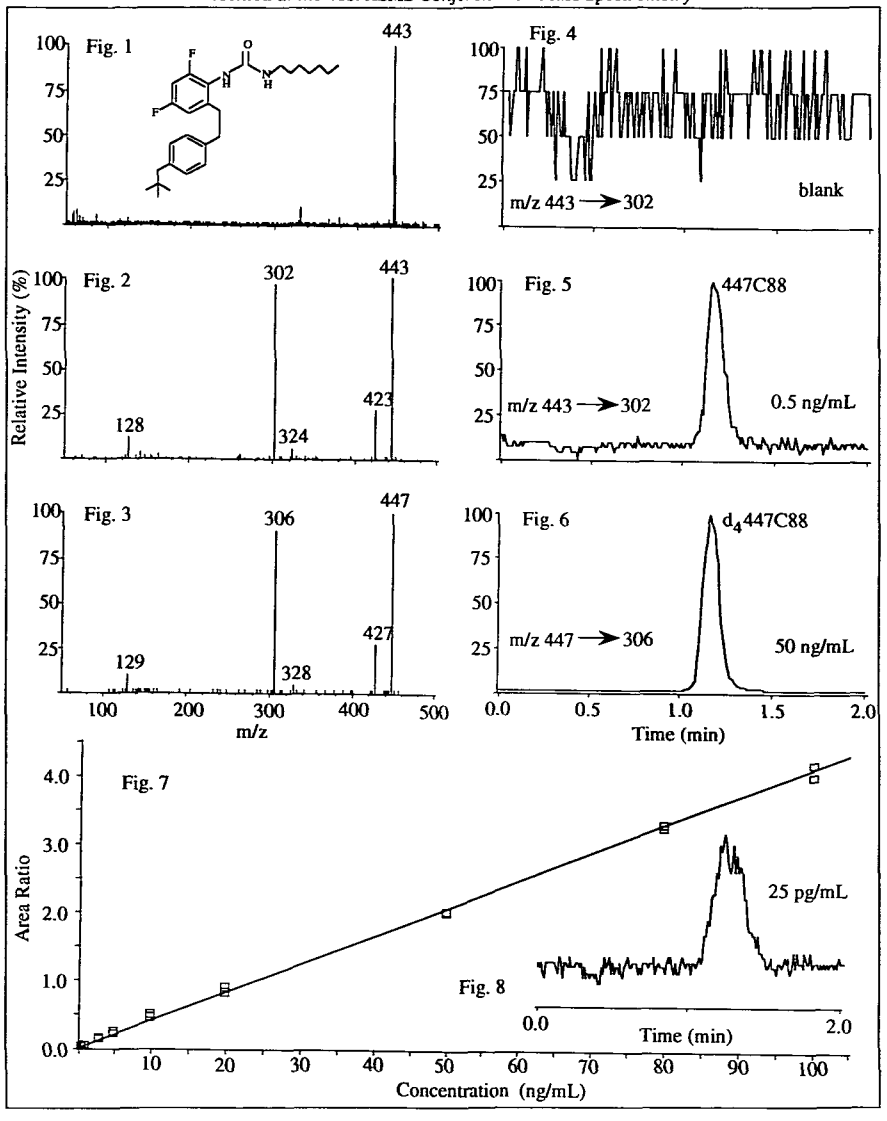
THE DETERMINATION OF A HYPOLIPIDAEMIC AGENT IN PLASMA BY GAS CHROMATOGRAPHY MASS SPECTROMETRY AND LIQUID CHROMATOGRAPHY TANDEM MASS SPECTROMETRY USING ATMOSPHERIC PRESSURE CHEMICAL IONISATION.

I. J. FRASER, R. A. CLARE and S. PLEASANCE,
Department of Bioanalysis and Drug Metabolism, The Wellcome Research Laboratories, Langley Court, Beckenham, Kent, BR3 3BS, U.K.

The compound *N*-Heptyl-*N* '-(2,4 difluoro-6-{2-[-4-(2,2 dimethylpropyl)phenly] ethyl}-phenyl) urea (447C88, Fig. 1) is a member of the new class of potential hypolipidaemic agents, the AcylCoA Cholesterol AcylTransferase (ACAT) inhibitors. Initial attempts to quantitate 447C88 in plasma using both UV and fluorescence detection were unsuccessful and led to the investigation of a sensitive and selective mass spectrometry based method.

A GC-MS method was initially developed to support pre-clinical work requiring the determination of 447C88 in both the rat and dog plasma. Samples were extracted using a phenyl solid-phase extraction cartridge, taken to dryness and derivatised with iodoethane in DMSO. The ethyl derivatives were back extracted into pentane, again taken to dryness and finally reconstituted prior to injection onto a Hewlett Packard 5970 mass selective detector. A deuterated [d4] analogue of 447C88 was used as internal standard and both molecular ions monitored using selected ion recording. While the GC-MS assay was both selective and sensitive, providing a detection limit of 0.4 ng/mL, the extraction and derivatisation procedure was labour intensive and sample turn round was slow due to long chromatographic run times (30 minutes).

The installation of a triple quadrupole instrument with atmospheric pressure ionisation offered the potential of an LC-MS-MS method with increased sensitivity and greater sample throughput. Both 447C88 and its deuterated analogue give an intense deprotonated molecule under negative ion atmospheric pressure chemical ionisation (Fig. 1) and also provided abundant product ions which can be used for multiple reaction monitoring (see Figs. 2-3). The increased selectivity and sensitivity offered by LC-MS-MS has two advantages: firstly, the sample preparation time can be dramatically reduced. Only the solid-phase extraction step is used from the GC-MS method with no concentration steps, no clean-up or derivatisation; Secondly, the run time can be shortened to less than 2 minutes per injection (Figs. 4-6). A short 3 cm C18 column is used with a mobile phase of 20:80 aqueous acetonitrile at 1 mL/min connected directly to the heated nebuliser interface. A 20 µL injection provided the same sensitivity to that obtained by GC-MS, but with a 24 hour turn around of a normal batch of 76 samples (90 with QCs, Stds and blanks) compared with 3-4 days for GC-MS. It has been possible to make 250 injections in a 12 hour period. The LC-MS-MS assay has subsequently been validated in rat, dog and human plasma, showing only limited bias (≤10%) and excellant precision (<10% expressed as pertentage CV) for both inter and intra-assay determinations (Fig. 7). With only minor modifications to the methodology (inclusion of a concentration step, an injection volume of 50 µL and decreasing the mass resolution) the assay can be readily extended to low pg /mL levels should it be required (Fig. 8).



Photographic Studies of Electrospray Aerosols

Edward W. Sheehan* and Ross C. Willoughby
Millipore/Extrel Mass Spectrometry
575 Epsilon Dr., Pittsburgh, PA 15238

Introduction

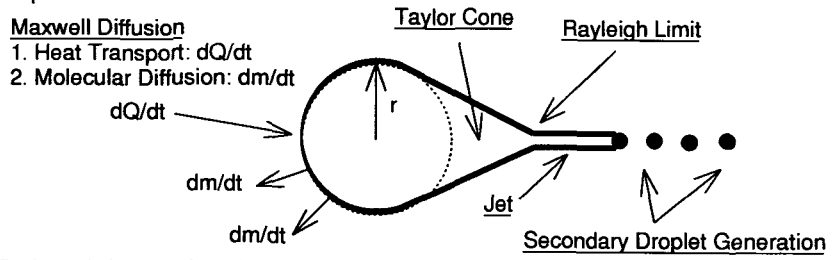
There have been many models used to explain the electrospray process; including, the "Coulomb Explosion" mechanism by Dole and coworkers[1], and "Ion Evaporation from a Liquid" mechanism proposed by Iribarne and Thomson[2].

The current studies are intended to propose and analyze a more comprehensive model for the physical behavior of electrospray LC/MS. Electrospray has demonstrated unique ability to generate ions of species heretofore thought involatile. We have proposed a three stage process of primary, secondary, and tertiary particle generation. The complete model is addressed in this poster and on poster by Willoughby and coworkers.

The objectives of the present work was to propose a model to explain "Secondary Droplet Production" and "Ion Production" from an aerosol of highly charged droplets based on photographic evidence.

Secondary Aerosol Generation (Figure 1.)

Secondary droplet generation is driven by the (1) evaporation of the primary charged droplet (Maxwell Diffusion), (2) formation of a Taylor Cone, (3) reaching the Rayleigh Limit, (3) forming a jet, and (4) then disruption of the cylindrical jet to form secondary droplets.



Drying of the droplet with a counter current of dry gas: (controlled by molecular diffusion, dm/dt)
Drying of the droplet with externally added heat: (controlled by heat)

Figure 1. Secondary Aerosol Formation from a Primary Droplet.

1. Dole et al, J. Chem. Phys.(1968),49, p. 2240.
2. Thomson and Iribarne, Reviews of Geophysics and Space Physics (1978), 16, p. 431.

The droplets continue this "cascade" of reaching the Rayleigh instability and generating smaller and smaller droplets till the droplet reaches the Ion Limit. Once the droplet has reached the ion limit, the energy required for evaporation of an ion is considerably larger then the energy needed for ion desorption.

Ion Formation (Figure 2.)

Ion formation is driven by the (1) evaporation of the secondary droplet (Gibbs-Kelvin effect), (2) formation of a Taylor Cone, (3) and reaching the Ion Limit.

Gibbs-Kelvin effect: rate of evaporation (dm/dt) changes from r^2 to r^3 relationship due to curvature.

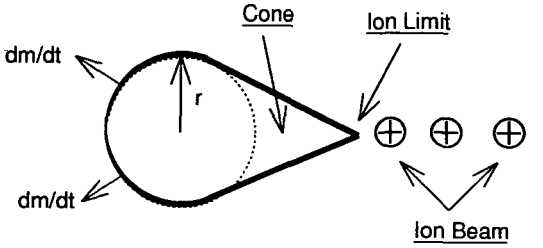


Figure 2. Ion Formation.

Conclusions

1. Secondary Aerosol Generation results from similar processes that occur in the Primary Aerosol Generation from the needle; a cone forms on a sherical droplet which accelerates the liquid to the Rayleigh Limit and a liquid jet emerges breaking into secondary droplets.

2. Secondary Aerosol Generation is initiated by evaporation of Primary droplets. Evaporation is augmented by increasing p_{0S} with heat or decreasing p_{∞} by adding dry gas.

3. Electron micrographic evidence shows significant residue from Primary and Secondary droplet products; thus not all analyte goes into the vapor phase.

