The integrator on the analogue PCB was controlled by external digital lines and its output was read by an external ADC. Operation of the electron gate, electron multiplier, and axial modulation was controlled also by external digital lines. The axial modulation source on the scan acquisition processor PCB was replaced by an external circuit with a relatively flat response over a range of frequencies from 10 to 500 kHz. By this means, the mass scanning rate for singly-charged ions was varied by a factor of ca. 8.7×10^7, that is, from 1.3×10^6 Da s^{-1}, through the normally fixed rate of 5555 Da s^{-1} to some 0.015 Da s^{-1}. Ion ejection was brought about by resonance excitation applied at a frequency somewhat reduced from that employed in the commercial instrument (q_z=0.86). The pressure of helium buffer gas was not markedly different from the normal pressure of 1 *mTorr*.

RESULTS

While mass resolution, R, is defined as the ratio of ion mass, m, the full width at half maximum (FWHM) of the mass peak, Δm, it is more informative to discuss mass resolution in terms of Δm which is the experimentally-observed quantity rather than the resolution which varies according to the mass chosen. In Fig. 1 is shown the variation of Δm as a function of scan rate (in a log-log format) for four ion species, *m/z* 69, 131, 414, and 614 derived from perfluorotributylamine. Axial modulation was carried out at q_z=0.86 and, for *m/z* 131, at q_z=0.43 also. The arrow marks the normal scan rate of the commercial instrument. As the scan rate is varied over almost 8 decades, the observed variation in Δm spans 6 decades.

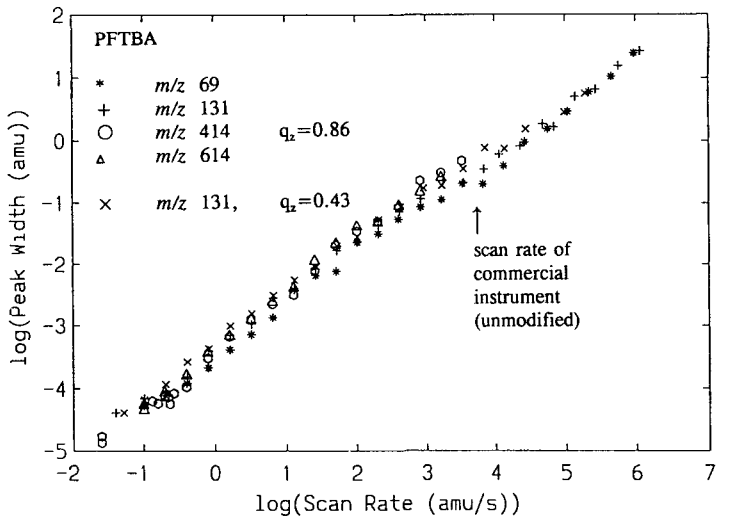

Fig. 1. Variation of peak width as a function of scanning rate, with q_z=0.86: * *m/z* 69; + *m/z* 131; o *m/z* 414; Δ *m/z* 614; and with q_z=0.86, x *m/z* 131.

The maximum RF drive voltage is divided into 2^{27} steps by the ganged 16-bit and 12-bit DACs. Consequently, the smallest increment is 48 μV which corresponds to a minimum peak width of 4.8 μDa. The minimum peak width (FWHM) observed for *m/z* 614 is 52 μDa corresponding to a mass resolution of 1.2×10^7.

A procedure for mass assignment has been explored in which a calibrant ion species and the ion species of unknown mass are isolated in the ion trap using a complex wave-form to eject unwanted ions during ionization. The intensities of the ion species are equalized using two successive ionization periods. Ion ejection is achieved by axial modulation using a composite waveform composed of two frequencies chosen such that the two species are ejected closely in time.

Parallels and Perpendiculars between Magnetic and Non-Magnetic Ion Traps

Alan G. Marshall† and Christopher E. Weaver

Department of Chemistry, The Ohio State University, 120 W. 18th Avenue, Columbus, OH 43210. (†also a member of the Dept. of Biochemistry)

Many of the same sorts of experiments may be conducted in much the same way in ICR and electric quadrupole ion traps (QIT). In their usual configurations, both traps depend on a d.c. quadrupolar potential to trap ions axially (i.e., along a line between the centers of the "end cap" or "trapping" electrodes). Moreover, the natural motion on which mass analysis is based occurs at a frequency which varies inversely with mass in both cases.

Additional insight is provided by analogy to a simple one-dimensional harmonic oscillator (mass-on-a-spring), as shown on the next page. In a conventional harmonic oscillator, the potential is of the form, $U(z) = kz^2/2$, in which the spring force constant, k, is independent of mass. Thus, the "natural" ("secular") frequency varies as $(1/\sqrt{m})$, as for axial oscillation of ions between the two end caps of either a d.c.-only Paul trap or an ICR ion trap. However, both the ion cyclotron frequency in an ICR ion trap and the axial oscillation frequency in an rf-only Paul trap (at low applied rf amplitude) vary as $(1/m)$, a result that may be considered to arise from a harmonic oscillator whose force constant itself varies with mass: $k \propto (1/\sqrt{m})$. Such an analogy explains why thermal ions of higher mass-to-charge ratio, m/z, have higher orbital radius (ICR) or higher axial oscillation amplitude (QIT), because the restoring force weakens as m/z increases (see also bottom right figure). Finally, in an ICR ion trap, the magnetron frequency is approximately independent of mass, corresponding to a harmonic oscillator whose force constant varies as, $k \propto \sqrt{m}$, so that the restoring force actually increases with increasing m/z (bottom right figure).

Based on the above analogies, many techniques originally developed for radial excitation in ICR are now being adapted to the quadrupole ion trap: single frequency, frequency-sweep, and stored-waveform mass-selective excitation and ejection;[1-4] CID; MS_n; and interface with a variety of ion sources. Conversely, dynamic trapping of ions of both charge signs, initially demonstrated for the quadrupole ion trap, has now been implemented in ICR ion traps.[5]

Compared to the QIT, ICR is inherently more linear, and offers higher mass accuracy. Moreover, ions may be trapped (and their chemistry investigated) at much lower temperature (e.g., thermal) in ICR. Also, ions of a much wider m/z ratio (e.g., electrons and negative ions) may be trapped simultaneously in ICR. Work supported by NIH (GM-31683), NSF (CHE-9021058) and The Ohio State University.

Penning Traps in Physics Research

Lutz Schweikhard, Institut für Physik, Staudinger Weg 7, 55128 Mainz, Germany

Penning traps are ion traps that use the superposition of a static homogeneous magnetic and a quadrupolar electric field which are static - as compared to the radio frequency or Paul traps. (Recently, the 'combined trap', a hybrid form of both Penning and Paul trap has also found some recent interest, e g G -Z Li, Z. Phys. D 14 [1989] 1.) Their name refers to F.M. Penning (Physica 3 [1936] 873) who first described this field configuration. Penning traps have been applied in physics research for a broad range of very different types of experiments, briefly outlined as follows.

They are used as mere storage devices, e g when protons from decaying neutrons are trapped and counted to determine the lifetime of the neutron (J Byrne et al., Phys. Rev. Lett. 65 [1990] 289) The first trapping and monitoring of an individual particle was performed in 1973 (D.J. Wineland et al , Phys Rev. Lett. 31 [19730] 1279) and an electron was continuously trapped for more than ten months (G Gabrielse et al., Phys. Rev Lett 54 [1985] 537). The most impressive of physics experiments on stored charged particles are probably those dealing with the g-value of the electron and the positron which date back to the sixties (H.G. Dehmelt et al , Phys. Rev. Lett 21 [1968] 127, G. Gräff et al., ibid. p 340) and culminated in measurements to 4 parts in 10^{12} (R Van Dyck, Jr , et al., Phys Rev Lett 59 [1987] 26) The stationary traps have furthermore been supplemented by movable systems, trapped electrons have been trucked across the U.S A (C H. Tseng et al., Hyp. Int 76 [1993] 381).

A feature of increasing interest in Penning trap research is the possibility of cooling the ion motions. Several techniques have been developed Light particles are subject to radiative cooling and also to resistive cooling by use of the coupling to an external tuned circuit. Recently, buffer gas cooling, which is very common in Paul traps, has been introduced for Penning traps as well (G. Savard et al., Phys. Lett. A 158 [1991] 247), where different modes of ion motion have to be coupled to prevent ion loss This coupling scheme is similar to the sideband cooling technique (H. Dehmelt, Nature 262 [1976] 777). To achieve extreme low ion temperatures, laser cooling can be employed. By this technique, ion clusters, i e crystal-like structures formed by trapped ions, have been observed (S.L. Gilbert et al., Phys. Rev. Lett. 60 [1988] 2022). Sympathetic cooling (D.J. Larson et al , Phys. Rev Lett. 57 [1986] 70) makes use of the interaction between different ion species where one of them is laser cooled In 'electron cooling' (G. Gabrielse et al , Phys Rev Lett. 63 [1989] 1360) antiprotons loose their energy to simultaneously trapped electrons and these in turn are cooled by synchrotron radiation

A major field of application is mass spectrometry. The cyclotron frequency of charged particles in magnetic fields is an ideal means for mass determination (ICR MS, ion cyclotron resonance mass spectrometry). Here two applications can be distinguished·

The mass (more specifically: the mass-over-charge ratio inferred from the cyclotron frequency) can be used to identify the trapped ion species, e g in investigations of the physical (as well as chemical) properties of atomic and molecular cluster ions. At Mainz, for example, we have developed a system that combines the advantages of ion storage and high-resolution ion selection (by resonant ejection) and/or detection (Fourier Transform ICR) with the sensibility of time-of-flight mass spectrometry (with ion counting techniques) by using the Penning trap as the first acceleration section of a Wiley-McLaren type mass spectrometer It has been used for collision induced dissociation studies and chemical reactions of small gold cluster ions (St. Becker et al , Fragmentation of Gold Clusters Stored in a Penning Trap, in preparation for Z. Phys. D). We will extend these investigations to other elements and other interaction schemes like ion or electron bombardment and photo detachment or fragmentation. Broad band mass spectrometry capabilities are also of interest to the analysis of highly-charged atomic ions (D A Church J Mod Optics 39 [1992] 423; S R. Elliott et al , EBIT Trapping Program, Hyp. Int., in print).

On the other hand, the ions may be already well-known and the investigation may aim at the most accurate mass determination possible. A very impressive example is the recent comparison of proton and antiproton mass which tests fundamental laws of physics. An improvement of a thousand as compared to previous results has been achieved (G. Gabrielse et al., Phys. Rev. Lett. 65 [1990] 1317). At Mainz, a system of two Penning traps has been developed for mass determinations of unstable nuclei for tests of nuclear models (St Becker et al. Int. J. Mass Spectrom. Ion Processes 99 [1990] 53-77; H. Stolzenberg et al Phys. Rev. Lett. 65 [1990] 3104). A similar set-up has been constructed for a metrological application, the accurate mass measurement of ^{28}Si (R. Jertz et al., Highly Accurate Determination of the Mass of ^{28}Si as a Contribution to a New Definition of the Kilogram, in preparation for Physica Scripta). The research groups of Pritchard, VanDyck, and Werth are working on similar problems (see e.g.: E.A. Cornell et al , Phys Rev Lett 63 [1989] 1674; F L Moore, Phys. Rev. A 46 [1992] 2653; Ch. Gerz et al., Z. Phys. D 17 [1990] 119)

The mass-to-charge ratios of the particles investigated range from that of the electron and positron to several (ten) thousands of amu/e for cluster ions, for example; i.e. they extend over almost eight orders of magnitude. Charged particles of matter and antimatter are investigated. And not only the inertial mass is being attacked. Penning traps may also play a significant role in a comparison of the gravitational mass of proton and antiproton (M H Holzscheiter in P. Carlson et al.[eds.] First Biennial Conf. Low Energy Antiproton Phys , World Scientific, Singapore, 1991).

The variety of experiments implies a variety of different trap designs optimized for their specific tasks, e g in respect to the creation and capture of the particles of interest. Ions may be created in the trap or (especially rare species) injected from external sources High energy antiprotons, for example, have to be slowed down from energies of several MeV to energies lower by several orders of magnitude (G. Gabrielse et al., Phys. Rev. Lett 57 [1986] 2504). In another experiment two Penning traps are employed and ion bunches of radioactive isotopes are transferred from one to the other (H. Schnatz, et al., Nucl Instr. Meth. A251 [1986] 17) The trap designs also differ in (optical and ion optical) access to the trap center, perfection of the electric (trapping) potential, magnetic field inhomogeneity and drift, excitation modes for manipulation of the ion motions, and/or detection schemes for the number of ions and/or their resonance frequencies For example, the electric trapping field is often shimmed by compensation electrodes (R S van Dyck, Jr et al., Appl. Phys Lett. 28 [1976] 446; G. Bollen et al , J. Appl. Phys 68 [1990] 4355) For high-accuracy spectrometry single ion detection methods are often used (G Gräff et al , Z Phys A 297 [1980] 35, R M Weisskopf et al., J Appl Phys 63 [1988] 4599). Alternatively, ion interactions are studied in detail (E A Cornell et al , Phys Rev A45 [1992] 3049)

The given space does not allow for a comprehensive review of the subject and the interested reader should refer to the literature given above and below. An overview of ion traps in general has been given by J Allison and R.M Stepnowski (Anal Chem 59 [1987] 1072A), on physics with ion traps by R.C. Thompson (Meas Sci. Technol. 1 (1990) 93-105) The principles of Penning traps have been thoroughly reviewed by Brown and Gabrielse (Rev Mod. Phys 58 [1986] 233) and high precision mass spectrometry with Penning traps by F Vedel and G. Werth (in C R.E. March, J F. Todd [eds.] Modern Mass Spectrometry, CRC Press, in preparation) Some aspects have been discussed in more FT-ICR oriented reviews by A.G. Marshall et al (Int J. Mass Spectrom. Ion Processes 118/119 [1992] 37) and by L Schweikhard et al. (Excitation Modes for FT-ICR MS, J. Am. Soc. Mass Spectrom., in print). Further detailed information can be found in various contributions to several workshops and conferences, as published e.g. in Physica Scripta (vol. T22 [1988] Phys of Low-Energy Stored and Trapped Particles, Stockholm, Sweden, June 1987, vol 46(3,6) Workshop on Physics with Penning Traps, Lertorpet, Sweden, June 1991), Hyperfine Interactions (vol. 76(1-4) Antihydrogen Workshop, Munich, Germany, July 92; Workshop on Traps for Antimatter and Radioactive Nuclei, Vancouver, Canada, Feb. 1993, to be published) and in the topical volume 39(2) [1992] of J. Mod Optics (Physics of trapped ions).

Biological Ion Trap Mass Spectrometry

Scott A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

The capability of the quadrupole ion trap for the analysis of high mass biomolecules has undergone remarkable growth over the past five years. Major advancements have been contributed by research groups at Purdue and Finnigan. A primary goal of our group at Oak Ridge has been to contribute to progress in this area as well. More recently, several other groups have joined in the development of the ion trap for biomolecule analysis reflecting a growing interest in the ion trap for biological research. This paper provides a brief overview of the current status of the ion trap as an analyzer for ions derived from high mass biomolecules and summarizes the efforts at Oak Ridge in this area over the past year.

Ion trap research at Oak Ridge this year directly related to biomolecule analysis can be divided into matrix assisted laser desorption (MALD) studies of mixtures (e.g. protein tryptic digests) [1], capillary electrophoresis combined with electrospray ion trap mass spectrometry [2], and the analysis of multiply-charged anions derived from oligonucleotides via ion trap tandem mass spectrometry [3]. MALD ionization of components of a tryptic digest of glucagon was performed including tandem mass spectrometry experiments. The latter capability makes the ion trap particularly attractive for tryptic mapping relative to time-of-flight mass analysis, for example. MALD ion trap experiments have also been successfully performed to distinguish tryptic digests of cytochrome C derived from horse, tuna, dog, and rabbit. These results, along with those contributed by other groups demonstrate the utility of the ion trap for analysis of ions derived from MALD.

Unlike MALD, electrospray is quite sensitive to matrix effects. For this reason, it is desirable to perform a separation step in the application of electrospray to a complex mixture. We have therefore devoted effort to solving problems associated with the coupling of capillary electrophoresis with electrospray and the ion trap. For example, we have applied random noise collisional activation both to reduce background in the total ion chromatogram and in the mass spectrum and to induce fragmentation in peptides in an on-line separation without mass selection or frequency tuning. In the former application, a relatively low amplitude signal is applied during the ion injection process to induce fragmentation of weakly-bound clusters. These species otherwise tend to fragment on the time frame of the ion trap experiment resulting in chemical noise in the spectrum. In the latter application, a relatively high noise signal is applied to the end-caps after ion injection sufficient to induce dissociation of the analyte ions. The goal of this work is to provide the capability for obtaining extensive structural information from a complex mixture, such as a protein tryptic digest, from a single injection of a sub-picomole/component mixture.

We have expended considerable effort over the past few years in understanding the behavior of multiply-charged oligonucleotides under ion trap collisional activation conditions. We believe that we now have a good overall understanding of these species, at least for oligomers of up to about 20 bases. This size currently constitutes the largest oligomer that we have yet studied. Figure 1, for example, shows the MS/MS spectrum of the $(M-12H)^{12-}$ anion derived from electrospray of 5'-d(AGCTAGCTAGCTAGCTAGCT)-3' acquired using random noise collisional activation. The major fragments are labelled and correspond to those predicted from our previous studies of smaller oligonucleotides. Complete sequencing of this oligomer is not possible from the major

fragment ions. However, all of the lower intensity fragments arise from various sequential decompositions. Perhaps with automated interpretation algorithms based on the rules of decomposition derived from our previous studies, extensive sequence information might be derived from a single MS/MS spectrum such as this one can be determined. We have made some initial steps in this direction [4].

Fundamentals and Recent Applications on an Atmospheric Pressure Ionization-Differentially Pumped Benchtop Ion Trap, Jack Henion, Alexander Mordehai, H.K. Lim, and Jianyi Cai, Drug Testing and Toxicology, NYS College of Veterinary Medicine,
Cornell University, 925 Warren Dr., Ithaca, NY 14850

INTRODUCTION

The pioneering efforts which incorporated electrospray ionization capability on the ion trap by the Oak Ridge National Laboratory (ORNL) group[1] has opened entirely new fields of research and applications capability for the ion trap. Recently we implemented atmospheric pressure ionization (API) technology on a benchtop IT mass spectrometer. There are several new features incorporated in our design: a liquid shield API ion sampling interface[2a], differential pumping of ion trap and electron multiplier regions for high helium pressure ion trap operation[2b] and recently two new computer IT operation modes for achieving selected windows ion monitoring(SWIM) mode. The focus of this report includes fundamental and applied aspects of this new system.

The liquid shield API interface provides an efficient means for on-line coupling of modern separation techniques such as capillary electrophoresis(CE) and high performance liquid chromatography (HPLC) with a mass spectrometer. Both micro-(a few uL/min) and megaflows(1mL/min) of HPLC effluents can be accommodated without splitting under ion spray conditions. Recently, we also implemented atmospheric pressure chemical ionization (APCI).

EXPERIMENTAL

One of the fundamental aspects of the new system is operation under high helium pressure (up to 1 x 10^{-2} Torr) to provide optimum trapping efficiency. It was found that the trapping efficiency for externally produced ions increases with increasing helium pressure in the trap with some mass resolution decrease. The optimum conditions were established at a pressure 5 x 10^{-3} Torr to provide unit mass resolution across the mass range (up to 650 Da). This higher helium pressure is unique for ion trap operation in our system so it was of interest to study the possible consequence of this aspect on major principals of ion trap operation such as resonance ion injection-excitation phenomena. To study the resonance phenomena a second computer (IBM 486) with an arbitrary wave form generator was implemented to allow the application of computer-designed wave-functions *(harmonic, chirp or broad-band) to the end-cap IT electrodes. It was found that harmonic* signals of 5-10 Vo-p efficiently eject resonating ions from the trap in the z-direction even at pressures of 5 x 10^{-3} Torr helium. To apply ion ejection technology for chemical noise reduction in analytical applications we synthesized a broad-band time domain signal(10 Vo-p, frequency range 25-500 kHz, step-quadratic phase encoding) with frequency notch at 50 kHz of 20 kHz width. Application of a such time-domain signal to the end-caps during the ionization event allows one to accumulate selectively only ions of interest in ~100 Da mass window while ejecting all other ions from the trap.

RESULTS AND DISCUSSION

The developed system was applied to some simple on-line analytical separations. As an example of micro-flow applications Figure 1 shows the standard curve from the CE/MS analysis of low fmol levels of isoquinoline alkaloids found in the bark of a medicinal tree that grow in Taiwan. This experiment was performed using 10 uL/min sheath-flow (no SWIM). Quantitative CE/MS analysis for berberine was done using

tetrahydroberberine as internal standard (RSD = 0.998). Figure 2 illustrates the use of SWIM for improving sensitivity and reducing chemical noise under on-line ion spray LC/MS conditions with a synthetic mixture containing three Benzodiazepines drugs (1 ng of each injected on-column) at a flow rate of 1mL/min (no split!). These results suggest that conventional-bore HPLC columns and their accompanying 1 mL/min flow rates may be used for high sensitivity LC/MS using the ion trap equipped with this API interface.

b. CNR, Servizio Spettrometria di Massa, C so Stati Uniti 4, 35100 Padova (Italy).

Significant mass displacements from the expected instrumental value have been observed with several odd and even electron cations[1]. This phenomenon could be, in principle, ascribed to many factors either instrumental or related to the intimate properties or reactivity of the ionic species investigated (space-charge effects, gas-phase ion-molecule interactions, supplementary a.c voltage effects or radiofrequency field effects)

Experiments devoted to the reduction of the ion concentration ruled out the influence of possible space-charge effects[2]. Moreover, the occurrence of chemical interactions among the ions stored within the ion trap was investigated by introducing a reaction time of variable length before the main r f. ramp. Chemical interactions should be time dependent and hence the negligible differences found in the δ_m values for increasing reaction times[2] exclude the involvment of these interactions on the observed mass displacements
The occurrence of an interaction between the ionic species with the auxiliary a.c. voltage was confirmed by two experiments consisting in the reduction of the intensity of selected $[M]^{+\cdot}$ ions with respect to the tickle voltage and in the measure of the mass displacement of the same ion generated either by collision or by the usual mass analysis[2]

Thus the phenomenon of mass displacement must be rationalized in terms of interaction of specific chemico-physical properties of the analytes and the radiofrequency field. The result of this interaction is a small, but well detectable, power comsumption of the r f. field, that reflects on the ejection of the ions at different q_z values (that is at different $V_{r.f.}$ values) This chemico-physical property was recognized to be the polarizability[3] that can lead to interaction with the radiofrequency field on the electron shell about a nucleous (electron polarizability) and/or may result from the forced alignment of the permanent dipoles along the field direction (dipolar polarizability) The polarizability, in fact, is the only property that can account for the different mass displacements observed with isobaric ions of equal elemental composition, but different structure or for the experimental observation that the δ_m increases as the dipole moment of the analyte increases Additional support to this hypothesis was found in the results obtained with isobaric ions of equal elemental composition but different structure analyzed by a quadrupole mass filter. Again, different mass values were found for different isomers, proving that the mass displacement phenomenon is general and occurs when ions experience quadrupole fields[4].

The mass displacements have been measured for a set of substituted benzene molecular cations For ions possessing a small or negligible dipolar component the mass displacements δ_m well correlate with the calculated electron polarizability, as shown in Figure 1 for of alkylbenzene ions[3]

ION REMEASUREMENT IN FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY

C. L. Hendrickson, V. L. Campbell, Z. Guan and D. A. Laude, Jr. Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX, 78712

Mass spectrometric detection is usually characterized as a destructive technique in which ions formed from the neutral analyte are detected by collision at the surface of a current-amplifying device. In contrast, Fourier transform ion cyclotron resonance mass spectrometry (FTICR) is distinguished from other mass analyzers because the basis for signal detection is the mass-dependent periodic fluctuation in image current generated by spatially coherent ion packets that pass in proximity to the detector electrodes of a trapped ion cell. Thus the FTICR detection process is not inherently destructive and the possibility exists that the ion population can be remeasured as a means to enhance the analytical signal or perform more intricate physical measurements. Unfortunately, FTICR remeasurement is complicated by competitive relaxation processes in the cell[8] and in most cases remeasurement efficiency would be small because the spatially focused ion population is not conserved.

Should an efficient approach to relaxation be found, then the remeasurement experiment as depicted in Figure 1 would become feasible. In this pulse sequence an initial population of ions is injected into the mass spectrometer, the axial motion is cooled and then an excite and detect event occur. At this point, rather than quench the ion packet, a remeasurement delay period occurs. This period, whether active or passive, must accomplish the task of returning the ion population to the center of the cell. McLafferty first demonstrated that for large molecules the angular distribution of ion trajectories after collision with small neutrals decreases as ion mass increases. Consequently, an ensemble of large biomolecular ions initially formed in the center of the trapped ion cell would be more likely to return to its orbiting center following excitation of the cyclotron mode for FTICR detection. We have demonstrated that unit remeasurement efficiency can be achieved for electrosprayed protein ions and real gains in signal enhancement can be achieved remeasuring the same ion population. Shown in Figure 2 are comparison FTICR spectra of Bovine albumin dimer remeasured 250 times after a 2 sec. cooling delay to obtain a 15-fold increase in S/N.

We have investigated conditions under which remeasurement efficiency is maximized. In general it is essential to minimize the radial electric field experienced by an ion during the course of the experiment because for this passive experiment there is necessarily a continuous outward movement of the ion as a consequence of each excite event. Shown in Figure 3 is a plot of electric field as a function of radial displacement for several trapped ion cells. What the data suggest is that remeasurement should be most readily accomplished in an elongated closed cell. We find this to be the case. Where unit remeasurement is achieved in a cell of aspect ratio two, both cubic closed and open cells exhibit far poorer remeasurement efficiency.

The remeasurement experiment just described is most effective for large molecules. It would be of great interest if the remeasurement process could be extended to small ions. To accomplish this, however, it is necessary to overcome the growth of the magnetron radius for the ion. Two approaches have been suggested for this type of cooling and therefore offer the potential for use in a remeasurement experiment. For example, following from work by Becker and coworkers, Marshall has recently shown that the magnetron radius can be decreased by inhomogeneous collisional cooling effects upon conversion of motion to the cyclotron mode. Jacoby and coworkers have demonstrated operation of the FTICR trapped ion cell as a Paul trap

to facilitate high pressure cooling of ions to the center of the cell. We have constructed a combined RF-ICR trap based upon an electromagnet system for the purpose of investigating these two types of cooling. The spectrometer was successfully constructed and preliminary data for cooling of naphthalene ions by both quadrupolar excitation and by RF cooling have been attempted. Shown in Figure 4 and 5 are preliminary data for the two techniques that suggest that cooling of the excited ion cloud for a small ion is possible. The effectiveness of the cooling appears to be similar for the data.

Ultimately it is realistic to expect that ion motion in the FTICR trapped ion cell will be sufficiently controlled to arbitrarily create and manipulate any ion population as desired. The present demonstration of nondestructive FTICR mass spectrometry is a specific example of this progress which increases the parallels to FTNMR and should provide new avenues for investigation in FTICR.

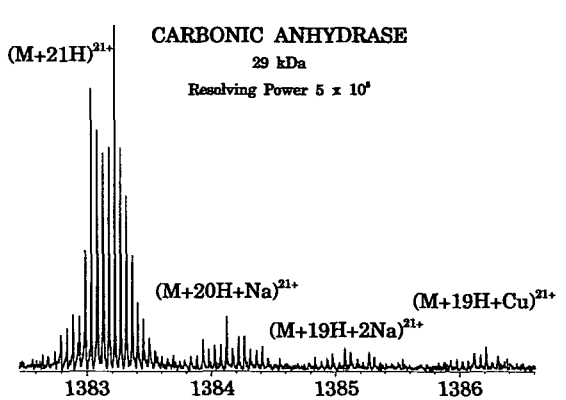
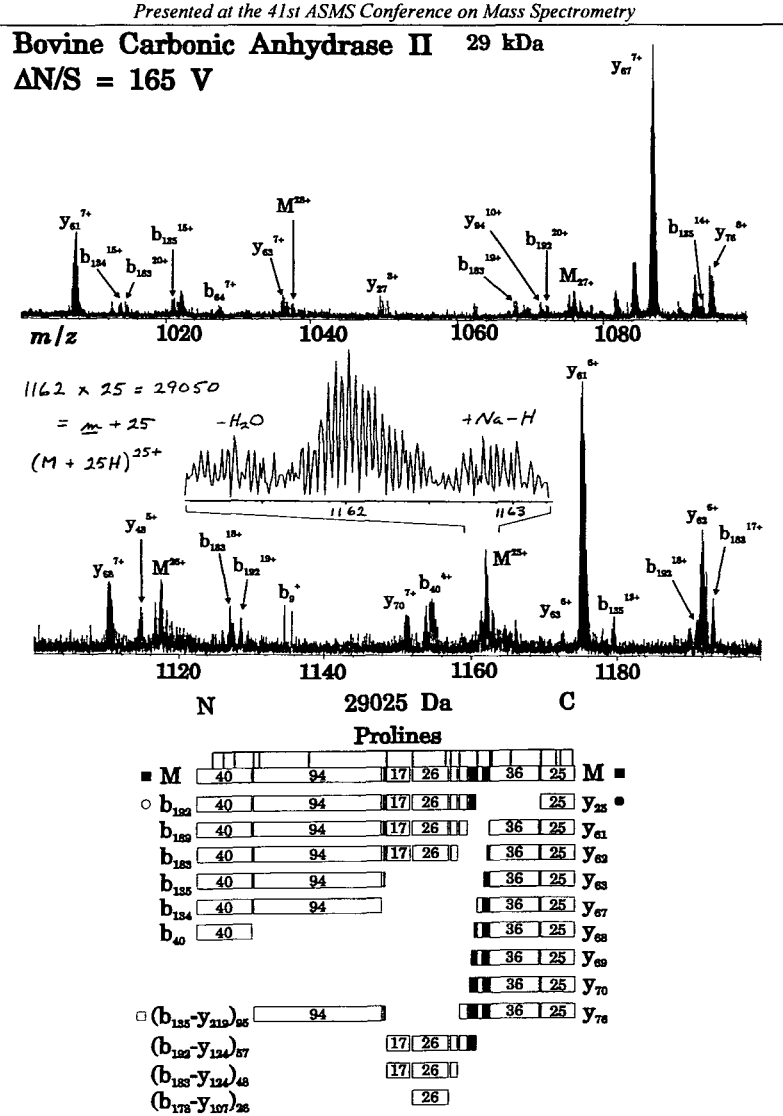
Characterization of Large Linear Molecules by Tandem Mass Spectrometry.

*Fred W. McLafferty, Steven C. Beu, Michael W. Senko, and Peter B. O'Connor. Chemistry Department, Baker Laboratory, Cornell University, Ithaca, NY 14853-1301.

Amino acid sequencing of oligopeptide (<3 kDa) mixtures is now done routinely by tandem mass spectrometry (MS/MS). Soft ionization produces a mixture of molecular ions separated by MS-I; dissociation of each separated ion species and MS-II mass analysis then provides the sequence information for each mixture component. Similar characterization of several kDa carbohydrates, nucleotides, and polymers have also been reported; this describes preliminary results of efforts to extend this technique to molecules at least an order of magnitude larger using electrospray ionization (ESI)/Fourier transform (FT) MS.

ESI has the advantage that even the highest mass ions still have small m/z values of 600-2000; heterodyne FTMS provides simultaneous measurement of all these peaks with resolving powers $>10^5$ and mass measuring accuracy of a few ppm. Such unit mass resolution of isotopic peaks also provides a mass scale to determine both m and z values, which is especially critical for MS-II spectra containing scores of fragment masses. The non-destructive ion detection in FTMS is also unique, so that the trapped ions can be measured repeatedly to improve signal/noise and can also be reacted and mass analyzed sequentially (MS^n); such multiple spectra can be measured simultaneously with Hadamard transform techniques. Characterization of trapped ions can not only be done by a variety of dissociation techniques, but also by ion-molecule reactions indicative of their three-dimensional structure. The potential for sequence information is illustrated using the ionic fragments from nozzle-skimmer dissociation of carbonic anhydrase (29 kDa) measured simultaneously by FTMS, followed by collisionally-activated dissociation of the Y_{67}^{7+} fragment ion.





REMEASUREMENT AND COLLISIONAL THERMALIZATION OF IONS BY QUADRUPOLAR EXCITATION IN A FOURIER TRANSFORM MASS SPECTROMETER[1]

Department of Chemistry, University of Georgia, Athens, Georgia, 30602

Quadrupolar excitation of ions with collisional cooling was first proposed by and demonstrated in a Penning trap by Savard et al. More recently, Marshall and coworkers have demonstrated axialization of ions in a dual cell FT-ICR, in which quadrupolar excitation occurred in one cell, and ion detection occurred in a second cell. Here we report quadrupolar excitation in a single cell FT-ICR instrument, and present several examples of the capabilities of this technique, as well as applications to ion chemistry studies.

The axialization of ions is found to occur with high efficiency, by using quadrupolar excitation in combination with collisional cooling. Ions of Rhodamine 6G, formed by laser desorption, can be remeasured over 500 times by axialization of the ions after detection, allowing a substantial increase in the S/N of the detected signal. Figure 1 shows the improvement in S/N that is obtained by remeasuring the m/z 443 ion of Rhodamine 6G 200 times, with signal averaging. The S/N is found to improve by a factor of 12. The remeasurement efficiency for this experiment was found to be greater than 99.5%.

An important feature of this method is that it allows ions to be retained in the ICR analyzer cell while they are exposed to thousands of collisions. Naphthalene ions can be retained after more than 100,000 collisions with methane. Quadrupolar excitation has been used to relax the excited states of transition metal ions, formed by laser ablation of a metal foil, by collisional thermalization. The reactions of thermalized transition metal ions with laser desorbed neutral molecules of peptides and amino acids have been studied. We find that the observed products of such reactions are quite different for metal ions that are thermalized with 5,000-10,000 collisions using quadrupolar excitation than for metal ions that undergo conventional thermalization with 50-100 collisions.

In addition to the capabilities for ion remeasurement and collisional thermalization, we have found that quadrupolar excitation with collisional thermalization increases mass resolution, by increasing the duration of the transients that are produced. Without quadrupolar excitation, laser desorbed m/z 443 ions of Rhodamine 6G produce a transient that lasts approximately 100 ms. When the ions are centered in the cell by quadrupolar excitation before their detection, coherent motion is found to persist for more than 2 minutes. The Fourier limited resolution for a 64 s transient of this mass in our 1 tesla instrument is $1x10^6$, but the observed resolution is $1x10^5$. "Dissection" of the transient reveals frequency drifts of the order of 0.1 Hz/s.

AVERAGING THEORY FOR ION MOTION IN A CUBIC FT-ICR CELL

Dale W. Mitchell, Bryan A. Hearn and Stephen E. DeLong

Department of Geological Sciences
University at Albany-S U N.Y.
Albany, New York 12222

The widely employed cubic ICR cell [1] offers an ideal test case for investigating the effects of electric field inhomogenieties and other perturbations on ion motion. This is because the motion of an ion in a cubic cell can be well approximated by simple harmonic oscillations (the quadrupolar approximation) with all other effects treated as perturbations. Also, the electric fields have exact solutions whose lowest order expansions are adequate zero-order approximations. Averaging methods which are based on transforming from a cartesian coordinate system to the amplitude-phase representation whose variables are the mode-radii and phases can greatly simplify the analysis of complicated problems. With the help of these methods, the essential physics can frequently be extracted from an otherwise intractable problem in a consistent manner, thereby allowing for the development of simple yet reasonably accurate models for physical processes. These methods have been applied to the calculation of frequency shifts from trapping field inhomogenieties [2] as well as the effects of excitation field inhomogenieties on ICR ion motion [3]. Here we outline results for the relatively simple case of low mass ions in a linearly polarized electric excitation field with magnitude E, cell length d and magnetic field B as shown in Fig.1 Only the linear terms are retained which allows for comparison with other results. We have only retained the resonance at $\omega_e = \omega_+ \approx qB/m$ which leads to simple solutions For on-resonance excitation, we find that the cyclotron radius $r_+(t)$ is

$$r_+(t) = \{r_{+0}^2 + (Et/2B)^2 + (Etr_{+0}/B)\sin(Q_{+0})\}^{1/2} \qquad (1)$$

where r_{+0} is the initial cyclotron radius and $Q_{+0} = \beta_{+0} - \beta_e$ is the difference between the initial cyclotron phase and the excitation phase, for the geometry shown in Fig.1 ($\beta_{e=0}$ in Fig.1). Figure 2 shows $r_+(t)$ calculated from Eq.(1) for an initial cyclotron radius of 0.25d for different values of initial phase. The phase $Q_+(t) = \beta_+(t) - \beta_e$ is related to $r_+(t)$ by the simple relation

$$\cos(Q_+(t)) = [r_{+0}/r_+(t)]\cos(Q_{+0}) \qquad (2)$$

Figure 3 gives plots of this quantity for different initial cyclotron radii for $Q_{+0} = -\pi/4$. The process of ICR phase synchronization during on-resonance excitation is contained in Eq.(1) and Eq.(2). The phase difference $Q_+(t)$ approaches $\pi/2$ as $r_{+0}/r_+(t) << 1$. From the geometry given in Fig.1 this value for the phase corresponds to the ion velocity being in-phase with the excitation field, as expected

Mass Determination of Trapped Micro-particles and Macro-ions by Optical Techniques (and Subsequent Chemical Analysis by Laser Pyrolysis Mass Spectrometry)

Gyorgy Hars*, Neil S. Arnold and Henk L.C. Meuzelaar
Center for Micro Analysis & Reaction Chemistry
University of Utah, Salt Lake City, UT 84112

* Visiting scientist from TU Budapest, Hungary

Extensive analytical interest in characterization of particulate matter extends in many applications to evalution of individual micro-particles. For complete chemical characterization of individual microparticles adequate measurements of both particle physical characteristics (e.g., size, mass) and chemical constituents are required. Like molecular species, particles may also be readily ionized and manipulated by electrical techniques based on mass to charge ratios. An approach favored by the authors would provide an accurate mass determination which could be followed by laser pyrolysis (ionization) mass spectrometry to determine the chemical composition. Both measurements can be carried out in the same ion trap but they require different electrical operating conditions. For particle mass determination the ion trap operates as an Electrodynamic Balance (EDB) [1] while the compositional analysis is performed in the Ion Trap Mass Spectrometer (ITMS) mode. Figure 1 shows the typical operating parameters for both of the two modes. For macro-ions and submicron particles the distinction between ions and charged particles may become blurred making it profitable to consider the ability to make mass measurements of individual submicropartciles based on optical detection techniques.

The present investigation utilized the apparatus illustrated in Figure 2. A 10 mW HeNe laser illuminates the particle through a 3 mm hole in the ring electrode. A high sensitivity CCD camera with a zoom lens detects 90° scattered light via a second hole in the ring or via a hole in the end cap. Particles are introduced from suspension in water or alcohol by syringe needle inserted through the end cap. Strong electric fields used for trapping provide particle charging in a "quasi electrospray" ionization manner.

In classical EDB operation, gravitational force is offset by a DC potential applied in a dipolar mode to the two end caps making it possible to calculate the mass to charge ratio from the DC voltage applied. To obtain an accurate measurement the particle is damped to a small trajectory at the center of the trap and the end cap voltage measured (see Figure 3). Such measurements have been made to a relative accuracy of 1 in 10^5 [2]. In ITMS mode, secular oscillations of various ions are used to selectively eject ions. These same oscillations could be used to detect macro-ions, but the rapid motion (>100 Hz) and poor light scattering tend to make optical detection impractical. One means to overcome this limitation is to excite "standing" patterns reinforced by repetition of the same trajectory. This is not readily obtained in the r-z plane, but if viewed through an endcap the particle is seen to traverse an elliptical "Lissajous" pattern in the x-y plane. Superimposed on this pattern are drive frequency oscillations forming a "star" pattern as in Figures 4 and 5. This pattern will rotate unless the trapping frequency is an exact integer multiple of the radial secular frequency. By measuring the precession rate the secular frequency is determined allowing the m/z value to be calculated. At present the resolution is limited by a "beating" of 2 radial secular frequencies causing the "star" to collapse to a line every 3-10 seconds. In spite of this limitation current m/z measurements can be made to 1 part in 10^3. Finally, actual mass measurements (rather than m/z measurements) may also be utilizing single electron loss events induced by UV radiation. In principle, therefore it is possible to determine the mass of a single macro-ion in the 10^9-10^{12} a.m.u. range with similar precision. Calculations suggest the possibility of extending this approach to particles in the 10^1-10^2 nanometer range (10^6-10^9 a.m.u.), thus indicating the feasibility of developing a novel optical method for high precision mass determination of a single macro-ion.

Non-Linear Resonance Effects During Ion Storage In a Quadrupole Ion Trap

Donald M. Eades* and Richard A. Yost
Department of Chemistry, University of Florida, Gainesville, FL 32611

Introduction

Realistically, construction of a purely quadrupolar ion trap is both impossible and impractical. Thus, all ion traps possess, to some degree, contributions from higher-order fields due to distortions in the quadrupolar field. Higher-order fields cause the resulting trapping field strength to no longer be linear with distance from the center of the trap. The resulting non-linear resonances (NLR) occur at specific ion frequencies which are unique to the contributing higher-order field. NLR's for hexapolar, octapolar, and dodecapolar fields are shown graphically on the Mathieu stability diagram in **Figure 1**. When stored at values of q_z (RF voltage) and a_z (DC voltage) corresponding to a NLR, an ion can absorb power from the higher-order field resonance causing frequency shifts [1] or ion ejection and/or collision-induced dissociation (CID) [2]. The work presented here shows experimental data used to characterize NLR effects on stored ions. All experiments were performed on a Finnigan MAT ion trap mass spectrometer which was controlled by ICMS v. 2.2 software [1]. The $C_2H_5^+$ ion (m/z 29) of methane was mass-selected and used as a chemical probe.

Results and Discussion

When storing mass-selected $C_2H_5^+$ ions (m/z 29) of methane for 50 ms at various q_z values along the a_z=0 line, m/z 29 ion intensity exhibits minima at q_z=0.65 and 0.80, mirrored by an increase in the ion intensities of m/z 27 and 41. At these points, $C_2H_5^+$ absorbs power from the octapolar (β_z=1/2) and hexapolar (β_z=2/3) NLR's and undergoes CID losing neutral H_2 to yield $C_2H_3^+$ (m/z 27) which then reacts with neutral methane to yield $C_3H_5^+$ (m/z 41). This chemical system was found to be very useful for characterizing NLR effects and was used as a probe to map the *experimental* stability region for $C_2H_5^+$. The results, displayed in **Figure 2**, show that the *experimental* stability region exhibits unstable regions along iso-β lines corresponding to β_z=1/3 (dodecapolar), β_z=1/2 (octapolar), β_z=2/3 (hexapolar), and β_r=1/2 (octapolar).

Factors contributing to the observation of NLR effects include: 1) ion displacement from the center of the trap, 2) ion population, 3) storage time, and 4) storage conditions (q_z,a_z values). Ion displacement influences NLR effects since the field at the center of the trap is nearly purely quadrupolar, with deviations observed only in the outer regions. Thus when displaced, ions interact with higher-order fields more than when in the center of the trap. Ion population directly influences the observation of NLR effects. Ion-ion repulsions cause displacement from the center of the trap and, when stored near a NLR, ions interact with the higher-order fields. This can be seen in **Figure 3** in which the higher ion population of $C_2H_5^+$ shows markedly increased ion losses when stored near q_z=0.65, a_z=0. Ion storage time exhibits a linear relationship to ion loss when storing near a NLR. Longer storage times allow more time for the ions to absorb power and thus undergo CID and ion ejection. This can be seen in **Figure 4** in which compares storage times near q_z=0.65, a_z=0.

Conclusions

Non-linear resonance effects can potentially affect any experiment in which the ions are stored at a q_z,a_z combination corresponding to a higher-order resonance. Factors enhancing NLR effects include ion dispacement from the center of the trap, high ion population, and long storage

times. Due to these factors, experiments such as resonant excitation, kinetic studies, ion injection, and chemical ionization can be particularly affected. It should be pointed out, however, that contributions from higher-order fields are not entirely detrimental. Indeed, Louris et al. [3] have reported improved resolution with the introduction of higher-order by the stretched design. Also, Franzen [1] has reported improved trapping efficiency with superimposed octapolar fields.

The authors acknowlegde the US-EPA/EMSL (Cincinnati) for funding this project. The authors thank Nathan A. Yates for valuable software development and helpful discussions.

DEVELOPMENT OF AUTOMATED SELECTED ION STORAGE FOR QUADRUPOLE ION TRAP MASS SPECTROMETRY

Barrie A. Shaffer, Joe Karnicky, and S.E. Buttrill, Jr.,
E.L. Ginzton Research Center, Varian Associates,
3075 Hansen Way, Palo Alto, CA 94304-1025

Quadrupole ion trap mass spectrometry has long been known to be an extremely sensitive technique for mass detection. Its sensitivity, however, is limited by the finite capacity of the ion trap for storage of ions. In applications such as gas chromatography/mass spectrometry (GC/MS) the compound of interest is often present at levels small compared to the amount of chemical background resulting from dirty samples or other sources. Selected Ion Storage (SIS) may be used to selectively store a particular ion mass or range of ion masses while ejecting all other species [1]. As a result, the ion trap may be filled to its maximum capacity with only those species of interest

A complex waveform applied across the endcap electrodes of an ion trap causes unwanted species to be resonantly ejected from the trap before mass analysis. The waveform may be calculated by a straightforward procedure, and includes discrete coherent frequency components which correspond to the characteristic oscillation frequencies of the species to be ejected [2]. These frequencies typically lie from 20 to 500 kHz. A well designed SIS waveform will eject all undesired species while leaving the desired ion masses within the trap.

Even a waveform containing only a single frequency can eject multiple ion masses if the amplitude is large enough. Consequently, storage of a single mass by a complex waveform is easily optimized by amplitude adjustment of a waveform having an absence of frequency components in the area corresponding to the secular frequency of that mass. For storage of widely separated masses, performance optimization requires a precisely tailored waveform, so that a single amplitude adjustment will affect the desired result over the entire mass range.

The widths of resonance ejection profiles were measured for several major ion species in calibration gas (perfluorotributylamine, FC-43) Ejection linewidths vary from slightly over 1 kHz at low mass to slightly under 1 kHz at high mass.

Complex SIS waveforms require the following: Each species to be ejected requires a waveform frequency component close to the secular frequency of that mass. This frequency component should have sufficient amplitude for ejection of the mass without broadening the linewidth profile. Each species to be stored requires an absence of frequency components within a frequency range corresponding to the ejection linewidth around the secular frequency. Nearby frequency components should not have amplitudes large enough to affect partial ejection of that mass.

Waveforms have been developed which satisfy these requirements by including discrete coherent frequency components. The calculated secular frequencies are rounded to the nearest 500 Hz (well within the ejection linewidth) and have amplitudes which are weighted as an inverse power of the mass. They may be used to effectively store low and high mass species while simultaneously ejecting all undesired species across the full mass range of the instrument.

Figures 1 and 2 show performance of the same waveform at low and high mass. Mass spectra were recorded (the sample is GC column bleed at 300 C) using Selected Ion Storage (SIS) over a range of applied waveform amplitudes. The percent change in intensity for each mass present is calculated at each applied amplitude. Note that the ejection efficiency is approximately the same for all masses which are to be ejected. The SIS waveform was designed to store m/z 73 and 355. Each of these species maintains nearly constant intensity over the range of applied waveform amplitudes.

ENVIRONMENTAL ANALYSIS WITH QUADRUPOLE ION TRAPS: PAST, PRESENT, AND FUTURE

Gary L. Glish, Department of Chemistry, University of North Carolina, Chapel Hill, NC 27599-3290.

The quadrupole ion trap was introduced to the main stream of the mass spectrometry community about a decade ago as a GC detector. It immediately made an impact due to its high sensitivity in the electron ionization mode of operation. Since these early days the ion trap has developed into a powerful, multipurpose mass spectrometer. One area in which the future contributions of the ion trap look very promising is in environmental analysis. This is true not because of its high sensitivity as a GC/MS instrument for routine EPA type analysis, but because of its versatility of operation, providing the mass spectrometrist with a number of tools to help solve demanding problems. Three aspects of operation of the ion trap that are important in the application of it to environmental problems are: resonant excitation/ejection, internal/external ionization, and ion/molecule reactions.

Each mass-to-charge ratio that is stored in the ion trap moves with characteristic frequencies in the axial and radial directions. By applying the appropriate frequency in the axial (or radial) dimension of the ion trap, ions moving with that frequency will absorb power and be accelerated. This resonant excitation of ions can lead to one of two possible results. If the rate of resonant excitation is fairly slow, then the ion will likely undergo enough collisions and remain in the ion trap long enough for collision induced dissociation (CID) to occur. This is the basis for CID MS/MS experiments in the ion trap. If the rate of resonant excitation exceeds the rates of activation and dissociation the ion will be ejected from the ion trap. The resonant ejection can be performed in a controlled, sequential manner, which allows a mass spectrum to be obtained. Conversely, the resonant ejection can be used to remove unwanted background ions from the ion trap to allow more analyte ions to be stored.

One of the most dramatic recent advances involving resonant ejection is the ability of obtain high resolution spectra with this mode of operation. By slowing down the scan speed of the ion trap to allow ions longer time to interact with the resonant excitation voltage, very high resolutions have been obtained. It is important to recognize though, that since resonant excitation can also lead to CID, the resolution may be limited by the rate of ion dissociation i.e. when dissociation becomes competitive with ejection. It is also important to note that the detection is done by measuring current from an electron multiplier. When the scan rate is slowed, the same number of ions will be detected over a longer period of time thus giving less current (coul./sec.) at the detector.

Just as the possibility of CID has to be considered when performing resonant ejection, loss of ions by resonant ejection is a possibility during CID MS/MS experiments. This is usually not a problem as evidenced by the high MS/MS efficiencies observed with the ion trap. While the rate of resonant excitation is typically slow for CID experiments, meaning that the collision energy is typically low, the ion trap has a couple of characteristics that lead to its high MS/MS efficiencies. One of these characteristics is that the ions are reaccelerated between collisions. This characteristic along with the long times available for resonant excitation (tens of milliseconds) allows hundreds of collisions to occur. The long activation time also minimizes kinetic shifts by giving ions several orders of magnitude longer time to dissociate versus beam instruments. A potential drawback to the CID process in the ion trap is that often only one or two dissociation channels are accessed, which gives limited structural information. However, because of the efficiency of the MS/MS experiment multiple stages of MS/MS (MS^n) can be performed. This can provide greater selectivity in an analysis since multiple conditions must be met for the final spectrum to be obtained. The MS^n experiment may not be feasible in many environmental analysis schemes, however, because the individual resonant frequencies of the ion depend not only upon

the operating parameters of the ion trap but also upon the number of ions present in the trap. To overcome this problem a broadband resonant excitation source can be used, such as noise. Use of broadband resonant excitation may well be a powerful future tool since this may make on-line chromatography/MS/MS achievable.

The variance in resonant frequency is a result of ion-ion interactions in the ion trap. These ion-ion interactions limit the absolute number of ions which can be stored at one time, which often limits the dynamic range of the ion trap. Resonant ejection can be used to extend the dynamic range by removing unwanted ions during the formation or injection of ions into the ion trap. Two possible scenarios are likely. The first is that the analyte is known and thus all ions except the analyte are resonantly ejected from the ion trap. The other scenario is that the analyte is unknown but there are known background ions from the matrix which are resonantly ejected to allow more analyte ions to be accumulated in the ion trap.

The number and type of background or matrix ions present in the ion trap will depend upon the ionization technique used. Much work has been done demonstrating different ionization techniques with the ion trap. The traditional techniques of forming the ions within the trapping field will work well for some applications. For others external ionization techniques will be desirable. One of the advantages of using external ionization techniques is that higher ionization efficiencies may be achievable because higher pressures can be used. These higher ionization efficiencies have to be considered in the context of the trade-off of the efficiency of injecting the ions into the ion trap. If ion injection can be done with reasonable efficiency, which appears to be the case, then the external ionization can provide increased sensitivity.

Another advantage of external ionization is that the neutral analyte and matrix is separated from the region in which the analysis takes place. This separation helps to minimize unwanted ion/molecule reactions. One example of an unwanted ion/molecule reaction is self chemical ionization. While it is thought by some that self-CI is an inherent problem for ion traps, the usual reason it occurs is from a lack of appreciation of the capabilities of the ion trap. If sample quantities of the same magnitude as used on beam instruments are introduced into the ion trap, self-CI often will readily occur. However, because of the sensitivity of the ion trap sample quantities at least one or two orders of magnitude smaller can readily (and should) be used with the ion trap to eliminate most occurrences of self-CI. Sometimes it is mistakenly assumed that shortening the ionization time will reduce self-CI. However, the majority of the "reaction time" during which the CI process occurs is not during the ionization time but during the scan, until the reacting ion is ejected to the detector. Thus, reducing the ionization time does not reduce self-CI.

While some ion/molecule reactions are unwanted, others can be very beneficial. One limitation of CID is that in activating an ion, it may have a lower barrier to isomerization than dissociation and thus the structure from which the ion dissociates is not the same as the structure of the ion that is being analyzed. Different isomeric structures, however, often have different chemical reactivities to various neutrals. Probing the reactivity of ions toward neutral reagents, which the ion trap is well suited for, could be a major future tool for environmental analysis.

While the ion trap will certainly play a role in future environmental analysis, the degree of success of the ion trap in this arena will depend upon the ability of the analyst to understand and control the processes which occur in the ion trap. The possibility of resonant ejection during CID MS/MS experiments or conversely, CID during resonant ejection must be considered. The competition between excitation and ejection will depend in part upon the nature of the ion and therefore selection of the appropriate ionization technique will be important. Finally, minimizing unwanted ion/molecule reactions and developing structure sensitive ion/molecule reactions will be important to maximizing the information available from ion trap experiments.

ON-LINE ANALYSIS OF SINGLE MICROPARTICLES BY LASER DESORPTION

M.V. Johnston*, K.R. Neubauer, B.A. Mansoori, P.G. Carson
Department of Chemistry and Biochemistry
A.S. Wexler, Department of Mechanical Engineering
University of Delaware, Newark, DE 19716

Aerosol particles affect local and global climate processes as well as human health. Over the past ten years, various microprobe methods have been employed to analyze individual particle that were collected in the field and transported to the laboratory for analysis. These off-line methods offer many advantages over bulk chemical analysis but still suffer from sample transformation between collection and analysis including loss of volatile components, and the relatively long time needed to analyze a significant number of particles We have developed a method to perform on-line analysis of single microparticles by laser desorption. Ambient particles enter the source region of the mass spectrometer and scatter radiation from a helium-neon laser beam The scattered radiation triggers an excimer laser which ablates and ionizes the particle. Instrumental details are given elsewhere in the proceedings. Either positive or negative ions can be detected, both organic and inorganic constituents can be monitored. Figures 1 and 2 show representative spectra of single particles taken with a single excimer laser pulse.

Our current work uses laboratory-generated aerosols to simulate field measurements for characterizing aerosols (chemical speciation, trace metal determination, source apportionment) and to study microchemical reactions of single particles (fractional crystallization, surface vs. bulk partitioning, gas-particle interactions) Methods have been established to distinguish chromium (III) and (VI) based upon the relative signal intensities of ions of the form $Cr_xO_y^-$. The ability of on-line laser desorption to perform semiquantitative analysis of trace metals has been been investigated. Preliminary results with metal salts dissolved in glycerol microdroplets suggest that the precision of on-line laser desorption is similar to that of off-line laser microprobe mass spectrometry (20-50% RSD for absolute signal intensities). Other experiments planned or in progress include fractional crystallization in droplets containing mixtures of salts and the detection of surface active organics Future work will involve chemical reactions between the gas and particle phases in aerosols.

High-Speed Two-Dimensional GC and GC/MS for Complex Environmental Samples

John B. Phillips, Liling Zhang, C. J. Venkatramani, and Christopher Boone, Southern Illinois University, Carbondale, IL 62901.

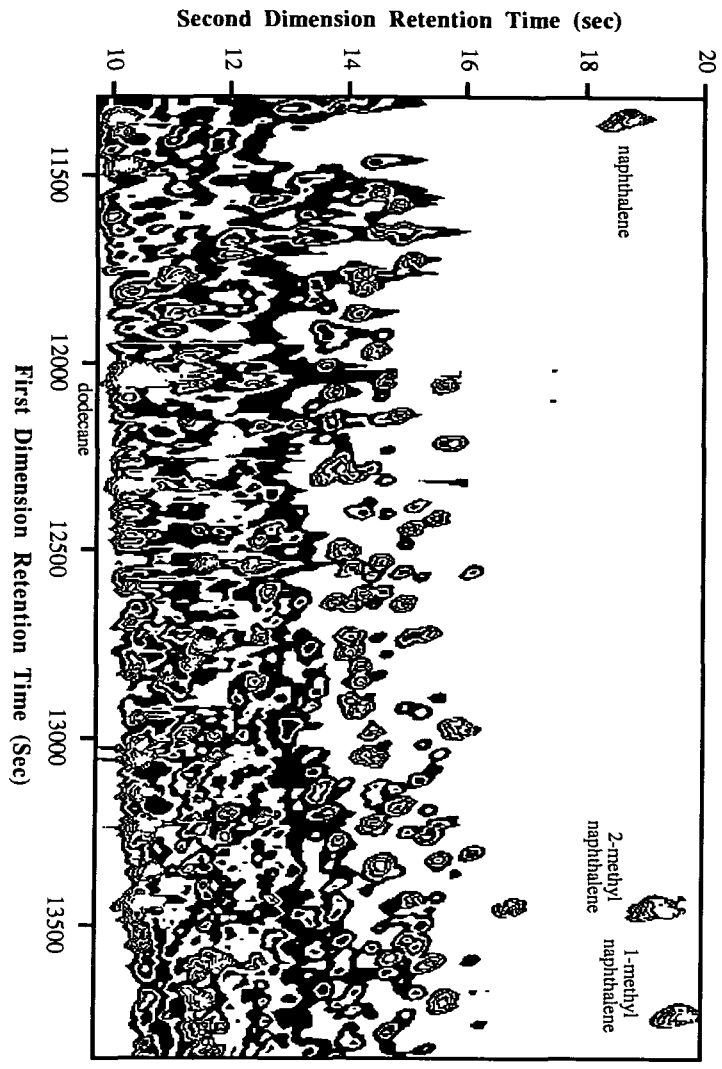
Environmental samples, especially at trace concentrations, are often extremely complex mixtures. The environmental contaminant to be determined may itself be a complex mixture, a crude oil spill, for example. Or, the matrix containing the contaminant may be complex.

These kinds of environmental samples often require high resolution chromatographic separations which are difficult and time consuming. If many substances are present and must be separated during the analysis, then a long chromatographic column and much time will be required. In special cases, using a sample cleanup before the chromatographic separation or a selective detector such as mass spectrometry after the separation can simplify the problem and save time.

Comprehensive two-dimensional gas chromatography can significantly increase analysis speed for a given resolution. In this technique, a first column separation passes through a second column with fidelity. That is, the presence of the second dimension does not significantly degrade the first dimension separation, all sample substances pass through both dimensions, and the resulting chromatogram consists of peaks on a surface. A comprehensive two-dimensional GC separation can be made orthogonal by tuning the temperature of the second column as a function of progress of the first dimension. Retention in the second dimension then does not depend on the first and the entire plane is accessible. The peak capacity of a comprehensive two-dimensional chromatogram equals the product of the two individual peak capacities and neither column need be especially long to obtain high resolution. The short and fast second column now limits the rate at which peaks pass through the detector. Separation speed in terms of peaks per second does not decrease with increasing sample complexity. In practice, the detector rather than the chromatography limits the overall analysis speed.

Combining this variety of GC with MS will require a fast MS detector such as a time-of-flight. Such an instrument will be capable of generating uncontaminated mass spectra of thousands of individual components separated from a complex mixture in a time comparable to that now required for relatively simple separations. More modest separations involving only hundreds of components may be completed much faster than is now required. Also, this method may eliminate the need for MS detection in many environmental analyses because the two-dimensional GC provides more reliable substance identification. The much greater peak capacity of the plane substantially reduces the probability of interfering substances. The two independent retention times may prove to be nearly as powerful an identification as a mass spectrum for many substances, particularly in hydrocarbon mixtures.

The following is a portion of a high resolution two-dimensional gas chromatogram. The first dimension uses a 50-m long, 250-µm i. d. column with a 2-µm methyl silicone stationary phase. The second dimension uses a 4-m long, 100-µm i. d. column with 0.2-µm OV-1701 stationary phase. The sample mixture is kerosene. Both columns were placed in the same oven and programmed together from 50 °C to 200 °C at 0.8 °C per minute. The shown data is approximately 20% of the entire chromatogram.



Membrane Introduction Mass Spectrometry and Biomolecular Self-Assembled Monolayers in Environmental Analysis, R. Graham Cooks, T. Choudhury, L. Dejarme, S. Bauer, J. Patrick, Purdue University, Department of Chemistry, West Lafayette, IN 47907

This paper deals in part with advances made in environmental applications of membrane introduction mass spectrometry (MIMS) since a 1992 review (1). Attention is given to the analysis of trace volatile and semi-volatile compounds in water. The advantages of MIMS, as utilized in this work, include: rapid response; selective permeation of analyte; very low detection limits; compound specificity of mass spectrometry; quantitation with external or internal standards; sample handling by flow injection analysis (FIA); simplicity and ruggedness of the method; linear dynamic range of several orders of magnitude.

Two MIMS experiments are described. In one, a direct insertion membrane probe (DIMP) (2) was adapted to an ion trap mass spectrometer (Fig. 1). In the second, a flow-over (3) capillary membrane interface was combined with a jet separator (CM/JS) and used with an ion trap detector (Fig. 2). The jet separator removes water, which permeates the membrane, as well as the helium which is used to pneumatically assist (4) transport of the permeate to the mass spectrometer.

The performance of the membrane probe system is illustrated in Fig. 3 which shows a full scan spectrum taken on a 1 ppb solution of chlorobenzene. The effects of changing experimental variables (such as membrane type and thickness, sample flow rate and probe temperature) were investigated. The effect of changing flow rate on the signal-to-noise ratio is shown in Fig. 4. Table 1 shows the detection limits for a number of volatile organic compounds of environmental under optimized conditions.

Direct comparisons of the DIMP with the CM/JS were made by connecting both systems simultaneously to the ion trap. The jet separator system gave a factor of 3 lower detection limit for selected compounds. For example benzene, chlorobenzene and trans-1,2-dichloroethene were measured directly at concentrations between 200-300 ppt.

In addition, a novel method for the detection of electrophilic alkylating agents is introduced. In these studies nucleic acid constituents are immobilized as self-assembled monolayers (SAM's) (5) then exposed to a dilute solution of an alkylating agent. The reacted samples are then analyzed directly by static secondary ion mass spectrometry. The general concept of the experiment is diagrammed in Fig. 5. The spectra shown in Fig. 6 are of 2'-deoxyguanosine-5'-monophosphate (dGMP) ionically adsorbed to an aminoethanethiol-silver SAM (A) and a similar SAM after exposure to 1 ppth N-methyl-N-nitrosourea (B). The spectra show ions characteristic of the base (GH_2^+, Ag-GH^+) in the control (A) and show reduced intensity for the base peaks as well as ions characteristic of the methylated base (Me-GH^+) in the reacted sample.

This work was supported by the U.S. EPA, BP America and the National Cancer Institute.

Application of ICP-MS to the Determination of Radioactive and Nonradioactive Trace Constituents in Water from Abandoned Uranium Mines

Vernon Hodge, Megumi Amano and Klaus Stetzenbach
University of Nevada, Las Vegas, Las Vegas NV 89154

Cathleen Webb and Arden Davis
South Dakota School of Mines and Technology, Rapid City, SD 57701

The inductively coupled plasma mass spectrometer (ICP-MS), with ultrasonic sample nebulization, can be used to rapidly determine the concentrations of many metals in environmental waters at part-per-trillion (picogram/milliliter) levels or below, sometimes eclipsing standard radiochemical techniques. As part of an ongoing study of the movement of ground water, samples were collected from standing water in an abandoned uranium mine, an excavation near the mine, a stock dam located down hill about one-half mile from the mine, a drinking water well from a ranch about one and a half-miles from the mine, and the Cottonwood Creek which is about six miles from the mine.

The Diane-A Mine is located on the southern flank of the Black Hills in Fall River County, South Dakota. Uranium was first discovered in the area in 1951 and mined until the late 1960's. Since then, all of the uranium mines have been abandoned, and a uranium mill that operated in nearby Edgemont has been closed and remediated. Annual precipitation is approximately 14 inches and an approximately two-acre pond fills the bottom of the mine. The pond, which holds runoff from the surrounding hills, is perched well above the regional water table and is readily accessible to wildlife. Uranium-bearing ores at the mine include carnotite, tyuyamunite, autunite and uraninite. In an attempt to conduct an initial elemental characterization of the water, samples were collected in the fall of 1992 and the spring of 1993.

The pH values of the samples taken from the mine in the fall of 1992 and spring of 1993 were 4.0 and 3.9, respectively. The low pH of the mine water is indicative of the formation of acid mine water by the interaction of iron bearing minerals with the water. Water from the stock dam also had an acid pH of 4.0, while the ranch well water and water from Cottonwood Creek had pH values of 7.0 and 8.2.

The ICP-MS was used to measure the concentrations of 65 elements and their respective analytical isotopes. In addition, several radiochemical measurements were made to complement the ICP-MS analyses. Preliminary semiquantitative analysis of the mine water indicated that it contained, in addition to uranium, relatively high concentrations of several other trace elements, such as manganese, cobalt, strontium and the rare earth elements. Quantitative measurements demonstrate that the mine water samples that were collected in the fall of 1992 contain 1200 parts-per-billion (ppb) of uranium and those collected in the

spring of 1993, 2600 ppb. As expected, these concentrations are high - about 100 times the maximum concentration proposed for uranium-238 in drinking water in the United States. These values compare to the 2 ppb levels of uranium reported recently for a large number of wells in South Dakota. Concentrations of uranium in waters from the stock dam, ranch well, and Cottonwood Creek are 19 ppb, 34 ppb and 22 ppb, respectively.

The analysis of uranium-238 (the major isotope by mass) and uranium-235 by ICP-MS, along with 32 isotopes of 20 other elements, takes approximately 2 minutes and requires about four milliliters of sample including the wash-in time. All uranium analytical standard deviations are less than five percent. By contrast, if the uranium in four milliliters of mine water is plated onto a stainless steel disk and the uranium determined by a radioactivity technique, alpha spectrometry, overnight counting is needed to get an analytical uncertainty of five percent for uranium-238. Much longer counting times would be required for an accurate analysis of uranium-235. It would be impractical to attempt to measure the uranium concentrations by alpha spectrometry in water from the stock dam, ranch well, and Cottonwood Creek in a four-milliliter sample. Larger volumes, preconcentration, and radiochemistry would be necessary to separate uranium from the bulk salts. Thus, the ICP-MS is the method of choice for quick-accurate determination of uranium-238 and uranium-235 in ground water. However, accurate measurements of the concentration of the shorter-lived uranium-234 would require radiochemical or high resolution mass spectrometry techniques.

The levels of thorium-232 were also measurable by ICP-MS without preconcentration in all samples. The mine water collected in the fall of 1992 contains 2 ppb; that collected in the spring of 1993, 0.7 ppb. Water from the stock dam, ranch well, and Cottonwood Creek contains 0.02 ppb, 0.006 ppb, and 0.09 ppb, respectively. Analysis of the thorium content in these waters by radiochemical techniques would require large volumes of water, tedious separation procedures, and long counting times.

Concentrations of cobalt in the mine water collected in the spring are about 800 ppb, while the concentrations in water from the stock dam, ranch well, and Cottonwood Creek are 25 ppb, 0.03 ppb, and 1.8 ppb, respectively. The concentrations of the rare earth elements (14) in the acid mine water are about 28 times higher than in the stock dam water, 9000 times higher than in the ranch well water, and 1200 times higher than that in the Cottonwood Creek water. The shale normalized pattern for the rare earth elements in water from all of the sample sites is roughly the same - enrichment of the rare earths in the mid atomic mass range relative to the light mass elements and heavy mass elements. A transuranium element, plutonium was found to be present in the mine waters in a concentration of about 10^{-7} relative to uranium-238. The origin of this element may be global fallout.

DETECTION OF TRACE DRUG AND EXPLOSIVE EVIDENCE BY ION MOBILITY SPECTROMETRY

Dean D. Fetterolf, FBI Laboratory, Forensic Science Research Unit, FBI Academy, Quantico, Virginia, 22135 USA

The FBI Laboratory has been involved in the development of new technology and the innovative adaptation of existing technology for use in the war on drugs and terrorism. Due to its small size and versatility, ion mobility spectrometry (IMS) has become the weapon of choice for field support of investigations.

The Barringer IONSCAN Model 250 (Barringer Instruments, South Plainfield, NJ) is capable of detecting as little as 5 ng of particulate cocaine trace evidence. Cocaine, heroin, methamphetamine, THC, LSD, PCP are readily detectable. Samples are collected on a teflon filter using a household vacuum and then thermally desorbed.

The IMS was used to uncover an ingenious new smuggling technique in which cocaine was smuggled in injection molded polystyrene pipe fittings (Figure 1). Three hundred and fifty five pounds of plastic was discovered. A plasmagram for the detection of cocaine in the plastic items is shown in Figure 2. Recently, several fiberglass airline dog kennels were recovered each containing seven pounds of cocaine molded within the fiberglass resin.

Drug detection canines and standard colorimetric tests were unable to detect the cocaine in the plastic and fiberglass matrix. Confirmation of the cocaine and identification of the solvents associated with this investigation was performed in the field using a portable VIKING GC/MS (Viking Instruments, Reston, VA).

The continuing threat of worldwide terrorism as evident by the World Trade Center bombing in New York in February 1993 emphasizes the need for continued efforts at developing improved explosive detectors. Counterterrorism applications of ion mobility spectrometry (IMS) involve detection of pre- and postblast explosive evidence. Laboratory results have determined the limits of detection for most common explosives to be approximately 200 pg. The common commercial and military explosives including NG, TNT, PETN, RDX and ammonium nitrate based explosives are readily detectable.

Detecting residue of explosives on a person or their possessions may be helpful in locating hidden explosives or identifying terrorists. The persistence of explosives on hands and transfer to other surfaces has been examined. An individual handled C-4 (RDX) plastic explosive and then carried out the steps associated with operating a motor vehicle. RDX was detected on all areas that were touched including the keys, car door, steering wheel, gearshift. In addition it required eight hand washings to remove detectable traces of RDX from the hands.

The screening of evidence at a crime scene can greatly reduce the amount of evidence forwarded to the laboratory for confirmation. Post-blast residue of NG was detected on fragments of improvised explosive devices constructed with double-based smokeless powder. Post-blast residue from C-4 (RDX) was detected on clothing from inside a suitcase following detonation. SEMTEX was also identified following the destruction of a portable radio. Figure 3 shows the detection of postblast PETN and RDX residue on the speaker magnet from a portable radio.

Application of Mass Spectrometry in Monitoring and Identification of Degradation Products of p-Phenylenediamine in Aquatic Environments

Yi Lin, Zamas Lam, and Rosanne M. Kannuck, E.I. du Pont de Nemours
Central Research and Development
Haskell Laboratory of Toxicology and Industrial Medicine
P.O. Box 50, Newark De, 19714

INTRODUCTION Phenylenediamines (PDA) are major industrial intermediates used in manufacturing a variety of polymers and consumer products. The environmental fate and toxicity of these materials are greatly influenced by their subsequent oxidative degradation in aqueous solution. This work focuses on the fate of p-PDA which has the shortest photolytic half-life (0.98 h) relative to the other isomers. The analytical methodology developed in this work utilizes information from HPLC retention time data and mass spectrometry (accurate mass, deuterated labeling, and fragmentation patterns) in confirming the structures present in the complicated environmental mixtures resulting from degradation of the parent compound.

The difficulties encountered in the separation of p-PDA water soluble oxidation products stem from the fact that these compounds are polar, with low volatility and have only slight structural differences. Ion-pair reversed phase HPLC has marked advantages over GC or conventional reverse-phase LC in this type of separation. However, the identification using LC-MS demands the use of volatile ion-pair reagents. To accomplish this, we have employed pentadecafluorooctanoic acid (PFOA) as the ion-pair reagent with LC-MS electrospray[1].

EXPERIMENTAL Separation of the components was achieved with a Zorbax RX-C8 (2.1 mm x 15 cm) column using an Acetonitrile/Ammonium acetate buffer (with PFOA) gradient at a flow of 0.2 mL/min. The optimization of LC and LC-MS conditions with respect to the concentration of PFOA and mobile phase pH shows that pH ≥ 5 and 10 mM PFOA provides satisfactory chromatographic separation. These conditions are adequate for LC-MS, although ionization intensity suppression (approximately 1/4) was observed with 10 mM PFOA vs. 3 mM. Experimental conditions for ESI/MS using a VG Quattro triple quadrapole were capillary, counter electrode and simmers voltages of 3.5 kV, 1.0 kV and 40 V, respectively. For LC-MS experiments, a split ratio to the mass spectrometer of 15:1 was employed. MS-MS experiments were also performed using the VG Quattro, with collision enrgy at 140 eV and attenuation at 60% and Argon as the collision gas. Typical conditions for FTMS experiments using an Extrel FTMS 2000, were CO_2 laser at 10.6 μm, calibrated with an internal standard.

RESULTS AND DISCUSSION LC-ESI/MS and ESI/MS/MS experiments were performed to monitor and identify degradation product formation as a function of time in aqueous solution (Figure 1). Using LC-ESI/MS, the retention time comparison for p-PDA in both water and D_2O provided information as to the number of exchangeable hydrogen. LD/FTMS, was used to distinguish p-PDA (MW 108.0682) from a degradant, quinone (MW 108.0206). The molecular profiles obtained from both LD/FTMS and ESI/MS experimental are comparable (Figure 2). Identification of some oxidation products agree with those previously reported in literature; specifically quinone, 4-4'-azodianiline, and nitroaniline. Additionally, the presence of nitrosodiphenylamine and Disperse Orange 3, were identified from the work.

One of the major oxidation products (referred to as **A**) with molecular formula $C_{18}H_{18}N_6$ (MW 318.1594) was derived from accurate mass measurement using direct probe (M^+= 318.1566) and LD/FTMS in negative ion mode (M-1 =317.1580). Comparison of ESI/MS data for both degraded p-PDA in water and D_2O indicates the structure has eight labile hydrogens. Both data from mass assessment and the labile hydrogen determinations suggest that the structure of **A** is that reported as Bandrowski's Base[2], a linear trimer of p-PDA polymerization. However, the fragmentation pattern obtained from both ESI/MS-MS and direct probe HRMS suggests that the product is benzidineazoaniline rather than the accepted structure of Bandrowski's Base. Comparison of the ion intensities of **A**, and a second product **B** (MW 301), indicates that product **A** is a precursor of **B**. This suggests that the structure of **B** is a highly conjugated azoanaline derivative (Figure 3). The proposed structure of **B** was also evidenced by fragmentation patterns of **B** both in water and D_2O. The formation mechanism of **A** and **B** might be explained by a benzidine rearrangement. Further structure confirmation of products **A** and **B** is in progress.

TANDEM MASS SPECTROMETRY STUDY OF CYANO CONTAINING PYRETHROID INSECTICIDES

Ian A. Fleet and *Lee W. Tetler
The Centre for Mass Spectrometry, UMIST, Manchester M60 1QD, UK
and
John J. Monaghan
ICI C&P Ltd, Runcorn Heath, Cheshire, WA7 4QD, UK.

Historically, the synthetic pyrethroids have developed following the discovery of the naturally occurring insecticidally active pyrethrins which are cyclopropane carboxylic acid esters[1]. Work on correlating stereochemical structure and insecticidal activity has led to the discovery of many synthetic pyrethroids having improved photo-stability and potency. Although the low toxicity of these materials to higher mammals makes their use attractive they are extremely harmful to aquatic life[2]. Thus loss of the insecticides and/or their metabolites to the environment requires the unambiguous detection of these materials at sub-microgram levels. To this end we have undertaken a programme of work devoted to the detection of cypermethrin, figure 1, and related materials using tandem mass spectrometry (MS/MS).

A VG Quattro tandem quadrupole mass spectrometer was used for both +EI MS and MS/MS experiments. Ionisation was carried out at 70eV for both sets of experiments with the source set at 180 deg C. All MS/MS experiments were obtained using argon gas in the radio frequency (rf) only hexapole collision cell. The gas pressure within the cell was adjusted so that 50% suppression of the selected ion was obtained. The collision energy was 25eV for each experiment. Ten microgram portions of each pyrethroid (cis/trans mixtures) as dichloromethane solutions were added to a direct insertion probe and the solvent allowed to evaporate prior to analysis.

The fissile nature of the bond between the ester oxygen and alpha carbon of the benzylphenoxy group, results in weak or non-existent molecular ions under EI conditions, (refer to table).

The inherent stability of ions associated with the benzylphenoxy portion of cypermethrin and related insecticides have been investigated by MS/MS using a variety of scan modes. We found that for cypermethrin and cyfluthrin, expulsion of HCN or both HCN and HF (cyfluthrin) occurs. The mechanism by which this neutral loss occurs can be rationalised in terms of proximity effects involving the phenoxy group and either the fluoro or cyano group. Expulsion of the stable species HCN or HF and the formation of a more stable (even electron) tropylium benzofuran type ion occurs by a Wagner-Meerwein type rearrangement involving ring expansion and formation of a more stable carbocation[3].

From MS/MS investigations we have assessed candidate ions for single ion monitoring.

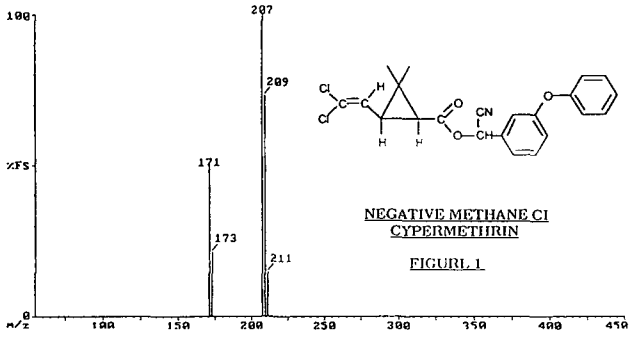
COMMON NAME	MW Da	m/z (% RELATIVE INTENSITY)													
		$M^{+\cdot}$	91	127	129	157	163	165	181	183	199	206	208	209	226
CYPERMETHRIN	415	4.6	80	74	26	--	100	78	87	--	--	--	64	69	--
FLUCYTHRINATE *	451	18	--	--	--	70	--	--	40	--	100	--	--	--	--
CYFLUTHRIN	433	1 4	44	35	12	--	100	76	--	--	53	81	--	--	43

* NON-DIVINYL HALOCYCLOPROPANE TYPE PYRETHROID

For cyfluthrin under +EI conditions using full scan and SIM modes we have found the following limits of detection (spiking experiments using potable water followed by neutral liquid/liquid extraction with dichloromethane):-

FULL SCAN MODE	SIM MODE	(ions m/z)
15ppm	0.05ppm	163; 206; 226

Using ammonia positive CI, cypermethrin shows a quasi-molecular ion $[M+NH_4]^+$.



NEGATIVE METHANE CI
CYPERMETHRIN

FIGURE 1

Under negative CI conditions using CH_4 , the spectrum of cypermethrin is dominated by intense ions at m/z 207(base)/209 corresponding to the carboxylate anion and reflecting the correct isotopic abundance (2 x Cl), while the ions at m/z 171/173 correspond to the expulsion of HCl from this ion. A product ion scan of the ion at m/z 207 shows little fragmentation, reflecting a stable species.

CAPILLARY GAS CHROMATOGRAPHIC INTRODUCTION OF ENVIRONMENTAL COMPOUNDS INTO A TROCHOIDAL ELECTRON MONOCHROMATOR/MASS SPECTROMETER

J.A. Laramée, S. Sonnen, and M.L.Deinzer
Department of Agricultural Chemistry and
Environmental Health Sciences Center
Oregon State University
Corvallis, Oregon 97331

A trochoidal electron monochromator attached to a quadrupole analyzer as described by Illenberger and co-workers (1979) recently was tested for the analysis of various environmental chemicals (Laramée et al., 1992). This system produces negative ions by electron attachment. Potentially the instrument provides advantages over the standard practice of moderating high energy electrons from an emitter with a buffer gas in the ion source. High electron capture cross sections are realized with discrete energy electrons that are produced in the ion source and the electron energy spectra are unique for any ion generated which can be useful for identification. Other advantages are anticipated from this device, but most of them can be realized only with additional modifications in the instrument including the interfacing of a gas chromatographic inlet system.

Hexachlorobenzene served as a standard to test the capillary gas chromatographic inlet to the electron monochromator/quadrupole analyzer. This compound captures electrons of optimal energy of 0.6 eV and produces almost exclusively the molecular radical anion cluster. The minimum amount of sample analyzed was 5pg with excellent signal to noise ratio (Figure 1). Narrow range mass scanning between 275-295 amu at a mass resolution sufficient to separate the chlorine isotopic cluster ions was achieved with a 10.8ng sample (Figure 2).

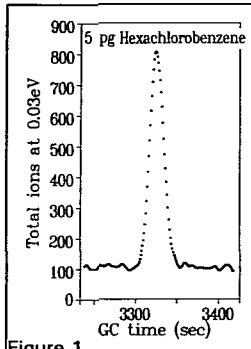

Figure 1

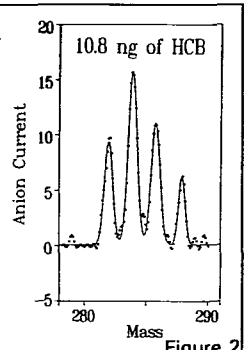

Figure 2

The utility of the system was further demonstrated by injecting Aroclor 1254 into the gas chromatograph and monitoring either the chloride ion or the total ion current. A total ion chromatogram at 0.03 eV electron energy shows a characteristic abundance of peaks due to the PCB isomers and congeners in the mixture. Chloride ion monitoring at 0.03 eV electron energy (Figure 3), shows a similar chromatogram. Excellent signal to noise ratio is observed with 45ng Aroclor sample injected.

The electron energy also was scanned under computer control for compounds introduced through the gas chromatograph. This is demonstrated by the total ion current produced from 2,4,6-trinitrotoluene (TNT) (Figure 4). A 20 eV electron energy range typically was scanned in 0.3 sec. Scanning the intensity of ion peaks at m/z 46 and m/z 47 with respect to electron energy from p-$^{15}NO_2$-labeled TNT showed that the ortho and para nitro groups are ejected at different electron energies (Figure 5). Non-linear deconvolution of the energy spectra revealed a set of negative ion resonances with energy maxima for loss of the para-nitro group at 0.17, 2.77, 4.52 and 7.31 eV, and loss of ortho-nitro groups at 0.13 (minor), 3.31, 4.90, and 7.25 eV.

CONGENER-SPECIFIC QUANTITATION OF POLYCHLORINATED BIPHENYLS BY GC/MS/MS

J. Lee, J. J. Bradford, T. Victorine, R. A. Lopshire ,and C.G. Enke
Department of Chemistry, Michigan State University, East Lansing, MI 48824

The goal of this study was to develop a rapid, reproducible methodology for the quantitation of the twelve most toxic PCB congeners. The toxicity of PCB congeners varies widely, with non-and mono-*ortho* substituted congeners exhibiting dioxin-like toxicity. The twelve non-and mono-*ortho* PCB congeners are able to achieve a coplanar conformation and hence are loosely referred to as the coplanar congeners. Some of the PCB congeners are stereochemically similar to the planar 2,3,7,8-tetrachloro-*p*-dioxin (TCDD) and, because of this similarity, exert biochemical activity and toxicity comparable to that of TCDD.

For risk assessment, congener-specific analysis is highly desireable. However, in a typical GC/ECD analysis time of 40 minutes several of the most toxic coplanar PCBs coelute with non-planar PCBs of higher chlorination level, precluding congener specific quantitation.[1] Also, electron capture detection is subject to interferences from other halogenated compounds. Due to the tendency for PCBs to undergo fragmention via successive loss of chlorines resulting in a similarity in the fragmentation patterns of the various congeners, only the most highly chlorinated coeluting congener can be quantitated by GC/MS.

The electron capture negative chemical ionization (ECNCI) GC/MS/MS methodology developed employs an oxygen-chlorine exchange reaction in the collision cell of a triple stage quadrapole mass spectrometer to yield a $[M\text{-}Cl+O]^-$ product anion 19 mass units lower than the selected molecular ion $[M]^{-\cdot}$. The reaction scheme is presented in Figure 1. The oxygen-chlorine exchange reaction occurs only with the odd electron molecular anion. By rapidly cycling the spectrometer in the multiple reaction monitoring mode between the unique precursor ion to product ion mass combinations specific to each level of chlorination, simultaneous chlorine number specific mass chromatograms are generated. The reconstructed ion chromatogram (RIC) and the selected reaction monitoring chromatograms for the twelve most toxic congeners are shown in Figure 2. The chlorine-number specific detection allows coeluting congeners of different chlorine numbers to be quantitated with minimal interferences. A surface catalyzed reaction specific for the coplanar congeners produces a $[M\text{-}nCl+nH]^{\cdot-}$ radical anion in the ion source. Being an odd electron anion, the $[M\text{-}nCl+nH]^{-\cdot}$ fragment also undergoes the oxygen-chlorine exchange reaction to produce product ions that appear in the selected reaction monitoring chromatograms of the lower-chlorinated congeners. Since the coplanar congeners are more highly retained on the GC column, and hence do not coelute with any of the lower chlorinated congeners, no loss of selectivity results from this reaction.

The method was evaluated in order to determine the linearity, sensitivity, selectivity, and reproducibility of the assay. Due to the variation of the detector response to the different congeners, multiple ^{13}C-labelled internal standards were employed. The relative response factors for the twelve most toxic congeners with respect to the ^{13}C-

labelled internal standards have been determined. The calibration curves for the twelve congeners are linear in the concentration range 5-100 ppb. Detection limits in the low ppb range have been achieved for each of the twelve most toxic congeners. The method was applied to the quantitation of the "toxic twelve" PCBs in a commercial Aroclor sample, and the results were compared with literature values.[2]

RELIABLE COMPOUND IDENTIFICATION AT LOW LEVELS IN COMPLEX ENVIRONMENTAL SAMPLES

*Bruce N. Colby, Pacific Analytical, 6349 Paseo Del Lago
Carlsbad, CA 92009 USA

and

Peter H. D'Arcy, Fisons Instruments/VG Masslab, Crewe Road
Manchester M23 9BE England.

The most significant challenge facing the environmental GC/MS analyst today is making reliable compound identifications at low levels and/or in complex sample runs. This problem is the result of spectral contributions from traditional background sources in the mass spectrometer, column and septum bleed from the GC, plus spectral interferences from closely eluted components. These combine to produce major difficulties at very low concentration levels where the TIC trace is primarily the result of instrument background or where important analytes are eluted very close to more concentrated components. The problem lies not with initial location of potential target analytes but with confirming or denying a target analyte's identification. It is also a problem when attempting to identify non-target analytes in a run.

The fundamental problem is removal of spectral contributions from non-analyte species. The challenge is in performing this spectral cleanup process in a reliable and consistent manner. Clearly an expert analyst with many years experience could do the job manually if cost, time and the limited availability of such experts were not prohibitive. Consequently, automated means are essential.

Several background subtraction algorithms are available in commercial GC/MS data systems. These range considerably in complexity and include:

- Subtraction of a scan adjacent to the peak (C-R)
- Subtraction of scans at both sides of the peak (C-LR)
- Evaluation of mass chromatograms for co-maximization[1] (BB+)
- Evaluation of mass chromatogram retention time centroids[2] (Dcn)

In order to evaluate the various background subtraction algorithms experimentally, a series of water samples containing 0.05, 0.5 and 5 µg/L of 57 volatile organic compounds was prepared. To simulate a complex environmental sample, each of these samples was spiked with 2000 µg/L of gasoline. These samples, plus blanks and neat standards, were analyzed according to EPA Method 524.2 on a Fisons MD800 connected to an OI purge & trap via a 20:1 split at the column head. A 75 m x 0.25 mm DB-625 column was used for the separations. The acquired data were inspected manually to identify the location of 45 non-gasoline target analytes. Adjacent scans were identified based on the start and end points for quantitation mass mass chromatogram peaks.

The acquired data were used to generate spectra using each of the above background subtraction techniques. In addition, non-background subtracted data (C) were investigated as a point of reference. The spectrum for each analyte was then compared with the NIST database spectrum of that analyte in order to generate a measure of how successful the background

subtraction had been. The spectrum was also searched against the NIST database to determine whether or not it was sufficiently pure to produce a correct "hit". For the purpose of this study, a hit was correct if the correct compound or a spectral isomer was in the top four hits.

Spectral comparison was accomplished by calculating a statistic consisting of the cosine of the angle between two hypervectors. One hypervector was the reference spectrum and the other was the background subtracted spectrum. Two variations of the statistic were calculated, one which included all mass peaks in the reference and data spectrum, and the other only for mass peaks in the reference spectrum. As a point of reference, these correspond to FOR (or PUR) values in some data systems and REV (or FIT) values in others, respectively.

The statistics for the 45 target analytes in the spiked samples were then combined for each background subtraction technique, sorted and plotted to generate relative cumulative frequency distributions. The same was done for samples which contained no spiked target analytes. The point at which two related sets of distributions crosses is the point at which the probability of generating a false positive equals the probability of generating a false negative. If the statistic value at this point were used as a threshold to accept or deny an analyte's identity, the error rates shown in Figure 1 would be expected. For all background subtraction techniques the REV (FIT) statistic is less effective than the FOR (PUR) statistic. This is important because some manufacturers provide targeting software with their data systems which relies heavily on this less effective statistic. Also, there is a clear trend in the effectiveness of the background subtraction techniques where the more complex ones provide significantly better results.

The library search results were tabulated according to percent of correct hits (Figure 2). The basic trend in background subtraction technique effectiveness follows closely that identified for target analytes. This trend is very noticeable at lower concentrations.

Monitoring Life Support Environments Via Ion Trap Mass Spectrometry

P.T. Palmer and C.M. Wong, NASA - Ames Research Center
MS 239-20, Moffett Field, CA 94035-1000

NASA research in advanced life support has created a significant demand for more powerful techniques to monitor air quality. MS is the method of choice for monitoring air composition and may be employed to evaluate the efficiency of trace contaminant removal subsystems, validate composition data obtained from alternate sensors, and characterize anthropomorphic, biogenic, and material emissions. These applications require the detection, identification, and quantitation of permanent gases, suspected volatile organic compounds (VOC's), and unknown compounds. Ion traps possess a number of characteristics which make them eminently suitable for meeting the analytical and development criteria for these applications [1]. This research describes the use of Thermal Desorption/Gas Chromatography/Mass Spectrometry (TD/GC/MS), GC/MS, and MS/MS methods on a modified version of a Finnigan model ITS40 ion trap instrument for several life support monitoring applications.

TD/GC/MS was employed to characterize the types and concentrations of VOC's in three plant growth chambers used in bioregenerative life support research. A Tekmar 6000 thermal desorption unit and a modified version of EPA method TO-1 were used in these analyses. Figure 1 shows a portion of a reconstructed ion chromatogram (RIC) from the analysis of a 1 L air sample collected from a plant growth chamber. Hundreds of VOC's were evident from this analysis, rendering interpretation a difficult and time-consuming task. Use of library searching on EI data, molecular weight information from CI data, and retention time confirmation enabled reliable identification of many of the VOC's, most of which are ubiquitous in laboratory environments (i.e.;

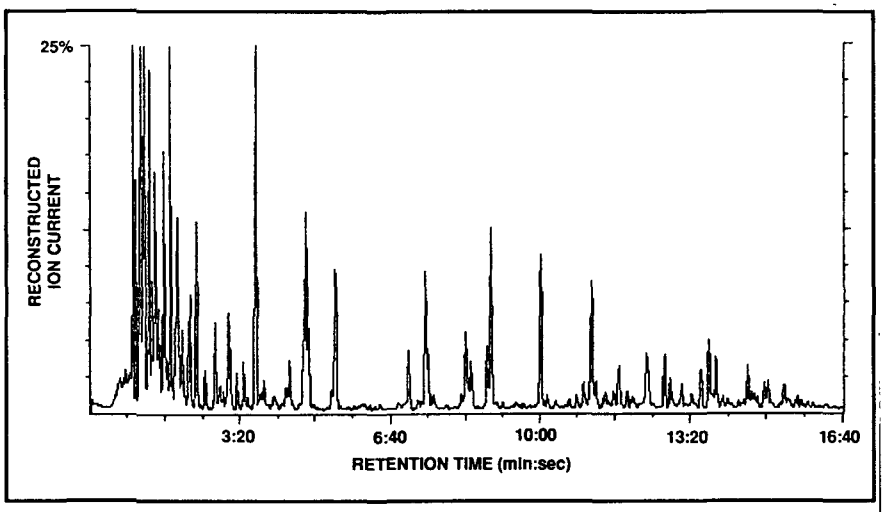

Figure 1. RIC trace from TD/GC/MS analysis of a 1 L air sample from a plant growth chamber.

freons, chlorinated hydrocarbons, aromatic compounds, etc.) and some of which could be attributed to biogenic emission processes (i.e.; terpenes). Nearly all of VOC's were present a concentrations at or below a part-per-billion volume (ppb/v) and individual VOC's could be detected at concentrations as low as a part-per-trillion (ppt/v). Note that these concentrations are well below the Space Maximum Allowable Concentrations (SMAC's) for these species, which are typically on the order of a part-per-million (ppm/v). TD/GC/MS is an excellent method for surveying the types and concentrations of VOC's down to ultratrace levels. However, it is time-intensive, requires stringent quality control procedures, and is unsuitable for in-situ monitoring.

GC/MS analysis of plant growth chamber air samples resulted in the detection of only a few species, as most VOC's in the samples were present at concentrations well below the detection limit of this technique. Note that a GC/MS analysis of a 10 ul injection of a 1 ppm gas standard did provide library matchable spectra for benzene, toluene, and o-xylene. GC/MS was also employed for permanent gas analysis and used to separate and identify oxygen, nitrogen, carbon monoxide, methane, and carbon dioxide. GC/MS will be employed in similar fashion to monitor trace VOC's and permanent gases for Space Station Freedom. Compared to TD/GC/MS, GC/MS is more straightforward in its implementation and its sensitivity is, in most cases, sufficient for monitoring known VOC's to ensure that their ambient concentrations are below their SMAC's.

MS/MS has been heretofore unfeasible for monitoring life support environments, as its size, cost, and complexity have not been competitive with conventional MS for these applications. The ion trap provides a small, relatively inexpensive, and very sensitive means for acquiring MS/MS spectra. Recently, the MS/MS capability was implemented on a Finnigan model ITS40 instrument [2], a benchtop-sized ion trap instrument. This advance is based on the use of a custom MS/MS scan and acquisition editors, the use of a two-step isolation method, and the SWIFT technique for resonant excitation. In recent characterization experiments, this method provided detection limits on the order of 10 pg and a dynamic range of five orders of magnitude. This development has important implications for life support monitoring and is currently being adapted for applications in this area.

The systems used to monitor air quality for manned space missions have, up to this point, been based on MS and GC/MS technology. This research has resulted in the development of the MS/MS capability on a smaller ion trap than is currently available commercially. This development obviates the need for chromatographic separation, provides a means for direct, on-line, real-time monitoring of VOC's, and may revolutionize the manner in which trace contaminant monitoring is performed for life support applications.

Trace Element Determination by GC/MS

David A. Herold, Suresh K. Aggarwal and Robert L. Fitzgerald
Laboratory Service, VA Medical Center, San Diego, CA 92161
and Dept. of Pathology, University of California-San Diego, La Jolla, CA 92134

Introduction

Ideally, elemental analysis should be accomplished with precision, accuracy and sensitivity with speciation of the metal on a readily available, easily used instrument. In the last four years we have advanced the analysis of trace elements using chelation followed by analysis by GCMS to explore these areas. The availability of fused silica capillary columns enhances the sensitivity and separation efficiency of different metal chelates. This obviated the need of chemically separating and purifying trace elements as sometimes required by other mass spectrometry techniques. Other advantages of GCMS methods over other MS techniques are as follows. Intensity ratio measurements are made in a mass range where the contributions from the background are very small and, the isobaric interfering elements are usually eliminated since various metal chelates have different GC retention times. Mass discrimination effects are fewer because the isotopic ions used for MS analysis have smaller relative mass differences. When performing isotope dilution experiments using an internal standard, the concentration of trace element can be calculated by employing both the molecular ion and fragment ion peaks, thus enhancing the confidence in the concentration data. Since the tracer calibration is also performed by reverse isotope dilution mass spectrometry, the experimentally determined ratios can be used directly to calculate the concentrations. MS coupled with isotope dilution is a powerful analytical tool for determining the concentration of trace elements in various matrices at levels ranging from major constituent to sub parts per billion. The determination of trace elements in biological materials such as urine, serum, plasma, whole blood, tissues and bone is gaining importance. The IDMS results are free from matrix effects and from the constraints of quantitative recovery of the analyte from the matrix, an essential requirement in other analytical techniques, which is difficult to achieve. This difficulty is due to the complexity of the biological matrices and the volatile or refractory characteristics of some of the trace elements which can lead to poor recoveries.

Experimental

Standards, sample preparation and instrument conditions are given in references 2-9 for the magnetic sector instrument results. Instrument conditions for the Finnigan 4500 quadrupole are given in the extended abstract by G.S. Baird et al in this volume. The preparation of the 4-fluorophenyl Grignard derivative used for the determination of the Pb is given in reference 11. The Pb samples and expected values were supplied by Patrick J. Parsons, Ph.D., State of New York, Department of Health. The extraction of the CH_3Hg^+ from 250 µL of blood was accomplished by adding 200 µL of 0.6 M HCl followed after 5 min with 1 mL of 0.2 M borate buffer (pH 9), then 500 µL of 20 mM fluorodiethyldithiocarbamatewas added to chelate the CH_3Hg^+ followed by extraction into CH_2Cl_2. The CH_2Cl_2 was reduced in volume and analyzed.

Results

The following results show that accuracy and precision of Pb determinations in whole blood and urine has been enhanced by reacting the chelated Pb with a Grignard reagent to form the stable organic Pb.

		Pb (µg/L) Measured	Pb (µg/L) Expected
Urine	(NIST-SRM-2670)	111 ± 7	109 ± 4
Blood	(N.Y. Dept of Health)	160 ± 5	150 ± 40
		431 ± 9	430 ± 40

When ionization is changed from EI to NCI a factor of 4 increased precision and 75x increased sensitivity results (12). The spectra of CH_3Hg(fluorodiethyldithiocarbamate) demonstrates speciation of Hg.

Discussion

In addition to the previously developed applications of GCMS to trace metal analysis, we have demonstrated that negative chemical ionization increased sensitivity by a factor of 75 as compared to electron impact for Pb and that these measurement can be accomplished on a quadrupole mass spectrometer equipped with an autosampler with increased precision as compared to a magnetic sector instrument. These results demonstrate the easy application of stable isotope dilution GC-MS to the measurement of Pb in blood and urine in the clinical laboratory. Additionally we have successfully extracted and analyzed CH_3Hg^+ from whole blood samples in addition to the total Hg in the specimen demonstrating the ability to speciate Hg.

Conclusion

GC/MS analysis of trace elements is maturing into a multielement (10) analytical method with good precision, accuracy and sensitivity and with speciation.

RADIOFREQUENCY PLASMA IONIZATION TIME-OF-FLIGHT MASS SPECTROMETRY

Mingin Wu, Xiaoli Ren, Milton L. Lee, and Paul B. Farnsworth
Department of Chemistry, Brigham Young University, Provo, UT 84602

Chung Hang Sin and Edgar D. Lee
Sensar Corporation, 479 West Universal Circle, Sandy, UT 84070

An orthogonal time-of-flight mass spectrometer (TOFMS) was developed for sampling ions produced under ambient pressure. Even a mass resolution of only several hundred is sufficient for elemental mass analysis. The simultaneous detection of all ions present also makes the TOFMS more attractive for isotope ratio analysis than other scanning type mass spectrometers. We are currently investigating both inductively coupled plasma and radiofrequency plasma for ionization in this TOFMS. The fast response of the TOFMS also makes it very suitable for detection of transient signals such as those found in chromatographic separation and flow injection analysis.

The radiofrequency plasma possesses several unique characteristics that make it a very promising ionization source. As shown below, the geometry of this plasma discharge cell is very simple. The plasma can be maintained at different power levels (from 1 W to 175 W) in a variety of pure gases or gas mixtures (N_2, He or Ar). By adjusting the power level, both atomic and molecular ions can be produced. Different discharge characteristics, such as direct plasma or afterglow can be obtained by arranging the discharge cell differently. This plasma is therefore flexible enough for different chromatographic systems (gas chromatography, supercritical fluid chromatography, or liquid chromatography).

The following figures show the atomic mass spectrum of chlorine (from methylene chloride), and the molecular mass spectrum of methylene chloride. The molecular and fragment ions were obtained when the sample was introduced from outside the plasma. The radiofrequency plasma can be generated by an inexpensive power supply. Different configurations can be adapted to suit the physical requirements of the mass spectrometer. The same hardware can be used for the determination of molecular species or for elemental analysis.

MULTI-CHANNEL He ICP MASS SPECTROMETER FOR ELEMENTAL ANALYSIS WITH TRANSIENT SIGNALS

Evan F. Cromwell and Peter Arrowsmith

IBM AdStaR, San Jose, CA 95193 and
IBM Canada, Toronto, Ontario, Canada

A challenge often encountered in materials applications is the need for elemental analysis of contaminant particles, small areas of deposited material, or inclusions in various materials. One technique that has sufficient sensitivity and is capable of semi-quantitative analysis is inductively coupled plasma (ICP) mass spectrometry with laser ablation sample introduction.[1] Compositional analysis of a small volume of material by the ablation technique requires a single, or small number of laser pulses to avoid sampling the surrounding material. The resulting signal is in the form of a transient and the currently available sequential plasma-source mass spectrometers are too slow to detect more than a small fraction of the ions in the short time available. Hence, these instruments are limited in the number of elements that can be determined.

We report here on the development of a new plasma-source mass spectrometer designed to overcome such problems. The instrument uses either a He or an Ar ICP as an ion source. The plasma is sampled by a differentially pumped vacuum system which maintains the final chamber at a pressure of $<1\times10^{-8}$ torr. The ions sampled are focused with an Einzel lens and a quadrupole lens pair onto the entrance slit of the mass spectrometer. The spectrometer, a Mattauch-Herzog double-focusing instrument comprised of dual electric and magnetic sectors, images ions from the entrance slit to a plane at the exit of the magnetic sector. Ions of different mass-to-charge (m/z) ratios are focused to different areas on that plane. A micro-channel plate (MCP) ion detector, coupled to a photo-diode array (PDA), is placed at the focal plane of the spectrometer in order to simultaneously detect and record all ions. The m/z range of ions detected is determined by the voltages applied to the mass spectrometer. A schematic of the instrument is shown in Figure 1.

The use of a He ICP with mass spectrometry has been demonstrated previously.[2] There are two important reasons for using a He ICP. Spectral interferences are reduced compared to an Ar plasma and, with the mass spectrometer used, the intense He^+ peak is directed off the low mass end of the MCP. Some of the drawbacks of a He plasma are a lower plasma temperature, which results in less efficient atomization and more oxides, and a secondary (pinch) discharge through the sampling cone. The He plasma has been run at a forward power of up to 2.5kW using an end-tapped load coil and a ceramic torch tube. At higher powers the distance from the load coil to the sampler cone must be increased to prevent arcing. The torch box is setup so that it can easily be switched over to a center-tapped load coil for generation of an Ar plasma.

The design of the Mattauch-Herzog mass spectrometer makes it ideally suited for interfacing with a MCP based detector. This combination has been demonstrated previously by different groups,[3,4] although their use has been with low intensity ion sources. This is the first known use with a continuous plasma ion source. In our design the

spectrometer has a 3" long focal plane and the magnet sector has a field of ≈5000Gauss. A 3" x 0.5" dual MCP, which is shielded from the magnetic field, is placed at the focal plane and is coupled, through a phosphor screen and a reducing fiber optic bundle, to a 2" PDA with 2048 elements. The read out time for the PDA is 8msec.

Interfacing the spectrometer to a plasma ion source has presented unique challenges. Background from scattered plasma light was eliminated by coating the electric sector region with graphite and shadowing the mass spectrometer entrance slit. These measures improved the signal-to-noise by >100. Tuning of the mass spectrometer was difficult because of large spreads in the ion kinetic energies. This is believed due to space charge effects in the sampler and skimmer cones. The ion optics had to be tuned to image a "well behaved" portion of the ion beam onto the mass spectrometer entrance slit in order to obtain the desired mass resolution. At an acceleration energy of 500V the m/z range 10 to 130amu was directed onto the MCP with unit mass resolution (FWHM) at m/z=130 (using a 0.004" slit width). At an acceleration of 300V, the range was 20 to 210amu with resolution becoming less than unity for the higher m/z species. The current sensitivity for the instrument is estimated at 10ppb for solution introduced with an ultrasonic nebulizer. The sensitivity is element dependent due to discrimination in the He ICP. It should be emphasized that the purpose of this instrument is to achieve high temporal resolution for a wide mass range, not extremely high sensitivities.

Isotope Ratio Measurement by Inductively Coupled Plasma-Multiple Collector-Mass Spectrometry Incorporating a High Efficiency Nebulisation System.

Andrew J Walder, Dagmar Koller, Nicola M Reed, Robert C Hutton, Philip A Freedman and John E Cantle.

Fisons Instruments Elemental, Ion Path, Road Three, Winsford, Cheshire, CW7 3BX, UK

Isotope ratio analysis by Inductively Coupled Plasma Multiple Collector Mass Spectrometry has been performed utilising a high efficiency desolvating nebulisation system for sample introduction.

Isotope ratio measurements of uranium, lead and hafnium reference materials corrected for mass bias at a concentration of 50 ng/ml are shown in Tables 1, 2 and 3 respectively. Use of the high efficiency device increased sample transmission and hence increased ion signal level by a factor of 10 compared to conventional nebulisation. The analysis of each uranium and lead solution required 29 ng of sample while the analysis of each hafnium solution required 290 ng of sample. The accuracy and precision of the measurements agree with the established values.

INTRODUCTION

Mercuric iodide crystals are semiconductors sensitive to gamma, x-ray, and photon radiation. Detectors manufactured from HgI_2 require no liquid nitrogen to achieve spectral resolutions of up to 1%. Mercuric iodide is synthesized from an aqueous solution of potassium iodide and mercuric chloride. The raw mercuric iodide goes through a series of purification steps which include vacuum sublimations, melts, resolidification, closed system sublimations and zone refining. The purified mercuric iodide is then grown into a single crystal by physical vapor transport. The crystals are cut and are fabricated into room temperature radiation detectors and photocells. Crystals that produce good resolution gamma detectors do not necessarily make good resolution photocells or x-ray detectors. Many factors including elemental impurities may contribute to these differences in performance. A method has been developed to utilize inductively coupled plasma-mass spectrometry (ICP-MS) to determine elemental impurities. Two methods employed to dissolve mercuric iodide. The first is to dissolve the solid HgI_2 crystal in a aqueous solution of 1% KI. This technique dissolves the HgI_2 matrix but is probably not rigorous enough to dissolve particulate contaminants within the crystal structure. This paper discusses these analytical methods as applied to purification methods for HgI_2 and KI.

Sample Dissolution Method

Dissolution of HgI_2 in high purity (Seastar) nitric acid was not successful even with microwave digestion. Aqua regia (3 parts HCl and 1 part HNO_3) is known to readily dissolve HgI_2 . However, for ICP/MS analysis, it is desirable to avoid high concentrations of chloride because the formation of metal chlorides and oxychlorides interferes with the analysis (e.g. $^{35}Cl^{16}O$ interferes with ^{51}V). Therefore, the minimum amount of HCl required to effect complete dissolution of HgI_2 was studied. Experiments showed that 0.5 g HgI_2 treated with 0.1 ml HCl + 5.0 ml HNO_3 + 30 minutes of microwave treatment at 50% power left a solid, black deposit with a metallic luster, presumably $I_2(s)$, on the walls of the Teflon digestion bomb. Addition of 0.5 ml HCl and further heating causes the solid to disappear and a white crystalline precipitate (thought to be I_2O_5) is observed in the concentrated nitric acid. The reaction is nearly stoichiometric. 0.5 grams of HgI_2 containing 2.2 mmoles of iodine requires 0.5 ml HCl to provide a slight excess of NOCl (the oxidizing species in aqua regia) to take the reaction to completion. Samples prepared in this manner show elevated ^{51}V signals possibly due to the formation of $^{35}Cl^{16}O$. Addition of 1.0 ml HNO_3 to the crystalline $HgNO_3$ product and subsequent re-evaporation steps (2) show a marked reduction in the $^{35}Cl^{16}O$ signal.

ICP-MS Instrumentation and Methods

A Finnigan MAT (San Jose, Ca.) SOLA inductively coupled plasma-mass spectrometer (formerly Turner Scientific) is used for elemental analysis. The standard instrument setup is used. The instrument is set to analyze for only one isotope per element of interest. Particular isotopes are avoided due to well known spectral interferences, as shown in Table I. Spectral studies show no interferences above 10 ppt in the Mo mass region due to Hg^{+2}. Furthermore, studies using synthetic solutions of Na, Co, In, Lu, Pb and U in different concentrations of HgI_2, show no significant ionization effects from salt loadings of up to 1% HgI_2 which are not adequately corrected using In as an internal standard. Solutions of mercuric iodide spiked with known concentrations of selected elements were used to determine the analytical accuracy of the method and blank limitations. For most elements recoveries at the 1 ppb level were possible to within a few percent. Notable exceptions were B, Si, and Ca due to blank limitations.

Table I. Known ICP-MS spectral interferences for HgI_2 analyses

Mass	Isotope	Interference
51	^{51}V	$^{35}Cl^{16}O^+$
63.5	^{63}Cu	$^{129}I^{+2}$
67	^{67}Zn	$^{35}ClO_2^+$
69	^{69}Ga	$^{37}ClO_2^+$
142	^{142}Nd	Tail of $^{127}I^{16}O^+$
143	^{143}Nd	$^{127}I^{16}O^+$
144	^{144}Nd	$^{127}I^{16}OH^+$
165	^{165}Ho	Tail of $^{39}K^{127}I^+$
166	^{166}Er	$^{39}K^{127}I^+$
235-238	$^{235}U,^{238}U$	$HgAr^+$

For regular crystal and salt comparisons a semi-quantitative analytical method is used. In this technique 61 elements are selected for analysis. All of the samples and reagent blanks are spiked with 50 ppb In, which serves as an internal standard. The relative sensitivity factors (used for calculation of concentrations) for all of the elements are set to unity. This allows for intercomparison of the relative concentrations of the elements, from sample to sample, without the need for complete standardization for all of the elements. For more rigorous sample intercomparisons and data base archival 15-20 elements are selected for full quantitative analysis. Quantitation is performed using 12 passes/scan, signal averaged, and 8 scans per analysis.

RESULTS AND DISCUSSION

The analysis of the raw synthesized HgI_2 and the six subsequent purification steps show that for most elements the concentrations change by less than 50% over the entire sequence of steps. A handfull of elements are purified up to a factor of ten. In a few cases some of the purification steps seem to show an increase in contamination for some elements. The levels of elemental contamination for the zone refined HgI_2 were higher in the center section than in either the front or rear sections for most elements. However, the rear section of the tube contains the highest levels of impurity contamination for Mg, Ca, Sc, Ti, Mn, Fe, Cu, Zn, and Sb. The front section of KI zone-refined tube contains the highest concentration of impurity contamination for most elements. The only exceptions are Cr, Mn, Ce, and Pb. The total elemental contamination for the front section is approximately 480 ppm, while the center and rear sections each contains 15 ppm total impurities. Presently we have not been able to establish any correlations between elemental impurities and detector performance. A limitation of the technique is that many of the elements are present in solution at blank levels or lower (ppt), making data interpretation very difficult.

SPUTTERED ATOM IONIZATION IN A PULSED RADIO FREQUENCY POWERED GLOW DISCHARGE

Changkang Pan and F. L. King,
Department of Chemistry, West Virginia University,
Morgantown, West Virginia 26506, U.S.A.

Glow discharge mass spectrometry (GDMS) is regarded as a powerful analytical technique for the direct determination of trace elements in solid materials. Although most GDMS systems operate with continuous power to yield a steady-state glow discharge plasma, pulsed power operation of the glow discharge provides some advantages over the steady-state operation. For example, higher instantaneous powers can be applied to increase sputter yields and absolute ion intensities. Interestingly, the ionization processes in the discharge vary in relative contribution during the on-off cycle of the plasma. Such variation permits the temporal discrimination of analyte signals from background signals as well as discrimination against certain spectral interferences.

The present study focuses on the temporal behavior of ionized sputtered atoms produced by a pulsed radio frequency (rf) powered glow discharge. The rf power is pulsed at a frequency of 50 Hz with a duty cycle of 25 %. The resulting temporal ion signal profiles at selected mass-to-charge ratios are monitored with an oscilloscope with sub-millisecond temporal resolution.

The temporal differences in the significance of mechanisms responsible for the ionization of sputtered atoms in a pulsed rf glow discharge are investigated. It is found that modulation of the discharge power generates time-dependent ion signals. Typical ion signal profiles obtained from the pulsed rf glow discharge ion source are shown in Figure 1. Ion signals from both sputtered atoms and support gas atoms exhibit unique, reproducible temporal profiles that do not match the applied rf power step function. As could be seen in Figure 1A, $^{40}Ar^+$ signal undergoes a surge in intensity upon the application of rf power, similar to the observations reported for pulsed dc glow discharges. This prepeak arises from the electric breakdown of support argon gas at the beginning of applied power initiation. Figure 1B is the first derivative of the temporal profile shown in Figure 1A. The negative peak indicates the temporal position of the maximum decay rate for argon ions. In contrast to the behavior of the argon ion signal, the $^{63}Cu^+$ signal shown in Figure 1C does not respond immediately to the initiation of rf power. There is a delay time of about 1 millisecond before the signal gradually begins to increase. This delay time arises because Cu atoms must first be sputtered off the sample surface by argon ion bombardment, and then diffuse to the negative glow region where they are subject to collisional ionization. Comparison of Figures 1A and 1C indicates the temporal correlation between the appearance of argon ion signal and the appearance of copper ion signal. The Cu ion signal only appears after argon ions have been formed by the electrical breakdown of the argon gas. After their initial appearance, it

takes about 2 milliseconds for Cu ion signal to reach a steady-state level. During the steady-state plateau time regime, the plasma is in a quasi-equilibrium condition characterized by constant atomization and ionization. After the termination of applied power, the sputtered ion signal displays a marked increase in intensity, followed by a gradual decay to the baseline value.

It is of particular interest to note that the position of the afterpeak for ionized sputtered atoms, Figure 1C, is temporally coincident with the maximum decay of argon ion, Figure 1B. This indicates that the formation of afterpeak correlates closely with the extinction of argon ions. This extinction arises from the recombination of argon ions with thermalized electrons, a process that generates metastable argon atoms. Upon termination of the applied power, the electric field collapses and the energetic electrons in the glow discharge quickly lose kinetic energy through collisions with other plasma species. The rapid collisional cooling of the electrons and the consequent increase in thermalized electron density favor the ion-electron recombination. As a result, recombination becomes the dominant electron removal process in the afterglow. Metastable argon atom formation is the result of a radiative recombination process. Recombination yields excited argon atoms in the *5p*-level excited state. These excited atoms rapidly decay to the *4s* level through radiative relaxation yielding argon atoms trapped in the metastable $^3P_0$ and $^3P_2$ states, $Ar_{(m)}^*$.

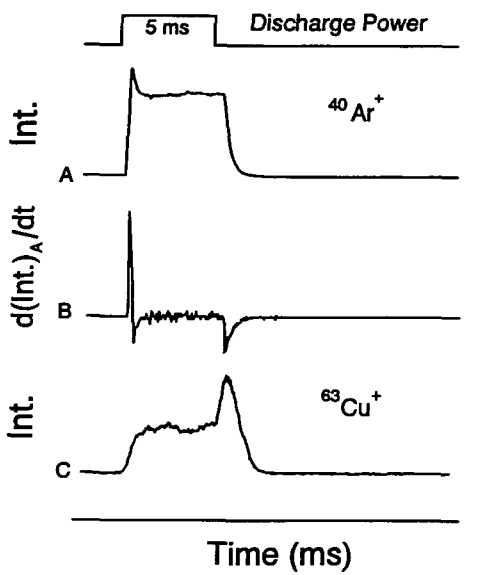

Figure 1. Temporal ion profiles in a pulsed rf glow discharge

The time-dependent production of sputtered ions varies with changes in plasma working parameters, such as rf peak power, sampling distance, duty cycle, and gas composition. The ions produced during the afterpeak appear to have greater average kinetic energies and narrower kinetic energy distributions than those produced during the plateau time regime. The use of time-gated detection with the pulsed rf glow discharge improves the analytical sensitivity and selectivity.

OPTIMIZATION OF A RADIO FREQUENCY POWERED GLOW DISCHARGE MASS SPECTROEMTRY (RF-GDMS) SYSTEM

Charles R. Shick, Jr. and R. Kenneth Marcus

Introduction:

Glow discharge mass spectrometry (GDMS) is a technique that has had a long history of application in the area of trace element analysis of metals and semiconductor materials. In recent years, a number of modifications and advances in GD ion source technology have lead to their much wider application; into areas such as atmospheric sampling, GC/MS, and LC/MS.[1] In the area of bulk solids and thin films analysis, the development of radio frequency (rf) powered devices has opened up the realm of materials to glasses, ceramics, and polymeric materials.[2] In this laboratory, we have focussed our recent efforts towards a better characterization of the ion source design and ultimately the analytical figures of merit of different sampling orientations. In this presentation, the operation and analytical characteristics of a pin-type source geometry coupled to a commercial quadruple GDMS system, the VG GloQuad, are detailed.

Experimental:

Figure 1 is a diagrammatic representation of the VG GloQuad system and the developed rf-GD ion source. The GloQuad is a differentially pumped, quadrupole mass spectrometer system which employs a cryo-cooled ion volume as a means of removing residual gases which have deleterious effects in reducing sputtering rates and causing the introduction of molecular species such as N_2^+ and metal oxides into the mass spectrum. No modifications are required to the mass spectrometer or data acquisition electronics. The sample is introduced to the ion volume attached to the end of a 0.5" diameter direct insertion probe (DIP) constructed in this laboratory. In the pin cell geometry, samples of up to 0.25" diameter may be analyzed directly. (The design of a "flat cell" geometry for larger diameter samples is described in a separate presentation.) The plasma is powered by a 13.56 MHz generator (RF 5S, RF Plasma Products, Marlton, NJ) at powers of up to 60 W. A parametric evaluation of the effects of discharge power, argon pressure, ion sampling distance, and cathode size was undertaken as a means of ascertaining the optimum operation conditions.

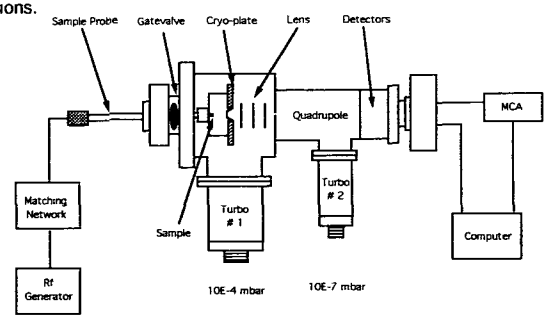

Figure 1. Diagrammatic representation of the rf-GD source coupled to a VG GloQuad.

Results and Discussion:

The results of the detailed parametric evaluation of the rf-GD coupling to the GloQuad are summarized in Figure 2. The pooled data indicate that there is a combination of discharge power density and ion sampling distance (from the tip of the cathode) at which maximum analyte beam intensity is obtained. Additionally, there is a finite range of discharge gas flows (pressures) within which the device operates effectively. The identification of such a set of dependences is useful because not all pin samples will be of the same length or diameter, but either the power density or sampling distance can be predictably set to achieve high (ca. 10^{-9} A) ion beam intensities.

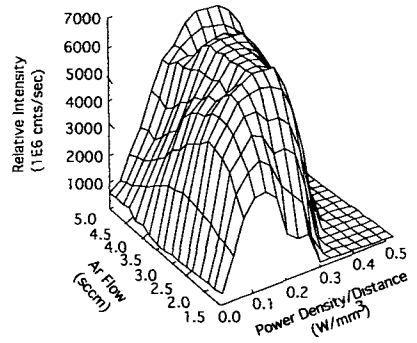

Figure 2. Effect of the discharge power density (per unit electrode separation) on ion beam intensities.

Other characteristics of importance in the implementation of the rf-GD technology include the time required to achieve stable ion beam currents, the relative stability of the beam over the analysis time frame, and the sample-to-sample precision for replicate measurements. Typical values of these characteristics are tabulated below for both conductive and glass samples. As can be seen, the rf glow discharge ion source coupled to a commercial quadruple GDMS system appears to have much promise Future studies will involve extensive methods development and characterization for analysis of wide ranging solid samples.

	stabilization time	beam current	int. precision
NIST 1259 / Al alloy	< 3 mins.	~2 X 10^{-9} A	0.7 % RSD
NIST 1412 / glass	< 2 mins.	~3 X 10^{-10} A	2.2 % RSD

RF Glow Discharge Ionization with FT/ICR/MS Detection

Patrick A. Limbach†, Alan G. Marshall†,§, Douglas C. Duckworth‡, and Michelle V. Buchanan‡

† Departments of Chemistry (and Biochemistry[2]), § The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210. ‡Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831

Marcus, Weller, and coworkers recently interfaced an rf glow discharge ionization source with a Fourier transform ion cyclotron resonance (FT/ICR) mass spectrometer for the analysis of conductive and insulating materials [1]. For their experiments, the glow discharge source was attached to the end flange of an FT/ICR mass spectrometer and ions were detected in the ion trap without the use of any external ion injection methods (e.g., quadrupole guide rods or electrostatic lenses).

In order to improve the sensitivity and detection limits for this method, we have added an easy-to-construct and use electrostatic ion guide [2] to focus the ion beam and inject it into the ion trap. The electrostatic ion guide controls the ion trajectories by the use of two low voltage (< 100 V) power supplies. The electrostatic ion guide allows for near-100% injection efficiency and allows for a seven order of magnitude decrease in operating pressure between the source and the detector. The use of this injection device reduces the analysis period relative to that in ref. 1, and improves the sensitivity of the measurement as well.

Figure 1 is a broadband (low-resolution) mass spectrum of a stock brass target. In this low resolution mode, the isotopic distributions of the copper, zinc, and lead present in the sample are easily resolved at a high signal-to-noise ratio. Figure 2 is a broadband (low resolution) mass spectrum of an NIST C1111 Red Brass C sample. Quantitative measurements from this sample are shown in Table 1. These values, calculated without the use of Relative Sensitivity Factors (RSF) normally employed in glow discharge experiments, demonstrate the potential analytical use of this instrument for glow discharge analysis. These results required a beam time half the amount reported in the previous results with a significantly smaller number of transients.

Improvements are underway to improve the sensitivity and resolution which include: replacing the diffusion pumps with cryopumps which should reduce the chemical background noise and reduce the operating pressure in the ion trap, and insulating the conductance orifice to allow for better control of the ion beam energies as they enter the electrostatic ion guide. With a dual cell instrument, we shall perform cooling experiments [3] and we shall also use an open-ended ion trap [4] to improve the ion transmission.

Using Ion-Molecule Reactions to Enhance High Resolution GD/ FTICR Mass Spectrometry

C.H. Watson, Bruker Instruments, Inc., Manning Park, Billerica, MA 01821
C.M. Barshick, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6375,
and J.R. Eyler*, Dept. Chem., Univ. of Florida, Gainesville, FL 32611-2046.

We have been involved in the past two years in a three-way collaboration aimed at exploring many aspects of Glow Discharge (GD) / Fourier Transform Ion Cyclotron Resonance (FTICR) mass spectrometry. In this presentation we describe some experiments carried out at Bruker Instruments, Inc., which demonstrate the utility of coupling high resolution GD/FTICR with the ability of FTICR mass spectrometers to trap ions and allow chemical reactions to take place prior to detection.

Our recent experiments have involved demonstration that GD/FTICR could be used to determine directly (without preseparation) the abundance of ^{238}Pu in the presence of ^{238}U. These two isotopes differ in mass by 1 part in 193,500. We have carried out feasibility experiments on the (non-radioactive) ^{204}Hg / ^{204}Pb isotopic pair, which differ in mass by 1 part in 456,300.

We show in Fig. 1 the separation of the ^{204}Hg / ^{204}Pb isotopic pair which we have achieved. It would be highly desirable in the Pu / U experiments to remove the (expected) excess of U^+ ions from the cell, leaving primarily Pu^+ behind. Direct elimination of ions from one species with retention of those from the other in the FTICR cell will be difficult because the masses (and thus cyclotron frequencies) of the two species are almost identical. It is difficult to eject one ion from the icr cell without also imparting excess energy to another of almost the same frequency. Thus we have explored other means, such as differential chemical reactivity, to help with this problem. An example of this approach is shown in Figs. 2 and 3. By reacting the ions of ^{204}Hg and ^{204}Pb, trapped in the FTICR analyzer cell after glow discharge formation, with benzene for progressively longer periods of time, the ratio of the two peaks is seen to change by almost a factor of 10. This is because the Hg^+ ion underwent charge transfer with benzene, while the Pb^+ ion did not. The Hg^+ ions were thus removed (converted to $C_6H_6^+$ ions), and the latter could be ejected from the cell since they are far removed in mass from the ions (Pb^+ in this case) of interest. Such ejection was not done in the experiments shown in Figs. 2 and 3, but could be implemented with relative ease. Note that the signal-to-noise ratio of the Pb^+ peak remains the same (ca. 3:1) in Figs. 2 and 3, since for these experiments no additional ions were being stored and detected in the FTICR analyzer cell, only the Hg^+were being removed.

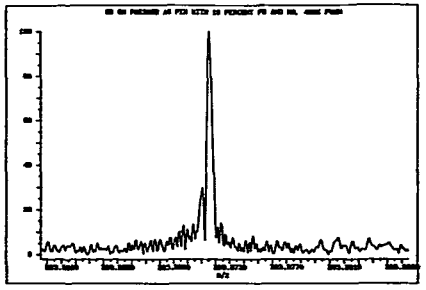

Fig. 1. High Resolution GD / FTICR Mass Spectrum of $^{204}Pb^+$(left) and $^{204}Hg^+$ (right) Ions.

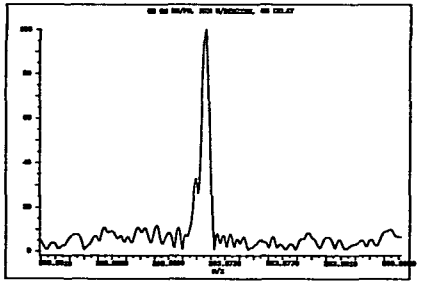

Fig. 2. Pb^+(left) and Hg^+(right) Peaks at m/z 204 before Reaction with Benzene.

DIRECT ANALYSIS OF SOILS BY RADIO-FREQUENCY POWERED GLOW DISCHARGE MASS SPECTROMETRY

Douglas C. Duckworth, Lee R. Riciputi, and David H. Smith
Oak Ridge National Laboratory,
Oak Ridge, TN 37831-6375

Introduction

Glow discharge mass spectrometry (GDMS) is a multi-element analysis technique which holds promise for the elemental analysis of soil. Because GDMS is a direct solids technique, arduous dissolution procedures, often required for soils, can be avoided. Such analyses can be performed utilizing direct current (dc) discharges, after mixing the soil with a conducting host matrix, or directly with radio-frequency (rf) powered glow discharges (i.e., no mixing with a conducting host). While the host element serves as an internal reference in dc-GDMS, its addition is undesirable due to dilution of the sample and the additional polyatomic interferences formed. These interferences can be significant due to combinations with the discharge gas and several low mass elements, often present at ≥ 1%. However, the elimination of the host matrix, which serves as an internal reference, requires that an alternative method of quantification be employed. In this study, the feasibility of elemental analysis of soils by rf-GDMS was investigated in terms of spectral characteristics and means of quantification. The use of mass balance quantification, where all minor elements are referenced to the sum of the majors (~100%), was investigated.

Experimental

The rf source was interfaced to a VG9000 double-sector mass spectrometer, which affords a high mass resolving power, beneficial for the analyses of such difficult matrices. Sample preparation for rf-glow discharge analyses consisted of heating the sample at 120 °C for 2 hrs and pelletizing (5mm diam. x 2mm) the soil, without binder. Samples prepared in this manner were nevertheless very rugged.

Results

The number and extent of isobaric, matrix-related polyatomic interferences in the rf glow discharge were determined from the analysis of various oxides, including Al_2O_3, Fe_2O_3, and SiO_2. As expected, a number of polyatomic interferences were observed. Analysis of aluminum oxide (~100%), for example, contributed the following interferences: AlO^+, 1%; Al_2^+, 4%; AlO_2^+, 70 ppm; $AlAr^+$, 0.1%; Al_2O^+, 0.3 ppm; AlO_3^+, 160 ppm; and $Al_2O_2^+$, 30 ppm. For minor and trace oxides present in soils, many such interferences are negligible; however, for the major constituents (SiO_2, Al_2O_3, Fe_2O_3) such interferences are detrimental. With a resolving power of 3 - 4 thousand, many such interferences can be circumvented.

Research sponsored by the U.S. Department of Energy, Office of Basic Energy Sciences, under Contract DE-AC05-84OR21400 with Martin Marietta Energy Systems, Inc.

"The submitted manuscript has been authored by a contractor of the U.S. Government under contract No. DE-AC05-84OR21400. The results of the mass balance quantification of NIST SRM 2711 Montana Soil are presented in Table 1. Elemental concentrations, based solely on ion beam ratios, are given in column three. Results, including a large error for carbon, differ from the certified values by an average 141%. Given the low relative sensitivity factor (i.e., high relative ion yield), it is likely that the additional carbon arises from residual gases entrained when pressing the pellet. Average error, excluding carbon (52%) is also shown.

Table 1. RF-Glow Discharge Mass Spectrometric Analysis of NIST SRM 2711 Montana Soil

Element	Certified Concen - trations	Elemental Concen - tration	% Error	Measured RSF Value	RSF Adjusted Concen - trations	%Error
C	(2) %	28.0 %	1300	0.067	1.30 %	35
O	-	9.40	-	9.00	57.0	-
Na	1.14	1.70	49	0.792	0.910	20
Mg	1.05	1.90	81	0.695	0.920	12
Al	6.53	7.60	16	0.827	4.20	36
Si	30.44	39.0	28	1.00	26.0	15
K	2.45	4.00	63	0.855	2.30	6
Ca	2.88	4.00	39	1.11	3.00	4
Ti	0.306	0.350	14	2.49	0.59	93
Fe	2.89	3.90	35	1.12	2.90	0.3
P	860 ppm	400 ppm	54	1.85	510 ppm	41
Mn	638	1200	88	0.808	670	5
Cd	41.70	86.0	106	0.563	33.0	21
Ba	726	140	81	3.42	490	33
Pb	1162	1400	21	0.395	370	68
			$\bar{x}$ = 141 (52)			$\bar{x}$ = 28 (27)

Relative sensitivity factors obtained through the analysis of NIST SRM's 2704, 2709, 2710, and 2711 Soils are shown in column five. The RSF adjusted concentrations (column 6) have significantly improved the average error, though some elements fared worse after RSF adjustment, illustrating the need for better characterized RSF values.

Conclusions

Glow discharge mass spectral characteristics arising from the analysis of soils indicate that some means of dealing with isobaric interferences (e.g., high mass resolving power, collision-induced dissociation) is necessary. This is particularly true for rf-GDMS, where most of the low-mass matrix elements have residual gas interferences, and no internal reference is available. (Silicon, the most abundant element, has residual gas interferences at each isotope.) In the absence of an internal reference element, the use of mass balance quantification is promising for semi-quantitative analysis. Carbon and oxygen determinations hinder the technique as errors arising from residual gas species are propagated through the analysis. For solid matrices of less complex composition, this method is even more promising.

THE APPLICATION OF GLOW DISCHARGE-FOURIER TRANSFORM ION CYCLOTRON RESONANCE (GD-FTICR) MASS SPECTROMETRY TO ISOTOPE RATIO MEASUREMENTS

Since its introduction at the 1991 ASMS meeting in Nashville, GD-FTICR mass spectrometry has met with a great deal of success. Quantitative capabilities have been shown to be as good as quadrupole and magnetic sector instruments. Detection limits have continually improved to a current level of < 100 parts-per-billion, and resolution, which was always a major advantage of the technique, has recently been shown to exceed 650,000 at m/z = 197.

One area that is absent from this list of accomplishments, however, is reliable isotope ratio measurements. Always suspect in FTMS, isotope ratio measurements are important because they impact a number of areas, including stable isotope enrichment for medical and military applications. Recently, we have begun evaluating how well GD-FTICR mass spectrometry can measure the abundances of several pairs of isotopes. Table 1 compares the results obtained using the VG9000 magnetic sector glow discharge mass spectrometer and the Bruker Apex 47e glow discharge mass spectrometer to measure the lead isotope ratios in a 10% PbO / 10% HgO / 80% silver powder sample. The absolute abundance ratios were not known but were assumed to be natural. Uncertainties given in Table 1 are one standard deviation (1σ). The Infinity Cell® designation in column 5 and column 8 refers to a cell design whose excitation voltages approximate the ideal (i.e., a cell that is infinitely long). In comparing column 7 and column 8, it is clear that the increased control of the ion excitation process afforded by the Infinity Cell® improves the precision of the isotope ratio measurement.

In addition to good precision for any one isotope ratio measurement, it is equally important to demonstrate a small bias between the measured values and the known values. Table 2 illustrates how the VG9000 and the Bruker Apex 47e compare in this regard. Run-to-run precision on the GD-FTICR instrument is poorer than in Table 1, due in part to the lower concentration of the analyte (5% NIST 987 $SrCO_3$ in silver powder). The biases are quite acceptable, although it is still unclear how GDMS biases vary in general.

One question that still remains after this investigation is: "How much precision is lost when measuring isotope ratios at resolution m / Δm > 200,000?" Research is continuing.

Table 1. Isotope Ratio Precision Measurements on VG9000 Magnetic Sector and the Bruker GD-FTICR (10% PbO / 10% HgO / 80% silver powder)

IMAGING ISOTOPE RATIO AND TRACE ELEMENTAL ANALYSIS OF GOLD ORE

*Ronald H. Fleming[1] and Barbara M. Bekken[2]

[1]Charles Evans & Associates, 301 Chesapeake Drive, Redwood City, CA 94063.
[2]Barbara M. Bekken, Department of Geological Sciences, Virginia Polytechnic Institute, Blacksburg, VA 24061-0420.

Isotope ratio measurements play a central role in deducing mineral ages and petrogenesis conditions. Different mineral genesis conditions often lead to isotope fractionation in light elements. Multiple petrogenesis episodes can then leave minerals with different isotope ratios in close proximity to each other. Imaging is an ideal way to study the resulting sample heterogeneity. Human observers instinctively comprehend the variability shown in an image.

We have developed secondary ion mass spectrometry techniques for measurement of $^{34}S/^{32}S$ isotope ratio images[1] in pyrite mineral grains. We have also extended relative sensitivity factors to images in order to quantitate gold in the pyrite rims. These measurements employ a CAMECA IMS-4f mass spectrometer operating with Cs^+ sputtering, negative secondary ions, and the ion microprobe (raster) mode of imaging. The imaging has the inherent problem of spreading already limited minor isotope ion signals among many pixels. Image processing methods diminish this problem by treating each image position as the sum of intensities from nearby pixels. In addition, new electron multiplier circuitry[2] accommodates more intense ^{32}S secondary ion signals which allows ^{34}S ion signals to accumulate faster. Dynamic emittance matching provides the high mass resolution imaging required to separate the ^{32}S signal from $^{16}O_2$ interference and the ^{197}Au from $^{133}Cs^{32}S_2$ interference. Although pyrite is a semiconductor, the grains are embedded in insulating minerals. The samples require careful neutralization of ion beam induced charging. For this, we use a combination of a conductive carbon coating on the sample, a normal incidence electron flood gun during sputtering, and low primary ion currents. We also invoke periodic mass recalibration for long data collection periods. Finally, improved software calculates isotope ratio images from multiple images of individual isotopes and element concentration images from trace element and matrix element images. Isotope ratio images of Canyon Diablo Troilite demonstrate that the isotope ratio measurements are invariant as a function of image position. Figure 1 shows the $^{34}S/^{32}S$ isotope ratio image of a pyrite grain from a sample of Carlin gold ore and Figure 2 shows gold concentrations of the same mineral grain.

High Spatial Resolution Isotope Ratio Imaging Using Secondary Ion Mass Spectrometry

Greg Gillen and David S. Bright, Surface and Microanalysis Science Division, National Institute of Standards and Technology, Gaithersburg, MD 20899

Isotope ratio imaging is a very powerful but as yet underutilized analytical capability of Secondary Ion Mass Spectrometry (SIMS). With recent advances in SIMS imaging systems it is possible to generate isotopic images with high mass resolution and high spatial resolution. The ability to characterize precisely the composition of isotopically heterogeneous materials on a micrometer spatial scale has many potential applications including biological tracer studies, studies of atmospheric particles and identification of isotopic anomalies in geological and cosmological materials.

We are studying the feasibility of high spatial resolution isotope ratio imaging using an ion microscope SIMS instrument (Cameca IMS 4F). In this instrument, the mass-resolved secondary ion image is projected (via ion-electron conversion at a micro channel plate) onto an imaging detector by the secondary ion optics. Precision isotopic ratio imaging has been hampered in the ion microscope by the non-linear behavior of the video cameras used to record the secondary ion images or by the low maximum input count rates that could be processed by the pulse-counting resistive anode encoder detector (RAE). Fortunately, two new imaging detectors that should minimize these problems are now available. The first is a newly designed "fast" Resistive Anode Encoder (RAE) detector (Charles Evans and Associates, Redwood City, CA) that uses a lower resistance anode, "hot" high strip current channel plates and new analog-digital converters to allow input count rates of > 1×10^5 counts/s before pulse pileup effects become significant. The second detector is a scientific-grade slow-scan CCD camera (Photometrics, Tucson, AZ). We have found that this camera is to be highly linear over more than 6 orders of magnitude of input count rate and is sensitive enough to detect single ion events. A significant advantage of this detector is that it can process over 3 orders of magnitude higher input count rates than the fast RAE detectors. This makes it appropriate for imaging of isotope ratios for species in which the low abundance of a minor isotope and the intense secondary ion signal of the major isotope make the use of an RAE detector problematic.

Newer ion microscope instruments can also be used in a microprobe mode of operation. In this mode, the spatial resolution of the image depends on the spot size of the primary beam which, for the 15.0 keV O_2^+ bombardment used in this study, was 0.25 micrometer (with Cs primary bombardment probe sizes of ~0.1 micrometer are possible). Our initial experiments with microprobe imaging have focused on isotope ratio imaging of 5 NIST-prepared research glass standards doped with lithium. Each of these glasses has a different $^6Li/^7Li$ ratio (6/7 ratios 21.6, 1.132, 0.477, 0.193, 0.084). The glasses were ground into fine particles and dispersed onto a carbon planchet with cyclohexane. ^6Li and ^7Li images were obtained from a variety of areas on the sample at various magnifications (180 s image acquisition times for each isotope). Figure 1B shows microbeam images of ^6Li and ^7Li from one of these glass particles. The field of view for this image is 16 micrometers, with the small inclusions being about 2 micrometers in diameter. To display isotope images in a meaningful way, we need to simultaneously present both spatially resolved information and quantitative intensity data to the observer. One way to do this is by using a transformation called Concentration Histogram Imaging (CHI) (1). To generate a CHI, we start with two registered Li isotopic images each represented by an array of pixels(x,y) which contain the intensity information for the given isotope. The CHI is constructed by incrementing an element of the

histogram image array h(i,j) where i and j correspond to the values of intensity for every location (x,y) in the two isotopic images. After the CHI array is calculated, we can display it as an image using a thermal scale constructed so that zero count is black, one count is red, and higher counts range from orange to yellow to white. As an example of the use of CHI for isotopic characterization, Figure 1A shows the CHI for the microbeam image of lithium glass particles. The CHI, which gives the intensity relationship between the ^7Li and ^6Li clearly indicates that the image contains regions with two distinct isotopic compositions. The ratios can be determined from least-squares fits along the displayed line. Having generated the CHI, the observer is likely to be interested in the relationship of features recognized in the CHI to features in the original maps. This relationship can be discovered with a modification of the CHI algorithm called the "traceback" function. The traceback function selects pixels in the CHI images on the basis of intensity correlations; a mask is created which then can be used to mark the original images. We have also found the CHI to be very useful for observing dead-time effects that may affect isotope ratio measurements. In this situation attenuation of the more intense isotopic signal gives a CHI with a curved line that is readily apparent.

In addition to the lithium glasses, we have also been studying the imaging of magnesium isotope ratios from B1 Ca-Al-rich inclusions in the Allende meteorite. These inclusions have been found to have ^{26}Mg excesses of 5-15%. Typically we acquire alternate images of ^{26}Mg and ^{24}Mg (to minimize variations in signal drift) which are summed after the analysis. Total counting times are typically 30 min. for ^{26}Mg and 10 min. for ^{24}Mg. If desired, we can correct for dead-time effects, mass bias and hydride interferences on a pixel-by-pixel basis. For these samples, because of the high secondary ion signal of Mg, it is possible to collect signals for the minor isotope exceeding 20,000 counts/pixel. This allows us to achieve a ratio precision of better than .7% on an individual pixel. Figure 2 shows an isotope ratio image $^{26}Mg/^{24}Mg$ in which a small grain demonstrates on enrichment in the ^{26}Mg of 6%.

HIGH PRECISION LIQUID CHROMATOGRAPHY-COMBUSTION ISOTOPE RATIO MASS SPECTROMETRY (LCC-IRMS)

Richard J. Caimi and J. Thomas Brenna
Division of Nutritional Sciences
Cornell University
Ithaca, New York

High precision determinations of carbon isotope ratios in bulk samples (eg–plant parts, petroleum) have been employed for a wide variety of studies of the natural world, and continue to have an important impact on geochemistry, ecology, oceanography and related topics. These measurements are widely employed for tracer experiments in the biomedical sciences, particularly in the context of breath tests and water isotope determinations for total body water and the doubly labeled water technique for energy expenditure. The high precision gas isotope ratio mass spectrometers (GIRMS) used in these applications are designed to analyze a few small molecules (CO_2 , H_2 , N_2) and produce 4-7 significant figures for isotope ratios on sample sizes greater than 100μg.

In recent years the capability to determine carbon isotope ratios at high precision for specific compounds ("compound specific isotope analysis", CSIA) has grown in applications principly because of the commercial introduction of gas chromatography-combustion isotope ratio mass spectrometry (GCC-IRMS) in 1990. Briefly, organic compounds eluting from a GC column are directed to a combustion furnace for quantitative conversion to CO_2 with subsequent drying and admission to the GIRMS instrument. Typical precision for $^{13}C/^{12}C$ determinations is 0.0003‰ (absolute) for sample sizes greater than 10 ng. We recently described a high sensitivity approach to tracer experiments coupling this instrumental method with the use of highly enriched perlabeled tracers (1). Our data suggests this approach is more sensitive than acceptable radiotracer doses for the majority of human applications.

We have recently constructed as system for interface of a liquid source, including liquid chromatography, to IRMS, to extend the technique to non-volatile and thermally labile compounds. The key consideration for such an interface operating at precision and accuracy levels quoted above is reliable removal of carbon-containing compounds, most notably solvents, from the analyte prior to combustion. Although a number of new interfaces have become popular for organic LC/MS in recent years (electrospray, thermospray, direct liquid injection, particle beam), the only interface which can be expected to accomplish this is the moving transport interface. We have modified a commercial moving wire device, originally designed for interface of LC to a flame ionization detector, to remove solvent, combust organic molecules to CO_2 prior to introduction to the IRMS. The combustion furnace is loaded with CuO which exists in equilibrium with Cu metal and O_2 at 800°C and

serves as a source of oxygen. A water trap has been installed in the line prior to the mass spectrometer to dry the stream prior to introduction to the GIRMS instrument.

The instrument is operated in one of two modes: flow injection, in which there is no LC column, or LC mode. Flow injection mode results in sharper peaks that LC mode and therefore is more sensitive and yields more precise numbers for a given sample load. Precision for replicate injections and a calibration curve were determined in flow injection mode. Isotopically calibrated linoleic acid was prepared in graded series from the terrestrial natural abundance range to about 0.1% enrichment above this level $0.010844 < {}^{13}C/{}^{12}C < 0.012285$. Data were calibrated against the known isotope ratio of lowest ^{13}C content. A plot of known isotope ratio versus LCC-IRMS ratio gives a correlation coefficient of 0.9998, with slope=0.996 (theoretical=1) and intercept=0.3 (theoretical=0). Average precision for these determinations was less than δ_{PDB} =0.5‰ .

Liquid chromatography mode was tested with a mixture of isotopically calibrated fructose, sucrose, and lactose. Calibration was made against the known isotope ratio of fructose. Baseline separation was achieved for all sugars. Precision for each was less than 1‰ and accuracy was 0.4‰ and 1.8‰ for sucrose and lactose, respectively. These figures are comparable to errors obtained for similar quantities of material analyzed by GCC-IRMS, estimated to be about 1 ng.

These data represent the first demonstration of on-line coupling of a liquid source with high precision GIRMS, and extend the CSIA to the full range of biomolecules.

Isotope Chemistry in the Jar: Direct Isotopic Analysis from Head Space Gas Mixtures using a GC-IRMS System

A. Hilkert and W. A. Brand,
Finnigan MAT, Barkhausenstr. 2, 2800 Bremen, Germany

Isotope ratio mass spectrometers for gaseous samples offer the highest precision available for isotope abundance studies. For carbon, the limitation of the required large sample size has recently been overcome by combining the isotope MS with a GC and introducing the sample together with the carrier gas (after complete oxidation to CO_2 in a combustion interface) into the ion source[1].
The precision of the method is 0.0003 at% or better. Sample sizes down to 20 pmol carbon in the ion source have been reported[2]. Extension of the method to other isotope ratios like $^{15}N/^{14}N$, $^{18}O/^{16}O$, $^{34}S/^{32}S$ is possible and has been demonstrated.
The technique is also applicable to gas mixtures by replacing the traditional cryogenic gas separation device with a GC.
We have tested this idea by combining a headspace autosampler with a GC-IRMS system. The effluent of the GC is passing through a combustion interface before entering the MS via an open split. The interface has a combustion tube for quantitative oxidation of effluent material, a reduction tube filled with elemental Cu, a water removal system and a means for reference gas injection. The furnaces are hot only when applicable.

Figure 1 shows results from a series of measurements of alcoholic beverages. 200 to 300 µl of liquid were filled in 2ml autosampler vials and septum capped. From the headspace samples were taken using a gas tight 100 µl syringe and injected into a GC (Hewlett Packard model 5890) equipped with a split injector and a capillary column for gas separation (Chrompack Poraplot Q 25m). Following on line combustion the isotope ratio was determined on a gas isotope MS (Finnigan MAT, model Delta S). The Delta values are given versus PDB, the international standard for ^{13}C analysis. The solid points represent the headspace measurements. The two open squares were obtained via total combustion of the respective sample, reflecting the overall ^{13}C value. The agreement between both types of measurement is satisfactory.
Most of the samples have isotope values around -25 permil. Notable exceptions are the synthetic alcohol, the Jamaican brands and two of the Whiskys. Pure Scotch should have a value close to -25 permil as represented by the single malt brands. The value of -16.5 indicates a blending procedure involving approximately 40% Scotch and 60% from another source derived from corn or, less likely, from sugar cain.
It is noteworthy that also beer with an ethanol content of only 5% and thus only 0.4 mb partial pressure can be measured with the technique. The CO_2 is separated by the GC and may be determined simultaneously. The same is true for wines or champaigns.

Figure 2 shows results for a well known classic of isotope ratio techniques, the equilibration of water with CO_2 for ^{18}O determination. The results were obtained on water amounts small as compared to the conventional technique (≈5ml). The Delta values are virtually independent of the sample size.

The technique is suitable for the measurement of methane, CO_2 from breath following oral ingestion of ^{13}C labelled nutrients or drugs, ^{13}C determination of the carboxyl group in aminoacids using the ninhydrin reaction and other analytical problems.

IMPROVEMENTS IN SENSITIVITY AND PRECISION ATTAINED WITH THE APPLICATION OF ION COUNTING TECHNIQUES TO ISOTOPE RATIO ANALYSIS OF ZINC AND IRON USING FAB/SIMS

David R. Flory, Leland V. Miller, Paul V. Fennessey and José A. Olivares.*

Departments of Pharmacology and Pediatrics, University of Colorado Health Sciences Center, Denver, CO 80262 and *Los Alamos National Laboratory, Los Alamos, NM 87545.

Introduction

Stable isotope technology is becoming the method of choice for nutritional studies involving a variety of elements. As study designs increase in complexity (i.e. multiple isotopes delivered, frequent sampling, etc) the sensitivity of isotope ratio measurement can become the limiting factor due to frequent sampling and the small sample volume. We have combined pulse counting hardware with a software control and acquisition system developed at Los Alamos to obtain an increase in both sensitivity and sample throughput. These modifications were made to an organic mass spectrometer (VG 7070EHF) using FAB ionization.[1]

Experimental

A linear-focusing electron multiplier (Thorn EMI C660) pulse counter, was added "on-axis" to the mass spectrometer so as not to interfere with the resident electron multiplier used for organic analysis. The pulses are counted by a counter/timer board (Data Translation DT2827) in an AT-compatible computer. The computer software is a menu-driven program written in HT Basic which acquires data by either ion current or ion counting measurements. This program also has the capacity to do either voltage or magnet switching for operation of the mass spectrometer. Various concentrations of zinc and iron (confirmed by atomic absorption) were used for isotope ratio measurements by magnet switching and the new pulse counting technique.

Results and Discussion

Previous FAB/SIMS techniques[1] using magnetic scanning and EM current measurements were both precise (RSD'S $\leq 2\%$) and accurate ($\geq 99\%$) but required sample loads of from 2 to 8 μg of analyte for analysis. With zinc and iron present in the plasma at ≤ 1 μg/ml, and with frequent sampling used in present studies, 2-3 minutes between samples, this results in a decreased sample volume (2 ml/sample). After loss of analyte which occurs with sample clean-up and isolation, often there was not enough analyte remaining for accurate isotope ratio analysis. The application of pulse counting to isotope ratio measurements of zinc, Figure 1, has increased the sensitivity of measurements while retaining equal precision and accuracy. However, the limits of sensitivity are dependent upon the specific isotope studied. In Figure 1a, the measured ratio $^{70}Zn/^{66}Zn$ remains precise throughout the 20-1000 ng range (RSD's 0.56-3.8%) but is inaccurate below 200 ng of sample. In Figure 1b, for $^{68}Zn/^{66}Zn$, the precision is about equal to $^{70}Zn/^{66}Zn$, but remains accurate to 100 ng with the possibility of getting useful data at only 20 ng sample loads. For ^{68}Zn, this is an actual increase in sensitivity of 1 order of magnitude (at 100 ng) with the potential of 2 orders of magnitude (at 20 ng). The differences between the sensitivities of ratios involving $^{70}Zn/^{66}Zn$ vs $^{68}Zn/^{66}Zn$ are related to natural abundances of each isotope. With a smaller natural abundance (^{70}Zn = 0.62% vs ^{68}Zn = 18.6%) there is a decrease in sensitivity. In Figure 2, the $^{54}Fe/^{56}Fe$ ratio remains very accurate ($\geq 99\%$) and precise (RSD $\leq 1.5\%$) at sample loads down to 50 ng. Beyond this level, the ratio deviates and becomes too

inaccurate for useful measurements. As in the case of zinc, when the least abundant isotope of iron is used, ^{58}Fe, precision is good but accuracy is only retained at sample loads of 200 ng or greater (data not shown).

The application of pulse counting to FAB/SIMS isotope ratio measurement has widened the focus of possible research to infant and initial plasma kinetic studies. These types of studies require increased sensitivity with equal accuracy and precision which is now available with pulse counting techniques.

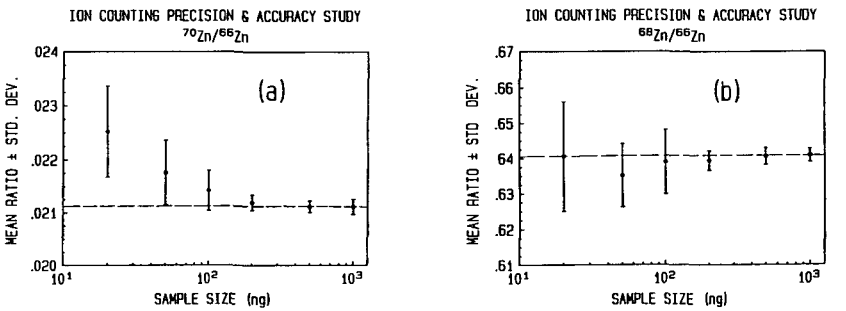

Figure 1. Isotope ratios of (a) $^{70}Zn/^{66}Zn$ and (b) $^{68}Zn/^{66}Zn$ are plotted against sample quantity used for isotope ratio measurement. Each data point is an average of 288 separate measurements at each of the masses. The FAB source was run at 8 kV and 1 mA. The line (-----) denotes the zero enrichment reference ratio.

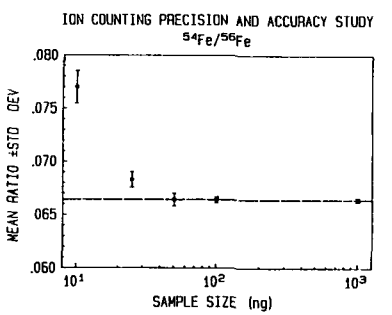

Figure 2. Isotope ratios of $^{54}Fe/^{56}Fe$ are plotted against sample quantity used for isotope ratio measurement. The number of measurements, FAB data, and line (-----) are the same as in Figure 1.

Metabolism of Δ^4-VPA To Glutathione Conjugates in the Rat: Identification of Novel Adducts Using Ionspray LC-MS/MS.

K. Kassahun, M.P. Grillo, M.R. Davis, L. Jin and T.A. Baillie
Department of Medicinal Chemistry, University of Washington, Seattle, WA, 98195

2-*n*-Propyl-4-pentenoic acid (Δ^4-VPA) is the terminal olefin metabolite of the antiepileptic drug valproic acid (VPA). Δ^4-VPA has been shown to be a teratogen in the mouse and a potent hepatotoxin in the rat (1,2). Several lines of evidence suggest that the hepatotoxicity of Δ^4-VPA may be mediated by reactive intermediate(s) arising from the metabolism of the compound (3,4). Since many electrophilic xenobiotic metabolites react with the cellular nucleophile glutathione (GSH), structural characterization of the resulting conjugates provides a valuable indirect means of identifying short-lived electrophiles. This approach frequently affords a valuable insight into the mechanisms of xenobiotic-mediated toxicity. In this study, we investigated the biliary excretion in rats of GSH adducts from Δ^4-VPA and [3,3-$^2H_2$]Δ^4-VPA.

Bile was analyzed by a Perkin-Elmer/Sciex API III triple quadrupole mass spectrometer equipped with an atmospheric pressure ion source and ionspray interface. Tandem mass spectrometry was based on collision-induced dissociation of ions entering the rf-only quadrupole region, where argon was used as the collision gas. Full scan mass spectra of synthetic compounds and product ion spectra of the corresponding $[M+H]^+$ parent ions were recorded by direct infusion of the sample (10 $\mu g\ ml^{-1}$) into the instrument at a flow rate of 5 $\mu l\ min^{-1}$. LC-MS/MS was performed by injecting 50 μl of crude bile onto a narrow-bore C_{18} HPLC column coupled to the mass spectrometer *via* a splitting tee. Samples were injected at 100% solvent A (0.06% aqueous trifluoroacetic acid) and, after 5 min, solvent B (0.06% trifluoroacetic acid in acetonitrile) was added to the mobile phase at a rate of 1% min^{-1}. The column effluent (flow rate 200 $\mu l\ min^{-1}$) was split such that the flow rate to the ion source was 50 $\mu l\ min^{-1}$, the remainder being diverted to a UV detector. GSH conjugates were detected by operating the instrument in the constant neutral loss scanning mode (loss of 129 Da).

Neutral loss scanning resulted in the detection of four GSH conjugates designated 'A' to 'D' according to their order of elution on HPLC. The major conjugate ('C') was identified as 5-GS-4-OH-VPA-γ-lactone on the basis of its LC-MS/MS properties which were identical to those of the synthetic reference sample, and conjugate 'D' likewise was characterized as the previously reported 5-GS-(E)-Δ^3-VPA (5). Metabolite 'B' was identified as the conjugate of the α,β-unsaturated ketone, 3-oxo-Δ^4-VPA. Metabolite 'A' was the most polar of the conjugates and afforded an $[M+H]^+$ ion 18 Da higher than that obtained for 5-GS-4-OH-VPA-γ-lactone. Hence, on the basis of its HPLC elution order and $[M+H]^+$ ion, metabolite 'A' appears to be 5-OH-4-GS-VPA-γ-lactone.

In a parallel experiment carried out with the deuterium labeled analog, [3,3-$^2H_2$]Δ^4-VPA, metabolites 'A' and 'C', which are considered to derive from a common metabolic pathway (Figure 1), retained both deuterium atoms. Conjugate 'D', which is believed to arise as a result of β-oxidation of Δ^4-VPA, retained only one deuterium and, as expected, conjugate 'B' was formed with loss of both deuterium atoms.

Based on the urinary excretion of the corresponding *N*-acetylcysteine conjugates, the GSH-dependent metabolism of Δ^4-VPA accounted for *ca.* 20% of a single dose of Δ^4-VPA to rats. Because reactive metabolites of Δ^4-VPA appear to be formed both in the mitochondria and endoplasmic reticulum (Figure 1), it may be expected that Δ^4-VPA would deplete both

mitochondrial and cytosolic GSH pools. Oxidative stress as a result of GSH depletion and/or interaction of reactive intermediates with mitochondrial components may contribute to the hepatotoxic effects of Δ^4-VPA.

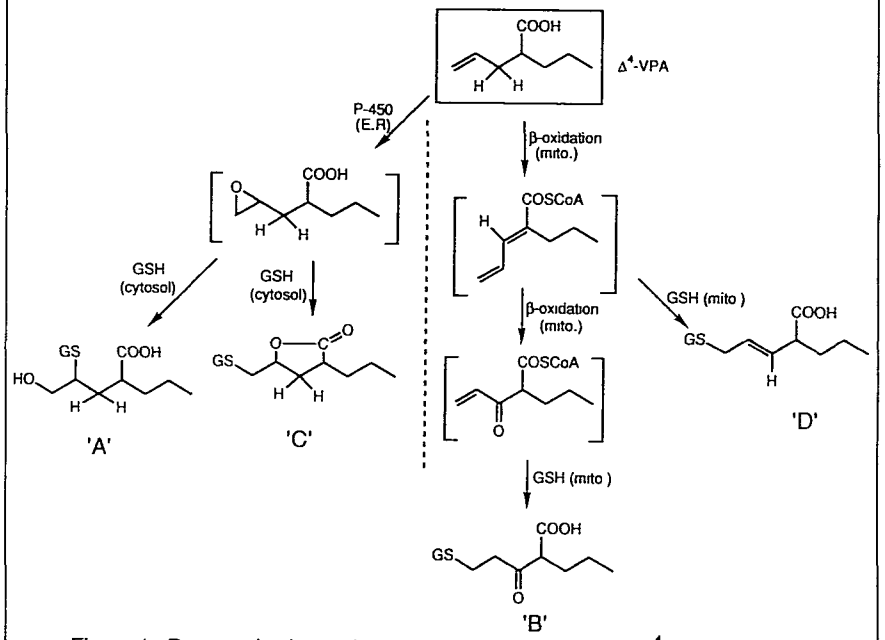

Figure 1: Proposed scheme for the metabolic activation of Δ^4-VPA in rat liver

Quantification of Topiramate, a Novel Anticonvulsant, in Rat Brain Fluid by In-Vivo Microdialysis and Thermospray Liquid Chromatography/Mass Spectrometry

John A. Masucci, Marta E. Ortegon, William J. Jones, Richard P. Shank and Gary W. Caldwell, The R.W. Johnson Pharmaceutical Research Institute, Spring House, Pennsylvania,19477

Topiramate, 2,3:4,5-bis-*O*-(1-methylethylidene)-ß-D-fructopyranose sulfamate, a potent anticonvulsant, was determined in the extracellular fluid of rat brain by in-vivo microdialysis combined off-line with thermospray mass spectrometry. Since topiramate, and its metabolites are subject to thermal decomposition during GC/MS analyses, and since these compounds have no UV chromophore, LC/MS analysis is the method of choice. Electron ionization and thermospray LC/MS and LC/MS/MS of topiramate has been previously reported.[1,2] The combination of in-vivo microdialysis sampling with thermospray LC/MS has also been previously demonstrated.[3] The purpose of this study was to extend the determination of topiramate to dialysates collected from rat brain extracellular fluid and compare them directly to blood levels. Dialysate samples are typically free from endogenous materials allowing direct analysis without further sample preparation.

Microdialysis was performed using a CMA 12 probe (Carnegie Medicin- diameter-0.5 mm, membrane A, length-3.0 mm) stereotaxically implanted and position later determined histologically. A CMA 100 pump (1 ml syringe) was used to deliver distilled water dialysate at 2 µl/min. Male Wistar rats (~250g) were dosed IV at a 50 mg/kg level of topiramate. Samples were collected at 15 min intervals. Blood samples (100 µl) were collected at 30 min. intervals via cannulized jugular vein. Probe recovery (8.8%) was determined in-vitro following collection.

Thermospray analyses were performed using a Finnigan MAT TSQ-70 mass spectrometer with TSP-2 thermospray source. The detection limit of topiramate by thermospray LC/MS analysis is typically in the 0.1 µM range (20 µl injected) using selected ion monitoring. The ammonium adduct ion $(M+NH_4)^+$, which is the base peak, was used for detection. An internal standard of D_{12} labelled topiramate was added for quantitation.

Dialysate samples were directly injected (20 µl) along with 20 µl (4 ng) of internal standard. Blood samples were diluted 1 to 100 with methanol prior to injection (20 µl) with internal standard (4 ng). This was the only sample preparation required. Results were determined directly from the linear calibration curve.

Extracellular rat brain fluid levels peaked 45 min. after topiramate administration at the 15 µM level, with succeeding levels between 8.5 and 14 µM during the remaining 5 hr collection period. Blood levels peaked 1 hr. after dosage at the 440 µM level dropping to 220 µM after 3 hrs. This limited pharmacological data would indicate that topiramate equilibrates quickly across the blood-brain barrier and brain fluid levels in the micromolar range are maintained over an extended period. These results agree with the previously obtained radioimmunoassay results in which micromolar levels of topiramate were detected over a 24 hr. period.

The structural diversity of modern therapeutic drugs is well documented. However, after entry into the body such compounds are subjected to a series of complex metabolic processes including absorption, distribution, metabolic transformation and excretion. These events modulate the efficacy of the drug in the treatment of disease, as well as determining its pharmacological and toxicological effects, and structural characterisation of resulting metabolites is vitally important to understanding the physical and biological effects of the parent drug.

The use of capillary electrophoresis (CE)-MS in the analysis of small organic molecules (<600-800 daltons) has received scant attention. However, the high efficiency separation of CE (>10^6 theoretical plates) coupled with MS provides a powerful structural analytical tool for drug metabolism studies.

Initial CE-MS studies focused on the metabolism of the neuroleptic agent haloperidol **(1)**. It was possible, using a mixture of **(1)** and six synthetic standards, to baseline resolve all seven components and detect them using CE-MS (Finnigan MAT 900 with PATRIC array detector) at the <100 femtomole level. Further *in vitro* studies demonstrated that differences in the metabolism of different animal hepatic microsomal incubates was possible to detect. A guinea pig incubate revealed the presence of four meabolites plus unmetabolised haloperidol, whereas a mouse incubation revealed CPHP, HP^+, unmetabolised haloperidol, RHAL and HNO. Differences observed were both quantitative and qualitative.

We also investigated the use of non-aqueous CE run buffer in conjunction with MS in the analysis of the H_2 receptor antagonist mifentidine **(2)**. It was demonstrated using 100% MeOH (20mM NH_4OAc) with 1% AcOH that CE-MS analysis of a guinea pig microsomal incubate revealed the presence of five metabolites plus unmetabolised parent drug.

Estradiol and Estradiol Metabolites Analysis by Electrospray Mass Spectrometry

Jennifer Duker*, Matthew J. Dilts, Edward W. Sheehan
Millipore Corporation, Extrel Mass Spectrometry, 575 Epsilon Drive, Pittsburgh, PA 15238

As a specific class of structurally complex molecules, steroid hormones have traditionally posed a special challenge to the analytical chemist. Previously, the mass spectral characterization of free steroids was dominated by gas chromatography/mass spectrometry. Less volatile and thermally labile steroids and steroids conjugates required derivatization to more volatile and stable compounds prior to analysis. Successful characterization of underivatized steroids have also been obtained using such techniques as desorption chemical ionization (DCI), fast atom bombardment (FAB), thermospray (TS), and particle beam mass spectrometry.

This prompted an investigation into the possibility of using electrospray ionization along with collisionally induced dissociation (CID) for the analysis of estradiol and estradiol metabolites. Our objectives for this study wereM (1)to demonstrate the utility of LC/MS (2)to alleviate the derivatization step necessary for GC/MS, and (2) to demonstrate quantitation data in the low ppm levels.

EXPERIMENTAL

This study evaluates the feasibility of utilizing a benchtop LC/MS with an Electrospray interface for the analysis of Estradiol Metabolites.

MASS SPECTROMETER

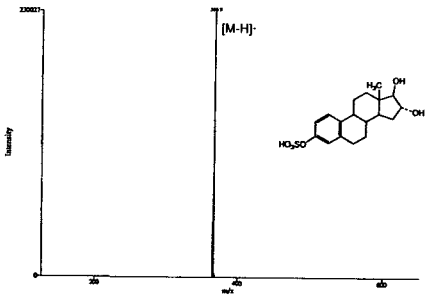
B. Estriol 3-sulfate



CONCLUSIONS

Negative Electrospray LC/MS Analysis of Estradiol Metabolites

- The compounds were successfully chromatographed and detected by negative electrospray LC/MS
- All five metabolite compounds generated interpretable spectra
- All compounds exhibited sensitivity at pgram levels
- Linear calibration of β-Estradiol 3-sulfate 17-glucuronide was demonstrated

ELECTROSPRAY MASS SPECTROMETRY ANALYSIS OF ISOMERIC C - GLYCOSIDIC FLAVONOIDS

M. Becchi, M. M. Flament SCA, CNRS, BP 22,69390 Vernaison, France
G. Tsoupras HEWLETT PACKARD S.A. Rue de Veyrot 39, 1217 Meyrin, Switzerland

Flavonoid glycosides are an important group of polyphenolic pigments found in plants[1]. They are of interest because of their significance in chemotaxonomy, their biological activity and their use as tracers in medicinal plant preparations.

Mass spectrometry is the method of choice for structure study of C-glycosidic flavonoids because of the resistance of the C-glycosidic bond to hydrolysis. This was achieved in the past by EI mass spectrometry of permethylated derivatives. More recently Fast Atom Bombardment technique in combination with CAD-MIKE or B/E linked scanning[2,3] has been shown to be very useful for the structural characterization of C-glycosidic flavonoids.

The present work is aimed at the differenciation between 6-C and 8-C monoglycosidic flavonoids using Electrospray mass spectrometry. In addition to molecular weight information, HP Electrospray can also provide structural informations through time-programmable collision induced dissociation. In this process the ions are forcefully collided with molecules of the bath gas (Nitrogen) by adjustment of the voltage difference between the capillary exit and the first skimmer. The best informative mass spectra are given by using a capillary exit voltage difference of 200 V. Differentiation between the series of 6-C and 8-C isomers can be directly obtained from the study of the mass spectra, without the need of MS/MS techniques as in FAB ionisation and with a better sensitivity. Leading differences are observed :

* more intense peaks for daughter ions from 6-C isomers than from 8-C isomers
* presence of a $[M+H-60-2H_2O]^+$ fragment ion for 6-C isomers and lack of this ion for 8-C isomers. This characteristic difference was already underligned in positive ion mode FAB mass spectrometry[3].
* the ratio R of $[M+H-150]^+$ / $[M+H-90]^+$ depends of the concerned isomer :

R ~ 1 for 8-C isomers and R ~ 6 to 35 for 6-C isomers

In conclusion Electrospray mass spectrometry is a significant method to analyse C-glycosidic flavonoids. Furthermore this attractive technique can easily be coupled to liquid chromatography for mixtures analysis.

Matrix-Assisted Laser Desorption Mass Spectrometry of Dynorphin A (1-17) Processing in Human Blood (*in vitro*) and Rat Brain (*in vivo*)

James Z. Chou, Isabelle M. Maisonneuve, Mary Jeanne Kreek, and Brian T. Chait
The Rockefeller University, New York, NY 10021.

In preparation for proposed dynorphin peptide pharmacokinetic studies in humans, it is essential to ascertain a) whether the dynorphin maintains its integrity after intravenous administration and b) whether any further processing or breakdown of dynorphin peptides occurs in fresh blood (without or with the addition of enzyme inhibitors) after it is drawn from a patient. To begin addressing both of these questions, we describe a study of *in vitro* processing of Dyn A (1-17) in freshly drawn human blood. We also describe first studies of the processing of exogenously administered Dyn A (1-17) in brain regions of freely moving rats.

The mass spectrometric analysis of the dynorphin peptides was carried out using matrix-assisted laser desorption at a laser wavelength of 355 nm with α-cyano-4-hydroxycinnamic acid as the matrix. The matrix was dissolved to a concentration of 5 g/L in a mixture of 33% acetonitrile and 67% 0.1% trifluroacetic acid (TFA) aqueous solution.

The *in vitro* processing study of Dyn A (1-17) in human blood was carried out by adding 0.5 mM Dyn A (1-17) into freshly drawn human blood to yield a final peptide concentration of 0.01 mM. This spiked blood was allowed to stand for a variable amount of time at room temperature prior to separation and mass spectrometric analysis. A portion of that blood was separated by refrigerated centrifuge (4°C) for 5 min at 2500 g, after different standing time intervals. 300 μl of each resulting plasma sample was then diluted with 1.7 ml of 1% TFA (containing 1.6 μM substance P as an internal standard) and filtered through microconcentrators with a 3000 mw cut off. The filtrate was concentrated in a speed vacuum concentrator before it was combined with matrix solution and analyzed by mass spectrometry.

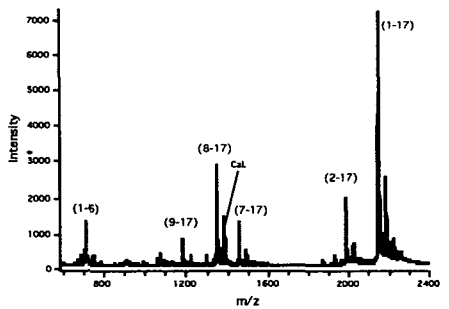

Fig. 1 Mass spectrum of processed products of Dyn A (1-17) in human blood at time=0

The major products resulting from the biotransformation of Dyn A (1-17) in human blood at time 0 is shown in Fig. 1. The most intense peak corresponds to unprocessed Dyn A (1-17). Major processed products identified from their measured nominal masses are Dyn A(7-17), Dyn A(8-17), Dyn A(9-17), Dyn A(1-6) and Dyn A(2-17). More than 10 other processed fragments of Dyn A (1-17) can be readily identified in smaller quantity. Through the use of an internal standard, substance P, the amounts of

processed products were determined as a function of time (Figure 2). The amounts of Dyn A (7-17), Dyn A(8-17), Dyn A(9-17) and Dyn A(1-6) were found to decrease after their maximum values were reached at ~ 20 min. By contrast, the amounts of Dyn A(2-17) and Dyn A (3-17) increased monotonically as a function of time (Fig. 2). This observation suggests that the dynorphin products generated by cleavage between the 6th and 7th amino acid residues are processed (by blood enzymes) differently than the processed products formed by losing the amino acid residues from the amino-terminus of the peptide.