4. The size and shape of residue particles supports the "Teardrop" model for ion production.

DOMINANCE OF SOLVENT DIELECTRIC CONSTANT IN DETERMINING ANALYTE CHARGE STATE IN NEGATIVE ION ELECTROSPRAY MASS SPECTROMETRY

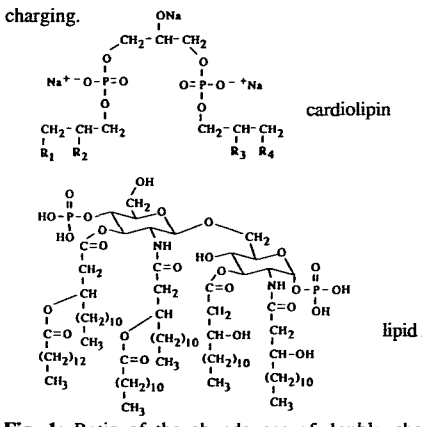
Richard B. Cole* and A. Kamel Harrata

Department of Chemistry, University of New Orleans, Lakefront Campus, New Orleans, LA 70148

The choice of solvent has been shown to exert a profound influence on the distribution of charge states in negative ion electrospray mass spectrometry (ESMS) [1]. Conceivably, many solvent characteristics could influence, to varying degrees, the preferred charge states appearing in the ES mass spectrum. Attributing observed electrospray mass spectral characteristics to individual solvent parameters, of course, is complicated by the inability to independently vary a single solvent parameter without simultaneously altering others. Competing forces arising from different solution properties can alter the appearance of the mass spectrum in subtle or conspicuous manners. Certain solvent characteristics, such as specific conductance, surface tension, and viscosity, which are known to influence electrospray performance in a variety of ways, exhibited no obvious correlation to the observed charge state distributions. Rather, experiments point to the dominance of solution polarity in determining the preferred ESMS charge state.

This study has investigated the influence that a series of solvents, having decreasing dielectric constants and increasing solvent basicities, gas-phase basicities and proton affinities, exerts on analyte charge state. Shown in Fig. 1 is the ratio of the abundances of doubly charged/singly charged ions of diphosphoryl lipid A from *Escherichia coli* (✚, 34 °C) and 'cardiolipin' (•, 34 °C) dissolved in various solvents ranked in order of decreasing dielectric constant as given by ε(T °C) [2]. The order of decreasing dielectric constant is also the order of increasing proton affinities and gas-phase basicities, with 2-propanol and 1-butanol (proton affinities and gas-phase basicities virtually equal) exhibiting the only anomaly to this latter ranking. Solution-phase basicities have also been measured [3,4] indicating an order of basicity: methanol < ethanol < 2-propanol which parallels the gas-phase basicity data. A clear trend displaying a decreased tendency toward formation of ions of higher charge state from solvents having low dielectric constants is evident. The fact that the gas-phase basicity and the proton affinity of the solvents are increasing from left to right (except for 1-butanol < 2-propanol) serves to indicate clearly that gas-phase factors are minor, perhaps negligible contributors to the removal of cations from analyte molecules. In other words, even though 2-propanol and 1-butanol have the highest affinity for protons in the gas phase, they exhibited the weakest ability to remove the second proton from diphosphoryl lipid A. Significantly, the importance of solution-phase basicity in determining the predominant charge state is also diminished. In examining methanol, ethanol, and 2-propanol, the higher charge state became less prominent for solutions of increasing basicity, indicating that more highly basic solutions were less effective at removing the second proton from diphosphoryl lipid A.

Evidence suggests that the solution dielectric is the dominant characteristic which dictates the charge state of the two investigated analytes subjected to negative ion electrospray mass spectrometry. For both chlorinated and non-chlorinated organic solvents, the higher the solution dielectric constant, the more the charge state distribution is shifted toward higher charge states. Solvents with high basicities (gas-phase and solution-phase) and high proton affinities, yet low dielectric constants, favor lower charge states in ESMS spectra of lipid A and cardiolipin from *E. coli*. This indicates that gas-phase processes and solvent basicity contribute much less toward ion formation than solution phase solvation via preferred orientation of the solvent dipole. Ionization of these analytes must then be occurring in solution, prior to entering the gas phase. These observations build upon the "electrophoretic" mechanism of droplet charging [5-7]. Solvents with high solution dielectric constants are considered to be most effective at stabilizing multiply charged ions (where charge separation is greatest), and they are likely to increase the level of droplet charging.



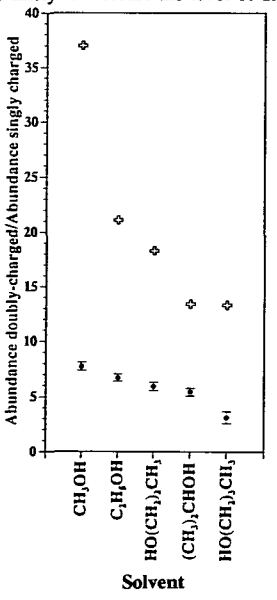


Fig. 1: Ratio of the abundances of doubly charged/singly charged ions of diphosphoryl lipid A from *E. coli* (✚, 34 °C) and 'cardiolipin' (•, 34 °C) dissolved in 10% chloroform and 90% of: methanol ε(34)=30.9; ethanol ε(34)=23.0; 1-propanol ε(34)=18.9; 2-propanol ε(34)=17.2; and 1-butanol ε(34)=16.0. Solvents are listed in order of decreasing dielectric constant [2].

Elemental Electrospray Mass Spectrometry

George R. Agnes and Gary Horlick
Department of Chemistry, University of Alberta
Edmonton, Alberta, Canada, T6G 2G2

An ideal elemental analysis technique for solution samples would provide both quantitative and qualitative information for all solution components. Solution components include anions and cations in elemental, molecular, and complexed forms. Elemental electrospray mass spectrometry (elemental ES-MS) is being developed with this goal in mind.

Three positive-ion modes have been developed and have been named for the type of information available from the mass spectrum; ion-cluster, metal-ion, and ion-counter-ion mode. The electrospray source operational parameters for positive and negative ion elemental ES-MS are listed in Table 1. The two most critical parameters to control are the sampling plate voltage and the curtain gas flow rate.

	Positive Ion			Negative Ion
	Ion-Cluster	Metal-Ion	Ion-Counter-ion	
ES Tip (kV)	3.5	5.0	5.0	-3.0
Front Plate (V)	700	950	950	-950
Sampling Plate (V)	35	190	190	-80
Skimmer (V)	5	5	5	-5
Curtain Gas Flow Rate (l/min.)	0.3	0.4	0.2	0.4

Table 1. Operational Parameters of the Elemental Electrospray Source.

The process of electrospray generates gas phase metal ion clusters directly from the liquid phase. Operation of the ES source under mild conditions will preserve the ion clusters. Figure 1a is a mass spectrum of a solution of manganese II chloride acquired with ion-cluster conditions. Probing of the solution phase environment for speciation purposes (oxidation state and associated ligands) is possible with the ion-cluster mode.

The metal-ion mode of operating the electrospray source causes the ion-clusters to be subjected to harsh conditions causing decomposition of the gas phase cluster. Figure 1b shows singly charged ions dominating the mass spectrum with few spectral interferences. In this respect, mass spectra obtained with the metal-ion mode of elemental ES-MS are similar in appearance to mass spectra obtained with ICP-MS. Molecular interferences, attributed to incomplete decomposition of the gas phase clusters, have been significantly reduced from that previously reported.[1]

The ion-counter-ion mode is depicted in Figure 1c where $MnCl(MeOH)_n^+$, n=0,1 clusters are detected. Ion-pairing of multiply charged metal ions with counter-ions present in the charged droplet reduces the solvation energy of the ion-counter-ion cluster. A reduction of the curtain gas flow rate decreases the rate of solvent evaporation from the charged droplets allowing more time for formation of the Ion-counter-ion clusters. The rate of ion evaporation from the charged droplets depends on the solvation energy of the desorbing cluster, hence the newly formed ion-counter-ion clusters experience a high rate of ion evaporation.

Negative-ion ES-MS permits direct investigation of solution anions. The halides and sulfur based anions have detection limits in the low ng/ml range. Utilization of both positive and negative ion Elemental ES-MS provides the researcher with a tool with which a complete ionic picture of a solution can be assembled. Positive ion (Figure 2a) and negative ion (Figure 2b) ES-MS was used to differentiate two chromium species. Vanadium and manganese species were similarly differentiated with elemental ES-MS.

Wavelength-Specific Resonance Enhanced Multiphoton Ionization for Isomer Discrimination via Fragmentation and Metastable Ion Analysis

Scott T. Fountain and David M. Lubman, Department of Chemistry
University of Michigan, Ann Arbor, MI 48109

Resonance-enhanced multiphoton ionization (REMPI) has been shown to be a highly sensitive and selective ionization technique when coupled with mass spectrometry. The spectroscopic dependence of the ionization process and the use of narrow-band tunable laser radiation allows selective ionization with little or no fragmentation. The molecular ion can then absorb additional photons via a ladder-switching mechanism thereby producing molecular fragmentation for structural analysis[1]. Since these fragments are often produced with a relatively narrow energy distribution above the ionization potential of the molecule, unique metastable ions are often observed. By analyzing the energy release associated with these metastable ions using a reflectron time-of-flight mass spectrometer, information on the fragmentation mechanism of the molecule can be obtained[2,3] If metastable ion decay is observed at the isomeric center of two isomers, molecular discrimination is possible[4].

Here it is shown that isomeric dipeptides containing leucine and isoleucine can be discriminated on the basis of their metastable ion decays in a reflectron time-of-flight mass spectrometer when using variable-wavelength REMPI. In particular it is shown that specific metastable ions are observed for the isomeric pairs Tyr-Leu/Tyr-Ile and Leu-Tyr/Ile-Tyr when using REMPI ionization at 266 nm and 193 nm respectively. By using variable reflectron voltages, two complementary spectra can be obtained showing stable ions (produced in the ion source) and lower-energy metastable ions (produced via decay in the drift tube). When a total reflectron voltage in excess of the ion extraction voltage is used, a complete ion spectrum is obtained which includes both stable ions and metastable ions. By decreasing the reflectron voltage to observe lower-energy metastable ions, the energy of these ions can be determined by observing the reflectron turning voltage necessary for ion reflection. Using this information, ion decay mechanisms can be obtained for the metastable transitions.

Figure 1 shows the 266 nm REMPI spectra of Tyr-Leu and Tyr-Ile. Both ions produce two metastable transitions from the molecular ion to give fragments at m/z 277 and m/z 188. However, the 266 nm REMPI spectra of Tyr-Leu contains an additional metastable transition not observed in the isomer which may result from further decay of the m/z 277 product (see Scheme 1). However, the 193 nm REMPI spectra of Tyr-Leu and Tyr-Ile are very similar and neither the stable nor metastable ion spectra show metastable fragmentation allowing isomeric discrimination. The most efficient REMPI wavelength for production of unique metastable ion decays was found to be dependent on the small changes in molecular structure. Figure 2 shows the 193 nm REMPI spectra of Leu-Tyr and Ile-Tyr. Here the 193 nm REMPI spectra provides unique metastable fragmentation allowing discrimination of the two isomers. Both Leu-Tyr and Ile-Tyr show metastable ion transitions from m/z 86 to m/z 30 An additional metastable ion is observed in Ile-Tyr due to rearrangement of the Ile -R functional group (see Scheme 2) thereby allowing isomeric discrimination. The 266 nm REMPI spectra of Leu-Tyr and Ile-Tyr were very similar and neither the stable nor metastable ion spectra allowed discrimination. The correct choice of REMPI wavelength appears to be crucial in optimizing the production of unique metastable ion transitions in such isomeric systems.[5]

Application of PSD-MALDI to the Localization of Modification Sites in Peptides

Bernhard Spengler, Raimund Kaufmann,
Inst. of Laser Medicine, University of Düsseldorf, Moorenstr. 5, D-4000 Düsseldorf, Germany
Matthias Mann,
European Molecular Biology Laboratory, Meyerhofstr. 1, D-6900 Heidelberg, Germany

A new technique for peptide sequencing and structure analysis, called PSD-MALDI (postsource decay - matrix assisted laser desorption ionization), has recently been developed[1,2,3], taking advantage of the versatility, high sensitivity, short analysis times and low cost typical of time-of-flight instrumentation coupled with the laser/matrix technique. The method is based on mass spectrometrical analysis of daughter ions formed by unimolecular and/or collision induced decay in the first field free drift region of a two-stage grid-reflectron time-of-flight mass spectrometer. The performance of the method has been evaluated for known peptides and has been found to be, in some features, superior to other methods of peptide sequencing. Peptides up to ≈3000u could be sequenced at good spectra quality and with high reliability. Full sequence information of Substance P could be obtained even from single shot spectra (consumed sample amount ≈ 400 attomol).

The method has been applied to localize modification sites of phospho- and lipopeptides of known amino acid sequence Determination of such modifications is an important task in protein and peptide chemistry, and is difficult to achieve with conventional biochemical techniques. Using PSD-MALDI, modifications could be localized unequivocally in all cases.

Figure 1, as an example, shows the PSD-MALDI spectrum of a lipopeptide (15 amino acids) with the most intense peaks labelled. The amino acid sequence was known for this peptide. The position and nature of the fatty acid, however, was unknown. From the parent ion mass the fatty acid has been identified as myristic acid (or an isomer with m=228.4 u) assuming an amide or ester linkage. In the low mass region fragment ions characteristic for the different amino acids appear (immonium ions and smaller fragments). All signals at higher mass correspond to either N-terminal ions containing the fatty acid or C-terminal ions not containing the fatty acid. The smallest ion containing the fatty acid is the b_1 fragment. Since the N-terminal amino acid is glycine, the fatty acid can thus only be located at the terminal amino group forming an amide.

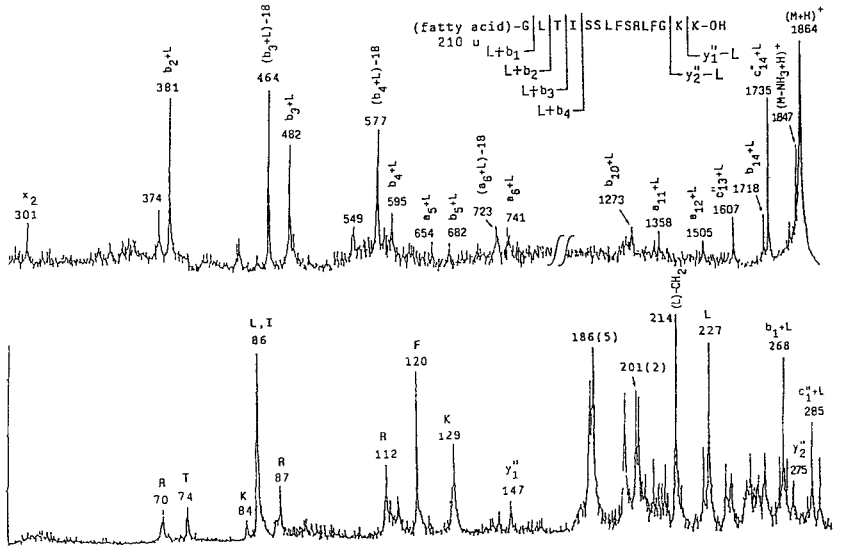

Figure 1 PSD-MALDI spectrum of a lipopeptide Position and nature of the fatty acid have been identified from the fragmentation pattern

Similar to the above example the modification site of a phosphorylated peptide has been identified (Figure 2) N-terminal ions b_2 to b_5 have been observed as unmodified peptide fragments. Larger ions b_6 to b_9 have been found to contain a phosphoryl group (+80 u). Correspondingly C-terminal ions y''_2 to y''_5 appeared as unmodified peptide fragments while larger ions y''_6 to y''_9 were modified by a phosporyl group. From these data the location of the phosphate group could be identified as the tyrosine molecule.

AN EVALUATION OF CRYSTALLIZATION METHODS FOR MATRIX-ASSISTED, LASER DESORPTION / IONIZATION OF PROTEINS

Scot R. Weinberger, Linear Scientific Inc, Reno, NV, USA, 89523

K. O. Boernsen, Ciba-Geigy Ltd., Basel Switzerland

Jeffrey W. Finchy, Vernon Robertson, Brian D. Musselman, JEOL USA Inc., Peabody MA, USA, 01960

The efficiency of MALDI has been shown to be dependent on a number of factors including laser intensity, matrix material, and sample preparation. The dynamics involved in routine formation of homogeneous matrix-analyte co-crystals have been poorly established. This work endeavors to demonstrate the co-crystalization efficiencies of static air dried, heat dried, and vacuum dried sample preparation methods using sinapinic acid and peptide mixtures Sample-matrix co-crystals will be examined for homogeneity using scanning electron microscopy. Additionally, each method will be contrasted in terms of minimal laser desorption fluence, average initial desorption velocity, resultant resolution, and ease of signal production.

Methods and Materials

Sample-matrix co-crystals were formed by mixing equal volumes of 100 mM Sinapinic Acid solutions (*Linear Scientific, MALDI-Grade*) with a 5 uM, peptide mixture of oxytocin, arg-8-vasopressin, angiotensin I, somatostatin, chicken atrial natriuretic peptide, human r-insulin, and r-hirudin (*Linear Scientific Peptide Standard*). One microliter aliquots of this mixture were deposited upon gold-plated probes and allowed to crystalize using static air, 100 watt heat lamp, and vacuum (10^{-2} torr) drying conditions. Resolution and ease of signal production studies were performed using a *Linear Scientific LDI-700 XP* automated MALDI-TOFMS fitted with a nitrogen laser (337 nm). All MALDI-TOFMS analyses were automatically performed by adding successive scans (each scan limited to a 3 - 10 signal to noise window using between one to five microjoules of laser energy) until a 70:1 total signal to noise ratio was achieved for r-insulin. The total number of shots required to produce this signal was taken to be inversely proportional to the ease of signal production. Resolution was calculated as flight time / 2 (half height width time). Minimal laser desorption fluence and initial desorption velocity studies were performed using a Linear Scientific LDI-1700 MALDI-TOFMS fitted with a nitrogen laser (337 nm). Minimum laser desorption fluence was defined as that laser energy of which a five percent decrease resulted in no ion signal. Minimum desorption velocities were extrapolated from a function derived by measuring insulin flight velocities at kinetic energies ranging from 10 to 30 KeV. Scanning electron micrographs were taken using a JEOL JSM 6300 scanning electron microscope.

Results

The average time required for matrix-sample co-crystallization for air, heat, and vacuum drying methods was: 2.66 (+/- 0.04), 1.33 (+/- 0.085), and 0.086 (+/- 0.0025) minutes,

respectively. The average minimal laser fluence required for desorption of air, heat, and vacuum dried sinapinic acid-insulin co-crystals was: 2.99, 2.80, and 2.84 mJ/cm^2, respectively. The average initial desorption velocities of air, heat, and vacuum dried sinapinic acid-insulin co-crystals was 537, 520, and 484 m/sec, respectively. The average resolution of air, heat, and vacuum dried sinapinc acid-insulin co-crystal TOF signals was: 300 (+/- 20.5), 280 (+/- 28.5), and 398 (+/- 19 5), respectively. The average number of laser shots required to create a 70:1 s/n mass-spectrogram of r-insulin for air, heat, and vacuum crystallization schemes was 406 (+/- 85), 485 (+/- 142), and 190 (+/- 50), respectively.

Scanning electron microscopic studies revealed: (1) Heat and air dried co-crystals were hollow hexagonal prisms with average lengths exceeding 100 microns. Vacuum dried co-crystals were irregular shaped, flat sheets with average lengths of 10-40 microns. Heat and air dried co-crystals were circumferentially distributed about the outer probe surface while vacuum dried co-crystals were seen evenly distributed throughout. Heat and air dried co-crystals exhibited a predominance of interco-crystalline voids where vacuum dried co-crystals did not. Heat and air dried co-crystals were observed in various positions upon the probe tip while vaccum induced co-crystals exhibited a smaller variation in their positioning.

Conclusions

It appears that the vacuum crystallization method is 20 - 30 times faster than either air or heat drying methods. Additionally, vacuum crystalized samples required fewer laser shots to create a 70:1 s/n spectra. The latter is postulated to be due to: (1) the overall regular distribution of vacuum-induced co-crystals upon the probe surface; (2) the absence of significant interco-crystalline voids; and (3) the smaller size and geometric pattern of vacuum created co-crystals, making them more easily transluminated by a given incident laser spot. The decreased time period required for sample preparation and signal production results in an overall increase in analytical sample throughput for vacuum induced co-crystalization schemes when compared to those of air and heat.

Vacuum formed sinapinic acid-insulin co-crystals yielded superior resolution for time of flight signals. Because the differences in flight tube pressure, average minimal desorption laser fluence, and average initial desorption velocities between air, heat, and vacuum co-crystalization schemes can not account for these resolution results, we believe the superior resolution of the vacuum co-crystallization scheme to be due to: the lower number of individual scans required to create a given signal; and a postulated narrowed distribution of initial desorption velocities due to the greater regularity of vaccum co-crystal arrangements in space.

Suppression of Metastable Interference in MALDI Spectra Obtained with a Reflecting Time-of-Flight Mass Spectrometer

W Ens, V Spicer, K G Standing and J Zhou
Dept. of Physics, University of Manitoba, Winnipeg, Canada R3T 2N2

The time-of-flight spectra obtained by matrix-assisted laser desorption are often characterized by rather poor mass resolution. In a linear time-of-flight spectrometer, the resolution is usually limited by the initial energy spread caused by the desorption and extraction processes [1 - 3]. Such energy spreads can be largely compensated with an electrostatic ion mirror illustrated in Fig. 1. However, fragmentation of the ions by the loss of small neutral daughters in the field-free region before the mirror causes increased complexity in the spectrum for smaller molecules and peak broadening for larger species (>~ 15 000 u).

We have developed a method to suppress the daughter ion contribution by increasing the acceleration voltage on alternate laser shots so that only daughter ions are reflected. That is, the mirror rejects parent ions on the basis of their higher energy. Two spectra are recorded in this way: the normal spectrum produced by parent and daughter ions, and a daughter-only spectrum. A spectrum of parent ions alone may be obtained by taking the difference. Fig. 2 illustrates the principle of the method. The top panel shows the molecular ion region of the reflected spectrum of bovine insulin. The smaller peak results from a daughter ion formed in the field-free region before the mirror by the loss of a neutral fragment of mass 17 u. The middle spectrum is the sum of transients recorded on alternate laser shots when when the acceleration voltage is increased so that the parent ion is not reflected. The bottom spectrum is the difference spectrum indicating the suppression of the metastable peak.

Fig. 3 shows an example of the method applied to mixture of myoglobin and insulin. The figure shows a linear time-of-flight spectrum, a normal reflected spectrum and the difference spectrum obtained when the daughter ion spectrum is subtracted from the reflected spectrum. The difference spectrum illustrates that much of the background observed in reflected spectra is due to metastable decay, and that much of the metastable broadening observed for larger molecular ions can be suppressed even though the daughter ion peaks are not resolved in time. The resulting mass resolution (FWHM) on the myoglobin molecular ion after subtraction is about 1000.