The *in vivo* processing study of Dyn A (1-17) in brain regions of freely moving rats was carried out in striatum and cerebellum. A thin plastic tube (0.67 mm, o.d.) was positioned in close proximity to a microdialysis probe, such that both were located in a brain region of interest. Dynorphin A (10 mM) was delivered (0.1 μl/min) through the plastic tube and the processed products were collected from the microdialysis probe through the constant infusion(1μl/min) of artificial CSF (146 mM Na^+, 2.7 mM K^+, 155 mM Cl^-, 1.2 mM Ca^{2+}, and 1.0 mM Mg^{2+}). The infusion of Dyn A (1-17) was terminated after 60 min of delivery, while the collection of dialysate was continued for another 2 hours. A constant amount of substance P was added to the dialysate as an internal standard.

Mass spectra similar to Figure 1 were obtained, where many processed products (more than 15) were readily identified. The amounts of a processed product, Dyn A (2-17), as a function of time in the living rat striatum and cerebellum are shown in Fig. 3. Similar time profiles were observed for other processed products. The data shows that more time was needed to process the dynorphin peptide in cerebellum than in striatum . This finding is in concert with the expected higher abundance of enzymes, which are believed to be more specific for dynorphin processing, in striatum than there are in cerebellum. Rapid Analysis of EA and its Metabolites using LC-MS and MS/MS*

M. Denise LeBlanc[1], Michael A. Quilliam[1], M. Ruth Bailey[2] and David H. North[2]

[1]Institute for Marine Biosciences, National Research Council of Canada, 1411 Oxford St., Halifax, Nova Scotia, Canada B3H 3Z1

[2] Health and Welfare Canada, P.O. Box 1060, 53 Queen St., Dartmouth, Nova Scotia, Canada, B2Y 3Z7

Erythromycin A (EA) is a macrolide antibiotic used in both agriculture and aquaculture to promote optimal health and growth of animals. There are concerns that residues of the antibiotic and/or its metabolites may remain in the edible portion of the tissue if proper withdrawal times are not implemented prior to slaughter.

HPLC analysis of EA is difficult due to the lack of a significant chromophore for detection, its polar, labile nature and its basicity. Earlier work [1] has demonstrated the utility of liquid chromatography coupled to ionspray mass spectrometry for EA analysis and several metabolites in salmon tissue were identified. However, quantitative analysis was limited by the lack of a robust clean-up method and somewhat long analysis times. We have developed a clean-up method for salmon tissue that has permitted the development of rapid LC-MS and FIA-MS/MS methods.

The extraction procedure utilized was similar to that of Takatsuki et al [2]. An additional solid phase extraction step, using a bonded aminopropyl silica cartridge, was developed to decrease the amount of co-extractives present in the final solution for analysis. A 15cm X 2.1mm i.d. RX-C8 column was employed in an isocratic mode with aqueous 30% acetonitrile and 0.2% formic acid. Analysis time was only 8 minutes. Figure 1 displays a typical chromatogram and selected ion chromatograms for EA and some of its metabolites and degradation products.

We have also demonstrated that flow injection analysis coupled with tandem mass spectrometry (FIA-MS/MS) can be used to provide a rapid screening for analytes. Selected reaction monitoring was employed for the following transitions 734 → 576, 734 → 558 and 734 → 158 for EA and 716 → 558, 716 → 540 and 716 → 158 for AEA (anhydroerythromycin A, the principal metabolites of EA). The calibration curves obtained for EA are shown in Figure 2.

Both methods were employed to determine the depletion of EA and metabolites in medicated salmon. Results from the LC-MS and FIA-MS/MS analyses compared favourably (Figure 3).

High Performance Liquid Chromatography/Electrospray MS/MS and MS/MS/MS for Metabolite Identification of a Peptide-Based Renin Inhibitor.

R. P. Schneider *, M. J. Cole, J. Wentland, M. R. Nocerini, and H. G. Fouda. Central Research Division, Pfizer Inc, Groton, CT 06340

Renin is an aspartic endopeptidase that is responsible for initiating the angiotensin cascade, resulting in vasoconstriction, sodium and water retention, and ultimately hypertension. Identification of a therapeutically useful renin inhibitor is desirable for the management of hypertension. [1,2]

CP-108,671 is a novel peptide (Figure 1) with promising renin inhibitory activity. We have employed on-line HPLC and triple quadrupole mass spectrometry to gain insight into the metabolic routes of this novel peptide.

Seventeen drug related metabolites were identified in the bile of an orally dosed dog (Summary Table). A variety of mass spectrometric experiments were performed, including precursor, neutral loss, and CAD product ion scans. For several ions of interest, MS/MS/MS conditions were employed by sufficiently raising the orifice voltage to produce the desired CAD product ion prior to the first quadrupole. These experiments were invaluable in assigning numerous sites of metabolism.

Metabolites identified included many Phase I single oxidation products, N and S demethylation, a Phase II O-glucuronide, a sulfoxide, and cleavage of the C-terminus with corresponding formation of a carboxylic acid. Several interesting and unexpected metabolites were found having multiple sites of oxidation on different portions of the molecule. These included N and S oxides, bis-phenyl oxidations, and a significant amount of a tri-oxidized metabolite resulting from a bis-phenyl oxidation and the formation of a ketone on the methylene bridge alpha to the phenyl moiety.

SUMMARY TABLE of CP-108,671 Metabolites found in 0.5 to 1 hr Fraction of Dog Bile Following a 10 mg/kg Dose

Drug or Metabolite	m/z	characterization	% relative to drug related material
I	647	drug	15.5
II	633	N-des methyl	9.6
III	633	S-des methyl	0.3
IV	605	loss of i-Prop to acid	1.6
V	823	O- Glucuronide	0.9
VI a	663	norstatine oxidation	16.1
VI b	663	norstatine oxidation	6.5
VII	663	phenyl oxidation	13.2
VIII	663	sulfoxide	3.3
IX	663	N-oxide on piperidine	0.3
X a	679	phenyl oxid. and	5.0
X b	679	norstatine oxid.	6.7
XI	679	bis-phenyl oxidation	5.0
XII	679	phenyl oxid + sulfoxide	2.5
XIII	679	norstatine ox.+sulfoxide	1.1
XIV	679	bis-norstatine oxidation	1.1
XV	679	N-oxide on piperidine + S-oxide	0.6
XVI	692	bis-phenyl oxidation + hydroxylation of a methylene bridge with dehydrogenation to a ketone	10.7

HPLC/MS Determination Of Components in Black Tea, Robert T. Rosen[1], Douglas A. Balentine[2], Steven Gobbo[2], Richard D. Hiserodt[1], Joseph Lech[1], Elaine K. Fukuda[1], Thomas G. Hartman[1] and Chi-Tang Ho[1], [1]Center For Advanced Food Technology, Cook College, Rutgers University, New Brunswick, N.J 08903 and [2]Thomas J. Lipton Company, 800 Sylvan Avenue, Englewood Cliffs, N.J. 07632

Recent studies have found that polyphenolics in green and black tea have potent anticarcinogenic activity in many laboratory animals. Epigallocatechin gallate (EGCG) has been shown to inhibit nitrosamine induced lung tumors.

Negative Ion Thermospray LC/MS (Negative ion discharge mode) as well as Particle Beam (EI, 70eV) LC/ MS was utilized to identify components in black tea. These components included catechins, theaflavins and flavonoid conjugates. A C-18 column was utilized for the determinations with 0.16% formic acid and 0.20% triethylamine in the aqueous mobile phase. The program started at 100% aqueous, and ended in 75 minutes at 57.5 % methanol. Superior LC resolution was achieved using this modified mobile phase. The triethylamine appeared to complex the polyphenols and appeared to significantly enhance the negative ion mass spectra, especially that of the flavonoids and their conjugates. The particle beam data showed each component eluting as a loosely bound complex with triethylamine. The complex dissociated upon ionization, not giving adduct ions, but rather enhancing the molecular ions of the disaccharides and glycosides.

Superior data was obtained for components such as epicatechin (EG), epicatechin gallate (ECG), epigallocatechin (EGC and epigallocatechin gallate (EGCG) as well as the flavonoid conjugates. Reasonable data was obtained for the compounds theaflavin and theaflavin gallate, but no data was obtained on theaflavin digallates and a class of oligimeric or polymeric compounds called thearubigens. The gallate ester linkage seems too labile and there is no evidence that these compounds even elute from the LC column indicating that the thearubigens may bind to active sites in the metal column. In a separate experiment, no ions were observed by LSIMS above 900 AMU, confirming the difficulty with the oligimeric or polymeric thearubigens. No LSIMS nor LC/MS data was obtained on extracts and other samples known to be enriched in thearubigens. Future work to elucidate the structure of this higher molecular weight class includes derivatization as well as analysis of a degallinated tea.

CHARACTERIZATION OF FLAVONOIDS BY LC/MS/MS TEA FLAVONOIDS

Yong Y. Lin[1], K.S. Kim[1], Cheng-mo J. Chen[1], and Kwokei Ng[2]

[1]Institute for Basic Research in Developmental Disabilities, Staten Island, New York.
[2]Schering-Plough Research Institute, Bloomfield, New Jersey, USA.

The history of tea in China might started as early as 5000 years ago, when it was discovered as an herbal medicine. Some significant pharmacological and health effects of tea plant, *Camellia sinensis*, have gained supports from scientific research in recent years. Among them, tea appears to have some significant biocidal effects including a strong antiviral effect against human immunodeficiency virus (HIV). Although the mechanism of the antiviral effect of catechins remains unclear, the strong antioxidant activity of the flavonoids as radical scavengers might play some role. In order to study structure-antiviral activity relationship, catechin flavonoids were extracted from *Camellia sinensis*, fractionated by HPLC, and their antiviral activity against herpes simplex 1 and human cytomegalovirus were studied. LC/TSQ-MS was utilized to characterize the catechin flavonoids.

[METHODS]

HPLC Fractionation: Column, reverse phase C-18(10 μm), 7.8 mm x 30 cm; liquid phase: 20 % acetonitrile in water (0.05 % TFA) with a flow rate 1 ml/min; detector, uv 280 nm

LC/MS/MS: Finigan-MAT TSQ 70 mass spectrometer with a thermospray LC/MS interface. CID spectra were obtained at 20-70 ev collision energy.

[REESULTS]

Using the thermospray LC/MS, $[M+H]^+$ ions of four major catechins, (-)epicatechin, (-)epigallocatechin, (-)epicatechin 3-O-gallate, and (-)epigallocatechin 3-O-gallate were quickly identified in a mixture of catechins extracted from the teaplant *Camellia sinensis*. Collision Induced Dissociation (CID) spectra of the $[M+H]^+$ ions gave simple fragmentation patterns, which permitted characterization of the substituents and the ring structure of the molecules.

Thermospray LC/TSQ-MS can be effectively used to identify flavonoids and their glycosides; their CID spectra showed three types of ring cleavages in the pyran ring of the flavonoids, and differentiation among flavanone, flavone, and flavonol was made. (Table 1).

Green tea extract and tea catechins showed strong antiviral activity against Human cytomegalovirus, while other plant flavonoids tested showed little antiviral activity. Polyphenolic antioxidants, such as methyl gallate and tannic acid, have been

reported to have antiviral activity; however, our study shows tea catechins are much potent antiviral agents.

ANALYSIS OF CAROTENOIDS IN HUMAN SERUM BY USING CAPILLARY COLUMN CONTINUOUS-FLOW FAST ATOM BOMBARDMENT LIQUID CHROMATOGRAPHY-MASS SPECTROMETRY.

Chien-Hua Huang, Steven J. Schwartz*, and Richard B. van Breemen
Departments of Chemistry and Food Science*
North Carolina State University, Raleigh, NC 27695

An essential dietary factor, vitamin A is composed of a number of compounds including vitamin A retinoids and a much larger group of provitamin A compounds called carotenoids. Besides being necessary for human growth, vision, and reproduction, the possible roles of these compounds in cancer prevention, treatment, and tumor prevention are of intense interest. Approximately 600 carotenoids have been characterized, and numerous geometric isomers and degradation products of each are possible. Because carotenoids are unstable in the presence of light heat, HPLC is the method of choice for the separation of carotenoid mixtures. However, HPLC retention times and UV/VIS absorbances are insufficient for positive identification of carotenoids. Therefore we are developing LC/MS and LC/MS/MS methods for identification of carotenoids extracted from food and human serum.

METHODS

High Performance Liquid Chromatography (HPLC). All HPLC analyses were carried out using an Applied Biosystems 140A Microgradient HPLC Pump and an isocratic solvent system consisting of methanol/acetonitrile/ethyl acetate (30:50:20; v/v/v). A Vydac 5 mm C18 narrowbore HPLC column (25 cm x 2.1 mm) was used for narrowbore HPLC separations at a flow rate of 100 μL/min. Sample volumes of 1 mL each were injected using a Rheodyne 8125 injector (see ref. 1). Capillary HPLC was carried out using an LC-Packings 5 mm C18 HPLC column (320 mm x 30 cm; or 320 mm x 50 cm for human serum) at a flow rate of 4 μL/min. The injection volume was 200 nL, and a Rheodyne 7520 injector was used for all capillary column separations (see ref. 2).

Mass Spectrometry. Positive ion continuous-flow fast atom bombardment (CF-FAB) liquid chromatography/mass spectrometry (LC/MS) was carried out using a JEOL HX110HF double focusing mass spectrometer. The resolution was 1,000 and the ion source temperature was 23°C (room temperature) for all measurements. Coaxial-flow addition of matrix solution (ref. 3) was carried out at a flow rate 1 μL/min. The matrix solution consisted of water/acetonitrile/3-nitrobenzyl alcohol (v/v/w). For narrowbore HPLC analyses, the solvent flow was split post-column using a pneumatiac splitter so that 5 μl/min entered the mass spectrometer. The split ratio was 1/20.

Extraction of Carotenoids. Tomatoes (40 g) were pureed in 150 mL methanol, filtered, washed twice with 100 mL portions of methanol, then extracted under N_2 30 min in 100 mL hexane. The extract was evaporated to dryness and redissolved in mobile phase for HPLC. Human serum (5 mL from pooled blood bank serum) was extracted with 5 mL of ethanol/ethyl acetate (1:1). The organic layer was removed, evaporated to dryness, and then redissolved in 1 mL hexane. The hexane extract was loaded onto an alumina solid phase extraction cartridge, eluted with 5 mL acetone to obtain the polar carotenoids, and then eluted with 5 mL hexane/acetone 90:10 to obtain nonpolar carotenoids. Each fraction was evaporated to dryness and redissolved in mobile phase for HPLC.

Compared to post-column addition of the FAB matrix, coaxial-flow matrix addition minimized band broadening. Therefore, coaxial-flow matrix addition was used in all subsequent analyses. As we reported previously for narrowbore CF-FAB LC/MS using post-column addition of the matrix, 3-nitrobenzyl alcohol (1), molecular ions, $M^{+\cdot}$, were detected instead of protonated molecules for all carotenoid species.

Using the capillary HPLC system, separation of lutein, lycopene, α-carotene, β-carotene standards was demonstrated. Next, the CF-FAB LC/MS limit of detection for lutein and α-carotene was determined to be 5 and 15 ng, respectively (see Figure 1).

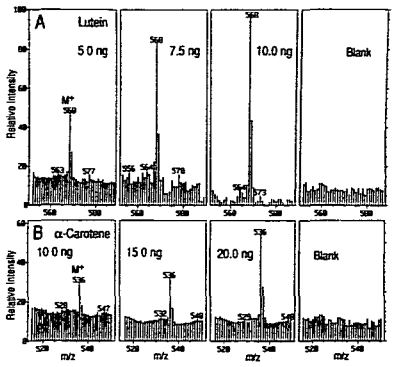

Figure 1.

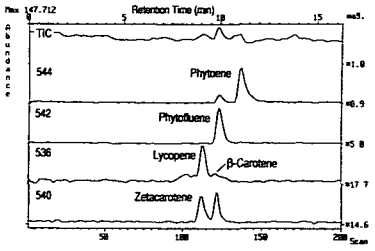

Figure 2.

Because important dietary carotenoids such as lycopene, α-carotene, and β-carotene have identical molecular weights but different HPLC retention times, LC/MS/MS was carried out. Fragment ions were identified that uniquely identified each of these isomeric carotenoids. Next, a tomato extract was analyzed using the narrowbore HPLC system. Abundant carotenoid molecular ions were detected for lycopene, phytoene, phytofluene, and two isomers of zetacarotene (see Figure 2). Finally, extracts of human serum were analyzed using the capillary LC/MS system. Only the most commonly observed carotenoid, lycopene, was detected in these initial analyses.

ACKNOWLEDGEMENTS. This research was supported by grants from the United States Department of Agriculture and the North Carolina Biotechnology Center.

FURTHER DEVELOPMENTS IN NEONATAL SCREENING BY AUTOMATED DYNAMIC LSI TANDEM MASS SPECTROMETRY

Donald H. Chace, Steven L. Hillman, David S. Millington, Department of Pediatrics, Mass Spectrometry Facility, Box 3028, Duke University Medical Center, Durham, NC 27710

Routine analysis of amino acids and acylcarnitines by LSIMS/MS from bloodspotted on filter paper has been demonstrated previously[1,2]. With this method, between 50 and 100 samples can be analyzed manually per day. So that sample throughput can increase, development of automated sample preparation and analysis is required. Blood droplets are spotted onto a special type of filter paper made from cotton fiber. The blood spots (approximately 30 μL) are dried. Two - 3/16" discs (approximately 12.6 μL) are punched from the larger spots into plastic vials. Up to 60 plastic vials are placed in a Gilson code 29 rack which fits into a programmable Gilson model 222 sample changer. The sample changer is used to add 400 μL of isotopically labeled internal standards in methanol. The discs are extracted for 30 min. The blood spot extracts are transferred to a parallel rack of clean vials. Solvent is removed by placing the rack in a custom-built warm air (50°C) evaporator (Grey Line Eng. model 2700). Samples are evaporated to dryness under a gentle stream of N_2. The rack is returned to the sample changer for addition of the derivatizing reagent (100 μL of 3N butanolic-HCl), covered by septum material and a rectangular weight and incubated at 65 °C (15 min) in a forced air oven. The cover is then removed and the reagent evaporated under N_2. The rack is returned to the sample changer and the vials are rinsed with 200μL of hexane. After hexane removal and drying under N_2, 50 μL of a methanol:glycerol (95:5) matrix containing the 0.025% of the surfactant, octyl sodium sulfate, is added to each tube. The sample rack is now placed in the autoinjector (Gilson model 231) for the programmed 2 minute, 15μL load, 500 μL rinse cycle for each sample injected into the dynamic LSIMS/MS system via a Rheodyne injector fitted with a 1μL loop. Matrix (85:10:5 Methanol:Glycerol:H_2O) is delivered at 7 μL/min. by an ISCO model 500D syringe pump The entire injector system is placed on a cart and wheeled into position with the Quattro tandem mass spectrometer The *length of 70 μM i.d., 0.53 mm o.d. deactivated fused silica capillary tubing is 0.75-1 meter. Sample is delivered to* a redesigned dynamic probe tip incorporating a filter paper wick. Our previous work (ASMS '92) was with a mesh screen probe. Problems with flow interruption at the mesh screen surface were overcome with this new design. This tip also uses a septum at closer proximity to an angular tip. A VG QUATTRO triple quadrupole with Lab-base data system was used with a cesium ion gun operated at 10 Kev. Argon was used as the collision gas. Samples were injected every 2 minutes and a neutral loss scan of 102 (scan time=3 sec.) continuously acquired for up to 60 minutes. Six summed baseline scans were subtracted from 6 summed scans over the peak top. The resulting mass spectra were smoothed.

Fifty six normal patient samples and 2 disease controls (PKU (hyperphenylalanemia) and MSUD (hyperleucinemia) and 2 blanks (unspotted filter paper) were analyzed. A Total Ion Elution Profile for a dynamic LSIMS/MS analysis of 60 samples is presented in *Figure 1*. *Figure 2a-f* are NTL 102 mass spectra of patients with normal amino acid profiles and patients with PKU and MSUD.

As is observed in Figure 1, peak shapes were adequately resolved for the first hours. An increase in baseline occurred during the 2nd hour. To insure that one sample spectra does not interfere with the next sample spectra, baseline subtraction to the left the peak top was performed. The adequacy of this procedure is demonstrated in Figures 2a-f, where the high phenylalanine in the PKU patient or high leucine in the MSUD patient did not carry over into the next normal patient sample. Improvements are needed to keep the dynamic LSIMS/MS system optimal for at least an entire rack of 60 (2 hours). We are working to extend this to about 240 samples per day per instrument (240 samples at a rate of 1 sample / 2 minutes = 8 hours). The design of the probe, especially the wick (absorbent material) appears to be important to background contamination. This is probably due to glycerol accumulation which reduces absorbancy. The automated sample preparation procedure described above currently takes approximately 3-4 hours to prepare a rack of 60 samples. The time for each sample analyzed is 2 minutes. The sample preparation procedure will be upgraded to prepare two racks simultaneously (120 samples) in the same time period with the same equipment. The results presented here are the first applications of automated preparation and automated analysis of amino acids in neonatal blood spots using robotic equipment and LSI-MS/MS. The versatility of the method will ultimately enable simultaneous analysis of acylcarnitine and amino acids in the same sample.

Structure Determination of Metabolites from the Neuroleptic Drug Haloperidol using Ion Trap MS^n

K.A.Veverka, G.F.Scanlan, L.M.Benson, K.L.Johnson, A.J.Tomlinson and S.Naylor

Biomedical Mass Spectrometry Facility, Dept. of Biochemistry and Molecular Biology and Dept. of Pharmacology, Mayo Clinic, Rochester, MN 55905, USA

The structural diversity of modern therapeutic drugs is well documented. However, after entry into the body such compounds are subjected to a series of complex metabolic processes including absorption, distribution, metabolic transformation and excretion. These events modulate the efficacy of the drug in the treatment of disease, as well as determining its pharmacological and toxicological effects, and structural characterisation of resulting metabolites is vitally important to understanding the physical and biological effects of the parent drug.

In this work we used the unique capabilities of the quadrupole ion trap (Finnigan MAT ITMS) to investigate the *in vitro* guinea pig microsomal metabolism of the neuroleptic agent haloperidol. By utilising the ability of the trap to capture and hold ions it is possible to trap all components of a metabolite mixture and then sequentially sweep out component ions, leaving only a specific metabolite in the trap. Such precursor (MH^+) ions remaining in the trap can then be subjected to MS^n experiments in order to acquire structural information.

We demonstrated this for a mixture of haloperidol and five synthetic standards, as well as for a guinea pig microsomal extract. Furthermore, we found five metabolites by using this metabolite mapping technique, namely CPHP (MH^+=212),RHAL (MH^+=378), HP^+(M^+=358), HTPNO ([MH-O]$^+$=358) and an N-oxide ([MH-O]$^+$=376) and this is shown in Figure 1.

Regioselective analysis of hydroxyeicosatetraenoate in phosphatidylcholines by LSI/MS/MS

*Ji Y. Zhang[1], Brian Nobes[1], Jiemin Wang[1] and Ian. A. Blair[1,2]. Department of Pharmacology[1] and Chemistry[2], Vanderbilt University, Nashville, TN 37232

The hydroxyeicosatetraenoic acids (HETEs) are biologically active eicosanoids derived from arachidonic acid. Three different isomeric compounds, 5(S)-, 12(S)-, and 15(S)-HETE can be formed via different specific lipoxygenase pathways. All three HETEs are incorporated into membrane phospholipids in a wide range of cell types (1). HETE containing phospholipids are lipids peroxidation products (2). Fast atom bombardment mass spectrometry (FAB-MS) and FAB-collision-induced dissociation tandem mass spectrometry (FAB-CID-MS/MS) techniques have been successfully used to characterize the structures of phospholipids. The present study reports a liquid secondary ion tandem mass spectrometric (LSI/MS/MS) method for the qualitative analysis of intact phosphatidylcholines containing HETE moieties.

The esterification of 5-, 12-, and 15-HETE (50 μg) to lysophosphatidylcholine (100 μg) was carried out in 1 ml of 125 mM Tris-HCl buffer (pH, 7.4) containing 2 mM $MgCl_2$ in the presence of coenzyme A (300 μg), ATP (4.4 mg) and rat liver microsome fractions (1.2 mg of protein/ml). The incubation was performed for 1 hr at 37 °C under nitrogen. After the incubation, the lipids were extracted with $CHCl_3/CH_3OH$/acetic acid (2/1/0.05, v/v/v) and then purified using HPLC. Phospholipids containing esterified HETEs were initially separated by normal-phase HPLC and reverse-phase HPLC as described below. Normal-phase HPLC was carried out using an Econosphere silica analytical column (3 μm, 4.6 x 100 mm, Alltech). The mobile phase consisted of a gradient of 70% solvent A (hexane/isopropanol, 3/4, v/v) and 30% solvent B (hexane/isopropanol/water, 4/6/1, v/v/v) held for 20 min then programmed linearly to 100% solvent B over 20 min. The solvent flow rate was 1 ml/min. The esterified HETE-phosphatidylcholines were collected and further purified by reverse-phase HPLC. Reverse-phase HPLC purification was performed using an Ultrasphere ODS analytical column (5 μm, 4.6 x 250 mm, Beckman). The column was eluted by a gradient from methanol/acetonitrile/water (910/40/50; v/v/v) containing 1 mM ammonium trifluoroacetate to methanol/acetonitrile/water (910/80/10; v/v/v) containing 1 mM ammonium trifluoroacetate over 60 min at rate of 2 ml/min. The UV absorbance was monitored at 235 nm.

Collision-induced dissociation (CID) mass spectra of individual HETEs and PCs containing HETEs were obtained from approximately 200 ng of material, which was dissolved in 5 μl DMSO, and placed on a liquid secondary ion (LSI) probe of a Kratos Concept four sector mass spectrometer. Negative ions were produced using triethanolamine as the liquid matrix. Cs^+ ions were accelerated to 2 kV. Argon was used as the collision gas at a pressure of 5 x 10^{-5} Torr. The collision energy was 4 kV. Precursor and product ion spectra were obtained using a Sun data system.

Characterization of phosphatidylcholines (PC) which containing HETEs at the C-2 position was carried out using positive and negative LSI tandem mass spectrometry. In contrast to the positive LSI spectra of these compounds which primarily give a pseudo-molecular ion at m/z 827, more structural information was achieved from their negative LSI spectra. An intense ion at m/z 811 was produced by a loss of CH_3 from the molecular ion. Major ions at m/z 283 and m/z 319 corresponded to carboxylate anions of fatty acids, stearate and a HETE substituent were also observed (Figure 1a). The CID of HETE species yielded fragment ions which indicated the positions of the hydroxyl groups at

HETE molecules. For example, CID of the m/z 319 from 5-HETE-PC produced fragment ions at m/z 115 and m/z 203, which were produced from a four ring rearrangement cleavage and an α-cleavage of a hydroxyl group, respectively. This clearly indicated a hydroxyl group at C-5 position (Figure 1b). For 12-HETE-PC and 15-HETE-PC, their CID spectra of the m/z 319 showed unique ions at m/z 179 and m/z 208, as well as m/z 219 and m/z 248, demonstrating the presence of hydroxyl groups at C-12 and C-15 positions, respectively.

In summary, a direct analysis of the PCs containing HETE molecular species using negative LSI/MS/MS has been developed. This technique allows important structural information of phospholipids containing HETEs to be obtained. This will contribute to the understanding of their mechanism of formation and their physiological significance.

EI, CI and FAB Mass Spectral Characterization and Identification of Noberastine Metabolites

W. N. Wu, J. A. Masucci, A. D. Gauthier, A. J. Streeter, P. L. Stahle, and P. N. Lucas
The R. W. Johnson Pharmaceutcal Research Institute, Spring House, PA 19477

INTRODUCTION: Noberastine (RWJ-27572) is currently being developed as a potential antihistamine agent for seasonal allergic rhinitis. The objectives of the present study were to profile, isolate, and identify noberastine metabolites in dog samples using TLC, HPLC, MS and NMR.

METHODS: Representative samples of plasma (0-24 h), urine (0-48 h) and feces (0-48 h) obtained from the dog (10 mg/kg dose) were pooled and purified for metabolite profiling, isolation and identification. Individual metabolite was isolated using peak collection method. All metabolites were characterized and identified by desorption CI (methane), EI and FAB (thioglycerol) mass spectrometry, and confirmed by NMR. Some of metabolites were further derivatized using diazomethane, and confirmed by MS. Chemical ionization and electron impact were obtained using a VG 7070E. Operating conditions for spectrometer included: Source temperature: 220 degree C; Reagent gas pressure: 2 torr; Ionization potential: 70 eV; Multiplier voltage: 1.8 KeV; Electrometer setting: 10^{-7}A/V; Mass ranges: 18-1000 m/z at 1 sec/decade; Sample inlet: Desorption probe; Sample size: 5 microliter. Fast atom bombardment spectra were recorded using a VG 7070E mass spectrometer. Operation conditions included: Source temperature: 25 degree C; Source type: Ion tech.saddle field design with agron gas at 8 KeV potential and 1 mA current; Multiple voltage: 1.8 KeV; Electrometer setting: 10^{-7}A/V; Mass range: 18-1000 m/z at sec/decade; Sample matrix: 5 microliter; Sample size: 2 microliter.

RESULTS: Approximately 86% of the dose excreted in the urine (48.4%) and feces (37.5%) in the eight days after oral administration of 14C-noberastine. TLC and HPLC metabolic profiles of the plasma, urine and fecal extract samples were obtained. Unchanged noberastine plus ten metabolites were isolated and identified from these samples. Unchanged noberastine accounted for <32% of the dose in excreta samples and >63% of the total 14C in plasma at 0-24 h pool after dosing 14C-noberastine. Identified noberastine and metabolites accounted for >75% of the total 14C in the plasma, urine and fecal samples. MS and NMR spectra of noberastine and representative metabolites are presented.

CONCLUSION: Biotransformation pathways for noberastine in the dog are depicted. Noberastine was substantially metabolized in the dog, and >50% of the dose excreted in urine and feces was represented by metabolites. FAB-MS, CI-MS and EI-MS analysis of the isolated noberastine and metabolites revealed apparent protonated molecular/molecular ions and prominent fragment ions for the structural elucidation of metabolites.

NEGATIVE-ION FAST ATOM BOMBARDMENT / COLLISION-INDUCED DISSOCIATION MASS SPECTROMETRY IN THE STUDY OF URSODEOXYCHOLIC ACID METABOLISM IN MAN

W.J.Griffiths, J.Zhang and J.Sjövall. Department of Physiological Chemistry, Karolinska Institute, S-10401 Stockholm, Sweden.
H-U.Marschall, H.Matern and S.Matern. Department of Internal Medicine III, Aachen University of Technology, D-5100 Aachen, Germany.

Ursodeoxycholic acid (UDCA) is used as a drug in the treatment of cholestatic liver disease. In the present study (24-^{13}C) labeled UDCA has been given to patiets with cholestatis. Their urine has been collected and the lipid content extracted by use of a Sep-Pak C_{18} column. The extract was analysed by negative-ion FABMS. A representative spectrum is shown in fig. 1. It is extremly complex as a result of the presence of steroids, fatty acids and bile acids.

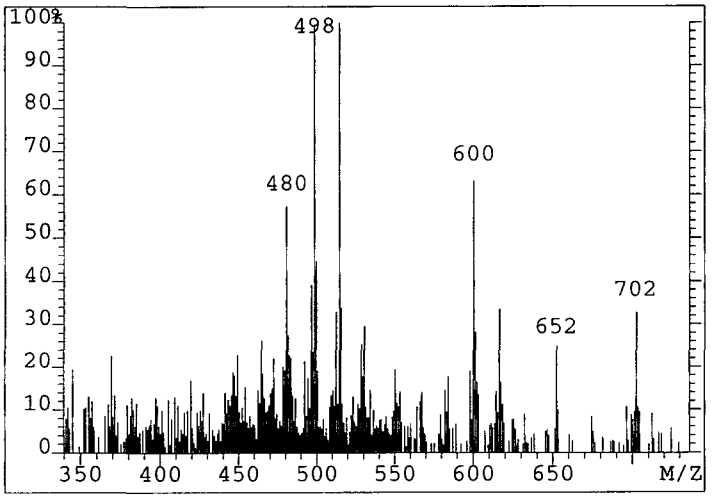

Fig. 1. Negative-ion FABMS of Sep-Pak C_{18} extracts.

To simplify matters the extracts were subjected to ion-exchange chromatography on a Lipidex-DEAP column. The resultant fractions, (1.neutrals and sterols, 2.unconjugated bile acids, 3.glycine conjugates, 4.taurine conjugates, 5.glucuronides, 6.sulphates) were then analysed by FABMS. Intense peaks at m/z 595 Da, 652 Da and 702 Da were observed in the unconjugated, glycine- and taurine- conjugate fractions respectively. These molecular weights are characteristic of the $(M-H)^-$ pseudomolecular ions of the unconjugated, the glycine and the taurine conjugated forms of (24-^{13}C) labeled N-acetylglucosaminyl-ursodeoxycholic acid.

Although FAB spectra give information as to the molecular weight of the bile acids, little information as to their structure is forthcoming. To obtain this, CID spectra are recorded on the $(M-H)^-$ pseudomolecular ions. It has been shown that taurine conjugated bile acid $(M-H)^-$ ions give intense charge-remote fragmentation (CRF) patterns which are of much value in structure elucidations[1]. The CID spectrum of the pseudomolecular ion at m/z 702 Da is shown in fig. 2. From the CRF pattern the ion structure is determined to be (24-^{13}C) labeled (7-N-acetylglucosaminyl)-ursodeoxycholyl-taurine.

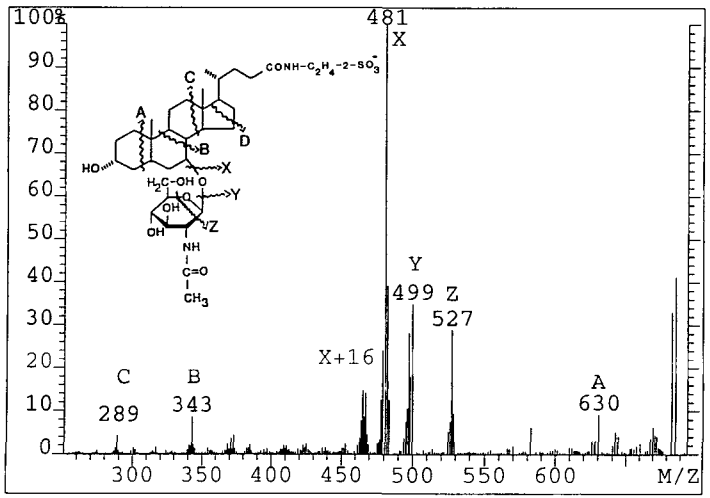

Fig. 2. Negative-ion FAB/CID spectrum of the ion at m/z 702 Da.

Unconjugated and glycine-conjugated bile acids give much less informative CID spectra than the taurine conjugates. To increase the structural information available these chromatographic fractions were derivatized with taurine (2-aminoethanesulphonic acid) using a recently developed rapid and simple method[2]. The derivatives formed were then analysed by negative-ion FAB/CID. In this way it has been established that the position of sugar conjugation in the novel bile acids conjugates N-acetylglucosaminyl-UDCA, and N-acetylglucosaminyl-UDC-glycine is at position 7β.

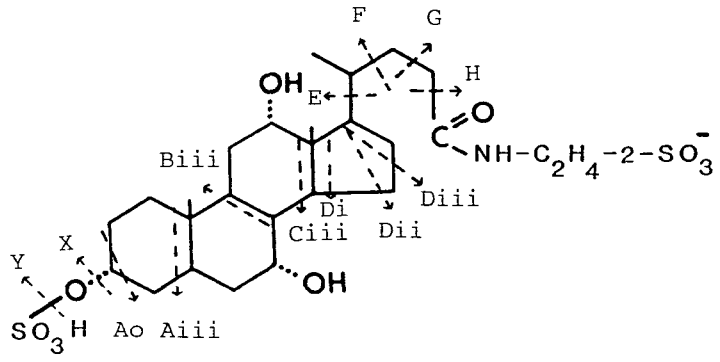
CHARGE-REMOTE FRAGMENTATION OF DOUBLY CONJUGATED BILE ACIDS

William J. Griffiths*, Jie Zhang, and Jan Sjövall. Department of Physiological Chemistry, Karolinska Institute, Box 60400, S-10401 Stockholm, Sweden.

Negative-ion fast atom bombardment mass spectra (FABMS) of bile acids show prominent $(M-H)^-$ pseudomolecular ions, and few fragment ions. Collision-induced dissociation (CID) of such pseudomolecular ions give charge-remote fragmentations (CRF) which are useful in structural identifications. It has been shown that taurine (2-aminoethanesulphonic acid) conjugated bile acids give more intense and informative CID spectra than unconjugated or other aminated bile acids. In this laboratory a procedure for the aminosulphation of biological samples for analysis by mass spectrometry has been developed. In the present study a comparision has been made of the CID spectra of a series of sulphated and glucuronidated bile acids and their 2-aminoethanesulphonate derivatives. Shown in figures 1 and 2 are CID spectra of the taurine derivatized forms of the 3-sulpho and 3-glucuronidyl choloic acid. CRF are prominent, and define the position of hydroxyl and conjugating groups. The structure of 3-sulphocholyltaurine is shown below. When charge is retained at the taurine SO_3^- group fragmentations are defined by capital letters. When charge is retained at the sulphate SO_3^- group small letters define the fragmentations. A similar notation is used for the fragmentation glucuronidated bile acid.



FABMS profiles of human urine reveal that bile acid-glucuronides and -sulphates are often found conjugated to glycine or taurine. Glucuronate and sulphate fractions from human urine have also been analysed CID mass spectrometry and the position of conjugation determined.

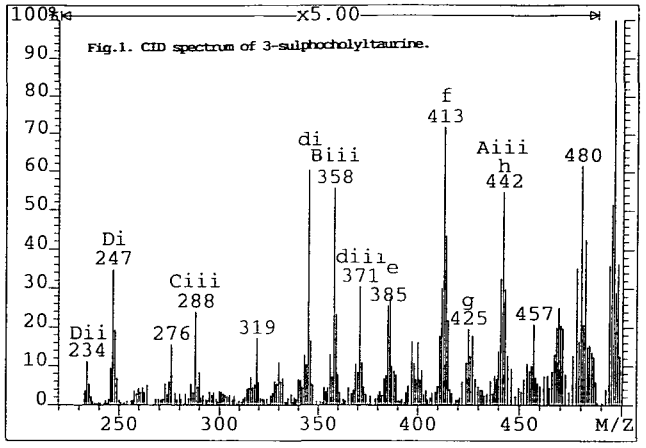


Fig.2. CID spectrum of 3-(glucuronidyltaurine)-cholyltaurine.

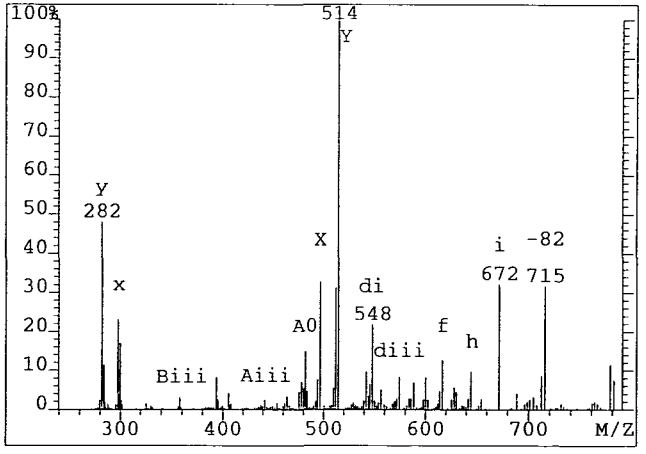
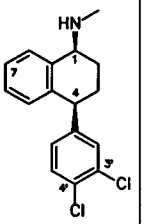


Mass Spectrometry of Sertraline and Related Compounds

Thomas R. Sharp, George J. Horan and Stephen V.O. Day
Analytical R&D, Central Research, Pfizer Inc., Groton, CT 06340 U.S.A.

The antidepressant drug substance sertraline -- 4-(3,4-dichlorophenyl)-N-methyltetrahydronaphthyl-1-amine -- was approved for use in the United Kingdom in 1990 and in the U.S. in late 1991. The hydrochloride salt is marketed under the trade names Lustral® (U.K.) and Zoloft® (U.S.). It is a selective serotonin reuptake inhibitor, departing from the therapeutic line of the tricyclic antidepressants and monoamine oxidase inhibitors.



The EI mass spectrum of sertraline is shown in Figure 1. No M^+ is observed, even at low ionization energies. Neutral loss of methylamine produces a base peak equivalent to the dihydronaphthalene. Many of the smaller fragments are those of this related compound, suggesting that the mass spectrum of sertraline is principally the mass spectrum of its primary fragmentation product. The chemical ionization (CI) and fast atom bombardment (FAB) behavior of sertraline are shown in Figures 2 and 3.

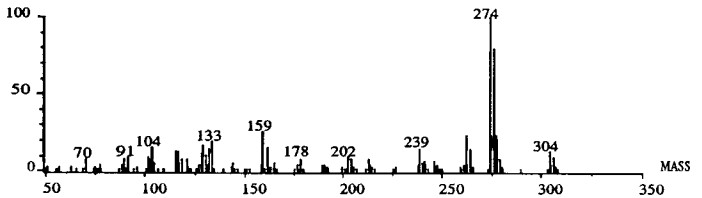


Figure 1: EI mass spectrum of sertraline.

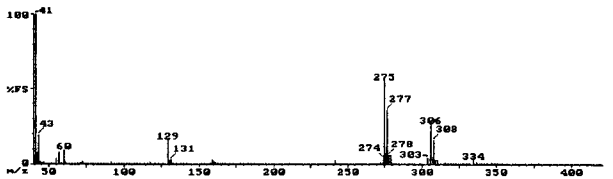

Figure 2: Methane CI mass spectrum of sertraline

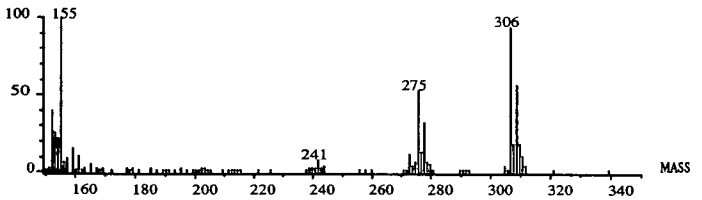

Figure 3: FAB mass spectrum of sertraline

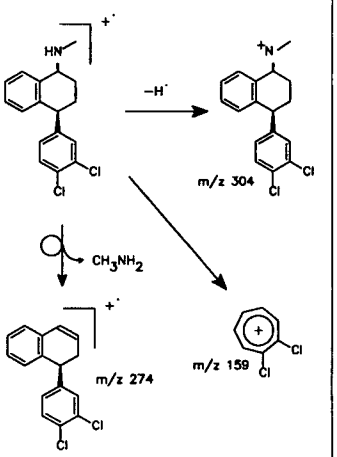
The absence of an M^+ in the EI spectrum is characteristic of all analogs which possess at least one active hydrogen attached to the nitrogen. Replacement of all active hydrogens with alkyl groups stabilizes the M^+ to an observable level. Substitution at position 7 with an OH or OCH_3 also increases the abundance of M^+. Introduction of a double bond, converting the tetrahydronaphthalene ring to a dihydronaphthalene, also stabilizes the $M^{+\cdot}$ so that it is observable. Complete aromatization produces a spectrum typical of a polycyclic aromatic hydrocarbon or a biphenyl, consisting primarily of the intense M^+.



Orientation of the amine group at position 1 with respect to the phenyl group at position 4 does not influence fragmentation, provided that protons are attached to carbons 1 and 4. When a group such as an alkyl or hydroxyl group is attached to carbon 4, the fragmentation changes dramatically. Neutral loss of alkylamine no longer occurs, and is replaced by neutral loss of the appropriately substituted benzene ($M\text{-}Bz^+$ in Table 1). Further, the *cis-trans* orientation of the alkylamine and substituted phenyl ring determines whether $M\text{-}Bz^+$ is the base peak or if it further fragments by loss of 29 daltons (-29 in Table 1).

The methane CI spectrum of sertraline (Figure 2) shows marked sensitivity to reagent gas pressure. EI fragments at m/z 159 and m/z 174 disappear from the spectrum as the reagent gas pressure is increased, the m/z 174 EI-induced methylamine neutral loss being replaced by methylamine neutral loss from $[M+H]^+$ to form the species at m/z 175. The $[M+C_2H_5]^+$ adduct is present at m/z 334 FAB fragmentation echos the true CI fragmentation in that neutral loss of CH_3NH_2 occurs from $[M+H]^+$.

Table 1: EI Fragmentation Relative Abundances

			Substitution Pattern*						EI Fragments (rel. abundance)					
Compound	rmm	stereo	N	N	4	7	3'	4'	M^+	$M\text{-}H^+$	$M\text{-}R_2N^+$	$Trop^+$	$M\text{-}Bz^+$	-29

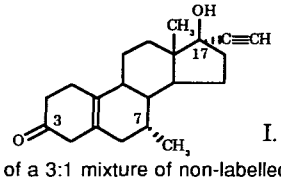
Fast Atom Bombardment Mass Spectrometry Using a Glycerol Matrix Saturated With a 3:1 Mixture Of Non-Labelled And Trideuterated Tetramethylammonium Hydroxide To Count The Number Of Anionic Sites

* P.L. Jacobs, G.J.H. Schmeits and M.P. de Vries.

AKZO, Organon International B.V., Scientific Development Group, P.O. Box 20, 5340 BH Oss, The Netherlands.

INTRODUCTION

A glycerol matrix saturated with tetramethylammonium hydroxide pentahydrate (TMAOH) was used to obtain FAB spectra of sulphated metabolites of the steroid Org OD 14 [1] in the presence of sodium acetate when glycerol failed. From the mass difference observed in the positive and negative ion spectra of these ion-pair complexes the number of sulphate groups present was calculated[1].



I. Org OD 14

We now report the use of a 3:1 mixture of non-labelled and trideuterated TMAOH in glycerol to produce characteristic artificial isotope patterns for the ion-pair complexes of anionic compounds in the positive ion FAB mode. These observed patterns allow the direct determination of the number of TMA-groups present and subsequently the calculation of both the (minimum) number of anionic sites and the molecular masses from the FAB(+) spectra only.

RESULTS AND DISCUSSIONS

Artificial isotope patterns obtained with this novel matrix of reference steroids with resp. one (Estrone 3-sulfate), two (Estradiol 3,17-disulfate) and three (Estriol trisulfate) anionic groups present are shown in Fig. 1 and the upper part of Fig. 2. The FAB(+) patterns of the ion-pair complexes of these steroids with resp. 2, 3 and 4 d_0/d_3-TMA counter-ions present can easily be distinguished. These patterns were used as reference patterns of mono-, di- and tri-anionic compounds and allowed the determination of the (minimum) number of anionic groups present in unknowns (sulfates, phosphates, glucuronides) as well as the calculation of their molecular masses. As an example the FAB(+) spectrum of 3, 17ß-disulfated Org OD 14 is shown in Fig. 3.

Both FAB(+) profile scans of ß-Estradiol 3-sulfate, 17-glucuronide (Fig. 2 bottom) and ß-Estradiol 3-glucuronide, 17-sulfate were recorded with this novel matrix to demonstrate that isotope patterns characteristic for di-anionic compounds could be obtained despite the low S/N ratio usually obtained for these compounds both with glycerol and TMAOH/glycerol[1]. Without the artificial isotope pattern the unambiguous determination of the molecular masses would not have been possible for these compounds with FAB(+) at the 10 µg level. The enrichment of the TMAOH/glycerol matrix with synthetically prepared d_3-TMAOH, and as a result the 3 Da spacing in the ion-pair clusters, still allowed the recognition of other isotopic contributions e.g. due to the presence of Br and Cl. It was furthermore observed that some compounds were -in part- methylated under these matrix conditions. In those cases a satellite isotope pattern was observed with a mass difference of 14 Da, the degree of methylation was usually <10%.

FIGURES

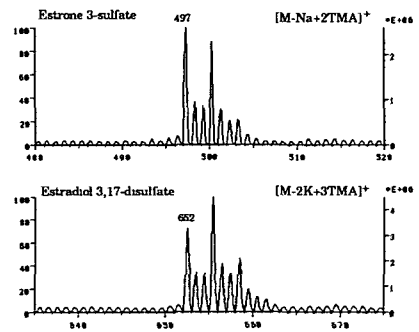

Fig. 1: FAB(+) spectra of Estrone 3-sulfate (upper) and Estradiol 3,17-disulfate (lower), obtained with a glycerol matrix saturated with d_0/d_3-TMAOH in a ratio of 3:1, showing the isotope pattern characteristic for the presence of 2 resp. 3 TMA groups.

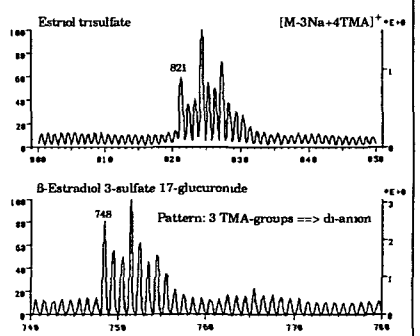

Fig. 2: FAB(+) spectrum of Estriol trisulfate (upper) showing the isotope pattern characteristic for the presence of 4 TMA-groups. The pattern observed for ß-Estradiol 3-sulfate 17-glucuronide (lower) clearly indicates the presence of 3 TMA groups.

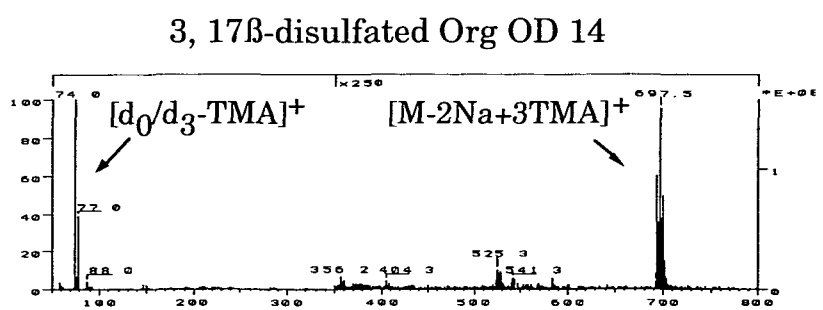

Fig. 3: FAB(+) scan of 3, 17ß-disulfated Org OD 14 showing both the d_0/d_3-TMA cations of the matrix (m/z 74/77) and the artificial TMA ion-pair pattern characteristic for a di-anionic complex.

GC-MS Analysis of Phenylacetic Acid Conjugates in the Rat Brain and Kidney *David A. Durden, Bruce A. Davis and Lillian E. Dyck, University of Saskatchewan, Saskatoon, SK. Canada S7N 0W0.

Phenylacetic acid (PAA), a normal metabolite of phenylalanine and the trace biogenic amine phenylethylamine, has been shown to be a neurotoxic agent damaging neurons and glia when injected into newborn rats and is abnormally excreted by patients with phenylketonuria. Phenylacetic acid is excreted by mammals as a variety of conjugates [1]: primates excrete PAA as phenylacetyl-glutamine (PAGln) whereas carnivores, rodents and other mammals excrete PAA as phenylacetyl-glycine (PAGly) and to a small extent as phenylacetyl-taurine. We have shown that in the rat brain 90% of PAA exists as a conjugate [2]. Neither free nor conjugated PAA levels were decreased by the MAO inhibitor pargyline but probenecid caused a slight increase in total PAA. These studies indicate that conjugates may regulate the amount of free PAA in the brain and thus control its toxic effects.

The conjugate in brain may be one of the excreted conjugates or another such as phenylacetyl-coenzyme A [3]. Since rodents excrete primarily PAGly we have attempted to quantitate it in both rat brain striatum and kidney using the ^{13}C labeled conjugate as internal standard. Several derivatives have been examined for their suitability for GC-MS analysis

Methods

The following derivatives were examined: trimethylsilyl (TMS), t-butyldimethylsilyl (TBDMS), pentafluorobenzyl (PFBz), trifluoroethyl (TFE), pentafluoro-n-propyl (PFnP), hexafluoro-isopropyl (HFIP) esters and these esters combined with the pentafluoropropionyl (PFP) or heptafluorobutyryl (HFB) amides

Tissues from 8 rats were pooled and homogenized in 7 ml of ice cold 2N HCl which contained 50 ng of PAA-d_5. The homogenate was centrifuged at 10,000 x g for 15 min at 4°C and six 1 ml aliquots were taken. Three aliquots were transfered to ampules which were then sealed and heated at 100°C for 4 hrs. After cooling these were transferred to test tubes. To each tube was added 90 ng of PAGly-$^{13}C_2$. The acids were extracted into ethyl acetate and the volume was reduced under a stream of nitrogen. The solutions were then transferred to Reactivials and the volume reduced to 100 µl and 100 µl of 1% triethylamine in benzene added and the solution taken to dryness. Pentafluoropropionic anhydride (50 µl) and trifluoroethanol (50 µl) were added and the sealed Reactivials heated at 80 °C for 1 hr. After cooling hexane (100 µl) and phosphate buffer (100 µl, pH 6.0) were added and mixed for 30 sec.The hexane layer was removed and transferred into a 100ml vial and the volume reduced to 20 ml.

Results

Tests of derivatives were carried out using PAGln and PAGly. PAGln is that it readily cyclizes under heat to form the pyroglutamate. The TMS and TBDMS derivatives decomposed on the GC column. The pentafluorobenzyl derivative gave good spectra for both PAGly and PAGln but the derivative of the latter had poor chromatographic properties. The EI spectra of all the derivatives using TFE, PFnP or HFIP and either PFP or HFB were

similar. The major fragment was m/z 91 and the highest mass ion was the M-91 fragment which had a low intensity. Reaction with PAGln gave many products including the derivatized cyclized product. Again the fragmentation is not very satisfactory.

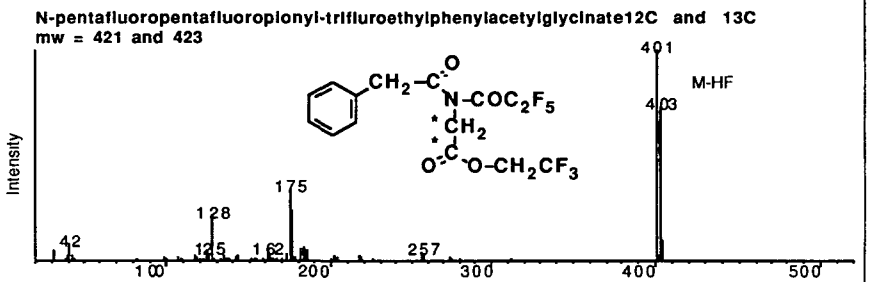

Fig.1 shows the NCI spectra of phenylacetyl-glycine. PAA-TFE exhibits a significant base peak at M-H. These ions were used for quantitation. Table 1. shows the effect of hydrolysis on PAA and PAGly in rat striatum and kidney It appears that in the kidney there is no contribution from another conjugate as the totals are similar. The amount of PAGly in the rat brain is considerable less than the amount of PAA normally measured after hydrolysis. This agrees with other observations [4] that incubation of brain homogenates with ^3H PAA did not synthesize radiolabelled PAGly and with Loo et al [3] that it is probably phenylacetyl-coenzyme A.

Table 1. Levels of phenylacetic acid and phenylacetylglycine in rat striatum and kidney.

	Striatum		Kidney	
	PAA (ng/g)	PAGly (ng/g)	PAA (ng/g)	PAGly (ng/g)
Normal	20	5.7 ±5	80.9 ± 8.1	840 ± 13.3
Hydrolyzed	31.1 ± 2.8	1.0 ± .9	716 ± 34	42.7 ± 6

Conclusions

The TFE-PFP derivative with NCI ionization is the most suitable procedure for analysis of PAA, phenylacetyl-glycine and phenylacetyl-glutamic acid. As expected phenylacetyl-glycine is the major conjugate of PAA in rat kidney and is readily hydrolysed. It appears from this data that the major conjugate of PAA in rat brain is not phenylacetyl-glycine.

Quantitative analysis of 11-hydroxy,8,9-epoxyeicosatrienoic acid from human umbilical venous endothelial cells (HUVECs) by GC/EC NCI MS

*Ji Y. Zhang[1], Chandra Prakash[1], Richard Hoover[3] and Ian. A. Blair[1,2]. Department of Pharmacology[1], Chemistry[2] and Pathology[3], Vanderbilt University, Nashville, TN 37232

Arachidonic acid is oxidized by the cytochrome P-450 monooxygenase to form four regioisomeric *cis*-epoxyeicosatrienoic acids (EETs). 8(S),9(R)-EET was a potent renal vasoconstrictor, but its activity was abolished by cyclooxygenase (COX) inhibitors (1). It was demonstrated that COX derived from human platelets or ram seminal vesicles metabolized 8,9-EET to 11(R)-hydroxy,8,9-EET (11-HEET) (2). 11(R),8(S),9(R)-HEET is a potent renal vasoconstrictor responsible for the vasoconstrictor activity caused by 8(S),9(R)-EET. In addition, both 11(R),8,9-EET enantiomers are potent mitogens for cultured rat glomerular mesangial cells (3). The present study examines the possibility that endothelial cells generate 11-HEET and convert 8,9-EET to 11-HEET. This study reports a sensitive GC/EC NCI mass spectrometric method to quantify 11-HEET in human umbilical venous endothelial cells (HUVECs).

HUVECs were cultured from human umbilical cord vessels. Confluent HUVEC monolayers were covered with 10 ml of 25 mM HEPES buffer, pH 7.4, containing 150 mM NaCl, 5 mM KCl, 1.8 mM $CaCl_2$, 1 mM $MgCl_2$, 6 mM glucose and substrate 1.5 µM 8,9-EET. The incubation mixture was kept for 4 hrs at 37 °C in an atmosphere of 5% CO_2 in air. In some experiments, cell culture was pretreated with indomethacin or stimulated with calcium ionophore. After incubation, the total lipids were extracted and further purified using HPLC. GC/EC NCI MS was carried out on a Nermag R1010C mass spectrometer using a 5 meter SPB-1 fused silica column (0.32 mm ID, 0.25 µm coating thickness; Supelco). The column was heated at 170 °C for 0.2 min then programmed to 260 °C at 20 °C/min. Methane was used as the reagent gas at a source pressure of $1x10^{-5}$ Torr. Helium was used as a carrier gas, and injection was made in the splitless mode.

A highly sensitive GC/EC NCI MS assay, based on the stable isotope dilution technique, was developed for the quantification of 11-HEET in HUVECs. [$^2H_4$]11-HEET was biosynthesized from [$^2H_4$]arachidonic acid and used as an internal standard. Derivatization of 11-HEET as a pentafluorobenzyl ester (PFB), t-butyldimethylsilyl ether (BDMS) allowed sensitive and specific analyses to be carried out. A 5 meter GC column was employed to avoid thermal degradation of the conjugated double bonds during GC analysis. The EC NCI mass spectrum of derivatized 11-HEET and its tetradeuterated analog showed intense ions at m/z 439 and m/z 443, respectively, which corresponded to a loss of the PFB group from the molecular ions. Quantitative analyses were carried out using SIM analysis of ions at m/z 439 and m/z 443. The limit of detection of the assay was 10 pg/sample with a coefficient of variation less than 10%. A typical selected ion current profile obtained for the analysis of 11-HEET in HUVECs is shown in Figure 1. The results showed that the level of endogenous 11-HEET in four HUVEC dishes were 158 ± 12 pg/$5x10^6$ cells. A dramatic increase of 11-HEET (17.83 ± 0.81 ng) in HUVECs was found when the cells were incubated with 5 µg of 8,9-EET. The formation of 11-HEET was increased in the presence of calcium ionophore and inhibited by indomethacin (Figure 2). These results strongly suggested that HUVEC COX can convert 8,9-EET into 11-HEET.

In summary, a sensitive GC/EC NCI mass spectrometric method to quantify 11-HEET in HUVECs has been established. The results demonstrated that human endothelial cells can convert 8,9-EET to 11-HEET, suggesting they may be involved in the transcellular metabolism of 8,9-EET *in vivo*. Further studies can now be carried out in different patient populations to explore a possible pathophysiological role for 11(R),8(S),9(R)-HEET.

MASS SPECTROMETRY-BASED STRATEGY FOR CHECKING ORIGINALITY OF METABOLITES IN BIOLOGICALLY ACTIVE FERMENTATION BROTHS

C. PONTHUS, JM. PEREILLO, C. PICARD
SANOFI RECHERCHE, 195, route d'Espagne, 31036 TOULOUSE CEDEX

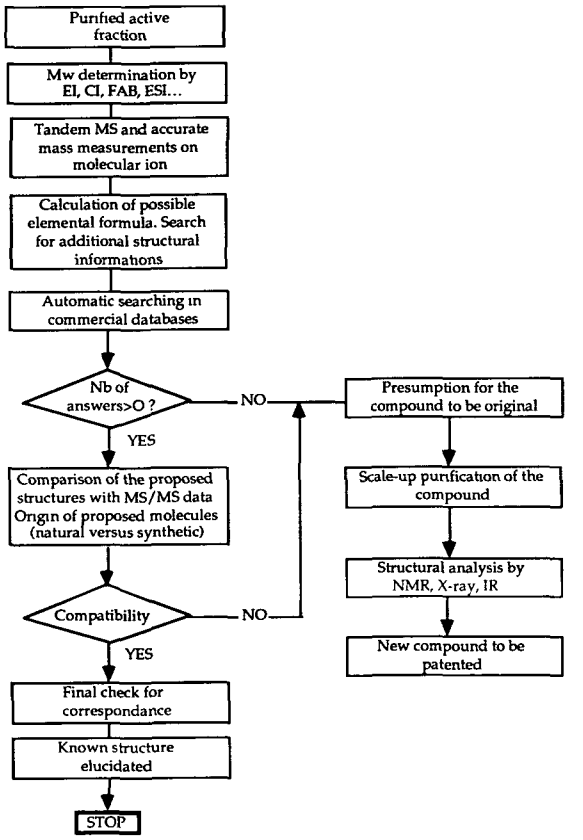
Two main different approaches are used in the pharmaceutical industry to find new, biologically active drugs. The most common one is to test chemically synthetized molecules. Another way is to screen complex mixtures such as fermentation broths from bacteria, moisture..., for activity. With this second approach, the probability is isolating an unknown structure, or family of compounds is quite low and is strongly dependant on (i) the originality of the micro-organism, (ii) the used culture medium, (iii) the relevance of the biochemical screening tests and (iv) the number of screened fractions.

However, the main problem encountered is to rapidly establish whether the active constituant(s) is original or not, even though the quantity of sample available at this early stage is very low (typically 10 to 100 µg).

That is the reason we developped a mass spectrometry-based strategy with the aim to check, as early as possible the originality of the active compound(s) before engaging time-consuming scale-up purifications.

The purified and tested fraction(s) is first analysed with various ionization techniques in order to determine the molecular weight of the compound. In a second step, accurate mass measurements and tandem mass spectrometry are performed on the molecular ion. The data obtained are then used as entry keys for automatic searching in commercial databases (mainly STN International).

Entry keys may be a logical combination of simple data such as possible elemental formula, detected elements in the structure like amico-acids or sugars etc... Assuming that all known structures are referenced in the Chemical Abstract database, an absence of answer form the automatic searching is then a strong presumption for the compound to be original. If answers are retrieved from the database, the spectra and the suggested structures are examined for compatibility of the experimental data with the proposed answers. Any additional information as for example the origin of the proposed molecule (synthetic *versus* natural) is also an item of importance. The following flowchart summarizes our approach :



Advantages of using mass spectrometry at the very beginning are its sensitivity and its ability to quickly provide some structural information, as well as possible elemental formula. Starting with an unknown sample, originality checking may, in effect, be completed within 48 hours. Using this strategy, only original compounds have to be prepared in mg-amounts necessary for the complementary but time-consuming structural analysis techniques such as NMR and X-Ray. Examples of compound identification are shown, illustrating the advantages of mass spectrometry as time-saving analytical tool for biologists working in the field of fermentation.

Characterization of 20-hydroxyeicosatetraenoic acid glucuronide by LSI/MS/MS

Yoshiharu Ohyama*[1], Ji Y.Zhang[1] and Ian A. Blair[1,2].
Department of Pharmacology[1] and Chemistry[2], Vanderbilt University, Nashville, TN 37232

Introduction

20-hydroxyeicosatetraenoic acid (20-HETE) is a major metabolite of arachidonic acid from cytochrome P-450 ω-hydroxylase in neutrophils and renal microsomes. 20-HETE is a potent vasoconstrictor and promotes sodium excretion. *In vitro* biosynthesis of 20-HETE from exogenous arachidonic acid by renal microsomes was increased during the development of hypertension in the SHR rat. This suggested a possible role for 20-HETE in blood pressure control. A highly sensitive method has been developed using gas chromatography/electron capture negative ion chemical ionization mass spectrometry for the quantification of 20-HETE in human urine. Using this method, in combination with β-glucuronidase treatment of human urine, 20-HETE was found to be excreted mainly as a glucuronide conjugate. The present study reports the use of LSI/MS/MS for the characterization of the site of glucuronidation of 20-HETE.

Experimental

20-HETE (20 μg), UDPGA (10 mg) and human liver microsomes (200 μl, 17mg protein/ml) in 1 ml of Tris-HCl buffer (pH 7.0) were incubated at 37 °C for 24 hr. The incubation was stopped by addition of 1 ml of ice-cold methanol. Samples were purified using C-18 Sep-pak and HPLC. Reverse-phase HPLC purification was performed using an Ultrasphere ODS analytical column (5 μm, 4.6 x 250 mm, Beckman). The mobile phase was programmed from 100 % solvent A (water/acetonitrile; 80:20, v/v) to 100 % solvent B (water/acetonitrile; 50:50, v/v) over 30 min at a rate of 1 ml/min, then held for another 20 min. Fractions containing radioactivity were collected and evaporated under nitrogen. LSI/MS/MS spectra were obtained using a Kratos Concept II HH (Kratos Analytical Ltd, Manchester, UK) four sector tandem mass spectrometer, which consists of two double-focusing forward geometry instruments (EBEB) that are interfaced to a Sun

computer system. The instrument was equipped with a commercial Kratos ion source. Negative ion data was obtained with Cs^+ gun at 4 kV and the accelerating voltage at 8 kV. The collision cell was floated at 4 kV. The argon gas pressure was 1.5×10^{-6} torr.

Results and Discussion

The negative LSI mass spectrum of 20-HETE glucuronide showed a deprotonated molecular ion at m/z 496. The collision-induced dissociation (CID) spectrum of m/z 496 is shown in Figure 1. Fragment ions at m/z 346, 319, 295, 247, 199, 159 and 87 are produced. The ion at m/z 346 was formed by the loss of {CH(OH)-CH(OH)-CH(OH)-CH(COOH)} from the glucuronic acid moiety of the molecular ion. A loss of glucuronic acid from the molecular ion generated an ion at m/z 319 $[M-175]^-$. The cleavage of the bond between C-16 and C-17 produced a fragment ion at m/z 247, which indicated that the glucuronic acid moiety was conjugated at the hydroxyl group. A loss of H_2O from the glucuronic acid moiety yielded the ion at m/z 159. The fragment ion at m/z 87 was formed from a cleavage between C-4 and C-5 bonds. The results indicated that negative ion LSI/MS/MS was a useful technique for characterizing the glucuronide derivative of 20-HETE.

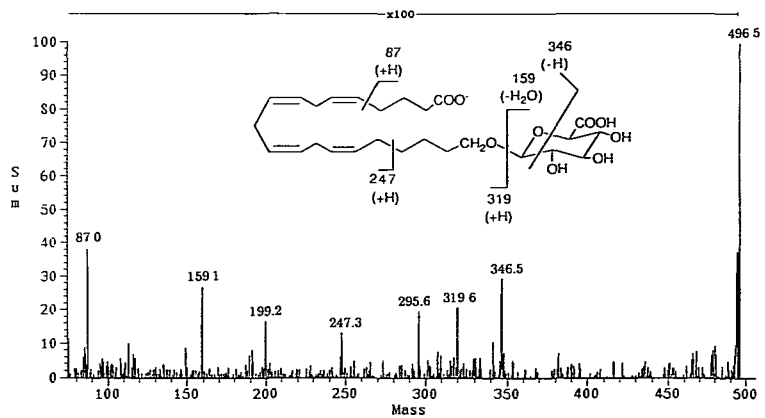


Figure 1. CID spectrum of negative LSI of m/z 496 from 20-HETE glucuronide.

A SINGLE ASSAY FOR THE DETERMINATION OF OXALIC, GLYCOLIC, GLYCERIC, GLYOXYLIC AND HYDROXYPYRUVIC ACIDS IN URINE BY POSITIVE ION CHEMICAL IONIZATION GC/MS

*Mark L.J. Reimer , Orval A. Mamer, E.Y. Osei-Twum, F. Lépine and J.A. Montgomery

Biomedical Mass Spectrometry Unit, McGill University, Montreal, Quebec, Canada H3A 1A3

Introduction. Primary hyperoxaluria encompasses two rare genetic diseases having in common the excretion of large quantities of oxalic acid. The two variants are distinguished by the elevated co-excretion of glycolic and glyoxylic acids (Type I hyperoxaluria) and hydroxypyruvic and glyceric acids (Type II). Ammonia positive ion chemical ionization (NH_3/CI) GC/MS has been used to determine the urinary concentrations of the trimethylsilyl (TMS) derivatives of all five organic acids in a single assay. The method involves the reduction of endogenous glyoxylic and hydroxypyruvic acids by sodium borodeuteride ($NaBD_4$) to ^{2}H-glycolic and ^{2}H-glyceric acids respectively, and these together with endogenous glycolic, oxalic and glyceric acids are quantitated against $^2H_2$-glycolic, $^{13}C_2$-oxalic and $^2H_2$-glyceric acids in a stable isotope dilution assay.

Materials and Sample Preparation. The labeled $^{13}C_2$-oxalate was purchased as the disodium salt from MSD Isotopes, Montreal. $^2H_2$-Glycolate and $^2H_2$-glycerate were prepared by the diazotization of $^2H_5$-glycine and DL-3,3-$^2H_2$-serine, also obtained from MSD Isotopes. Aliquots of urine (1 ml) were made basic (pH>12) with 5N NaOH. To these were added 25 μl of an aqueous standard solution containing 0.25 mg/ml $^2H_2$-glycolic acid, 13.4 mg/ml $^{13}C_2$-oxalic acid and 0.21 mg/ml $^2H_2$-glyceric acid. $NaBD_4$ (2 mg) was added and the resulting solutions were heated at 50°C for 10 min, cooled to room temperature, and extracted with 2 ml of diethyl ether (extract discarded). The aqueous phases were acidified with 2N HCl, saturated with NaCl, and extracted three times with 2-ml volumes of ether. The extracts were combined, dehydrated with anhydrous Na_2SO_4, and concentrated to 1 ml, of which approximately 300 μl was evaporated to dryness in a conical autoinjector vial. Trimethylsilyl derivatives were made by dissolution in 100 μl of a 1:1 mixture of N,O-bis-trimethylsilylacetamide and pyridine.

Instrumental. GC/MS analyses were performed using an HP 5890A gas chromatograph coupled directly to an HP 5988A quadrupole mass spectrometer. Samples were introduced by splitless injection (1.0 μl) onto a fused silica DB-1 capillary column (30 m x .25mm; 0.25 μm) heated from 80 to 160°C at 5°C/min. Ammonia CI spectra were obtained at a source temperature of 200°C and at a source pressure of 0.70 Torr. Selected ion monitoring (SIM) of the $[M+NH_4]^+$ ions for glycolic-$(TMS)_2$ (m/z 238), ^{2}H-glycolic-$(TMS)_2$ (m/z 239), $^2H_2$-glycolic-$(TMS)_2$ (m/z 240), oxalic-$(TMS)_2$ (m/z 252), $^{13}C_2$-oxalic-$(TMS)_2$ (m/z 254), glyceric-$(TMS)_3$ (m/z 340), ^{2}H-glyceric-$(TMS)_3$ (m/z 341), and $^2H_2$-glyceric-$(TMS)_3$ (m/z 342) acids were used for quantitation.

Results. Acid concentrations were calculated using a BASIC program that corrects raw SIM areas for isotopic impurities in the internal standards and for natural heavy isotope substitution in labeled and endogenous acids. Table 1 shows the acid concentrations (expressed relative to creatinine levels) for patients A, T and M, who are thought to have an oxalic aciduria; the values for two controls (O and L) and published normals are also shown.

Table 1. Urinary Oxalic, Glycolic, Glyoxylic, Glyceric and Hydroxypyruvic Acid Concentrations in Three Patients and Two Controls.

	Acid Concentrations (mg/g creatinine)				
Patient	Oxalic	Glycolic	Glyoxylic	Glyceric	Hydroxypyruvic
A	1192.1	72.2	6.8	1004.8	8.3
T	243.4	22.0	0.4	289.4	2.3
M	289.1	80.8	1.2	2039.0	15.8
O	172.0	24.4	1.2	46.6	0.02
L	51.5	22.4	0.4	109.7	0.01
Normals[a]	10-40	22-69	1.4-4.7	ND	U

[a]published normals (mg/day); ND = not detected in normals; U = previously undetermined.

Patient A excretes large amounts of oxalic and glyceric acids, suggesting a Type II oxalic aciduria. Patient T excretes lesser amounts of the acids of interest than A and may represent a Type II in remission or with a less severe deficiency of D-glyceric acid dehydrogenase activity. Patient M, also a Type II, excretes lesser amounts of oxalate than A, but much larger amounts of glycerate and hydroxypyruvate. Control O is remarkable only by its elevated level of oxalate, which is probably attributable to a daily consumption of 1 g. of ascorbic acid The four other acids are in accord with those of control L.

Discussion. The $NaBD_4$ reduction of the α-carbonyl functions in urinary glyoxylate and hydroxypyruvate to 2-^{2}H-glycolate and 2-^{2}H-glycerate respectively allows the analysis of all five acids to proceeed with comparable stabilities and extraction efficiencies. The glyoxylate-to-glycolate reduction may minimize losses of this reactive aldehyde arising from condensation with other urinary constituents; early reduction may also avoid similar losses of hydroxypyruvate, a significant problem because of enolic tautomerism between the keto and hydroxy functions. The method exhibits a high degree of precision as shown in six replicate analyses (%SD): glycolate, 1.1%; glyoxylate, 3.7%; oxalate, 1.0%; glycerate, 0.6%; hydroxypyruvate, 7.5%.

USDA/ARS Children's Nutrition Research Center, Dept. of Pediatrics,
Baylor College of Medicine, Houston, TX 77030

Introduction

Organic molecules with strong electron capture ability give simple negative chemical ionization mass spectra (NCI-MS), but limited structural information. The chief advantage of NCI-MS is the superb analytical sensitivity of some molecular structures. We have used the n-propyl ester, N-heptafluorobutyramide derivatives of amino acids to quantify protein synthesis and turnover in humans (1, 2). This derivative is easy to prepare, it is chemically stable, and it has excellent gas chromatographic separation of nearly all amino acids. In the course of conducting stable isotopic tracer studies of serine and glycine metabolism, we observed a substantial variability in ion production from some amino acids, but not others This variability was due to ion source temperature, as described below.

Methods

The PrHFB derivatives were prepared from a commercial amino acid standard containing 2.5 µmole of each amino acid. The NCI mass spectra were determined using either a Hewlett-Packard HP-5988A or HP-5989A GC/MS. Spectra were recorded near the optimum methane source pressure of 0.65 torr (HP-5988A) or 1.3 torr (HP-5989A), and at 25 °C increments from 100 °C to 300 °C. Ion source pressure strongly influenced sensitivity, but not the fragmentation pattern. The instruments were tuned at the beginning of each day, and only the ion source temperature was changed during the measurements. The samples were chromatographed on a 30 m x 0.32 mm DB-5ms capillary column using a temperature program from 80 - 220 °C at 10 °C/min. About 6.25 pmole of each AA was injected on-column. Spectra were recorded from m/z 100 - 650, at 3 scans/second.

Results

AA derivatives with two HFB groups (Thr, Ser, Lys, Tyr) gave 5-7 times stronger total ion current than AA with a single HFB. At low ion source temperatures (<150 °C), the major ion in most spectra was the $[M - HF]^-$ ion. At higher temperatures, the major fragmentation pathways involved sequential loss of up to 5 HF. Hydroxy AA (Thr, Ser, Tyr) generally produced more complex spectra than other AA, and were more thermally unstable (Figure 1). Hydrophobic and acidic amino acids (Ala, Gly, Leu, Ile, Phe, Asp, Glu) showed the least tendency to dissociate, even at 300 °C (Figure 2) At 300 °C, fragmentation was observed in all amino acids due to sequential loss of HF, loss of propanol, and various C-C fragmentation processes. Although these fragmentation processes may be useful for determining structure, the apparent sensitivity of NCI spectra to temperature may explain sporadic reports in the literature of erratic quantitative behavior. Moreover, selective fragmentation may be useful in quantitative work to distinguish between isotopomers present in different positions in a molecule.

Interfering Substances in the Gas Chromatographic Analysis of Diamines in Seafood

Edward L.E. Jester, Don E. Mowdy, Anthony M. Guarino, and
F. Aladar Bencsath, Gulf Coast Seafood Laboratory,
Food and Drug Administration, Dauphin Island, AL 36528

The α,ω-diamines cadaverine and putrescine are naturally occurring microbial spoilage products in food of animal origin, and used as indicators of decomposition in seafood.

Traditionally, a gas chromatographic procedure has been used with a packed column and a nitrogen/phosphorus specific detector (NPD) to analyze these diamines in fishery products [1]. The dried and re-dissolved pentafluoropropionylated fish extract is purified by passing it through an AL_2O_3-column and concentrated prior to gas chromatography (GC). The two time-consuming solvent evaporating steps can be omitted and the sample preparation process shortened if the more sensitive electron capture detector (ECD) is used instead of the NPD [2].

93 fish-samples (ground scallop, ground cod, and american plaice) were analyzed using this simplified procedure. Some of the ECD chromatograms showed serious interferences that normally were not seen in the NPD chromatograms. The corresponding samples were re-analyzed using the original procedure with the NPD, and they were also analyzed with capillary GC/MS using electron ionization, and positive and negative chemical ionization. A dozen peaks appeared in the GC/MS chromatograms in the time domain of the relevant diamine-peaks, and most of the eluting components could be identified such as fluoroacylated histamine, hydroxy-methylphenol, di-t.butyl-cresol, di-t.butyl-quinone, and benzthiazol derivatives. All these components were well resolved by the GC capillary. No interference was observed on the mass chromatograms obtained for the molecular ions and several intense fragment ions of the diamines. The results of the quantitative estimations using the protonated molecular ion traces (positive CI) agreed well with those computed from the NPD-chromatograms.

Thus, in order to maintain the high specificity of the analysis, a capillary column should be used with the electron capture detection.

VERIFICATION OF LEWISITE EXPOSURE: QUANTIFICATION OF CHLOROVINYLARSONOUS ACID IN BIOLOGICAL SAMPLES

E.M. Jakubowski, J.R. Smith, T.P. Logan, N. Wiltshire, C.L. Woodard, R.A. Evans, and T.W. Dolzine

US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD, 21010-5425.

Lewisite (dichloro-2-chlorovinylarsine)is a chemical warfare agent that is capable of causing blisters, immediate pain, and almost immediate systemic arsenic poisoning.[1] Since arsenic can be found in a variety of agricultural chemicals and natural sources,[2] assaying for elemental arsenic is non-specific. At least two metabolites in urine are predicted based on the chemistry of lewisite. The in vitro acid hydrolysis compound, 2-chlorovinylarsonous acid, $ClCH{=}CHAs(OH)_2$, is expected to be the primary metabolite. The polymeric base hydrolysis product of lewisite, 2-chlorovinylarsenious acid (lewisite oxide), $(ClCH{=}CHAsO)_n$, may also be present in trace amounts.[3,4] In general, arsonous acids and their related oxides react with 1,2-ethanedithiol to produce a substituted five-membered 1,3-dithio-2-arseno ring. This reaction can occur even in an aqueous environment. A similar derivatization method was shown to be of value in the analysis of environmental samples.[5] The derivatized lewisite is then analyzed by GC/MS using derivatized phenylarsine oxide (PAO) as the internal standard. The preservation of key structural components in the alkyl sidechain of the analyte make positive identification possible.

Human volunteer and guinea pig urine along with sheep and guinea pig plasma were spiked with CVAA. To 1.0 mL of spiked urine or serum phenyl arsonous oxide (PAO, 1000 ng/mL) was added as the internal standard. Addition of 1,2-ethanedithiol (3 μg/mL) was followed by extraction with toluene (3 x 0.3 mL). The combined extraction volume was reduced to near dryness and redissolved in 0.1 mL toluene. Injections of 1 μL were made onto a DB-5 Gas chromatographic column (20 m x 0.189 mm, 0.4 μm film thickness) using helium as the carrier gas at 33 cm/s. The temperature program was as follows: splitless injector 250°C, initial column temperature of 60°C (0.75 min) increased at 30°C/min, and a final temperature of 250°C (3.00 min). The purge off time was 0.75 min. Electron ionization based data was collected by a Hewlett-Packard model 5970B MSD in the selected ion mode using ions at m/z 107, 165, 167, 228, and 244. Initial assay development and MS/MS studies used a VG Quattro triple quadrapole MS/MS under EI and methane CI conditions.

Derivatization with 1,2-ethanedithiol was optimal when the reagent-to-analyte ratio (EDT/CVAA) was between 2 and 10. Derivatized CVAA had a retention time of 7.25 minutes while derivatized PAO appeared at 8.8 minutes as seen in Figure 1. The very small peaks at 6.97 minutes and 7.28 minutes represented the gem and cis isomers of CVAA, respectively. A huge excess of the dithiol reagent caused the formation of polymers that increased noise in the chromatogram. A dimer of EDT was also visible as a fourth peak in many of the full scan ion chromatograms but does not interfere in the quantitation of analyte or internal standard.

CVAA could be quantitated in urine and serum in the range of 20-

4000 ng/mL. The most remarkable aspect of the assay is the sample preparation and in particular the analyte derivatization. EDT is added directly to the urine or plasma/serum followed by extraction. The stability of CVAA in spiked human urine at room temperature was determined at pH 3.40, pH 6.10, pH 7.97, and pH 9.56. Results are reported for each isomer as a half-life in Table 1. According to this information a pH 6.10 solution would provide optimal stability. Normal human urine is in the range of pH 5 to pH 7 which should ensure adequate stability.

Table 1
CVAA Isomer Half-life versus pH in Spiked Human Urine (in hours)

pH	gem	cis	trans	total
3.40	11.3	32.0	19.1	19.0
6.10	27.9	16.2	41.6	42.5
7.97	5.62	4.09	3.74	3.22
9.56	2.50	1.04	0.767	0.820

Collision Induced Intramolecular Claisen Condensation In Triglyceride Negative Ions and Assignment of Positional Isomers.

*E. de Hoffmann, R. Rozenberg, E. Deffense# and V. Stroobant.
University of Louvain, Place Pasteur 1, 1348 Louvain-la-Neuve, Belgium.
#Fractionnement Tirtiaux, Chaussée de Charleroi 601, 6220 Fleurus, Belgium.

No mass spectrometric method allows up to now the non ambiguous assignment of the triglyceride positional isomers. Up to now the 2-position analysis via lipolysis remains the only method for determining the fatty acid in the 2-position. It can only be applied to isolated triglyceride or to natural fats, but not to blends, via the Van der Waal-Coleman theory of the 1,3-random distribution ([1]).

We report here a method that allows such a positional assignment through CID fragmentation of triglyceride negative ions at very low collision energy, typically 0.5 eV on Xe (Finnigan-MAT TSQ70). Figure 1 displays the fragment ions obtained by CID of the palmitic-oleic-stearic-triglyceride, abreviated POS, pseudo-molecular negative ion (m/z 859). The ions at m/z 255, 281 and 283 correspond to the three fatty acids, and allow the determination of their masses. The ions at m/z 475, 477 and 503 correspond to anions of ketones containing the hydrocarbon chain of two of the fatty acids and a carbonyl, minus a proton. Scheme 1 displays the proposed mechanism for their formation.

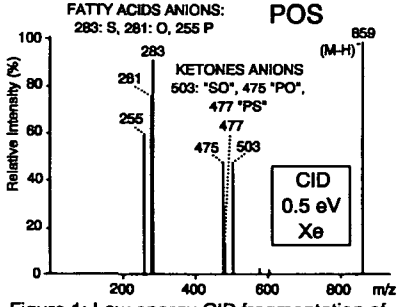

Figure 1: Low energy CID fragmentation of POS triglyceride [M-H]⁻anion. "XY" designate (ketones-H)⁻ containing the hydrocarbon chains of fatty acids X and Y.

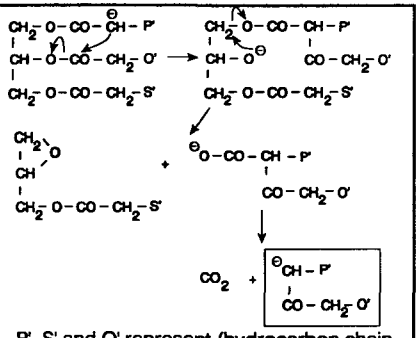

P', S' and O' represent (hydrocarbon chain less CH_2) of the corresponding fatty acids.

SCHEME 1

Figure 1 shows that the "ketone" anions corresponding to fatty acids on vicinal positions on the glycerine moiety, thus for POS, "PO" and "OS", are formed preferentially. Checked on more than 20 triglycerides of known structures, this has been found to be a general rule, thus allowing the assignment of the positions of the fatty acids on the glycerol.

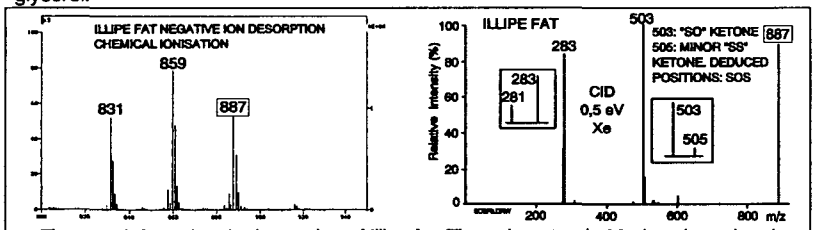

Figure 2: left: molecular ion region of Illipe fat. The anion at m/z 887 is selected and submitted to CID, at the right. From this spectrum, on can deduce the masses of the fatty acids, of the "ketones", and assign the positions on the glycerol moiety.

As shown on figure 2, the method can be applied to mixtures of triglycerides if they contain only one position isomer for each. From their masses at m/z 281 and 283, it can be deduced that the fatty acids are stearic and oleic, and from the molecular mass that there are two stearic and one oleic acids. The "SO" ketone predominates, thus the positions are SOS. This is in agreement with the known structure for this Illipe fat.

This method thus allows to easily assign, for a given triglyceride in a mixture, which are the contained fatty acids and their positions on the glycerol moiety, for so far there is only one position isomer present. No attempt has been made to apply this to position isomers mixtures. No relation has been found between the fatty acids anions intensities and their positions.

The preference for the vicinal condensation has been checked with the diacetates of ethyleneglycol and 1,3 propanediol. The first one yields the acetone anion, while the last doesn't.

Isolation and Detection of Drugs from Spent Fly Puparia:Drugs in Bugs

**Mark L. Miller, Wayne D. Lord, Brian Donnelly, Laboratory Division, FBI, Washington, D.C. 20535; M. Lee Goff, Dept. of Entomology, University of Hawaii at Manoa, Honolulu, HI 96822*

The forensic use of insects and their remnants has been well established in the determination of time of death, but has only recently been generally recognized as an alternative toxicological specimen. The development of methods for various toxins and controlled substances can make an important contribution to the assessment of cause/manner of death in cases of advanced decomposition. The usual toxicological samples are often absent when mummified/skeletalized remains are found and entomological samples may provide the only clues. A key difference in the extraction of chitinized insect remnants from pathological samples, such as tissue, is the use of strong acids or bases to break down the chitin so the drugs can be released. After the acid or base step and pH adjustment, some of the more routine drug screen extraction methodology can be employed for analyte isolation. GC/MS with chemical ionization was utilized to detect the presence of toxins in extracts.

In October, 1991, the mummified remains of a middle-aged white female were discovered at her residence. Subsequent investigation revealed the decedent had died of multiple drug intoxication in mid-January 1989. Toxicological analysis of desiccated brain and stomach contents revealed lethal concentrations of amitriptyline and its metabolite nortriptyline, as well as diphenhydramine and cocaine. Empty fly puparia(Phoridae), cast beetle skins(Dermestidae), beetle fecal material(frass) were analyzed for amitriptyline and nortriptyline using a modified hair extraction technique. In addition, controlled studies were made for correlating the amount of drugs in tissues with the level in spent fly puparia(Sarcophagidae). Rabbits were injected with zero, 0.5, 1.0, and 2.0 median lethal dosages of drugs. Two sets of experiments were conducted using amitriptyline (tricyclic antidepressant) for the first and phencyclidine (anesthetic) for the second. After the drugs were administered the rabbits were sacrificed and the livers harvested for feeding to the fly larvae.

A comparison was made of acid versus base extraction for the drugs of interest. The base extraction of basic drugs was carried out by using 100 mg of sample and enough 0.1 N NaOH to cover puparial casings. Deuterated internal standards were added and then the sample tubes were heated at 70-80°C for one hour. The NaOH layer was extracted with n-butyl chloride and centrifuged. Back extraction of the organic layer was then accomplished with 1 N HCl. After removal of the organic layer the HCl was adjusted to pH 9.5. Chloroform was added and then the mixture was vortexed and centrifuged. The chloroform was dried with anhydrous sodium sulfate and then evaporated. For GC/MS analysis the residue was reconstituted in methanol. Acid extraction of the basic drugs was performed by weighing out 100 mg of puparial casings and then adding 1 N HCl and deuterated standards. The samples were heated overnight at 65°C and adjusted to pH 4. Using conditioned Tox-Clean RC (Alltech) SPE tubes the extracts were eluted at 1 mL/minute for sample cleanup. The tubes

were washed with water, air dried, and then washed again with hexane and methylene chloride. Elution of the basic drug fraction was accomplished with basic MeOH (2% NH_4OH). The eluent was diluted in water and extracted with 200 microliters of methylene chloride. After centrifugation the methylene chloride layer was collected for GC/MS.

In the case of the amitriptyline controlled studies its metabolite nortrip-tyline was found at a level of about 1/5 to 1/2 that of the parent drug in the puparia. The highest level of amitriptyline was found in the puparia from the one median lethal dosage because the rabbit given the double dosage died rapidly from an overdose. The rapidity of death did not allow enough time for the drug to circulate as fully to the liver as at the lower dosages. This is also supported by the fact only a trace of nortriptyline was found in the 2.0 median lethal dosage puparia.

In conclusion, amitriptyline and its metabolite nortriptyline can be detected in insects and in insect remnants. The ratio of amitriptyline to nortriptyline is consistent with acute ingestion in case findings, otherwise the ratio would be less than one. Acid or base extraction gives very similar results for these basic drugs. No phencyclidine was detected in the PCP controlled studies because its concentration is estimated to be 1000X smaller than the amitriptyline levels (from liver concentrations). A more sensitive method is needed for levels <1 ng/mg.

The Characterization of 4- Quinolones by Chemical Ionization Ion Trap Mass Spectrometry.

Armando Colorado and Jennifer S. Brodbelt, Department of Chemistry, University of Texas, Austin, Texas, 78712.

The history of the 4-quinolones began with the synthesis of nalidixic acid, the progenitor of all quinolones. Since then, several new classes of quinolones such as the flouroquinolones have been developed. These compounds are active against 37 different kinds of bacteria and are used in treating various bacterial infections (1). Quinolones are not only used for human related infections. Eel and yellowtail fish farms are treated with these antibiotics for the prevention and treatment of infectious diseases in fish (2).

Up to date, only HPLC/MS, PD/MS, and EI/MS have been used to identify quinolones (3,4). FAB/MS and CI/MS have been attempted with the newer quinolones but no molecular ion information has been obtained(3).

In these series of experiments, nine quinolones, separated into four different groups, were structurally characterized by the utilization of various selective chemical ionization reagents and by performing collisional activated dissociation.

Experiments were performed on a Finnigan Ion Trap Mass Spectrometer equipped with a Hitachi/Teledyne HST-1000 High Sensitivity Trap Accessory. Sample pressures were typically at $2X10^{-6}$ torr. Reagent pressure was nominally at $1X10^{-5}$ torr and raised to nominally 1 mtorr with helium. Trap temperature was set at 120 degrees celcius while the solids probe temperature varied from 120-200 degrees celcius.

Seven chemical ionization reagents were evaluated: dimethyl-ether (DME), vinylmethyl-ether (VME), acetone, allyl alcohol, acetic anhydride, trimethylsilane and propylamine. Of the seven chemical ionization (CI) reagents used, four of them formed characteristic adducts in addition to protonation . Dimethyl-ether formed $[M + 15]^+$ and $[M + 45]^+$ ions while vinyl-methyl ether and trimethyl-silane formed $[M + 15]^+$ and $[M + 73]^{+\cdot}$ ions respectively. The CI reagent that showed the most promising selective behavior was propylamine. Selective adduct formation within each group was observed. Within group I, for example, enoxacin formed only the protonated species, while norfloxacin formed both the $[M + H]^+$ and $[M + 17]^+$ ions. Ciprofloxacin produced the same adducts as norfloxacin plus an $[M + 60]^+$ adduct which corresponded to propylamine attachment. The [M + 17] ions, found only in Group I, were attributed to attachment of ammonia. Cinoxacin (Group 2), piromidic acid (Group 3), nalidixic acid and flumequine (Group 4) were the other compounds producing propylamine adducts. Acetone, allyl alcohol and acetic anhydride did not promote formation of any characteristic product ions.

Unusual and interesting behavior was observed when the protonated quinolones were subjected to collisional activated dissociation (CAD) in the presence of different CI reagents. Depending on the CI reagent used, activation of the protonated quinolones results in the formation of characteristic fragment ions that may rapidly react with the neutral CI reagent, resulting in new adducts. CAD in the presence of DME reagent results only in fragment ions, but acetone, allyl alcohol, acetic anhydride, trimethylsilane and propylamine all undergo attachment to the fragment ions/or to the activated protonated quinolone.

Thus, performing CAD with these latter CI reagents may offer certain advantages. For example, both fragmentation and reactivity patterns are obtained in a single experiment. Secondly, the quinolone ions are selective for reagents possessing certain types of functional groups, such as alcohols and ketones but not ethers. Acetic anhydride was especially useful because both fragmentation and subsequent adduct formation occured with the quinolones. Trimethylsilane and

propylamine, on the other hand, induced complete conversion of quinolone fragment ions to adduct ions.

In fact, after each protonated quinolone has undergone dehydration, it may attach to an intact quinolone neutral. The reason for this self-reaction was elucidated from reactions of models. Further studies with model compounds possessing only carboxylic acid or ketone functional groups show that these do not undergo dehydration and spontaneous attachment of a second ligand. However, if both functional groups are present, then the attchment process does occur. Thus, the quinolones themselves have promise as selective, albeit non-traditional, CI reagents with specific functional group reactivity towards alcohols and acids.

CAD of the product ions formed from selective chemical ionization provides additional structurally diagnostic details. The $[M + 15]^+$ and $[M + 45]^+$ ions from DME chemical ionization fragment in ways similar to the protonated quinolones, and the $[M + 45]^+$ is clearly a direct precursor of the $[M + 15]^+$ ion. The TMS adducts of the group I quinolones are especially intriguing because activation of these adducts may result in formation of even larger product ions.

In conclusion, selective CI reagents afford new opportunities for generating structurally informative mass spectra of quinolones. Although the various reagents often produced similar types of product ions for the different quinolones, in conjuction with CAD each quinolone could be distinguished. Dehydrated quinolone ions are particularly reactive towards molecules containing certain functional groups, such as alcohols and acids, and this may prove to be important for develping a diagnostic scheme which targets the quinolone class, or for developing selective quinolone reactants.

THE ANALYSIS OF 1,4-BENZODIAZEPINES BY SELECTIVE ION-MOLECULE REACTIONS WITH DIMETHYL ETHER IONS IN A QUADRUPOLE ION TRAP

Tracy Donovan McCarley and Jennifer Brodbelt, Department of Chemistry, University of Texas, Austin, TX 78712-1167

The 1,4-benzodiazepines are the most widely prescribed drugs in the world, with diazepam (Valium) being the most well known. They are a class of sedatives and tranquilizers that are used commonly to treat anxiety, insomnia, muscle spasms and seizures. The combination of site selective ion-molecule reactions with collisionally activated dissociation (CAD) offers greater promise for differentiation of related 1,4-benzodiazepines due to the enhanced specificity of ion-molecule reactions. In this study, the chemical ionization of 1,4-benzodiazepines by selective ion-molecule reactions with dimethyl ether and ethylene oxide ions has been examined in a quadrupole ion trap mass spectrometer. The 1,4-benzodiazepines chosen for this study include diazepam, nordiazepam, temazepam, oxazepam, and nitrazepam. As can be seen from Figure 1, they only differ by subtle substituent variations at positions 1, 3, and 7, so they afford a useful set of molecules for systematic evaluation of site-selective bimolecular reactions.

The ion-molecule reaction products of the 1,4-benzodiazepines and dimethyl ether ions are listed in Table 1. Upon reaction with the dimethyl ether ions, all of the 1,4-benzodiazepines were protonated, all compounds formed *either* $(M + 13)^+$ *or* $(M + 15)^+$ adducts, and most formed $(M + 45)^+$ adducts. The selective formation of $(M + 13)^+$ and $(M + 15)^+$ adducts is analytically useful since it allows differentiation of two groups of 1,4-benzodiazepines. Diazepam, nordiazepam, and nitrazepam which do not have hydroxyl substituents at position 3 form $(M + 15)^+$ adducts but <u>not</u> $(M + 13)^+$ products, while both temazepam and oxazepam which have hydroxyl substituents at position 3 form $(M + 13)^+$ adducts, but <u>neither</u> forms $(M + 15)^+$ adducts.

The basis of the selectivity for formation of $(M + 13)^+$ and $(M + 15)^+$ products has been investigated further by studying the ion-molecule reactions of dimethyl ether ions and simpler compounds that serve as models of potential reactive sites in the more complex 1,4-benzodiazepines. The reactions of the model compounds with dimethyl ether ions are summarized in Table 2. Based on the comparison to model compounds, the imine group is the predominant reactive site in the formation of $(M + 15)^+$ adducts.

The determination of gas-phase basicities of compounds is not only fundamentally important for obtaining a correlation of organic structure with thermodynamic properties, but also analytically useful as a further means to predict nucleophilicity and reactive behavior of new classes of compounds. Thus, the bracketing technique was used to estimate the gas basicities of the 1,4-benzodiazepines. Diazepam was selected as a representative of the non-hydroxylated 1,4-benzodiazepine class, and temazepam was selected as a representative of the hydroxylated 1,4-benzodiazepine class. They were each introduced into the vacuum system with compounds of known gas-phase basicities. The standards and 1,4-benzodiazepines were each protonated by dimethyl ether ions. Then each protonated molecule was isolated and held for a reaction period during which the proton could be transfered to the other organic compound. The gas-phase basicities of both diazepam and temazepam are thus determined to be less than 222.2 kcal/mol (from diethylmethylamine) but greater than 220.7 kcal/mol (from 4-amino-1-butanol). This range suggests that the diazepines are most likely protonated at the imine site, not the lactam site.

The ion-molecule reactions of dimethyl ether ions with 1,4-benzodiazepines have been shown to be analytically useful for probing small structural differences in the 1,4-benzodiazepines in a quadrupole ion trap mass spectrometer. Characteristic $(M + 13)^+$ adducts are formed by 3-hydroxy-1,4-benzodiazepines, whereas $(M + 15)^+$ adducts are formed by 1,4-benzodiazepines that do not have hydroxyl substituents. In addition, the 3-hydroxy-1,4-benzodiazepine can be differentiated by the formation or lack of formation of an $(M + 27)^+$ adduct, and the 7-nitro- or 7-chloro-1,4-benzodiazepines without hydroxyl substituents can be distinguished by characteristic high mass fragment ions in the ion-molecule reaction spectra. The CAD spectra of 1,4-benzodiazepines allow further structural identification of the 1,4-benzodiazepines.

Hoffmann-LaRoche is gratefully acknowledged for their donation of 1,4-benzodiazepine samples. This work has been supported by the Welch Foundation (F1155), ACS-PRF (25485-AC5), the NSF (CHE-9122699), the NIH (RO1 GM46723-01), and a grant from American Cyanamid.

IDENTIFICATION OF METABOLITES OF A NOVEL PLATELET ACTIVATING FACTOR ANTAGONIST BY MASS SPECTROSCOPY

William DeMaio*, D. Cosulich, J. Ashraf, M. Rashed, G. Morton

American Cyanamid Company, Medical Research Division, Pearl River, NY, 10965

A novel platelet activating factor (PAF) antagonist, CL 184,005, is currently under development for treatment of septic shock. Characterization of the metabolism of CL 184,005 was necessary to support this development. Identification of metabolites, determination of metabolic profiles, and *in vitro* species comparison of CL 184,005 were investigated in the rat and in rat, dog and human liver preparations using ^{14}C labeled CL 184,005. Thermospray-MS, GC/MS, high resolution MS and NMR spectroscopy were used to identify four of the metabolites. (See the proposed biotransformation pathway in the Summary Figure.) Prior to structural identification, metabolite samples were prepared by glusulase hydrolysis of rat urine followed by semi-prep HPLC purification. The presence of the ^{14}C label on the thiazole ring and the characteristic fragment $[\underline{m}\text{-HO-}C_6H_4\text{-}CH_2]^+$ (*m/z* 107) assisted structural identification efforts.

^{14}C-CL 184,005 is extensively metabolized by the rat. Several polar radioactive metabolites were observed in rat urine. These metabolites were found to be mainly sulfates and glucuronides of low molecular weight phenolic compounds M1, M2, M4a and M4b. In plasma, up to six hours post-dosing, unchanged drug is estimated to represent 49% of AUC for total radioactivity. The same conjugates observed in urine accounted for the balance of radioactivity found in plasma. From rat feces, 87% of radioactivity was recovered, of which 66% was due to unchanged drug and 32% due to a very polar component. Rat and human liver preparations formed common metabolites, M4. The conjugates of M4 are also the major circulating metabolites as well as being one of the major urinary metabolites. Metabolic cleavage of the phosphate ester linkage resulted in our ability only to trace the labeled portion of the molecule. Further studies are planned with compound labeled on the benzoic acid carbonyl carbon. This would enable us to complete the metabolic profile and the mass balance of CL 184,005.

The proposed metabolic scheme is shown in the Summary Figure. Figure 1 shows a mass spectrum of the M4a metabolite showing the characteristic *m/z* 107 fragment ion and the enhanced M+2 ion at *m/z* 224 from the ^{14}C label. These features were typical of the mass spectra of the CL 184.005 metabolites identified in this work.

Mechanistic Studies on the Metabolic Oxidation of Terminal Olefins to Carboxylic Acids.

P. R. Sheffels, M. P. Grillo and T. A. Baillie

Dept. of Medicinal Chemistry, University of Washington, Seattle, WA 98195

Terminal alkenes have been reported to form carboxylic acids metabolically,[1,2] yet little is known about the underlying mechanism. It has been postulated that an aldehyde may be an intermediate in the process, although details of the initial oxidation remain obscure. During the course of investigating the metabolism of the hepatotoxic terminal olefin, 2-*n*-propyl-4-pentenoic acid (Δ^4-VPA), in the perfused rat liver, the corresponding dicarboxylic acid, 2-*n*-propylglutaric acid (PGA), was identified as a biotransformation product by GC-EIMS techniques.[1] When an analog of Δ^4-VPA labeled with two atoms of deuterium on the olefinic terminus ([5,5-$^2H_2$]Δ^4-VPA, 97 atom % excess) was employed as substrate with rat hepatocytes, the PGA formed was found to have retained a single deuterium atom (95 atom % excess). This result indicates that metabolic oxidation of the 4,5-double bond of Δ^4-VPA to the corresponding carboxylic acid involved a hydrogen shift, and GC-EIMS methods were employed to localize the deuterium atom in PGA at the sub-terminal (C-4) position. The position of the deuterium was assigned to C-4 based on the shift of the McLafferty rearrangement ion at *m/z* 74 [MeO-C(=$\overset{+}{O}$H)-$\dot{C}H_2$] in the unlabeled spectrum to *m/z* 75 [MeO-C(=$\overset{+}{O}$H)-$\dot{C}$HD] in the labeled spectrum (Fig. 1). These deuterium labeling experiments thus have afforded a valuable insight into the molecular mechanism by which terminal olefins are oxidized to carboxylic acids, and have provided the basis for a revised scheme for the interactions of mono-substituted olefins with mixed-function oxidase enzyme systems. Future work in this area will entail "trapping" the aldehyde intermediate

to confirm that two atoms of deuterium are retained when [5,5-$^2H_2$]Δ^4-VPA serves as substrate.

Automated Static Headspace Sampling With Gas Chromatography - Mass Spectrometry for the Identification and Quantitative Analysis of Volatile Organic Impurities in Drugs and Pharmaceuticals

Kevin J. Mulligan* and Heather McCauley
US Food & Drug Administration
National Forensic Chemisty Center
Cincinnati, Ohio 45202.

Volatile impurities in bulk drugs and pharmaceutical preparations can arise from sources such as: manufacturing byproducts, the degradation of ingredients, and the solvents used in processing. All are of concern from a toxicological perspective and, moreover, may provide a qualitative and/or quantitative chemical profile of a specific manufacturer's product. This can have forensic implications.

Official methods (1) for residual solvents establish limits for select substances at 100 mg/kg in the bulk drug except as shown: benzene, chloroform (50 mg/kg), 1,4-dioxane, methylene chloride and trichloroethylene.

The objective of this work has been to develop some understanding of the performance of a commercial automated static headspace sampler in combination with narrow-bore capillary GC-MS for the identification and determination of residual solvents in bulk drugs.

A liquid sample is confined in a 9-mL glass vial which is sealed with a teflon-lined butyl rubber septum in a crimp cap. After equilibration at a given temperature, helium is added to the vial to raise the pressure to 5 psi whereupon the headspace is vented through a 0.25 mL sampling loop under a backpressure which is roughly equal to the headpressure on the column. Then, the flow to the column is directed through the sampling loop (105°C), transfer line (115°C) and capillary union (180°C) to a cryofocussing trap (-130°C). Sufficient transfer time is allowed for the internal volume of the transfer line to be swept 2.5X. The analytes are revolatilized by rapidly increasing the trap temperature (200°C) and enter the column. Column temperature is maintained at 10°C for 2 min and increased (10°C/min) to 180°C.

The instrument consists of an Equilibrium Headspace Autosampler (7000/7050, Tekmar) which has been plumbed with electroform nickel tubing (Valco). Aliquots of the headspace are cryofocussed on the first 8 cm of the column (Rtx-200, 30m X 0.25mm id X 1000nm film, Restek) by a Cryofocussing Module (Tekmar) attached to the GC-MS (5890 Series II GC/5971A MSD, Hewlett Packard(HP)). Column flow (@ 50°C) is adjusted to 30 cm/s by tracking the elution of CO_2. No special effort is made to optimize the tuning of the MS, rather the standard adjustments returned by the software (1034C, HP) are used.

Although hydrocarbons in water exhibit extremely low coefficients for the distribution of solute between solvent and gas phase (<10), most mixtures have values above 300 so that the volume of solution has a minimal effect on the gas phase concentration (2). For a volume of 0.5 mL, equilibrium is reached within 10 min.

These studies focussed on the solvent, dimethylacetamide (DMAC), since a drug of interest, sulfamethazine, is highly soluble in DMAC (>40% w/v) but only slightly soluble (< 0.1% w/v) in water. The mass

spectrometer was configured for scanning (20 amu to 250 amu at 2.9 Hz). A mixture of standards (0.4 to 2 mg/L) was equilibrated at 105°C for 10 min and after analysis, the S/N ratio at each peak (TIC) was defined as Peak Height/Baseline Width(RMS). For S/N >=3, a PBM(reverse) search of the spectrum against the Wiley Library yielded the compound as the first or second hit. A 20-fold dilution of the test mixture was examined using selected ion monitoring for the major ion in each analyte spectrum (dwell = 50 ms, 12.3 Hz). The sensitivity improved by a factor of 25 to 100. To examine the effect of temperature, solutions were incubated at 25°C, 65°C, 105°C and 145°C. The chromatography degraded substantially at 145°C which may be due to excess DMAC. Plots of ln(Peak Area) vs. T(K) were generally linear (m_r > 0.99) and the relative increase in peak area as a function of temperature was determined to be 2 to 5 %/K. A direct comparison of 10%(v/v) aqueous DMAC (85°C) to DMAC (105°C) showed that while the aqueous system is generally more effective, the difference is not usually drastic particularly for those materials with appreciable solubility in water. Water elutes during the early part of the chromatogram and produces peak broadening of C1 - C3 alcohols.

This system has been applied to the determination of acetone in the sulfonamide antibiotic, sulfamethazine. A 0.2 g portion of the solid sample was dissolved in 0.5 mL of DMAC with 2-pentanone added at 2 mg/L to serve as an internal standard. The sample was incubated at 105°C for 15 min and a 0.25-mL aliquot of the headspace was examined by selected ion monitoring at 43 amu. Calibration curves were prepared from 0 to 6 mg/L by plotting concentration vs. the ratio of the peak area of acetone to that of 2-pentanone (normalized to its concentration). Low level samples were spiked with 300 to 1000 ng of acetone and demonstrated recovery of 89(+/- 4)% (n=8). A system blank limited the LOD (3 X S_{blank}, n=51) to 0.3 mg/kg of acetone in the bulk drug. Within-day precision was 3%(@ 1mg/kg, n = 18) or 2% (@ 13 mg/kg, n = 28) while the between-day precision was about X 3 higher.

Analyte	Concentration for S/N = 3 Scanning (mg/L)	SIM (ug/L)	Temperature Coefficient (%/K)	Relative Signal DMAC vs. H2O

A COMPARISON OF GAS CHROMATOGRAPHY-MASS SPECTROMETRY ASSAYS FOR *IN VIVO* LIPID PEROXIDATION

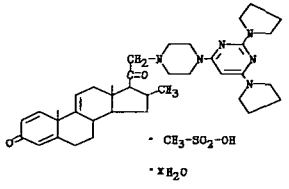
W. R. Mathews, R. McKenna, D. M. Guido, T. W. Petry, and R. A. Jolly
Biochemistry and Investigative Toxicology, The Upjohn Company, Kalamazoo, MI 49001
J. D. Morrow and L. J. Roberts, II Clinical Pharmacology, Vanderbilt University School of Medicine, Nashville, TN 37232.

INTRODUCTION

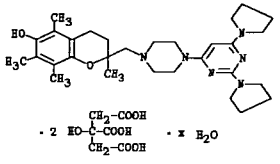
Oxidant stress has been implicated in a wide variety of disease processes. Peroxidation of lipids is a well known sequela of free radical injury. Limitations with methods available to assess oxidant stress and lipid peroxidation *in vivo* are a well recognized problem Peroxidation of cellular arachidonyl lipids results in the formation of hydroperoxy-arachidonic acids (HPETES) and hydroxy-arachidonic acids (HETES). More recently, it was discovered that a series of prostanoids (F_2-isoprostanes) are also produced *in vivo* as products of lipid peroxidation. Both of these classes of lipid peroxidation products are amenable to analysis by GC-MS and sensitive, quantitative assays have been developed. Therefore, we compared these two approaches of measuring HETES and F_2-isoprostanes in rats following induction of lipid peroxidation *in vivo* by administration of CCl_4.

METHODS

GC/MS lipid peroxidation assays. The methods used for the GC-MS analysis of HETES and F_2-isoprostanes have been described previously (1, 2). 12-HETE, 11-HETE, 9-HETE and 8-HETE were assayed as Me ester, TMS ethers by electron impact GC-MS. 16-hydroxy-heneicosatrienoic acid was employed as the internal standard. F_2-isoprostanes were measured as pentafluorobenzyl ester, TMS ethers by negative ion chemical ionization GC-MS. D_7-9α,11β-PGF_2 was used as the internal standard. Tissue samples were subjected to base hydrolysis to release the free acids of the HETES and F_2-isoprostanes prior to GC-MS analysis.
CCl_4 toxicity. Male Sprague-Dawley rats were treated with U74006F, U78517G, or vehicle 24 hrs (200 mg/kg, p.o.) and 5 min (6 mg/kg, i.v) prior to CCl_4 (600 µl/kg, i.p.) administration. Three hours later the animals were sacrificed and blood and liver samples taken. Liver samples were divided in half and frozen immediately in liquid N_2. After addition of the internal standard to the plasma samples they were carried through 2 steps of solid phase extraction. The partially purified plasma samples and half of the liver samples were sent to Vanderbilt for F_2-isoprostane analysis. The remaining liver samples were assayed for HETES.



U74006F



U78517G

RESULTS AND DISCUSSION

Administration of CCl_4 resulted in a significant increase in the amount of HETES (average 7-fold increase) and F_2-isoprostane (75-fold increase) esterified to liver lipids (Table I). Increased levels of the F_2-isoprostanes were also detected in the circulation (25-fold above baseline). Two antioxidant compounds were examined for their ability to inhibit lipid peroxidation in this *in vivo* model. U78517G, when administered prior to CCl_4, inhibited CCl_4 induced lipid peroxidation, while U74006F had no effect. Both assays gave similar results; for example U78517G reduced tissue F_2-isoprostane levels to 37% of the CCl_4 stimulated value while HETE levels were reduced by an average of 38% of the stimulated levels. Plasma levels of F_2-isoprostane were reduced to 35% of the CCl_4 stimulated values.

Table I. Lipid Peroxidation Products in Rats following Carbon Tetrachloride Administration

Sample	F_2-Isoprostane		Tissue HETES (ng/g)			
	Plasma (pg/ml)	Tissue (ng/g)	12-	11-	8-	9-
CONTROL	14±4	7.5±1	120±37	75±19	402±129	644±306
U74006F	16±3	7.8±0.5	139±25	118±35	550±147	411±134
CCl_4	344±90	573±108	1022±142	597±69	2693±497	1955±497
CCl_4 + U74006F	442±106	533±159	1199±172	735±90	3192±458	1923±345
CCl_4 + U78717G	119±42	214±56	352±13	238±17	1009±63	813±91

These results suggest that both methods can detect increases in lipid peroxidation of cellular lipids *in vivo*. Both assays gave qualitatively similar results. The HETE levels detected in the tissue lipids were significantly higher than the F_2-isoprostane levels in all cases. This could be due more facile formation of these compounds or to greater clearance of the F_2-isoprostanes from tissue lipids. Perhaps due to the lower basal levels, the fold increase in lipid peroxidation products was higher for F_2-isoprostane than the HETES. This suggests that the F_2-isoprostane might be more sensitive for detecting low levels of lipid peroxidation. Finally, the ability to measure free F_2-isoprostanes in the circulation to assess lipid peroxidation represents a significant advantage of this assay.

ANALYSIS OF POLYETHYLENE GLYCOLS WITH THERMOSPRAY LC-MS

*S.Auriola, K.-M.Rönkkö, K.Kananen, and A.Urtti, Dept. Pharm. Technology, University of Kuopio, P.O.Box 1627, SF-70211 Kuopio, Finland

After instillation of an eyedrop, typically less than 3 % of the applied drug penetrates the cornea and reaches intraocular tissues. Drug permeability in the membranes is influenced both by the properties of the penetrant and membrane. Permeability is affected by the lipid/water partitioning, charge, hydrogen bonding capacity, and molecular size of the compound.

The dependence of transmembrane permeability on molecular size has been often studied using polyethylene glycols (PEGs) as probes. The structure of this polymer is $H\text{-}(O\text{-}CH_2\text{-}CH_2)_n\text{-}OH$. The physicochemical properties of PEGs do not change drastically with increasing molecular size as happens within a series of alkyl homologues. HPLC is the technique of choice for separation of PEGs, but the detection is difficult as the molecules do not contain a chromophoric structure. PEGs have been widely used in TSP optimization and tuning experiment. TSP LC-MS has also been used for analysis of PEGs in wastewaters [1].

In this study a TSP LC-MS method was developed for simultaneous determination of wide molecular weight range of PEGs (238 - 986). The method proved to be suitable for transmembrane permeability studies performed with an in vitro apparatus. The PEGs were chromatographed with a polymeric PRP-1 column (Hamilton) using isocratic 0.1 M ammonium acetate - acetonitrile (79:21) eluent, and quantitated by SIR of the ammoniated molecules. Polypropylene glycol (PPG) was used as the internal standard.

The TSP mass spectra of PEG oligomers show ammoniated molecules at M+18 as the base peaks and other adduct ions at M+23 (MNa^+), M+39 (MK^+), M+59 (MNH_4^++acetonitrile) and at M+81 (unknown). No significant fragmentation of PEG was observed (Fig. 1). The molecular weight difference between two PEG oligomers is 44 mass units (C_2H_4O). The MNH_4^+ ions (M+18) were diagnostic for each oligomer and there were no overlapping adduct or fragment ions. This means that the various oligomers are well resolved from one another, although chromatographic baseline separation was not achieved for all oligomers. The chromatographic peaks show some tailing, but this might result also from the memory effect, caused by contamination of the ion source with PEG (Fig. 2).

The signal to noise ratio was between 10 and 50 at level of 30ng of PEG 300, 60 ng of PEG 600 and 100 ng of PEG 1000 polydisperse mixture per injection. This means that the TSP LC-MS method is at least hundred times more sensitive than the previously described HPLC methods using refractive index detection or UV-detection.

TSP LC-MS method allows determination of permeability coefficients for a range of PEGs with different molecular sizes. This method may prove useful in the studies of molecular weight dependence in membrane penetration and effects of penetration

enhancers on biomembrane leakiness. Highly purified PEG with narrow molecular weight distribution is not needed, because the method analyses each molecular weight of PEG separately from the sample. This may decrease the need of animals in research, because in each penetration experiment whole series of PEGs can be used and determined simultaneously.

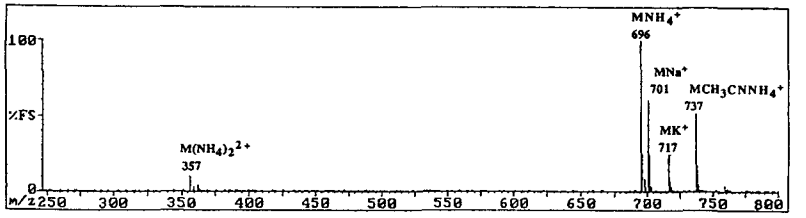

Figure 1. TSP mass spectrum of a PEG oligomer (molecular weight 678).

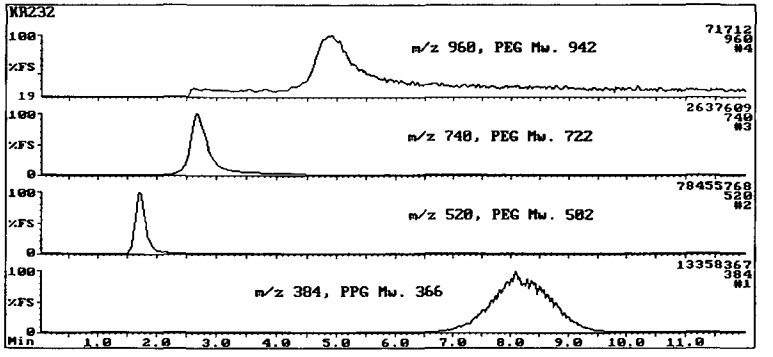

Figure 2. SIR chromatogram of a polydisperse PEG mixture taken from the receptor cell at 60 min. Polypropylene glycol (PPG) is used as an internal standard.

Selective Detection Of Phosphopeptides By Electrospray LC/MS

Michael J. Huddleston, Roland S. Annan, Mark F. Bean, and Steven A. Carr, Physical and Structural Chemistry, SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

We have developed an MS-based strategy for selective identification of peptides containing phosphate linked to Ser, Thr or Tyr without the need for radiolabeling. The method involves the generation and detection of phosphate-specific fragment ions while simultaneously acquiring molecular ion information during negative-ion LC-ESMS analysis of protein digests (1). The present work is an outgrowth of our earlier studies on methods for selective glycopeptide detection (2,3).

Positive- and Negative-Ion In-Source CID of Phosphopeptides: Positive-ion and negative-ion electrospray mass spectra of the phosphopeptides were recorded over a wide range of orifice potentials (65V to 250V in positive-ion; -65V to -500V in negative-ion). On the Sciex quadrupole mass spectrometer, the orifice voltage (OR) is the source declustering potential, and this voltage is also used to control the degree of collision-induced dissociation (CID) occurring in the high-pressure region between the orifice and Q1. No characteristic low-m/z fragment ions were observed in the positive-ion data for the three types of phosphopeptides over the range of OR values studied. Fragments formed by loss of H_3PO_4 from the pseudomolecular ions could be observed for the peptides phosphorylated on serine or threonine in both the positive- and negative-ion spectra. The loss of phosphoric acid was more pronounced in the positive-ion data and appeared at lower collisional excitation potentials than in the negative-ion data.

Optimization of Marker-ions and Molecular-Ions of Phosphopeptides by Negative-Ion ESMS: At sufficiently high orifice potentials (collision energies), the negative-ion ES mass spectra for all three varieties of phosphate linkage showed two unique phosphopeptide fragment ions: m/z 79 (PO_3^-) and m/z 63 (PO_2^-) (see Figure 2). Negative-ion ESMS was optimized for detection of the phosphopeptide-specific marker ions using the phosphoserine-containing peptide which gave the weakest response of the three types of phosphorylated peptides. At OR values ranging from -65V to -115V we observed $(M-H)^-$, $(M-H+TFA)^-$ and $[M-2H+(TFA)_n]^{2-}$ ions where n = 1 - 8 depending on the voltage and the peptide composition. TFA adducts to the molecular ion were greatly diminished at -115V in comparison with the standard -65V setting. Minimization of adducts simplifies the spectral data, facilitates molecular weight measurements when dealing with mixtures, and improves the intensity of individual signals.

Selective Detection of Phosphopeptides by Negative-Ion LC-ESMS: The orifice voltage setting, which controls the CID potential, needs to be adjusted so as to maximize within each spectrum the characteristic fragment-ion signals and to minimize parent-ion fragmentation. These contradictory requirements are met by scanning or stepping the orifice voltage during full-scan acquisition in a manner analogous to that previously described for selective detection of glycopeptides in LC-ESMS (2,3). The OR setting of -115V, which is sufficient to effectively reduce TFA-adducts to the parent ions, and the -350V OR setting used for generation of phosphopeptide-marker ions were combined into a single scan by computer-controlled stepping of the OR voltage. This full-scan, stepped collision energy negative-ion LC-ESMS method was applied to the mixture of peptides shown in Figure 1. While both the UV (Figure 1a) and TIC (not shown) traces provide relatively non-specific detection of peptides and phosphopeptides, the reconstructed-ion chromatogram (RIC) for m/z 79 (Figure 1b) is specific for phosphopeptides. The molecular weights of the six peptides were indicated by significant, singly-charged, deprotonated molecular-ions together with their less-intense TFA adduct satellite peaks. Useful data were readily obtained at the low picomole level using packed fused-silica HPLC columns. In cases where even greater sensitivity is required, SIM detection of m/z 63 and 79 may be employed (1).

In summary, negative-ion with CID provides unique phosphopeptide fragment ions for each of the three types of phosphopeptides. SIM of m/z 63 and 79 provides the highest sensitivity for selective detection of phosphopeptides. Stepping the collision energy (orifice voltage) during full-scan acquisition permits detection of phosphopeptide marker ions and molecular-weight related ions for peptides and phosphopeptides. Good sensitivity has been achieved using standard TFA-containing mobile phases for reversed-phase HPLC. Relatively high orifice voltages (> -250V) are required for the best response of the phosphopeptide marker ions. Work is now in progress to use these techniques to identify phosphopeptides in more complex mixtures such as would result from enzymatically digested phosphorylated proteins (4,5).

Application of Electrospray Mass Spectromtry to the Identification and Quantitation of a Novel Variant in a Dimeric Recombinant Protein.

* Victor T. Ling, Eleanor Canova-Davis,and Marian L. Eng. Genentech, Inc., 460 Point San Bruno Blvd., South San Francisco, CA 94080 USA

In the biosynthesis of recombinant proteins in mammalian cell systems, unexpected post-translational modifications often result in the occurrence of variants along with the desired product. The development of purification processes is greatly aided by the availability of quick and facile means for the discovery, identification and quantitation of these variants.

NGF normally exists as non-covalent dimers. Post translational C-terminal processing results in the formation of (1-117) and (1-118) variants from the (1-120) polypeptide. These variants then pair up to form homo- and hetero-dimers in all possible combinations. The molecules are readily separated by ion-exchange chromatography in dimeric form. A quick and facile means for definitive identification of the components of each fraction was desirable. C-terminal amino acid analysis is tedious and uncertain because of the -RRA terminal sequence. Reversed phase chromatography proved insufficiently rugged as the variants separate poorly. It was found that when these dimers are examined by electrospray mass spectrometry (ES-MS) in acidified methanol / water, dissociation readily occurs to provide a mass for each monomer, providing unequivocal identifications.

An unexpected post-translational modification was also observed . A peak obtained by cation exchange chromatography showed a component with a loss of 30 mass units. This was consistent with a serine to glycine modification. The transformation was confirmed by MS / MS spectra and Edman sequence analysis of the N-terminal tryptic peptide. It was found to have occurred at the n-terminal serine. Preliminary evidence indicates it may be due to a pyridoxal catalysed serine hydroxymethyl transferase.

ES-MS of the intact protein was also compared to other analytic methods as a technique for the quantitation of variant proteins in a mixture. Intensity measurements on deconvoluted spectra were within 2% of calculated values in samples where normal rhNGF was added back to material containing the glycine N-terminal variant to give defined ratios. MS quantitation also proved to have good reproducibility : the result from 12 observations on a sample at concentrations ranging from 3-30pM was 24.6±1.1 percent. These results proved comparable to quantitation by tryptic mapping or ion-exchange separation.

ELECTROSPRAY MASS SPECTROMETRY OF NON-COVALENT COMPLEXES

Jaquinod M., Leize E., Potier N., Albrecht A.M., Biellmann J.F. and Van Dorsselaer A.
Laboratoire de Spectrométrie de Masse Bio-Organique, URA 31 CNRS-Université Louis Pasteur, Strasbourg, France.

INTRODUCTION:

Electrospray Mass Spectrometry (ESMS) has become a rapid and routine method for the measurement of the molecular mass of proteins up to 100 kDa with an accuracy of 0.01%. At first it seemed that the ESMS ionisation/volatilisation process would not allow the study of non-covalent assemblies. Later, several authors demonstrated that non-covalent complexes could be analysed by ESMS to some extent [1], but it is still difficult to answer the question "How tight must be the complex to resist the electrospray process". In order to help answering that question, we have tried to analyze different types of non-covalent complexes with decreasing stability.

In this study, we would like to show that if several parameters (pH, ionic strength, temperature, source voltage parameters) are carefully controlled, ESMS can be used as a general method for the study of non-covalent interactions. We believe that in fact it is possible to study non-covalent assemblies by ESMS provided that the conditions used before the MS study do not lead to a decomposition of the complexes. Most of the reported ESMS studies make use of MeOH/ H_2O (1/1, 1% AcOH) as solvent. This solvent easily produces a stable electrospray but often destroys weak interactions.

Three types of complexes were tested to determine the ESMS conditions which preserve the integrity of such compounds during the ionisation process:

- a *ferric ion complex with a synthetic analogue* of the bacterial siderophore ferrichrome A (ligand L),
- two *sulphur-ions proteins* (rubredoxin and ferredoxin),
- two *cofactor/protein complexes* (myohemoglobin, aldose reductase/NADPH complex).

EXPERIMENTAL:

Synthesis: Ligand L has been prepared as described elsewhere [2]. Horse heart myohemoglobin and *Porphyra umbilicalis* ferredoxin were purchased from Sigma (St Louis, USA). Rubredoxin was purified from *Clostridium thermosaccharolyticum* [2]. Aldose reductase was purified from pig lens [2].

ESMS: ESMS spectra were obtained by using a Bio-Q quadrupole with a mass to charge (m/z) range of 4000 (VGBioTech Ltd, Altrincham, UK). Values used for the extraction cone voltage (Vc) ranged from 30 to 250 volts. The source temperature was set at 50°C and at 40°C for the aldose reductase. In all cases, electrospray was pneumatically assisted.

RESULTS:

Study of the ligand L/iron (III) complex: Both solutions were prepared in pure methanol and the spectra recorded at Vc = 50 V. For the solution without $FeCl_3$, the major peak corresponds to the doubly-protonated free ligand L (1284.5 Da). For the solution with 2 $FeCl_3$ equivalents, the major peak corresponds to the complex of ligand L with two ferric ions (1389.8 Da). The mass difference measured between the free ligand and the complex with two ferric ions is 105.5 Da and not 111.7 Da (2 x Fe^{3+}). This shows that the complexation of the two ferric ions is accompanied by the loss of six protons from the hydroxamate groups of the ligand L. When Vc was increased to 250 volts, no loss of iron was detected. This fits with the very high affinity of ligand L for iron ions.

Study of the iron-sulphur proteins:

Rubredoxin: The rubredoxin active center consists of one ferric ion surrounded by 4 cysteine thiolates. The spectrum of rubredoxin recorded in MeOH/H_2O (1/1) at Vc = 50 V displayed three series of multiply charged ions corresponding to aporubredoxin (no iron, A series, expected mass: 5936.5 Da), holorubredoxin (one iron, B series) and holorubredoxin with a K^+ adduct (C series).

Ferredoxin: These proteins involved in photosynthesis, are known to carry two possible types of active centers (2Fe/2S or 4Fe/4S). All ferric ions and sulphur ions are complexed by cysteine thiolates. The spectrum of ferredoxin recorded in pure water at Vc = 70 V displayed two major complexes (measured mass: 11232.7 Da and 11177.5 Da) correspond to the proteins with a 4S/4Fe active center and a 4S/4Fe active centre plus one extra unexpected iron atom. Two minor complexes, corresponding to proteins with a 2S/2Fe active centre (11003.9 Da) and a 2S/2Fe active center plus one extra unexpected iron atom (11059.8 Da), were also detected. In MeOH/H_2O (1/1, 1% AcOH), the ESMS analysis detected only the apoprotein.

Study of two cofactor/protein complexes:

Myohemoglobin: Myohemoglobin was dissolved in a pyridinium acetate buffer (50mM, pH = 5.0). Spectrum recorded at Vc = 40 V: at this low voltage, a single peak was detected at 17570.5 Da, corresponding to myohemoglobin (exp. mass: 17568.5Da). A small peak (5%) at 16950.5 Da reveals a minor loss of the heme (616.5 Da) which is normally attached to myoglobine by interaction of one ferric ion with the proximal histidine F8. Spectrum recorded at Vc = 65 V: both species, myoglobin and myohemoglobin were present. The loss of the heme induced by collisions in the interface converts myohemoglobin to myoglobin. At Vc = 100 V, the conversion is complete. Such conversion was also observed , when using organic solvents or pH < 4.5.

Aldose reductase/NADPH complex (Fig. 1): The spectrum of the complex recorded in a 10 mM Tris-HCl buffer at pH = 5.0 and at Vc = 55 V displayed a peak at 36527.4 Da corresponding to holoprotein aldose reductase/NADPH. The spectrum of the holoprotein obtained after RP-HPLC shows that the complex is a non-covalent complex.

CONCLUSION:

In this work, ESMS has been shown to be a useful tool for the study of weak interactions. ESMS also appears to be an easy and general method for ascertaining the number of metal ions present in such supramolecules. A non-covalent complex can resist the ESMS ionization step with only minor dissociation. The experimental conditions allowing such studies depend on the complex analysed. The solvent and the pH used must not decompose the complex and the ESMS interface conditions (Vc, temperature,...) must also be adapted. It is still not possible to evaluate how "tight" must be the complex to stand the ESMS analysis in term of kcal/mol.

ESMS could provide a new and rapid method to evaluate the relative affinity of several inhibitors for a protein.

ELECTROSPRAY IONIZATION MASS SPECTROMETRY OF HEMOGLOBIN ADDUCT FORMATION IN RATS

Robert D. Stevens[1], David S. Millington[1], Douglas C. Anthony[2], Doyle G. Graham[2], Joseph Bonaventura[3], and Celia J. Bonaventura[3] Mass Spectrometry Facility, Box 3028[1], Department of Pathology[2], Duke University Medical Center, Durham, N.C. 27710 and Duke University Marine Laboratory[3], Beaufort, N.C. 28516.

Hemoglobin adducts are commonly employed as biomarkers for monitoring exposure to toxic compounds. Typically, characterization and quantitation involves isolation of the globin chains, protein degradation, derivatiza tion and gas chromatography. Electrospray ionization mass spectrometry (ESI-MS) offers the possibility of analyzing hemoglobins for adduct formation without extensive sample preparation. Rats are frequently used as animal models for toxicological studies. The structure of rat hemoglobin is complex and consists of at least six hemoglobins. There are two forms of the globin α chain and three forms of the β chain. We report here ESI-MS studies of hemoglobin adduct formation in rats chronically exposed to the neurotoxin, acrylamide, and the development of complementary in vitro methods to study hemoglobin adduct formation.

In vivo: Sprague-Dawley rats were exposed to different levels of acrylamide (0.1, 0.2, 0.3 mmol/kg/day) by repeated intraperitoneal injection. After 21 days the globin chains were isolated from hemolysates by oxalic acid/acetone precipitation and subjected to Sephadex G25 chromatography prior to analysis. In vitro: Normal Sprague-Dawley rat erythrocytes were washed and lysed. The hemolysate was extensively dialysed prior to the removal of ionic cofactors by Sephadex G25 chromatography. Rat hemoglobins were fractionated by anion exchange chromatography on DEAE Sephadex using a Pharmacia FPLC system. Rat hemoglobins were analyzed directly by ESI-MS. The time course of the reaction of total rat hemoglobin (0.5 mM) and isolated individual hemoglobins (0.05-0.5 mM) with acrylamide (10 mM) was monitored by ESI-MS by direct loop injection of the reaction mixture. ESI-MS: Solutions of rat globins or hemoglobin were electrosprayed in water containing 50% acetonitrile and 1% formic acid. Mass spectra were acquired using a Fisons/VG Trio 2000 quadrupole mass spectrometer. Mass spectra were transformed to molecular mass spectra using the manufacturers' software.

The molecular mass spectra of normal rat globins and those from rats that were chronically exposed to different levels of acrylamide are shown in Figure 1. In the control rat both types of α globin chain are resolved. The β chains, however, are not clearly resolved but appear to be dominated by a major component with a molecular mass of 15848. No acrylamide adduction is found for the α chains of globins from animals exposed to acrylamide. In contrast, the β chains are extensively modified. The molecular mass of the of the adducted globin chain is 15920 This corresponds to an increment of 72 mass units which is close to the expected value of 71 as a result of the formation of the thioether by reaction of acrylamide with the sulfhydryl of cysteine. The extent of adduct formation correlates with the degree of exposure to acrylamide. The results of the in vitro reaction of acrylamide (10 mM acrylamide for 3 hours) with hemoglobin are shown in Figure 2. The results are similar to those from the in vivo experiments and show that in the isolated rat hemoglobin under these conditions only β chains react with acrylamide. The degree of resolution of the β chain region does not permit any conclusions as to which β chains are adducted, as is the case for the in vivo experiments. In an attempt to clarify which hemoglobins react with acrylamide, rat hemoglobin was fractionated by anionic exchange chromatography. Four major fractions were obtained. The globin composition of the hemoglobins in the different fractions are given in Table 1. Only hemoglobins that contain the β_1 globin chain form adducts with acrylamide. The β_1 chains are very reactive and under the experimental conditions the majority of the β_1 chains are converted to the adducted form. Figure 3 illustrates the sequential adduction of fraction 2 ($(\alpha_2)_2(\beta_1)_2$) of rat hemoglobin. Prolonged incubation results in further adduction of the less reactive sites not only of the β_1 globin chain but also of the α_1 globin chain in the hemoglobin tetramer. The molecular mass data from these studies are summarized in Table 2. The general applicability of the approach is illustrated in Figure 4 which shows the molecular mass spectrum of human hemoglobin (HbA_0) before and after prolonged incubation with acrylamide.

The present study demonstrates the potential of ESI-MS to study hemoglobin adduct formation. Previous GC/MS studies of acrylamide adduct formation in rats have shown that the the cysteine residues are the most reactive. The ESI-MS studies show that both in vivo and in vitro exposure of rat hemoglobin to acrylamide leads to the formation of an adduct with a mass that is expected for the for the formation of the thioether and that under under most conditions only hemoglobins that contain β_1 globin chains have any appreciable reactivity towards the neurotoxin. This globin chain has an exposed cysteine at position 125 in the hemoglobin tetramer. The development of a staightforward in vitro -on line- method to study the time dependence of adduct formation allows the comparison of relative reactivities of animal hemoglobin towards acrylamide and other environmental pollutants. Chain separation followed by proteolytic digestion and HPLC/ESI-MS will permit the determination the relative reactivities of specific sites in the hemoglobin tetramer.

An Ion Spray Mass Spectrometric Study of Molecular Recognition between the Vancomycin Family of Antibiotics and a Model Bacterial Cell Wall Mucopeptide Precursor.

H. K. Lim[1,2], Y.L. Hsieh[2] and J.D. Henion[2], [1]Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543 and [2]Drug Testing and Toxicology, Cornell University, Ithaca, NY 14850.

The vancomycin family of antibiotics which include vancomycin and ristocetin are selective towards gram-positive bacteria. Vancomycin is the only member of this family that is still used clinically in the treatment of infections caused by staphylococci, streptococci, enterococci and clostridium. NMR and UV spectroscopies show that antibiotics of the vancomycin family bind specifically and noncovalently to a model precursor of the bacterial cell wall mucopeptide: di-N-acetyl-L-Lys-D-Ala-D-Ala [DALAA] (1,2). Furthermore, a specific C-terminal sequence of the mucopeptide ending in -D-Ala-D-Ala is absolutely required for the host-guest molecular recognition of the bacterial cell wall by the vancomycin antibiotics (2). Such well characterized noncovalent interactions are suited for investigation by the rapidly emerging utilization of ion spray mass spectrometry (IS-MS) to study molecular recognition processes in biology. The aim of this communication is to explore the feasibility of using IS-MS to study this important molecular recognition process in chemotherapy of bacterial infections.

The ion spray mass spectra from infusion of a 1:1 mixture of 25 µM each of either vancomycin or ristocetin and DALAA under relevant aqueous physiological pH and mild declustering conditions (30 V) are illustrated in Figures 1 and 2. The base peak in each mass spectrum is the doubly charged antibiotic+DALAA complex (m/z 911.5 [vancomycin+DALAA] and m/z 1220.7 [ristocetin+DALAA]); other ions present include the protonated DALAA (m/z 373.2), doubly charged antibiotic (m/z 725.4 [vancomycin] and m/z 1034.6 [ristocetin]), and protonated antibiotic (m/z 1449.8 [vancomycin] and m/z 2068.9 [ristocetin]). That the ions at m/z 911.5 and 1220.7 are the noncovalent complexes is supported by collision-induced dissociation of the complex to the protonated DALAA and the respective protonated antibiotic product ions. Furthermore, that this host-guest molecular recognition process is undoubtedly specific is indicated by the dramatic reduction in the noncovalent complex formation upon changing the last C-terminal amino acid residue in the ligand (di-N-acetyl-L-Lys-D-Ala-D-Lys and di-N-acetyl-L-Lys-D-Ala-D-Lactic Acid) used in the binding study with either vancomycin (Figure 3) or ristocetin (Figure 4). Similar reduction in complex formation was obtained upon substituting other polypeptide antibiotics with different mechanisms of action (bacitracin and rifampicin) as host in the study.

Competitive studies between vancomycin and ristocetin for DALAA show the formation of ternary (doubly and triply charged vancomycin+ristocetin+DALAA at m/z 1945.9 and 1297.3, respectively) and quaternary (triply charged vancomycin+ristocetin+2DALAA at m/z 1421.6) noncovalent complexes which apparently result from molecular recognition of the antibiotic-bound DALAA by another antibiotic. Interestingly, no complexes observed involved binding of DALAA with either two vancomycin or ristocetin molecules. The above observation is supported by the absence of these types of noncovalent complexes upon replacing either the ligand DALAA with di-N-acetyl-L-Lys-D-Ala-D-Lys or one of the antibiotic host with bacitracin in the study. Preliminary investigation by MS/MS did not reveal any differences in binding strength between either vancomycin or ristocetin and DALAA.

Mass Spectrometry of Bi-Substrate Inhibitors and Their Targeted Protein Kinases

Denes Medzihradszky*, Susan L. Chen, Wade M. Hines,
George L. Kenyon and Bradford W. Gibson
Department of Pharmaceutical Chemistry, University of California,
San Francisco, CA 94143

Several receptor protein tyrosine kinases, including insulin-like growth factor 1 receptor (IGF-1-R), are expressed at high levels in certain tumors, such as breast and ovarian carcinomas [1]. Several receptor kinases including epidermal growth factor receptor (EGF-R), are known oncogenes [2]. Although the kinase domain is presumably responsible for the effects of activation of the receptor, little is known about the biochemistry of the kinase domains. Our studies have concentrated on two areas, the expression of the kinase domain of IGF-1-R and EGF-R, and the development of bi-substrate inhibitors of protein tyrosine kinases. We are in the process of examining several expression systems for production of active, soluble kinase domain of IGF-1-R. Electrospray HPLC-MS is being used for the characterization of expressed IGF-1-R kinase domain, both intact and digested forms. The formation of insoluble inclusion bodies for this kinase domain has presented special problems for our protein characterization efforts. This protein will be used for detailed kinetic studies, inhibitor assays and crystallographic analysis.

We have constructed a new protocol for the synthesis of bi-substrate analogs based on the appropriate peptide substrate with covalently attached AMP, ADP and ATP moieties (**Fig 1**). The peptides were synthetised on solid phase using Fmoc chemistry, phosphorylated, phosphate protecting groups selectively removed, and the activated adenosine-phosphate [3] was coupled to the immobilized phosphopeptide. After TFA cleavage AXP peptides were isolated with good yield. These peptide chimeras are currently being evaluated as inhibitors of cAMP-dependent protein kinase, the only protein kinase for which a crystal structure has been determined [4, 5].

We found that these potential transition state analog inhibitors readily form metal complexes, being detected in abundance in positive liquid secondary ion spectra. Tandem mass spectrometry and CID analysis were used for the characterization of the synthetic peptide analogs for which some unique and characteristic fragment ions have been observed (**Fig 2**).

The Use of Packed Capillary LC/MS to Monitor Phosphokinase Activity in Rat Cardiomyocytes

B.L Ackermann, B.T. Regg, J.E. Coutant, K.A. Diekema, and R.J. Dinerstein
Marion Merrell Dow Research Institute, Cincinnati, OH 45215

Protein kinases are an important class of enzymes that regulate cellular responses by changing the conformation of proteins through phosphorylation. Knowledge of which kinases are activated in response to various stimuli is therefore important to understanding the mechanisms of cellular control. Kinases are most often studied in their *isolated* form in conjunction with [γ-^{32}P]-ATP to study the phosphorylation of a particular substrate by a *single* kinase. This presentation describes our initial effort aimed at developing a method to monitor the activity of *multiple* kinases at the *cellular* level. The approach taken involves the addition of five exogenous peptide substrates for target kinases to rat cardiomyocytes immediately upon lysis; the phosphorylated substrates are then isolated and detected through the use of packed capillary LC/MS with electrospray ionization (ESI) using multiple ion detection (MID).

Initial studies were performed to determine the number of cells required for extraction and the working range for analysis. Figure 1 shows the single and doubly protonated ions for phosphokemptide (KT-P) isolated from rat cardiomyocytes stimulated for maximal Protein Kinase A activity in 1 mM cyclic AMP (cAMP). The combined area of these peaks was 67-fold greater than a similar analysis of cells extracted under basal conditions (no stimulus). In an analogous experiment, the ability to detect the phosphorylated forms of all five peptide substrates was demonstrated. For this experiment, the kinase substrates (100 µM ea.) and ATP (100 µM) were added to cells immediately upon lysis and allowed to react at 37C for 20 min. The phosphorylated substrates were isolated by a procedure involving centrifugation, ultrafiltration, and solid phase extraction. The amount injected for LC-ESI-MS corresponded to an extraction of about 5.4 x 10 E4 cells.

In order to demonstrate linearity over the anticipated working range of analysis, standard curves were prepared for all five substrates. Linearity was obtained between 2.5 and 250 pmol for each substrate. Figure 2 shows data from the injection of 250 pmol of the five phosphokinase substrate standards along with 100 pmol of the internal standard leucine enkephalin (LE). Also present is a trace for phosphokemptide (KT-P). This standard was prepared enzymatically using Protein Kinase A. We are in the process of preparing phosphorylated standards for the four remaining substrates. Ultimately, the standard curves used for quantitation will be prepared using phosphorylated standards which are extracted to account for recovery.

Smithkline Beecham Pharmaceuticals, King of Prussia, PA.
[1]Department of Physiology and Biophysics, SUNY Stony Brook, Stony Brook NY.

In the mid 1950s, phosphorylation was recognized as a reversible means of modulating protein function. By phosphorylating specific serine, threonine and tyrosine residues, protein kinases alter the functions of their target proteins. The fact that a specific kinase can selectively phosphorylate a wide variety of proteins, has led to the question of how the enzyme recognizes specific residues from among the many hydroxyl groups found in the substrate protein. Additionally important is the identity of the residues and domains in the kinases themselves which are responsible for protein recognition. It is largely the lack of information in this area which has made it difficult to reconcile the frequent exceptions found when attempting to predict protein phosphorylation based on phosphorylation site motifs.

It was nearly 30 years after the discovery of the cAMP dependent protein kinase, that the first tyrosine-protein kinase was identified. Since that time, nearly 20 additional tyrosine phosphorylating kinases have been discovered. Although phosphotyrosine accounts for less than 1% of all phosphorylated amino acids, tyrosine-protein kinases have proved to be intensely interesting since at least eight of them are the protein products of retroviral oncogenes. Because abnormal tyrosine phosphorylation is manifest in cells transformed by many of the viruses, the idea has been put forth, that phosphorylation of tyrosine in critical cellular proteins may be a signal initiating cell transformation. Unfortunately proof of this has not be forthcoming. A large part of the problem in understanding the function of tyrosine-protein kinases has been a lack of success in identifying natural substrates, other than autophosphorylation sites, whose functions have been modified in a way that would explain transformation events. In order to determine optimal peptide substrates for specific protein kinases, amino acids in critical positions of known phosphorylated sequences (e.g. autophosphorylation sites) are randomized. These synthetic peptide "libraries" are then incubated with the enzyme and the phosphorylated peptides determined. We have been attempting to probe the catalytic domains of tyrosine-protein kinases using peptide substrate libraries in conjunction with mass spectrometry.

Cellular and viral Src are members of the non-receptor subfamily of tyrosine-protein kinases. Both proteins are membrane bound via an N-terminal myristoyl. c-Src is phosphorylated by an unknown kinase at Tyr^{527}, allowing a head to tail association of the C-terminal region with the SH2 domain, leaving it inactive. The function of c-Src in normal cells is unknown. The viral form of Src, which is expressed by the Rous Sarcoma virus gene *v-Src*, lacks the Tyr^{527}, and is a potent tyrosine-protein kinase. A peptide covering the autophosphorylation site of vSrc, R^{408}RLIEDAEYAARG^{420} was randomized at position 8, and the resulting "library of peptides" reacted with vSrc. Figure 1 shows the positive ion LC-ESMS analysis of 20µL from the reaction. The expected substrate, the $[Glu]^8$ Src peptide is not phosphorylated. Manual inspection of the data reveals an [M+H]+ ion which corresponded to a $[His]^8$ phosTyr substitution. The RIC of this peptides spectrum is plotted against the TIC. Independent synthesis of the authentic $[His]^8$ peptide and reaction with Src showed it was, in fact, a substrate for the enzyme.

The process of manually inspecting LC-MS data for prospective phosphorylated peptides among substrate libraries is tedious at best. The task becomes daunting when either the number of random positions or the number of templates is increased beyond one. The same can be said for inspecting enzyme digests of large phosphorylated proteins. We have, therefore, been investigating ways to selectively detect phosphopeptides in complex mixtures. In ESMS, at high declustering potentials, the negative ion spectra of phosphopeptides show ions at m/z 63 and 79 corresponding to PO_2^- and PO_3^- respectively (For more information see Huddleston et.al. this volume). Figure 2 shows the negative ion, stepped collision energy LC-ESMS analysis of 20µL of a Kemptide library reaction with the cAMP-dependent protein kinase. In this library, the 2 position in the sequence LRRASLG has been randomized. The MS was scanned discontinuously from m/z 50-100 at OR = -350V and then from m/z 400-1000 at OR= -115. The RIC is sum of m/z 63 and 79 and is plotted against the TIC. The results from this experiment show that

with L*RASLG as a template each peptide in the library is phosphorylated to some extent by cAMK. Furthermore, this suggests that the use of negative ion stepped-collision energy MS is an efficient way to approach the problem of looking for enzyme substrates in peptide library reactions.

ACKNOWLEDGEMENTS The authors are very grateful to Mike Huddleston (SmithKline) for assistance with the negative ion MS and Jeff Till (Stony Brook) for work on the enzyme reactions.

Analysis of Iron-Sulfur Proteins by Electrospray Mass Spectrometry

***E. Forest[1], Y. Petillot[1], J. M. Moulis[2], J. Meyer[2]**
[1]Institut de Biologie Structurale, [2]Département de Biologie Moléculaire et Structurale, 38 Grenoble, France

In order to characterize iron-sulfur proteins, we have implemented electrospray ionization mass spectrometry (ESI-MS), which has proved to be a valuable technique for precise mass determinations of biopolymers. However, as the interface conditions are selected to provide efficient ionization and sufficient excitation for a good desolvation, labile species are most often dissociated. The iron-sulfur proteins are a typical case of such an occurrence: since the iron-sulfur bonds are weaker than the other bonds involved in proteins, the metal centers are likely to be removed during implementation of the method.

Thus, we have carried out a comparative analysis of several iron-sulfur proteins with various stabilities: a high potential iron protein (HiPIP) from *Chromatium tepidum* (Moulis et al., 1993), a ferredoxin and several forms of rubredoxins from *Clostridium pasteurianum*. Rubredoxins are small proteins, the active site of which consists of an iron atom coordinated to four cysteinyl sulfur atoms. Three forms were analysed in positive and negative modes. With a recombinant rubredoxin expressed in *E. coli*, a partial loss of the iron ion appears in the positive mode spectrum, whereas there is no evidence for apoprotein formation in negative mode. This indicates that the conditions of ionization in the positive mode are somewhat detrimental to the protein. The spectra of the native rubredoxin from *C. pasteurianum* show a major component corresponding to a formylated N-terminal methionine together with an unblocked protein. The ratio of holoprotein to apoprotein is much larger in the case of the formylated rubredoxin than in the case of the non-formylated one. This suggests a greater stability of the formylated rubredoxin, as compared to the non-formylated one. Mass spectra of another protein expressed in *E. coli*, allow to identify it as a rubredoxin with a zinc atom replacing iron. In positive mode, no holoprotein is detected and conversely, in negative mode, no apoprotein is present (Figure 1). With a ferredoxin containing 2 [4Fe-4S] clusters and also extracted from *C. pasteurianum*, the negative mode spectrum also exclusively shows a peak corresponding to the holoprotein, whereas in positive mode, the apoprotein is mainly detected. The influence of the solvent is shown with mass spectra of a high potential ferredoxin contening one [4Fe-4S] cluster and isolated from *C. tepidum* and its expected stability is confirmed through these analyses.

From the data presented in this study, the negative ion mode can be anticipated to be more adapted to the investigation of small iron-sulfur proteins such as rubredoxins and ferredoxins: most of these proteins are acidic, and are therefore negatively charged at neutral pH, where their stability is highest. This opens the way to the detection and analysis, of less stable iron-sulfur proteins. One might then be able, by ESI-MS, to gain access to an often missing and most important piece of structural information, namely the precise composition of the metal centers.

Effect of Proline Residue on Transition Metal Ion Binding in Peptides Studied by ^{252} Cf-PDMS

*Zhaohong Hu and R.D.Macfarlane
Department of Chemistry, Texas A&M University
College Station, TX 77843.

^{252}Cf-PDMS has been used to study the coordinations between transition metal ions and peptides in our group for the past three years. The study of the interactions between Cu(II) and angiotensin (ANG) / bradykinin (BRK) peptides is reported here.

To acquire a spectrum of a peptide, the aqueous solution of 5 x 10^{-4}M of the peptide was prepared and deposited on a sample target. Nitrocellulose (NC) was used as the matrix to adsorb the peptide from solution onto its surface. To obtain a spectrum of a metal-peptide, equal volumes of 1 x 10^{-3}M ANGII and $Cu(NO_3)_2$ solutions were mixed together to gave a Cu-ANGII solution of 1:1 molar ratio and 5 x 10^{-4}M concentration. The solution pH was adjusted from acidic to neutral (*ca.* pH 2 to 7) by trimethylamine. This solution was mixed at room temperature for 10 minutes before it was deposited on a NC sample target.

The ANG peptides studied include ANGII, ANGI, and N$_\alpha$-acetyl-ANGI. Cu(II) is found to bind to ANG peptides primarily at two sites: the N-terminal amino group and its vicinity deprotonated amide nitrogens, and the imidazole ring of His residue and its adjacent deprotonated amide nitrogens. Between the two sites, the N-terminal site has a much stronger affinity towards Cu(II) than the other site. As an example, Figure 1 shows the mass spectrum of Cu-ANGII.

A Pro residue in a peptide functions as the breaking point to metal ion binding due to its lack of NH in the amide bond formed. Both ANG and BRK peptides contain Pro residues. In ANG peptides, the Pro residue is located next to His residue near the C-terminus of the peptides. In BRK, the Pro residue is the second one from the N-terminus. Our study demonstrates that ANG and BRK peptides display completely different properties in Cu(II)-binding due to the location of the Pro residue in the peptides. The Cu-BRK mass spectrum shown in Figure 2 presents this result.

In conclusion, we demonstrate that oligo-peptides in general have multiple Cu(II)-binding sites. The numbers of the sites can be evaluated by the molecular ions observed in the mass spectra. The N-terminal amino group and its adjacent amide nitrogen are important in Cu(II)-binding in oligo-peptides.

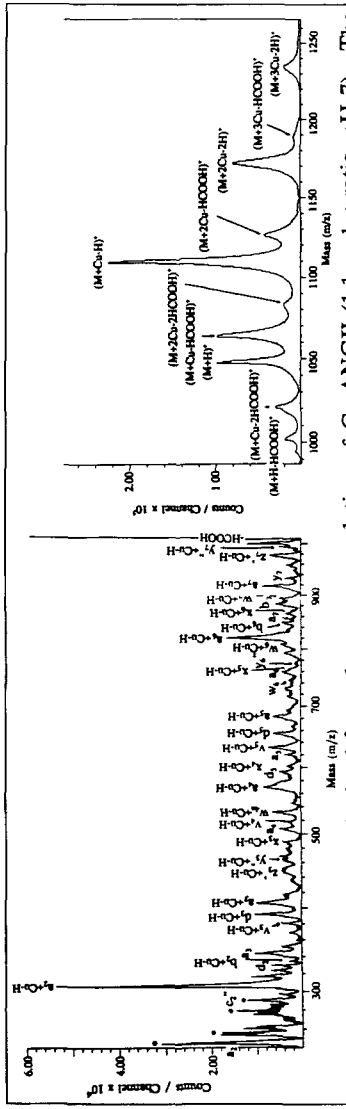

Figure 1. The spectrum obtained from the aqueous solution of Cu-ANGII (1:1 molar ratio, pH 7). The intense a_2+Cu-H peak indicates a strong Cu(II)-binding sites at the N-terminal end. The C-terminal Cu-containing ions provide evidence that His residue is a weaker Cu(II)-binding site. The molecular ions observed reveals three Cu(II)-binding sites.

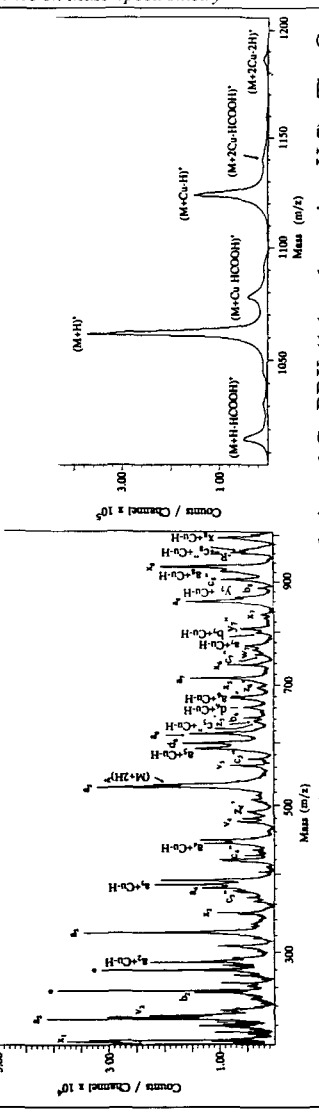

Figure 2. The spectrum obtained from the aqueous solution of Cu-BRK (1:1 molar ratio, pH 7). The Cu-containing ions are of much lower intensities compared to the non-Cu-containing ions. The result indicates that BRK has a much weaker affinity to Cu(II) compared to ANGII.

Studies of Anticancer Drugs Binding with the Metal-Detoxification Protein, Metallothionein II, by Ion Spray Mass Spectrometry

Y.L. Hsieh[1], Y.T. Li Hsieh[1], J. Henion[1], and B. Ganem[2]
[1] Drug Testing, Cornell University, 925 Warren Dr., Ithaca, NY 14850. [2] Department of Chemistry, Cornell University, Ithaca, NY 14853

Metallothionein II (MT II), a cysteine-rich protein with a three-metal cluster (two zinc plus one cadmium) and a four metal cluster (four cadmium)[1,2], coordinates with heavy metal ions and, therefore, confers resistance to metal-containing anticancer drugs, e.g., carboplatin (CP) and cisplatin[3,4]. The three-metal cluster is relatively less stable and exchanges the metal ion with hydrogen ions more rapidly in acid solutions. In this study we investigate the noncovalent coordinate complex formation between platinum from cisplatin and CP with sulfhydryl groups from MT II. The observed molecular weight of apo-MT II is 6119 Da (Figure 1). The molecular weight of the stronger four cadmium binding cluster in MT II, obtained by adding acid (pH~3) to remove the weaker two zinc and one cadmium binding cluster, is 6566 Da (Figure 2).

The mass spectrum obtained from binding of MT II with three CPs is from replacement of the three metal cluster (one cadmium and two zinc) in 10 mM ammonia acetate (pH=7) prior to adding 1% formic acid and 50/50 acetonitrile/H_2O + 1% formic acid shows coordinate complexes with one CP (Mr=6937), two CP (Mr=7308), and three CP (Mr=7679) (Figure 3). Alternatively, two hydrolyzed cisplatin products are shown to coordinate with four cadmium MT II. That this coordination reaction is highly specific for the platinum-based anticancer drugs is indicated by the absence of complex formation with actinomycin D and doxorubicin. The overexpression of MT II is confered to resist the antineoplastic angents, e.g., cisplatin and carboplatin, but only modest resist doxorubicin[5]. Support for a coordination complex between CP and four cadmium MT II was obtained by tandem mass spectrometry (MS/MS) (Figure 4). CID of the 5^+ CP-four cadmium MT II complex (m/z 1388) at 250 eV and 550 eV collision energy produces CP (m/z 372 at 1^+) and four cadmium MT II (m/z 1643 at 4^+). The results of MS/MS are consistent with the concept of a coordinate complex between CP and MT II.

FORMATION STUDY OF METAL COMPLEXES SELF-ASSEMBLY BY ESMS

Leize E.[1], Krämer R.[2], Lehn J.M.[2] and Van Dorsselaer A.[1]
1 Laboratoire de Spectrométrie de Masse Bio-Organique,URA 31 CNRS-Université Louis Pasteur, 2 Laboratoire de Chimie Supramoléculaire, URA 422 CNRS-Université Louis Pasteur, Strasbourg, France.

INTRODUCTION:

Self-assembly is one of the basis of life chemistry. The determination of the different steps and the driving forces involved in the formation of large biological complexes is one of the major goal of modern biochemistry. Weak interactions play a particulary important role in this field. Some important molecule families are: phospholipids (they spontaneously build biological membranes), proteins (they cluster to form active enzymatic complexes and even form extremely complex machinery such as flagella constituted of more than 300 different proteins), DNA (they form the double helix, interact with specific proteins). Electrospray Mass Spectrometry (ESMS) may play an important role in these studies. The study of the polynuclear complexes self-assembly could help understanding the formation of large biological complexes.

Analytical challenge: The task consists in determining the different types of supramolecules formed at different stoichiometries of ligands and metal ions. This is an difficult analytical problem because diluted solutions (10^{-4} to 10^{-6} M) must be used. UV-vis spectrophototmetry is ususally considered as the method of choice for these studies. But in the case of multicomponent systems, spectrophotometric titration data are difficult to interpret. An analytical technique that would allow the identification of the different complexes formed during the titration would permit the interpretation of the UV-vis spectrophotometric data. ESMS seems to be appropriate for this kind of studies. It has been already shown that it is possible to obtain ESMS-spectra of polynuclear complexes in diluted solutions (10^{-5} to 10^{-6} M) without fragmentation and reduction [1].

Description of the model studied (Fig. 1): In this work we will investigate the possibilities of ESMS as a detection method of the different molecular species formed in solution when an increasing amount of Cu(I) is gradually added to a 1/1 mixture of both ligands: L^1 and L^2 [2]. The results from ESMS will be compared to the one obtained from a parallel UV-vis spectrophotometry. Our model is rather simple and UV-vis spectrophotometry can be used to determine the amount of the different species present in solution. This comparison should allow us to answer the key question: *Is it possible to use the intensity of the peudomolecular ions obtained by ESMS for quantization?*

RESULTS:

Spectrophotometric titration: A computer analysis of the titration data revealed that a chemical model including the formation of complexes **1** and **2** (Fig. 2) alone is close to the real situation. The formation constants and the species distribution for **1** and **2** were calculated. The initial formation of the yellow complex **2** and its transformation into the blue complex **1** can also be followed optically.

ESMS (Fig. 3): For the solution with 1.0 equivalent Cu(I), the major peak corresponds to the doubly-charged ion of **2** (m/z = 516.1). For the solution with 2.5 equivalents Cu(I), two intense peaks: the triply-charged ion **1** (m/z = 616.3) and the doubly-charged ion of **2** (m/z = 516.0). For the solution with 6.0 equivalents Cu(I), the spectrum was dominated by the fully assembled complex **1** at m/z = 616.3. The ionization of the complexes consisted in the loss of all the counter-ions PF_6^- and in the protonation of the uncoordinated basic ligands.

Comparison between ESMS and spectrophotometry (Table 1): The ESMS spectra confirm the appearance of complexes **1** and **2** during the titration. Moreover, the relative ESMS peak intensities for **1** and **2** fit well the species distribution obtained by spectrophotometry. A small amount of the complex **3** is revealed by ESMS alone. **3** might not be detectable by spectrophotometric analysis (intensity < 15%).

CONCLUSION:

ESMS appears to be a very valuable technique for the analysis of metal complexes that are in thermodynamic equilibrium in diluted solutions. For the study described here, the results obtained with

ESMS fit very well with those obtained with UV-vis spectrophotometry. The amount of species **1**, **2** and **3** deduced from the UV-vis spectrophotometric data and ESMS spectra are very close. *Then we can conclude that it is possible here to use the ESMS intensity of the peudomolecular ions for a quantization.* Furthermore both techniques show that complex **3** is immediatly transformed in **1** after its formation. This demonstrates *the high cooperativity of this system.*

STUDIES OF METALLOTHIONEIN AND ANTICANCER ALKYLATING AGENT INTERACTIONS

Xiaolan Yu, Zhuchun Wu, and Catherine Fenselau
Department of Chemistry and Biochemistry,
University of Maryland Baltimore County, Baltimore, MD 21228

INTRODUCTION: Metallothionein (MT) is an important family of metal-thiolate proteins with high metal and cysteine content [1]. It is responsible for much of the intracellular sequestration of Cd and cells tolerate the toxicity of Cd, at least temporarily, by massive amplification of the MT gene. It is our interest, however, to study the hypothesis that MT (also) covalently sequesters alkylating agents. The alkylating agents cis-diamminedichloroplatinum, melphalan, and chlorambucil are commonly used in cancer treatment. Their therapeutic values are attenuated by the development of drug resistance in patients receiving them. Cells with overexpressed MT levels conferred resistance against these alkylating agents [2]. Increased intracellular drug binding is considered to be one of the mechanisms that are responsible for the phenomenon of acquired drug resistance.

EXPERIMENTAL: Rabbit liver metallothionein 2 (MT-2) was purchased from Sigma. Reversed phase high performance liquid chromatography (HPLC) was conducted using a C8 column (Aquapore RP-300, 250 x 4.6 mm). Electrospray ionization mass spectrometry (ESMS) was performed on a Vestec (Houston, Texas) electrospray source fitted to a Hewlett-Packard (Palo Alto, CA) 5988A quadrupole mass spectrometer, with a Phrasor (Duarte,CA) high energy dynode detector and a Technivent (St.Louis, MO) data system. Samples in a mixture of water:methanol:acetic acid (47:50:3) were injected through a Rheodyne (Cotati, CA) 7125 loop injector, with a flow rate of 10 μL/min. The stainless steel needle was held at 2.2 kV and the source temperature was at 240°C. Fast atom bombardment mass spectrometry (FABMS) and tandem mass spectrometry (MS/MS) experiments were performed on a JEOL HX110/HX110 tandem mass spectrometer (Tokyo, Japan), controlled by DA 5000 and DA 7000 (Complement) data systems. The FAB gun was operated at 6 kV and the accelerating voltage was 10 kV. Helium was used as the collision gas and the collision cell was floated to 4 kV in MS/MS experiments. MT was Cys-methylated and HPLC purified before trypsin digest.

RESULTS: Native metallothionein was incubated with the alkylating agent melphalan *in vitro* at near physiological conditions for 30 minutes. The reaction mixture was then desalted and analyzed by HPLC and ESMS. About 10% of the protein was alkylated to form a 1:1 covalent adduct with melphalan. The alkylated MT was also purified by HPLC and weighed by ESMS (Fig. 1). The alkylated MT was then Cys-methylated and digested with trypsin to provide peptide fragments for analysis by ESMS. We were able to map the entire protein sequence and two new fragments from the alkylated MT were characterized to be 1:1 melphalan adducts. MS/MS experiments were then used to locate the exact alkylation site(s). It was determined that one cysteine in each peptide was alkylated by melphalan, as shown in Fig. 2.

CONCLUSIONS: It was determined that MT covalently sequesters alkylating agent melphalan *in vitro*. This is consistent with the hypothesis that induction of MT is involved in the development of drug resistance against melphalan and some other alkylating agents. Computer modeling allows us to rationalize this fairly specific drug-protein interaction.

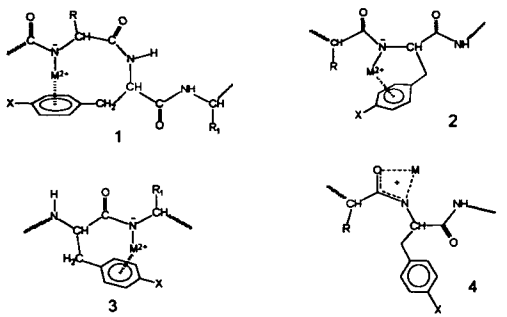
Influences of Peptide Side Chains on the Metal Binding Site in Metal Ion-Cationized Peptides: Participation of Aromatic Ring in Metal Chelation

Peifeng Hu, Curt Sorensen, and Michael L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304

The aromatic residues (Phe, Tyr, His, Trp) influence strongly the fragmentations of the metal-cationized peptides containing these residues when transition metal ions are involved. A metal-bound immonium ion of the aromatic residue and an (a_n - H) ion formed by reactions at the site of aromatic residue are the dominant fragment species. These residues direct the decompositions of alkaline earth metal-cationized peptides in a similar manner only for small peptides (e.g., tripeptides).

We interpret the side chain- and metal-dependent fragmentations to result from specific metal-side chain binding. The metal ion binds to a deprotonated amide nitrogen and chelates to the aromatic ring of the aromatic residue (**1-3**). The participation of the aromatic ring in the metal binding increases the populations of these structures by enhancing their relative stabilities with respect to the structures in which only amide group binding is involved (**4**). The fragmentation of structure 1 gives the (a_n - H) ion (Scheme I) whereas that of **2** produces immonium ions (Scheme II).



Labelling experiments show that formation of the (a_n - H) ion at the site of aromatic residue from transition metal-complexes involves an amide hydrogen rearrangement which is the opposite to the non-amide hydrogen transfer from alkaline earth metal-complexes. This contrast is explained by the differences of the two metal classes in their ability to bind to an aromatic ring. Transition metal ions (especially Ni^{2+} and Co^{2+} studied here) bind to aromatic ring so strongly that the formation of (a_n - H) ion occurs by the mechanism in Scheme I. Alkaline earth metal ions interact with aromatic ring weakly, and the formation of the appropriate (a_n - H) ion may proceed by a mechanism proposed previously[1] in which a hydrogen on the methylene carbon is transferred.

Disulfide Bond Analysis of Recombinant Proteins Using FAB and MALD-TOF Mass Spectrometry, J.E. Vath, E.B. Nickbarg, A.S. Harris, M.C. Huberty, W. Yu, S.A. Martin, H.A. Scoble, Genetics Institute, 1 Burtt Road, Andover, MA 01810

The disulfide bonds between cysteines are covalent modifications which define proximal regions in a protein. An understanding of the disulfide linkages is essential in order to gain insight into features of a protein which extend beyond the primary structure. We have been using mass spectrometry as an integral part of disulfide bond analysis in our laboratory. Two recent examples where it has been applied, in conjunction with N-terminal sequence analysis, are in the analysis of recombinant interleukin-12 human heterodimer (rhIL-12) and murine heavy chain (rmIL-12hc). Both FAB on a sector instrument and MALD-TOF on a reflector instrument were employed for these analyses and served to reveal some of the strengths and weaknesses of the techniques. This presentation focuses on certain aspects of sample preparation and illustrates some of the strengths of FAB and MALD to address disulfide analysis.

Mass spectrometry, as well as other disulfide detection schemes, require cleaving the protein backbone while leaving the disulfide bonds intact. In the case of the IL-12, Achro-K was used to cleave at the C-terminal side of lysine. Coeluting Cys containing peptides on the RP/HPLC map were identified by N-terminal sequence analysis. A strength of mass spectrometry is the ability to detect a mass corresponding to the oxidized state of disulfide-linked peptides, which provides direct evidence that a disulfide bond exists. This conclusion can be substantiated by the observation of the mass of the peptide component(s) under reducing conditions, which should reveal a shift in mass when compared to the oxidized peptide.

Direct analysis of the reduction reaction can be achieved in both FAB and MALD. For FAB, the sample is reacted in 1:1:1 glycerol/thioglycerol/30% ammonia under a heat gun (80-90°C) for 15 sec, followed by an addition of 1 part ammonia and heated again. For MALD, the sample (0.1-2 pmol/μL) is reacted in 20 mM Tris or phosphate buffer (pH 8), 10 mM DTT for 30 min at 50°C and 1 μL of the mixture is mixed with 2 μL of matrix solution, dried in air and analyzed. We have found that FAB is best for the analysis of intramolecular disulfide bonds on a single peptide such as that shown in **Figure 1**. In this case, the mass difference between the oxidized and reduced peptide is 2 u and would not be identified by MALD due to limited resolution and mass accuracy. FAB on a sector instrument is able to resolve the isotopic pattern of the peptide and unambiguously determine such a difference as seen in our example of the ^{12}C isotope shifting from m/z 2716.2 to 2718.3 upon reduction. MALD has a number of advantages including pmol sensitivity, extended mass range and tolerance for additives and buffers. For cases where multiple cysteines are in a single peptide, it is necessary to cleave between them in oreder to assign disulfide pairings and this often involves the use of multiple enzymes. The products of secondary digests can be analyzed by MALD directly from digestion buffers without purification. Furthermore, there is considerable evidence from our laboratory that a significant portion of the signal in MALD is made up of metastable fragment ions. In several examples, we have used a reflector at reduced potential to analyze the fragments for structural information for peptides (TP133) and carbohydrates (TOA910). Fragmentation of disulfides bonds can also be analyzed in this manner yielding information that is equivalent to partial reduction which can be useful for cases of four or more peptides bound together, as in **Figure 2**. This figure shows the reconstructed spectrum from four different potentials applied to the reflector and gives pairing information (i.e. M25 bound to M28 and not M29) that may not be recognized in a conventional experiment.