In order for the energy selection described above to be effective, the parent and daughter ions must have well-defined energy distributions. Since the energy distributions vary considerably from shot to shot, being broader for shots that produce more intense molecular ion signals [3], it is necessary to select shots with approximately the same intensity, preferably rather small. As a result several hundred laser shots are normally required to obtain a good difference spectrum, and each transient must be examined by the computer. To minimize acquisition time, a fast SCSI interface to a CAMAC controller has been configured with a LeCroy TR8828D transient recorder. This arrangement is able to select and accumulate 10 kB transients at a repetition rate of about 10 Hz.

HEAT LOAD ON GUEST MOLECULES IN MATRIX-ASSISTED LASER DESORPTION

A. Vertes
Department of Chemistry, The George Washington University
Washington, DC 20052

In a continuing effort to understand the underlying mechanism of matrix-assisted laser desorption (MALD) we investigated the thermal load on "probe" molecules embedded in the matrix. A probe molecule experiences two different environments during the desorption process. The first phase is the period when the molecule is still fixed near to the surface of the matrix. As the laser pulse heats the surface the probe molecule is subjected to energy exchange with matrix molecules. As soon as the phase transition releases the probe molecule its environment changes into an expanding and rapidly cooling plume. Matrix plume temperatures, T_M, can drop to around 100 K in 100 ns [1]. It is the net effect of the first heating and the second cooling phase that determines the internal temperature of probe molecules, T_P.

Heating phase ($T_M > T_P$)

Hydrodynamic calculations of surface heating, plume formation, and expansion were carried out [1] on sinapinic acid, ferulic acid, and nicotinic acid commonly used for MALD in the ultraviolet spectral region. Short transient surface heating was observed followed by expansion cooling of the generated plume.

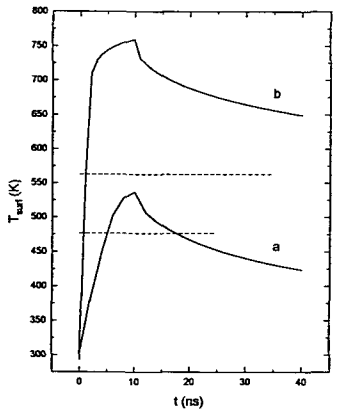

Figure 1 *shows the effect of a 1 MW/cm², 10 ns, 308 nm laser pulse on the surface temperature of sinapinic acid (a). The sublimation temperature of sinapinic acid (477 K) is marked by the dashed vertical line. Superheating of the surface (present for about 12 ns) leads to strong evaporation and plume formation. Irradiation of the sodium salt of sinapinic acid (10 MW/cm², 10 ns, 308 nm) leads to much higher surface temperatures (b) and possibly thermal decomposition.*

Probe molecule temperatures can be lower than the matrix temperature if the probe molecules absorb the laser light less efficiently. The energy exchange between matrix and probe molecules in the solid phase has been discussed earlier [2]. The driving force of the energy exchange is the difference between matrix, and probe molecule temperatures:

$$\frac{c_{p,P}}{V_{M,P}}\frac{dT_P}{dt}=\alpha_s\left(\frac{c_{p,M}}{V_{M,M}}T_M-\frac{c_{p,P}}{V_{M,P}}T_P\right) \qquad (1)$$

where c_p, and V_M denote the specific heat, and the molar volume of the matrix and the probe

molecule indexed by M, and P, respectively. The solid phase energy exchange coefficient, α_s, can be evaluated using the exponential energy gap approximation [2]. The heating phase for a given probe molecule ends when the matrix evaporation entrains it into the gas phase. During the superheated period explosive phase transition also may occur. In this regime the explosive phase transition cuts short the time available for the heating phase.

Cooling phase ($T_M < T_P$)

The cooling phase for a probe molecule starts with entering the gas phase. We assume that the typical probe molecule travels with the maximum density portion of the matrix plume.

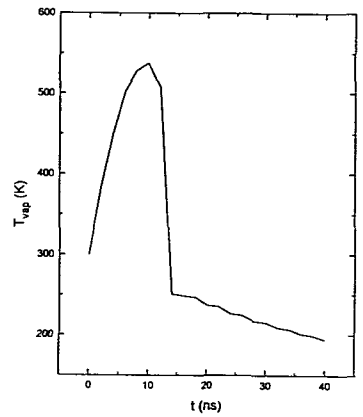

Figure 2 *shows the sinapinic acid plume temperature, T_{vap}, at the maximum of the plume density distribution (laser pulse: 1 MW/cm², 10 ns, 308 nm). During the laser pulse hot matrix material enters the plume. Expansion takes over at the end of the pulse and rapidly cools the plume below room temperature.*

Energy exchange between matrix and probe molecules during the cooling phase also can be described using Eq. (1) by replacing the specific heat, the molar volume, and the energy exchange coefficient with their vapor phase values. The most significant difference stems from the density dependence of the vapor phase energy exchange coefficient, α_v.

The relative duration of the heating and cooling phase, the corresponding matrix temperatures and the energy transfer coefficients determine the net thermal load on the embedded and entrained probe molecules. Calculations on laser desorption with and without matrix indicated higher threshold irradiances for desorption and/or higher heat load on the desorbing molecules in the absence of matrix.

Depending on energy deposition and transfer rates the guest molecules may leave internally "cold," "warm" or even "hot." This coherent description can account for the lack of fragmentation in MALD and for metastable decay of guest molecular ions under certain circumstances.

Measurement of Neutral Velocities in the Matrix-Assisted Laser Desorption Experiment

Richard C. King & Kevin G. Owens*, Department of Chemistry, Drexel University, Philadelphia, PA 19104

The formation of a molecular beam in the matrix - assisted laser desorption / ionization experiment has been suggested to explain the formation of intact molecular ions with initial velocities of 750 m/sec.[1,2] If a molecular beam is formed, it should have properties similar to molecular beams formed by expansion of a gas from a high pressure region through an orifice into a low pressure region. These systems have been studied extensively and are well characterized.[3] Supersonic molecular beams have several distinquishing properties, the most fundamental of which is that random thermal motion is converted into directed mass motion, causing the mean speed of molecules in the direction of the expansion to increase. The final velocity of the expansion depends on the mole fraction mass of the gas mixture expanding, the size of the orifice and the change in pressure or temperature which occurs during the expansion. Table 1 shows the final velocities of ideal gasses expanding from room temperature calculated for several different masses.

Predicted Flight Time Shifts from Calculated Initial Velocities (Vo) for 1000 volts Acceleration

Expansion Gas Mass (amu)	Vo (m/sec)	Δ TOF (nsec)

Measured Initial Velocities for Different Mass Analyte Molecules at 1000 volts Acceleration

Compound	Mass (amu)	Analyte Vo (m/sec)	Matrix Vo (m/sec)
Rhodamine B	442.52	566	723
Acridine Orange	265.36	462	741
Cinnamic Acid	148.16	580	759
Indole	117.15	521	723

Table 2.

In the experiments reported here, a post - ionization laser is used to ionize the neutral matrix / analyte released into the gas phase during the matrix assisted laser desorption experiment. Since

the ion time - of - flight depends on the initial velocity of the ion (Vo) as well as the ion mass to charge ratio, ions formed from neutrals having a gas phase thermal velocity distribution (mean Vo = 0) will have a longer flight time than ions formed from neutrals released during the MALD process (mean V0 > 0). Measurement of the flight time shift ($\Delta TOF = TOF_{Vo=0} - TOF_{Vo>0}$) gives a direct measure of the initial velocity of the neutral before post - ionization. Table 2 shows the velocities measured for neutral sinapinic acid molecules at several different delays 4.41 mm above the sample surface.

The large number of collisions that occur during the expansion cause a decrease in the distribution of molecular speeds along the direction of propagation. This velocity narrowing continues until the gas becomes rarified. The narrowness of the velocity distribution is observed in the time - of - flight spectrum as a narrowing in the ion peak width.

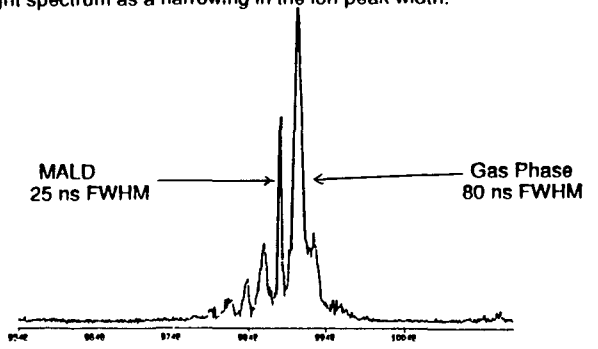

Figure 1 shows the two peaks due to the two different initial velocity distributions, gas phase (mean Vo = 0) and MALD (mean Vo > 0). The peak on the right is produced by ionization of gas phase triphenylene while the peak on the left is produced by post - ionization of neutral triphenylene released during MALD using a sinapinic acid matrix. The narrow velocity distribution of the desorbed neutrals accounts for the difference in width between the two peaks.

When a small amount of analyte is seeded in a large excess of expansion gas, the analyte molecules obtain the same velocity as the expansion gas due to the collision process. This is found to be true for analyte molecules of all masses. Table 3 shows the velocities of the sinapinic acid matrix and the analyte molecules of different masses measured by post - ionization of desorbed neutrals. The results show that the analyte molecules have the same velocity as the matrix neutrals for all masses tested.

Supersonic molecular beams are known to be highly directional. The angular distribution of material is found to approximate a cosine[3] distribution. Results of measuring the width of the released neutrals from MALD at several positions above the sample surface also approximates a higher order cosine distribution.

The measured properties of sinapinic acid matrix neutrals released during the MALD experiment are consistent with known properties of supersonic molecular beams. The values obtained for neutral velocities suggests that small neutral matrix fragments are created during the desorption event and that they are involved in the expansion.

Although gel electrophoresis is probably the most widely used separation technique and the most widely used molecular weight determination technique for proteins, its mass accuracy compares poorly with modern mass spectrometry methods. Currently many labs electroblot proteins from gels to membranes (polyvinylidine difluoride (PVDF), nitrocellulose, and nylon) for further characterization especially by immunological methods. Proteins absorbed on PVDF can be inserted directly into microchemical (Edman) sequencers. Thus membranes are a well established way to handle very small amounts of proteins and a potentially useful way to bring them to mass spectrometry.

Figure 1 shows the "chromatogram" obtained using a Kratos Kompact MALDI III bench top matrix-assisted laser desorption mass spectrometer with a 337 nm nitrogen laser from a strip of PVDF on which cytochrome c had been spotted and then covered with the matrix α-cyano-4-hydroxycinnamic acid. The strip was scanned by firing two thousand laser shots across it. Every fifty shots were averaged. Two spectra from different locations on the PVDF are also shown. After LDMS, the strip was stained with Coomassie Blue confirming that the mass spectrometer could read the membrane to locate the protein (Figure 2).

Figure 3 shows the "chromatogram" (Figure 3a) and one spectrum (Figure 3b) obtained while scanning an electroblotted lane of a gel electrophoresis separation of a BNPS-skatole treated protein under study in our laboratory. This sample was digested with trypsin on the membrane, and the spectrum of a product obtained from the same position is shown in Figure 3c.

Further development is underway to scan electroblotted membranes and to provide molecular weights of proteins before and after digestion directly on membranes.