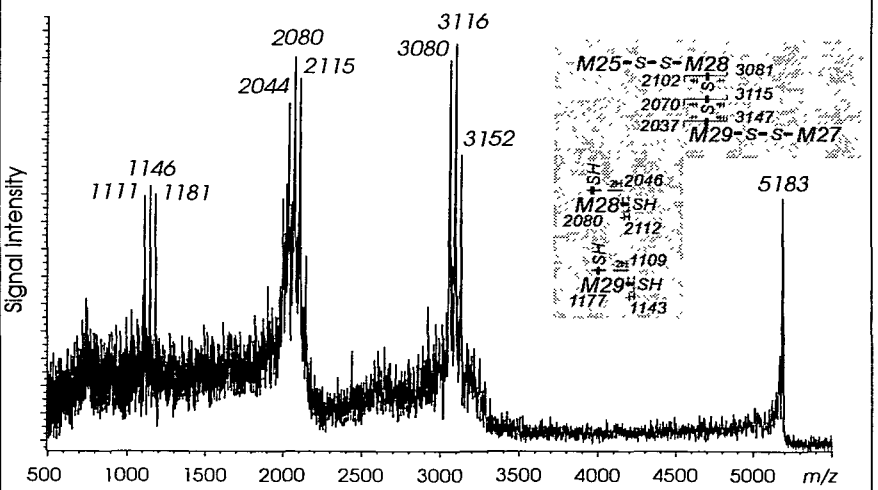

Figure 2. The MALD-TOF reflector spectrum of a rmIL-12hc disulfide cluster of five Achro-K peptides constructed by varying the reflector potential in four steps (30, 18 190, 12 224, and 6.828 kV)

Strategy to Determine Disulfide Bridge Arrangements, Investigation of Selective Reduction of Cystines using TCEP *A. G. Craig, E. Mahe, W. H. Fischer, W. R. Gray† and J. E. Rivier. The Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, P.O. Box 85800, San Diego, CA 92186-5800. †University of Utah, Salt Lake City

One of the advantages of tris(2-carboxyethyl) phosphine (TCEP) [1] is that it reduces organic disulfides to thiols in water at an acidic pH. TCEP was used with matrix assisted laser desorption ionization and liquid secondary ionization mass spectrometry (LSIMS) for the reduction of cystines in peptides. TCEP reduced bovine insulin *in situ* in vacuum when mixed with glycerol and m-nitro benzyl alcohol [2]. Insulin, K-toxin and a large number of other cyclic peptides and toxins contain pairs of adjacent cysteine residues. As a result, these peptides are not amenable to chemical or enzymatic proteolyses that would result in single disulfide bridge containing fragments generally required for determining disulfide arrangements. An alternative approach would be to selectively reduce a particular cystine (e.g. the specifically reduced cystine could be labeled and the connectivity determined if scrambling can be avoided) [3].

In the case of insulin (M = 5729.7 Da) the A-chain and the B-chain (M = 3395.7 Da) are linked by two inter disulfide bridges, while the A-chain (M = 2334.0 Da) contains an intra disulfide bridge. Both inter disulfide bridges must be cleaved to eliminate A-chain and B-chain fragments. As shown in the LSI mass spectra (Figure 1) measured directly after addition of TCEP and introduction into the mass spectrometer the measured mass of the A-chain fragment monoisotopic species (m/z 2338.9) remains constant with time. This measured mass indicated that the intra disulfide bridge of the A-chain was reduced prior to the remaining inter disulfide bridge.

The disulfide bridging arrangement of K-toxin (M = 2428.0 Da, single peptide chain with three bridges) has not been previously characterized. Since all disulfide bridges in a single chain peptide are intra-molecular we investigated proteolysis conditions to produce two fragments (F_1 and F_2) preferably with both inter and intra disulfide bridges. Proteolysis with trypsin in a phosphate buffer at pH 6.5 was found to result in no scrambling The LSI mass spectrum of the crude digest contained a major species at m/z 2175.7. This corresponded with the calculated mass of two fragments (F1 and F2, 1527 6 and 647 2 Da respectively) linked together and containing 3 disulfide bridges (where both F1 and F2 contain three Cys residues). The LSIMS spectrum of the major species after TCEP treatment contained monoisotopic $[F+H]^+$ ions at m/z 1531.6 and 651.2 corresponding with fully reduced fragments (i.e the observed masses were consistent with each fragment containing 3 cysteine residues). We conclude that either 3 inter disulfide bridges link the fragments or the intra disulfide bridges are reduced prior to the single inter disulfide bridge. In the former case the linkage between the two fragments is not useful for investigating the specificity of TCEP.

We have investigated partial reduction with TCEP of the intact K-toxin followed by HPLC purification to isolate three intermediates (R_1, R_2A and R_2B) with retention times intermediate the native (N) and fully reduced (R_3) species. We have alkylated R_1, R_2A and R_2B and observed a number of different species with HPLC. LSIMS analysis of each of the alkylated products of R_1 indicated that each species had 2 alkyl groups added to K-toxin. Similarly all of the R_2A and R_2B alkylated products had masses consistent with addition of 4 carboxy amido methyl (Cam) groups to K-toxin. CZE analysis of R_1 indicated that two species were contained within this broad HPLC peak while only one species was present within both R_2A and R_2B. We are observing four of six possible intermediates suggesting that one disulfide bridge is less readily opened.

We have monitored TCEP reduction of both insulin and a tryptic fragment of K-toxin *in situ* with LSIMS. Using this approach we observed a selective reduction of the intra disulfide bridge of insulin. This and other evidence (e.g. chromatographic and chemical labeling) indicated that TCEP reduction of disulfide bridge containing peptides was at least partially selective. Further studies are planned with peptides of differing disulfide arrangement, in order to generalize these findings and further investigate the level of specificity (e.g. is the intra bridge of insulin opened before or after the first inter bridge). This class of reagent presents unique advantages for elucidating the disulfide arrangement of peptides with adjacent cysteine residues.

USE OF MASS SPECTROMETRY TO MONITOR CHEMICAL REACTIONS IN PROTEINS

Rong Wang[1], Steven Birken[2] and Brian T. Chait[1]
[1]The Rockefeller University, New York, NY 10021,
[2]College of Physicians and Surgeons of Columbia University, New York, NY 10032

I. INTRODUCTION

Mass spectrometry finds important use in monitoring organic reactions because both final products and reaction intermediates can often be readily detected and identified, and reaction kinetics can be monitored. Such information can be of considerable assistance in the elucidation of reaction mechanisms. The advent of new ionization techniques, like matrix-assisted laser desorption, allows such reactions to be monitored in large complex molecules such as peptides and proteins.

Seleno-methionine (SeMet) is an analog of native methionine (Met) in which sulphur is replaced by selenium. The biosynthetic replacement of methionine residues by selenomethionine has been used in the determination of the three-dimensional structures of proteins by multiwavelength anomalous diffraction. (1)

However, in some cases (e.g. human chorionic gonadotropin), it has been found that crystals of the SeMet-substituted proteins do not produce useful diffraction patterns even though crystals of the Met-containing proteins diffract well. What causes this?

It has been reported (2) that selenomethionine is not as stable as methionine during acid hydrolysis and hydrogen peroxide oxidation. Therefore, one hypothesis to explain the difficulty in the crystallography study described above is that selenomethionine residue undergoes a significantly different oxidation chemistry than methionine. This oxidation of selenomethionine may disorder the structure of the protein or cause the loss of selenium.

II. EXPERIMENTAL

I. Oxidation Peptide samples (5 µg) were dissolved in 10 µL water or desired buffers. 100 µL of 30% hydrogen peroxide was added to the peptide solution and the oxidation reaction was allowed to proceed at room temperature for a desired time. The reaction mixture was then analyzed by mass spectrometry without separation and purification.

II. Matrix-Assisted Laser Desorption Mass Spectrometry Matrix-assisted laser desorption mass spectrometric analysis was carried out on a device constructed at The Rockefeller University. α-cyano-4-hydroxy-cinnapinic acid (4HCCA) was used as matrix. 1 µL of reaction solution was mixed with 10 µL of 4HCCA and 1.0 µL of this mixed solution was applied onto the sample probe.

III. RESULTS AND DISCUSSION

Two model peptides were used in this study. These two peptides share the common sequence Arg-Ala-Ala-Ala-X-Asn-Pro-Thr-Leu-Glu, where the X is methionine for the Met-peptide (M.W. 1073.2 Da) and X is selenomethionine for the SeMet-peptide (M.W. 1121.2 Da) respectively. Figure 1a and 2a are the spectra of these two peptides prior to any chemical treatment.

Figure 1b and 2b are the spectra of these two peptides after 20 minutes oxidation by

30% hydrogen peroxide in water (pH 6.4) at room temperature. The oxidation of the Met-peptide yielded the sulfoxide (M.W. 1089.8 Da) and the sulphone (M.W. 1106.1 Da) as previously reported. (3) However, the SeMet-peptide yields homoserine as the major oxidation product (M.W. 1043.6) rather than the selenoxide and the selenone. Some of the other reaction products were also detected by mass spectrometry (for example, the dehydro-2-aminobutyric acid residue formed by β elimination, peak at m/z 1027.6). These observed products lead us to propose the following reaction mechanism: the oxidation of selenide renders the methyl selenoxide a good leaving group with strong electron-withdrawing tendency. The oxidation can be followed either by a radical reaction forming the homoserine residue or β elimination forming the dehydro-2-aminobutyric acid residue.

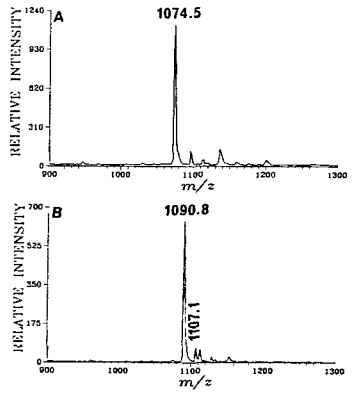

Figure 1 MALDMS spectra of Met-peptide before (a) and after (b) oxidation reaction.

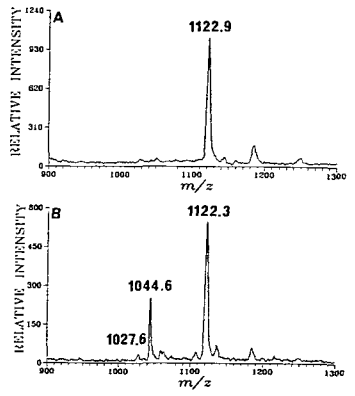

Figure 2 MALDMS spectra of SeMet-peptide before (a) and after (b) oxidation reaction.

We have also tested the sensitivity of the two peptides to oxidation by hydrogen peroxide. Under the same experimental conditions (pH 6.4), the Met-peptide shows a much higher sensitivity to oxidation than the SeMet-peptide. However, when the peptides were exposed to air, the SeMet-peptide is much more sensitive to oxidation than the Met-peptide.

The oxidations of both peptides are affected by the pH of the solution. The oxidation of the Met-peptide is much faster in basic conditions than in acidic conditions. Conversely, the oxidation of SeMet-peptide is much faster in acidic conditions than in basic conditions.

This study shows that mass spectrometry is a rapid, accurate, and sensitive means for monitoring chemical reactions in peptides and proteins

Oxidative Properties of Electrospray Ionization in the Analysis of Peptides

Kenneth Morand, Gert Talbo, *Matthias Mann

Protein and Peptide Group,
European Molecular Biology Laboratory,
Heidelberg, Germany

Electrospray ionization mass spectrometry (ESMS) has seen an increasingly important role in the analysis of large polar and labile compounds such as peptides and proteins. As a result of its wide applicability, many researchers have used ESMS to quantify components present in mixtures. For example, a popular use of ESMS is the determination of the purity of a peptide or protein, such as the determination of protein heterogeneity or the presence of oxidation. In uses such as this it is important that the behavior of the ES source be understood as thoroughly as possible.

Here, we report the observation of an adduct ion of the type [M+H+16]+ present in the electrospray ionization mass spectra of several synthetic and naturally occurring peptides. Initial results have shown that the appearance of the adduct ion is dependent on the field strength at the electrospray needle and the flow rate of the solution passing through the capillary. MS experiments of peptides containing the +16 Da adduct attributed the change to the selective oxidation of either a methionyl, tryptophyl, tyrosl, residue present in the peptide. These results were further confirmed by MS/MS experiments of peptides with a methionyl residue at either the N- or C-terminus, or within the peptide chain. This effect can occur under normal operating conditions and therefore care must be taken in the analysis of samples containing these oxidizable residues. Conversely, the selectivity of the oxidative process may be used to enhance the information obtained from the mass spectrometric analysis. For example, we show results for the analysis of an unknown neuropeptide where the occurrence of the $[M+H+16]^+$ ion is used along with MS/MS data to elucidate the peptide sequence and also that this method may allow one to rapidly screen peptide samples for their occurrence enhancing the information obtained from the analysis of a digestion.

The occurrence of the electrospray-induced oxidation may have further reaching analytical possibilities. While a number of amino acids are subject to oxidative reactions using this method, initial results suggest that methionine and tryptophan appear to give by far the most pronounced effect. More importantly, these amino acids are the only two for which the genetic code is not degenerate (i.e. for which there is only a single neucleotytic base triplet which codes for them). This feature makes them very desired in the construction of oligionucleotide probes used in genetic hybridization studies and, hence, it would be desirable to provide a means of screening unknown peptides for their appearance. Oxidation may also be inducible on the small, polar compounds in the analysis of which ESMS is increasingly used. Similar to the peptide case, our findings may have significance for the avoidance of artifacts created by the ionization method as well as for the selective detection of easily oxidizable compounds. We are currently exploring both of the above possibilities.

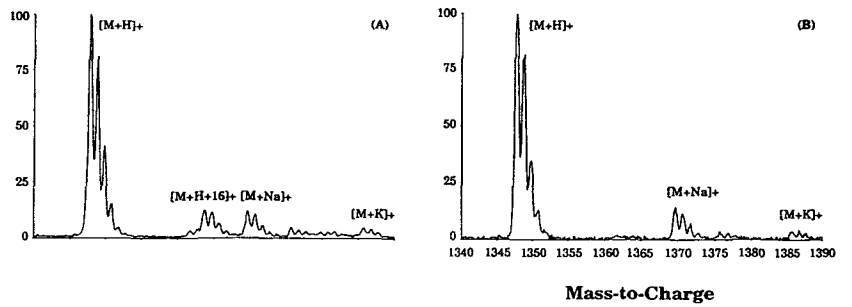

Figure 1: ESMS of substance P (RPKPQQFFGLM, M_r 1347.6) showing the presence of the $[M+H+16]^+$ adduct ion. The flow rate was 5 µL/min and the analyte concentration 25 pmole/µL. The voltage applied to the needle was varied between (a) 5kV and (b) 2.5kV.

Gas Phase Reduction-Alkylation For The Identification of Disulfide Bonds At Subnanomole Levels

R.S. Johnson and K.A. Walsh
Dept. of Biochemistry, University of Washington, Seattle, WA 98195

Disulfide bond formation between cysteines is a major post-translational modification of proteins. Identification of disulfide bonds can provide structural constraints within proteins of unknown three-dimensional structure, provide a basis for confirmation (or rejection) of homology between proteins, or provide evidence that a recombinant protein has folded properly. Typically, identification involves proteolytic or chemical cleavage such that peptides connected by single disulfide bonds are obtained; by sequencing these peptides the disulfide bonds can be identified. Usually such cleavage products can only be obtained from non-specific proteases,e.g., pepsin. This has the effect of greatly increasing the complexity of the mixture, making it impractical to purify individual peptides for Edman sequencing. Thus, mass spectrometry has been used to determine pre- and post-reduction molecular weights (1,2). Alternatively, the facile cleavage of disulfide bonds resulting from high energy collisions has been shown to be useful for identifying disulfide bonded peptides (3). Unfortunately, this cleavage has not been observed in low energy collisions, and chemical reduction / alkylation must be carried out when using a triple quadrupole instrument.

A protocol has been developed whereby a proteolytic digest is analyzed by LC/MS to determine the pre-reduction m/z values. A portion of the LC/MS eluent is split and fractions are collected by hand following detection by UV absorption. These fractions are dried and subjected to a single step gas-phase reduction / alkylation (using triethylphosphine and vinylpyridine), and post-reduction m/z values are determined by ionspray mass spectrometry. Correlations are made between pre- and post-reduction m/z values, and MS/MS is used to identify the reduced and alkylated peptides. In many cases, CID gives rise to a very abundant fragment ion of m/z 106 (protonated vinylpyridine); thus parent ion scans for m/z 106 can be employed for rapidly locating peptides containing pyridylethylated cysteine in multicomponent LC fractions. The use of a gas phase reaction reduces the degree of sample contamination and losses such that less than 100 pmol of disulfide-containing peptides can be analyzed. Shown in Fig. 1a is the ESI mass spectrum of a 2 pmol/ul solution of the disulfide-containing peptide oxytocin. Figure 1b depicts the same concentration of oxytocin after reduction / alkylation. The peptide concentration used to obtain Fig. 1b (reduced/ alkylated) was the same as Fig. 1a; indicating that there was little loss of sensitivity upon chemical treatment.

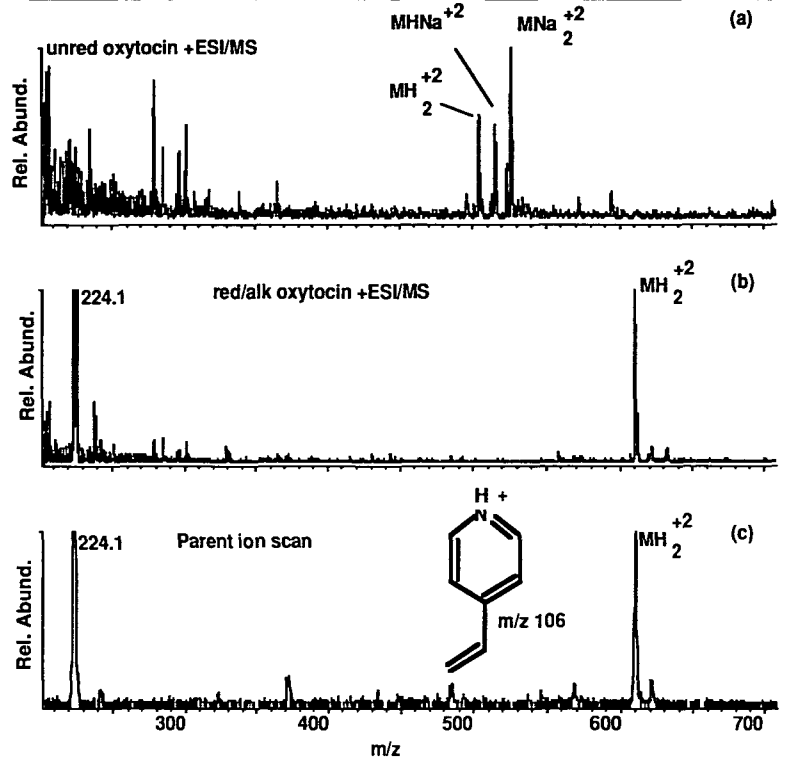

Figure 1: **(a)** +ESI/MS of unreduced oxytocin. **(b)** 80 pmol oxytocin dried in glass tube and subjected to gas phase reduction / alkylation. 500 ul of vinylpyridine (Sigma) and 500 ul of 1 M triethylphosphine in THF (Aldrich) was placed in the bottom of a modified amino acid hydrolysis chamber. A wad of glass wool served to support the sample tubes above the reagent positioned in a bulge of the chamber such that no condensation could run into the sample tubes. The reagents were frozen with liquid nitrogen, evacuated to approx. 130 mTorr, sealed, and warmed to room temperature. The reaction was complete within 1.5 hrs, after which the reagent was frozen, the vacuum released, and the sample tubes briefly placed on a Speed Vac to remove volatile reagent and contaminants. Both reduced and unreduced samples were dissolved in 50% MeOH + 0.1% formic acid at a conc of 2 pmol/ul and analyzed directly by +ESI/MS. **(c)** The same material as in (b), but analyzed by scanning Q1 while statically transmitting only ions of m/z 106 through Q3 (parent ion scan).

The Reactive Site of an Enzyme Inhibitor Complex of the Thiol Protease Cruzain Determined by High Energy Tandem Mass Spectometry

Zhonghua Yu§¶, Ann Eakin§, Patrick R. Jones¶, Charles S. Craik§ and A.L. Burlingame§
§ Department of Pharmaceutical chemistry, University of California, San Francisco, CA 94143, and ¶ Department of Chemistry, University of the Pacific, Stockton, CA 95211

Introduction

A cysteine(thiol) protease, named cruzain, has been found as a key metabolic enzyme in the parasite *Trypanosoma cruzi*, which is the etiologic agent of Chagas' disease, a debilitating disease affecting millions of people in South and Central America. Cruzain's protein sequence has been determined. The native active form of this protease contains 224 amino acid residues. A mutant of this protease, which contains 215 residues having a molecular weight of 22,696 daltons, has the same activity as the wild type [1].

The activity of the protease was effectively inhibited by benzyloxycarbonyl-phenylalanine-alanine-fluoromethyl ketone (Z-Phe-Ala-FMK). The mechanism of inhibition and the reactive site(s) of the protein must be determined to facilitate possible drug designs for the treatment of Chagas' disease. We employed a mass spectrometric strategy to address this issue and determined that one inhibitor is covalently bound to the side chain of cysteine 25.

Procedures

The molecular weight of the inhibited protein was determined by electrospray mass spectrometry. Then the protein was reduced and alkylated. Enzymatic cleavage was carried out by using trypsin, chymotrypsin, V8 and Asp-N protease respectively. The resulting peptides were separated on HPLC and their masses determined by either LSIMS or ESIMS. Subdigestion was performed to cleave the inhibitor containing peptide in order to obtain peptides of appropriate size for MS/MS experiments. High energy CID mass spectra were obtained from a Kratos Concept tandem mass spectrometer of EBEB geometry.

Results

Electrospray mass spectrometry of the inhibited protein showed a molecular weight of 23,062±4 daltons. The mass difference between the inhibited and the uninhibited protein is 365 daltons, which corresponds to one inhibitor residue (M.W.=367daltons). This experiment demonstrated a stoichiometry of one inhibitor per protein molecule.

From peptide mapping of the enzymatic digests, one peptide was found to match the mass of residue 18 to 49 plus one inhibitor. Chymotryptic subdigestion of this peptide generated another peptide, with an MH+ of 1407.5, which corresponds to residue 18-26 plus one inhibitor.

A high energy collisional induced dissociation (CID) tandem mass spectrometric experiment was performed on this peptide. The CID spectrum unambiguously revealed the structure of this peptide, with one inhibitor covalently attached to the side chain of cysteine 25 (Fig.1).

Discussion

Covalent modifications often change the structure and function of a protein, resulting in promotion or inhibition of the protein's biological activity. Characterization of the types and sites of modification is a major step in elucidating the mechanism of a specific process. For characterizing the modification site of cruzain, previous nuclear magnetic

resonance (NMR) experiments suggested that the inhibitor might bind to the side chain of histidine 162. In our work, LSIMS alone has already provided negative evidence for this assignment because the peptide of MH+ 1086.4 only corresponded to the peptide 161-170. However, high energy CID mass spectrometric experiment was required to assign the exact modification site.

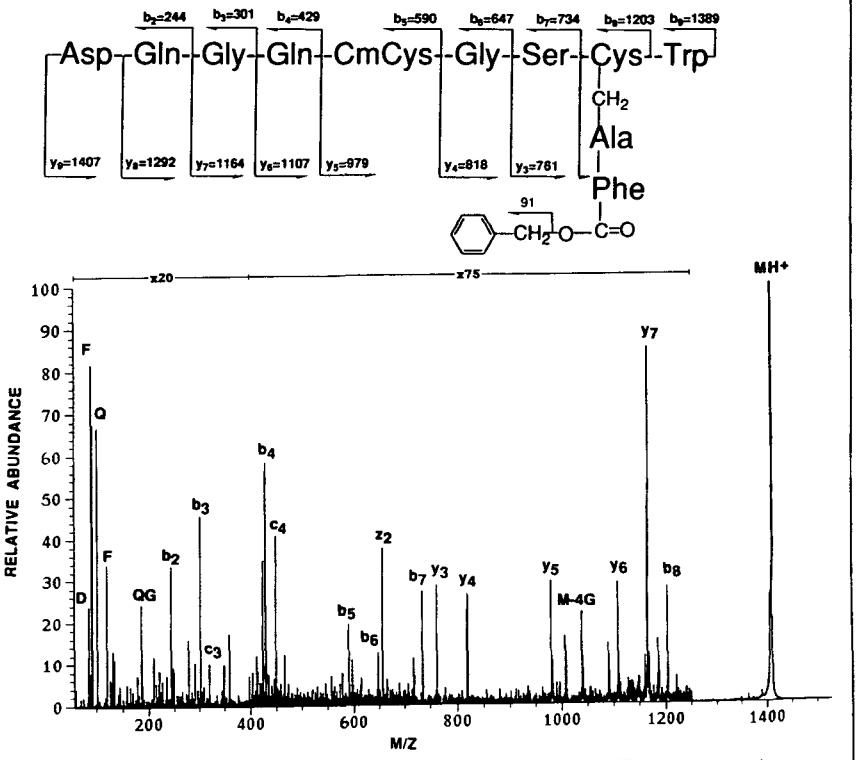

Figure 1. High energy CID mass spectrum of the modified peptide. The b and y series ions were the major products.

THE DETERMINATION OF THE PRIMARY STRUCTURE OF THE GLUTAREDOXIN ISOLATED FROM HUMAN ERYTHROCYTES (hErGrx)

Vladimir V. Papov and Klaus Biemann
Dept. of Chemistry, Mass. Inst. of Technology, Cambridge, MA 02139

Glutaredoxins, (also known as thioltransferases), are important in the synthesis of deoxyribonucleotides and are also thought to play a role in cellular sulfhydryl homeostasis. Glutaredoxins exhibit a high degree of homology and are thus of interest in evolutionary studies. A human erythrocyte glutaredoxin has been isolated and characterized by J.J. Mieyal *et al.*, and has been shown to possess catalytic and metabolic properties common to other mammalian glutaredoxins.[1] The human glutaredoxin has been described as a single polypeptide (having an M_r of *ca.* 11,300 by SDS-PAGE) possessing a blocked amino terminus and containing four cysteine residues. The human erythrocyte glutaredoxin is believed to play a role in the maintenance of reduced sulfhydryls in the red blood cells. The primary structure of the human erythrocyte glutaredoxin has now been determined solely by tandem mass spectrometry following a strategy used previously in this laboratory to determine the amino acid sequence of the glutaredoxin from rabbit bone marrow.[2]

Prior to the tandem mass spectrometry experiments, the molecular weight (M_r) of the native human erythrocyte glutaredoxin was determined by matrix-assisted-laser-desorption-ionization time-of-flight (MALDI-TOF) mass spectrometry to be 11,841. The MALDI-TOF mass spectrum of the native glutaredoxin is shown in Figure 1A. The M_r of the S-ethylpyridylated protein, (mass spectrum shown in Figure 1C) increased by 373 u to 12,214. Analysis of the reduced glutaredoxin, (mass spectrum in Figure 1B), revealed that the M_r had decreased to 11,688 and that the mass difference (526 u) from reduced to the S-ethylpyridylated protein now corresponded to the incorporation of five ethylpyridyl groups.

The S-alkylated human glutaredoxin was enzymatically digested and the resultant peptides partially fractionated by reversed-phase HPLC. The molecular weight of the peptides was determined by fast atom bombardment mass spectrometry (FABMS). S-carbamidomethylated glutaredoxin was first digested with trypsin and several of the larger tryptic peptides were further digested with Endo-Asp-N. The amino acid sequences were derived from the collision-induced-dissociation (CID) mass spectra of the peptides. Overlapping sequences from a separate chymotryptic digest of glutaredoxin were used to align the peptides and to assign their position in the glutaredoxin sequence. Lys and Gln (having the same nominal mass) were differentiated on the basis of the specificity of Endo-Lys-C. All of the twenty-one Leu and Ile residues in the human glutaredoxin were differentiated based on the d_n and w_n ions in the CID spectra of tryptic and chymotryptic peptides.

The experimentally determined masses (by MALDI-TOF-MS) for the reduced and S-alkylated glutaredoxin were in close agreement with the calculated masses based on the mass spectrometrically derived glutaredoxin sequence. The human glutaredoxin was found to be highly homologous to the other mammalian glutaredoxins and also contains an acetylated N-terminus. Mass spectrometry has revealed some of the unique features of the human glutaredoxin including five rather than four cysteines, the absence of Met, His at position 52, and a possible heterogeneity (Asp and Asn) at position 51 in the glutaredoxin sequence.

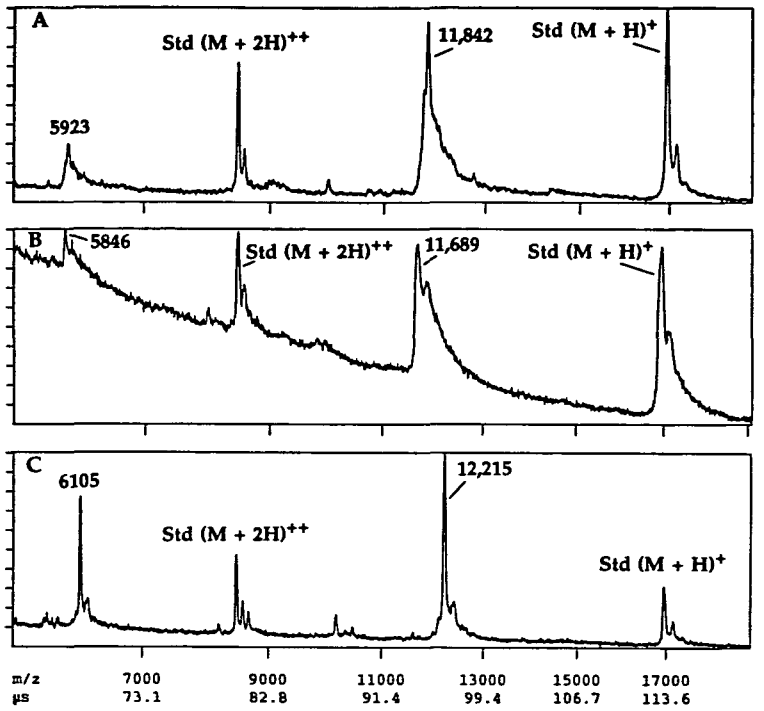

Figure 1. MALDI-TOF mass spectra of glutaredoxin isolated from human erythrocytes. The ions labelled Std $(M + H)^+$ and Std $(M + H)^+$ at *m/z* 16,952.5 and 8476.8, respectively, are due to the internal standard (horse heart myoglobin). **A:** native, **B:** reduced, **C:** S-ethylpyridylated. The matrix was sinapinic acid and the low intensity signals adjacent to the major peaks are adducts of the matrix.

Introduction

Mambas (*Dendroaspis*), Cobras (*Naja, Hemachatus*) and Coral Snakes (*Micrurus*) all possess venomous bites, where 90 % of the dried venom consists of small molecular weight protein components. The number of toxins present in snake venoms have been estimated at around thirty by conventional methods[1], but CE-ESI-SIM-MS experiments indicated the presence of around 100 toxins in the venom of *Dendroaspis polylepis* [2]. We are interested in how much preliminary information about complex peptide mixtures (snake venoms) can be gleaned simply from the mass spectra acquired using ESI-MS and MALDI-TOF-MS.

Results and Discussion

Both ESI-MS and MALDI-TOF-MS can provide useful information about the molecular masses of species present within a snake venom. The acquisition of ESI-MS spectra was routine and run to run reproducibility was superior to MALDI-TOF-MS. Ease of acquisition of MALDI-TOF-MS spectra of the snake venoms was dependent on the matrix identity and the polarity of the accelerating voltage.

The low resolution of linear MALDI-TOF-MS means that baseline resolution of peptides with closely related molecular masses can be difficult. The abundant low mass peptides in the venom from *Hemachatus haemachatus* have molecular masses between 6740 and 6940 daltons. In this region of the ESI-MS spectrum we noted 13 peptides including the sequenced toxins 11, 11A, 12A and 12B. In comparison the best MALDI-TOF-MS results noted 6 major peptides Similarly, the major peptides in the venom of *Micrurus fulvius* have molecular masses around 13400, but the low resolution of MALDI-TOF-MS only allows definite mass assignment of the base peaks. In these cases MALDI-TOF-MS provides a useful indication of the approximate molecular weights of groups of ions whereas ESI-MS provides extra resolution for improved characterization of species within the group

The molecular mass assignments provided by ESI-MS and MALDI-TOF-MS have been used to provide confirmation of sequences reported in the literature Spectra of the full venom can definitely confirm the presence of a peptide of a particular molecular mass but cannot prove unequivocally that a toxin is not present because suppression was noted with both methodologies Mass analysis of the individual peptides would be desirable to unequivocally confirm the published sequences. Of the 24 sequenced peptides, for which molecular masses could be assigned from the ESI-MS spectrum the mass accuracy mainly ranges from 0.006% to 0.05%. This compares to a mass accuracy of 0 1% obtained with external calibration for MALDI-TOF-MS

Ion suppression in the MALDI-TOF-MS spectra

The venom of *Dendroaspis polylepis* has been roughly quantified; the major component of the venom, Toxin I (M_r=7132.4), constitutes 20% of the venom[1]. The electrospray spectrum is dominated by the $(M + 7H)^{7+}$ and $(M + 6H)^{6+}$ ions of Toxin I at *m/z* = 1020 and *m/z* = 1190, respectively, but the positive ion MALDI-TOF-MS spectrum using sinapinic acid (+SA) matrix is dominated, instead, by an ion of *m/z* = 6806 resulting from Toxin C (1.5% of venom)[1], while the base peak in the negative ion spectrum, using sinapinic acid (-SA), results from Protein CM-3 (m/z = 7336). The relative abundances of species seen in the electrospray spectrum have been

further clarified by CE-ESI-SIM-MS experiments and other significant peptides in this venom which only show a small response with sinapinic acid, include peptides of molecular weights 7986 (Toxin δ) and 8004 daltons[2]. This suppression of specific peptides can be overcome by use of alternative matrices. The positive ion MALDI-TOF-MS spectrum obtained using α-cyano-4-hydroxycinnamic acid (+CA) as the matrix yielded the $(M + H)^+$ ion of Toxin I as the base peak together with a significant response for both Toxin δ and the peptide of molecular weight 8004. This selectivity is helpful where less abundant peptides yield larger responses than indicated by other methods, such as the enhanced signal, observed using sinapinic acid, for peptides around molecular weight 7300-7400 and 7670 daltons in the venom of *Dendroaspis polylepis* relative to α-cyano-4-hydroxycinnamic acid (CA)

Ion suppression in the ESI-MS spectrum

Reports in the literature state that cobra venoms contain a phospholipase A_2 fraction with molecular masses around 13000 daltons. Two phospholipase A's extracted from the venom of *Hemachatus haemachatus* comprised 10% of the total venom [3]. The ESI-MS spectrum of *Hemachatus haemachatus* provides no indication of larger peptides, but MALDI-TOF-MS spectra, even when acquired at low laser powers to aid the detection and resolution of smaller molecular weight peptides, yielded some response for the phospholipase fraction particularly when sinapinic acid matrix (positive ion) was employed

The ESI-MS spectrum of *Naja melanoleuca* indicated the presence of peptides of molecular masses 13344 and 13432 daltons, but a truer measure of the relative abundances of peptides in the venom of *Naja melanoleuca* was felt to be the total ESI-MS spectrum obtained after CE-MS, where the peptides in the venom were essentially admitted to the source one at a time. The peptides of molecular weights around 13000 daltons had a much higher relative ion abundance than indicated by flow injection analysis

Conclusions

Both ESI-MS and MALDI-TOF-MS provide valuable information for the preliminary characterization of snake venoms. Where many closely related peptides are present ESI-MS is more useful because the resolution of MALDI-TOF-MS is too low to differentiate fully between them, and this can lead to the obscuring of some major components. MALDI-TOF-MS, however, is particularly useful for indicating the full range of peptides present as suppression of higher molecular weight peptides occurs during ESI-MS Suppression during MALDI-TOF-MS is more difficult to predict but can be overcome through the use of alternative matrices. The use of both techniques to provide complementary and confirmatory information is desirable to provide as much preliminary information about complex peptide mixtures such as snake venoms.

Analysis of Free Sulfhydryl Content in Proteins by Heavy Atom Derivatization and Matrix Assisted Laser Desorption Ionization Mass Spectrometry

E. J. Zaluzec[1], J. F. Leykam[1], D. A. Gage[1], and J. T. Watson[1,2]
Departments of Biochemistry[1] and Chemistry[2]
Michigan State University, East Lansing, MI 48824

One approach in differentiating cysteine and cystine funcionalities that may exist simultaneously in proteins is to exploit the reactivity of free sulfhydryl groups for metal ions prior to analysis by MALDI-MS. Although many mono- and divalent metal ions can react with sulfhydryl groups, mercurial reagents are known to be especially selective because of the strong affinity of mercury ions for thio groups.

The mass shift determined by comparing the MALDI mass spectrum of the derivatized and underivatized protein can be related to an integral number of free sulfhydryl groups that have reacted with a particular reagent. By using a reducing reagent prior to derivatization, one can further deduce the number of cysteine groups that were originally present in the form of disulfide bonds. Because derivative formation between an organomercurial and cysteine promotes a large mass shift, appropriate use of these reagents to modify the analyte prior to analysis can provide structural information in spite of the limited resolution and mass accuracy in MALDI-TOF-MS, especially in the analysis of proteins over 100 kD.

Free sulfhydryl groups in the protein were derivatized by adding a 5-fold molar excess of mercury reagent and reacting for 10-30 minutes. The total number of cysteines in the protein (those initally free plus those involved in disulfide bonds) were similarly derivatized, but samples were first reduced using either 100mM sodium borohydride, or a 2% solution of tri-n-butylphosphine. Reduction by sodium borohydride permits easy removal of reducing reagent by acidification.

Figure 1a is the MALDI mass spectrum of 100 pm of human hemoglobin A that was dehemed by extraction in acidic acetone, and adsorbed onto ZETABIND immobilization membrane fixed to a stainless steel probe tip. The unmodified protein shows peaks for both the α-chain $(M + H)^+_{calc}$=15,127, and the β–chain $(M + H)^+_{calc}$=15,868. To a similarly prepared sample was added a 5-fold molar excess (over total thio) of p-hydroxymercuribenzoic acid (pHMB). In this case, the MALDI mass spectrum shows mass spectral shifts corresponding to derivatization of the single free cysteine residue of the hemoglobin α-chain, and the two free cysteine residues of the hemoglobin β–chain (figure 1b).

Figure 2a shows the region of the MALDI mass spectrum containing the B- and C- chains of α-chymotrypsin that was first reduced for 30 minutes by 100 mM sodium borohydride prior to analysis $(M + H)^+_{calc}$=13,925 and 10,067, respectively. After sodium borohydride reduction followed by pHMB derivatization, mass spectral shifts corresponding to the derivatization of the 5 cysteine residues of the reduced C-chain and the 4 cysteine residues of the reduced B-chain of α-chymotrypsin were observed..

Derivatization of free sulfhydryl groups can be easily determined at low levels though derivatization with organomercurials prior to analysis by MALDI-MS. In contrast, determination of the total cysteine content has proven to be more difficult experimentally because of the relative poor solubility of reduced proteins, and in that the reducing reagent must be removed before derivatization to prevent reduction of the organomercurial.

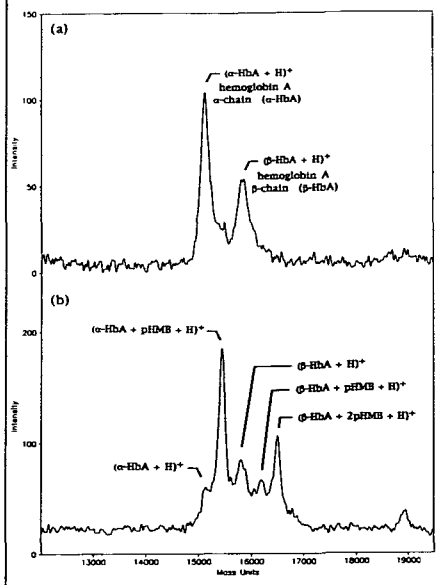

Figure 1

Introduction

Thiol groups in proteins are involved in important biological functions such as protein processing and membrane transport. Chemically and structurally selective thiol reagents acting as thiol markers and protein folding probes are therefore of increasing interest. Phenylarsinoxide (PAO) is a potential candidate to perform these demands. Up to the recent literature, PAO is considered as strongly interacting with thiol groups in proteins[1] and is even applied as a tool for thiol protein purification[2]. In contrast to these various applications, its reactions with sulfhydryl groups have not yet been characterized at a molecular level. In the present study, thiol model peptides and proteins have been modified with PAO and the chemical and structural selectivity of these reactions have been characterized by Fast Atom Bombardment(FAB)- and Electrospray mass spectrometry (ES-MS).

Methods

First, PAO itself was characterized by FAB- and EI-MS. It readily forms adducts with matrices as glycerol and 4-nitro-benzylalcohol and only low intense molecular ions of the monomer were obtained. In contrast EI-MS spectra yielded intense molecular ions of cyclic two- to five-mers.
Oxytocin (sequence: CYIQNCPLG) was reduced with DTT and served as a bifunctional thiol model peptide and its reaction products were compared to those of the monofunctional sequence peptide TCVEWLRRYLKN in order to evaluate the chemical selectivity of PAO Various reaction conditions were tested for applying those found optimum to protein investigations. The structural characterization of the peptide adducts was carried out with FAB-MS using glycerol/0.1% TFA matrices.
Thioredoxin was chosen as a model protein containing two closely spaced sulfhydryl groups in its active site being sterically well accessible due to forming a protruding loop. In addition there is a third thiol group located distant from the active center, so that this protein can work as a mono- as well as bifunctional model system. Thioredoxin is a ubiquituous redox active protein involved in various biological processes, for instance carbondioxide assimilation and protein folding. In this study, recombinant thioredoxin f, a spinach chloroplast's species, obtained by over-expression in E.coli[3], was employed. The molecular weight of the recombinant protein was determined by Electrospray(ES)-MS and its primary structure was characterized by HPLC-ESMS of tryptic and V8-protease digests. The same techniques were applied to determine grade and location of the protein derivatization by phenylarsinoxide comparing the spectra of intact and degraded protein in the native and modified state respectively.

Results

The reduced dithiol peptide oxytocin (m/z 1010) was exposed to 5 - 100-fold molar excesses of PhAsO at pH 2,3...8 and a 5-fold excess PhAsO in the presence of a 10-fold excess of 2-mercaptoethanol at pH 2-4 were the optimum conditions yielding intense molecular ions of the stoichiometric 1/1 peptide-AsPh adduct (m/z 1160) with minor amounts of byproducts. Meanwhile, the monofunctional thiol sequence peptide TCVEWLRRYLKN (m/z 1581) revealed a molecular ion at m/z 1823, due to addition of PhAs+AsO or PhAs+glycerol, a fragment thereof caused by loss of AsO or glycerol (m/z 1733), as well as large amounts of remaining educt, when reacting with PhAsO in a 1:5 molar ratio at pH 2.
Recombinant thioredoxin f was then first characterized in its native state, yielding a molecular mass of 13990 amu (theoretical average mol. mass: 13991) determined by ESMS. After DTT-reduction and carboxymethylation tryptic and V8-protease digests covered over 90% of the protein sequence especially showing intense molecular ions of both cysteinyl peptides of interest (34-53, containing the active site with C^{49} and C^{52}; 74-81, including C^{76}). DTT-reduced thioredoxin was modified with PAO applying standard alkylation conditions (e.g. used for carboxymethylation, enzyme/DTT/PhAsO 1/50/110, pH 8) as well as adjusting pH to 4 (using the same protein/reagent ratios), which turned out to be optimum, when modifying the model peptides. At both pH conditions the active site was selectively derivatized resulting in a stoichiometric 1/1 adduct of PhAsO and the tryptic peptide 34-53, elucidated by LCES data i.e. a selective mass shift from 2282 amu for the carboxymethylated species to 2316 amu for the PhAsO-derivative respectively, meanwhile all other tryptic peptides remained unaffected by the PhAsO-reaction. Furthermore, the HPLC-profile supports this finding showing a delayed HPLC-elution time (about 15 min, water/0.1%TFA//acetonitrile/0.08%TFA gradient, 15-45% B in 60 min, reversed phase C_{18}-column) of the modified relative to the unmodified peptide 34-53 being expected due to the hydrophobic phenyl-arsenic substitution. To confirm the selective addition of PhAsO to the closely spaced cysteinyl residues in the active site, Electrospray mass spectra of PhAsO-modified thioredoxin were monitored and compared with those of the native enzyme mentioned above, revealing a 10 amu mass shift of the $[M+15H]^{15+}$ and $[M+14H]^{14+}$ ions yielding a molecular weight of the PhAsO-modified thioredoxin of 14137 D. This is close to the theoretically expected MW of 14142 D and confirms the selective derivatization of the dithiol containing active site.

Discussion

The present study characterizes **phenylarsinoxide** as a highly **dithiol specific** reagent not affecting other functional groups in amino acid side chains. It can be applied over a wide pH-range (4-8) without loss of selectivity. Its selectivity towards thiol groups differing in the tertiary structure environment is still to be determined. However, phenylarsinoxide is a highly potential candidate for functioning as a protein folding probe due to its preference of inserting into reduced disulfide bridges and, combined with mass spectrometric peptide mapping, it can be efficiently applied in elucidating disulfide bridge patterns. Further investigations with monothiol selective reagents and different model enzymes and mass spectrometric techniques are under way.

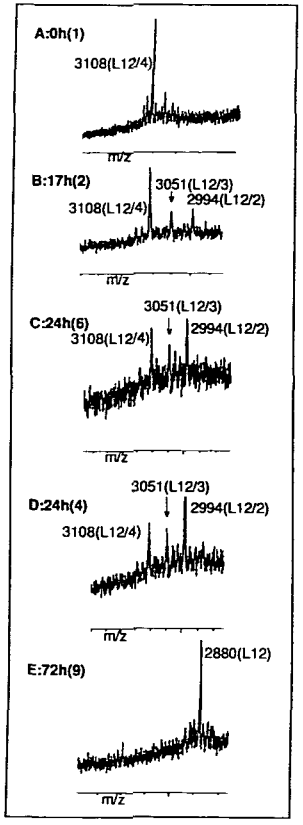

Fig. 1: FAB-MS Spectra of Refolding Intermediates after Lys-C Digestion.

Macrophage Colony Stimulating Factor (M-CSF) is a cytokine of increasing interest within the pharmaceutial and medical communities (1), especially because of its activity as an anti-infective in immune compromised patients (2). It is a hematopoietic growth factor that stimulates the survival, proliferation, differentiation and function of mononuclear phagocytes (3,4). The recombinant human M-CSF (rhM-CSF) we studied here was cloned and expressed from *E. coli* as a truncated form (residues 4 to 221) of the longest cDNA clone (M-CSF β) (5). rhM-CSF contains 9 disulfide bonds, three of them participating in intermolecular bridges resulting in a 49 kD homodimer. We recently reported the locations of the disulfide linkages in rhM-CSF β (6). rhM-CSF is produced in *E. coli* as insoluble and inactive inclusion bodies. Isolated inclusion bodies are reduced, denatured and diluted under appropriate conditions to initiate folding into an active molecule (5). An *in vitro* refolding process is a key step in the production cycle, and therefore, merits special investigation. In order to better understand *in vitro* renaturation and oxidation of rhM-CSF, refolding intermediates were trapped (7) and subjected to proteolysis.

The dimer content of iodoacetamide-alkylated half cystines of trapped refolding intermediates was estimated by SE-HPLC. Intermediates trapped at each of several time points were partially purified using RP-HPLC and were analyzed using FAB-MS in a reducing matrix. The first underalkylation observed occurred at Cys157 and Cys159 and corresponded to the first sample (17 h time point; Fig. 1B) containing disulfide linked dimer. In samples containing only monomer, no disulfide bond formation could be detected (Fig 1A), therefore, disulfide shuffling at the monomer stage can be ruled out under the refolding conditions tested. These results suggest that initial oxidation occurs simultaneously with dimerization. Using the M-NSF-60 analysis (8) no biological activity was found for the monomer M-CSF

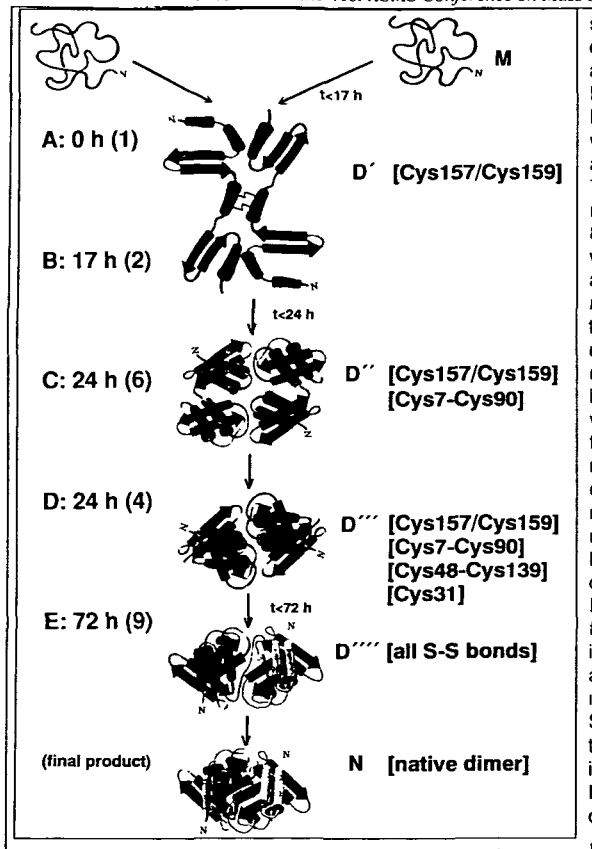

Fig 2: Suggested in vitro refolding pathway for rhM-CSF.

samples. The 24 h time point contained 35% immature dimer and very little biological activity. Four fractions were separated by RP-HPLC and all peptides were partially alkylated (Fig. 1C and 1D) By 72 h of refolding, 79% of the sample was in dimer form and the protein was 86% active. Three isomers were obtained by RP-HPLC and studied by peptide mapping (Fig. 1E). All cysteines were found to be nonalkylated, therefore, all isomers contained nine disulfide bonds. The data from this investigation support the following refolding pathway for rhM-CSF *in vitro* (Fig. 2). In early refolding events, monomers (M) form intermediates that have no disulfide bonds under the redox conditions employed here Initial oxidation leads to the formation of the inactive dimer intermediate (D′) with Cys157 and Cys159 forming the first intermolecular disulfide bonds. Subsequent folding leads to the formation of further intermediates (D″, D‴, and D⁗) that form more and more disulfide bonds until the native homodimer (N) is developed.

MALDI mass spectra of POD derivatives used in an enzyme immuno assay

K.-D. Klöppel, I.Rohm *GBF, D-3300 Braunschweig, Mascheroder Weg 1, Germany*
F.J. Mayer-Posner, U.Rapp *Bruker-Franzen Analytik GmbH, D-2800 Bremen 33, Fahrenheitstraße 4, Germany*

Introduction

Matrix-assisted laser desorption (MALDI) is an established powerful ionisation technique for the mass spectrometrical analysis of biopolymers up to the 10^5 Da mass range. The application of different matrices enables the detection of a large variety of biotechnological relevant compounds. This contribution investigates the application of MALDI for the detection of horseradish peroxidase (POD) derivatives synthesised for a new enzyme immuno assay system for the quantitative determination of mouse immunoglobuline G (IgG) [1]. This enzyme immuno assay is a non competitive homogeneous test system that works on the principle of immuno activation of suitable POD antibody conjugates [2]. Mass spectrometry results of synthesis products were compared with those obtained from photometric techniques usually applied up to now.

Methods

A brief reaction scheme is given in fig.1. Horseradish peroxidase, enzyme immunoassay (EIA) grade, were purchased from Boehringer Mannheim. Further amino groups were introduced into activated POD using 1,4 Diaminobutan. Stabilisation of product was achieved with $NaBH_4$-solution followed by dialysis. Maleimidation of the modified POD was done in a SMCC/dioxan mixture. Purification was achieved by subsequent dialysis against N_2-degased Na-phosphate buffer. $F(ab')_2$-fragment from anti mouse IgG (Dianova) used for the conjugation of maleimid activated POD was reduced with mercaptoethylamine. Conjugates were purified by gel filtration applying TSK G3000 SW (Tosohaas) or Superdex 75 HR columns (Pharmacia). For comparison an activated maleimid-POD was purchased from Merck. Photometry was used to determine the number of free amino and maleimid groups. Amino groups were determined due to the method of Habeeb [3] using lysine solutions as standards. Quantitation of POD maleimid groups was done via calibratrion with solutions of known maleimid (sulfo-SMCC) concentrations [4].

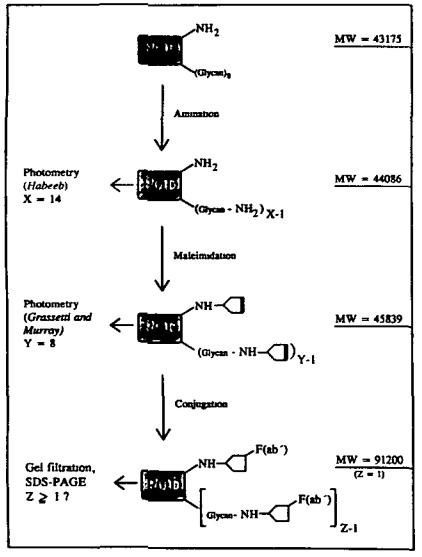

Fig. 1: Reaction Scheme

Mass spectra were obtained using a REFLEX™-TOF mass spectrometer (Bruker-Franzen Analytik GmbH). Ions were produced using a pulsed nitrogen laser at 337 nm using sinapinic acid as matrix. Internal and external mass calibration was achived with bovine serum albumin (BSA).

Results

Basic condition for the successfull synthesis of a POD conjugate for a new enzyme immuno assay test system was the supporting analytic. Hereby, most important is the control with suitable methods of single steps during synthesis of modified POD. Educts, intermediates, products and conjugates have been measured by photometry, gel

filtration, SDS-PAGE electrophoresis and MALDI. Applying photometric methods prove the successful coupling of 12 additional amino groups, and the further incorporation of 8 maleimid groups. For the reference POD 13 maleimid groups were determined, in accordance to specifications of Merck. However, gel filtration and SDS-PAGE electrophoresis of final conjugates only show an average value of 1-3 F(ab') molecules per POD. In contrast to these results mass spectrometric analysis yielded partially lower molecular weights, i.e. lower amino, maleimid and F(ab') amounts in the conjugates (s Table 1). Mass of POD amine was even lower than that of native POD. Peak shapes are broader than expected only by isotopic distribution. Broadening is caused by contributions of adducts of impurities, matrix molecules and especially here the different sample components. Native POD is a mixture of more than 10 isoenzymes. Main component (90%) is the isoenzyme C containing 8 glycans and different amounts of serin. A minor component containing 9 glycans is apparent in the MALDI-MS spectrum (s. Fig. 2). The detected molecular masses of intermediates leads to the assumption that 2 glycans were cleaved off partially at the GlucNAc-GlucNAc bond of the chitobiose unit during amination step, while due to photometric results the remaining glycan residues are multiply aminated (Σ=12). MS-results show further the incorporation of 8 maleimid groups which could be used for conjugate formation. The purchased maleimidated POD contains due to MS-results at least 10 maleimid groups. For final and reference POD a distribution of 1-2 F(ab') molecules per POD were determined by MALDI-measurements, i.e. somewhat lower than average amounts found by gel filtration and SDS-PAGE.

Compound	x	y	z	MW_{theor}	MW_{meas}	MW_{diff}
POD_{nativ}	-	-	-	43.175	43.191	+ 16
POD_{amin}	14	-	-	44.088	42.260	- 1.828
POD_{mal}		8	-	45.839	43.875	- 1.964
POD_{merck}	14	13	-	46.934	46.317	- 617

Table 1: Comparison of MALDI-MS results

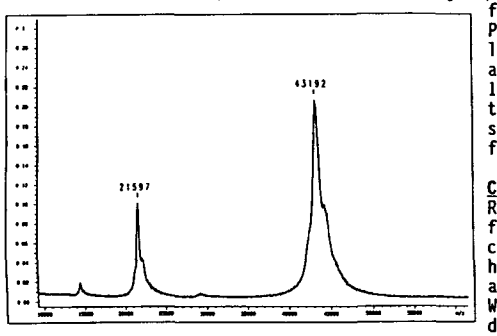

Fig. 2: MALDI mass spectrum POD_{nat}

Conclusions

Results show, that MALDI is a powerful analytic technique applicable for control of steps during synthesis of high molecular weight compounds in addition to conventional methods. While photometric results of intermediates let expect a higher F(ab')-part in the POD-conjugates, the MS-results show that the at least determined amount of 1-3 F(ab') per POD is more realistic. F(ab')-POD-conjugate successfully was established for the set up of a homogeneous enzyme immuno test. Further measurements showing the exact distribution of F(ab')-POD in conjugates of test systems are in preparation.

MALDI measurements of Intermediate Filament Proteins in Chaotropic Buffers

W.D. Lehmann, J. Schweizer, German Cancer Research Center, D-6900 Heidelberg, Germany

U. Rapp, F.J. Mayer-Posner, Bruker-Franzen Analytik GmbH, D-2800 Bremen, Germany

Introduction

Intermediate filament proteins are the constituent proteins of 10 nm filaments that are part of the cytoskeleton of mammalian cells. They represent highly insoluble proteins. Molecular weights of the keratins are generally determined by SDS-PAGE size estimation or by molecular cloning and calculation on the basis of the derived amino acid sequence. We attempted to use matrix-assisted laser desorption mass spectrometry (MALDI-MS) as additional and independent method for the determination of the molecular weight of keratins. In this approach either total keratin fractions from newborn mouse epidermis or purified individual keratins were investigated.

Methods

Isolation of Total Epidermal Keratins

Total keratins from heat separated newborn mouse epidermis were extracted using a guanidinium thiocyanate buffer as described (1). They were reconstituted by extensive dialysis against water and dissolved in a urea buffer (6M urea, 100 mM Tris pH 7.5, 1% mercaptoethanol) for molecular weight determination.

Isolation of Individual Keratins

Total keratins from adult mouse foot sole epidermis were separated by SDS-PAGE according to Laemmli (2) and visualized by (A) Coomassie blue staining or (B) ammonium acetate staining. Single keratin bands were cut out from the gel and resolubilized by homogenization in guanidinium thiocyanate buffer. After centrifugation, the keratin supernatant was dialyzed against water, freeze-dried and the proteins redissolved in urea buffer for molecular weight determination.

Mass Spectrometric Analysis

Measurements were performed using a REFLEX™MALDI/TOF mass spectrometer (Bruker-Franzen Analytik GmbH, Bremen Germany). Data were acquired in linear mode and positive ionization using 35 kV accelerating voltage. Ions were formed by laser desorption at 337 nm (Nitrogen laser, 3 ns pulse width).

For mass calibration bovine serum albumin (Sigma A-4378) was used as external standard. For calculation the mass value 66,431 Daltons was applied.

The samples were prepared with sinapinic acid as matrix and a total loading of around 5 picomoles of keratins on the target.

Results

1. Total Keratins

Mixture analysis of total keratins of newborn mouse epidermis by gel electrophoresis and MALDI-MS showed a similar pattern of the molecular weight distribution, the range of molecular weights extending from about 50 to 67 kD. The molecular weight of one of the main keratin components in newborn mouse epidermis as determined by MALDI-MS was found to be 58,282 D ± 21 D (S.D.) (n=3). This signal corresponds to keratin 10 with a molecular weight of 57,711 D as determined by molecular sequencing (4). The difference of 571 D is due to a posttranslational modification (e.g. addition of several phosphate groups). Similar comparisons cannot be made for the remaining keratins due to lack of full length sequence data.

2. 70 kD Keratin

Sequence data of the main keratin of adult mouse epidermis predict a molecular weight of 70,980 (5). When this keratin is isolated and analyzed by MALDI-MS a molecular weight around 70,900 D is observed. However, as evident from separations by two-dimensional gel electrophoresis, this fraction is a mixture of up to ten in vivo generated components differing in the degree of phosphorylation and in the proteolytic loss of a few amino acid residues. In the mass spectrum these modifications result in a relatively broad peak exhibiting a fine structure around the peak center.

Conclusions

This study has shown that molecular weight determinations of highly insoluble proteins such as keratins can be successfully performed by MALDI-MS. This is demonstrated by using both total and keratin fractions and isolated individual keratins. The data obtained suggest that by means of the MALDI technique subtle molecular weight changes caused by posttranslational processing or phophorylation can be detected.

QUANTITATION OF PROTEIN MULTIMERIC SPECIES USING MALD TOF MS

Terry B. Farmer and Richard M. Caprioli
The Analytical Chemistry Center and the
Department of Biochemistry and Molecular Biology
University of Texas Medical School, Houston, Texas 77030

Introduction

Matrix assisted laser desorption mass spectrometry (MALD MS) in conjunction with chemical crosslinking has been used to qualitatively assess the quaternary structure of multimeric proteins[1]. Previous comparison of MALD MS with sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) with subsequent densitometric scanning of the silver stained gel showed that there were some differences in the quantitation of the multimeric species present in solution after crosslinking[2]. To examine these results more closely multimeric proteins were crosslinked and then separated on a gel filtration column to isolate individual species of the crosslinked proteins. The separated protein multimers were then recombined in a 1:1 molar ratio and examined by MALD mass spectrometry.

Experimental

Protein Crosslinking: Gluteraldehyde (Sigma Chemical Co.) was used as the homobifunctional crosslinking agent for carbonic anhydrase (CA), bovine serum albumin (BSA), and glucose 6-phosphate dehydrogenase (G6PD)(Sigma Chemical Co.). Solutions of 10 pmol/μl protein were prepared and glutaraldehyde was added to 0.8% by volume. The UV absorbance for each uncrosslinked protein was determined before and after the addition of crosslinker using a Gilford 250 UV/Vis Spectrophotometer and no observable change occurred in the absorbance at 280 nm. The crosslinking reaction was terminated after 60 minutes by the addition of an excess of $NaBH_4$ (Aldrich Chemical Co.). The protein solution was dialyzed against Milli Q water for >3 hours using Spectra/Por 6 10000 MCO dialysis tubing (Spectrum) then concentrated against a 20% solution of PEG 20000 (EM Chemical Co.).

Gel Filtration Chromatography: CA was separated on a Sephadex G-100 column (40 cm x 1.5 cm) with a mobile phase of 1% ammonium bicarbonate/0.5 M NaCl and a flow rate of 0.195 ml/min. G6PD and BSA were separated on a Sephadex G-200 column (60 cm x 0.9 cm) with a mobile phase of 0 1 M Tris base/0.5 M NaCl (pH 8.0) and a flow rate of 0.035 ml/min. The fractions were collected and the absorbances were read at 280 nm. The identity of the separated multimers in the fractions was confirmed by SDS-PAGE (Weber-Osborne method[3]) and the gels were silver stained (Bio-Rad). The fractions containing the multimers of interest were dialyzed against Milli Q water until the sodium concentration was below 1 μM and then concentrated against a 20% solution of PEG 20000. Protein concentration was determined using Beer's Law ($A = \epsilon bc$).

Matrix Assisted Laser Desorption Mass Spectrometry: Spectra were obtained on a Vestec ResearcH instrument with a flight tube length of 1.2 m using a N_2 laser and acceleration voltage of 22.5 kV and a multiplier voltage of 4 kV. A saturated solution of sinapinic acid (Aldrich Chemical Co.) in a 70% acetonitrile/30% water/0.1% TFA solution was used as the matrix. The individual protein multimers (2-5 pmol) were added to 1 μl of the sinapinic acid solution, mixed, and dropped onto a stainless steel pin at room temperature. 1.1 molar ratios of the isolated protein multimers were made and added to 1 μl of the saturated sinapinic matrix and then treated as the individual protein multimers. The preparations were mass analyzed (Fig.s 1-2).

Results and Conclusions

In the present experiments we have quantitated protein samples by MALD TOF. These

experiments measure overall mass discrimination from sample preparation to data analysis. Glutaraldehyde crosslinked proteins were separated and recombined in a 1:1 monomer:dimer molar ratio and mass analyzed. Two assumptions were made for this work: crosslinking does not affect any of the MALD MS conditions (drying with the matrix, ionization, etc.) or the extinction coefficient of the UV absorbance of the protein at 280 nm.

The contribution of multimers and multiply charged ions was determined. The peak area of the M^{+2} and $2M^{+}$ ions were calculated from the spectra of the isolated monomers and dimers and used to correct the peak areas obtained from the recombined mixtures.

The effect of laser intensity on peak area was also investigated. Increasing laser intensity decreased the M^{+} peak area slightly, but caused significant deterioration in peak shape and width (resolution).

The spectra of CA 1:1 monomer:dimer indicated mass discrimination is 3:1 monomer:dimer from 30 kD to 60 kD while for BSA the mass discrimination is 2:1 from 66 to 135 kD. These data indicate a 6·2:1 discrimination from 30 to 135 kD. The data were very reproducible (±2 %) as long as the laser intensity remained constant for subsequent mass analysis. Semi-quantitation of crosslinked multimeric species present in solution for the tested mass range can be accomplished. Work is currently in progress to analyze other proteins such as hemoglobin, lactate dehydrogenase and lysozyme to better characterize the process.

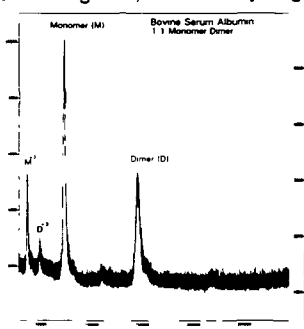

Figure 1

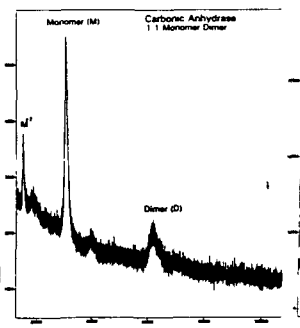

Figure 2

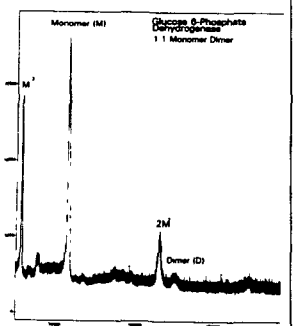

Figure 3

The result of the 1:1 monomer:dimer mix of G6PD showed no overlap of the mass for the monomer $2M^{+}$ peak with the M^{+} dimer peak. This is due to differential addition of glutaraldehyde. Using MALD MS, atypical glutaraldehyde crosslinking can be quickly and easily determined.

CHARACTERIZATION OF PEPTIDES AND GLYCOPROTEIN DIGESTS USING CAPILLARY ELECTROPHORESIS COMBINED WITH IONSPRAY/TANDEM MASS SPECTROMETRY

Kevin J. Volk, Jinping Liu, Mike S. Lee, Steven E. Klohr, Edward H. Kerns, and Ira E. Rosenberg, Bristol-Myers Squibb Company, 5 Research Parkway, Wallingford, CT 06492

Micro-separation techniques such as capillary electrophoresis (CE) can be used to quickly and efficiently separate complex biological mixtures. These techniques are rapidly gaining acceptance in the bio-pharmaceutical industry for the separation, analysis, and characterization of mixtures such as those produced from protease digestions. The high separation efficiency of CE (1,2) and micro-LC (3) combined with tandem mass spectrometry is an extremely powerful approach for the structural characterization of peptides and proteins in complex mixtures. The profiling strategies we have developed for micro-LC/MS (3) utilizing various enzymatic methods can be applied when CE is coupled with mass spectrometry.

We have coupled a Beckman P/ACE unit to a SCIEX API III triple quadrupole mass spectrometer via a coaxial interface. The conventional Ionspray interface was modified to accommodate standard 360µm o.d. x 50µm i.d. CE columns. All separations were performed at 30kV (25µA) using an uncoated column (100cm) with a running buffer of 25mM ammonium formate, pH 2.5. A make-up buffer (80/20) methanol/0.2% formic acid in water was added at a flow rate of 5µl/min. The mass spectrometer was scanned from m/z 350 to m/z 2200 with a step size of 0.4 Dalton and a dwell time of 0.7 mSec. Deglycosylation was performed using peptide-N-glycosidase F (PNGase F).

The utility of CE coupled with Ionspray tandem mass spectrometry is illustrated with the on-line separation and detection of a peptide mixture (Figure 1). Here we demonstrate the ability to detect peptides at the sub picomole level with a wide scanning range. Various glycoforms of glycoproteins can be separated and characterized using this methodology. The UV electropherogram of a model glycoprotein, Ribonuclease B, is shown in Figure 2. A comparison of the full scan and deconvoluted Ionspray mass spectra of the Ribonuclease A impurity and various Ribonuclease B glycoforms (Figure 3) indicates the molecular weight and heterogeneity of these glycoforms. Products of microscale enzymatic reactions with proteins and glycoproteins were also profiled by CE/MS and CE/MS/MS. Since not all intact glycoproteins yield interpretable mass spectra without deglycosylation, a coordinated approach using a combination of enzymes such as trypsin and PNGase F followed by CE/MS and CE/MS/MS analysis provides complementary information such as carbohydrate composition, sites of N-linked carbohydrates, and sequence information.

In summary, the unique separation mechanism of CE permits the rapid and efficient separation of closely related components such as protein glycoforms as well as structurally similar proteolytic fragments. Coupled on-line with MS, molecular weight information can be rapidly assessed. In addition, MS/MS can provide sequence and substructure information for tryptic peptides and glycopeptide fragments at the sub picomole level. The general profiling methodologies were developed to characterize glycoproteins and are applicable for the characterization other post-translational modifications.

FROM DIPEPTIDES TO OLIGOPEPTIDES : ANALYSIS BY CAPILLARY ELECTROPHORESIS/ELECTROSPRAY MASS SPECTROMETRY.

Darren Wycherley, Malcolm E. Rose, *Department of Chemistry, The Open University, Milton Keynes, MK7 6AA, UK.*
Kevin Giles, Stuart A. Jarvis and Mark A. McDowall, *Fisons Instruments, VG BioTech, Altrincham, WA14 5RZ, UK.*

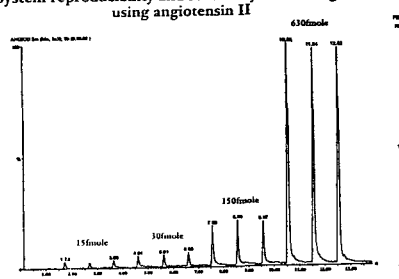
Capillary electrophoresis (CE) has found application to a broad range of separations including peptides, nucleotides, surfactants and environmental compounds. CE is complementary to standard HPLC but offers rapid high resolution separations with efficiencies between, 10^4 to 10^6 theoretical plates, and can be used for difficult separations. The standard detection method for CE is UV absorption, however, the utility of the technique is greatly enhanced using mass spectrometric detection; more specifically, electrospray ionisation (ES). The system utilised a nebulisation-assisted triaxial flow probe for coupling the CE column to a quadrupole mass spectrometer. Two CE/MS systems were developed for this work: the ISCO 3850 CE instrument coupled to a VG Quattro, and the Beckman P/ACE 2100 CE system fitted with a mass spectrometer interface coupled to a VG Platform benchtop API mass spectrometer. To date, volatile buffers composed of ammonium salts have been most extensively used for CE/ES. However these studies utilized involatile buffers composed of phosphoric acid and β-alanine at low concentrations.

Peptides, in contrast to amino acids, are excreted in urine of healthy individuals only in minute amounts. Strongly increased excretion of some peptides is indicative of dermatological disorders such as chronic skin ulceration. Frequently, susceptibility of dermal collagen to enzymatic degradation appears to be responsible for small peptides and dipeptides in particular, in the urine of such patients. During the course of work on urinary acylcarnitines by GC/MS it was noticed that several neonates excrete high levels of certain dipeptides (e.g. Ala-Leu or Ala-Ile, Pro-Ile or Ile-Pro.) Results have now been obtained by CE/MS for a number of dipeptides leading to the analysis of real neo-natal urine suspected to contain such compounds. In addition, data are presented on the CE/ES analysis of a peptide mixture (Bradykinin, Leucine-enkephalin-Arg, Angiotensin I, Angiotensin II and Angiotensin III) together with a sensitivity study.

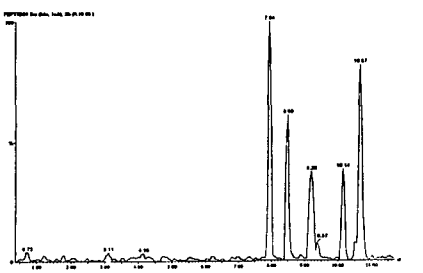
A standard mixture of 6 dipeptides was examined by CE/ES. All six dipeptides, despite being very similar in structure, are separated and exhibit peaks for the expected singly protonated molecule in their electrospray spectra.
The urine sample examined was shown to contain various peaks of interest. For instance, the peak corresponding to *m/z* 114 is most likely to be creatinine, which is known to be present in all human urine. The peak at *m/z* 132 is consistent with the protonated molecules of the amino acids, leucine, isoleucine or hydroxyproline. It is hoped that future work will lead to the unambiguous

The reproducibility of the system was examined by introducing three 5-second hydrodynamic injections of Angiotensin II at five different concentrations from 220 pg/nl to 5 pg/nl (630 fmol to 15 fmol injected) as figure 1. A scatter-point calibration graph plotted from the resulting peak heights gave a correlation coefficient of 0.9999.

System reproducibility and sensitivity chromatogram using angiotensin II



Full scan of the 5 peptide mix, 2.5pmol of each injected



A total ion chromatogram obtained from 2.5 picomoles each of the five peptides by full scanning was recorded, giving baseline separation within a total analysis time of about 15 min, (figure 2). Subsequently, ES spectra were obtained from this chromatogram. The doubly- or triply-charged species of each peptide were most prevalent.

The selected-ion reconstructed chromatogram of the five peptides, 300 femtomoles of each being injected onto the capillary over 5 seconds, was also obtained.

Peptide elution order: Angiotensin III, Bradykinin, Angiotensin I, Leu-enkephalin-Arg and Angiotensin II.

Despite having the largest mass, angiotensin I migrates rapidly through the CE column because it has the largest number of basic residues in its sequence. Consistent with this, its ES spectrum displays a prominent $[M + 3H]^{3+}$ ion.

By combining CE and ES efficient separation and identification of compounds can be achieved. The results shown demonstrate how samples of biochemical significance can be analysed by CE/ES. Coupling of both CE instruments (Beckman and ISCO) to the VG Platform and Quattro mass spectrometers, respectively, produced results illustrating the feasibility of performing these types of analyses at physiologically significant levels.

Mass Spectrometry of Proteins Isolated from Capillary Gel Electrophoresis

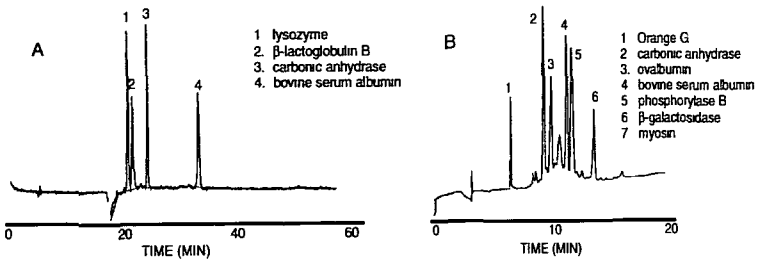
R. Takigiku, T. Keough, M. P. Lacey, R. E. Schneider and M. P. Purdon
The Procter & Gamble Co., Miami Valley Labs, PO Box 398707, Cincinnati, OH 45239-8707

We describe our efforts at collecting proteins from capillary gel electrophoresis (SDS-PAGE) and analyzing them by mass spectrometry. Performing SDS-PAGE in capillaries has a number of advantages. Because it is a fully instrumental method, capillary SDS-PAGE offers automation, as well as improved reproducibility and quantitation (relative to traditional slab-gels). Additionally, on-line fraction collection is possible, eliminating the need for staining, destaining, excising and electroeluting proteins. A significant advantage of fraction collection is that it makes protein available for analysis with complementary biochemical methods such as automated Edman sequencing.

Though capillary SDS-PAGE yields molecular mass information, mass spectrometry offers far greater accuracy and precision. In particular, electrospray and matrix-assisted laser desorption ionization mass spectrometry (MALDI) have demonstrated mass measurement accuracies of between ± 0.01 and 0.2%. Hence, we sought to couple the micropreparative capability of capillary SDS-PAGE with the mass measurement capabilities of mass spectrometry.

In order to accomplish this task, we developed a method for removing detergent from protein isolates. This was necessitated because trace amounts of SDS suppress mass spectrometry ionization methods. Purified proteins could then be analyzed by both ionspray (pneumatically assisted electrospray) on a triple quadrupole instrument, and by MALDI on a time-of-flight instrument.

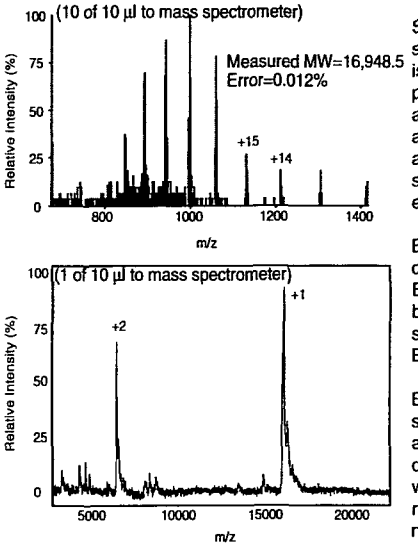
Capillary SDS-PAGE was accomplished with a home-made acrylamide gel-filled capillary, and with a commercially available SDS-PAGE system (Beckman eCAP SDS 200). For comparison, electropherograms of protein standards analyzed on a home-made acrylamide (3%T, 5% C) gel-filled capillary (A) vs. the Beckman eCAP SDS 200 system (B) are shown below.



For fraction collection, the migration time of the analytes from the injector to the UV detector were used to calculate the overall migration times to the outlet of the separation capillary. Multiple isolates were pooled by repeated collection of a peak of interest into the same collection vial.

All isolates were collected into an Amicon Microcon 3 (for acrylamide gel-filled capillaries) or Amicon Microcon 10 (for Beckman eCAP SDS 200 gel-filled capillaries). Amicon Microcons are ultrafiltration devices that accept 1.5 ml microfuge tubes (Microcon 3 has a nominal cutoff at 3 kD, whereas the Microcon 10 is at 10 kD).

solates were washed and reduced to approximately 3-5 µL on a speed-vac at room temperature and brought back up to ca. 10 µL with a 1:1 solution of 10% formic acid and methanol.



Shown at left are ionspray and MALDI mass spectra of duplicate samples of myoglobin isolates. Although neither quantitation nor percent recoveries of the isolates was thoroughly assessed, a pooled sample of 10 isolates (from an acrylamide gel capillary) corresponds to approximately 4 pmoles (because no internal standard was used for this particular MALDI experiment, a measured mass is not given).

Both carbonic anhydrase and BSA were also collected and analyzed by ionspray and MALDI. Both proteins yielded recognizable spectra from both MS approaches. However, a pooled sample of at least 20 isolates were required for BSA (ca. 8 pmoles).

Both forms of capillary SDS-PAGE used here sieve proteins reproducibly. However, the acrylamide gel-filled capillaries must be discarded after the formation of air bubbles, wherease the eCAP SDS 200 simply requires refilling the capillary with fresh medium (a step normally done prior to each separation).

Additionally, whereas isolates from the acrylamide gel-filled capillary could be prepared using Amicon Microcon 3 ultrafiltration devices, the polymer used in the eCAP SDS 200 system necessitated the use of the Microcon 10 devices. Because the the Microcon 10's have higher nominal cut-offs, smaller proteins may not be recoverable in sufficient quantities for mass spectrometry.

The mass accuracies of the isolated proteins appear to be near those expected for standard preparations (ca. 0.02%), but may be slightly higher. These errors may be due to adduct formation with components not removed with the SDS-cleanup process.

Further work is in progress to determine percent recoveries both from the capillaries and through the isolate preparation. This information will be necessary to determine the overall sensitivity of the method.

Matrix-Assisted Laser Desorption Mass Spectrometric Analysis of a Pegylated Recombinant Protein.

Introduction

The administration of proteins for therapeutic treatment is severely hampered by short half-lives in the circulatory system. It has been shown that the covalent attachment of polyethylene glycols to enzymes and proteins has a major effect on their physical and activity properties. Several reports have demonstrated the effect of increased circulating lives from the use of such PEG conjugates without any complications arising from immunogenicity (1-3) and as a result the characterization of these PEG-protein adducts has attracted an ever increasing attention in recent years. While electrophoretic (4) and chromatographic (5) techniques have been reported for separating and characterizing these molecules, there are no satisfactory methods reported for determining the exact number of PEG units covalently bound. We have investigated the use of MALDI as a technique for determing the number of PEG units covalently attached to the recombinant protein.

Mass spectrometry was performed using a Vestec Model VT 2000 laser-desorption time-of-flight mass spectrometer (Vestec Corp. Houston, TX, USA). The PEG-SCF sample was prepared for MALDI using a matrix of sinapinic acid.

Results and Discussion

The reaction of SS-PEG with proteins results in the covalent attachment of PEG (average molecular weight of 6000) at lysine e-amino groups. There are 14 lysines in SCF that can undergo reaction, and since the reaction is not expected to result in complete derivatisation, considerable heterogeneity is introduced into the PEG-SCF complex. Consequently the covalent attachment of PEG to proteins can result in the formation of a species that is both heterogeneous in size and charge. Figure 1 shows the laser desorption mass spectrum obtained from PEG-SCF sample. A series of ion signals are observed with molecular weights of 18770, 24650, 30550 36550 and 42400. daltons, at about 6000 daltons apart. Each PEG attached to SCF will contribute approximately 6000 daltons to the total mass of the modified protein and this information permits the identification of the ions shown in Figure 1 as being consistent with the covalent addition of one, two, three and four PEG units. The ion signal at 18770 Da closely agrees with the calculated molecular weight of SCF (18600). The series of peaks at 18275, 15275 and 12325 daltons are doubly charged species derived from the above parent ions. All of the ion signals can therefore be explained as being derived either from parent compounds or from doubly charged ions. The spectrum permits characterization of all of the PEG-SCF adducts present allowing the number of PEG units covalently bound to be readily determined as well as providing for an estimation of relative amounts present.

The results presented here are of practical importance and demonstrate the utility of matrix-assisted laser desorption as a highly promising technique for determining the number of PEG units covalantly attached to proteins.

Introduction

We have recently developed a program that allows the rapid identification of proteins in sequence databases by the masses of their tryptic peptides [1]. Briefly, for each protein in the database the masses of all the predicted peptides for a given enzyme specificity are generated. If peptides of a sample of unknown identity are mass analyzed, the program can match the peptide mass pattern against the predicted peptide masses. Such a capability is useful for alleviating the workload in a protein analysis laboratory, because often the task of the laboratory is the confirmation of the identity of a sample. Furthermore, many putatively unknown proteins turn out to be contained in the databases.

The specificity of the pattern matching is determined by several experimental parameters, such as mass accuracy, number of 'correct' peptides (i.e. those obeying the enzyme cleavage rules) and the mass range of the peptides considered for the match. We have previously shown that ESI-FTMS and MALDI-FTMS have the capability for ultra-high mass accuracy measurements (< 3 ppm) of peptides and proteins.[2]

All experiments were carried out using a Bruker Bio-Apex™ 47e external ion source FTMS, which has been previously described.[2] For the myoglobin example, 2 nmol of equine myoglobin was digested by trypsin and fractionated by HPLC. Fractions containing about 1 nmole of peptide material were collected and about 100 picomole was used for ESI-FTMS analysis. The same amount was also applied to the probe tip for the MALDI analysis, but less than 10 picomole of material was actually consumed.

The databases searched were the SWISS PROT release 24 (from the March 1993 EMBL CD ROM; 28154 entries) and the Protein Identification Resource (PIR, release 36), also on CD ROM. The PIR divisions searched were PIR I, PIR II, PIR III, and PATCH X, with a total of 84,000 entries. The program used was a modified version of PeptideScan, running on Macintosh computers with a CD ROM.

For this work, the ESI- and MALDI-FTMS spectra of several of the tryptic peptides from myoglobin were obtained. The calibration was done externally using a mixture of peptides. The mass accuracies for the determination of the myoglobin peptide exact masses are summarized in Table 1, for both the ESI and MALDI-FTMS measurements. In the case of the ESI work all spectra were measured and calibrated in broadband mode. For the MALDI results the calibration was performed and the accurate masses measured in high-resolution mode.

The search by three peptides from the myoglobin digest with a specified error of 0.008 Da resulted in a unique match even though no restrictions were put on the target mass range and two incomplete digestion sites were allowed. The same search at mass accuracies of 0.05 and 0.3 Da resulted in 16 and 108 false matches. These results are in agreement with statistical considerations. Additionally, we repeated the search with 10 arbitrary, non sequence related masses simulate a high "background". Again, myoglobin was the only match. The above results also held when searching the 84000 entries of the PIR database instead of SWISS PROT.

In another experiment we measured the mass of a single peptide from our laboratory practice with high accuracy. Since the protein was known to be small an upper

mass limit of 18 kDa was put on the protein mass range considered. Four matches were found in SWISS PROT two of which were easily discarded on the basis of the species of origin. The two other matches were the correct protein.

In conclusion we have shown that searching with very high mass accuracy had the expected effect of drastically improving the specificity of the search. Accuracies of below 5 ppm could be used to remove all restrictions on the search and still find a unique match with only a few peptides as input. In some cases it may even be possible to identify proteins or contaminants in protein preparation on the basis of the accurate mass of a single peptide. In the near future most of the common peptides will have been sequenced and then the methods described here will be of even more general utility. the successful search of over 80,000 entries in the PIR database suggests that the methods described here will be robust enough to work with expanded future databases. We have further shown that both ESI- and MALDI-FTMS can provide ultra-high mass accuracy data for input to the PeptideScan program. We are currently investigating the use of orifice fragmentation to further increase the specificity of the searches. Laser desorption also results in metastable daughter ions. Since the masses of daughter ions can also be measured to high mass accuracy by FTMS, a single peptide measurement together with some of its fragment masses should be enough to uniquely identify a protein in the database.

Table 1. Myoglobin Peptide Fragment Exact Mass Analysis

Peptide	MASS	ESI	Err(ppm)	MALDI	Err(ppm)
1	1814.896	nm		1814.892	1.7
2	1605.847	1605.848	0.6	1605.839	5.0
3	1270.656	1270.652	3.1	1270.654	1.2
10	1377.834	1377.834	0.0	1377.846	8.7
13	1852.954	1852.961	3.8	nm	
16	1884.015	1844.008	3.8	1884.011	2.1
AVG:			2.3		3.8

note: nm = not measured

Matrix-Assisted Laser Desorption Mass Spectrometry in the Determination of Subunit Stoichiometry of Giant (3,900 kDa) Earthworm Hemoglobin

Klaus Schneider[1], David W. Ownby[2], Hao Zhu[2], Ronald C. Beavis[3], Austen F. Riggs[2] and Brian T. Chait

[1]The Rockefeller University, 1230 York Avenue, New York, N.Y. 10021,
[2]Department of Zoology, University of Texas, Austin TX 78712,
[3]Department of Physics, Memorial University of Newfoundland, St. Johns, Newfoundland, Canada, A1B 3X7.

The giant extracellular hemoglobin of the earthworm, *Lumbricus terrestris*, has ~ 200 chains that form a two-layered hexagonal structure of 3.9 ± .2 MDa. The sequences of the four major heme-binding chains a, b, c, and d, have been determined. Chains *a*, *b*, *c* form a disulfide linked trimer. Additional structural components, "linker chains," deficient in heme, are necessary for the assembly and integrity of the 3900+ kDa molecule. The stoichiometry of the trimer, chain *d* and the linker chains and the heme content of the molecule have been controversial. We report here determination of the stoichiometry of chains and of the heme content by new, unambiguous techniques that utilize high performance liquid chromatography, amino acid analysis and matrix-assisted laser desorption mass spectrometry[1].

Molecular masses of all the individual chains and of the trimer were measured by matrix-assisted laser desorption mass spectrometry. Chain *a* was found to be glycosylated in agreement with earlier results. The molecular mass of chain *d* was found to be 142 u lower than calculated from the sequence indicating that the published sequence may be incorrect. The molecular mass of linker chain L_1 was substantially higher than calculated from the determined sequence[2], indicating glycosylation. To determine the sites of glycosylation chain *a* and linker chain L_1 were subjected to mass spectrometric peptide mapping. Digestion of chain *a* by Lys-C endoproteinase revealed that peptide 68-105 contains the glycosylation site (figure 1). The heterogeneity observed for this peptide agrees well with the heterogeneity observed for the intact protein. The linker chain L_1 was subjected to digestion by several enzymes (i.e. Lys-C endoproteinase, pepsin, trypsin) The results show that the site of glycosylation is within the peptide 88-104, probably at Asn^{103} (N-linked). The mass spectrum of the Lys-C-endproteinase digestion mixture is shown in figure 2.

The proportions of linker chains, trimer and chain *d* were determined by reverse phase HPLC, with simultaneous determination of heme content. A weight proportion of linker chains of 0.163 +/- 0.023 was determined by integration of the absorbance at 220 nm and verified by amino acid analysis. These values, together with sequence- and mass spectrometry derived masses, give a molar ratio of *abcd* chains to linkers of 8:1 corresponding to the minimal unit, $(abcd)_2L$. This ratio suggests that 24 $(abcd)_2$ units and 24 linker chains form the complete structure with a total calculated molecular mass of protein of 3975 kDa composed of 216 chains. The mass spectrometric masses of the chains indicate an additional mass of 133 kDa, attributed to carbohydrate.

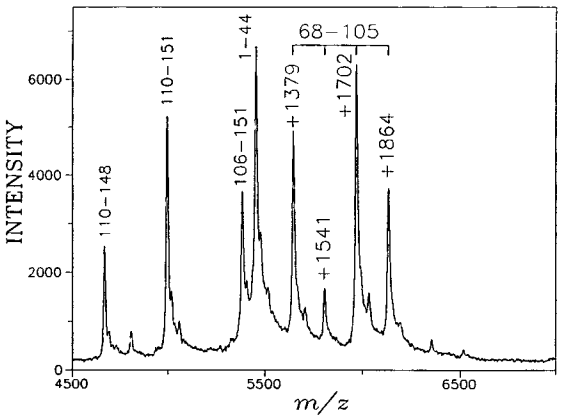

Figure 1
Matrix-assisted laser desorption mass spectrum of earthworm *Lumbricus terrestris* hemoglobin chain *a* after reduction with dithiothreitol and digestion with Lys-C-endoproteinase (matrix: 4-hydroxy-α-cyano-cinnamic acid). Peptide 68-105 was found to be glycosylated.

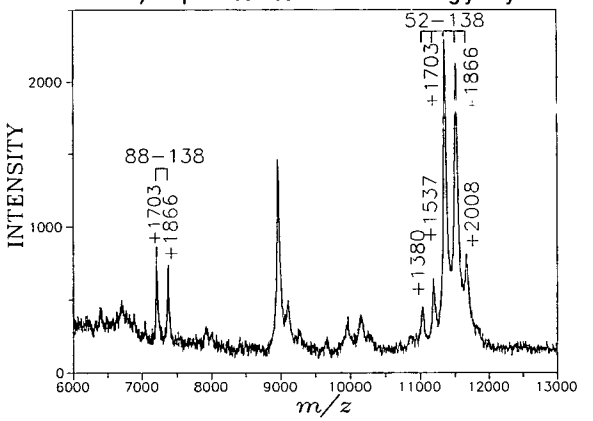

Figure 2
Matrix-assisted laser desorption mass spectrum of earthworm *Lumbricus terrestris* hemoglobin linker chain L_1 after reduction with dithiothreitol and digestion with Lys-C-endoproteinase (matrix: 4-hydroxy-α-cyano-cinnamic acid).

On-Line Magnetic Sector LC-MS-MS Analysis of a Tryptic Digest of β-Lactoglobulin by CF-LSIMS with Array Detection

P.Ireland, D. Jones, P. Ryan, S. Evans, R.J.Greathead
Kratos Analytical, Barton Dock Road, Manchester M31 2LD, UK

Introduction

Recently, tandem mass spectrometry has been recognised as an analytical technique that enables the primary structure of proteins and peptides to be determined, as well as being suited to the investigation of post-translational modifications. The analytical method usually involves the analysis of the fragmentation products of the protonated molecular ion produced by collision-induced dissociation (CID). The practical limit for sequence analysis of peptides with tandem, high-resolution mass spectrometers is approximately 3,500 daltons, primarily as a result of the inefficiency of the CID process for large molecules.

The strategy for analysis of larger peptides and proteins involves a prior proteolysis stage, usually in the form of an enzyme digestion. This is followed by liquid chromatography (LC) to separate the individual tryptic fragments and then subsequent amino acid sequence analysis by MS-MS.

Often only relatively small amounts of sample are available. In order to achieve the required low levels of detection of fragments ions, an array detector on a tandem, high resolution mass spectrometer is highly desirable.

This study illustrates the use of a magnetic sector, high resolution, tandem mass spectrometer coupled with continuous flow LSIMS interface and utilising array detection. The array detector is of a novel design, incorporating a charge-coupled device (CCD). This enables MS2 to be scanned and the data obtained treated as normal scanning data. This is in contrast to photodiode array detectors which necessitate changing the magnetic field in a stepwise fashion in order to monitor a wide mass range and maintain resolution. The individual windows produced by the photodiode array have to be reconstructed into a continuous spectrum through software processes before interpretation.

The scanning capability of the CCD array also provides a scan time compatible with chromatographic separations whilst retaining the advantages of high sensitivity detection.

A widely available and characterised protein; β-lactoglobulin was used as a model sample to illustrate the general analytical technique outlined.

Experimental Conditions

The 2-sectro analyses were performed at a resoluiton of 1000 (10%valley) with a CF-LSIMS source operating at 70°C. The range 1200 u to 100 u was scanned in 1 second. 4-sector analysis used a cell voltage of 4 kV with helium collision gas at a parent ion attenuation of 70%. The LC column was a 2mm x 150 mm ODS-1 using a flow rate of 0.2 ml/min split to 5 µl/min and a solvent gradient of100% A to 100% B over 30 mins (solvent A: 100% water with 0.06% TFA; solvent B: 80% acetonitrile 20% water with 0.06% TFA)

Results and Discussion

Table 1 shows the BioPolymer Sequence software report for the predicted peptide fragments produced by the enzymic digestion of bovine β-lactoglobulin with trypsin. The fragments are listed in sequence order, but could equally be ordered by molecular weight or HPLC retention index. Figure 1 to 3 show some of the results obtained in this study.

This combination of HPLC and continuous flow LSIMS mass spectrometry is capable of providing speedy analysis with moderate ease, without resorting to off-line separation of components or derivatisation procedures.

The addition of a scanning array detector enhances the detection of amino acid sequence fragment ions in the MS-MS spectra, with a cycle time capability compatible with the chromatographic separation.

Freedom Area High School, Freedom, PA 15042
Millipore/Extrel Mass Spectrometry
575 Epsilon Dr., Pittsburgh, PA 15238

Introduction

There is a definite need for a quick and relatively simple method to obtain molecular weight information from proteolytically produced mixtures of peptides. For example, a normal protein can be compared with a modified protein containing a substituted amino acid. Protein digest are easily separated by gradient HPLC and detected by UV absorbance, but no structural information is provided. Electrospray (ESI) LC/MS can be used to separate, detect and confirm the molecular weight of the peptides from an enzymatic protein digest.

Protein mapping places high demands on both the chromatographic system and the electrospray interface. The objectives of the present work was to examine the use of two chromatographic approaches to the ESI LC/MS analysis of a tryptic digest of the protein α-lactalbumin.

Experimental

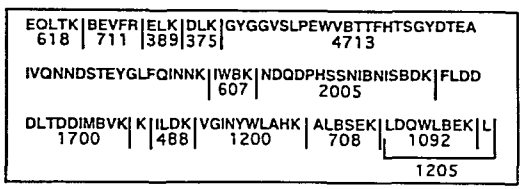
Trypsin Digest: 2 mg/ml α-lactalbumin with 5% trypsin in 0.1 M ammonium acetate buffer (pH 7.8) for 24 hours. The reaction was stopped by the addition of formic acid.

Instrument: Extrel benchmark™ ESI/LC/MS system

Conventional Chromatography: Waters MS600 with a C-18 μBondapak (2 x 300mm) column using a linear gradient of water/2-propanol (95/5 with 1% formic acid) to water/2-propanol/methanol (5/80/15 with 1% formic acid) for 25 minutes, at a flow rate of 0.35ml/min. Flow was split 100/1. Amount of sample injected was 25 μl (3.5 nmoles).

Capillary Chromatography: Protype capillary LC (cLC) system from Waters, designed for gradient chromatography at 1-10 μl/min. A C-18 (0.32 x 150mm, LC Packings) column using a linear gradient of water/acetonitrile (95/5 with 1% formic acid) to water/acetonitrile (40/60 with 1% formic acid) for 40 minutes, at a flow rate of 3μl /min. The entire flow was introduced into the electrospray source. Amount of sample injected was 0.5 μl (3.5 pmoles).

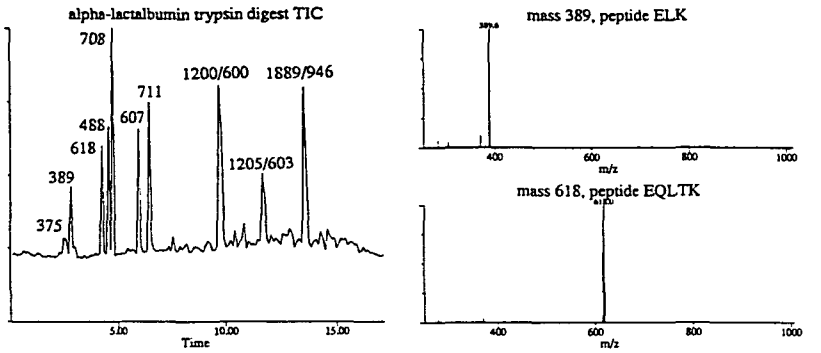
α-lactalbumin Trypsin Peptides



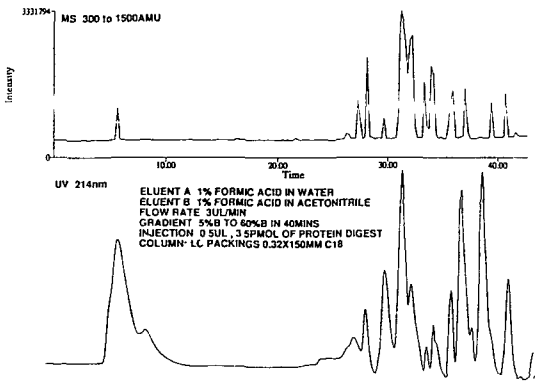
Results:

Shown below are the chromatographic separation of trypsin generated peptides for conventional LC and cLC.

Conventional LC



cLC



Conclusion:

- Molecular weight analysis of all the tryptic peptides from a protein digest was accomplished at a sensitivity level of low picomole, delivered to the needle.
- With a cLC system, low picomolar amounts were injected.
- Tryptic peptides were detected as the singly or doubly charged ion. One histidine-containing peptide gave a triply charged ion.
- Formic acid containg eluents are a viable alternative to TFA-containing eluents for a peptide mapping and offer sensitivity advantages for ESI/LC/MS

Development of Methods for Structural Confirmation of Peptides

Y. Karen Wang, John R. Strahler, and David M. Lubman
Chemistry Department, The University of Michigan, Ann Arbor, MI 48109

Introduction

Selective removal or addition of certain groups from /to the specific amino acid residues can be characteristic of a mass spectrum for the confirmation of the presence of those residues in the sequences. Both enzymatic digestion and chemical derivatization can be designed to serve the purpose, which is especially needed in the cases where a choice must be made among several possible candidates.

Methods

Carboxypeptidase Y immobilization: CPY(1 mg/ml, 3ml) was stirred with immobilized ConA(1 mg ConA/1g gel) for 30min at 4°c in sodium phosphate buffer(20 mM, 0.15M NaCl, pH7.4). After washing, crosslinking of the ConA-CPY conjugate with glutaraldehyde was accomplished under the following conditions: 0.1M sodium phosphate buffer, pH8, 2ml buffer/1ml settled gel, 0.5% glutaraldehyde, 1h at 4°c. The enzyme activity was determined by the rate of the enzymatic hydrolysis of CBZ-Phe-Ala, which is measured spectrophotometrically by the decrease in absorbance at 224nm.
CPY digestion: A physiologically important protein, OP18, was isolated with 2-D PAGE. *In situ* tryptic digest was then carried out on gels. The resultant peptides were recovered by elution with aqueous TFA-acetonitrile, and separated by reverse phase HPLC. One of the tryptic peptides, TP34, was used in this study. The digest of 10pmol TP34 with about 0.1g immobilized CPY was carried out in 100ul of 50mM ammonium acetate buffer pH6.5 for 2h at 37°c.
***In vitro* phosphorylation of kemptide:** The reaction mixture containing 1mM kemptide, 60mM Mes, 12.5mM $MgCl_2$, 0.25mM EGTA, 5mM ATP, and 10ug/ml of cAMP-dependent protein kinase at pH 6, was incubated at 30°c for 30min. Phosphokemptide was then separated from the non-phosphorylated by reverse phase HPLC.
Methyl esterification of phosphokemptide: 200ul aliquot of a solution containing 1.6ml of acetyl chloride in 10ml of methanol was added to 5 nmol vacuum dried phosphokemptide. The reaction proceeded for 2h at room temperature.
Acetylation of phosphokemptide: About 2 nmol of phosphokemptide was mixed with 45ul aliquot of the reaction solution with 0.102g acetyl anhydride, 0.101g triethyl amine, 0.012g dimethylaminopyridine in 10ml dimethyl foramide. The reaction was carried on for 3h at room temperature under agitation.
Dephosphorylation of phosphokemptide: About 2 nmol phosphokemptide was incubated in 20ul 25mM ammonium bicarbonate pH7.9 with 1ul of bacterial alkaline phosphatase(150units/ul) at 37°c for 1h.
Mass spectrometry: Vacuum dried samples were dissolved in 50%CH_3CN-H_2O for ES/MS and 0.1%TFA-H_2O for MALDI/MS analyses. The laser desorption matrix a-cyano-4-hydroxy cinnamic acid was dissolved in 30% CH_3CN with 0.1% TFA to make a saturated solution at 20°c. The peptide solutions were added to the matrix solution to give a final concentration of 0.5-5uM, and a small aliquot (1.5ul) of this mixture was used for analysis. VT-2000 linear TOF was used for MALDI/MS and VT-201 for ES/MS.

Results

Four possible candidates were given by the search against OP18 sequence for tryptic peptide TP34 (m/z 1549, by MALDI/MS), RASGQAFELILSPR, ENREAQMAAKLER, LREKDKHIEEVR, and NKESKDPADETEAD. The digestion with CPY led to the final identification of the peptide.

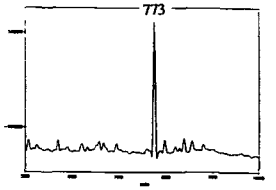

Fig.8 MALDI/MS of dephosphorylated phosphokemptide.

Conclusion

- With the use of carboxypeptidase Y, the number of possible candidate peptides was narrowed down. The identity of a tryptic peptide from a physiologically important protein was given.

- Chemical derivatization and enzymatic digestion proved to be useful for confirming the presence of specific amino acid residues in a sequence, such as acidic, basic, or phosphorylated amino acids.

Reactions may be designed against a specific group on the side chain of a specific residue. Factors, such as volatility of reagents, reaction yield, detectability of the derivatives, all affect the usefulness of a derivatizing reaction on the characterization of an unknown peptide with mass spectrometry.

NON-COVALENT INTERACTIONS OF CROWN ETHERS WITH CYTOCHROME C USING ELECTROSPRAY MASS SPECTROMETRY

Norman Sproch and Terry L. Kruger
Department of Chemistry, Ball State University
Muncie, Indiana, 47306

INTRODUCTION

The soft ionization technique of electrospray mass spectrometry (ESI/MS) has recently allowed the observation of non-covalent complexes between small molecules and proteins. This technique has been used here to study the binding of three different crown ethers to three types of cytochrome c. Previous work has shown the binding of certain crowns to the surface of proteins such as cytochrome c [1]. The suggested binding site on the protein is that of the solvent exposed protonated lysine residue. We report here the binding of 18-Crown-6, Dicyclohexano-18-Crown-6, and Dibenzo-18-Crown-6 to Tuna Heart (Albacore, M_r=12,029 [4]), Horse Heart (M_r=12,360 [4]), and Baker's Yeast (Saccharomyces cerevisiae) Cytochrome c as observed using ESI/MS.

METHODS

The ESI source is of our own design in the configuration of a probe using a standard 1/2 inch vacuum lock (Figure 1), details of its construction will be reported elsewhere. This design uses the heated metal capillary of the type used by Chowdhury, Katta and Chait [2]. An Extrel ELQ 400 (2000 AMU) single quadrupole instrument was used. The experiments showing binding of crowns to cytochrome c were done by adding 1, 2, and 3 mol ratios to a 70 pmol/uL mixture of the three different cytochrome c's. The solutions were prepared with equal parts of methanol/water with 1% acetic acid. Typical sample conditions were, 95 degrees C, 2 uL/min, 4000 VDC on the syringe, 170 VDC on the capillary tube (Figure 1), and 60 VDC on the skimmer (Figure 1).

RESULTS

The binding of crowns increases with increasing concentration (Figure 2) with a large excess producing a spectra showing a pronounced set of peaks corresponding to a protein/protein-crown complex which in addition exhibits a new species with a greater number of charges (Figure 3). This bimodal distribution may be representative of a conformational change in the protein [3]. The molecular weights of the cytochromes were determined from linear plots of each of the proteins set of characteristic m/z peaks vs. 1/z (Figure 4). The slope of the line giving the experimental molecular weight. These values were in close agreement to previously published molecular weights [4]. Similar plots were made to determine the molecular weight of the protein/crown complexes.

CONCLUSION

Signals representing the complex resulting from non-covalent binding of crown ethers to cytochrome c are observed in the ESI mass spectra. Because the crown ethers do not change the proteins charge the characteristic charge envelope remains. The increase in mass of the complex is seen as an intercalated envelope of a slightly higher m/z. The linear plots of m/z vs. 1/z passing through the origin have proven to be a simple method for finding the molecular weight of the proteins, protein complexes and a test for correct charge assignment. The suggested conformational change of the protein with increasing crown concentration is an interesting result and may be due to an increase of the surface hydrophobicity as suggested by recent work using other approaches [5,6]. We are continuing to investigate the suggested conformational changes, the reversibility and stoichiometry of crown binding, and in applying computational/molecular modeling methods using the SYBYL modeling program toward more precise interpretations of the experimental data.

How Big Are Gas Phase Proteins? Collision Cross Sections for Multiply Charged Protein Ions

T.R. Covey and D.J. Douglas, Sciex, 55 Glencameron Rd. Thornhill, Ontario, L3T 1P2 ,Canada

Introduction

Little is known about the physical properties of gas phase protein ions formed by electrospray. Here, we describe a novel method for the measurement of collision cross sections for these ions, based on the energy loss of ions as they pass through a collision cell filled with an inert gas. Results are given for motilin, ubiquitin, myoglobin, cytochrome C, and bovine serum albumin. Cross sections give a measure of the size of proteins. The results here suggest that this new method may be of use for probing the conformations of gas phase protein ions.

Collision Model

Consideration of the kinematics of a collision of an ion of mass m_1 with a neutral of mass m_2 shows that in passing through a collision cell the ion will lose translational energy E as

$$\frac{E}{E_o} = e^{-nl\sigma(ln\alpha')} \tag{1}$$

where E_o is the initial ion energy before collisions, n the number density of gas in the cell, l the length of the cell, σ the collision cross section and α' is given by

$$\alpha' = \frac{(m_1 + m_2)^2}{m_1^2 + m_2^2} \tag{2}$$

Fitting experimental energy losses to equation (1) allows determination of collision cross sections. A Monte Carlo simulation of the energy loss of ions supports this approach (ref.1).

Experimental

Ions formed by ionspray were passed through the collision cell (Q2) of a Sciex API III triple quadrupole mass spectrometer. Stopping curves were obtained with the rod offset of the third quadrupole (Q3) for a range of collision cell pressures. Ratios of stopping potentials with and without collision gas were equated to the ratios E/E_o of equation (1). Cytochrome C ions were formed from aqueous (9:1 water:acetonitrile) and organic (1:1 water:acetonitrile) solutions. Cytochrome C in aqueous solution produced ions in comparatively low charge states (+7–+10) and in organic solution in a broader range of higher charge states (as in ref.2).

Results

Table 1 shows experimental cross sections for all ions studied Collision cross sections generally increase with the charge of an ion. Figure 1 shows cross sections for cytochrome C ions formed from aqueous and organic solutions. Ions formed from aqueous solution show somewhat smaller cross sections than the same ions formed from organic solution and also smaller cross sections than expected from extrapolation from the higher charge states observed from organic solution.

Discussion

It is immediately evident that cross sections for proteins are much larger than those observed for small organic ions (typically 10–100 $Å^2$). Cross sections generally increase with the charge state of the ion. To some extent this might be expected from the larger ion-induced dipole attraction from more highly charged ions. However calculation of ion-induced dipole (Langevin) cross sections gives results 3–8 times lower than those of Table 1. It therefor seems unlikely that the increase in cross section with charge is solely an ion-induced dipole effect; rather, it is plausible that the increase reflects a more open extended structure for the more highly charged ions. The observed charge distributions of cytochrome C imply a more open (denatured) conformation in organic solution and a more closed conformation in aqueous solution. The cross sections of Table 1 and Figure 1 suggest the gas phase ions retain some memory the solution conformation. The energy loss method for determining cross sections may be of use for further studies of the conformations of protein ions.

Characterization of histone H1 heterogeneity by electrospray mass spectrometry

J S. Andersen, L. Essalouh*, C. Dechesne*, J. Parello* and P. Roepstorff.

Department of Molecular Biology, Odense University, Campusvej 55, DK 5230 Odense M, Denmark and *Laboratoire de Chimie des Médiateurs et Physiochimie des Interactions Biologiques associée au CNRS, Université de Montpellier 1, 15 avenue Ch. Flahault, F-34060 Montpellier, France.

Histone H1 is involved in the maintenance and regulation of higher order structure in chromatin in relation to its peripheral position along the nucleofilament. Chromatographic and electrophoretic studies have demonstrated that H1 histones contain closely related subtypes. It is believed that the heterogeneity of the H1 histones has important biological consequences (1). Therefore, we have attempted to characterize the molecular heterogeneity of H1 in order to establish to which extent the heterogeneity is caused by variations in sequence or post translational modifications.

H1 extracted from mouse myoblast cells was separated by reverse phase high performance liquid chromatography (RP-HPLC) and capillary zone electrophoresis (CZE). Electrospray (ES) mass spectra were acquired on a Vestec model 201 single-quadrupole mass spectrometer (Vestec Corporation, Houston, TX, USA) with a skimmer voltage of 12 - 20V and a block temperature of 150 - 250°C. H1 histones were digested with endo proteinase Asp-N and Staphylococcus aureus V8 protease (Na_2HPO_4 buffer, pH 7.2 at 37°C for 3h, substrate:enzyme ratio 1:50 (w:w)).

Five sub fractions (F1-F5) were resolved by RP-HPLC. ESMS of F1-F5 resulted in the identification of six major variants. Three of these were in accordance with the nucleotide sequences known for H1.e, H1.c and H1° (Table 1). Fractions F2 - F5 were digested with endoproteinase Asp-N to verify the identity of the components corresponding to H1.c and H1.e and to determine whether the additional components observed were due to sequence variations or post translational modifications. Two peptides (NT and CT) were obtained for each components and analysed by ESMS. Taking into account the formation of fragment ions (see below) the obtained peptides confirmed the identity of H1.e and H1.c and indicated the presence of sequence variations in the additional components.

Extensive fragmentation was observed in the ES-mass spectra of H1 due to dissociation at specific Pro residues in the N-terminal region. Complete dissociation could be induced thermally or by offset of the skimmer voltage in the ES-interface region. Preferential dissociation of the ions with the highest charge states produced characteristic ion abundance profiles observed for the intact proteins (21kDa) as well as for the enzymatically derived N-terminal peptides (6kDa). H1 has an acetylated N-terminal region composed of mainly Ala and Pro residues followed by a sequence with >30% basic residues resulting in highly charged ions. Consequently H1 becomes very susceptible to collision induced dissociation in agreement with previously reported observation of preferential dissociation at Pro residues in charge site-remote regions (2 and references herein). The different fragment ions observed in ESMS confirm the identity of H1.c and H1.e and support the presence of sequence differences in the additional components. Acetylation of the N-terminal Ser residue was also confirmed.

Mass spectrometric peptide mapping showed that H1° was partially acetylated at the N-terminal Thr residue. A mass discrepancy of 15Da between calc. and meas. M_r of H1° suggest an additional modification. Partial phosphorylation of regenerated rat liver histone H1 and the testis specific histone H1.t were localized to the C-terminal region. The relative degree of phosphorylation of H1 histones were determined by ESMS and CZE. This show that ESMS can be used in a quantitative fashion. Changes in the ion abundance profiles were observed only for modifications affecting the number of potential charges.

Our results demonstrate that ESMS in addition to accurate mass determination of intact proteins can provide additional structurale information based on examination of ion abundance profiles and fragmentation patterns.

GLYCOPEPTIDE MAPPING AND STRUCTURAL CONFIRMATION BY ELECTROSPRAY LC/MS.

T. Hutton and B.N. Green, Fisons Instruments/VG BioTech, Altrincham, WA14 5RZ, UK.
M.J. Geisow, Biodigm, Bingham, Nottingham, NG13 8SS, UK.

Electrospray mass spectrometry (ESMS) is a fast evolving analytical technique which can be used to determine the molecular weights of intact proteins and glycoproteins. The mass accuracy of the technique is in many instances better than 0.01% and masses differing by as little as 0.1% can be resolved. This resolution can be increased by the application of maximum entropy (MaxEnt) to the data. Electrospray is therefore ideal for detecting and assigning post translational modification of intact proteins. Furthermore, the coupling of liquid chromatography and electrospray mass spectrometry provides a fast and highly sensitive method for the detection of glycopeptides produced from an enzyme digestion of a glycoprotein.

Glycoprotein glycoforms affect the biological activity and pharmacokinetic behaviour of many glycoconjugates. Their detection and analysis has become increasingly important in structure function studies as well as in the manufacture of recombinant glycoproteins. Although full characterisation of glycoprotein glycan requires their release from the protein, it would be of considerable advantage to be able to detect particular glycoforms in the intact protein.

In this study we demonstrate the resolving power of electrospray mass spectrometry using MaxEnt applied to the intact plant glycoprotein horseradish peroxidase showing that the individual glycoforms can be resolved. This can be compared with data obtained from a recombinant horseradish peroxidase and two variant strains. The glycopeptides produced by enzyme digestion of HRP were mapped and analysed by LC/MS and compared to those peptides produced from the recombinant non glycosylated protein produced in E.coli.

The data were obtained on Fisons Instruments/VG BioTech Quattro triple quadrupole and Platform single quadrupole mass spectrometers using electrospray ionisation at atmospheric pressure. The horse radish peroxidase was obtained from Sigma Chemical Co., St Louis, MO. The recombinant HRP and the two variants were supplied as part of a collaboration with Dr Andrew Smith, University of Sussex, Brighton, UK.

HRP and recombinant HRP were digested with trypsin and the resulting peptides and glycopeptides were analysed by on-line LC/MS.

Using the MaxEnt algorithm on the multiply charged ion electrospray mass spectrum of natural horseradish peroxidase, identifiable peaks corresponding to both full length and C terminally truncated HRP molecules with either 8, 7 or 6 Nlinked glycans could be seen in the MaxEnt spectrum. Variants of these differing by one hexose unit (eg. manose) and 13 other peaks were also resolved. These included both hexose, deoxyhexose and Nacetylhexosamine variants. The mean mass error between observed and calculated glycoforms was 1.5Da.

The molecular weight determined for the recombinant protein and variant horseradish peroxidase proteins F142A and R38K were 34041.8, 33965.5 and 33979.3 respectively. The differences between the expected and calculated molecular weights for the recombinant protein and the F142A variant were 0.3 and 0.1Da respectively. The variant R38K is outside this range and may in fact be a double mutant. Other possible mutations accounting for the mass difference could be either His→Cys, Met→Pro, Phe→Ile/Leu or Tyr→Gly.

On line separation of the tryptic peptides and glycopeptides obtained from both recombinant HRP and the natural glycoprotein, analysed in positive ion electrospray, produced the chromatograms shown in Figures 1 and 2. The digested natural HRP was also analysed by on-line LCMS in the negative ion mode). The peaks in the chromatogram are labelled according to the corresponding tryptic peptide or glycopeptide fragment number. Several of the chromatographic peaks contain more than one component. These unseparated components can be easily identified by mass analysis.

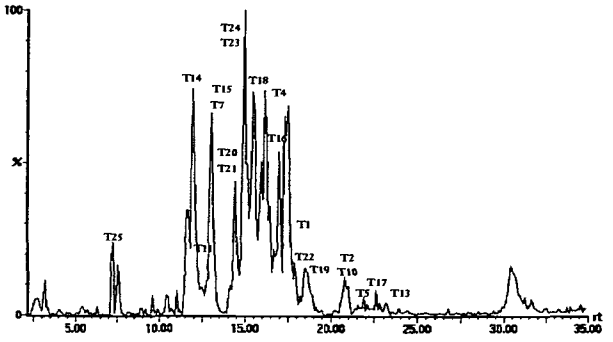

Figure 1. Base peak intensity (BPI) chromatogram of separated peptides from recombinant horseradish peroxidase protein. The peptides are labelled with their tryptic fragment number.

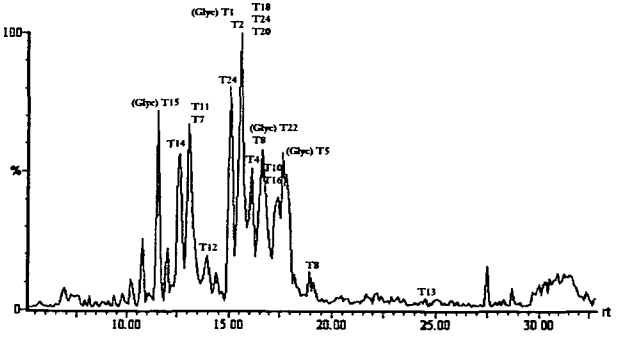

Figure 2 BPI chromatogram of separated peptides and glycopeptides from natural horseradish peroxidase.

A Novel, Rapid and Semi-quantitative Method for the Optimization of Synthetic Peptide Substrates

D.B. Kassel[1], M.D. Green[1], R. Whiebe[2], R. Swanstrom[2] and J. Berman[1]
[1]Glaxo Research Institute, 5 Moore Drive, Research Triangle Park, NC 27709
[2]Lineberger Cancer Research Center, University of North Carolina, Chapel Hill, NC 27599

INTRODUCTION

Knowledge of the subsite specificities (substrate activity relationship) of enzymes is important in the development of both synthetic substrates and inhibitors. Modifications which increase specificity often translate into enhanced inhibitor potency. Identification of high affinity substrates, however, is often the first and one of the more difficult steps in the process of identifying suitable enzyme inhibitors. This problem is particularly evident when attempting to identify favorable substrates for enzyme that exhibit a broad activity range (i.e., proteases which cleave at multiple sites) In an earlier communication (1), members of this laboratory described a novel, systematic approach to optimizing enzyme substrates using defined synthetic peptide substrate mixtures. The method relied principally upon HPLC for the semi-quantitative determination of relative rates of turnover (i.e., enhanced k_{cat}/k_m) for substrates of collagenase. Extensive HPLC optimization and long analysis times (>90 min) was required to achieve baseline chromatographic resolution and quantitate the turnover rates. In order to apply this approach to the rapid optimization of any novel protease substrate k_{cat}/k_m would require tremendous time and effort in establishing optimum HPLC separation conditions. Depending on the complexity of the mixture being screened, baseline separation may not even be achievable by this method This is especially likely if attempting to screen complex mixtures, such as synthetic peptide libraries (2)

We have investigated an alternative approach to screening complex mixtures of peptides This method is based solely on electrospray ionization to screen complex substrate mixtures and quantitate the relative turnover rates. The method requires a simple desalting step and an isocratic elution of all peptide substrates simultaneously into the ion source of the mass spectrometer. This approach has been used to assess the relative k_{cat}/k_m of a defined synthetic HIV protease substrate mixture A mixture of twenty heptapeptides, differing only in a single amino acid substitution (using the 20 common amino acids) at the defined P1' site (Ser-Gln-Asn-Tyr-***Xaa***-Ile-Val) was incubated in the presence of HIV protease and relative rates of turnover were assessed by ESI-MS. The results are presented below HIV protease has been identified previously as a relatively non-specific endoprotease, though the enzyme has shown a preference for cleavage at Tyr-*Xaa* bonds An equimolar mixture of twenty peptide substrates, differing only in their substitution at the P_1' site (C-terminal to the tyrosine residue) (*i.e.,* S-Q-N-Y-X-I-V), was incubated with HIV protease over the course of a 50 min time period. We sought to establish whether mass spectrometry could be used alone to quantitate peptide turnover rates by monitoring the disappearance (turnover) of the peptide substrates as well as by monitoring the appearance of tripeptide products

RESULTS AND DISCUSSION

The averaged mass spectra for incubation time-points A (0 min) and F (30 min) are compared in Figures 1a and 1b. The orifice potential was set to a value sufficient to produce abundant MH+ ions for all twenty peptides (in the m/z range 780-909). The mass spectrum generated for time-point F was characterized by abundant peaks in the low mass region m/z 328, 330, 344, 378 and 394, which corresponded to the cleavage of the peptides by HIV protease at the Tyr-Xaa bond to produce the tripeptide products, P-I-V, V-IV, [L,I]-I-V, F-I-V, and Y-I-V, respectively These peaks were noticeably absent in the zero time-point mass spectrum. The full scan MS spectra acquired at different incubation times (0 min and 30 min) could be used qualitatively to identify the peptides turned over to the greatest extent. In order to determine quantitatively the turnover (rel k_{cat}/k_m) of the individual peptides, we monitored both the disappearance of substrate and appearance of product from their respective selected mass chromatograms. This could be accomplished either by plotting the disappearance of substrate or by plotting the expected masses for product ions *vs.* incubation time for all twenty peptides. Additionally, we could monitor the appearance of product for a number of the peptide substrates. Reconstructed mass chromatograms could be used not only as a tool to rapidly screen the mixture for turnover, but could be used additionally to provide a semi-quantitative assessment of the relative k_{cat}/k_m for this mixture. From these mass chromatograms, integrated areas were then calculated for each peptide at the individual incubation time-points. Figure 2 shows a plot of Integrated Area *vs.* Incubation time for the disappearance of proline substrate (m/z 820) and appearance of its corresponding product (P-I-V, m/z 328). This figure clearly demonstrates that as substrate is consumed by the protease, an equivalent amount of product is produced, thus demonstrating that mass balance is achieved and the method of

electrospray ionization can be used as a semi-quantitative tool. From these data, relative k_{cat}/k_m determinations were made. Most peptides were not turnover at all. Only Pro, Val, Leu, Ile, Phe and Tyr were turned over to any appreciable extent.

The data generated using electrospray ionization alone was consistent with the turnover rates determined from HPLC/MS analyses (data not shown), suggesting that indeed this method could be used effectively as a semi-quantitative tool for assessing turnover for complex substrate mixtures. The major limitation of this method is the inability to distinguish between isobaric or isomeric species Leu and Ile could not be distinguished in the MS analysis nor could Gln or Lys The design and synthesis of defined peptide substrate mixtures should be made in the context of the limitations of the particular screening method. For example, if a goal is to assess the affect of *l- vs. d-* amino acids, then one might consider preparing two distinct mixtures to avoid the problem of the inability to distinguish isomers.

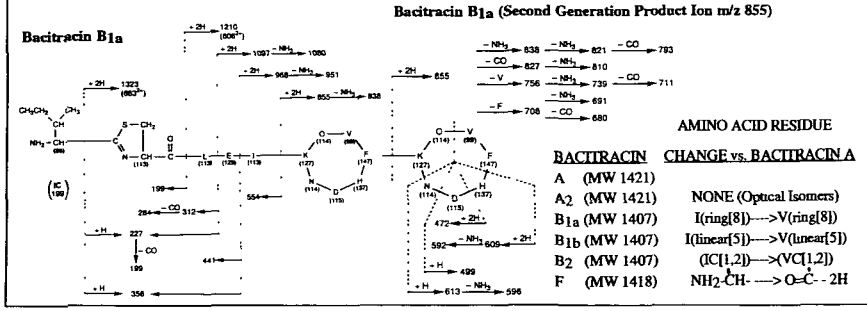
SEQUENCE ANALYSIS of BACITRACIN A and RELATED COMPONENTS by ELECTROSPRAY MASS SPECTROMETRY

Marshall M. Siegel[1]*, Jingfan Huang[1], Russ Tsao[1], Charles G. Edmonds[2]
[1]American Cyanamid Company, Medical Research Division, Lederle Laboratories, Pearl River, New York 10965; [2]Pacific Northwest Laboratory, Chemical Sciences Department, Richland, Washington 99352

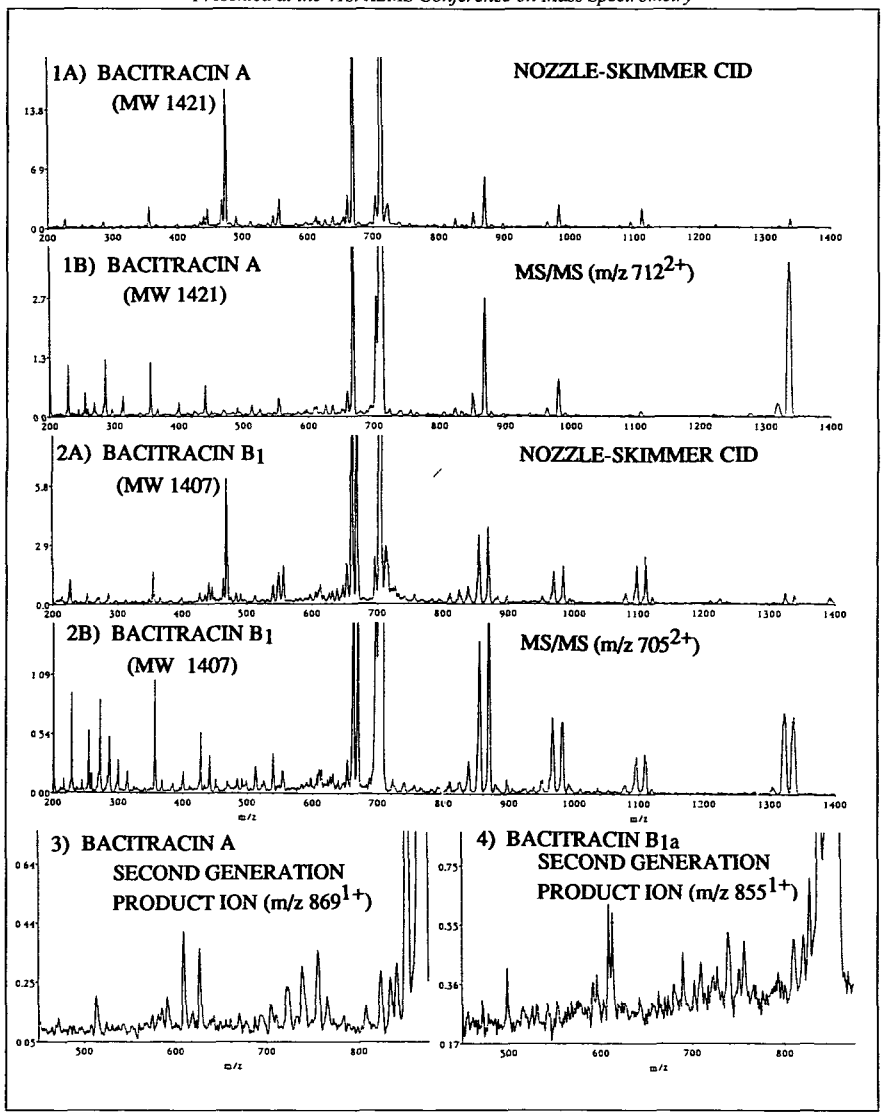
INTRODUCTION Bacitracin is a commercially important antibiotic complex consisting principally of bacitracin A and a number of other minor components. Bacitracin A (MW 1421) is a peptide containing a total of 12 amino acid residues, 5 in a side chain and 7 in a ring. The structures of the bacitracin minor components are thought to be related to that of bacitracin A but have not been fully elucidated due to the difficulties in isolating large quantities of high purity materials and the technical difficulties associated with sequencing cyclic peptides with side chains. Preparative HPLC methods were developed for isolating bacitracin A and the minor components which were then characterized by analytical HPLC, amino acid analysis, fast atom bombardment (FAB) mass spectrometry (MS) and electrospray ionization (ESI)/MS. The side chain residues were sequenced by ESI/Nozzle-Skimmer Dissociation (CID)/MS and ESI/MS/MS and the ring sequences were elucidated by ESI/Nozzle-Skimmer Dissociation (CID)/MS/MS.

EXPERIMENTAL The samples isolated and analyzed by the above techniques were bacitracins A, A_2, B_1, B_2 and F. The ESI experiments were performed on a SCIEX TAGA 6000E tandem quadrupole mass spectrometer (Thornhill, Ontario, Canada) equipped with an atmosphere/vacuum interface and ion source previously described [Smith, et al., Anal. Chem. **60**, 1948 (1988), J. Am. Soc. Mass Spectrom. **1**, 53 (1990)]. Nozzle-skimmer dissociation (CID) experiments in the atmosphere/vacuum interface were performed with a difference of 215 volts between the nozzle and skimmer electrodes. MS/MS was performed with a laboraory frame collision energy of 75 volts and an argon collision gas thickness of 1.5 x 10^{14} atoms/cm^2. These two sets of experimental conditions were combined for ESI/nozzle-skimmer CID/MS/MS experiments, Solutions of the bacitracin components were prepared at approximately 1 nmol/µL in 5% aqueous acetic acid and delivered at 0.5 µL/min in combination with a sheath flow of 3 µL/min of methanol.

RESULTS A unique feature of the ESI sequencing experiments of bacitracin components is that the linear side chain can be sequenced with the data from the nozzle-skimmer CID and MS/MS experiments and the cyclic portion of the peptide can be sequenced by selecting that ion and performing a nozzle-skimmer CID/MS./MS experiment. The nozzle-skimmer CID and MS/MS spectra for bacitracin A are illustrated in Figures 1A and 1B, respectively, and for bacitracin B_1 in Figures 2A and 2B, respectively. Two components, bacitracin B_{1a} and B_{1b}, can be detected in the spectra of bacitracin B_1. The sequence ion assignments are illustrated below for the linear portion of the bacitracin B_{1a} sequence. Figures 3 and 4 illustrate the second generation product ion spectrum of the m/z 869 ion of bacitracin A, and the m/z 855 ion for bacitracin B_{1a}, respectively. Each ion corresponds to the cyclic portion of the molecule. The sequence ion assignments for the cyclic portion of the bacitracin B_{1a} molecule are illustrated below. The C-teminus sequence ion assignments for bacitracin A differ by 14 daltons to those of bacitracin B_{1a}. The Table below summarizes the structural assignments for the isolated bacitracin components.



BACITRACIN	AMINO ACID RESIDUE CHANGE vs. BACITRACIN A
A (MW 1421)	
A_2 (MW 1421)	NONE (Optical Isomers)
B_{1a} (MW 1407)	I(ring[8])---->V(ring[8])
B_{1b} (MW 1407)	I(linear[5])---->V(linear[5])
B_2 (MW 1407)	(IC[1,2])---->(VC[1,2])
F (MW 1418)	NH_2-$\overset{+}{C}$H- ---> O=$\overset{+}{C}$- - 2H



Dilithiated Fragments of a Mono-lithiated Ion? Unraveling B/E Linked Scan Spectra Using Labeled Lithium Ions.

*J P. Kiplinger; Pfizer, Inc., Groton, CT 06340

An investigation of the mass spectral fragmentation of rapamycin (**1**) and related macrocyclic immunosuppressants has been undertaken recently in our laboratory. Negative ion techniques, commonly used with this series, are effective in ionization but offer few structurally useful fragments.[1] In positive ion LSIMS, cationization with alkali metal cations is most effective in determining molecular mass, since these compounds do not readily form MH^+ ions. However, $(M+Na)^+$ and ions formed with larger metal ions do not fragment effectively.[2] Lithium cationization, most often carried out by adding lithium salts to the LSIMS liquid matrix, is becoming an increasingly popular technique in mass spectrometric structure elucidation due to the useful charge-remote fragmentations that $(M+Li)^+$ ions undergo.[3] We have found that cationization of rapamycin with Li^+ ion provides a good yield of $(M+Li)^+$ ions as well as reasonable amounts of structurally significant fragment ions.

The LSIMS spectrum of rapamycin, lithium-cationized using a matrix of 'magic bullet' to which LiCl had been added, is shown in Figure 1. A number of ions in the spectrum were not immediately attributable to the matrix, and were verified as fragments of the m/z 920 ion using linked scanning at constant B/E. Assignment of structures to these ions was undertaken using high resolution and rapamycin analogues.

Intense fragment ions are observed in both the full scan LSIMS spectrum and in the B/E scan at m/z 604 and 586. We attempted to derive structures for these important fragments first, but met with immediate difficulty. No reasonable mechanistic pathway could be derived for monolithiated fragments at these masses. We suspected that these fragments had lost the lithium ion, contrary to the expected charge-remote pathway. Attempted cationization with sodium and other metals produced weak and ambiguous fragment ion spectra. Cationization with $^6Li^+$, however, proved much more helpful

The spectra shown in Figure 2 are partial B/E linked scans of the fragments produced from the $(M+Li)^+$ ion formed from rapamycin. In Figure 2a, the precursor ion is the $(M+Li)^+$ ion at m/z 920. In 2b, the precursor is $(M+Li)^+$ at m/z 919. The strong fragments at 604 and 586 in Figure 2a must contain two lithium ions in order to be shifted by 2 daltons, while the fragment at 591 apparently only contains one It is thus obvious that the B/E scans contain fragment ions produced from two precursors -- the $(M+Li)^+$ ion visible in the LSIMS spectrum, and an $(M+2Li-H)^+$ ion which is not seen in the LSIMS spectrum. The confusion arises from the poor precursor ion resolution obtainable in the linked scanning experiment.

It has often been pointed out in the literature that care must be taken in interpreting B/E linked scanning results due to possible interferences from nearby precursors. However, in this unusual case, no peak for the interfering precursor is seen. This lithium-labeling technique will prove useful in cases where possible artifact peaks exist due to interferences from $(M+H)^+$, $(M+Li)^+$, or $(M+2Li-H)^+$ ions when fragments of only one are desired. Since lithium cationization appears to be a technique which is growing in popularity, as does linked scanning, we can safely assume that these artifacts will be observed more frequently. The use of $^6Li^+$ offers a simple way to deconvolute the fragment ion spectra of lithium-cationized molecules.

CHARGE-REMOTE FRAGMENTATION OF POTENTIAL SENSITIVE DYES BY FAB MASS SPECTROMETRY AND MS/MS

Richard E. Carlson, Kenneth L. Busch, and Kenneth D. Hughes
School of Chemistry and Biochemistry
Georgia Institute of Technology, Atlanta GA 30332

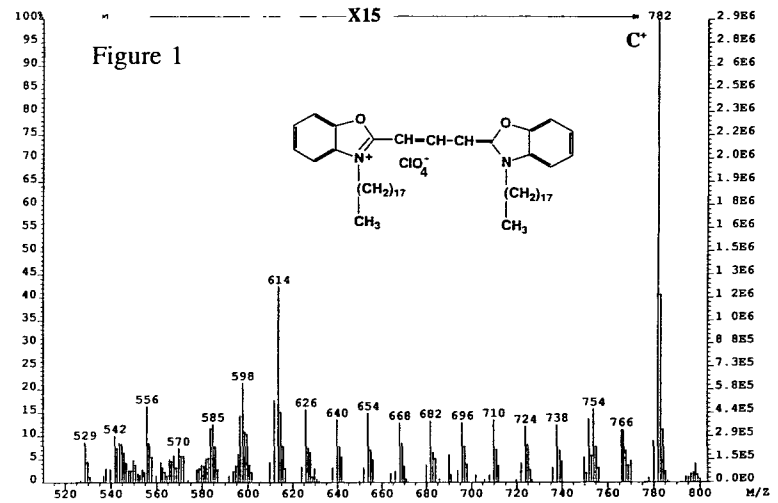
A series of fluorescent, potential-sensitive dyes were studied using positive ion fast atom bombardment (FAB MS) mass spectrometry. Such dyes can be used as non-invasive molecular probes to aid in understanding biophysical processes. Typically, absorbance or fluorescent detectors are used to track the progress of these dyes through biological systems, thus sample purity is important. Mass spectrometry has provided valuable results in the characterization of these samples, and produced some interesting fragmentation mechanisms.

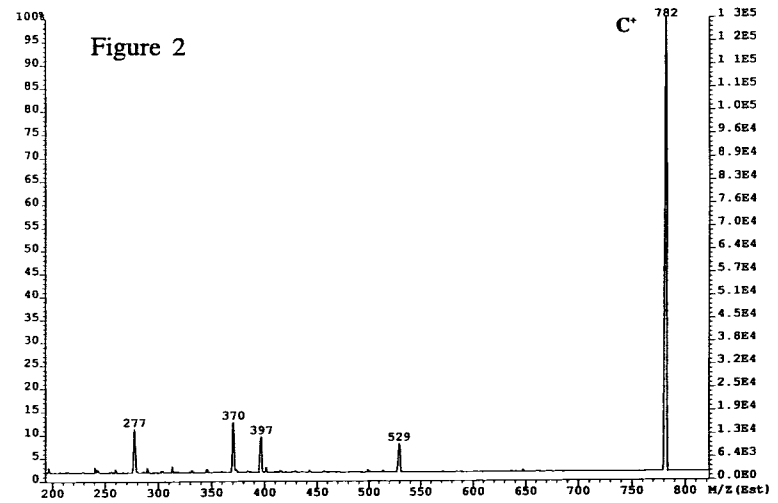
All FAB mass spectra were recorded on a VG70-SEQ mass spectrometer of EBqQ geometry using a Cs ion gun operated at 35 keV. m-Nitrobenzyl alcohol was used as a matrix. In the MS/MS experiments, Ar was used as the collision gas and the collision energy was varied from 10 to 300 eV.

FAB MS and CID MS/MS Experiments:

A portion of the MS spectrum of D-275 (3,3'-dioctadecyloxacarbocyanine, perchlorate) is shown in Figure 1. The spectrum shows a singly charged cation at m/z 782, followed by successive losses of CH_4, CH_3, and CH_2 groups, terminating at m/z 529. Consistent with charge-remote fragmentation mechanisms, these losses originate within one alkyl chain on the charged carbocyanine ring.

Figure 2 shows the CID MS/MS spectrum of D-275. The singly charged cation at m/z 782 was selected as the parent ion, and produced major fragment ions at m/z 529, 397, 370, and 277. As previously indicated, m/z 529 arises from cleavage of one alkyl side chain. The peak at m/z 397 originates from cleavage of the alkyl chain between the carbocyanine groups, m/z 370 is produced from the cleavage of a carbocyanine ring with an intact side chain, and m/z 277 results from the loss of both alkyl side chains from the aromatic rings. The MS/MS spectrum of this compound was expected to show charge-remote fragmentation, based on the results obtained in the MS mode. The calculated E_{cm} for the MS/MS experiments is 9.7 eV. In general, charge-remote fragmentation has been observed in several compounds ionized with FAB and then subjected to high-energy collision-induced dissociation. Charge-remote fragmentation is **not** observed in the mass spectrum, but in the MS/MS spectrum. Here we have a **different** case in which the MS shows the charge-remote fragmentation, but we cannot access this process in MS/MS. Some fraction of the **cations** in the source may be highly energized, but those that survive through to the collision cell apparently are not.





SURFACE-INDUCED DISSOCIATION OF FULLERENES

John H. Callahan and Melvin A. Park, Chemistry Division, Naval Research Laboratory, Washington D.C. 20375. Vicki Wysocki and Arpad Somogyi[a] Department of Chemistry, Virginia Commonwealth University, Richmond, VA.

[a] On leave from Central Research Institute for Chemistry of the Hungarian Academy of Sciences, H-1525 Budapest, P.O. Box 17, Hungary.

From the time of its original discovery by Smalley and coworkers, buckminsterfullerene has been the subject of a variety of studies aimed at studying its physical properties by fragmentation mass spectrometry.[1] With the development of a synthetic technique for the synthesis of bulk quantities of fullerenes,[2] a number of mass spectrometry studies have probed the fragmentation behavior of fullerenes[3]. Most of these studies have shown C_{60} to be relatively difficult to fragment, with successive C_2 loss being the primary fragmentation mechanism. Recently, Whetten and coworkers have used ion-surface collisions to study fullerenes.[4] This work showed that C_{60} is stable toward fragmentation in surface collisions of up to 250 eV. Work by Cooks and coworkers,[5] and by Wysocki and coworkers,[6] has shown that modification of surfaces using perfluorinated self-assembled monolayers (SAM) can significantly increase the amount of internal energy deposited in the parent ion. The explanation for this behavior is not fully known, however, part of the efficiency increase may arise from the increased mass of the atoms (F vs. H) that are struck in the collision. Additionally, differences in the amount of energy taken up by the surface may play a role in the increased energy transfer.

We have used the tandem quadrupole instrument at Virginia Commonwealth University to investigate the behavior of C_{60} in collisions with surfaces treated with self-assembled monolayers formed from derivatized thiols. Collisions with thiol treated surfaces occurr between the first and second quadrupoles in a 90° tandem configuration, at energies between 10 and 160 eV. Fullerene ions were formed by thermal desorption and electron ionization.

Initial studies showed that no fragmentation could be observed between C_{60}^{+} and stainless steel or surfaces covered with octadecanethiol (C_{18}) at collision energies up to 160 eV (consistent with Whetten's results). Some fragmentation could be observed from collisions of C_{60}^{2+} with both surfaces at collision eneries of 250 eV (Figure 1a shows the results for the C_{18} surface). Only singly-charged fragments are observed, due to reduction of doubly charged products. In collisions of C_{60}^{2+} with a perfluorinated surface (PF; $CF_3(CF_2)_7CH_2CH_2SH$), far more extensive fragmentation is observed (Figure 1b). Both singly- and doubly charged fragments are observed, consistent with the higher ionization energy of the perfluroinated surface. The more extensive fragmentation observed from the perfluorinated surface is consistent with greater energy deposition. In fact, the energy deposition is high enough that fragments can be observed from singly charged C_{60} at energies as low as 125 eV. The results indicate that as much as 50% of the translational energy may be converted to internal energy.

We have also obtained results indicating that C_{60}^{2+} undergoes reactions with adsorbates or fragments on SAM surfaces. Collisions of the doubly-charged ion with the perfluorinated surface at 320 eV results in the formation of an ion at m/z 372. This is not likely to be C_{31}^{+}, since it is not readily formed. Thus, it seems likely that this is a reaction product of C_{60}^{2+} with C_2. Evidence that this occurs was also observed on other self-assembled monolayers. Figure 2 shows the result of collisions of C_{60}^{2+} with a surface covered with $NH_2CH_2CH_2SH$. Although the products are reduced to singly-charged ions, the results show evidence for pickup of at least 4 C_2 groups. This indicates that a C_2 growth mechanism is plausible for fullerenes.

David A.Leigh , Andrew E.Moody and Frances A.Wade
Department of Chemistry, UMIST, Manchester, M60 1QD

The discovery of the fullerenes and their subsequent characterization as the third well defined allotrope of carbon has given rise to a whole new branch of chemistry. Reports have appeared in the literature detailing the reactivity of fullerenes to oxygen, hydrogen, halogens, metals and amines. Mass spectrometry has played a key role in the identification and characterization of these new compounds.

In an attempt to increase the solubility of the fullerenes in polar liquids, we reacted them with a number of water soluble reagents including amines. The reaction with aza crown ethers provides stable monoaddition products. Experimental details of the addition products will be published elsewhere.

Two sources of fullerite were used in the experiment. The first batch was produced at UMIST using a benchtop fullerene generator as described by Koch et al. and the fullerite mixture was soxhlet extracted from the soot using toluene. The second batch was supplied by the Strem Chemical Co. (Newburyport, MA, 01950, USA). The two batches provided identical results.

Mass spectrometry was carried out on a Kratos Concept IIHHM four sector tandem mass spectrometer (Kratos Analytical, Urmston, Manchester, UK) operating under fast atom bombardment ionisation conditions with xenon atoms of 8keV energy. Nitrobenzylalcohol (NBA) was the matrix of choice. MS1 was used to obtain the double focused mass spectrum. Collisional activation (CA) was employed using helium as collision gas such that 70% of the precursor ion beam was attenuated with the collision cell floated at 4kV. Array detection was employed after MS2. All data was obtained in the positive ion mode.

Interestingly the reaction of fullerite (the C_{60} and C_{70} mixture) with dimethylamine has so far only yielded C_{70} products. There appear to be up to eight additions of dimethylamine to the C_{70} ring but the most interesting aspect of these materials is their fragmentation patterns under MS/MS[1]. For up to six dimethylamine groups added onto the fullerene species, the MS/MS spectrum varies according to whether there are an even or odd number of dimethylamine groups attached to the ring. If there are an even number of groups attached to the ring, the fragmentation is stepwise i.e one group is lost at a time. If there are an odd number of groups attached then the loss is two groups at a time. Tandem mass spectrometry of these species reveals the presence of helium incorporation in the substituted precursor ions, whereas the endohedral complexes had previously only been observed for pure carbon compounds.

The complexes formed by the reaction of pure C_{60} with a variety of aza crown ethers yield more readily interpretable tandem mass spectra. The predominant ion in the mass spectra of the $[1A12C4+C_{60}]^+$ complex is m/z 892.3 which is 4Da below the

expected value for the protonated complex. This corresponds to the loss of two hydrogen molecules, a phenomenon also found with the dimethylamine products. We speculate that this may be because of a stabilisation of the ring structure which only becomes apparent when the fullerene molecule has another group attached onto it.

The MS/MS of the m/z 892.3 ion is shown in Figure 1. The predominant fragments correspond to m/z 734 (where the nitrogen atom of the aza crown ether is attached to the C_{60} ring, suggesting this is the site of binding), m/z 720 (C_{60}), and m/z 172, 128 and 100 which are related to fragmentation of the crown ether (crown ether molecule, loss of CH_2CH_2O and further loss of CH_2CH_2 respectively).

The potential of fullerenes for the synthetic organic chemist is exciting but owing to the complexity of the molecular addition products, characterisation by typical methods such as NMR and infrared may prove somewhat difficult. Mass spectrometry has a major future in assisting in the characterisation of this whole new branch of chemistry.

A Systematic Study of Surface Characteristics Associated With Enhancement of Both Surface-Induced Dissociation (SID), Reaction and Energy Deposition

*Thomas E. Kane, Árpád Somogyi, and Vicki H. Wysocki.
Virginia Commonwealth University, Richmond, VA 23284.

INTRODUCTION Ion-surface collisions deposit high amounts of internal energy into the projectile ion in a process called surface-induced dissociation (SID)[1]. In addition to fragmentation of the selected ion, an ion may (i) neutralize, (ii) exchange its charge with material native to the surface, also known as chemical sputtering, and (iii) react with material from the surface. These other processes are often far less pronounced than SID, particularly when larger polyatomic projectiles are employed. The degree to which these alternate processes occur for a selected ion may better describe the chemical and physical condition of the surface. Organic self-assembled monolayer films provide well characterized surfaces with which to investigate surface-induced dissociation, reaction, and neutralization.

EXPERIMENTAL A tandem quadrupole instrument is arranged in a 90° geometry with the surface positioned 45° to Q1.[2] The collision energy is varied by increasing the source potential relative to the surface potential. Surfaces are highly ordered monolayer films of organic thiols, spontaneously assembled onto gold. Self-assembled monolayers include n-alkanethiolates, and 2-(perfluorooctyl)ethanethiolate. The surface holder allows for the investigation of five surfaces without venting the instrument.

We show that dimethylsulfoxide (DMSO, m/z 78) and its deuterated analog (m/z 84) act as excellent probes of available hydrogen on the surface. Unlike benzene, which was investigated earlier,[3] DMSO is more sensitive towards H-addition, and is capable of detecting trace hydrocarbon on self-assembled monolayer films. Surfaces representing short chain, disordered films (C4 and C8), and long chain, more crystalline films (C12 and C18)[4] were probed with DMSO, and the hydrogen addition measured. The fluorinated surface was probed, and then damaged with a 70eV $Ar^{+\cdot}$ beam for 15 hours. The increase in surface damage was monitored with DMSO-d6.

Atomic ions eliminate the possibility of projectile fragmentation and facilitate the investigation of the processes that compete with SID. All ions appearing in the spectrum, other than the $M^{+\cdot}$, are therefore the result of energy imparted to the surface via the initial collision energy and the ionization energy of the atom. Ions from group I, VII and VIII are collided into monolayer surfaces, and their ionic products are plotted as a function of collision energy.

DISCUSSION Two possible sources of hydrocarbon exist for alkanethiolate monolayers; adventitious material physisorbed to the surface (e.g., from pump oil), and the hydrogen-containing alkanethiolate monolayers. Only trace amounts of hydrocarbon contaminant are expected on the undamaged, low free energy alkanethiolate layers. The amount of H-addition observed for DMSO-d6 decreases with the chain length of n-alkanethiolate monolayer surfaces, suggesting a decrease in the amount of adventitious hydrocarbon on the film (Figure 1). The hydrogens available to DMSO reaction therefore become increasingly limited to the terminal methyl groups of the monolayer. Our data show a decrease in H-addition to DMSO-d6 for all surfaces as a function of the time the surfaces are exposed to the thiol solution. This suggests that a *second* ordering process occurs for monolayer films *in solution,* perhaps as a result of thermodynamically driven repacking of the thiolate chains after the initial self assembly. The magnitude of this second process decreases with increasing chain length. It is therefore likely that this second process depends on the amount of order that occurs during the initial assembly. After extensive bombardment of the fluorinated surface film, hydrocarbon peaks become more

intense than fluorocarbon, suggesting surface damage and increased adsorption of chamber contaminants (Figure 2). SID spectra of large polyatomic ions (peptides) obtained on damaged and unused fluorinated surfaces are virtually identical. For the atomic ions, the amount of chemical sputtering increases with increasing collision energy and recombination energy of the impinging ion.

A QUADRUPOLE/TOF MS/MS EXPERIMENTS TO STUDY EFFECTS OF IMPACT OF MACROMOLECULAR IONS ON SURFACES

R.Zubarev, J.Axelsson, J.Eriksson, P.Demirev, P. Håkansson, C.Reimann, B.U.R.Sundqvist,
Dept. Radiation Sciences, Uppsala University, Box 535, Uppsala, 75121 SWEDEN

A "multiply-charged macromolecular accelerator" (MUMMA) is being constructed at Uppsala University for studies of macromolecular ion impacts on surfaces [1,2]. An electrospray ion source and a quadrupole mass spectrometer (MS1) are employed to generate and select positive ions from peptides with mass M from 0.5 to 66.3 kDa and charge Z up to 60, in the M/Z range below 2000. The system is modified by addition of ion optics for transport of the generated ions towards an external target held at a potential U_a of up to - 20 kV. The U_a used in this study was -10 kV, corresponding to primary ion energies Z·10 keV(up to 600 keV for albumin projectiles). A straight time-of-flight (TOF) spectrometer (MS2) has been used for mass analysis of the ejected negative secondary ions as a result of a single macromolecular ion impact on different organic and inorganic targets (Fig.1). The initial experiments, reported here, were performed at a typical pressure in the experimental chamber of $5 \cdot 10^{-7}$ Torr maintained by an oil diffusion pump (an UHV-style experimental chamber is currently under construction).

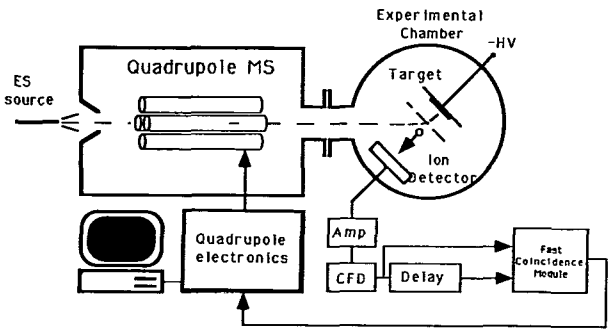

Fig.1 A quadrupole/TOF MS/MS experimental set-up.

Two modes of MS/MS data collection have been developed. Initially MS1 was tuned to a particular M/Z and complete TOF spectra were collected by MS2 (Fig. 2). The negative ion TOF spectra have been obtained using as a start signal either the ejected secondary electrons or H^- ions. Although different target materials have been tested (valine, CsI, bare stainless steel, etc.), 95 to 98 % of the detected secondary ions were not target-specific. Spectra contained mainly peaks of low mass hydrocarbon ions which might have originated from the contamination layer on the target and/or from the projectile. That mode of operation has been employed for estimates of the secondary ion multiplicities (i.e. number of registered secondary ions with different masses per impact event) as a function of different projectile parameters [3]. Our results demonstrate that the average multiplicity of secondary ions ejected in macromolecular impact events scales sublinearly with the projectile velocity [3].

In the second mode fast coincidence electronics is employed to record yields of secondary ions within a predetermined M/Z window (i.e. MS2 collecting ions within a specified arrival time in the TOF spectrum) while the quadrupole (MS1) is scanned through M/Z 500 to 2000, thus resulting in a spectrum of the projectile ions in different charge states (Fig. 3). The secondary electrons emitted during the impact can be magnetically deflected and thus the mass spectrum will contain only secondary ions and/or

fragments from the primary ion projectile. We note the applicability of this approach for resolving the individual components of an electrosprayed mixture (of e.g. peptides), provided that component-specific fragments are detected in the secondary ion TOF spectrum. By choosing a time window for that particular ion the projectile ion spectrum for that component will be accordingly enhanced. So far we have not been able to demonstrate that approach with this particular set-up since we cannot pinpoint a fragment, specific for the primary ion, most probably due to contaminations on the target.

Separation and Analysis of PAH-DNA Adducts by CE Combined to MS/MS Using an Array Detector.

J. M. Y. Wellemans, R. L. Cerny, M. L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304, USA.

INTRODUCTION. The covalent binding of Polycyclic Aromatic Hydrocarbons (PAH) to purine bases of DNA has been proposed by Cavalieri et al. [1] to be the result of an one-electron oxidation mechanism leading to the formation of a tumor.

Mass spectrometric studies of *in vitro* samples show the attachment of PAH to N7 or C8 of the base to form stable and unstable adducts, respectively [2].

Studies of *in vivo* samples, where less than $1/10^6$ base is modified (femtomole range), involve complex mixtures and low quantities of samples. This necessitates efficacious and sensitive detection techniques. To achieve such detections, we propose to combine capillary zone electrophoresis (CZE) with tandem mass spectrometry via a coaxial continuous flow FAB (cf-FAB) [3]. Because of the high efficiency of CZE and the narrow peaks (half height of 3-10 sec), it is difficult to obtain MS/MS data when scanning MS-2. To overcome the problem, we propose to use a VG ZAB-T tandem mass spectrometer, of reverse Mattauch-Herzog type geometry, equipped with a 15-cm channel electron multiplier array for simultaneous acquisition of major portions of a CAD spectrum.

RESULTS & DISCUSSION. The reference samples, dibenzo[a,l]pyrene-N7-guanine, dibenzo[a,l]pyrene-C8-guanine and 6-methylbenzo[a]pyrene-N7-guanine, were diluted with DMSO/MeOH (1:1). The coaxial cf-FAB was custom-built. The matrix, glycerol/water (25/75) was flowed through a 150-μm i.d. fused-silica capillary at 800 psi by using a μLC Micro Flow pump (ISCO, Lincoln NE). The bomb was pressurized with He at 600 psi to flow the eluent (i.e., water and the samples) through a 10-μm i.d., 140-μm o.d., fused-silica capillary 2 meters in length. For sample injection, the bomb was pressurized at 600 psi for 10 sec., corresponding to a volume injection of 6 nL.

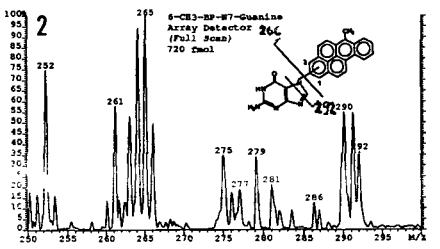
The L-SIMS ion source was at 30 °C and held at 8 kV acceleration voltage. The Cs^+ gun was operated at 30 kV. The collision cell voltage was floated at 4 kV where the collisions with He, as a collision gas, was at a pressure sufficient to reduce the parent beam by 60%. The detection was either a single point or the array detector.

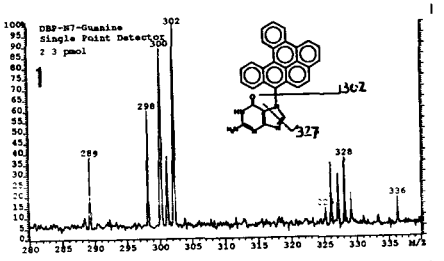
The first goal is to establish the detection limits for the analysis of the PAH-DNA adducts. With the single point detector, MS-2 scans were from 100 u to $[M+H]^+$ at 2 sec/decade. With a 10-sec injection, only 5 scans were recorded. With the array detector, 9 exposures were obtained when covering the same mass range. Each exposure lasted 1 second over a mass ratio of 1.21:1. In addition to a better sensitivity, the array detector allows us to obtain that portion of CAD spectrum that contains most of the structural information with a single exposure, focussing on a specific mass range. For a 10-sec injection, 9 to 10 exposures are recorded for that limited mass range. This way of operating the array detector allows for better detection limits while still obtaining most of the structural information. (See table 1 and spectra 1, 2 and 3).

The next goal is to determine the capability of coupling CZE with the mass spectrometer. The system was tested with model compounds, a tripeptide MLF (methionine-phenylalanine-leucine) and a tetrapeptide FLEEI (phenylalanine-leucine-glutamic acid-glutamic acid-isoleucine). The separation, due to the migration of charged analyte in an electric field, was performed in a 13-μm fused-silica capillary filled with ammonium acetate 5×10^{-3}M at pH 8.5. By using the array detector, 75 fmol of MLF was detected. Most of the major fragments were identifiable.

CONCLUSION. We have shown that, with the array detector, better detection are achieved compared to those with the single point detector. When using the coaxial cf-FAB instead of the static probe, the improvement is approximately three orders of magnitude.

We also have shown, with two peptides, that CZE coupled to our tandem MS can give structural information at low femtomole level. In the future, we will seek better means of desorbing or ionizing the modified nucleobases so that detection limits for MS/MS studies can be reduced to the low femtomole level.





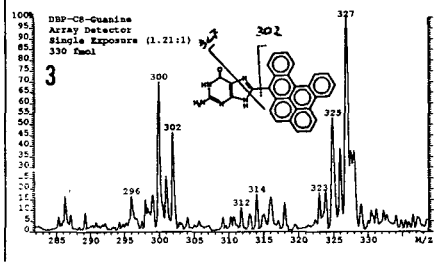


Table 1. Detection limits for coaxial cf-FAB.

Adduct\Mode	Single Point	Array	
	Scan (full scan)	Full Scan	Single Exposure (1.21:1)
DBP-N7 Gua	2.3 pmol	350 fmol	110 fmol
DBP-C8 Gua	1.3 pmol	330 fmol	90 fmol
6-CH_3-BP-1/3-N7Gua	1.4 pmol	350 fmol	86 fmol

Introduction

High-energy collision-induced dissociation (CID) mass spectrometry provides a rapid, sensitive means for determining the primary sequence of peptides. The low-mass region of the CID spectra of peptides contains several types of fragment ions, including dipeptide ions, immonium ions and other related ions. Immonium ions (general structure $[H_2N{=}CH{-}R]^+$, where R is the amino acid side chain) and related ions characteristic of specific amino acid residues give information as to the presence or absence of these residues in the peptide being analyzed. A data base of 228 high-energy peptide CID spectra has been established, the frequency of occurrence of various ions indicative of specific amino acid residues has been determined, and a model scheme for computer-aided analysis of the amino-acid content of unknown peptides has been developed.

Methods

Mass Spectrometry MS/MS experiments were carried out on a Kratos Concept IIHH 4-sector instrument equipped with an LSIMS source and a multichannel array detector with a 4% mass window. Precursor ions were generated with an 18 keV Cs^+ primary beam. The collision cell (He) was floated at 4 kV.

Data analysis. CID spectra were recorded as peak profiles. A peak detection routine [1] and a threshold were applied to each spectrum. Peaks were classified as strong, medium or weak in the following way. All of the peaks below mass 200 were renormalized such that the largest peak in this range was assigned an arbitrary abundance value of 25. Those peaks with a renormalized abundance of between 5 and 25 were deemed strong, those between 1 and 5 as medium and the remainder were defined as weak. Computer programs for analyzing spectra were written in C and run on a Sun SPARCstation IPX computer. Our database for this study was derived from a larger selection of CID spectra of peptides of known sequence. Programs were designed to suggest residues that were likely absent ("excluded") or present ("required") in the peptide. In cases where no prediction could be made, the residue was "allowed." Predictions were restricted to genetically encoded amino acids. Predictions for Gly and Ala were not attempted as we did not scan low enough to detect their immonium ions. No attempt was made to distinguish the isomeric pair, Leu and Ile, or the isobaric pair, Lys and Gln.

Results

We used the data base to test various possible schemes for computer-aided interpretation of amino acid composition. This "amino acid composition module" was designed to be used in combination with the computer-aided spectral interpretation program developed in our laboratory [1]. The logic for one possible automated scheme for determining amino acid composition is shown in Table 1. This scheme takes account of possible interferences between indicator masses from different residues and also makes use of (crude) ion abundances. In this scheme, peaks are defined as being strong, medium or weak (see Methods).

In developing logic to screen CID spectra for indicator ions, two key points must be borne in mind. First, it is not possible to determine all residues in every case with complete certainty. This conclusion underlines the basic premise of our computer-aided interpretation software, namely that **the computer can be an extremely valuable assistant in the process, but human interaction is essential.** The second key point is that one is required to establish a balance between the desired level of accuracy and the fraction of cases for which a definite prediction can be made. At one extreme, perfect accuracy is required, and all or nearly all tests produce the result "allowed." At the other extreme, definite predictions are required in all cases, but many are incorrect. The scheme shown in Table 1, when tested against the data base, gave 67.5% correct results, 27.7% indeterminate and 4.8% incorrect. In our laboratory we use a variation of this scheme, in which no predictions are attempted for Cys, and Asp, Ser and Glu are never excluded. This reduces the percentage of incorrect results to 2.4%, but at the cost of further increasing the number of cases in which no prediction is made to 39.3%.

AA		Test	Prediction
Simple*		immonium ion mass strong or medium	+
		immonium ion mass absent	-
		all other cases	0
Asn		87 strong or medium and Arg predicted absent	+
		87 absent	-
		all other cases	0
Pro		70 strong or medium and 87, 100 and 112 all absent	+
		70 absent	-
		all other cases	0
Ser		60 strong or medium and Arg predicted absent	+
		60 absent	-
		all other cases	0
His		110 strong	+
	or	110 medium and at least 2 of 82, 121, 123, 136 and 166 present	+
		110 absent	-
		all other cases	0
Arg		100 strong or medium, 87 and at least two of 59, 70, 112 or 129 present	+
		100 strong or medium, 87 and less than two of 59, 70, 112 or 129 present	0
	or	87 or 100 present and at least one of 59, 70, 112 or 129 present	0
		all other cases	-
Lys/Gln		84 and 101 strong and weak (either order) or both medium	+
	or	84, 101, 112, and 129 all present	+
		84 and 101 both absent	-
		all other cases	0
Trp		130 and 159 strong and weak (either order) or both medium and 171 present	+
		130 and 159 strong and weak (either order) or both medium and 171 absent	0
	or	130 and 159 both present	0
	or	171 present and either 130 or 159 present	0
		all other cases	-
Tyr		136 strong or moderate and at least one of 91 or 107 present	+
		136 absent	-
		all other cases	0

Table 1. Scheme for determining the amino acid composition of a peptide. The prediction "+" means that all candidate sequences must contain this residue, "-" means that none may contain it, and "0" means that the sequences may or may not contain it. *"Simple" refers to residues for which only the normal immonium ion peak is used (Cys, Asp, Glu, Phe (91 not used), Ile/Leu (72 not used), Met(61 not used), Thr, and Val).

Conclusions

The low-mass region of high-energy tandem CID spectra of peptides contains information that definitively shows the presence or absence of many amino acid residues, although the complete amino acid composition cannot be deduced in most cases. Both positive and negative conclusions are extremely valuable in generating or narrowing the choice of possible candidate sequences for sequence determination. Logical rules can be developed to provide computer-assisted evaluation of peptide amino acid content. This process can be integrated into an overall computer-aided spectrum interpretation scheme, or used in manual interpretation.

Acknowledgments

We are indebted to Fred C. Walls for acquiring most of the spectra used for this study. This work was supported by grants from NIH (RR01614) and NSF (DIR 8700766) to A. L. Burlingame.

Effect of Electrospray Ionization Conditions on Low-energy MS/MS spectra of Peptides.

Greg W. Kilby and Margaret M. Sheil
Dept. of Chemistry, University of Wollongong, Northfields Ave, Wollongong, NSW 2522, Australia

MS/MS spectra of peptides are known to be dependent on collision-induced decomposition (CID) parameters such as ion energy, target gas and target gas pressure[1]. There have been fewer studies, however, of the effect of ionization mode and conditions on MS/MS spectra of peptides[2]. In the case of electrospray ionization (ESI) in particular, the skimmer potential can influence both the the initial internal energy of the ions and the nature of the ions formed and thus may have a significant effect on low-energy MS/MS spectra. In this study we investigated low-energy MS/MS spectra of a range of peptides (500 - 1200 Da) following ESI focussing on: the influence of ESI conditions (solvent pH and skimmer potential) on the type(s) of the ions generated from the peptides for subsequent MS/MS analysis; the effect of varying the electrospray skimmer potential on MS/MS spectra at different collision energies; and the influence of peptide structure on low-energy ES/MS/MS spectra.

In many instances for MS/MS experiments, especially for small peptides and peptides with a number of basic residues (for which multiply-charged species tend to dominate with ESI), it is often desirable to generate $[M+H]^+$ ions. For ESI of most peptides a high solvent pH and high skimmer voltage (B1) has been found to optimize $[M+H]^+$ ion production. Solvent pH also affects the degree of source fragmentation observed in ESI mass spectra. For example, a low pH (2.5) results in more extensive source fragmentation at any given skimmer potential than a high pH (10.5). This effect is much more pronounced with peptides containing a number of basic residues and may in part be due to there being a greater population of doubly-charged species which fragment more readily at low pHs.

That higher skimmer potentials generate ions with increased initial internal energy was reflected in the MS/MS spectra of all the peptides studied. In the MS/MS spectra of Met-Enkephalin shown in figure 1, more extensive fragmentation was observed under the same collision conditions when higher skimmer potentials were employed. This effect was more apparent at lower collision energies, and was found to be a general one for a range of cyclic and linear peptides. For each peptide, however, there was a unique optimum skimmer potential which represented a balance between generating $[M+H]^+$ ions with high internal energy and using too high a potential such that the intensity of $[M+H]^+$ ions was reduced by the onset of other processes *i.e.* source fragmentation etc.

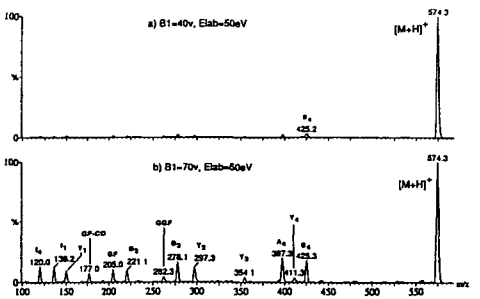

Figure 1 ES/MS/MS spectra of $[M+H]^+$ Met Enkephalin at two different skimmer potentials (B1). E_{lab} = 50 e, argon collision gas.

MS/MS spectra of $[M+cat]^+$ ions of peptides often yield different fragments to $[M+H]^+$ ions. We have found in the case of cyclic peptides which form $[M+NH_4]^+$ ions that these fragment more readily compared with the $[M+H]^+$ ions while still yielding the same structural information. This is illustrated in the ES/MS/MS spectra of valinomycin shown in figure 2. Extensive fragmentation is observed in the MS/MS spectrum of the $[M+NH_4]^+$ ion even with no collision gas. The potential of using NH_4^+ ions to "activate" fragmentation is limited, however, to the small number of peptides that will form $[M+NH_4]^+$ ions.

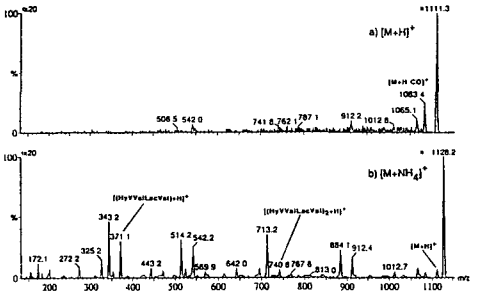

Figure 2 ES/MS/MS spectra of valinomycin $[M+H]^+$ and $[M+NH_4]^+$ ions. No collision gas.

Finally, the influence of peptide structure on low-energy ES/MS/MS spectra was investigated. Gaskell *et al.*[3] have proposed that in order to generate extensive fragmentation in low-energy MS/MS spectra of peptides there must be an even distribution of charged sites within the precursor ion population. This is reflected in the ES/MS/MS spectra of $[M+H]^+$ ions of Arg-Met Enkephalin (RYGGFM) versus Met Enkephalin (YGGFM) and of bradykinin (RPPGFSPFR) compared with des-Arg-bradykinin (PPGFSPFR). The peptides with Arg at the N-terminus (which is probably a preferred protonation site) showed poor fragmentation efficiency compared with the corresponding peptides without an N-terminal Arg. Further, it was not possible to increase the extent of fragmentation in the ES/MS/MS spectra of Arg-Met Enkephalin or bradykinin by increasing either the initial internal energy (increased B1) or the collision energy_ thus supporting the view that it is the charge sites rather than the available energy that is the dominant factor in this case.

Thus low-energy MS/MS spectra of peptides have been found to be very dependent on electrospray ionization conditions. For a given peptide, the source skimmer potential, the solvent pH and the collision conditions all need to be optimized to generate the maximum degree of fragmentation. In some cases, however, especially for basic peptides, the distribution of charged sites within the peptide may have a more significant effect on the fragmentation than either the ionization or collision conditions.

Experimental

All experiments carried out on a VG Quattro triple quadrupole. The solvents were either 50% aq MeCN & 1% Formic Acid or 50% aq MeCN &1% NH_3. Solvent flow rate was 5 µl/min. The collision gas used was argon at a pressure corresponding to ~30% transmission for each MS/MS experiment. The peptides were dissolved in aqueous solutions with concentrations in the range of 300 - 500 pmol/µl.

CAD/MS/CAD/MS Of Multiply Charged Peptides With Electrospray Ionization

Joseph A. Loo

and

Richard D. Smith
Pacific Northwest Laboratory
P.O. Box 999, Richland, WA 99352

Sequencing of large polypeptides by tandem mass spectrometry has been facilitated by advances in ionization methods such as electrospray ionization (ESI). Multiply charged species from large peptides may be induced to fragment through collisionally activated dissociation (CAD) methods. ESI-product ions may be generated in the collision chamber of a tandem mass spectrometer (low energy collisions with a triple quadrupole instrument or high energy collisions with a magnetic sector instrument) or in the atmospheric pressure/vacuum interface region of the ESI source (low energy collisions) through control of the nozzle-skimmer or capillary-skimmer voltages. Increasing the collision energy in the interface often changes the relative abundance of product ions. For example, at a nozzle-skimmer potential of + 250 V, an abundant series of $b_{2\text{-}10}$ ions are produced for substance P (M_r 1347). At + 350 V, an additional series of $a_{4\text{-}10}$ ions are generated, most likely from further dissociation of b_n ions.

Deciphering the amino acid sequence information is often straightforward, although for more highly charged precursors, multiply charged product ions may be produced. The combination of CAD with higher resolution analyses allows for direct determination of product ion charge state, and therefore product ion mass. For example, low energy CAD in the ESI interface of a magnetic sector instrument (Finnigan MAT 900 with a heated-glass capillary electrospray interface) of melittin (M_r 2846) produces abundant singly- and doubly-charged y_n and b_n type product ions from the first 19 (out of 26) residues. CAD spectra taken at a resolving power of 3000 allows resolution of isotope peaks of the multiply charged molecules and product ions (Figure 1).