MATRIX ASSISTED LASER DESORPTION IONIZATION OF AEROSOLS

Kermit K. Murray and David H. Russell
Department of Chemistry, Texas A&M University, College Station, TX 77843

We have recently constructed an apparatus that allows continuous liquid aerosol introduction into a matrix assisted laser desorption ionization (MALDI) time of flight mass spectrometer (TOF-MS). The utility of such an apparatus is twofold. First, MALDI TOF-MS has the potential to be an excellent method for liquid chromatography (LC) detection. Second, aerosol MALDI provides a new perspective from which to view MALDI processes. Aerosol introduction provides a continuous and consistent flow of sample for ionization. Ionization occurs without the interference of a metal surface and without the reproducibility problems that often appear in conventional MALDI solid sample preparation.

A detailed description of the aerosol MALDI apparatus is given elsewhere.[1,2] Aerosols are formed by a pneumatic aerosol generator with a liquid flow rate of between 0.5 and 1.0 ml/min. Aerosols are passed through a heated drying tube to remove solvent before ionization. The aerosols are ionized by 355 nm photons from the frequency tripled output of a pulsed Nd·YAG laser focused with a cylindrical lens. Mass separation is achieved in a 1.1 m TOF-MS with extraction voltages of between 5 and 15 kV. Ions are detected with a microchannel plate particle multiplier and the signal is recorded with a digital oscilloscope.

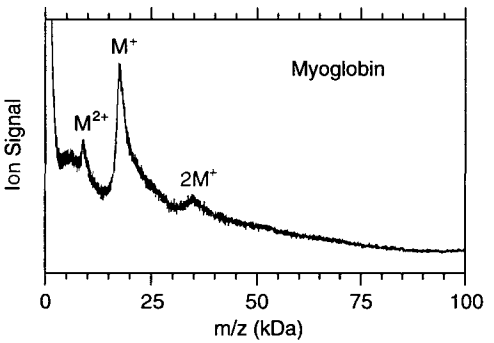

Figure 1. Aerosol MALDI mass spectrum of horse heart myoglobin with α-cyano-4-hydroxy-cinnamic acid matrix.

A number of biomolecules have been ionized by aerosol MALDI including erythromycin, bradykinin, gramicidin S, gramicidin D, vitamin B-12, melittin, bovine insulin, cytochrome C, lysozyme (chicken egg white), myoglobin (horse heart) and bovine albumin. We have had good results using the matrices 4-nitroaniline and α-cyano-4-hydroxy-cinnamic acid. Mass resolution of 125 has been observed for bradykinin (MW = 1060). Figure 1 shows a aerosol MALDI mass spectrum of myoglobin (horse heart, MW = 16,951) with α-cyano-4-hydroxy-cinnamic acid matrix. The aerosol solution contained 100 nmol of analyte and 10 μmol of matrix per mL of methanol solution acidified with 5 % trifluoroacetic acid (TFA). The extraction voltage was 10 kV and the laser irradiance was 160 MW/cm^2. The mass spectrum is the result of averaging over 1000 laser shots. The M^+ peak is the seen at approximately 17 kDa and the peak width corresponds to a mass resolution of 8. There are probably multiple peaks under the M^+ envelope corresponding to $[M+H]^+$, $[M+Na]^+$, $[M+Matrix]^+$ but these are not resolved. Peaks are seen for doubly ionized analyte M^{2+} and for the $2M^+$ cluster. The low mass portion of the spectrum is dominated by peaks corresponding to methanol clustered to H^+ and Fe^+.

The utility of aerosol MALDI with LC/MS was investigated for the separation of bovine insulin and gramicidin S. A 125 μl sample with 40 nmol bovine insulin and 200 nmol gramicidin S in water solution was injected onto a C_{18} column. The column effluent was mixed with a 10 μmol/mL solution of α-cyano-4-hydroxy-cinnamic acid in a TFA acidified methanol solution. Mass spectra were downloaded from the oscilloscope and saved to disk at 10 s intervals. A contour plot of the resulting mass spectra is shown in Figure 2. The x axis is the ion flight time and the y axis is the column retention time. The gray shading indicates the log of the ion signal with darker shades corresponding to larger signals. The individual mass spectra have been smoothed and the number of data points reduced for the purposes of the plot. At a retention time of 6 minutes the total ion signal increases as the first of the effluent comes off the column. Bovine insulin is seen at 10.5 minutes at a flight time of 103 μs. Note that at this time there is decrease in the total ion signal, particularly evident for low mass ions. The peak of the gramicidin S ion signal is seen at 18 minutes and a flight time of 43 μs. Leading and trailing edges of the gramicidin S peak are seen because separation conditions have not been optimized.

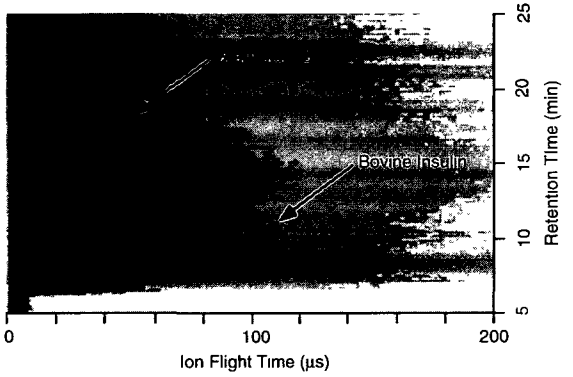

Figure 2. Liquid chromatography separation with MALDI-MS detection for bovine insulin and gramicidin S. Darker shades indicate greater ion signal.

We are currently working to improve the sensitivity, resolution, mass range, and data acquisition rate of the aerosol MALDI apparatus. The basic goal is to maximize the efficiency of aerosol delivery and desolvation while at the same time minimizing the gas load and pressure in the region of ion formation Maximizing data acquisition rate will require a high repetition rate ionization laser and high speed and high capacity data acquisition system. With these and other improvements, aerosol MALDI promises to be a useful method for LC/MS of large biopolymers.

The authors wish to thank T. M. Lewis for help with the LC/MS experiment.

New desorption strategies for the mass spectrometric analysis of macromolecules

T. William Hutchens and Tai-Tung Yip

Protein Structure Laboratory, USDA/ARS Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, 1100 Bates, Houston, TX 77030.

Summary

We present two new desorption strategies for the mass spectrometric analysis of macromolecules. These desorption strategies are based on the construction of two general classes of reactive probe surfaces specifically designed to enhance 1) the desorption of intact macromolecules without matrix (neat), and 2) the affinity capture of selected macromolecules directly from unfractionated biological fluids and extracts. Specific examples of Surface-Enhanced Neat Desorption (SEND) and Surface-Enhanced Affinity Capture (SEAC) laser desorption time-of-flight mass spectrometry are presented to illustrate the potential for increased sensitivity (fmol) and mass accuracy. Use of these new probe surfaces as solid phase reaction centers should facilitate protein discovery through molecular recognition *in situ* and also macromolecular structure analysis through the sequential chemical and/or enzymatic modification of the adsorbed analyte *in situ*. The availability of probe surfaces derivatized with or composed of multiple types and defined numbers of energy absorbing molecules should also facilitate investigations of energy transfer and desorption/ionization mechanisms.

Introduction

The ability to measure accurate *differences* in molecular mass enable problems associated with unknown protein structures to be solved more readily. Thus, the future of *biological* mass spectrometry will be defined by simpler and more sensitive means to monitor specific changes in protein and peptide mass.

The introduction of matrix molecules to assist the laser-induced desorption/ionization (MALDI) of intact macromolecules (particularly mixtures) has enabled small quantities (pmol) of large nonvolatile biopolymers to be evaluated by time-of-flight (TOF) mass spectrometry (1). Many new types of investigations have been enabled by this technology. Our laboratory has developed MALDI-TOF to explore various specific ligand-ligate interactions and to analyze protein structure (e.g., 2-9); both approaches have been based largely on biochemical reactions performed directly in situ to expoit the availability of analyte not consumed by previous laser-induced desorption events. However, the required presence of a large molar excess of acidic matrix and the random deposition of embedded macromolecular analytes in and around an undefined array of matrix crystals has limited the use of the probe surface as an effective stationary phase for sequential (i.e., differential) mass spectrometric approaches to the investigation of protein structure and function.

An effective mass spectrometric strategy for protein structure analysis may be realized if each of several diagnostic alterations in mass can be brought about as a result of controlled chemical and/or enzymatic modification events performed directly and sequentially in situ (i.e., directly on the probe surface). In fact, alterations in both covalent and noncovalent structures (including higher order macromolecular assemblies) may be evaluated more readily once 1) conditions are defined to minimize or eliminate the negative influence of matrix molecules, and 2) an active rather than passive means of protein deposition on the probe surface is developed. Our previous experience with the matrix-assisted desorption of peptides and proteins directly from electrophoretic gels and various membrane protein blots provided less than desirable results (e.g., low yield, low resolution). Thus, we have attempted

to advance protein structure and function analyses based on laser desorption TOF MS by redesigning probe surfaces to contain the necessary density of energy absorbing molecules so that the need for matrix can be eliminated.

We introduce here matrix-free methods of introducing large molecular weight biopolymers into the gas phase without fragmentation. We call this approach Surface-Enhanced Neat Desorption (SEND) time-of-flight mass spectrometry. To enhance our investigation of bioregulatory molecular recognition events, we have designed a second class of probe surfaces to be used as affinity capture devices to augment the detection of trace macromolecules present in unfractionated biological matrices, particularly *in vivo*. To distinguish this approach from other indirect strategies we suggest the term Surface-Enhanced Affinity Capture (SEAC) laser desorption time-of-flight mass spectrometry.

Results

We show that macromolecular analytes (proteins/peptides) can be desorbed efficiently from insulating surfaces like nylon, polystyrene, polypropylene, and glass by the normal MALDI process with no apparent fragmentation. Some differences in desorption selectivity were observed among the various surfaces tested

Surface-enhanced neat desorption (SEND) MS experiments performed with myoglobin showed a symmetrical peak with no evidence of matrix adduct, fragmentation, or low molecular weight ions other than those observed from buffer contamination. Other examples of SEND with 6 to 8 kDa synthetic protein surface domains as test analytes showed that cinnamamide was not effective as a matrix when used in the conventional way for MALDI-TOF. When cinnamamide was covalently bonded to the sample presenting surface, however, the resulting structure was transformed to enhance desorption of the peptides in a neat form with no apparent fragmentation and adduct formation.

Surface-enhanced affinity capture (SEAC) laser desorption time-of-flight mass spectrometry was used to detect low quantities (2.5 pmol) of lactoferrin extracted from the urine of a preterm infant. In contrast to the spectrum obtained for the unfractionated infant urine (no lactoferrin signal detected; the use of SEAC resulted in a clean, unambiguous, and significant signal of lactoferrin. The affinity capture and transfer to the probe surface is specific and efficient.

REMPI AND MASS SPECTRA OF COLD PERFLUORINATED POLYETHERS

Deon S. Anex, Mattanjah S. de Vries, H. Russell Wendt, and Heinrich E. Hunziker

IBM Research Division, Almaden Research Center, 650 Harry Road, San Jose, CA 95120-6099.