Further dissociation of product ions generated in the ESI interface (CAD/MS/CAD/MS) often yields additional sequence information and confirmation of product ion assignments. Figure 2 shows the CAD/MS/CAD/MS spectrum of the y_{13}^{2+} product ion from melittin. The y_{13}^{2+} "parent" ion was generated by low energy collisions and was further subjected to high energy (2.5 keV laboratory energy, B/E linked scan) collisions. In this manner, additional sequence information from the COOH-terminus of melittin was obtained.

In most cases studied, product ions generated in such experiments are the "expected" types (*e.g.*, MS/MS of a b_{10} fragment ion may produce a series of $a_{1\text{-}9}$ and $b_{1\text{-}9}$ product ions.). However, in selected examples such as substance P (RPKPQQFFGLM-NH_2) and substance P analogues, the tandem mass spectra appear to indicate that the peptide has isomerized during or after the initial CAD step. Both low energy and high energy MS/MS of the b_{10}^{2+} product ion of substance P yields fragments from the successive loss of Phe^8, Phe^7, and Gln^6 instead of loss of residues 9 and 10 (Gly and Leu, respectively). Tandem mass spectrometry of the $(M+2H)^{2+}$ ion of substance P (1-9) yields the expected series of a_n/b_n product ions. MS/MS of the b_9^{2+} product ion of full substance P (only 16 Da difference from substance P (1-9) because of the missing terminal amide) produces a more abundant series of ions from loss of Phe, PhePhe, and PhePheGln. For the peptide [His^9]-substance P, MS/MS of the doubly-charged b_{10} and b_9 ions produced no evidence for "isomerization". However, dissociation of the b_8^{2+} product yielded ions

from loss of Gln, GlnGln, and GlnGlnPhe. One possible explanation is that following a dissociation event (occurring in the interface) that energizes the molecule, the gas-phase peptide isomerizes in which the COOH-terminus cyclizes towards residues 4 or 5. Isomerization is hindered by a positively-charged residue near the COOH-terminus (*e.g.*, [His^9]-substance P).

Conclusion. Sequence information for large polypeptides can be obtained by CAD/MS of multiply charged molecules, producing multiply charged product ions. Sequence information from product ion mass spectra can be more easily assigned by assignment of product ion charge states from data taken with higher resolution mass spectrometers. However, for certain peptides, gas-phase isomerization processes may contribute to CAD mass spectra, adding another degree of difficulty to the interpretation process. More work is needed to understand the energetics and structural constraints of dissociation events for large polypeptides.

THE MECHANISM OF FORMATION OF PEPTIDE d_n AND w_n IONS EVALUATED BY REACTION INTERMEDIATE SCANNING ON A BEqQ HYBRID

Kevin D. Ballard and Simon J. Gaskell
Center for Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030

Ions of the d_n and w_n types, *representing side-chain cleavages from peptide [M+H]+ ions* and observed during tandem MS under high energy CAD conditions, are useful for distinguishing isobaric amino acid residues such as leucine and isoleucine. The formation of these ions requires the cleavage of two covalent bonds. When the origins of these ions were first studied[1,2], it was suggested that d_n and w_n ions were formed via the sequential fragmentation of a_n+1 and z_n+1 product ions, respectively. Evidence for this was based upon the observation of d_n and w_n ions *during product ion scanning analyses of source-formed a_n+1 and z_n+1 ions, respectively.* Although those data provided good evidence for the proposed mechanisms, that approach did not directly address the events occurring in the ion beam of the mass spectrometer. Presumed source-formed product ions are not necessarily structurally identical to ions of the same mass formed under high energy CAD conditions in a collision cell. The previous studies also did not consider whether the two sequential fragmentations necessarily require consecutive collision events. These issues have *now been addressed using the sequential MS capabilities of a BEqQ hybrid mass spectrometer.*

Experimental. Tandem MS experiments with synthetic peptides were performed with a VG ZAB-SEQ hybrid instrument of BEqQ configuration. Reaction intermediate spectra were obtained by scanning B and E simultaneously (with B/E constant) over a narrow range encompassing the intermediates of interest formed in FFR1, with Q set to transmit the second generation product ion of interest formed in q.

Results. *Most of the d_n ions studied so far by reaction intermediate scanning are formed via the* intermediacy of the a_n+1 species, with the second decomposition occurring spontaneously. Thus, once the requisite a_n+1 ions are formed by high energy CAD, a proportion can spontaneously decompose to a d_n species. An exception is the d_3 ion from RKDVY, the reaction intermediate scan for which is shown in Figure 1; this signal aligned well with the *m/z*-deconvoluted B/E linked scan of the a_3 ion. Thus, this d_3 ion arises through the initial formation of the a_3 species. Interestingly, when the aspartic acid residue is replaced with glutamic acid, or if the aspartic acid is methylated, the d_3 ion is formed via the a_3+1 species.

All of the w_n ions studied thus far originate through z_n+1 ions, as determined by reaction intermediate scanning. In some cases, however, the signals representing the w_n ions in the reaction intermediate spectra are strong even in the absence of added collision gas. This indicates that, in some instances, w_n ions can be formed from FAB generated $[M+H]^+$ precursor ions without an absolute requirement for collisional activation. This is demonstrated in Figure 2, which depicts the sequential product ion spectrum (obtained without added collision gas) representing the $[M+H]^+ \longrightarrow z_6+1 \longrightarrow$ products reaction sequence for the peptide VHLTPVEK. Here, the w_6 ion and the z_5 ion are clearly detected. Ions of these types are generally not seen in product ion spectra obtained under low energy CAD or unimolecular decomposition conditions. Even with this peptide, the w_6 and z_5 ions are not evident in the low energy CAD conventional product ion spectrum. This is another instance where the higher-order mass spectrometric experiment reveals fragmentation processes not evident in the lower order experiment.

THE TANDEM MASS SPECTROMETRY OF HIGHLY BASIC PEPTIDES*

Jonathan M. Curtis[1], Pierre Thibault[1], Robert K. Boyd[1], Su Chen[2], Peter J. Derrick[2] and Bruce A. Thomson[3]. [1]*Institute for Marine Biosciences, National Research Council, Halifax, Canada B3H 3Z1;* [2]*Institute for Mass Spectrometry and Dept. of Chemistry, University of Warwick, Coventry CV4 7AL, UK;* [3]*SCIEX, 55 Glencameron Road, Thornhill, Ontario, Canada L3T 1P2.*

Determinations of peptide sequence by tandem mass spectrometry (MS/MS) [1] can be routine, but in some cases the method fails. A well known example concerns a round-robin organized by the ASMS [2], in which only one of about 35 participating groups reported any data for an "unknown" peptide stated to have molecular mass of about 1800 Da. An account [3] of the efforts of the (partially) successful group has been published. It turned out that the "unknown" peptide was dynorphin 1-17 (dynorphin A), YGGFLRRIRPKLKWDNQ. The most striking feature of this sequence is the large number of basic residues (3 Arg plus 2 Lys), all located within the central 8 residues. One purpose of the present work was to investigate whether the large number of basic residues was the explanation for the lack of success of a number of expert groups in sequencing this peptide by MS/MS. The original success [3] was achieved using SIMS of a dry sample on a nitrocellulose substrate, with MS/MS achieved by correlation of neutral and ionic fragments from metastable $(M+H)^+$ precursors in a reflecting TOF instrument. Since then two rival techniques have become more widely available. The first exploits high-energy (keV) CID of singly-protonated peptides $(M+H)^+$ produced by LSIMS, in four-sector instruments fitted with array detectors. The second approach exploits the ability of electrospray and ionspray ionization to produce multiply-protonated peptides, in which the Coulombic stress activates fragmentation of the ion, even under low-energy CID (tens of eV) conditions. The present work compared the sequence-specific fragmentations of a series of peptides (endorphins and dynorphins) containing large numbers of basic residues, using both high-energy CID of $(M+H)^+$ ions and low-energy CID of multiply-charged ions.

Figure 1 compares low-energy CID fragment spectra (SCIEX API III triple quadrupole with ionspray interface and a novel collision cell permitting better sensitivity and resolving power for fragment ions) of $(M+2H)^{2+}$ and $(M+3H)^{3+}$ ions from dynorphin 1-13 (YGGFLRRIRPKLK, M=1603.0), while Figure 2 shows the 4 keV fragment spectrum of $(M+H)^+$ (Kratos Concept II-HH EBEB, with scanning array detector). These spectra are representative of most of the peptides studied. The $(M+3H)^{3+}$ provided even less sequence information than the $(M+2H)^{2+}$, demonstrating that coulombic stress alone is not a sufficient condition for useful fragmentation at low energy; in addition it is necessary [4] for one of the ionizing protons to be mobilized along the peptide backbone to permit charge-site initiated reactions. The high-energy spectra (*e.g.* Fig.2) were invariably richer, with abundant sidechain cleavage ions characteristic of a localized ionizing proton promoting charge-site-remote reactions [5]. However, coherent fragment series permitting deduction of the complete sequence were not often observed for these highly basic peptides. In addition, observation of a peak at almost every mass can be a disadvantage, as such a spectrum can be interpreted as consistent with many candidate sequences.

In the case of dynorphin A itself (data not shown) the high-energy CID spectrum was of good signal/noise, with peaks covering the mass range. However, the intense peaks were scattered amongst all of the well-known fragment series [1], providing limited sequence information [2] (no extended coherent fragment series was obtained). When the threshold for peak acceptance was lowered, the "peak-at-every-mass" phenomenon began to be a problem. The low-energy CID spectra of $(M+2H)^{2+}$ and $(M+3H)^{3+}$ of dynorphin A were qualitatively similar to Figure 1, but contained more doubly-charged fragments.

It is emphasised that the problem addressed here is not an artificial one; the dynorphins and other endorphins are important bioactive peptides, which inherently contain large numbers of basic residues.

Capillary LC-Tandem Mass Spectrometry of Amadori Compounds

Terry Sumpter and Nancy J. Jensen
Research Center
Philip Morris USA
Richmond, VA 23261-6583

Introduction: Amino-carbonyl condensation reactions (Maillard reaction) and the subsequent slow Amadori rearrangement of the Schiff-base (aldimine) intermediate to give various ketoamine products provide a starting point for pathways leading to a multitude of flavor and aroma agents. There are typically many simultaneous reactions occurring in these processes, generating many components possessing a wide range of molecular weights, volatilities, and thermal stabilities. In addition, the non-enzymatic glycation of proteins has been observed in several cases *in vivo*. This work uses model compounds to demonstrate the application of a variety of MS and tandem MS methods to the characterization of individual components and classes of compounds produced by these reactions.

Experimental: Mass spectra were acquired using a JEOL SX102/SX102 four sector (BEBE) tandem mass spectrometer. Accelerating potential was 10 kV, resolving power was *ca.* 1000, and Xe at 6 kV was used for FAB ionization. Constant neutral loss spectra were acquired by collision of the precursor ions using He (80% precursor ion beam reduction) in the first field free region after the ion source in MS I. Detection of those product ions resulting from the specified neutral loss from the precursor was by the appropriate linked scan function using MS I. For this direct probe work, tetramethylene sulfone was the FAB matrix. For LC-CI experiments, the frit interface was equipped with a CI chamber attachment and an electron energy of 200 eV at an emission current of 300 μA was used. The source temperature was *ca.* 175 °C. For LC-EI experiments, ionization was by EI at 70 eV, 300 μA emission, and the source temperature was *ca.* 175 °C. Capillary HPLC separation of components was accomplished using a Waters 600-MS pump with a precolumn solvent split to reduce the flow into the MS to *ca.* 4-5 μL/min. An LC Packings 0.32 x 150 cm C_{18} column was used, and the mobile phase was 100% A (water, 1% glycerol, 0.1% TFA) to 100% B (MeCN, 1% glycerol, 0.1% TFA) in 20 min for peptide studies. For LC-CI and LC-EI, the mobile phase was 90% MeCN/10% water, with the same column as was used for the peptide studies. MS/MS experiments were accomplished by selecting the precursor ion with MS I, and colliding the mass selected ion in the interface between MS I and MS II. Helium was the collision gas, at a pressure sufficient to reduce the parent ion beam by *ca.* 80%. Detection of the resulting fragment ions was by a B/E scan using MS II. .

Results: The purpose of this study was to combine the separation capability of HPLC, which avoids potential thermal degradation, with the specific structural characterization capability of mass spectrometry to characterize a wide range of compounds. To this end we have applied LC-EI and LC-CI to the analysis of small, volatile model compounds, namely, a series of substituted 1,4-pyrazines. Figure 1 shows a typical LC-EI spectrum obtained, in this case for 10 ng of 2-isopropyl-1,4-pyrazine. This spectrum is dominated by a large $[M + H]^+$ ion, with little fragmentation observed. In most applications of this LC-EI technique, a combination of EI and CI processes is observed. The preponderance

of the CI process for these compounds is due in part to the proton affinity of the pyrazines. In addition, it may be that the large proportion of MeCN used in the mobile phase suppresses radical cation formation by acting as a free radical "scavenger". The LC-CI spectrum of the same compound shows a large $[M + H]^+$ ion as well, though there is a larger chemical background associated with the LC-CI technique under these conditions.

It is also useful to be able to screen for classes of compounds in these reaction mixtures. The amino sugars are characterized by a loss of 17 u upon CID. This permits the use of constant neutral loss (CNL) linked scanning to identify this class of compounds. A CNL spectrum for loss of 17 u by L-rhamnosylamine is shown in Figure 2. This specificity of analysis should provide for functional group identification of components in mixtures.

The non-enzymatic glycation of proteins was investigated using a model system reportedly leading to the dihydroxypropylation of lysine residues and the amino terminus. The use of four-sector MS/MS with rapid linked scans (0-2400 u/5 s) and sequential precursor ion selection has been successfully applied to the model protein, cytochrome c (Figure 3) at the 30 pmol level. However, the expected adducts have not been observed with the treated system. It appears that the adducts are not being formed. Further work in this area is planned.

Diastereomeric Selectivity Using Metal Complexes: A MIKES Study

Thuy Thanh Dang and Julie A. Leary
Department of Chemistry, University of California, Berkeley, CA 94720

Chirality is an important determinant of molecular recognition in biochemical systems.[1] While one enantiomer of a molecule shows biological activity, the other enantiomer may show little or no activity. In addition, it is known that in pharmaceutical drugs, the non-desired enantiomer can cause side effects.[2] The increasing need for optically pure compounds has made their synthesis an important focus of current research in both academic and industrial laboratories. New chromatographic techniques, such as enzymatic columns and gas chromatography using a chiral stationary phase, are able to separate enantiomic pairs.[3] However, there have been only a few techniques using mass spectrometry to analyze chiral isomers.[4] We have developed a new technique utilizing fast atom bombardment mass spectrometry (FAB-MS) in combination with MS/MS and kinetic energy release (KER) measurements to distinguish enantiomeric diols.[5]

In this study we have combined various optically pure diols with R,R and/or S,S, threohydrobenzoin (THB) with a racemic mixture of cobalt trisacetylacetonate ($Co(acac)_3$). The complexes formed were analyzed by FABMS and subsequently selected ions were chosen for Mass-Analyzed Ion Kinetic-Enery Spectroscopy (MIKES) study. These experiments were also performed using Mg $(acac)_2$, $Zn(acac)_2$, and $Ca(acac)_2$ to determine whether there were differences in the degree of chiral recognition when the complex studied had either octahedral or tetrahedral geometry.

Table 1 shows the KER values measured for the product ion *m/z* 393 of the $[Co(acac)_2DIPT]^+$ system.[6] The KER values indicate that when the diastereomers $[Co(acac)_2/L\text{-}DIPT]^+$ and $[Co(acac)_2/D\text{-}DIPT]^+$ are formed in the presence of RR- or SS- THB, a chemical kinetic resolution[7,8] effect takes place. This effect occurs when one enantiomer of $Co(acac)_2$ is preferentially coordinated to the DIPT. The KER values of the diastereomic pairs D-DIPT/RR-THB and L-DIPT/SS-THB are the same upon the production of *m/z* 393. In contrast, the KER values for the L- and D- DIPT without of THB are identical, indicating no difference in their structures.

The same chemical kinetic resolution effect is also observed for the $[Mg(acac)_2DET+H]^+$ system.[6] The KER values are reported in Table 2. Both the $[Co(acac)_2DIPT]^+$ and $[Mg(acac)_2DET+H]^+$ complexes have octahedral geometry and clearly show the same trends as discussed above.

The MIKES study was also performed on $[Co(acac)DIPT]^+$. No chemical kinetic resolution effect is observed in the presence of THB. The KER values are reported in Table 3. The geometry of the $[Co(acac)DIPT]^+$ complex is tetrahedral.

Using MIKES in conjunction with KER, we established that chiral recognition of metal coordinated diol complexes requires all of the following conditions: 1) A chiral auxilary agent, threohydrobenzoin (THB) must be present in order to help coordinate the diol to the metal bisacetylacetonate complex. THB acts as a kinetic resolution agent and aids in the enantioselectivity of either D and L forms of the tartrates. 2) The geometry of the metal coordinated complex must be octahedral.

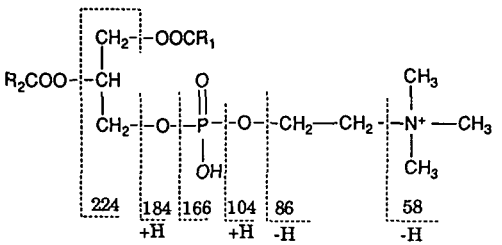
Characterization of Lipids in Marine oils by LSI/MS/MS

*Feng-Yin Hsieh[1], Brian J. Nobes[1], Harry L. Greene[4], and Ian A. Blair[1,2,3].
Departments of Pharmacology[1] and Chemistry[2] and Clinical Nutrition Research Unit[3],
Vanderbilt University, Nashville, TN 37232 and
Mead Johnson Nutrition Group[4], Mead Johnson Research Center, Evansville, IN 47721.

The separation, identification and determination of phospholipids (PLs) in marine oils were based on Solid-Phase Extraction (SPE), HPLC, and Liquid Secondary Ion(LSI) mass spectrometry. SPE using aminopropyl bonded cartridge provided a rapid extraction method and high recovery of PLs. The marine oils contained only trace amounts of PLs and so it was necessary to extract up to 100 mg of the oil. By using a series of columns it was possible to isolate sufficient material for identification of individual PLs. HPLC was carried out using a gradient of hexane/iso-propanol/water in combination with a normal phase silica column. LSI/MS/MS of the purified PLs was carried out on a Kratos Concept IIHH tandem mass spectrometer operating in the positive and negative ion modes. Confirmation of PL class and the molecular weights of individual PLs was carried out by positive and negative LSI MS. The total fatty acid composition of the PLs and the fatty acids attached to individual PLs were identified by negative LSI MS and LSI/MS/MS, respectively. Three major docosahexaenoic acid (DHA) containing phosphatidylcholines (PCs) ($[MH]^+$ *m/z* 879, 833, 807) were identified. In addition, a mixture of structurally similar new glycerolipids was isolated from the PC region during HPLC purification. The mass spectra of the PC mixture and the mixture of new glycerolipids each contained intense ions at *m/z* 58, 86, and 104 indicating the presence of choline. Structures of the PCs, together with assignment of the fragment ions are shown in Figure 1.



phosphatidylcholine

	MW	R_1/R_2
M_1	878	22:6ω3/22:6ω3(DHA)
M_2	832	18:1/22:6ω3(DHA)
M_3	806	16:0/22:6ω3(DHA)

Figure 1: Fragment ions observed in the positive LSI mass spectrum of PCs from marine oil.

The positive LSI mass spectrum of the mixture of new glycerolipids (Figure 2) lacked ions at *m/z* 166, 184 and 224 observed with PC, but contained ions at *m/z* 132, 178 and 218. The ions at *m/z* 178 and 218 were six daltons lower than expected for a PC. The $[M+H]^+$ ions were also six daltons lower than expected for PCs. The negative LSI spectra lacked ions at *m/z* 79 (PO_3^-) and 97 ($H_2PO_4^-$), but an ion appeared at *m/z* 73. These data indicated that the compounds lacked a phosphate group but contained a choline moiety. LSI/MS/MS analysis suggested that the three new choline-containing glycerolipids ($[MH]^+$ 873, 801, 773) all contained DHA. After methylation of the glycerolipids with diazomethane, the positive LSI spectrum contained $[M+CH_3]^+$ ions and an ion at *m/z* 232 instead of at *m/z* 218. Ions

at *m/z* 58, 86, and 104 were unaffected by methylation. This suggested that there was carboxylic acid group between the choline group and glycerol backbone. The presence of a carboxylic acid group was further established by a deuterium exchange experiment using D_8-glycerol/D_6-dimethylsulfoxide as the LSI matrix. $[M+D]^+$ ions and an ion at *m/z* 219 replaced the $[M+H]^+$ and *m/z* 218 ions in the positive LSI spectrum. These data suggested that the choline-containing glycerolipids contained a [OCHO-COOH] group instead of the phosphate residue found in PCs.

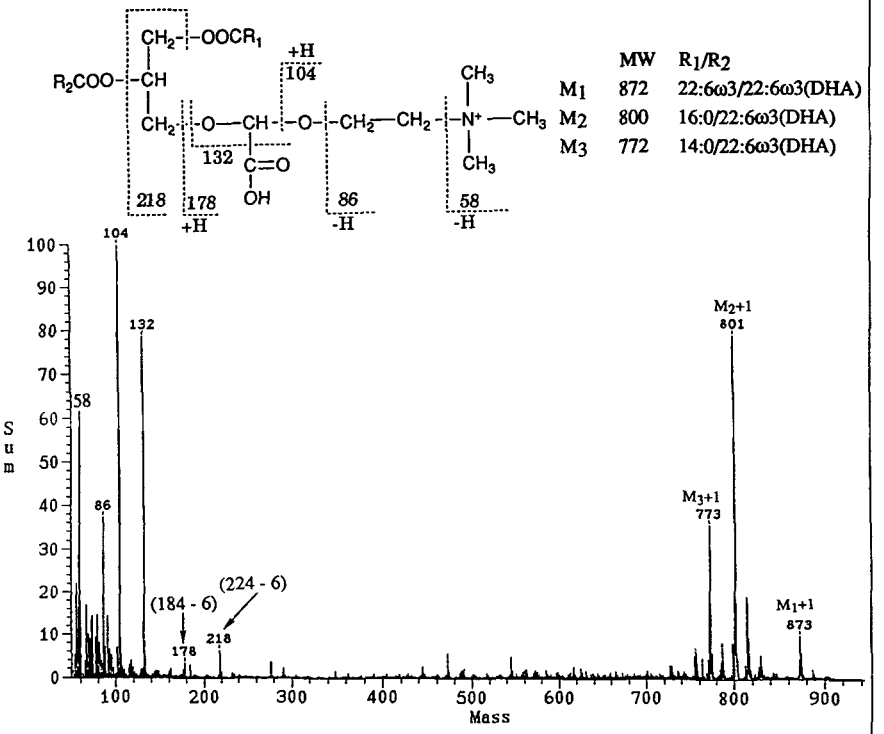


Figure 2: Positive LSI mass spectrum of choline-containing glycerolipids from marine oil.

In summary, LSI/MS and LSI MS/MS were useful for characterizing individual lipid classes in marine oils and for providing fatty acid composition of the lipids. During the course of these studies a new group of glycerolipids was identified that contained glyoxylic acid acetal in place of the phosphate normally found in PCs.

A Kinetic Treatment of Resonant Excitation in the Ion Trap Mass Spectrometer

A M Franklin†, J F J Todd† and R E March‡.
†Chemical Laboratory, University of Kent, Canterbury, UK, CT2 7NH. ‡Department of Chemistry, Trent University, Peterborough, Ont., Canada. KJ9 7B8.

Collisional excitation of mass-selected ions in the ion trap may be brought about by applying a supplementary RF 'tickle' field to the endcap electrodes. Computer simulations of the ion motion during tickling revealed that, in the absence of buffer gas collisions and for constant operating conditions, the product of [tickle time]x[tickle amplitude] needed for ions to acquire trajectories which exceed the boundaries of the trap was a constant for ions of different starting conditions. This product has been termed the 'fluence', and the reciprocal the 'absorbance'[1]. An ion with a large absorbance readily absorbs energy and rapidly leaves the trap; comparison of the three tickle modes showed that the absorbance for dipolar:monopolar:quadrupolar excitation are approximately 4:2:1.

Experimentally it is found that during tickling the rate of decrease in parent ion intensity with tickle time for constant tickle voltage is exponential, and from measuring the rate of decay at different tickle voltages, a value for the absorbance may be obtained; this has led us to develop a 'kinetic' model in order quantify the tickling process. In practice, of course, an optimised pressure of a buffer gas such as helium is present in the trap to enhance performance, and tickling of the ions may then induce them to undergo collisional dissociation so that the decrease in precursor ion signal may reflect both the loss of ions from the trap and the formation of product ions. Initial accounts of the model [2,3] were restricted to treatment of the rate of loss of the precursor ion; this presentation examines the intensities of both precursor and product ions during tickling.

The process of resonant excitation may be represented in the following manner. Ions are created internally, or externally, some are lost but those captured by the RF drive potential undergo collisions with the helium buffer gas atoms which will remove some of the ions' energy and the cooled ions migrate towards the centre of the trap. Upon tickling these ions, those in resonance with the tickle frequency are drawn from the centre of the trap. The amplitude of the tickle voltage is generally <1eV yet the collision activation requires ~3-4eV therefore this process must derive kinetic energy from the drive potential. While the ion is tickled it may either collide with a helium atom, lose energy and migrate to the centre or be energised by the RF drive potential, become internally excited and possibly fragment through a high energy collision with an atom.

This scenario gives rise to the idea of 'mean free time' which is the time within which the ion can move to a position in phase space where it gains energy from the drive field before it experiences a low energy collision returning the ion to the centre. The fact that as the helium pressure is increased the tickle amplitude at which CID occurs must also be increased supports this idea. At high tickle voltages the ion may be accelerated out of the trap before CID can occur. This suggests that for high energy CID collisions to occur it may be necessary for there to be a collision in order to arrest the ion before it is ejected from the trap. In practice tickle times of several milliseconds are required to achieve a reasonable degree of fragmentation and so it is probable the ions are 'simmered' involving many cycles of collisions. Ion loss may occur at low tickle voltages after a collision as the ion may not be at a favourable coordinate lying within the phase space ellipse corresponding to that relevent phase angle of the drive potential.

The experiments were carried out with an ITMS™ at *ca* 10^{-4} Torr of helium buffer gas. The scan function comprised an ionisation step (5ms); DC isolation of the parent ion; a tickle step during which the parent ion is held at q_z=0.45, a_z=0 or q_z=0.25, a_z=0 and tickled by dipolar excitation; finally a data acquisition step. Sample was introduced via a calibration gas valve and bled into the trap at a constant pressure of *ca* 10^{-6} Torr. Samples used were **o-dichlorobenzene** and *n*-butylbenzene with parent ions *m/z* 146 and *m/z* 134 respectively. Dynamically programmed scanning was utilised to tickle the parent ions from 0 to 10 ms in 0.05ms steps at a range of tickle voltages. The resulting data were converted to text files by a DWRITE© program and these files converted by a simple BASIC program into a format which could be read by a graph plotting program AXUM© V2.0.

Plots of $-\ln(X_t/X_o)$ *versus* t were obtained for a range of tickle voltages (V_t) and for each sample. At low tickle times there is a flat portion, the length of which becomes shorter as the value of the tickle voltage is increased. This induction period is followed by two approximately linear portions after which the curve begins to flaten out at long tickle times. From these plots the first linear portions are utilised and the gradients k_1 are recorded. The slopes of the plots of k_1 *versus* V_t have the units of absorbance, and are equal to 2.101 and 10.647 $(V\ ms)^{-1}$ for *o*-dichlorobenzene and *n*-butylbenzene respectively at q_z = 0.45. A parallel first order reaction method was used so the rate of product ion formation could be characterised. This leads to values of the absorbance (and fluence) for both the disappearance of the precursor ion and the formation of product ions.

From this study we conclude that the curves representing the loss of parent and the formation of daughter ions seem to obey the first order kinetic theory enabling the calculation of absorbances and fluences for the respective ions of *o*-dichlorobenzene and *n*-butylbenzene. Comparison of the absorbances of *m/z* 134 and *m/z* 146 from *n*-butylbenzene and *o*-dichlorobenzene respectively for both q_z values shows that *m/z* 134 has a higher absorbance which is possibly due to weaker bond strengths compared with that of the *m/z* 146 ion. The absorbance of *m/z* 134 from *n*-butylbenzene at q_z = 0.45 is lower than that at q_z = 0.25, this could be due to more ions being lost at the lower q_z value as the Dehmelt's pseudo-potential well depth is shallower at low q_z values. From the calculation of the absorbances of the parent and daughter ions of *o*-dichlorobenzene at q_z = 0.45, 46% of the absorbtion of *m/z* 146 is responsible for the formation *m/z* 111, 8% for the formation of *m/z* 75 and 4% for the formation of *m/z* 74, 43% is responsible for ion loss.

ACKNOWLEDGEMENT

A M Franklin wishes to thank the British Mass Spectrometry Society for the John Beynon Studentship Award.

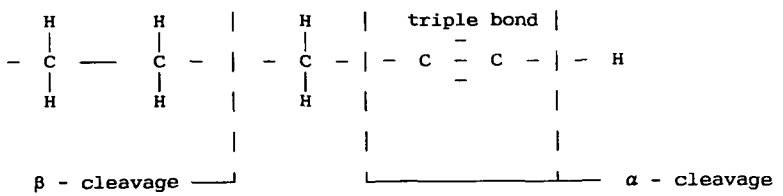
Mass Spectral Fragmentation of 1,9-Decadiyne, and 1,2,9,10-^{13}C-1,9-Decadiyne

* Ronny C. Robbins, James Jensen
U.S. Army
Aberdeen Proving Ground
Edgewood Area
APG, MD 21010-5423

The peculiarities of 70 eV mass spectra with Dempster mass spectrometers of alpha-omega diynes were previously noted in a program to obtain reference mass spectra for exhaust gas component identifications by the United states Bureau of Mines, Bartlesville, Oklahoma.[1] The 70 eV mass spectra of 1,6-heptadiyne (Mol. Wt. 92), 1,7-octadiyne (Mol. Wt. 106), and 1,8-nonadiyne (Mol. Wt. 120) contain an intense peak at m/Z 91 and a weak peak at m/Z 45.5 which suggests the presence of tropylium ions. A tropylium ion has a single ring and a composition of $[C_7H_7]^+$. The mass spectrum of 1,9-decadiyne (Mol. Wt. 134) contains an intense peak at m/Z 91, but no peak at m/Z 45.5 suggesting that the m/Z 91 ions in its spectrum may not be tropylium ions.

From classical fragmentation pathways of hydrocarbons that contain a terminal triple bond, one might expect that the main fragmentation process is cleavage beta to the triple bonds.



Previous work with carbon-13 labeling strongly indicate that the 1,8-nonadiyne molecule curls into a "U-shaped" configuration and that two carbon atoms are lost from the center of the ring structure.[2] This linear chain curling takes time. Tropylium ions may appear in the spectrum of 1,9-decadiyne if more time is allowed between ionization and detection. Much longer residence times for ions can be obtained in "ion trap" type mass spectrometers.

1,9-Decadiyne was labeled with carbon-13 in the 1,2,9,10-positions and analyzed in a Finnigan ITMS system at 70 eV. The comparison of the labeled versus unlabeled spectra shown in figures 1 and 2, indicate that the tropylium ion was formed from the terminal carbon atoms.

Unimolecular Kinetics of Neutrals and Ions

*David W. Kuhns and Frantisek Turecek, Department of Chemistry,
BG-10, University of Washington, Seattle, WA 98195

A new technique is described to measure the rate constants of ion and neutral dissociations in the 10^4 - 10^7 s^{-1} range. The neutral species is prepared by charge exchange from a precursor ion transmitted through MS-I of the tandem quadrupole acceleration-deceleration (QADQ) mass spectrometer and accelerated to 8 kV. The neutrals are allowed to drift through an ion conduit maintained at a variable potential. Oxygen is leaked into the conduit region as a reionization gas and cuts the beam to 70%. Reionization of the neutral within the conduit electric field produces the corresponding ion whose total energy depends on the neutral kinetic energy and the conduit electrostatic potential. The conduit is segmented to allow a combination of four potential settings (Figure 1). This allows one to change simultaneously the drift time for the neutral species while extending that for the ions (and vice versa) by applying positive and negative potentials on different segments of the conduit.

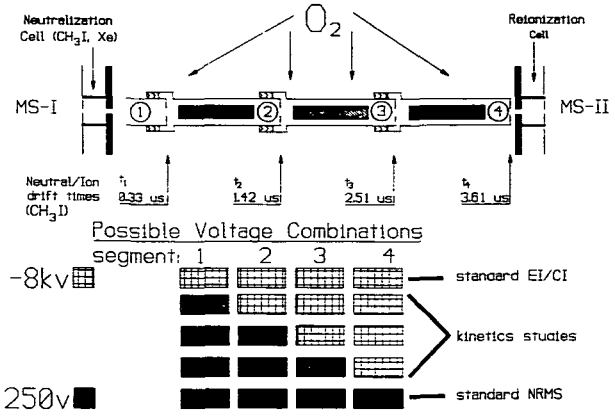

Figure 1

Only ions of a preselected total kinetic energy and mass are transmitted through MS-2 and detected. Therefore neutrals ionized in a 250 volt region will retain their high (keV) kinetic energy and be energy filtered by a chicane lens. Only stable neutrals and their fragments that pass the 250 volt region will be seen because they will be reionized in the -8kV region with the proper energy and not be energy filtered. Increasing the length of the 250V region (setting 1-4) increases the neutral lifetime and decreases the ion lifetime. By monitoring the ratio of the precursor to the daughter fragment we can observe the amount of dissociation as conduit settings are changed. A stable neutral will show little change in $[AB^+]/[A^+]$ even as the neutral lifetime is extended, as long as after reionization the ion fragmentation is not extensive. If the neutral has a rate of dissociation within experimental parameters then as the drift time is increased the

$[AB^+]/[A^+]$ ratio should decrease corresponding to the rate. However this ratio will also depend on the ion rate of dissociation upon reionization. The neutral rate (k_n) and the ion rate (k_i) constants are therefore convoluted. However, the ratios are measured at four conduit settings, thus the system is overdetermined, and the constants can be deconvoluted. The products AB^+, A^+ and B^+ can be formed by the pathways shown in (Figure 2). Equations 1 and 2 describe the dependence of AB^+ and A^+ on time and the rate constants. The velocity (v_{AB}) and the number density of the reionization gas (N) will cancel upon taking the ratio of $[AB^+]/[A^+]$.

$$\overline{AB^+} = \frac{1}{(t_2-t_1)\,k_n} AB_o S_{AB} N v_{AB} \int_{t_1}^{t_2} \left[e^{(-k_n t_1)} - e^{(k_n t)}\right] e^{(-k_i(t_2-t))}\,dt \qquad (1)$$

$$\overline{A^+} = \frac{1}{(t_2-t_1)\,k_n} AB_o S_{AB} N v_{AB} \int_{t_1}^{t_2} \left[e^{(-k_n t_1)} - e^{(k_n t)}\right] e^{(-k_i(t_2-t))} \left[1-e^{-k_i(t_2-t)}\right] + S_A(t_2-t)\,(1-e^{-k_n t})\,dt \qquad (2)$$

Comparing the experimental ratios with the theoretical ratios calculated at each conduit drift time while inputing a matrix of k_n vs k_i produces a plot of the residuals of the model (Figure 3).The minimum gives the best fit for the experimental data.

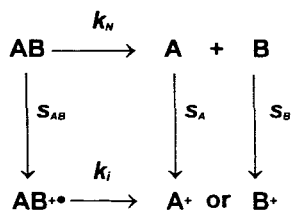

Figure 2

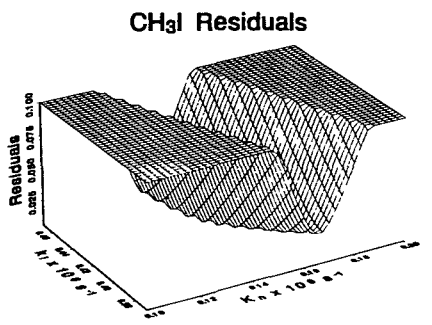

Figure 3

Initially the simple system of $CH_3I^{+\bullet}$ to I^+ and CH_3 was tested with different neutralization gases. Neutralization of $CH_3I^{+\bullet}$ with CH_3I leads to k_n = 1.33 x 10^5 s^{-1} and k_i = 3.70 x 10^5 s^{-1} corresponding to neutral and ion effective temperatures of 2111 K and 3130 K, respectively. Neutralization with Xe gave higher rates of k_n = 3.69 x 10^5 s^{-1} and k_i = 6.09 x 10^5 s^{-1} corresponding to higher temperatures of 2283 K and 3260 K, respectively.

A Comparative study of MS-MS data produced by tandem magnetic and hybrid MS-MS instruments and the implications of the conclusions on the design of a hybrid magnetic sector-orthogonal acceleration time-of-flight MS-MS instrument.

R H Bateman, R S Bordoli and C Braybrook, VG Analytical, Manchester, UK.,
E Clayton, Zeneca Pharmaceuticals, Alderley Park, Macclesfield, Cheshire, UK.

Molecular structure determinations by MS-MS require full product ion spectrum with highest achievable sensitivity over the whole spectrum, unit mass product ion resolution, reliable nominal mass assignments and acquisitions within chromatography time scales.

Gas phase ion-molecule collisions with high "centre of mass" collision energy have been the most commonly used and generally most successful method for generating structurally informative decomposition products. To generate "d" fragment ions in peptides a minimum value of E_{com} of 15 ~ 20 eV is required (Ref 1,2). Figure 1 shows the normalised average d_n/a_n ratios for n = 5,10,11 and 12 as a function of E_{com} for the product ion spectra of Renin Substrate acquired on a VG Analytical AutoSpec-T tandem system. This relationship holds irrespective of target gas mass or laboratory collision energy. It also holds for so called "low energy" quadrupole type collisions cells. Figure 2 shows the presence of the "d" fragment ions in the product ion spectrum of Renin Substrate acquired on a VG Analytical AutoSpec-Q hybrid system at 500 eV collision energy using Xenon as the target gas, for which E_{com} = 35 eV. At a laboratory collision energy of 800 eV when using Xenon collision gas, E_{com} is greater than 25 eV for precursor ions up to mass 4000 Da.

In time-of-flight (TOF) mass spectrometers, unlike scanning instruments, all ions are transmitted to the detector. This offers the potential for fast, high sensitivity full spectra acquisitions thereby meeting several of the requirements for MS-II in MS-MS instrumentation. Conventionally the ion source needs to be pulsed, and resulting ions should not have excessive spatial, energy and temporal spread, a combination which TOF instruments cannot accommodate without severe limitations in resolution. However, the product ions have a relatively large energy spread in the direction of travel, and large spatial and temporal spread owing to the uncertainty as to where and when within the gas cell each decomposition takes place. An alternative approach is to use an orthogonal acceleration(OA) TOF mass analyser (Ref 3). Ions selected by a magnetic sector mass analyser may be decelerated to 800 eV (or less) energy before passing through a gas collision cell. The precursor and product ions would then pass into the orthogonal acceleration chamber of the TOF analyser. The ion source is in the form of an ion beam with spatial and energy spread orthogonal to the direction of travel, and which may be accomodated by the OA-TOF arrangement. The equal velocities of precursor and product ions leaving the gas cell results in equal sampling efficiences for all masses. The OA-TOF mass analyser allows operation with continuous (and pulsed) ion beams and in combination with a sector instrument appears to meet the requirements for MS-MS instrumentation listed above.

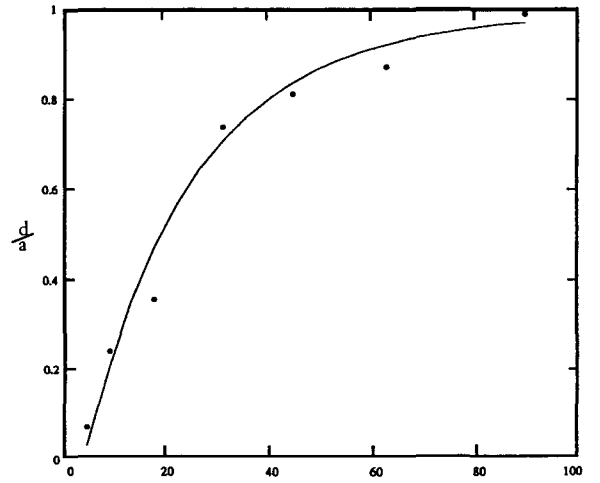
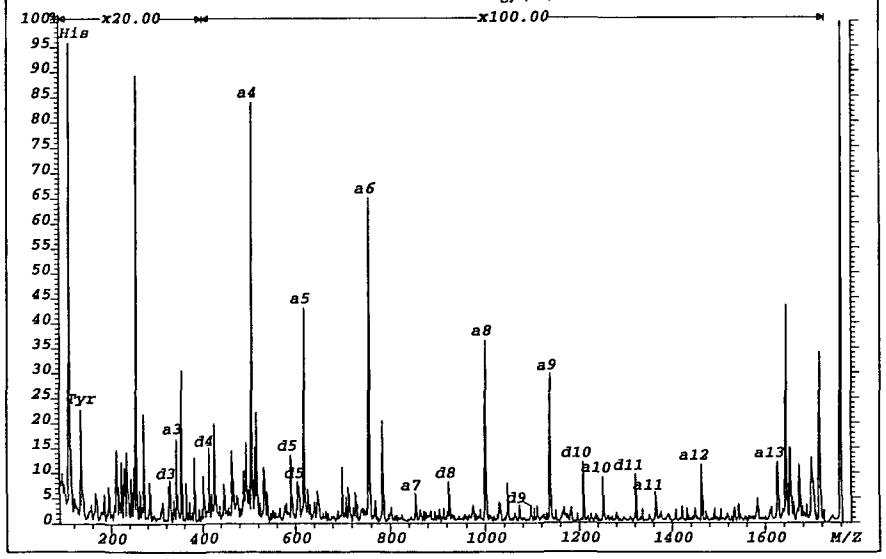
Average normalised d/a ratios for d5, d10, d11 and d12 from Renin Substrate





A HYBRID TANDEM MASS SPECTROMETER.

A Duhr, R. Guckert and H. Wollnik
2. Physikalisches Institut der Justus–Liebig–Universität, 6300 Gießen, Germany.

A new hybrid tandem mass spectrometer (Tandem–MS) has been build for the study of molecular fragmentation reactions. The first stage of the Tandem–MS is a reversed–geometry sector field type. The second stage is a Time–of–flight(TOF) Instrument that allows simultaneous detection of the fragment ions. Special emphasis was laid on optimizing the interface between the two different mass spectrometers. The collision cell was build by using a microchannel plate as collision target in order to obtain high fragmentation efficiency and high ion transmission [1, 2, 3, 4].

The purpose of the interface is to cut the continuous ion beam that leaves the first stage MS into discrete bundles or bunches. These bundles can then be mass analyzed in the time of flight MS. TOF start pulse was generated by the ions impinging on the collision microchannel plate. The spectrum is aquired by measuring the time difference between the start pulse and a stop signal generated by a second detector at the end of a drift tube (see Fig. 1).

For the detection of the secondary electrons that are emitted from the surface while primary ions transfer some energy two different setups are tested. In one setup crossed electric and magnetic fields of variable strength in front of the channel plate guide the electrons to a detector. The flight time is numerically optimized to be 10± 2 ns for electrons emerging from the channels with angels of ± 20°normal to the microchannel plate and with an energy range of 1 to 100 eV relativ to the surface of the microchannel plate.

Only electric fields are used to direct the electrons to the detector in another setup tested for the purpose as interface. This setup uses no magnets or coils together with the advantage of better vacuum characteristics. The electron flight time variation however was calculated to be slightly larger.

First results were obtained by using the pyrene mother ion ($C_{16}H_{10}$, 202 u) as precursor. Extensive fragmentation is shown with fragmentation efficiencies in the order of 75 %. Charge transfer is also obvious in the presence of a double charged mother ion at mass 101. At masses smaller than about 60 the spectrum is overlapped with SIMS products that are desorbed from surfaces and grids in the collision cell.

Although the protocol for tandem mass spectrometry in the quadrupole ion trap is well established, the versatility of the technique is still limited in some instances The parent ion isolation portion of an MS/MS experiment has typically been post ionization or ion injection. As the ion number density in the trap changes, the optimum frequency for fragmentation also changes. Tuning of excitation frequencies is, therefore, always required. Furthermore, for MS^n the tuning difficulties are even greater. Using the filtered noise fields method of Kelley [1] allows analyte ions to be selectively stored during formation or injection The stored ions can then be fragmented by the application of an FNF which is constructed with a finite bandwidth to account for the changes in secular frequency due to the formation of product ions. For MS^n FNFs can be used to simultaneously fragment the parent ion, trap and fragment the product ion(s). This paper describes the use of FNF during the ion injection period to isolate ions of interest formed in an atmospheric sampling glow discharge ionization source. The mass selective ion accumulation step is followed by the application of subsequent FNF to induce fragmentation in targeted ions The MS/MS experiment can also be simplified by combining ion accumulation, isolation and fragmentation using a single FNF.

A Finnigan ITMS modified to include an Atmospheric Sampling Glow Discharge Ionization Source (ASGDI) was used for all experiments and is described elsewhere [2]. FNF capability was added to the system using a TELEDYNE/HITACHI HST-1000 Enhancement Kit. A diagram of the system is shown in Figure 1 The ion trap was operated in negative ion mode for all experiments The scan function used for these experiments is shown in Figure 2 In all experiments, an isolation FNF is applied during the ion injection gate to accumulate only ions of interest Unwanted ions are expelled by the FNF Tickle frequencies can be applied by the ITMS or Tickle frequencies or frequency bands can be applied using FNF. In the case of MS/MS the Fragmentation FNF need have only one band. For MS/MS/MS two bands are used, one for the fragmentation of the precursor ion, another to fragment a product ion. The resulting product ion(s) are then scanned out and detected.

Figure 3 shows the MS/MS of DNT using FNF for both selective ion accumulation and fragmentation. An advantage of using FNF to provide fragmentation frequencies is that the FNF can provide multiple frequencies or frequency bands to allow simplified MS/MS without the need for careful tuning for each experiment. In MS/MS/MS and higher orders of MS^n the problems of tuning and frequency selection are further magnified. FNF can easily be used for any number of steps of isolation and fragmentation. There are several methods of using FNF for MS^n, one is to use subsequent FNF to sequentially isolate, fragment, isolate, fragment, etc. Another method is to combine fragmentation steps into a single FNF. This is demonstrated in Figures 4 and 5. In Figure 4, the m/z 123 (loss of C_2H_5) anion of diethyl methylphosphonate (DEMP) is selectively accumulated using an FNF then fragmented to m/z 95 which is then fragmented to m/z 79 using the same FNF.

The use of FNF for both selective ion storage and fragmentation yields multiple benefits over earlier techniques. The combination of ion storage/accumulation and ion isolation yields much higher sensitivities for ions of interest Unwanted ions are expelled from the trap and the space charge capacity of the ion trap can be used for ions of interest FNF can be used to provide frequency bands to allow fragmentation of selected ions without the need for careful tuning. FNF offer great flexibility in designing experiments as they can easily be used, as in these experiments, to combine steps, but also can be used to sequentially isolate and fragment ions Since all of these experiments were competed without using DC operation, MS^n can now be a reality on rf only instruments. FNF provide a new flexible tool to greatly extend the use of the ion trap for enhanced and simplified MS^n.

GAS CHROMATOGRAPHY-TANDEM MASS SPECTROMETRY IMPLEMENTED ON A BENCH-TOP QUADRUPOLE ION TRAP-BASED INSTRUMENT USING RANDOM NOISE TO EFFECT COLLISION-INDUCED DISSOCIATION

Gary J. Van Berkel and Douglas E. Goeringer
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

A next logical step in the advancement of quadrupole ion traps as detectors for gas chromatography (GC) is implementation of routine methods for inducing fragmentation so as to perform MS/MS analyses. The protocol for MS/MS in the ion trap mass spectrometer (ITMS™) is well-established with collision-induced dissociation (CID) being the general method of choice for effecting fragmentation. CID is typically accomplished by resonance excitation of ion secular motion; as the amplitude of oscillations grows, ion-bath gas collisions become more energetic causing a gradual increase in ion internal energy which ultimately results in fragmentation. Resonance excitation is commonly performed via application of an auxiliary, single-frequency signal to the endcap electrodes. Although the same method for CID could be incorporated into commercial bench-top quadrupole ion trap instruments, several factors limit its practical utility. Recently, our group[1] demonstrated that random noise, tailored via amplitude and bandwidth adjustment and applied to the endcaps of an ITMS, is an effective means for inducing CID of trapped ions. We have now adapted the technique on a commercially available, bench-top quadrupole ion trap to implement GC-MS/MS. This new CID methodology provides an instrumentally simple means to overcome the need for frequency tuning, space-charge related frequency shifts, limited fragmentation, and the inability to fragment ions of unknown mass/charge that are inherent in the single-frequency CID method.

The Finnigan-MAT ITS40 quadrupole ion trap mass spectrometer equipped with a Varian Model 3400 GC was used in these experiments. A broadband noise generator (NoiseCom Model NC6103) with a flat power spectrum from 10 Hz - 500 kHz served as the random noise signal source. The scan function used for CI-MS/MS was the nominal CI-MS function provided with the instrument, but used without the ARC feature. The random noise signal, triggered from the electron gate pulse, was applied to one endcap during the final 10-20 ms of the CI portion of the scan function. The standard axial modulation signal was applied to the other endcap.

The particular scenario used here to demonstrate the application of random noise CID in bench-top GC-MS/MS involves the analysis of amphetamines. Amphetamines as a compound class, when ionized by EI, tend to fragment extensively such that no molecular species is readily discernable. In such cases, CI is often used to form a molecular species so as to determine molecular weight. However, little structural information is available from CI due to limited fragmentation, or from EI fragment ions since only low mass/charge species are generally observed. A more direct method for obtaining useful structural information is to acquire a random noise MS/MS spectrum of the protonated molecule.

1. McLuckey, S.A., Goeringer, D E.; Glish, G.L. *Anal. Chem.*, **1992**, *64*, 1455-1460.

A major advantage of random noise CID over single-frequency CID is the capability for acquisition of MS/MS spectra of each component in a separated mixture without the need for parameter tuning for each individual component. This is demonstrated in Fig. 1 which shows the extracted ion current profiles (a-c) and random noise CI-MS/MS spectra acquired during an on-line separation of methamphetamine (d, 100 pg) and amphetamine (e, 200 pg). Although no frequency tuning was necessary in this experiment, the noise power spectrum was adjusted with a low-pass filter (20 dB/decade roll-off above 30 kHz) to avoid excessive fragmentation and potential ejection for low *m/z* ions. Note that the two compounds yielded the same major CID product ions at *m/z* 119 and *m/z* 91. The MS/MS spectra are much more informative than the CI mass spectra (not shown), which contain only very low abundance signals for fragment ions at the previously noted *m/z* values, and than the EI mass spectra (not shown), which have intense signals only at low (< 60) *m/z* values. The data in Fig. 2 also point out the greater demand on separation efficiency imposed by the use of random noise CID for MS/MS. Because the excitation is non-mass selective, coeluting species will undergo simultaneous fragmentation. As such, the MS/MS spectra represent a combination of each molecular species and their respective product ions. A method that at least allows the possible determination of coeluting species is to switch the noise signal on and off, thereby acquiring mass and MS/MS spectra in an alternate fashion during peak elution.

Comparison of an Octopole with a Quadrupole as a Collision Cell in a Hybrid Instrument Todd D.Williams[1], Geoffrey Bott[2], Julie A. Leary[3], Carl Braybrook[4]; [1]University of Kansas, Lawrence, KS 66049; [2]GB Scientific, Novato, CA 94945; [3]College of Chemistry, UC Berkeley, Berkeley, CA 94720, [4]VG Analytical, Manchester, UK M23 9LE.

Introduction: The substitution of a quadrupole with an octopole rf only collision cell in a hybrid mass spectrometer has been shown to improve CID performance in a VG ZAB2E-Q (1). In this study, the performance of the same octopole design has been compared to the standard quadrupole collision cell in a VG AUTOSPEC-Q.

Experimental: Mass Spectra were obtained on an AUTOSPEC-Q tandem hybrid mass spectrometer (VG Analytical Ltd, Manchester, UK). This instrument is of EBEqQ configuration. Fast atom bombardment ionization was performed using a cesium gun. Collision induced decomposition (CID) experiments were conducted with precursor ions attenuated 50% with xenon in the collision cell. The analyzer quadrupole was tuned to 1.5 amu full width at half height and the precursor ion was transmitted with MS1 tuned to 1500 resolution. The scan rate was 1sec/100 amu and 3-6 scans were integrated. The standard quadrupole was replaced by an octopole (GB Scientific, Novato, CA) fitted directly in the quadrupole housing. The detector after MS2 was maintained at the same gain for all experiments. MS^3 experiments were carried out by performing CID in the FFR2 collision cell using He collision gas (50% attenuation) and selecting the ESA2 energy to transmit a fragment ion into the rf only cell. CID in the rf cell was with Xe (50% attenuation). The peptides used were Renin Substrate (MW 1758), Substance P (MW 1347), Gramicidin S (MW 1141), FLEEI (MW 649) & Leucine Enkephalin (MW 554).

Results: Fragmentation Efficiency: MS/MS

A series of peptides with molecular weights of mass 500 to 1700 amu was used to compare the fragmentation efficiencies (FEs) of the two cells as a function of collision energy. FE is defined here as: FE = [sum of all product ion current / (sum of product ion+precursor ion current)] *100). The difference in performance is demonstrated in figures 1 and 2. The octopole provided significantly enhanced low mass product ion abundance and greater over product ion yield (see table 1). **The octopole generally provide significantly better product ion yield and much better low mass ion abundance.**

Transmission: To test the relative transmission behavior of the two rf only cells, CsI ions of masses 133 to 2472 were passed from MS1 through to MS2 with no gas in the cell while maintaining the same detector gains for each configuration. The ratio of signals MS2/MS1 was the same for the octopole compared to the quadrupole for all ions. **The transmission characteristics for unattenuated precursor ions are identical.**

MS^3: A MS^3 experiment in which a MIKES generated fragment is transmitted into the collision cell requires focusing of a diverging beam from ESA2 into the rf only cell. Two MIKES product ions were transmitted to explore two energy regimes entering the rf only cells. The FEs for the product ions from the transitions of 650 -->519 (or 390) --> are found in table 1 at two collision energies in the rf only cells. The sample load on the FAB probe for each of these experiment was approximately the same (a "saturated" sample was used) to keep the precursor ion current approximately the same throughout the MS/MS/MS experiments. Precursor ion current at the MS2 detector was constant within a factor of 2 for all

experiments. **The octopole provided more efficient fragmentation than the quadrupole.** These experiments further suggest that the optics of the instrument provide a well focused beam sufficient for the octopole.

Nodes: The variation of intensity of precursor and fragment ions of CsI m/z 1952 with collision energy demonstrated that the quadrupole had significantly sharper nodes in transmission of the precursor ion. In the quadrupole the fragment ion nodes tended to coincide at the same energy. The appearance of nodes became much less pronounced with lower mass fragments and higher collision energies in the octopole. **Tuning was easier with the octopole** because it is harder to fall into a nodal "well" using the octopole while searching for an optimum collision energy.

Conclusions: At higher collision energies the low mass region of the CID spectra from the higher mass peptides was significantly enhanced in the octopole relative to the quadrupole. Overall the octopole provided better quality collision data except from the low mass peptide.

Performance Characteristics of a New Hybrid Mass Spectrometer System

M. Ishihara, and F.. Kunihiro, JEOL Ltd., Akishima, Japan and B. Musselman*, JEOL USA, Inc., 11 Dearborn Road, Peabody, MA 01960

A novel MS/MS interface has been fabricated for use in hybrid mass spectrometer systems. The novel feature of the lens system used in this interface is that it facilitates both directional focusing, and ion deceleration as required in such instruments. A quadrupole doublet lens assembly is located immediately after the exit slit of the high resolution mass spectrometer to provide for directional focusing of the ions exiting the double focusing instrument. This directional focusing was attempted in order to reduce the height of the ion beam exiting the sector-based mass analyzer without using a restriction slit. Reducing the beam height was desired in order that we could inject the ions into the quadrupole-based RF-only collision cell with maximum efficiency. A series of cylindrical lenses are then employed to provide for uniform deceleration of the ions to the ion energy suitable for CID in the RF-only quadrupole. The combination of these elements improves the transmission efficiency for ions between the two mass analyzers, thus improving the performance of the hybrid instrument.

Ion optical calculations were completed by using the MSPLEX and ELECTRA programs developed at Osaka University. The values of the potentials of the nodes on the lenselectrodes are given by MSPLEX, followed by using ELECTRA-based calculations for the electric field and ion trajectories.

Characteristics of the ion optics of the quadrupole-doublet had been know from initial calculations on the use of this type of ion focusing element on our tandem mass spectrometer instrumentation. The problem of effecting both the deceleration and focusing of ions was approached iteratively solving for individual ions with ion energies varying from 10 to 250 eV. Based on the results of those calculations the lens system was fabricated and tested.

Collision induced dissociation was completed on a variety of different molecular ions. The results were comparable with those expected for this instrumentation. Unit resolution was observed for all product ions as expected, even at scan speeds in excess of one per second. Product ion m/z mass assignments were within +/- 0.3u.

Studies on Reducing the Scale of a Double Focusing Mass Spectrometer*

David M. Chambers, Hugh R. Gregg, Brian D. Andresen
Lawrence Livermore National Laboratory
P.O. Box 808, Livermore CA 94551

Introduction

The need for portable mass spectrometers has increased in recent years primarily for use in environmental monitoring applications. The widespread application of quadrupole and ion trap mass spectrometers has encouraged several groups to adapt commercial systems into portable units. Similarly, with the advent of high-energy-product magnet materials, fabricating a miniature sector mass spectrometer becomes more feasible. A reduced-scale-sector instrument has the potential to be robust, requiring only simple electronics and less power than those requiring an rf field. Sector mass spectrometers have already been developed with the goal of remote sensing in confined spaces or portability [1–3]. Although theory for high resolution and mass accuracy is well understood, such specifications have not yet been achieved on a reduced-scale instrument. These shortcomings are the result of compromises made to achieve the objective for a low-cost, simple and robust instrument.

In our laboratory, experiments were conducted to develop and optimize a miniaturized sector mass spectrometer. The instrument studied in this work is similar to the ones developed for the Viking project [2], but was further modified to be low cost, simple and robust. Design features that highlight the simplicity of our instrument include the use of a modified Varian leak detector ion source, source ion optics that use a single extraction voltage and an unshunted fixed nonhomogeneous magnetic sector. The effects of these design simplifications on ion trajectory were studied by manipulating the ion beam through the electrostatic energy analyzer (ESA) and translatable magnetic sector.

Experimental

The mass spectrometer design included a Nier-Johnson configuration with a 90° angular deflection through each the electric and magnetic sector. The magnetic sector could be translated perpendicular to the incoming ion beam. The instrument studied is similar to the one described by Andresen *et al.* [4]. The present instrument has a mass range of 230 m/z and a resolution m/Δm of over 300 (full width half maximum). A significant drop in resolution was seen at m/z values above 100 and is attributed to electronic ripple as well as nonhomogeneous and fringing field effects. The accelerating potential was scanned linearly down from 1500 V and the ratio of the accelerating potential to ESA potential was varied from 4.446 to 4.611.

Results and Discussion

One obstacle encountered with incorporating nonhomogeneous fixed magnets into a sector mass spectrometer is estimating the effective flux density, B_o. For the initial design, we estimated the flux density to be approximately 7000 G. The effective flux density determined from this study was 7178 G. Having the ability to adjust the magnet assembly position made it possible to correct for differences between estimated and effective values. Because B_o was

[1] M.P. Sinha and A.D. Tomassian, Rev. Sci. Instrum **62**, 2618 (1991).
[2] D.R Rushneck *et al.*, Rev. Sci. Instrum. **49**, 817 (1987).
[3] A. Bacs, B. Eckenrode, and R. Drew 38th ASMS Conference on Mass Spectrometry and Allied Topics; Nashville, TN; May 19–24, 1991; p. 164
[4] B.D. Andresen, J.D. Eckels, J.F. Kimmons, W.H. Martin, D.W. Myers and R F. Keville, U.S Patent 5,153,433 (1992).

assumed to be 7000 G in the initial design, signal and resolution had to be optimized by shortening the radius through magnetic sector, r_m. This adjustment could be made either by moving the magnet assembly or by deflecting the ion beam out of the ESA to bisect the magnetic sector at a smaller entrance radius. Although this action complicates ion movement by increasing the velocity and angle of trajectory for ions leaving the ESA, the configuration could be optimized by fine-tuning the magnet assembly position.

At a fixed l_{e1}, r_e, r_m and l_{m2}, the experimental system exhibits an $l_{e2}+l_{m1}$ of 9.407 cm, which is 5.75 mm shorter than what theory predicts (i.e., 9.982 cm). This discrepancy is within an acceptable range with respect to potential errors from extrapolating experimental results and a broad optimum range. Breadth of optimum range can be seen in Fig. 1 for the Xenon doubly charged ions where resolution and signal remain relatively unchanged when moving the magnetic sector position nearly 5 mm perpendicular to the incoming ion beam. For the above calculations, the effective field boundary for the magnet was approximated to the lowest order at the magnet boundary itself. From the accelerating potentials and experimentally determined r_m values, the effective magnetic flux density was determined to be 7178 G.

Conclusion

The mass spectrometer instrument presented here is highlighted by its inexpensive and simple analyzer and electronics design, especially the use of fixed nonhomogeneous magnets for the magnetic sector. Because the magnetic flux density cannot be accurately predicted, a key to successful ion beam focusing is flexibility in instrument geometry. In the system presented, focusing was achieved by manipulating the ESA potential and magnet position. From these studies it was determined that the estimated flux density was lower than the effective value derived from our experiments. To correct the instrument geometry, r_m should be reduced. Future modifications could include decreasing l_{m2} as well as the horizontal position of the detector assembly.

PHOTODISSOCIATION OF MALDI GENERATED PROTEINS VIA 193 NM AND 118 NM PHOTONS IN A TOFMS

Gary R. Kinsel, Mary E. Gimon, Ricky D. Edmondson, and David H. Russell
Texas A & M University, Department of Chemistry, College Station, TX 77843.

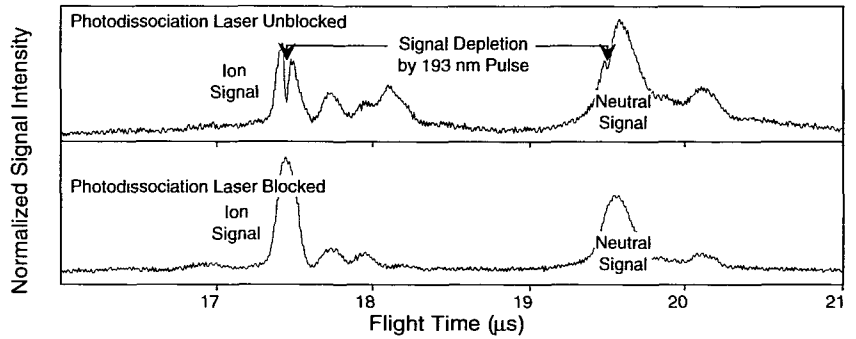
Extremely large proteins have recently become amenable for mass spectrometry through the development of the Matrix Assisted Laser Desorption Ionization (MALDI) technique. In general, MALDI is found to be an efficient method for introducing large biomolecules into the gas phase under soft ionization conditions. Little or no structural fragmentation of the protein is typically observed in the molecule mass spectrum. An appropriate evolutionary goal is the development of efficient methods of dissociating large proteins to produce structurally significant product ions. Pulsed laser photodissociation offers an attractive approach to addressing this need due to its inherent compatibility with the pulsed ion formation nature of MALDI in a time-of-flight mass spectrometer (TOFMS).

We have recently developed a two-stage linear TOFMS instrument which allows photodissociation of MALDI generated ions to be performed. In this instrument MALDI generated ions are accelerated from 15 kV to 5 kV across the source region and then drift down a 0.4 m flight tube liner floated at 5 kV. Analyte ions and matrix ions separate in this first drift region. Simultaneously, intact parent ions may metastably dissociate to form metastable product ions and neutrals which drift together with the intact analyte ions. A 193 nm photodissociation light pulse is timed to intersect the analyte ions in a field free photodissociation region at the end of the first drift region. The photodissociation product ions and remaining intact parent ions are then accelerated from 5 kV to ground. All ions then drift through a second 0.6 m drift region where the product ions and parent ions separate in time. All ions are then detected at the end of the flight tube by a microchannel plate detector. The resultant mass spectrum combines ion signals from all of the described processes.

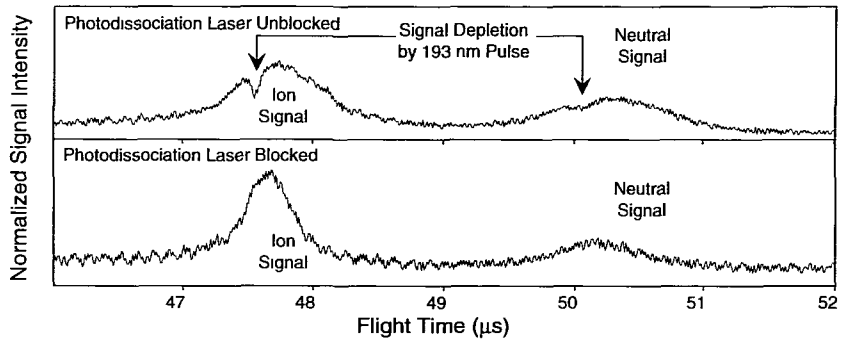
Initial investigations focused on identifying and quantifying the background metastable processes which must be subtracted before identification of photodissociation product ions can be attempted. Retarding grid investigations, where analyte ions are deflected at the end of the flight tube, showed that a large fraction of MALDI generated analyte ions may metastably dissociate during their passage through the combined ca. 1.0 m flight path from the ion source region to the ion deflector. Up to 40 % of the parent ions for a given analyte have been observed to metastably dissociate in these experiments. The results of these studies for several analyte ions are given in the table below.

Analyte	Molecular Weight (Da)	Neutrals/Total Signal X 100 (%)
Arg-Lys-Glu-Val-Tyr	693.7	39 +/- 19
Bradykinin	1040.7	17 +/- 6
Mellitin	2844.8	16 +/- 3
Bovine Insulin	5733	23 +/- 6

Once the metastable processes were identified, 193 nm photodissociation of intact analyte ions was attempted. When the timing for the photodissociation laser pulse was properly adjusted a significant depletion of the analyte ion signal was observed. An example is shown below for the pentapeptide R-K-E-V-Y. In addition, a depletion of the neutral signal was also observed and was attributed to photoionization / dissociation of the neutral metastable product molecules.



Successful photodepletion studies have also been performed on several larger analyte ions. Photodepletion of analytes as large as bovine insulin has been observed experimentally and an example of the signal obtained is shown below. This result suggests that even relatively large proteins may be photodissociated in the instrument described.



Initial studies have demonstrated the feasibility of photodissociation of large peptides and proteins in a linear TOFMS. Future studies will focus on improving both ion and laser optics to enhance the photodissociation product ion yield. Methods for separating and identifying the product ions are also under development. The results presented here demonstrate that photodissociation is a promising approach to initiating fragmentation of MALDI generated peptides and proteins.

MS/MS OF MULTIPLY CHARGED IONS: DETERMINATION OF CHARGE STATES BY MEDIUM RESOLUTION LINKED SCANS

R. Pesch, E. Schroeder, H. Muenster,
Finnigan MAT GmbH, Barkhausenstr. 2, 28197 Bremen, Germany

ESI-MS and ESI-MS/MS are widely used techniques for the analysis of biopolymers, technical polymers and a variety of other polar and labile compounds.

Using high resolution magnetic analyzers with ESI offers high mass resolution and accurate mass assignment. These capabilities have already been described elsewhere for main beam ions.

Sector analyzers exhibit higher mass resolution not only in main beam experiments, but also under MS/MS conditions. This opens the possibility of reading the charge states of daughter ions from multiply charged precursors directly by evaluating the isotopic clusters. This is true, because isotope peaks are spaced by 1/z dalton, with z being the charge state of the ion. For a peptide with a molecular weight of 3000 dalton, the required mass resolution would be at least 3000 (FWHM).

The experiments have been performed with a Finnigan MAT 900 forward geometry mass spectrometer, using the standard fast scanning focal plane detector (PATRIC).

Because of the large distance between collision chamber and entrance slit (about 600 mm) virtually all daughter ions are formed before the entrance slit and very few decompositions occur between entrance slit and ESA. For this reason, the MAT 900 maintains its double focussing condition also for linked scan daughter ions. As a result, daughter ion resolution in excess of 10,000 (FWHM) is possible.

The capability of determining charge states in the above described way has been tested by fragmenting the quadruply charged molecular ion from melittin. Ionization mode was ESI, collision gas was He, MS main beam resolution was set to 4000 (10% valley)

The daughter ion spectrum, acquired under these conditions exhibits a resolution of 6000 (FWHM). It is shown below (Fig. 1), along with two zoomed-in parts of the mass scale (Figs. 2 and 3).

From the data it is obvious, that charge states of daughter ions can be directly read from B/E linked scan spectra; a possibility significantly easing interpretation.

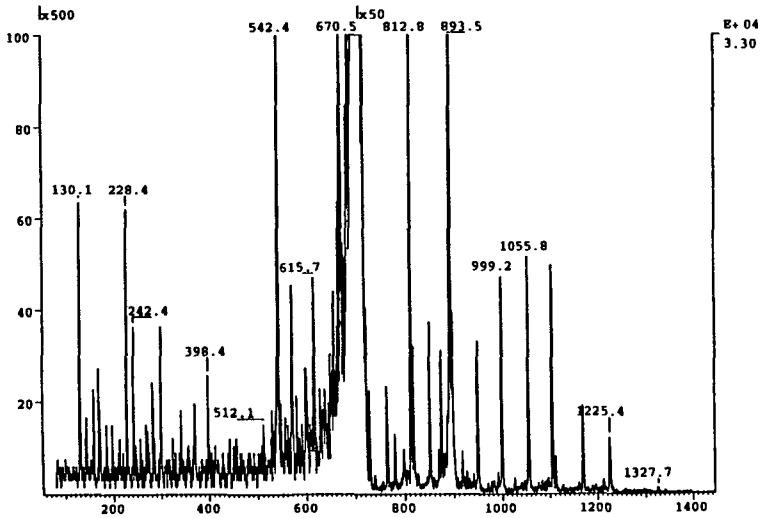


Fig.1 B/E = const. linked scan spectrum of MH_4^{4+} from melittin

Rapid, Continuous Recording of High Energy Collision-Induced Dissociation Spectra Using Charged Coupled Device (CCD) Detection Under Mach 3 Control On A Kratos 4-Sector Concept IIHH: Application to Peptide and Protein Sequence Analysis

F.C. Walls, S.C. Hall, K.F. Medzihradszky, Z. Yu, and A.L. Burlingame
Dept. of Pharmaceutical Chemistry, University of California, San Francisco 94143

S. Evans, A.D. Hoffman, R. Buchanan, S. Glover,
Kratos Analytical, Manchester, England

Primary structural characterization of proteins isolated from natural sources continues to push the detection limits of 4-sector mass spectrometers to lower levels because many times isolation procedures yield only a few picomoles of purified protein. Having to work at such low sample levels necessitates improving ion detection capabilities such that good quality CID mass spectra can be obtained routinely on femtomole quantities of peptides. We have accomplished this goal by making two major modifications to our 4-sector instrument. The first modification involved sample introduction using a continuous flow probe. Since liquid secondary ion mass spectrometry (LSIMS) is a surface sputtering technique, the signal size and lifetime depend on the surface activity of the analyte. Using a conventional batch LSIMS probe for less surface active molecules produces poor signal-to-noise ratios at low sample levels, while hydrophobic samples frequently give intense precursor ion intensities whose lifetimes are shorter than the duration of the MS-2 scan time when our stepped photodiode array is used for detection. Recently, CID sequencing of peptides in the femtomole range has been reported by Kenny and Orlando [1] using a continuous flow probe and 20% array detection. The improved signal-to-noise ratio was attributed to the reduction in chemical background noise which was accomplished by the ability to use a lower concentration of matrix with dynamic sample introduction compared to conventional batch methods. In our laboratory, using a continuous flow probe for sample introduction on our 4-sector instrument has resulted in a dramatic improvement of data quality and overall sensitivity.

The second modification of our 4-sector instrument involved replacing the conventional stepped photodiode array detector with a scanning CCD [2, 3]. The photodiode array consisted of a microchannel plate of one inch in length in the dispersive plane consisting of 1048 channels and detecting signals simultaneously from ±2% of the mass-to-charge ratio focused at the center of the detector. The CCD consists of 1152 channels, spanning 4% of the mass range, which are clocked sequentially through the device and are read out at the last channel. The array clocking speed is synchronized with the ion beam movement across the array face such that the ion current associated with each ion accumulates as the beam travels, which eliminates stepping dead time. Thus, significant time savings is realized since recording of a single CID spectrum can be taken in less than five seconds compared to approximately three minutes using the stepping mode. Also, the capability of scanning rapidly plus the addition of the continous flow probe as our standard method of sample introduction permits on-line HPLC/MS/MS experiments to be performed on a 4-sector mass spectrometer. Incorporating a continuous flow probe and CCD detector on our 4-sector instrument has resulted in a 10-fold increase in detection sensitivity. As an illustration, Figure 1 shows the high energy CID spectra of tryptic peptide (MH^+ = 1033.6 Da) from Galβ1,3(4)GlcNAc α2,3-sialyltransferase isolated from rat liver. Approximately 100 picomoles of this peptide was loaded using the conventional batch mode probe and photodiode array detector. It took approximately three minutes to record this single scan.

In comparison, Figure 2 represents the high energy CID spectra of a synthetic peptide of the same sequence recorded in twenty seconds with the continuous flow probe and the scanning array detector. Approximately 8 picomoles of peptide were consumed during this scan. This spectrum is of equal quality to the 100 picomole spectrum of the same peptide obtained using the batch mode probe and stepped photodiode detector.

A Tandem Time-of-Flight Mass Spectrometer Using Photodissociation

M. A. SEETERLIN, R. D. MCLANE†, P. R. VLASAK, D. J. BEUSSMAN, and C. G. ENKE,
Department of Chemistry, Michigan State University, East Lansing, MI 48824

The tandem time-of-flight (TOF) instrument constructed in our laboratory has been designed to obtain complete MS/MS spectra from compounds eluting from a capillary gas chromatographic column, while maintaining unit mass resolution for both precursor ion selection and product ion analysis. To meet this goal, the instrument needs to acquire at least 10 product spectra per second. Such spectral generation rates require maximum utilization of sample molecules and ions, efficient fragmentation of precursor ions, and array detection of the product ions produced. The use of continuous electron impact ionization with ion storage between pulsed extractions, TOF separation and reflectron focusing of precursor ions at an interaction region, pulsed laser induced fragmentation, TOF separation and reflectron focusing of product ions, and array detection of all products formed, meets each of these criteria. Details of instrument design have been presented [1]. Here we present a preliminary report of the achievement of high resolution laser selection of precursor ions and high-efficiency photo-induced dissociation (PID) consistent with the overall instrumentation goals.

For precursor ion selection we rely on the laser pulse interacting with exactly one precursor *m/z* value. The laser pulse is focused to a width of approximately 1 *mm*. The isomass ion packets are also focused to 1 *mm* in length (resolution = 1200 FWHM). At *m/z* 1000, the trailing edge (FWHM) of the *m/z* 1000 ion is separated from the leading edge of the *m/z* 1001 ion by 0.2 *mm*. During the 17 *ns* temporal length of the laser pulse, the *m/z* 1000 ion packet travels 0.2 *mm*. At higher *m/z* values, the distance between ion packets becomes smaller than the distance traveled in 17 *ns*, and unit resolution for precursor selection is not achieved. Figure 1A is a spectrum of the molecular ion region of bromobenzene. With the laser on and the delay time between source extraction and laser firing set such that the laser pulse arrives at the interaction region at the same time as the precursor ions, interaction between the ions and photons occurs. Selection of a new precursor ion simply involves changing the laser delay time to the calculated value for the desired precursor *m/z* value. Figures 1B-1D are the spectra obtained when the laser delay times are set to coincide with the ion packet arrival times for *m/z* 156, 157 and 158 successively. The ion depletions associated with each of these times, being limited to the selected ion, demonstrate the effectiveness of precursor selection by laser timing adjustment.

The high degree of spatial and temporal overlap obtained by this instrument also provides optimal PID efficiency. The laser used in this system is a Questek 2580vβ excimer, in this case operating with ArF (193 *nm*) at 30 *Hz*. The efficiency of the PID process is determined by the efficiency of fragmentation and the efficiency of collection of the ions. We can let P and P_O represent the precursor ion current with and without laser excitation, respectively, and $\sum F_i$ the total current of all fragment ions. The fragmentation efficiency is $E_F = \sum F_i / (P + \sum F_i)$, the collection efficiency is $E_C = (P + \sum F_i) / P_o$, and the overall PID efficiency is $E_{PID} = E_F \times E_C = \sum F_i / P_o$. Product spectra from precursor ions for several compounds were collected. Efficiencies are given in Table 1. In most of these studies, the ions were focused at a temporary detector placed approximately 20 *cm* beyond the interaction region, rather than at the interaction region. This configuration improved product ion resolution, but resulted in lower PID efficiencies. When reflectron 2 is used in the final instrument configuration to focus the product ions, space focus will be achieved at both the interaction region and at the final detector. To determine the effect of improved focusing on PID efficiency, two precursor ions (indicated by asterisks in Table 1) were studied with the focus at the interaction region. As hypothesized, PID efficiencies were increased.

Collection efficiencies of greater than 100% were sometimes observed. This is believed to be the result of greater detector gain for ions with higher velocity (lower *m/z*) [2]. The overall PID efficiency of 104% achieved for bromobenzene is comparable to the high efficiencies achievable in the CID process in a triple quadrupole instrument. These results give evidence that PID can be an analytically useful fragmentation technique when implemented in a system with high ion/photon overlap.

Figure 1

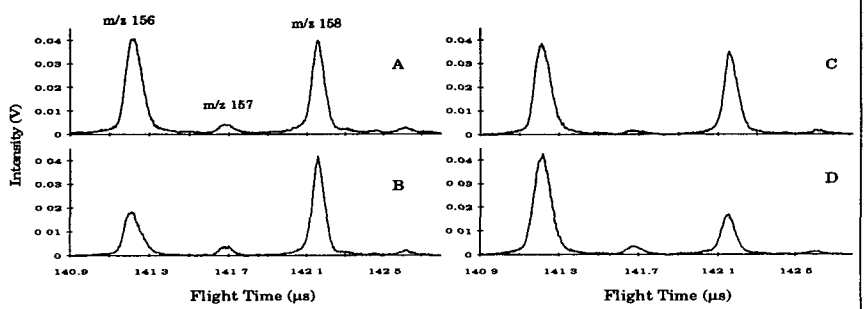

Table 1

Compound	Precursor Ion *m/z*	Laser Pulse Energy (*mJ*)	Fragmentation Efficiency (%)	Collection Efficiency (%)	PID Efficiency (%)
bromobenzene	156	150	56	116	65
	77	160	30	93	28
	156*	130	79	132	104

The use of tandem mass spectrometry in the study of complex mixtures

J H Scrivens, H Yates, K Rollins, R J K Jennings, J Lewis
ICI Materials PO Box 90 Wilton Cleveland England TS6 8JE

1. Introduction

Many industrial formulations are in fact complex mixtures. This reflects the use of inexpensive, multicomponent feedstocks and the need to address a variety of properties in one product. Tandem mass spectrometry techniques have been used to characterise a series of complex ester formulations. These are made up from a variety of cyclic polyhydroxy compounds reacted with various mixed acid feedstocks. A combination of product and precursor ion scanning has been used to simplify the data obtained with both derivatised and non derivatised systems. LSIMS has been the ionisation method of choice combining stability, longevity of spectra and sensitivity.
Many of these formulations have a variety of isomers present and experiments have been carried out to evaluate the ability of tandem mass spectrometry to differentiate similar structures.

2. Experimental

This work was carried out on a Fisons VG ZAB-T four sector instrument of BEBE geometry[1]. The instrument incorporates an inhomogeneous ESA in MS2 enabling the mass range simultaneously detected using the array detector to be varied up to 1.4:1. All product ion scans were obtained with a ratio of 1.2.1 and a resolution of >1000 (FWHH). The collision energy was 4kev. Precursor ion scans were carried out by selecting an ion with MS2 and scanning MS1[2]. A collision energy of 2kev was used and the wide energy transmission of MS2 (1.34:1) enabled all precursors to be detected. Sequential product ion spectra were obtained using the first and third collision cells. First generation products formed in FFR1 were selected using B1 and E1 and the product collisionally activated in FFR3[3]. LSIMS using 35kev caesium ions was the ionisation method employed.

3. Results

Precursor ion scans have been shown to be very useful in simplifying the complex formulations. Both alcohol type and acid component can be picked out by selecting appropriate ions from the LSIMS spectra. Residual unreacted OH groups can result in water loss which can mask the presence of other alcohol components. This has been demonstrated by sequential product ion spectra. Forming derivatives can help but has to be used with caution in unknown systems. Acetylation can often give dominant (M-60) ions which can complicate interpretation. The potential of tandem mass spectrometry in distinguishing closely related structures has been demonstrated for a number of systems. Figure 1 shows a series of $C_6H_{12}O_5$ isomers typical of alcohols used in these formulations. Figure 2 shows the product ion spectra obtained from the m/z 165 ions. All eight isomers can be differentiated using this method The differences are outside those that can be attributed to the normal reproducibility variations (which have been studied). The major source of variation was found to be the tuning of MS2.

USING CLUSTERS AS A TOOL TO PROBE MALDI MASS CALIBRATION

R.D. Edmondson, G.R. Kinsel, L.M. Preston, K.K. Murray,
T. Solouki, and D.H. Russell
Department of Chemistry

Mass Calibration of TOF spectra of large molecules is hampered by the lack of high mass standards with accurately determined molecular weights. Recently, MALDI spectra of bovine insulin which contain clusters as large as twenty monomeric units were obtained on a linear TOF instrument in our laboratory. These cluster peaks offer an approach to producing high mass species with accurately determined molecular weights. A calibration curve that extends past 100,000 mass units can be created by using these cluster peaks as standards. We are now using this method to accurately determine molecular weights of high mass analytes. In this paper, the method of calibration is presented, discussed, and applied to an "unknown" analyte, Subtilisin (M.W. 27288). Sample preparation methods that enhance cluster ion formation are also discussed.

Figure 1 shows a mass spectrum of bovine insulin clusters, and was obtained as follows: a methanol solution that contains 3% Trifluoroacetic acid was used to dissolve 1 mg of bovine insulin. 2 μl of this solution was added to the probe tip. Then 2 μl of a 15 mg/ml solution of α-cyano-4-hydroxycinnamic acid was added. The laser beam power was varied by a neutral density wheel to optimize the relative abundance of the cluster ions.

The bovine insulin cluster peaks were curve fitted to determine their centroids. Figure 2 shows that a two component fit results in a smaller residual trace (a better fit) than does a single component fit. Figures 3 and 4 show plots of time (t) versus $(M/Z)^{1/2}$ for bovine insulin clusters. In Figure 3 the centroid was determined by the curve fitting method mentioned above, whereas in Figure 4 the centroid was determined by the center of mass method. The mass calibration equation ($t = k\,(M/Z)^{1/2} + b$), shows that a plot of (t) versus $(M/Z)^{1/2}$ should result in a straight line with a slope of k and a y-intercept of b. The b arises from the delay between laser firing and data acquisition. It is evident that a better correlation coefficient (R^2) was obtained from the plot in Figure 3 as opposed to Figure 4. Comparing the b values from these plots suggests that Figure 3 provides a more accurate calibration curve. Typical values for b on this instrument should fall between -0.03 to 0.03. The value of b in Figure 3 (-0.0248) falls in this range, while the value for b in Figure 4 (0.4108) is unrealistic.

A mass spectrum of an "unknown" analyte, Subtilisin, is shown in Figure 5. Subtilisin was chosen because its accurate molecular weight has previously been reported by Beavis and Chait.[1] This spectrum was mass calibrated in the conventional manner of using a low mass ion (Na^+) and an internal standard (bovine insulin) to generate a calibration curve, which resulted in an M/Z value of 27301. The same spectrum was mass calibrated using three bovine insulin cluster peaks, which resulted in an M/Z value of 27289. The value reported by the curve fitting method gives a value closer to the 27288 reported by Beavis and Chait. This shows that using cluster peaks as calibration standards provides a more accurate calibration curve than the conventional extrapolation based on low mass ions.

It should be noted that cluster ions of other proteins can also be produced. For instance, we have been able to acquire mass spectra of lysozyme (M.W. 14306) containing cluster ions as large as 14 monomeric units. Future plans include finding other, larger proteins that will form cluster ions. In addition, a study is planned to measure the neutral content from metastable decay under the cluster peaks.

A plot of flight time versus $(M/Z)^{1/2}$ for Bovine Insulin clusters, where the centroids of the cluster peaks were chosen by their center of mass

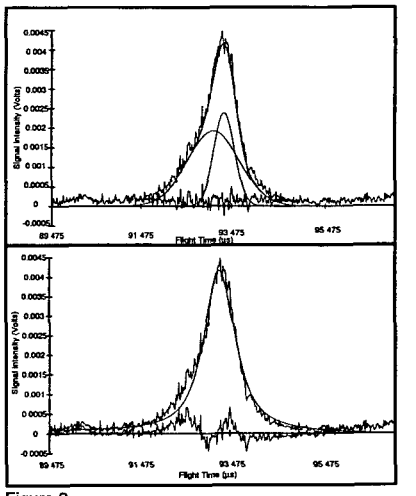

Figure 2
The upper trace shows a two component fit to the 5th Bovine Insulin cluster peak. The lower trace shows a single component fit Note the smaller residual (a better fit) on the upper trace.