Laser desorption has become an important tool for the study of complex molecules, making it possible to introduce non-volatile substances into the gas phase. It can be combined with entrainment of the desorbed material in a supersonic expansion to cool the molecular internal degrees of freedom. This enhances the selectivity and sensitivity of resonance-enhanced multiphoton ionization (REMPI), providing a versatile approach to forming ions for time-of-flight mass spectrometry. Unfortunately, many species do not have suitable intermediate states. The polymers that we are interested in, perfluorinated polyethers (PFPE's) of the poly(trimetheleneoxide) type, are such an example. However, if these polymers are substituted with a chromophore-containing end group, they can be ionized using REMPI. We have explored the use of a substituent chromophore as a tag in the substituted PFPE

$$\mathbf{R_a}\text{-}[OCF_2CF_2CF_2]_n\text{-}F \qquad \text{I}$$

where $\mathbf{R_a}$ is the aromatic end group: C_6H_5-O-CH_2CH_2-O-(C=O)-CF_2CF_2-, which absorbs near 274 nm. These polymers are available as Demnum SP® from Daikin Industries. We are interested in whether mass spectrometry through REMPI of a chromophore tag is useful for obtaining polymer length distributions and how the polymer may influence the absorption of the chromophore.

A beam of cold molecules was generated by laser-induced desorption in front of a pulsed jet orifice. The liquid samples were applied to activated charcoal and were desorbed using the 532 nm output from a pulsed YAG laser. A xenon pulse was timed to intercept the plume of desorbed material and entrain, cool and sweep it into the source region of a linear time-of-flight mass spectrometer. There the cold molecules were ionized by either an excimer laser at 193 nm or by a doubled dye laser tunable near 274 nm.

Mass spectra obtained at 193 nm extend to 7000 amu and are dominated by parent ions of the polymer. It is thus possible to determine the parent mass distributions of functionalized PFPE's using this method. Measured distributions resemble those determined with a cationization technique for a similar sample.[1] Minor peaks correspond to van der Waals dimers of **I**, as well as polymers that are substituted at both ends:

$$\mathbf{R_a}\text{-}[OCF2CF2CF2]_n\text{-}O\text{-}\mathbf{R_a} \qquad \text{II}$$

The sensitivity of this technique is sufficient for the measurement of REMPI wavelength spectra for the polymers ranging in size to 1778 amu (n=9), in a short chain length sample, by scanning the ionization wavelength in the vicinity of the electronic origin of the first excited electronic state and monitoring the ion signal at a particular mass to charge ratio. The spectra of **I** consist of a broad feature (about 70 cm^{-1} wide) peaking at 273.4 nm and do not vary with chain length for the measured range of n (5 through 9).

To better understand the polymer REMPI spectra, we studied a series of model compounds that show the evolution of the spectrum from the simplest molecule, phenol, representing the chromophore in the end group of the polymer, through intermediate model compounds representing portions of the polymer of increasing length, to the polymers themselves. The compounds that we used include phenol, anisole, phenoxyethanol, a series of phenoxyethyl esters of straight chain perfluorinated carboxylic acids, PFPE's with n=1 through 3 and having branched repeat units and the straight chain PFPE's themselves (**I**, with n=5 through 9). In this series, the total wavelength shift is about 200 cm^{-1}. The spectra show that this shift is essentially insensitive to structural changes more than six atoms removed from the chromophore. The spectral bandwidth also increases with chain length, due to the presence of multiple conformers and low frequency motions, up to about two repeat units, thereafter becoming independent of length. For the polyethers, no further change is seen in the spectrum for those containing three or more repeat units and no difference was observed between the branched and straight polymer chains. The preferred conformation for each of the three smaller esters (perfluoroacetate, perfluoropropionate and perfluorobutyrate) is strikingly sensitive to the perfluoroalkyl chain length.

The REMPI spectra of the van der Waals dimers of the straight chain PFPE's, **I**, and the spectra of the PFPE's with two phenoxy end groups, **II**, show a striking similarity, suggesting an accompanying similarity in structure. This is evident in the mass spectra collected at two excitation wavelengths. In panel A of the figure the excitation was at 273.5 nm, near the peak of the polymer absorption. The spectrum is dominated by the parent masses of **I**, ranging from n=5 to n=13 and indicated by the closed circles. Moving the excitation wavelength to 274.8 nm, a shift comparable to the well known redshift for van der Waals dimers of aromatic molecules, yields the spectrum shown in panel B. Here the coincidence with the absorption of the van der Waals dimers is demonstrated by the appearance of the peaks indicated by the open circles. These peaks are accompanied by the appearance of a new series indicated by the crosses, corresponding to the masses of **II**. They also exhibit a redshift, characteristic of a dimerized aromatic ring. In fact, scanning the excitation wavelength shows that the spectra of the van der Waals dimer of **I** and the doubly substituted polymer, (**II**) are shifted and broadened relative to the singly substituted polymer (**I**) in essentially the same way.

We argue that in both cases van der Waals complexes are formed between the two chromophores, which are *inter*molecular for the dimer of **I** and *intra*molecular for **II**. The formation of the intramolecular complex is an indication of the flexibility of the polymer chains and the strength of the interaction between chromophores. The barriers to internal rotation in the polymer must be low enough to allow the two ends of the chain to dimerize before the conformations are frozen. This requires a chromophore dimerization energy substantially larger than the critical barrier heights.

Hydrocarbon Polymer Analysis by Laser Desorption/Chemical Ionization Fourier Transform Mass Spectrometry (LDCI/FTMS).

Michael S. Kahr and Charles L. Wilkins, Department of Chemistry, University of California, Riverside, CA 92521

Laser desorption FTMS of nonpolar hydrocarbon polymer samples is generally more difficult than for polar polymers. Polar polymers containing heteroatoms such as oxygen and nitrogen undergo ionization via alkali metal ion attachment. An effective alkali metal ion attachment site often does not exist for hydrocarbon polymers and thus many hydrocarbon polymer samples yield only fragment ions upon laser irradiation. Because the laser desorption event produces intact gas phase neutral analyte molecules, ionization may be accomplished by us of an appropriate chemical ionization reagent.

Silver nitrate is an attractive candidate as a chemical ionization reagent for hydrocarbon polymers and has been investigated in our laboratory. Silver nitrate is a solid that can be codeposited with the sample. Because silver nitrate is a nonvolatile solid, it does not produce a gas load for FTMS analysis. Also, during the laser desorption event, reagent ions are generated in close proximity to desorbed hydrocarbon neutrals, producing spatial overlap between the analyte neutrals and the reagent ions. Finally, the results of this study indicate that silver offers excellent reactivity toward hydrocarbon polymer analytes.

Narrow molecular weight standard samples of polystyrene, polybutadiene, polyisoprene, and polyethylene were obtained for this study. These polymers span the range of hydrocarbon polymer structural categories. Polystyrene represents phenyl functionality and is the least challenging. Polyisoprene and polybutadiene represent branched and linear unsaturated hydrocarbons of moderate difficulty. Polyethylene is linear, saturated, and is the most challenging. Gel permeation data provided by the manufacturer were compared with spectra obtained for silver nitrate LDCI spectra. Figure 1 shows that, even for polyethylene, high quality mass spectra may be readily obtained.
In an effort to extend the mass range capabilities of this technique, a commonly-used matrix-assisted laser desorption/ionization (MALDI) matrix, 2-5 dihydroxybenzoic acid, was added to the sample and silver nitrate. Results for a polystyrene GPC Mn = 8000 sample are presented in Figure 2.

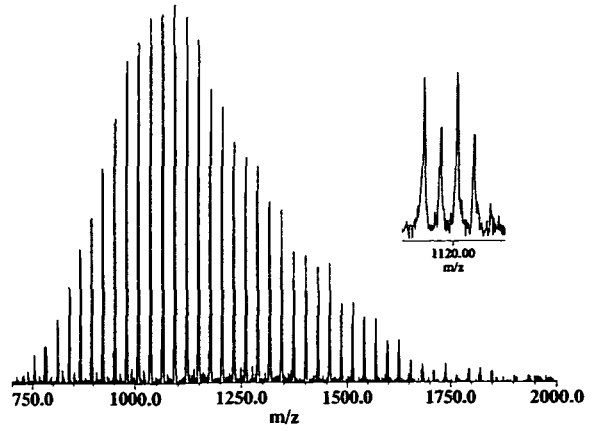

Figure 1: Polyethylene GPC Mw 1214, AgNO3 Mw 1193.
Inset shows the n=36 silver attached oligomer, resolution 7626 at mass 1118.
This spectrum was obtained using SWIFT excitation.

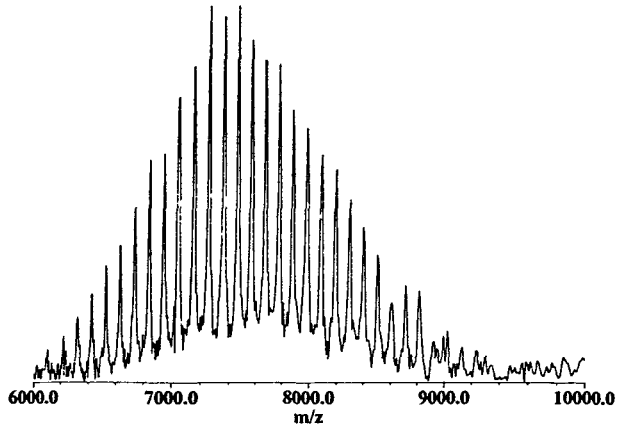

Figure 2: Polystyrene GPC Mn 8000.
This is the MALD/CI spectrum obtained when 2,5-dihydroxybenzoic acid and silver nitrate are present. Excitation was performed using SWIFT.

MALDI MASS SPECTROMETRY OF GEL-ELECTROPHORETICALLY SEPARATED PROTEINS

Kerstin Strupat, Michael Karas, Franz Hillenkamp
Institute for Medical Physics and Biophysics, University of Münster, Robert-Koch-Str. 31, 48149 Münster, FR Germany

Christoph Eckerskorn, Friedrich Lottspeich
Max-Planck-Institute for Biochemistry, 82152 Martinsried, FR Germany

Combining exact determination of the molecular weight by matrix-assisted laser desorption ionization mass spectrometry and the high-separation capacities of gel-electrophoresis forms a challenging analytical approach. Though the use of a laser ablation source to analyze separated immobilized proteins directly in the gel or from blot membranes seems straightforward at a first glance, the elucidation of adequate experimental and preparation conditions in order to fulfil the requirements of MALDI-MS poses a major task to be solved. The ease of MALDI of proteins dot-blotted onto a membrane (1) only proves the general usability of an organic polymer as a substrate for MALDI, but the experimental situation after SDS-PAGE/electroblot is by far more demanding.

In a series of experiments relevant progress for this adaptation was elucidated in a step-by-step procedure. As a general starting point for this work, SDS-PAGE (one-dimensional) and subsequent electroblots onto immobilizing membranes were carried out under standard conditions. Preliminary results have been reported in (2). MALDI mass spectrometry was performed on a laboratory-built reflectron TOF instrument equipped with ports for both UV- (Nd.YAG, 355 nm) and IR-lasers (Er YAG, 2 94 μm)

First promising results were obtained with the IR-laser and from proteins electroblotted onto membranes. Further work therefore followed this line, the mass spectra obtained under standard preparation for IR-MALDI served as a criterion for the quality of the mass spectra to be obtained. In addition, initial experiments were done on unstained proteins in order to avoid foreseeable problems due to peak broadening and mass shifts. In a first optimization cycle, different membranes - differing both in chemical composition and physical structure (pore size and specific surface) -, IR-matrices and preparation conditions (solvents, concentration, moment of matrix incubation) were inspected. The key finding was that soaking of the wet membrane into a saturated aqueous solution of the matrix yielded highly improved results in terms of shot-to-shot reproducibility, signal intensities and width; succinic acid and a number of different aliphatic carboxylic acids were used as matrices. All membranes typically used for electroblots enabled MALDI results, improved signal quality was obtained for polyvinylidene difluoride (PVDF) and polypropylene (PP) of high specific surface (see Figure 1)

The influence of the staining of the proteins usually applied to visualize the protein bands was investigated in an subsequent series of experiments. Whereas organic dyes, such as coomassie blue, resulted in broad peaks shifted in mass and showing a distribution of tagged dye molecules, were colloidal pigments, such as gold and ink, found compatible to MALDI mass analysis (see Figure 2).

The characteristics of IR-MALDI obtained under the above optimized experimental conditions, such as high ion yields, high S/N for single shots and excellent reproducibility

for several shots from the same laser spot and from spot-to-spot, form the necessary prerequisites for a practical SDS-PAGE/MALDI-MS combination; no changes in the standard GE and electroblotting procedures are required. Sensitivity, though not optimized yet, is in agreement with typical protein loads to SDS gels of 0.1 to 1 μg/7 mm. It should be noted that focussing of small protein quantities in high-resolution 2D-gels should enable mass analysis of even fmolar amounts of proteins. The precision of the mass determination given by the correlation of the different molecular ion signals is ± 0.05 % for bovine serum albumin, calibration with proteins on the same blot membrane is suggested to yield the same mass determination accuracy.

Laser Desorption/Ionization of Small Biomolecules

P.T.A. Reilly, T. King, and J.P. Reilly
Indiana University, Bloomington, IN 47405

While the development of matrix assisted laser desorption represents a spectacular advance for biomolecule mass analysis, the method has some noteworthy drawbacks. Because the ionization process necessarily involves molecular collisions, it is not precisely localized in space and can significantly affect the velocity distribution of the nascent ions. Selectivity associated with the ion formation process may also not be desirable. In an attempt to improve this situation, we have been exploiting the matrix assisted laser desorption phenomenon simply to introduce neutral macromolecules into the gas phase. Once volatilized, we use resonantly enhanced multiphoton ionization (REMPI) to ionize our samples.

In our initial studies, we have focussed on the ionizing characteristics of small biomolecules. Having previously demonstrated that laser ionization propensities can be strongly influenced by excited state relaxation, we recorded mass spectra of amino acids and small peptides using both nanosecond and picosecond pulses of ultraviolet laser light. Remarkably few differences in the spectra were noted, both exhibiting considerable ion fragmentation. Previously published mass spectra of these same compounds taken with supersonic cooling of the laser desorbed material displayed substantially less ion fragmentation, suggesting that our sample molecules are desorbed hot. In order to probe this issue, we have recorded the wavelength dependence of the two step ionization yield of tryptophan and have measured the velocity distribution of neutral molecules desorbed from the surface. The most noteworthy results are that the velocity distribution is narrowed and the mass spectral fragmentation is reduced upon using higher light intensities. These observations support the theory that some jet cooling of desorbed molecules does indeed take place and that this cooling depends on the incident laser fluence.

LASER VAPORIZATION AND REMPI-TOF DETECTION FOR DNA SEQUENCING

Robert J. Levis, Department of Chemistry, Wayne State University, Detroit, MI 48202.

The mass spectroscopic detection of biological molecules in the gas phase is promoting the development of a number of new biological, biochemical and medical probes. Advances in the vaporization and detection of these fragile molecules are driven in part by emerging laser-based techniques. Our laboratory is investigating two such processes required for mass spectroscopic detection. The first process is laser vaporization and this involves transferring the fragile biomolecule from the solid state into the gas phase with no decomposition. The vaporization is accomplished by directing an intense laser pulse through a thin solid film composed of the biomolecule and a light absorbing chromophore. The second process we are investigating is the subsequent ionization of laser vaporized, neutral biomolecules. This post ionization is accomplished using a series of laser pulses intersecting the plume of cooled biomolecules. Laser ionization is studied in this laboratory because of the potentially high ionization efficiencies (near 100% for atoms) and the considerable increase in ultimate mass spectral resolution (when compared to MALDI, for instance). The ionized molecules are then detected using a linear time-of-flight mass spectrometer.

This laboratory is studying the vaporization and ionization of oligonucleotides to develop a high speed DNA sequencing system based on mass spectrometry. The advantage of a mass spectroscopic sequencing method is that the products of a Sanger dideoxy sequencing reaction for a 500 base DNA strand could be analyzed in less than one second, giving rise to enormous sequencing rates. These rates have been estimated to be 10^4 to 10^7 times faster than conventional gel electrophoresis-based analysis. In addition, with the mass spectroscopic approach, sequence specific irregularities (i.e. missing bands), can easily be identified and corrected. This is because the mass spectroscopic approach precisely and reproducibly determines relative as well as absolute strand lengths. The amount of material required for the sequence may ultimately be less than that required for standard radiographic analysis.

These experiments are performed in a turbopumped linear time-of-flight mass spectrometer. The samples are prepared in aqueous rhodamine 6G (Rh 6G) and are deposited as a ring onto a quartz cover slip. The cover slip is then fixed onto the end of a hollow sample tube and inserted into the four grid ionization and extraction assembly of the spectrometer. The sample is vaporized using a gaussian output coupled, Nd:YAG laser. The 532nm pulse of duration 2.7 ns and intensity 30 mJ/cm^2 to 5 J/cm^2 is directed through the Rh 6G film from the back side (through the glass/film interface first). Ions formed in the vaporization process are removed using axial deflection grids. The neutral sample is then ionized using a two color laser ionization scheme. The pump photon is produced using an excimer-pumped dye laser and is tuned from 350 nm to 400 nm. The probe beam is picked off of the XeCl excimer laser and is fixed at 308 nm. The ionized sample is accelerated in a dual slope extraction field to 1 keV and is then allowed to drift 63 cm to a hybrid high mass detector. The ion current is then amplified and smoothed at 1 MHz and recorded by a LeCroy 7200A digital oscilloscope. The resulting spectra is then transferred to a 486 computer via GPIB . All spectra are recorded in the single shot mode with no averaging.

Our investigations of the laser vaporization process began with an evaluation of Rh 6G as a thin film chromophore for vaporizing fragile biomolecules. This laser dye was chosen so that green light could be employed in the vaporization step, to avoid absorption by the sample molecules. This color (532 nm) is not absorbed by DNA and photochemical complications are eliminated. Initially, gel electrophoretic and direct radiographic analysis of the vaporization products were performed to understand the vaporization process. These studies revealed that the oligonucleotides vaporized molecularly with a $\cos^{120}$ spatial distribution. This tight spatial distribution strongly suggests that the vaporization of macroscopically thick films of material (1000 layers of Rh 6G) mimics the physics of adiabatic expansion in a free jet molecular beam. Vaporization of radio-labeled nucleotides at low powers results in extensive phosphodiester bond scission. Increasing the vaporization laser power to 300 mJ/cm2 leads to molecular vaporization of the nucleotide. Experiments with radio-labeled oligonucleotides reveal the same general trend.

Single strands of DNA as long as 2000 bases have been molecularly vaporized using this technology. These results are favorable for DNA sequencing using a mass spectrometer for several reasons. The highly directed product beam in a small solid angle implies that a large portion of the sample can be interrogated by the ionization beam. Also the large density (10^{12} molecule/mm^3) of material expanding into the vacuum may preclude the need for seeding the sample into a free jet for subsequent cooling.

The strategy for ionizing the laser vaporized, neutral DNA is the same as that for the vaporization step, employ photons which cannot be absorbed by DNA. A photoionization tag molecule is chemically attached to the DNA. This eliminates both multiple charging of a given DNA strand and photochemical fragmentation and reionization of the gas phase DNA. Either process would serve to complicate the mass spectrum and the subsequent determination of the sequence. The tag molecule is chosen to absorb light at wavelengths where DNA does not and also to have a high photoionization cross section. The tag molecule used in this investigation is based on anthracene, a three ring polycyclic aromatic hydrocarbon. The ionization scheme relies on exciting the anthracene into its lowest lying electronic state with one photon and pumping this excited molecule just into the ionization continuum with a second photon. In this way no excess energy is deposited into the ion, limiting fragmentation processes. The study begins with measuring the two color photoionization spectrum of anthracene. Here the pump photon is scanned from 340 to 370 nm and the probe photon, fixed at 308 nm. With this arrangement we measure the 0-0 band of anthracene to be 361.5 nm. Measurements of anthracene molecules with hydrocarbon moieties attached to the 9' position serve to shift the 0-0 band approximately 12 nm to the red (375 nm). A study of the photoionization spectrum of laser vaporized, anthracene-labeled DNA reveals a broad absorption feature centered at 378 nm. Knowledge of the photoionization spectrum of tagged DNA allows us to perform ultrasensitive (<fmol) detection of vaporized species.

Investigations of the velocity distributions of the laser vaporized molecules allow insight into the mechanisms of laser vaporization of biological molecules. Determination of the velocity distribution of the gas phase species is simply obtained by measuring the mass spectrum as a function of delay between the vaporization and ionization lasers. Velocity distributions are extracted from the time distributions using a density weighted Jacobian transformation. These velocity distributions typically peak between 400 and 1200 m/s for DNA and at 2000 m/s for Rh 6G. The full width at half maximum (FWHM) for the velocity distributions is usually 300 m/s. The most probably velocities correspond to Boltzman temperatures of thousands of K while the FWHM of the velocity distributions corresponds to temperatures of hundreds of K. Such nonthermal velocity distributions again suggest adiabatic cooling is present in the vaporization process. Calculations based on the measured velocity distributions suggest that approximately 1/2 of the vaporized material can be interrogated with a 5 x 5mm ionization beam 30 mm down stream from the vaporization region.

Our investigations of velocity distributions result in two significant contributions to understanding the processes of laser vaporization. The first finding results from measurement of the velocity distributions of Rh 6G, labeled nucleotide and various DNA fragment ions. For the thin films the velocity distributions of the fragments were virtually equal to that for the Rh 6G. The peak in the velocity distribution of the tagged-nucleotide was less than half that for the Rh 6G, however. This velocity slip allows us to suggest that the fragmentation observed in the mass spectrum occurs during vaporization, not during ionization. Measurements of the velocity distribution of the labeled nucleotide as a function of film thickness reveal that the peak in the velocity distribution increases monotonically with film thickness until reaching approximately 90% of the Rh 6G peak velocity. This suggests that thicker films have less velocity slip and will more efficiently cool the vaporizing sample. Mass spectra for laser vaporized thick films reveal virtually no DNA fragmentation.

Matrix-Assisted Laser Desorption Mass Spectrometry of Oligonucleotides

Klaus Schneider and Brian T. Chait
The Rockefeller University, 1230 York Avenue, New York, N.Y. 10021

Several groups have recently reported the use of MALDI to analyze relatively short stretches of single stranded DNA (generally < 60 nucleotides in length). However, a general finding of these experiments is that the mass spectrometric response falls off precipitously for DNA fragments longer than approximately 20 nucleotides in length.

During the past year we have carried out a series of experiments designed to understand this falloff in the mass spectrometric response as a function of oligonucleotide length. We found that dT homopolymers yielded intense mass spectra for species containing as many as 180 bases (i.e. a molecular weight of 54,000 daltons)[1]. By contrast, we found that the mass spectrometric responses to dA, dC, and dG homopolymers were virtually non-existent, except for very short polymers. We discovered 20 different laser desorption matrix compounds that were found to produce mass spectra of dT_{18}. Significantly, none of these matrices produced usable spectra from dG_{18}[1]. These results strongly confirmed the earlier observation of Parr *et al.* that base composition is a critical factor for the analysis of oligonucleotides[2].

We hypothesized three possible causes for the lack of response to polyguanosine: (i) unwanted aggregation of polyguanosine chains and/or "non-ideal" interactions of the polyguanosine molecules with the matrix molecules, (ii) low ionization efficiency, and (iii) high degree of fragmentation. We consider each of these in turn:

(i) Our working hypothesis is that a good matrix-assisted LD mass spectrometric response requires appropriate interaction of DNA with the matrix molecules, leading to the incorporation of analyte into the matrix materials as isolated molecules. To study the incorporation of the oligonucleotides dT_{18} and dG_{18}, we adapted the method developed by Beavis for the study of the incorporation of proteins into crystals of sinapinic acid. In the present experiment, we crystallized sinapinic acid in the presence of acridine orange, which effectively stains single-stranded DNA. Without oligonucleotide present, the sinapinic acid crystals did not become colored indicating that acridine orange was not incorporated. When dT_{18} or dG_{18} were added to the sinapinic acid/dye solution, the crystals obtained were intensely in orange color demonstrating the incorporation of a dT_{18}-acridine orange or a dG_{18}-acridine orange complex. The similar intensity in color of the sinapinic acid crystals indicated a comparable degree of incorporation for both oligonucleotides, which was confirmed by HPLC analysis of the redissolved matrix crystals. Therefore, lack of incorporation of dG_{18} is likely not the primary reason for our failure to obtain a mass spectrometric response for dG_{18}. However, this conclusion assumes that the microscopic environment and the distribution of sample molecules within the crystals do not affect the mass spectrometric response and do not change for dG_{18} versus dT_{18}. Possible causes for microscopic differences in incorporation may arise form the different tendency for association of bases and from differences in the oligonucleotide solution structures.

(ii) Measurements on very short stretches of polyguanosine (e. g. dG_7) gave a reasonably intense response, indicating that low efficiency for ionizing polyguanosine is not the primary reason for our failure to observe longer stretches of polyguanosine.

(iii) The mass spectra of dG_7 showed evidence for a substantial degree of fragmentation of the parent ion in the mass spectrometer Mass spectrometric fragmentation may therefore explain our

inability to observe longer stretches of polyguanosine (e.g. dG_{18}). Experiments on chemically modified polynucleotides provide independent evidence that the detailed chemical nature of the bases have a profound effect on the amount of fragmentation observed. For dU_{18} we obtained a mass spectrum very similar to dT_{18}. The intense peaks for dU_{18} demonstrate that the 5-methyl group in thymidine does not affect the mass spectrometric response. On the other hand, the total lack of response for dC_{18} under identical conditions revealed a major influence of the 4-amino group in cytidine. The spectrum of dI_{18} exhibited distinct broad peaks at masses approximately consistent with the intact molecule (figure), demonstrating that substitution of the 2-amino group of guanosine by hydrogen (or the substitution of the 6-amino-group of adenosine by a keto group, respectively) dramatically improved the response. However, the low-mass tailing of the peaks and the narrower width of the peak corresponding to the doubly charged ion compared with that from the singly charged species strongly indicate a rapid fragmentation of these ions during the time required for ion acceleration (0.8-1.2 µsec). The improved spectrum for dI_{18} compared to dG_{18} (and dA_{18}) may be explained by a lesser tendency for fragmentation for dI_{18} caused by the substitution of the exocyclic amino group.

Of the three hypothesized causes for the lack of mass spectrometric response for polyguanosines in contrast to the strong responses for polythymidines the contribution of fragmentation dominated. The basis for this increased tendency for fragmentation is currently under investigation.

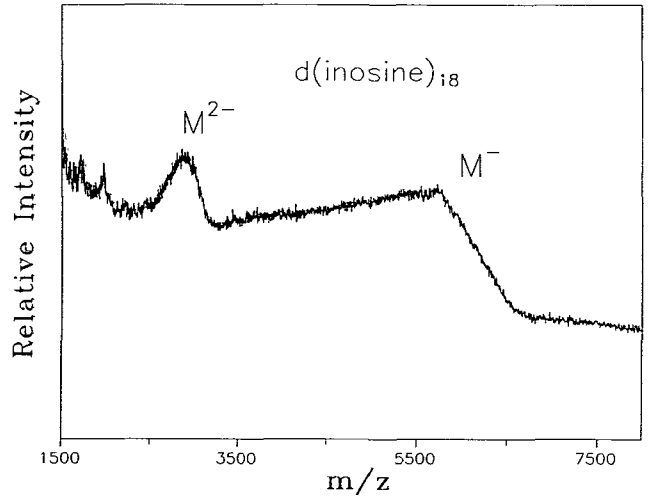

Figure. Negative ion mass spectrum of $d(inosine)_{18}$ (acceleration voltage - 20 kV, matrix: ferulic acid, total amount of sample:1 pmol).

We are investigating matrix-assisted laser desorption mass spectrometry as an alternative to electrophoretic separation of fragments generated by standard DNA sequencing reactions. We have reported that poly $d(T)_n$ samples yield reasonable mass spectra, while poly $d(G)_n$ samples give essentially no response(1). The objective of this study was to determine whether fragmentation might be a factor in the behavior of these molecules.

Poly $d(T)_n$ and poly $d(G)_n$ (n = 2, 4, 6, 8 and 10) were synthesized, purified and subjected to mass spectral analysis. Using 2,5-dihydroxybenzoic acid (2,5DHBA) as the matrix, $d(G)_n$ samples were found to undergo extensive fragmentation yielding a series of peaks represented by the formulae G_n and pG_n and corresponding to cleavage of an O-P bond (fig. 1). A peak corresponding to the loss of a single base moiety is also observed. The intensity of the fragment peaks increases dramatically with the length of the parent molecule, as shown in figs. 2 and 3. For the longer molecule, peaks apparently due to a double fragmentation, represented by the formula pG_np, are also observed. Poly $d(T)_4$ and $d(T)_8$ gave virtually no fragmentation under identical conditions.

The oligodeoxynucleotide, d(TTTTGGGGTTTTTTT), was also sythesized, purified and subjected to mass spectral analysis using 2, 5-dihydroxybenzoic acid and 3-hydroxypicolinic acid (3HPA), (2), as matrix materials. The results are shown in fig. 4. Several peaks corresponding to cleavage of guanine 3' O-P bonds were observed with 2,5DHBA. However, no fragment ions were observed when 3HPA was used as the matrix. These results clearly indicate that the fragmentation process(es) is matrix dependent.

In conclusion, fragmentation appears to account, in large part, for the lack of success in the mass analysis of larger poly $d(G)_n$, and mixed base oligodeoxynucleotides with the MALDI technique using 2,5DHBA as a matrix. Conversely, the absence of fragmentation must be a factor in the successful mass analysis of oligodeoxynucleotides using 3HPA as a matrix.

ION TRAP MASS SPECTROMETRY

R.G. Cooks, R.K. Julian, Jr, C.D. Cleven, S.A. Lammert and M. Soni,
Department of Chemistry, Purdue University, West Lafayette, IN 47907

The performance of ion trap mass spectrometers continues to be improved; the current situation is summarized in Table 1. The features listed include best as well as (in parenthesis) usual levels of performance. Areas in which further improvement is clearly needed include (i) internal energy deposition, where DC pulse activation offers prospects for internal energy depositions much greater than the 5 eV values now typical, (ii) mass measurement accuracy, where internal calibration and improved initial conditions are leading to improvements beyond ±50 ppm, and (iii) dynamic range, where selected waveform (SWIFT) and related methods are improving performance.

An important tool in improving performance is simulation of ion motion. In this laboratory two simulation programs have been developed, one, ITSIM, operates on a PC computer and gives animated displays, trajectory and phase space plots for small collections (<100) of ions.[1] The other, NQS, is a program written for supercomputers and designed to simulate mass spectra by following the motion of 10^4-10^5 ions.[2]

The NQS program first showed[2] that ions are ejected only when both the applied RF and AC have the appropriate polarity that an integral frequency relationship between these signals is desirable and that there is a strong phase dependence on ion ejection which has a dramatic effect on mass resolution. A fixed phase experiment has now been implemented[3] (Figure 1) and it shows that ions can be made to eject at each RF cycle.

Hand-in-hand with simulations as a means of characterizing ion motion in the ion trap are tomography experiments. In one such experiment, acetophenone molecular ions are subjected to a rapid DC pulse in the axial direction and their passage through the trap center is detected by photodissociation using a crossed laser beam.[4] Figure 2 shows results from such an experiment in which the photofragment is m/z 77. Fourier transformation of the time resolved data yields the ion frequencies present in the activated ion cloud. An ITSIM simulation of ion motion reveals the secular frequency, f_z, (Figure 3) and additional frequency components occur when the simulation is done using the real as opposed to the ideal fields.

Fast DC pulses can be used to drive ions into the electrodes and cause surface induced dissociation (SID)[5] and simulations are revealing much of interest in this experiment too. Figure 4 contrasts the phase space plots recorded under conditions when n-butylbenzene ions are subjected to a 104 volt and a 187 volt DC pulse. The former experiment shows equal abundances of the low and high energy product m/z 92 and 91, while the latter gives exclusively the high energy product.

The important task of trapping ions of desired m/z ratios (eliminating matrix ions) is facilitated by using the SWIFT technique. Selected multiply-notched waveforms can be applied during ion injection as shown in Figure 5.

While much has been accomplished to develop ion traps into high performance mass spectrometers, much remains to be done. The availability of powerful simulation methods is likely to be an important aid in this future work.

Mass Resolution in a Quadrupole Ion Trap

R.E. March[1], F.A. Londry[2] and G.J. Wells[3]

[1]Department of Chemistry, Trent University, Peterborough, ON K9J 7B8 (Canada); [2]Department of Physics, Trent University, Peterborough, ON K9J 7B8 (Canada); [3]Varian Associates, Inc., Walnut Creek, CA 94598-0916 (U.S.A.)

INTRODUCTION

The mass resolution of the commercial quadrupole ion trap, which has a fixed mass scanning rate, is ca. three times the ion mass such that the mass resolution at the mass limit (650 Da) is ca. 2000. The mass resolution may be varied by changing the mass scanning rate in a modified instrument. Mass resolution has been improved by the application of axial modulation,[1] a combination of modest ion trap size and frequency reduction with axial modulation,[2] and reduction of the RF voltage scanning rate.[2,3,4,5,6]

EXPERIMENTAL

The experimental results described here were obtained with a modified version of the standard commercial quadrupole ion trap, model Saturn I gas chromatograph/mass spectrometer, manufactured by Varian Associates Inc. The insrument was modified to permit wide variation of the RF drive voltage amplitude scanning rate. Control of the RF voltage amplitude was transferred from the analogue printed circuit board (PCB) to two external (and externally-controlled) digital-to-analogue converters (DACs), of which one was 16-bit and the other was 12-bit. The summing circuit was configured such that the 16-bit DAC spanned the same mass range as the 12-bit DAC on the analogue PCB which normally controls the RF voltage level; the full range of the 12-bit external DAC was equivalent to one increment of the first.