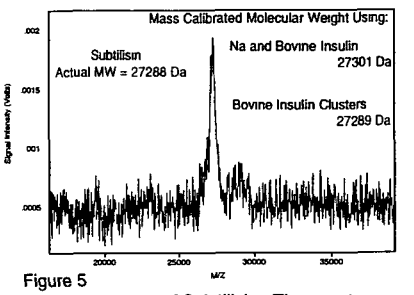

Figure 5
A mass spectrum of Subtilisin. The spectrum was calibrated by two methods: the conventional extrapolation from low mass, and the new method of using Bovine Insulin clusters. Note the calibration by clusters gives a more accurate value for the molecular weight of Subitilisin.

Post Source Pulse Focusing with Linear Time Of Flight Mass Spectrometry and Laser Desorption Ionization

J.M. Grundwürmer, M. Bönisch, G.R. Kinsel* and J. Grotemeyer

Institut für Physikalische Chemie, Universität Würzburg, Marcusstr. 9/11,
D-8700 Würzburg, Germany
*present adress : Texas A&M University, Dep.of Chemistry, College Station, Tx, 77843

Non-volatile molecules are successful introduced into the gas phase by Laser Desorption / Ionization.This method is easily combined with a linear TOFMS for mass spectral analysis.

However a major drawback of the linear TOFMS, particularly severe for LD experiments, is the poor resolution of the detected ion signals. There is need for higher resolutions to be obtained, particularly when investigating high mass ion signals. Higher resolutions are required for improvements for distinguishing between various protonated, sodiated and/or adduct ions which may be formed during LDI and accurate mass determination.

Post Source Pulse Focusing (PSPF) is a method which is expected to improve the resolution of the ion signals in a linear TOFMS by applying a compressing voltage pulse to the ion packet of interest after accelerating the ions from the TOFMS source region using conventional electric fields [1, 2]. Investigations under direct LD/I and matrix assisted LD/I conditions all demonstrate the dramtic improvements in ion signal resolution which could be achieved using this simple technique in a linear TOFMS. A mass resolution of 4800 (FWHM) has been achieved for Zn-mesoporphyrin (MW 656) and 800 (FWHM) for Cytochrome c (MW 12360).

Identifying the mass of the detected requires a well defined mass calibration. The kinetic energy of molecules affected by PSPF depends from the delay time between the desorption laser pulse and the time, when the post source pulse field is turned on. This relation requires a non linear

equation. Therefore, following equation is extrapolated, which allows to calibrate the postsource pulsed TOFMS well with three or more calibrating masses:

$$t = c_0 + c_1 * m^{\frac{1}{4}} + c_2 * m^{\frac{1}{2}} + c_3 * m^{\frac{3}{4}}$$

The constant factors c_i can be found by gaussian minimation of the square of the errors. This equation allows a mass determination of less than 0.02 % [3].

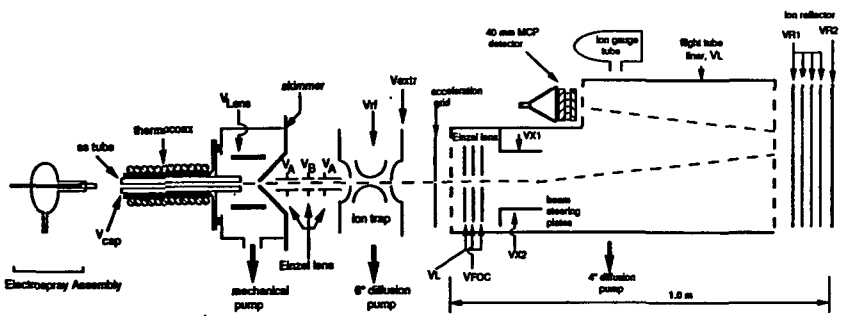
Ion Trap Storage/Reflectron Time-Of-Flight Mass Spectrometer Performance with Various Ionization Sources

Steven M. Michael, Benjamin M. Chien, and David Lubman
The University of Michigan
Department of Chemistry
Ann Arbor, MI 48109

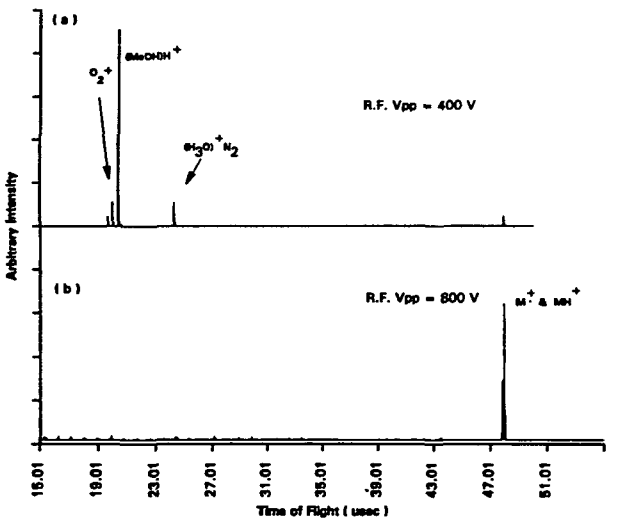
An ion trap storage/reflectron time-of-flight mass spectrometer's performance with electrospray, atmospheric pressure plasma discharge, reduced pressure plasma discharge and resonance enhanced multiphoton ionization sources is displayed. This instrument combines the high mass capability, speed, and resolution of the time-of-flight device with the sensitivity and selectivity of the quadrupole ion trap. The innovative feature of this device is that the trap enables coupling of time-of-flight, an inherently pulsed technique, with continuous ionization sources, electrospray and plasma discharge, with 100% duty cycle. This duty cycle is independent of the experimental repetition frequency thus allowing this instrument to serve as a real time on line detector for GC, LC, and CZE without the need for special high speed data collection electronics as the experiment can be run at a low enough frequency to allow for manageable data collection without sacrificing duty cycle.

Figure 1 shows the instrumental configuration with the electrospray ionization source in place Resolution >3000 and detection limits (S/N = 3) less than a single femtomole of analyte are typical for the electrospray experiment.



The selectivity advantage of the quadrupole ion trap as a front end source for TOF is demonstrated in figure 2 where, above, the spectrum is dominated by background peaks with only a trace of the peak of interest, however, by increasing the RF amplitude, the stable trapping region is shifted towards higher m/z thereby eliminating the unwanted background and enhancing the now dominant peak of interest.

Reduced Pressure Glow Discharge Ionization of Dibenzothiophene, MW 184. 5 ms trapping time.



A Compact, High Performance Time of Flight Mass Spectrometer

D. M. Murphy
Aeronomy Laboratory, National Oceanic and Atmospheric Administration, Boulder, CO 80303.

A new design is presented for a compact (67 cm) time of flight mass spectrometer, to be used in field measurements of the composition of aerosol particles. This application poses three challenges: The spectrometer must be portable, the initial ion temperature is very high (>6000 K), and different particles produce widely varying ion yields. An extended post source pulse focus region is used to obtain better than unit resolution for m/e from 1 to 300, covering most species of atmospheric interest. The mass spectrometer uses a two stage detector with nonlinear electronics to attain a dynamic range of over 10^5 from a single laser shot with a precision of approximately 5%. The design presented here is optimized for very hot ions produced in a highly confined region. However, the design is flexible and can compensate for other causes of low resolution.

A wide variety of techniques have been used to improve the resolution of time of flight mass spectrometers, with the most common being the reflectron and time lag focusing. The design presented here uses post source pulse focusing (PSPF), described by *Kinsel and Johnston* [1989]. This technique was chosen over a reflectron because of its simplicity, the ability to compensate for a spread in ionization time, and because a reflectron cannot fully compensate for differences in the initial *directions* of energetic ions. Kinsel and Johnston applied PSPF to obtain the highest possible resolution for one or two mass peaks. The design presented here is, to my knowledge, the first application of PSPF to a wide mass range.

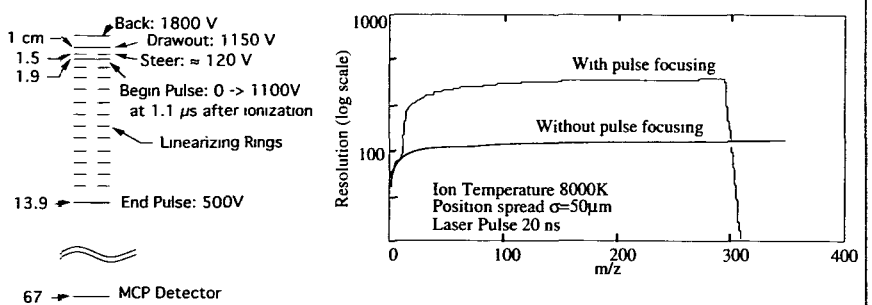


Figure 1: Design and theoretical resolution of the spectrometer for conditions typical of ionization from aerosol particles. Positions of the plates are in cm relative to the backing plate. As shown on the right, PSPF has different effects on three classes of ions. Ions below about m/e 10 u are in the drift region when the pulse is applied and are not affected. Ions with m/e 10 to 300 u are in the pulsed region at the time of the pulse and are observed at enhanced resolution. Finally, heavy ions have not yet reached the beginning of the pulsed region and are either defocussed or are unaffected.

The spectrometer is fully operational and is being used for the analysis of single aerosol particles with laser ionization. The design has also been optimized for near unity ion transmission and convenient operation of steering voltages. The predicted enhancement in resolution has been

observed, as indicated in the next figure:

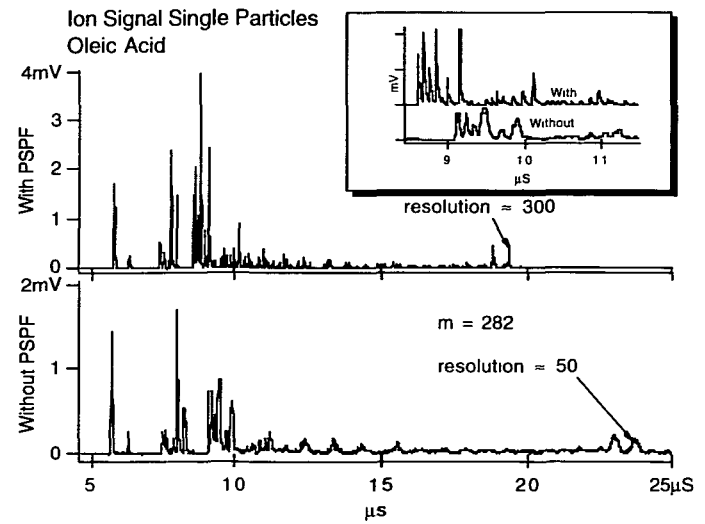

Figure 2: Observed spectra of oleic acid particles with and without PSPF. The PSPF both improves the resolution and changes the mass scale due to the extra acceleration from the pulsed voltage. The inset shows a small area of the two spectra near 10 μs delay.

It is also possible to optimize a design for ions with less kinetic energy but more initial spatial spread. This is accomplished merely by changing the drawout voltage from 1150 to 1650 V and delaying the pulsed voltage to a later time. The range of masses with enhanced resolution can be adjusted with the time delay, as shown below.

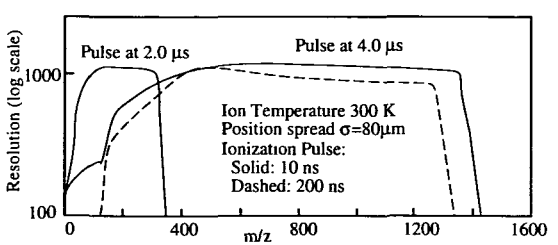

Figure 3: Performance of a compact PSPF spectrometer optimized for cooler ions. It is also possible to obtain good resolution with quite long ionization pulses.

TIME-OF-FLIGHT MASS SPECTROMETER FOR ON-LINE SINGLE PARTICLE ANALYSIS

M.V. Johnston*, P.G. Carson, K.R. Neubauer, Department of Chemistry and Biochemistry
A.S. Wexler, Department of Mechanical Engineering
University of Delaware, Newark, DE 19716

A new mass spectrometer has been constructed to detect single micron-size particles on-the-fly by laser desorption. Particles enter the source region through a differentially pumped inlet and scatter radiation from a continuous helium-neon laser beam. The scattered radiation triggers an excimer laser (193 or 248 nm) which ablates each particle in-flight and the time-of-flight mass spectrum is recorded. Hundreds of particles can be analyzed per minute with each particle giving its own unique mass spectrum Figure 1 shows the basic experimental setup Figure 2 shows the scatter collection and mass analyzer components in more detail Applications of this instrument to aerosol chemistry and example spectra are presented elsewhere in the proceedings

Aerosols are generated with a vibrating orifice aerosol generator (liquids) or a powder dispenser (solids, particulate matter on filter media). The aerosol is sampled by selectively transmitting particles through a two-stage momentum separator The transit time between the inlet and source region is approximately 0 5 ms, so loss of volatile components is minimized Indeed, cluster ions corresponding to $H(H_2O)_n^+$ can be observed from particles containing a substantial water content The helium-neon and excimer lasers are aligned to give the largest frequency of particles that are detected by light scattering and subsequently ionized by laser desorption. The laser beam waists are estimated to be between 100 and 200 μm diameter Since the particle velocity is approximately 200-300 m/s and the time-delay between detecting a scatter pulse and firing the excimer laser is 0 5 μs, minimal displacement of the excimer laser beam relative to the helium-neon laser beam is required. Ions can be generated and mass analyzed in a number of ways. Normally, ions formed directly from the desorption event are detected It is also possible to postionize neutrals with a pulsed electron beam. Mass analysis can be performed with linear, reflectron, or post-source pulse focusing time-of-flight modes. Each mode has specific advantages and disadvantages relative to mass resolution and sensitivity. Both positive and negative ions can be detected To aid in quantitative analysis, mass spectra can be pre-selected on the basis of the helium-neon laser scatter signal, or the excimer laser pulse energy

This instrument was designed for studies of laboratory-generated aerosols Development of a more compact version for field measurements is feasible Space and electrical power constraints are primarily determined by the vacuum pumps

Tandem Time-of-Flight Mass Spectrometry of Organic Molecules by Surface Induced Dissociation

David Fenyö and Brian T. Chait,
The Rockefeller University, 1230 York Avenue, N.Y., N.Y. 10021

Surface induced dissociation, i.e. dissociation of molecules due to high internal energy acquired in a collision with a surface, provides a means for the study of the fragmentation of organic molecules [1]. Most commonly a plane surface is used for the collisions but also the walls of the channels of a microchannel plate (MCP) has been utilized [2]. The use of an MCP allows an in-line geometry which is suitable for time-of-flight mass analysis. Such a time-of-flight analysis provides a highly efficient means for detecting the products of surface induced fragmentation.

The aim of this study was to construct a simple tandem time-of-flight mass spectrometer for the investigation of the fragmentation of molecular ions produced by matrix assisted laser desorption. For this purpose, a thin (250 μm) MCP, with grounded grids on each side, was placed as a collision cell in the field-free region of an existing time-of-flight mass spectrometer (Figure 1). The potential on each face of the MCP could be independently varied to set the collision energy ($q[V_a-V_c]$) as well as the extraction field (ΔV_c) in the channels. The MCP used had an angle of 0° between the channel long axis and the surface normal (the ion beam axis). The potential on the channel plate was pulsed to allow only ions of interest to reach the channel plate and undergo fragmentation. The fragmentation was studied for the cationic dyes brilliant green (MW 386 u), methyl red (MW 270 u) and Janus green (MW 476 u) as well as for the peptides Substance P (MW 1349 u) and [Arg^8]-Vasotocin (MW 1050 u) in a matrix of α-cyano-4-hydroxycinnamic acid. The fragmentation pattern was studied as a function of the collision energy and the extraction field in the channels.

For low energy collisions (0-200 eV) intense fragmentation spectra characteristic of the structure of the organic dyes were obtained (Figure 2). The fragmentation efficiency was approximately 10%. The fragmentation pattern could be varied by changing the collision energy. Smaller fragments were obtained when using higher collision energy. The size of the extraction field (ΔV_c) is critical for efficient extraction of the fragment ions.

In contrast to the results obtained for the dyes, the fragmentation spectra of the peptides were dominated by low mass ions that do not provide useful sequence information. Possible reasons for the difference in the information content of the fragmentation spectra of dyes versus peptides include: (i) differences in internal energy (the dye molecules absorb the laser light) and (ii) differences in charge neutralization upon impact with the surface.

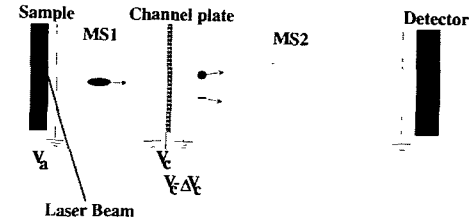

Figure 1. The experimental setup.

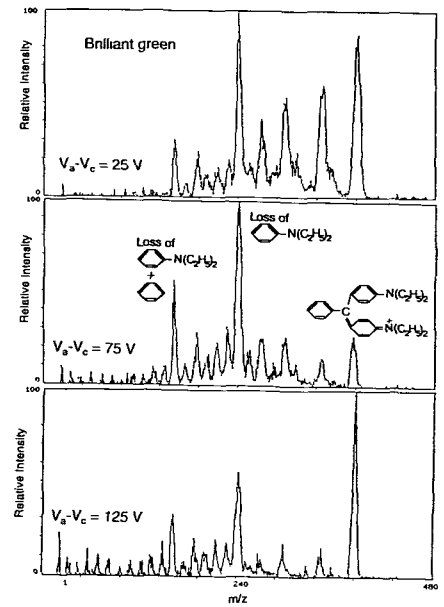

Figure 2. The fragmentation spectrum of the cationic dye brilliant green (MW 386 u) for different collision energies.

On-line Laser Mass Spectrometrical Analysis of Atmospheric Particles

K.-P. Hinz, R. Kaufmann, *B. Spengler

Inst. of Laser Medicine, University of Düsseldorf, Moorenstr. 5, D-4000 Düsseldorf, Germany

Investigation of atmospheric aerosol particles is an important task for e.g. air pollution research or the understanding of chemical processes taking place in the atmosphere. Until recently, analysis of individual single particles was possible only by sampling them in the atmosphere with impactors followed by transport to and preparation in the laboratory. Volatile components were not detectable with this method. This limitation can be overcome by interfacing the aerosol phase directly to a laser time-of-flight mass spectrometer [1]. We developed a new instrument for automatic detection, ionization and mass analysis of single particles (Figure 1). The instrumental setup consists of a differentially pumped nozzle system [2] for particle introduction into the mass spectrometer's ion source and a linear time-of-flight analyser with two-stage acceleration. Particles traversing a certain ionization volume are detected by scattered light from a He-Ne laser beam. The discriminated signal from the photomultiplier is used to trigger a UV laser for ionization. The total residence time of particles in the apparatus is less than 1 ms. A liquid phase covering the particles will thus be partially conserved by freezing.

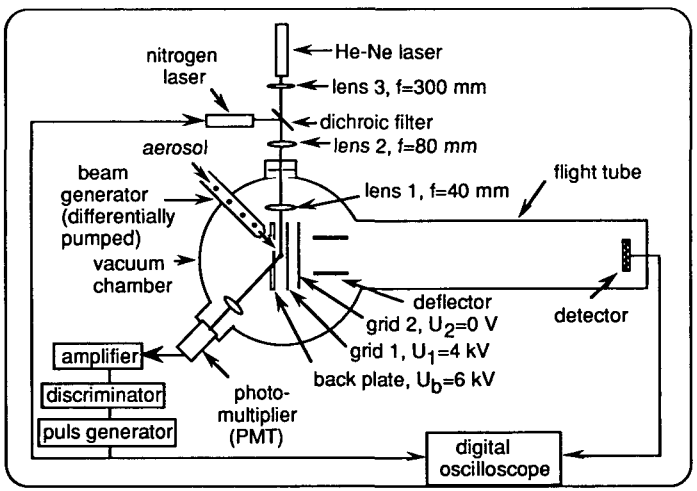

Figure 1: Instrumental setup of the laser time-of-flight mass spectrometer for on-line analysis of airborne particles.

Preliminary investigations of particles from alkali halides, smoke and other available sources gave good sensitivity and a mass resolving power of several hundred.

Particle-size selectivity can be achieved by choosing a proper delay between the photomultiplier signal and the ionization laser trigger, due to the mass dependence of the particle velocity.

Figure 2, as an example, shows a typical mass spectrum of small aerosol particles (<1µm) from room air, characterized by carbon cluster ion distributions. Larger particles from room air, on the other hand, predominantely contain silicate structures. A mass spectrum of a tobacco smoke particle (diameter ≈0.2 µm [3]) is displayed in Figure 3. Besides signals of alkali salts and hydrocarbon compounds it contains a characteristic peak of the nicotine radical ion.

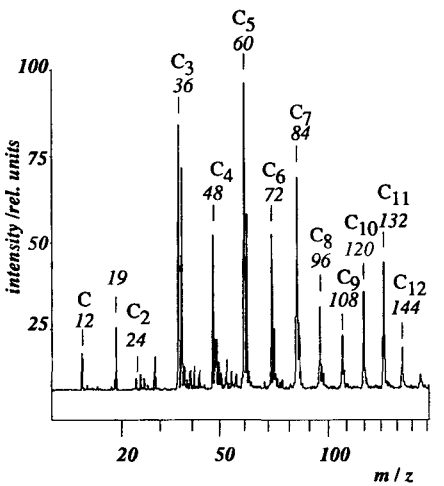

Figure 2: Positive ion mass spectrum of a typical aerosol particle from room air (particle diameter <1µm).

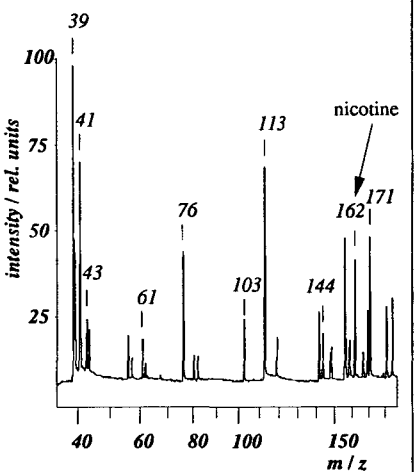

Figure 3: Positive ion mass spectrum of a tobacco smoke particle (particle diameter ≈ 0.2 µm).

Accurate Mass Measurements in a MALDI Reflector Instrument Using External Calibration

Gert Talbo, Kenneth Morand, Laura Margis and *Matthias Mann

Protein and Peptide Group,
European Molecular Biology Laboratory,
Heidelberg, Germany

MALDI TOF is a fast and simple method for peptide and protein analysis in the life science laboratory. It is in principle capable of high mass accuracy when used with internal calibrants. However, in practice several factors often prevent the use of such calibrants: (i) it is difficult to determine the correct nature and amount of calibrant that leads to a spectrum of comparable peak height and peak shape as the unknown. (ii) the measurement is complicated and prolonged by the necessity of mixing other proteins into the solution containing the unknown. (iii) when dealing with very small amounts the calibrants may suppress the sample peptides. Here we investigate the possibility of obtaining high mass accuracy with MALDI TOF using external calibration.

An ion reflector was used in these studies because some of the mass measurement errors are due to the energy uncertainty of the ions which the reflector compensates. Further experimental parameters to control include the acceleration voltage and the laser irradiance as well as the type of matrix but not the sample concentration.

MALDI TOF experiments were performed on a Bruker REFLEX instrument equipped with a reflectron and two double channel plate detectors. A 400 MHz digital storage oscilloscope (LeCroy 9450) was used to digitize the detector output and the "LaserOne" data system running on a Macintosh Quadra 950 controlled the instrument. A 16 bit high precision controller (FUG Probus III) was used to set the analog input voltage with an accuracy of 20 ppm of a long term high stability power supply (FUG). With this combination the voltage stability and reproducibility should at least be in the low 10^{-5} range and hence not be a limiting factor in mass determination.

To study the influence of laser irradiance we measured peptide mixtures at different attenuation settings of our filter for two matrices.. Figure 1 shows the result for a peptide of mass 1854. Da. Curves for all other measured masses were similar. The observed increase in flight time with increased laser irradiance is much smaller than it is in linear mode (data not shown) but it needs to be taken into account for reflector measurements as well. There is furthermore a difference in flight time between matrices which uncorrected would lead a difference in assigned mass of about 0.5 Da in this case.

We conclude from out investigations that the following factors have to be carefully controlled

- Accuracy and reproducibility of the acceleration and reflector **voltages**.
- Level of the **laser irradiance**. For routine, high accuracy measurements with a reflector it is best to measure in a range somewhat above threshold, where there is little dependence of flight time on laser irradiance.
- Change between **different matrices**. Correction factors between matrices or different sets of calibration constants for different matrices have to be used.

Results from repeated measurements over several days (see figure 2) suggest that it is then possible to obtain unit mass accuracy from reflector MALDI TOF using external calibration. For best results it may be advantageous to perform several independent analysis on the same sample.

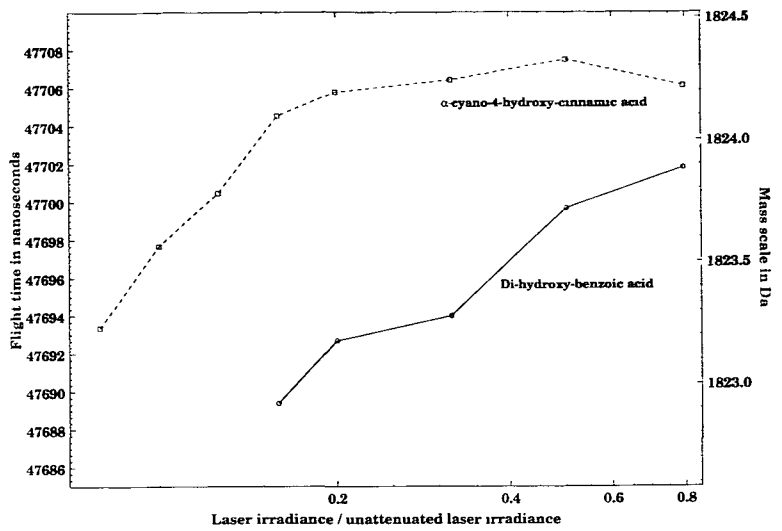

Figure 1 Influence of the irradiance and matrix type on measured flight time and assigned mass of a peptide. Measurements are in the reflector mode and the right hand y axis is based on constant calibration values

A DUAL REFLECTRON TANDEM TIME-OF-FLIGHT MASS SPECTROMETER

Timothy J. Cornish and Robert J. Cotter
Johns Hopkins Medical School, Baltimore, MD 21205

While CID analysis of biomolecules is becoming routine on magnetic sector instruments, the expense and expertise required to generate high resolution CID data is prohibitive for many biochemistry laboratories. The application of simpler time-of-flight technology to this type of analysis would significantly reduce the complexity of the instrumentation needed to generate CID data. We have been developing a dual reflectron tandem TOF mass spectrometer incorporating a pulsed molecular beam of neutral gas to promote fragmentation of gate selected ions.[1] In the CID mode of operation, the first reflectron is used to energy focus the precursor ions, while the second is used to both energy focus and mass disperse the fragment ions.

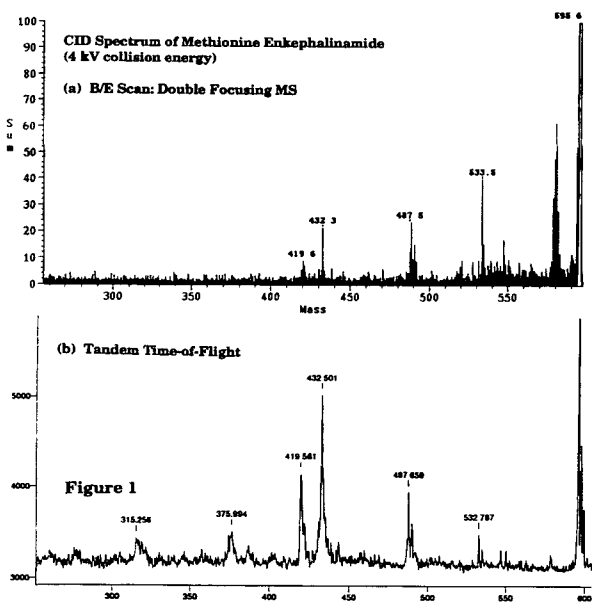

Figure 1

The first successful CID spectrum of a peptide is shown in Figure 1. The ($M+Na^+$) ion of methionine enkephalinamide (594 Da) is mass selected and reacted with helium (4kV collision energy) to generate the product ion spectrum. While the relative peak intensities in the two spectra are somewhat different, the pattern and mass of product ions formed are nearly identical. Likewise, the spectrum of the peptide dermorphin, shown in Figure 2, is also quite similar to the B/E scan. Modifications of the instrument to produce high resolution product ion spectra, as well as isotopically resolved mass selection in MS 1, are currently under development.

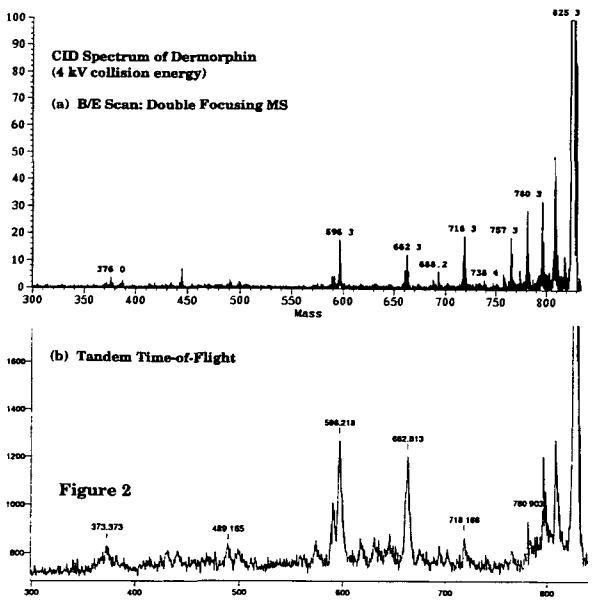

Figure 2

Kinetic Energy Measurements Of Matrix Assisted Laser Desorption Generated Ions With An Electrostatic Analyzer Based Time-Of-Flight Mass Spectrometer

*Robert S. Brown, Katherine H.A. Bogart and Donald L. Dick, Department of Chemistry, Colorado State University, Ft. Collins, CO 80523

The measurement of both the average ion kinetic energy and ion kinetic energy distributions for matrix assisted laser desorbed (MALD) ions can offer significant insights into the ionization mechanism and processes involved in this increasingly important new ionization technique. Recently, the Manitoba group has reported on the ion energies of MALD generated ions in the presence of a strong extraction field. This work indicates MALD generated ions have an actual ion energy deficit relative to the applied extraction field. This ion energy deficit was observed to be dependent on the mass of the ion and also depended upon the relative signal strength. These studies utilized a reflecting time-of-flight mass spectrometer to deduce ion energies. This poster presents preliminary results with an electrostatic analyzer based time-of-flight (ESA-TOF) mass spectrometer for the measurement of ion kinetic energies of MALD generated ions.

The ESA-TOF mass spectrometer was constructed by modifying a VG 7070F mass spectrometer. This entailed removal of the magnetic sector and placing a suitable ion detector (discrete dynode type) at the exit of the ESA. The ion source was removed and replaced with a conventional two stage TOF ion source which could be operated at a maximum accelerating voltage of 18 kV (limited by the electrical feedthroughs). The laser beam was brought in through a quartz window attached to an existing port and the field ionization port was utilized to bring the sample via a direct insertion probe on axis to the ESA's ion flight path. Variable ESA power supplies were added to accommodate the higher ion energies of the new ion source. A suitable transient digitizer and computer were also added. Relatively large exit apertures (1 mm minimum) are employed at present to insure adequate ion signal transmission. This produces an ion energy resolution with the ESA of ≈ ±38 eV at 15 kV accelerating potentials. While this limits the accuracy of determining the width of the ion kinetic energy distribution, average ion kinetic energies (and therefor the measurement of ion kinetic energy deficits of MALD generated ions) are not affected. While both sensitivity and mass resolution are not yet optimized, they are sufficient to measure the kinetic energies of MALD generated horseheart cytochrome C (mw=12360.1 Da) ions and to resolve the matrix adduct ions from protonated molecular ions.

A problem with the systematic examination of a parameter, such as applied ESA voltage or ion accelerating voltage, during MALD ion generation is the sample to sample variations in ionization intensity and the effect of sample history (i.e., extent of laser irradiation) on the observed ion signal intensity. This makes a systematic study of ion energies very difficult. To minimize this problem, a complicated sampling scheme is utilized. The sample is divided typically into 12 regions (like the face of a clock) and at each sample point, the average of several laser shots (typically 5) are taken and the intensity of the ions of interest are recorded. The variable is then changed and the process repeated on the same sample surface over the entire range of the variable to be examined (in this case ESA voltage). A new spot is rotated into the laser beam and the process repeated except the parameter is offset so that the first value is moved to the end of the order. This is repeated for each successive spot examined. The signal is then summed for each variable examined.

Our initial results with this instrument indicate significantly higher ion energy deficits (as much as 200-400 eV) for MALD generated ions than have previously been reported. These differences may arise from differences in the laser power utilized, ion extraction field strength and geometries and even the numbers of laser pulses employed. This latter effect can be observed in the ion energy distribution for porcine insulin shown in Figure 1. This data shows that the ion energy deficit get smaller and the ion energy distribution gets narrower when the ions produced by the first 50 lasers pulses are compared to the ions produced by the second 50 laser pulses on the same surface. This decrease in the ion energy deficit tracks the corresponding narrowing of the ion peaks observed in the TOF mass

spectra themselves. The narrowing always occurs at the high time side of the peak which would correspond to ions with lower velocity (i.e., larger ion energy deficit). Figures 3 and 4 show the most precise and accurate measurements we have made to date in terms of ion energy resolution and kinetic energy deficits. These results, as well as results with porcine insulin indicate that at laser irradiances slightly above threshold (8×10^6 watts/cm^2), the ion energy deficit appears to be independent of mass.

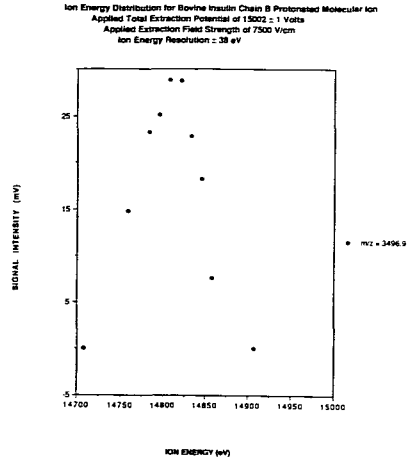

Figure 4

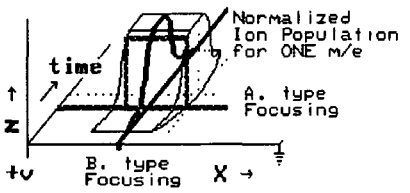
Variable Distance Time-Of-Flight Mass Spectrometer

W.C. Blanchard, Blanchard & Co., Inc., 27 Glen Alpine Rd., Phoenix, MD 21131

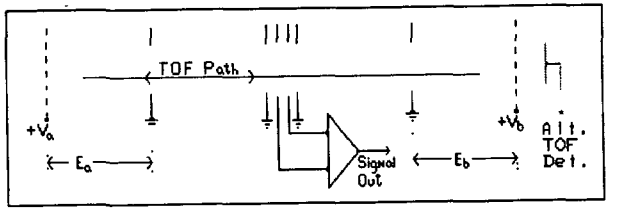
A new mass spectrometer configuration is being developed that provides a variable time-of-flight distance. The configuration can provide an increased flight length as the mass is increased. The problem addressed is how to focus ions that are created at different times, different locations, and with different energy levels, thus increasing resolution as mass increases.

Ions created in an electric field are normalized to zero initial velocity. This simplifies the problem to two variables. Two independent methods are then used to focus the ions: A. Focusing the ions created at the same time but at different locations, and; B. Focusing the ions created at the same location but at different times.



One MS configuration compatible with the above focusing requirements is:

The reflector grids use symetrically positioned wires for maximum repeated ion reflections. A vacuum of 10^{6} torr is used for long ion life.

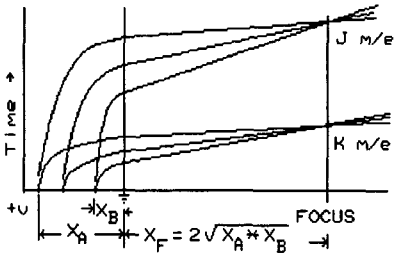


Additional features of this configuration are: low resolution one pass TOF (w/ $E_b=0$), or high resolution cumulative TOF (w/ $E_a=E_b$); repeated detection for enhanced signal/noise, like ICR, with signal processing using a Fourier series; various ionization; trapping of mass ranges (using $E_b=0$); small size/vacuum chamber, 10-50 in^3.

A. For ions created at the same time but at different equipotentials, at X_A and X_B, the ions at the lower equipotential will exit the electric field first but at a lower velocity than the ions exiting later. These later exiting, faster ions will catch up to the slower ions in the TOF region and become focused. They will focus at a TOF distance of:

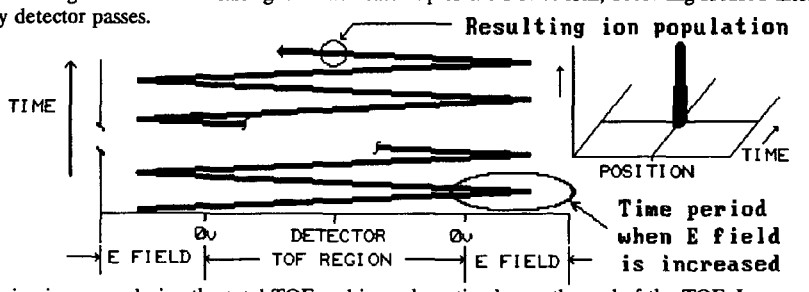
$$X_{focus} = 2\sqrt{X_A * X_B}$$

X_{focus} is independent of m/e and the electric field.



When they focus, the ions are detected not by impact but by induced charge, like ICR. The structure is mirrored for multiple reflections and detections to obtain the desired TOF. The ion population is a geometric distribution, and this arithmetic focus technique introduces errors that will limit resolution after 10,000 m/e.

B. For ions created at the same location (equipotential) but at different times, the ions are made to experience a small increasing electric field early in their flight, such as their first time through the reflecting field. The ions exiting later will catch up to the slower ions, becoming focused after many detector passes.



Focusing improves during the total TOF and is made optimal near the end of the TOF. Larger m/e's have broader normalized time spreads. Larger m/e's are slower and therefore experience this increasing electric field over a longer time. The longer time required to focus larger m/e's is compatible with the longer TOF distance required to provide separation. The focusing m/e range is limited by a smaller and faster m/e approaching this focusing electric field a second time as a larger m/e is just exiting the field.

A small detector size maximizes the induced charge caused by the passage of the focused ions. Two parallel detector rings with guard rings, and differential detection, are used to detect and obtain the ions' direction. A detector assembly has been tested by placing it between the filter and the Faraday cup of a UTI 100C Quad. MS. Room air was sampled and N_2 was detected at approx. $1*10^{-11}$a. This detector has been incorporated into a Variable Distance TOF MS structure described and is undergoing tests. The structure under test is 7 cm. long (excluding an external electron impact ionizer).

One signal processing approach is for constructive/destructive interference of the signal I(t), contributing to the intensity for all masses. A weighting phase factor depends on the true periodicity of each mass t_m. A Fourier series, not at discrete frequencies but at discrete "effective mass" intervals that are inversely proportional to the mass, is used. The higher the mass, the more terms (detections) must be included to resolve the m/e. The intensity of mass m:

$$S(m) = \sum_{j=1}^{n} I(t)\exp(2\pi i j t/t_m)$$

Ion Peak Shape Calculations and Time-of-Flight Mass Spectrometer Instrument Design

Richard C. King and *Kevin G. Owens, Department of Chemistry, Drexel University, Philadelphia, PA 19104

In previous work[1], a simplex optimization routine was used to design a reflectron time - of - flight mass spectrometer (TOFMS). The program uses minimum and maximum power supply voltages and the overall instrument length as the only limits for design. All voltages and distances inside the instrument are allowed to vary within these limits. The simplex response is calculated using a Monte Carlo method to simulate an ion peak from input initial temporal, potential energy and kinetic energy distributions. In addition to these initial distributions, the program takes into account the effect of electric field inhomogeneities near wire mesh grids on the detected ion peak width.

This work indicated that the use of grids to separate regions of different electric field does affect the performance and optimum design of a reflectron TOFMS. The work suggested that a grid material with more wires per inch would improve the instrument performance. The results also indicated that very long reflecting fields would improve resolving power. Unfortunately, both of these conditions will also work to reduce the ion transmission of the instrument. Since the previous version of the program did not consider the ion transmission as part of the simplex response, the optimum designs could show excellent resolving power but unrealistically low ion transmission. The work presented here uses the initial off axis velocity distribution along with the off axis velocity gained by passing through a grid to predict the loss of ions due to the off axis velocitiy. This, along with the optical transmission of the grid material, is used to estimate the ion transmission of the instrument.

Table 1.

	Ideal	70 LPI	110 LPI	300 LPI
TOF (ns)	115353.6	115279.2	115301.4	115337
Peak Width (Std Dev.)	2.88	23.7	7.53	3.21
Resolving Power	11.12	1.350	4.25	9.97
Optical Transmission (%T)	100	43.52	9.54	1.88
Initial Off Axis Velocity (%T)	54.30	25.26	6.06	1.08
Grid Effect (%T)	N.A.	3.70	2.14	0.12

Table 1 shows the results of placing different mesh size grids in an instrument designed on the assumption that the grids create no electric field inhomogeneities (ideal grids). The results shown are for gas phase laser ionization of a room temperature gas with a mass of 300 amu. When the grid effects are included, the resolving power decreases from that predicted by the ideal case. The resolving power increases by more than a factor of seven as the mesh size is increased from 70 LPI (90% optical T) to 330 LPI (61% optical T) while the ion transmission is reduced by 97%. Replacing the 70 LPI grids with 110 LPI grids will improve the resolving power

by a factor of three and reduce the in transmission by 42 %. To improve our understanding of the trade - off between ion transmission and resolving power in a TOFMS the effect of each source of ion loss was calculated at each grid in the instrument. This is shown in figure 2.

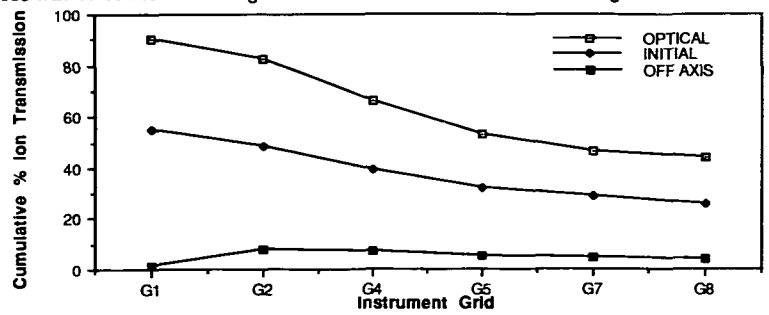

Figure 2.

The figure shows that for gas phase intial distributions with this instrument design, the off axis velocity gained by going through a grid is the largest contribution to the loss of ions; exceeding the losses due to the initial off axis velocity distribution and the optical transmission of the grids.

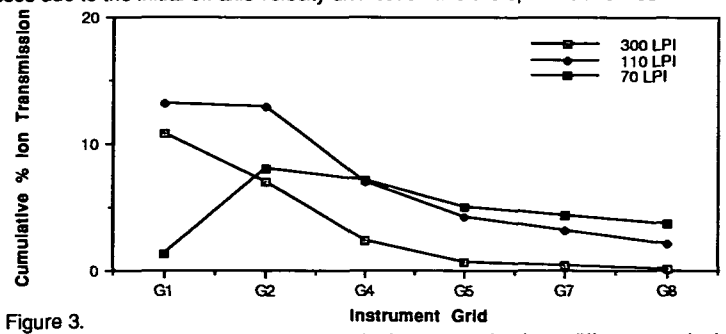

Figure 3.

Figure 3 shows the loss at each grid in the instrument for three different mesh size grids when all three contributions to ion loss are considered. The results indicate that replacement of the 70 LPI grid material in the source region (G1 and G2) will improve the ion transmission and possibly the resolving power of this instrument design.

Replacement of 70 LPI mesh grids with other grid materials may be a way of improving the performance of an existing design but a more efficient approach is to design the instrument taking grid effects into account. When the effects of electric field inhomogeneities are accounted for, a different instrument design is suggested by the simplex optimization routine. This design with 70 LPI grids has ten times better ion transmission and resolving power that is five times better than that found when 70 LPI grids were placed in the instrument designed assuming ideal grids.

Automation of Sample Analysis by Matrix Assisted Laser Desorption Mass Spectrometry.

J. P. Ricketts, C. W. Sutton, and *J. S. Cottrell, Finnigan MAT Ltd., Hemel Hempstead, Herts. HP2 4TG, UK.

Matrix assisted laser desorption mass spectrometry has become a widely accepted technique for the analysis of peptides, proteins, carbohydrates, and related materials. Time per analysis can be as short as three or four minutes, but much of this time is spent waiting to achieve a working vacuum after the sample has been introduced into the instrument. One approach to increasing throughput is to load multiple samples onto a single substrate so that they can be introduced into the vacuum system simultaneously.

We have developed an automatic sample handling system in which up to 48 samples may be deposited along a flexible strip which is then wound onto a rotatable drum inside the ion source. Sample loading spots are defined by concentric rings of surface roughness, (Figure 1). A droplet of half a microlitre will sit comfortably within the central spot, while larger drops, up to 1.5 microlitres, will overflow to fill the surrounding rings. Between each loading position is a cutout, which acts as a gutter to prevent adjacent samples mixing, should spots be grossly overloaded. The autosampler mechanism just hooks onto the side of the Lasermat in place of the standard sample loading hatch One feature of the design is that the autosampler mechanism permits one of the standard single sample targets to be placed in front of the drum even though a strip is already wound onto the drum. This means that it is possible to interrupt the analysis of a long sample strip to slip in a single "emergency" sample.

For unattended operation, the Lasermat software uses a spreadsheet approach. This enables all instrument control and data processing parameters to be manipulated for individual samples while still providing an overview of the entire analysis at a glance. Figure 2 shows a portion of this spreadsheet, termed a "Sequence Table" Each row of the Sequence Table represents a single analysis and the columns delimit the parameter sets which control each aspect of instrument operation and data processing At the top of the Sequence Window is general header containing information such as the filename root which will be used to generate filenames when saving data to disk. The Sequence Table allows for up to 999 rows, equivalent to 20 sets of independent analysis conditions for each of 48 samples Each cell of the Sequence Table contains the name of a parameter set. For example, AUTOSAMP REP is the name of a disk file containing a unique set of parameters to control the display of data on the screen, the saving of data to disk, and the generation and printing of reports. By clicking the mouse on any cell of the Sequence Table, a dialog box is invoked containing the full parameter set for inspection or editing.

The throughput of the autosampler has been benchmarked at 1 minute per sample using a 486 PC. This is for averaging 10 laser shots, performing peak detection and calibration, saving the data to disk, and printing out a single page summary containing the spectrum.

PRIMARY ION PRODUCTION FROM VARIOUS GASES FOR SPONTANEOUS DESORPTION MASS SPECTROMETRY

M.A. Park and E.A. Schweikert, Chemistry Department, Texas A&M University, College Station, TX 77843

It is now apparent from the literature that the spontaneous desorption (SD) of spontaneous desorption mass spectrometry (SDMS) is due to a backsputtering process [1]. According to the backsputtering mechanism, primary ions are generated by field desorption from the wires of a grid immediately in front of the sample. These primary ions are accelerated to keV kinetic energies by the electric field between the sample and grid. When the ions strike the sample, they cause the emission of secondary ions and electrons. In the large majority of studies, the secondary electrons are used to identify the time of impact of a primary ion.

One of the difficulties associated with SDMS is that the nature of the primary ions striking the sample is largely unknown. In the present study, we examine the nature and origin of the primary ions by measuring the count rate and yield of secondary particles as a function of the pressure of residual gases in the chamber. The instrument used for these SD studies has been described in detail elsewhere [2]. Briefly, it consists of a sample deposited on a flat, stainless steel sample holder, a high transmission grid at ground (90% transmission, Buckbee-Mears, St. Paul, Minn.) parallel to and a few millimeters from the sample surface, a field free drift region, and a microchannel plate (MCP) detector. The sample and MCP detector are located on opposite sides of the drift region. Ion flight times were measured using a time-to-digital converter produced at IPN in Orsay, France [3]. A single CsI sample was used throughout these experiments.

For the purpose of these experiments, it was assumed that the number of primary ions corresponds to the number of start signals. Both the primary ion and I^- secondary ion count rate were measured as a function of the pressure of methanol and trichloroethylene (TCE) in the chamber. The primary ion and I^- count rates show a roughly linear increase in primary ion count rate with pressure. This is what one would expect if field ionization were responsible for primary ion production. The rate of ion production by field ionization is proportional to the concentration (pressure) of molecules in the ionization region.

For methanol, the increase in primary ion count rate is observed above the contaminant type primary ion count rate only at pressures of methanol above about 2 X 10^{-5} torr. In contrast, TCE shows no such "appearance" pressure. This may be explained within the field ionization model as due to a difference in ionization potentials (IP_{MeOH} = 10.85 eV, IP_{TCE} = 9.47 eV). That is, a molecule of higher ionization potential would have a lower probability of being ionized in a given time period thus a higher pressure would be required to produce a given ionization rate.

The count rate of I^- does not increase as rapidly with pressure when methanol is used as the introduced gas as when TCE is used as the introduced gas. This may be an indication that primary ions produced from TCE are more efficient at sputtering I^- than those produced from methanol. This difference in efficiency can readily be explained as

an effect of the difference in the mass and complexity of TCE and methanol molecules (132 amu vs. 32 amu) and therefore presumably the primary ions produced.

The percent yield of I^-, $\%Y(I^-)$, as a function of pressure was calculated using:

$$\%Y(I^-) = \{ N(I^-_e) / S \} \times 100\%$$

where $N(I^-_e)$ is the number of counts in the I^-_e peak, and S is the number of starts signals. The change in percent yield with pressure was roughly linear. However, yields calculated this way are not the I^- yields due to methanol or TCE type primary ions but the average of yields from all primary ions produced at a given pressure. By subtracting the I^- and primary ion counts due to contaminant type primary ions, the "true" yield from introduced gas type primary ions can be calculated. The "true" I^- yield from methanol and TCE type primary ions was found to be 0.16 ± 0.01% and 0.42 ± 0.02% respectively compared to 0.6 ± 0.1% from contaminant type primary ions. This seems to indicate not only that the TCE type primary ions are more massive/complex than methanol type primary ions but that the contaminant type primary ions have a higher mass/greater complexity than methanol or TCE type primary ions. The results of PDMS analyses of frozen residual gas show that this may be the case. This analysis produced ions indicative of pump oil (m/z = 149, m/z = 393).

The order-of-magnitude larger error bar seen above on the I^- percent yield from the contaminant vs. TCE type primary ions is due to the fact that over the course of about one day, the I^- yield from the contaminant type primary ions changed from 0.75 ± 0.02% to 0.52 ± 0.02% while that from TCE changed from 0.44 ± 0.01 to 0.40 ± 0.03%. This indicates the nature of contaminant type primary ions changed over the course of the experiments. Most likely, this is a result of a change in the composition of the contaminant near or on the grid wires.

The $\%Y(I^-)$ from TCE type primary ions is observed to become constant vs. pressure at 0.43 ± 0.02% (the "true" yield from TCE type primary ions) at pressures above about 1.5 X 10^{-5} torr. This indicates that the contaminant type primary ions do not influence the measurement above this pressure. This opens the possibility of performing reproducible quantitative SDMS measurments in a manner similar to that of secondary ion mass spectrometry.

The reversibility and reproducibility of both the primary ion count rate and secondary ion yield were shown by measuring the primary ion count rate and secondary ion yield as a function of time while changing the pressure of the introduced gas from about 10^{-7} to about 4 X 10^{-5} torr or vise versa at irregular intervals. The results for both methanol and TCE show little change in the primary ion count rate or yield from one cycling of the pressure to the next.

Analytical Characteristics of an Inductively Coupled Plasma-Time-of-Flight Mass Spectrometer (ICP-TOFMS)

***D. P. Myers, G. Li, G. M. Hieftje, Department of Chemistry, Indiana University, Bloomington, IN 47405**

Introduction

Research in our laboratory has recently focused on coupling an atmospheric-pressure plasma with a time-of-flight mass spectrometer (TOFMS). Specifically, we have employed an inductively coupled plasma (ICP) as the ion source. In general, the inductively coupled plasma-mass spectrometer (ICP-MS) has emerged as a powerful instrument for performing trace multielement analysis. Historically, ICP-MS instruments have employed quadrupole or double-focusing sector mass analyzers. Yet, a TOFMS potentially offers more speed, simultaneous extraction/analysis of all masses, and equal or better sensitivity than quadrupole mass spectrometers now used in ICP-MS. The TOFMS constructed in our laboratory employs right-angle extraction of the continuous supersonic ion beam generated by the ICP. This orthogonal sampling of the beam is similar to that in instruments described previously (1-5), and offers improved resolution, sensitivity, and duty factor over in-line beam-modulation techniques (2,5).

Instrument Description/Methods

The mass spectrometer includes a three-stage differentially-pumped vacuum chamber interfaced to a time-of-flight mass spectrometer constructed by R.M. Jordan Co. (Grass Valley, CA). The ICP is sampled through a 0.75-mm orifice to create a supersonic expansion, which is skimmed 10 mm downstream of the sampling orifice. These ions are extracted through a 1.3-mm orifice into the low-pressure stage (1 X 10^{-5} Torr) of the interface. In this stage the ions are focused into the right-angle extraction zone with a simple einzel lens arrangement. A 2.5-mm slit placed in the last element of the einzel lens reduces divergence of the ions entering the orthogonal sampling zone. Three extraction configurations were tested for the mass spectrometer. Each configuration was compared for ion noise, sensitivity, and resolution. The best configuration is shown in figure 1. In this setup the acceleration field (G2) was dropped linearly across 4 rings (2.54-cm) to the entrance grid (G1) which was maintained at ground while the repeller (R) is pulsed positive.

Results

Ion noise from the continuous ion beam has been an ongoing problem in our ICP-TOFMS, and all three extraction geometries produced different levels of ion noise in single-shot spectra. Unfortunately, the highest level of ion noise was seen in the configuration shown in figure 1. This ion noise is largely due to the highly divergent ion beam exiting the last element of the einzel lens. Still, the best resolution and sensitivity were seen with this configuration. A resolution (FWHM) of 500 has been obtained with proper optimization of the center element of the einzel lens. However, this optimization causes a resulting loss in signal intensity. Figure 2 shows the resolution of Pb and Bi, the two heaviest non-radioactive elements which are separated by one mass unit. Figure 3 shows resolution (R) and signal-to-noise ratio (S/N) versus the potential of the center element of the einzel lens.

Another interesting characteristic of this mass spectrometer is the effect of mass-independent velocities in the supersonic beam. The steering plates shown in Figure 1 compensate for the velocity component of the ion beam orthogonal to the TOF direction. Because the supersonic beam has all ions of the same velocity, ions of higher mass have greater energy. Therefore, the steering of these ions with electric fields is biased. In figure 4, ion signals for light to heavy ions as a function of steering voltage show this effect. The current sensitivity of the instrument is about 500 ppb for lighter elements and increases to about 1 ppm for heavier ions.

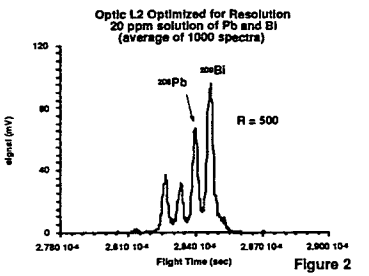

Figure 2

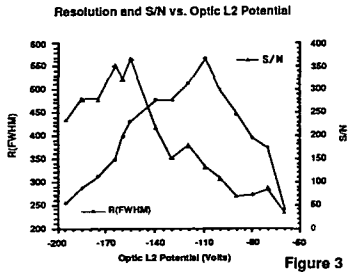

Figure 3

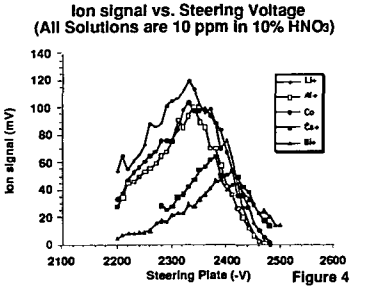

Figure 4

Conclusions

The orthogonal TOFMS we have constructed exhibits unit-mass resolution for the elements; however, the sensitivity is still much worse than quadrupole-based ICP-MS instruments. Presumably, the sensitivity will improve by incorporating better ion optics which focus ions in the supersonic beam into the plane of orthogonal extraction. In addition, the current resolving power of 500 may not insure the abundance sensitivity expected in conventional ICP-MS instruments. Work is underway to use an ion mirror to improve resolution.

CORRELATION MEASUREMENTS FOR THE DETERMINATION OF THE STRUCTURE OF SOME ALAMETHICIN PEPTIDES

N. Poppe-Schriemer[1,2], W. Ens[1], J.O'Neil[2], K.G.Standing[1], J.B.Westmore[2], A.Yee[2],
Departments of Physics[1] and Chemistry[2], University of Manitoba, Winnipeg, Canada.

Introduction

The alamethicins are a series of antibiotic peptides produced enzymatically (*ie* not from RNA) by the fungus *Trichoderma viride*. The amount of each peptide produced, and perhaps also its sequence, is sensitive to the environment in which the fungus is grown. The sequences of the two main components of the alamethicins grown under standard conditions are known. An alternative preparation method gives a different mixture of components[1]. We report our work on some of these components.

Experimental

Secondary ion mass spectrometry was used with both the linear and the reflecting modes of our time-of-flight spectrometer, TOF II[2], to give sequence information for alamethicin III. In the reflecting mode, correlation techniques[3,4] were used to examine the daughter ion spectra of the molecular ion and the prompt fragments.

Much of the peptide sequence could be inferred from the direct spectrum with the mirror off. Since the alamethicins are unusually metastable, most of the sequence was confirmed using the correlation technique.

Results

An extensive series of B ions, as well as some A and C+2 ions, was observed in the direct spectrum, with corresponding neutral peaks in the neutral spectrum. The only C terminal ions observed clearly were Y_7+2 and Y_{19}+2, both corresponding to cleavage before Pro residues.

Many correlation spectra were taken to study the unimolecular decay of parent ions for several of the alamethicins. A few examples of alamethicin III are shown in figure 1. All other alamethicins examined show similar decay patterns and a comparable wealth of sequence information.

The $(M+H)^+$ ion decays into a partial series of B ions, the Y_7+2 ion and a few internal fragments beginning at Pro_2. The daughters of the B ions were predominantly B ions and a series of ions with Pro_2 at the N terminal end. The daughters of the Y_7+2 ions are predominantly (Y_7B_n) fragments.

The molecular ion region of the 23.33 minute HPLC fraction has *two* peaks. Examination of the correlation spectra shows that an amino acid substitution occurred at position 6 as shown in figure 2. The mass differences are consistent with a partial interchange between Ala and Aib. Other correlation spectra and the molecular ion peaks suggest that a partial interchange between Glu and Gln at residue 18 has occurred, in conjunction with the first interchange. Subsequent chromatography confirmed that two peptides were present and that one had an ionizable group.

The first fourteen amino acids of the 24.53 minute fraction are like those in the 23.33 A and B fractions. The Y_7+2 coincidence spectra suggest a partial interchange between Aib and Val at position 17 which would be consistent with the molecular masses if an interchange between Gln and Glu is also present.

Conclusions

All of the alamethicins examined so far are rich in α-aminoisobutyric acid(Aib), and have an acetyl group at the N terminus and a phenylalaninol at the C terminus.

The 21.34 minute fraction (alamethicin III) has the following sequence:

$$Ac\text{-}Aib_1\text{-}Pro_2\text{-}Aib_3\text{-}Ala_4\text{-}Aib_5\text{-}Ala_6\text{-}Gln_7\text{-}Aib_8\text{-}Val_9\text{-}Aib_{10}\text{-}Gly_{11}\text{-}Leu_{12}\text{-}Aib_{13}\text{-}Pro_{14}\text{-}Val_{15}\text{-}Aib_{16}\text{-}Aib_{17}\text{-}Gln_{18}\text{-}Gln_{19}\text{-}Phe_{20}\text{-}ol$$

The 23.33 minute fraction, A (alamethicin I) is as above, except for a Gln/Glu interchange at at position 18. The 23.33 minute fraction, B(not yet named) has an Aib at position 6 and a Gln at position 18. Investigations are continuing to finalize the sequence determination of the three peptides in the 24.53 minute chromatography peak.

The overlapping peptide maps obtained by the correlation method are a useful means of determining the sequence and also provide information regarding the decay of closely related ions. The peptides were very susceptible to cleavage before the Pro residues, as was also observed for neutralized bradykinin[5]. This cleavage occurred more often for unimolecular decay than for fast fragmentation. However, fast fragmentation allowed the charge to be on either side of the broken bond. We plan to investigate all these effects in greater detail.

HIGH-SPEED DATA ACQUISITION AND PROCESSING SYSTEM FOR TIME-OF-FLIGHT MASS SPECTROMETRY

Edgar D. Lee and Harold G. Lee, Sensar Corporation, Sandy, Utah 84070

One of the limitations of time-of-flight (TOF) mass spectrometry in the past has been that the majority of the data generated was lost because the acquisition system could not acquire and save the data at the same rate as it was produced from the mass spectrometer. In the recent past processor based timed array detection schemes and digital storage oscilloscopes have been developed and continue to improve to accommodate larger and larger amounts of data.

The ideal data acquisition system for TOF-MS would want to be as flexible as possible allowing for a wide rang of experiments to be performed. These would include both static such as laser desorbtion mass spectrometry and dynamic such as chromatography mass spectrometry applications. Also the ability to profile the peak shapes in the mass spectrum, collect and save mass spectra simultaneously, process data as it is acquired, assist with user interpretation, and be expandable for future improvements in technology would be desired characteristics of such a system.

This data acquisition system (Figure 1.) acquires an analog signal, converts it to digital data, and compresses the large volume of accumulated data into a format that can be handled in a microcomputer environment. The system can operate in two modes:

1. Burst mode, optimized for speed (500 Msamples/sec), in which data is continuously collected with 2 nanoseconds of resolution without loss of data.

2. Pass through, optimized for signal averaging and data storage (up to 2 gigabytes), in which data is continuously collected and averaged with 2 nanoseconds of resolution for long periods of time and no data loss.

The uniqueness of this system lies in its ability to rapidly and continuously acquire and process large volumes of data and to compress and store that data uninterruptedly. Because of its signal averaging and data compression algorithms, the system can be used for applications that require uninterrupted high-speed sampling over long periods of time.

This high speed data acquisition system is designed to take advantage of the major benefits of both non-averaging and averaging. That is, when single shot data (no averaging) is desired, the system acquires and passes data uninterrupted. When averaging is required, the system acquires, averages, and passes averaged data, again, uninterrupted.

There are several paths that can be taken, depending upon the type of data requested in the long term storage area. Because averaging occurs in real time, the averaging decision has little impact on the balance of operations. The decision to average is made prior to each test and cannot be changed during a test. If averaging is to occur, the lone variable associated with it is the number of averages to be taken. Again, if averaging is active, it occurs essentially as a background task to the remaining operations and has little or no influence over their timing.

A second variable in the main system flow is the decision of whether or not to use the burst storage area. The burst storage area is a high speed memory storage area designed to accommodate single shot data through the ADC in real time. As it is very high speed, it is also depth limited. Additionally, its use precludes the downloading of data into the long term storage area without terminating the acquisition cycle. Therefore, the accepted tradeoffs for using burst storage are twofold: the test length is limited, and the test must stop during the period when data is being offloaded from the burst storage to the long term storage.

The decision of whether or not to use the burst area is based on the data throughput requirements. If the burst mode is not used, data flows *via* a high speed bus to the long term storage area. Therefore, if the transfer speed is sufficient, the burst area need not be used. Note also that the data is transferred after averaging has occurred, providing extreme advantage if averaging is in place.

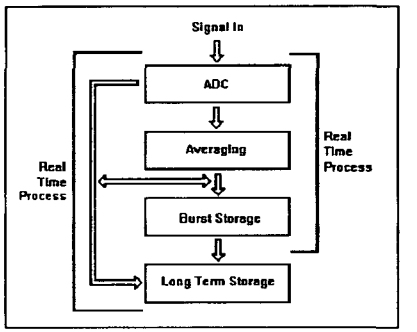

Figure 1

SUB-PPB DETECTION OF IMPURITIES IN HIGH PURITY GASES BY ATMOSPHERIC PRESSURE CHEMICAL IONIZATION TIME-OF-FLIGHT MASS SPECTROMETRY

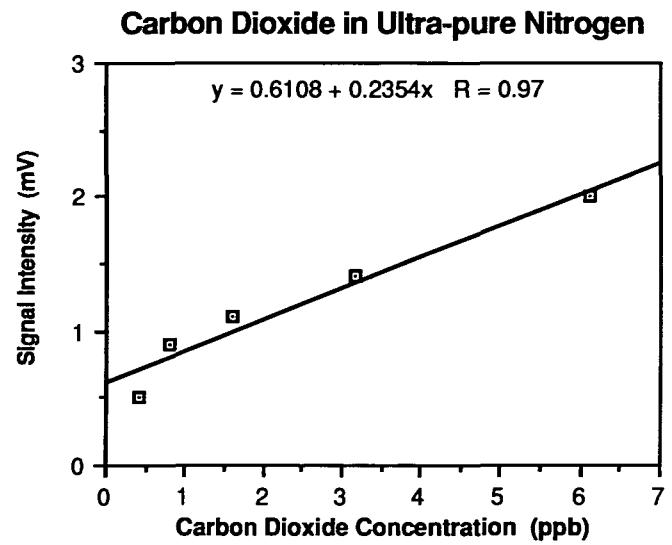
Karin E. Markides, Fred J. Haydock, Chung Hang Sin, and Edgar D. Lee,
Sensar Corporation, 479 West Universal Circle, Sandy, UT 84070, USA

Sensitive and fast detection of impurities in gases are becoming more and more important in semi-conductor manufacturing industries. A new type of time-of-flight mass spectrometer (TOFMS) has been developed to meet these challenges. This TOFMS utilizes an efficient corona discharge source for ion production. Also, the flight tube is configured perpendicularly to the ion beam so that the duty cycle is dramatically improved.

In the ion source, the corona discharge initiates a series of ion-molecule reactions at atmospheric pressure. Nitrogen and water are the major reactant ions. Through charge transfer, ions are produced from the analytes. The ionization efficiency can be as high as 100% for trace analytes. The ions are then introduced into the mass spectrometer chamber by supersonic expansion through an orifice. As the ion beam fills up the ion pulsing region, an electric pulse will push all of the ions in that region into the flight tube. Because the ion beam is perpendicular to the flight tube, no neutrals will be sent to the detector. The perpendicular orientation also makes it easier to prevent the ion beam from interference. The mass resolution in a TOFMS depends very much on the velocity distribution of the ions. The supersonic expansion also helps in narrowing down this distribution and thus improves the mass resolution.

Another advantage of the perpendicular orientation is that the duty cycle of ion sampling can be improved dramatically. If the ion beam is parallel to the flight tube, very narrow pulses (*e.g.*, 100 ns) must be used for maintaining a reasonable mass resolution. This is because the flight time is in the μs regime. However, in a perpendicular orientation, an electric pulse can be applied long enough for all of the ions inside the pulsing region to enter the flight tube without worsening the mass resolution. Unlike the on-axis case, all ions in the region will move at the same time once the pulse is switched on. As a result, the number of ions sampled per pulse are orders of magnitude greater than in the case of on-axis beam introduction. The ion sampling duty cycle can actually approach 100%. The use of an atmospheric pressure ion source makes it very convenient for direct gas and vapor monitoring. The current emphasis is to develop this TOFMS for gas impurities analysis. As shown in the following figure, sub-ppb detection limits are achievable for trace impurities in high purity nitrogen.

In addition to sensitivity, this TOFMS is also extremely fast. It is useful for capturing transient signals such as those found in chromatography and flow injection. A fast data acquisition system is being developed for storage and averaging the fast incoming data from this instrument. Due to its sensitivity and speed, this TOFMS is also suitable for on-line monitoring in processing stream and detection of illegal chemicals.



THE E_2/E_1cb MECHANISM IN THE GAS PHASE: COMPETITIVE LEAVING GROUP EFFECTS. John E. Bartmess*, Terry Sumpter, John Farrar, Kurt Wiegel, and Robert Holman, Dept. of Chemistry, Univ. of Tennessee, Knoxville TN 37996-1600, and Dept. of Chemistry, Western Kentucky Univ., Bowling Green KY 42101.

A persistent problem in ion/molecule chemistry is the narrow time/pressure window that is available for reactivity measurement. Reactions with small transition state barriers are insensitive to structural effects, proceeding at collision rate. A method is needed to probe the TS effect on the observed kinetics, separate from the dominating effect of the collision rate.

For example, CH_3CH_2Cl and CH_3CH_2Br both yield halide at collision rate on reaction with hydroxide. Even for Et_2O as substrate, the rate constant for the poor leaving group ethoxide is only a factor of four slower, giving a Brønsted coefficient of 0.02! Only if ΔH_{rxn} is less than ca. 10 kcal/mol (much weaker base) are large leaving group effects on the rate constant seen. No general differentiation of kinetic leaving group ability can thus be made.

The solution to this is to use <u>competitive reactive groups</u> within a single molecule. The collision rate cancels out, and the ratio of two possible products reflects the internal barriers leading to each. We choose the elimination reaction as a demonstration of this effect.

All ion/molecule work was done with the Tennessee ICR spectrometer, using rapid scan detection. This is a more accurate mode than FT-ICR for intensity measurements. Care must be taken to avoid contamination of the neutral compound RY with HY impurities. This could be detected as a rapid rise of one leaving group anion (proton transfer), and a more gradual increase in the other (elimination). For pure compounds, both leaving groups appeared at the same rate, but in the varying ratios.

We must also define the thermochemistry of the systems involved. Leaving group abilities are evaluated as ΔH_{elim}, the enthalpy of:

$$CH_3CH_2Y \rightarrow H^+ + CH_2{=}CH_2 + Y^-$$

This, minus ΔH_{acid} for the conjugate base of some acid XH, yields ΔH_{rxn} here:

$$X^- + CH_3CH_2Y \rightarrow XH + CH_2{=}CH_2 + Y^-$$

Thermochemistry of EtY Elimination:

Y-	ΔH_{elim}	Y-	ΔH_{elim}	Y-	ΔH_{elim}
MeO-	396.3	$MeCO_2$-	364.3	Cl-	350.3
$tBuCH_2O$-	387.3	$EtCO_2$-	363.2	Br-	342.7
CF_3CH_2O-	377.7	$iPrCO_2$-	361.8	CF_3CO_2-	339.6
PhO-	364.8	$ClCH_2CO_2$-	352.2		

Due to the entropy factor (2 species -> 3 species), a base with ΔH_{acid} up to 9 kcal/mol weaker than ΔH_{elim} should still be able to react.

$ClCH_2CH_2CH_2Br$ was first chosen, as a molecule with a common proton leading to elimination of either halide; the <u>molecule</u> chooses the better leaving group.

Base	$\Delta H_{rxn}(Br^-/Cl^-)$	Br^-/Cl^-
$MeCO_2^-$	-5.9/+1.7	>100
$iPrCH_2CH_2O^-$	-32/-23	ca. 95
HO^-	-48/-40	4

At equilibrium, Br^- would be favored by 10^6. It requires ca. 40 kcal/mol of exothermicity to even start to approach parity in reactivity/ selectivity.

Carboxylate esters were then chosen as the leaving groups. These can be closely balanced as leaving groups so should be more sensitive probes. Also, (1) the thermochemistry is precisely known, (2) the atoms forming the breaking bond are constant, and (3) the change in reactivity is due solely to a "distant" substituent.

Results:

	$MeCO_2$-$CH_2CH_2CH_2$-O_2CR				$MeCO_2$-CH_2CH_2-O_2CR		
R	ΔH_{rxn}	Base	$RCO_2^-/MeCO_2^-$	R	ΔH_{rxn}	Base	$RCO_2^-/MeCO_2^-$
Et	-16.3/-17.5	MeO^-	1.6	Et	-18.0/-19.1	MeO^-	1.26
	-6.6/-7.7	F^-	2.45		-8.1/-9.2	F^-	2.37
iPr	-16.3/-18.8	MeO^-	10.0	iPr	-18.0/-20.5	MeO^-	4.0
	-6.6/-9.1	F^-	50.0		-8.1/-10.6	F^-	12.0
CF_3	-16.3/-41.0	MeO^-	>100.0				

Note that the better leaving group is always favored, and the moreso, the less exothermic the reaction is.

For the glycol substrate, where the protons being lost are not the same, the selectivity is less. We attribute this to polarizability effects:

$MeCO_2$-$\bar{C}HCH_2$-O_2CR is less stable than $MeCO_2$-$CH_2\bar{C}H$-O_2CR based on the size/ polarizability of the proximal alkyl groups. To the extent that negative charge is present in the transition state, the poorer leaving group is favored. This parallels our earlier studies of E_1cb reactions.

For Cl-$CH_2CH_2CH_2$-O_2CCH_2Cl, the leaving groups are comparable thermochemically (Cl^- 2.1 kcal/mol better in ΔH_{elim} than $ClCH_2CO_2^-$). Cl^- is the only product observed for reaction with MeO^- or F^-. This is a more subtle transition state probe, using electronegativity.

For Cl-$CH_2CH_2CH_2$-O_2CCF_3, now the $CF_3CO_2^-$ group is the major product (36:1 with MeO^-): thermochemistry overcomes the electronegativity effect at 10.7 kcal/mol better leaving group ability.

We thank the National Science Foundation for support of RWH through the Summer Research Program in Chemical Analysis, grant CHE-9023377.

BY WHAT MECHANISMS DO ANIONIC NUCLEOPHILES REACT WITH DI-*tert*-BUTYL PEROXIDE?

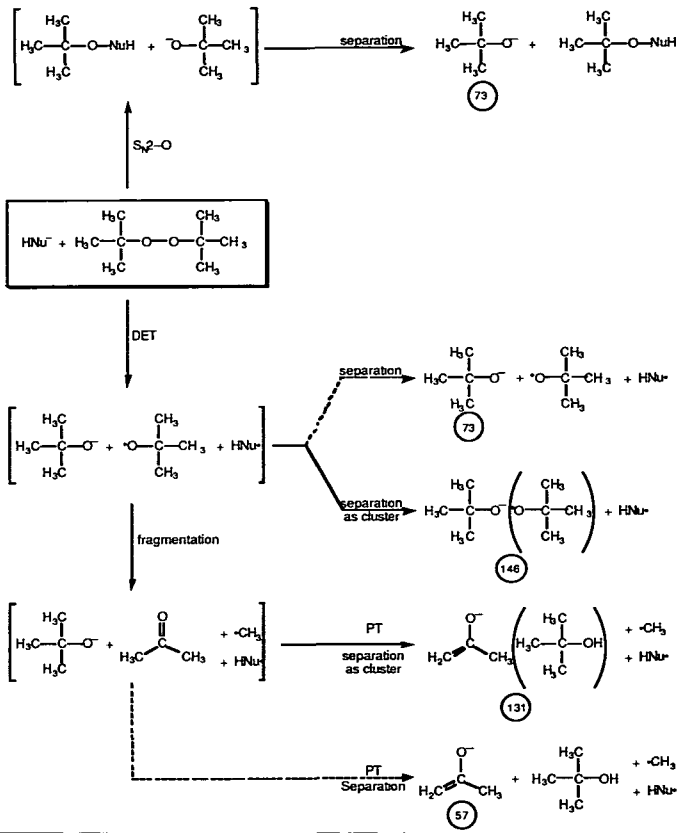
Joseph J. Grabowski,† Jeehiun Lee§ and V. Murugesan†
Departments of Chemistry,
†University of Pittsburgh, Pittsburgh, PA 15260
§Harvard University, Cambridge, MA 02138.

The organic chemistry of peroxides has a long history; such species are key players in many areas, ranging from the immune response to polymerization initiators to bleaches and disinfectants to key ingredients in stereospecific synthetic procedures to oxidation chemistry in atmospheres. Inorganic peroxides are also widely involved as intermediates in a variety of processes; for example, Cl_2O_2 is a intermediate in the catalytic destruction of ozone. While the synthesis, characterization and transformations of peroxides are well-documented in the literature, surprisingly little consensus is available about the detailed mechanisms by which organic peroxides react. Many condensed phase mechanistic studies have been hampered by the high reactivity of these compounds (low O-O bond dissociation energy) and the difficulty in distinguishing between electron transfer and nucleophilic pathways. In an effort to improve our understanding of the mechanisms of these molecules, we have been investigating their reactions in the gas-phase.

We have examined the thermally-equilibrated (298 K), gas-phase, ion-molecule reactions of di-*tert*-butyl peroxide with a large number of anionic nucleophiles by means of the flowing afterglow technique. Special care was taken to ensure proper identification of any chemical reaction occurring via free electrons. Inspection of the data set (not shown) reveals that a E2 mechanism by which dialkyl *ethers* react is essentially absent for the peroxide (only minor amounts of $t\text{-BuOO}^-$ is ever found). Further examination of the data reveals that there are two classes of reactions: the first of which yields primarily *m/z* 73 ($t\text{-BuO}^-$) from ions such as H_2N^-, RO^-, $C_6H_5^-$, $CH_3SCH_2^-$ and $PhCH_2^-$; and the second of which yields primarily *m/z* 131 and 146 from ions such as $H_2C{=}CH\text{-}CH_2^-$, NO^- and O_2^-. Reaction rates vary, representative data are: H_2N^- displaying a reaction efficiency of 95%; HO^-, 99%; $H_2C{=}CH{-}CH_2^-$, 1.1%; MeO, 88% and NO^-, 37%.

The predominance of the *m/z* 131 product for anionic nucleophiles that are relatively weakly bound (EA < 0.5 eV) is diagnostic of a dissociative electron transfer process since *t*-butoxy radicals are well known to undergo unimolecular fragmentation to acetone and a methyl radical. We therefore postulate that $H_2C{=}CH\text{-}CH_2^-$, NO^- and O_2^- react primarily, if not exclusively, by the DET process shown in the bottom half of the scheme. This assignment is further supported by the correlation of the rates of these reactions with the anion binding energy.

The other pathway that produces *m/z* 73 as the predominant ion could either be a nucleophilic substitution at oxygen, a concerted proton transfer-internal displacement at oxygen to produce *m/z* 73 and an epoxide, or an E2 followed by fast and extremely, efficient epoxidation by the formed peroxide anion of the alkene product *within* the product ion-molecule complex. There are difficult aspects with each of these three mechanisms; the attached scheme shows the simplest of these three mechanisms for convenience. It seems likely that additional work now in progress will allow us to rule out the concerted proton transfer-internal displacement while initial examination of the second step of the third mechanism suggests that it too is an unlikely process.



New Insights into the Gas Phase Anion Chemistry of Nitrous Oxide.

*Richard A.J. O'Hair, Scott Gronert and Charles H. DePuy
Department of Chemistry & Biochemistry, University of Colorado, Boulder CO 80309-0215

Nitrous oxide has proven to be a useful reagent gas for the determination of carbanion structure via gas phase ion-molecule reactions. Previous studies have demonstrated its utility at distinguishing isomeric anions and have revealed its diversity of reactions.[1, 2] The mechanistic pathways for such processes are not immediately obvious since all three atoms of N_2O are potential sites of attack.

We have studied the kinetics and products of a wide range of reactions between various anions and N_2O (Table 1) in a flowing afterglow-selected ion flow tube (FA-SIFT).[3] Many of these reactions are best explained by mechanisms involving initial attack of the anion at the terminal nitrogen of N_2O to form an energized diazenyl oxide anion intermediate [R-N=N-O$^-$] which then undergoes either proton transfer or rearrangement followed by decomposition (eqn. 1). Recently we have discovered a way of synthesizing the proposed intermediate (eqn. 2).[4] By carrying out this reaction in the source flow tube of the FA-SIFT, we are able to subject the diazenyl oxide anions to CID reactions (eqn. 3). The products of these CID reactions (eqn. 3) are the same as those observed in the direct reaction of R$^-$ with N_2O (eqn. 1).

Further evidence to support the intermediacy of the diazenyl oxide anion comes from a study of the reaction of the phenyl anion with N_2O. Two products are observed: the phenoxide ion and an adduct. The structure of this adduct was probed by CID (Figure 1a). It exhibits a virtually identical CID spectrum (Figure 1b) to that of the diazenyl oxide anion Ph-N=N-O$^-$, synthesized in the source (eqn. 2). We therefore propose the mechanism shown in Scheme 1 to account for this reaction.

$$R^{\cdot} + N_2O \longrightarrow [R\text{-}N{=}N\text{-}O^{\cdot}] \longrightarrow \text{PRODUCTS} \qquad (1)$$

$$RNH^{\cdot} + R'ONO \longrightarrow R\text{-}N{=}N\text{-}O^{\cdot} + R'OH \qquad (2)$$

$$R\text{-}N{=}N\text{-}O^{\cdot} \longrightarrow \text{PRODUCTS} \qquad (3)$$

CS_2 is often used to probe the reactivities of gas phase ions, and especially as an electrophile with anions. Regioselectivity has been often observed. For example, Sheldon et al. have studied the reaction of H_3Si^- with CS_2, which by a regioselective attack at a sulfur atom leads to H_3SiS^- and CS.

In the course of a study on gas phase anion-molecule reactions induced by CS_2 as an electrophile, we have observed that in a CH_4/N_2O chemical ionisation source CS_2 yields two anions, $CS_2^{\cdot-}$ and CHS_2^- in about a 3/1 ratio. The latter ion is generally referred to in the litterature as being the dithioformate anion. We have got evidence that it is actually a mixture of HS-CS$^-$ and H-CS_2^- having both a regiospecific reactivity toward CS_2. These findings have been confirmed by 6.31G^{++} ab initio calculation.

Gas-Phase Chemistry of Halocarbene Radical Anions: Acidities of Radicals and the Related Molecules

Monique Born, *Steen Ingemann and Nico M. M. Nibbering

Institute of Mass Spectrometry, University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

The gas-phase ion/molecule reaction of the atomic oxygen radical anion with halogen substituted methanes, CH_3X (X = F, Cl, Br and I), in a Fourier Transform Ion Cyclotron Resonance (FT-ICR) instrument results in the formation of $^{-}{}^{\cdot}CHX$ carbene radical anions by a formal $H_2^{+\cdot}$ abstraction (eq. 1).

$$O^{-\cdot} + CH_3X \longrightarrow {}^{-}{}^{\cdot}CHX + H_2O \qquad (1)$$

Based upon the occurrence/non-occurrence of proton transfer in the reactions of the halocarbene radical anions with selected reference acids, the gas-phase acidities (ΔH^{o}_{acid}) of the $^{\cdot}CH_2X$ radicals have been determined (see Table).

Table. Gas-phase acidities of the CH_3X and $^{\cdot}CH_2X$ species together with C-H bond dissociation energies (BDE) and electron affinities (EA) (all values in kJ mol^{-1})

X	ΔH^{o}_{acid} $^{\cdot}CH_2X$	BDE $^{\cdot}CH_2X$	EA CHX	ΔH^{o}_{acid} CH_3X	BDE CH_3X	EA $^{\cdot}CH_2X$
F	1662 ± 9	402	52 [a]	≈ 1716 [b]	423 [c]	19
Cl	1607 ± 10	412	117 [a]	≈ 1657 [b]	422 [c]	77
Br	1589 ± 8	417	140 [a]	≈ 1643 [b]	427 [c]	96
I	1559 ± 11	409	162 [a]	≈ 1617 [b]	433 [d]	128

[a] Taken from ref 1. [b] From ref 2. [c] From ref 3 [d] Taken from ref. 4

The acidities of the $^{\cdot}CH_2X$ radicals in combination with the known electron affinities (EA) of the CHX carbenes[1] (Table) lead to the following heats of formation of the CHX carbenes: ≈ 150 kJ mol^{-1} (CHF), ≈ 320 kJ mol^{-1} (CHCl), ≈ 370 kJ mol^{-1} (CHBr) and ≈ 420 kJ mol^{-1} (CHI). The acidities lead also to the homolytic C-H bond dissociation energies (BDE) of the $^{\cdot}CH_2X$ radicals with use of eq. 2. An approximately constant value

for the C-H BDE is obtained indicating that the increase of the acidity in the series $^{\cdot}CH_2F$, $^{\cdot}CH_2Cl$, $^{\cdot}CH_2Br$ and $^{\cdot}CH_2I$ is determined by the electron affinities of the carbenes.

$$\Delta H^{o}_{acid} = BDE(^{\cdot}CH_2X) - EA(CHX) + IE(H^{\cdot}) \qquad (2)$$

A similar situation applies to the CH_3X molecules, i.e. the increase of the acidity in the series CH_3F, CH_3Cl, CH_3Br and CH_3I is a result of the trend in the electron affinities of the $^{\cdot}CH_2X$ radicals (Table).[2] For a given halogen, the acidity increases with roughly 55 kJ mol^{-1} when going from the molecule to the radical mainly as a result of a larger electron affinity of a given CHX carbene than of the corresponding $^{\cdot}CH_2X$ radical.

The $^{-}{}^{\cdot}CHX$ ions react with the parent compounds to form X^{-} ions predominantly by direct nucleophilic attack (eq. 3a) and only to a minor extent by initial proton transfer yielding a $[^{\cdot}CH_2X + {}^{-}CH_2X]^{*}$ complex, which reacts further by nucleophilic substitution (eq. 3b).

$$^{-}CH^{35}Cl + CH_3Cl \longrightarrow Cl^{-} + CH_3\dot{C}H^{35}Cl \qquad (3a)$$

$$\downarrow$$

$$[CH^{35}Cl \;\; {}^{-}CH_2Cl]^{*} \longrightarrow {}^{35}Cl^{-} + CH_3\dot{C}HCl \qquad (3b)$$

In addition to overall proton transfer (eq. 4a), the reaction with aliphatic alcohols results in X^{-} ions by a process, which involves initial proton transfer and a subsequent nucleophilic attack on the generated radical as indicated in eq. 4b.

$$^{-}CHX + ROH \rightarrow [RO^{-} \;\; {}^{\cdot}CH_2X]^{*} \nearrow R\text{-}O^{-} + {}^{\cdot}CH_2X \qquad (4a)$$

$$[RO^{-} \;\; {}^{\cdot}CH_2X]^{*} \searrow [R\dot{O}CH_2 \;\; X^{-}]^{*} \rightarrow R\dot{O}CH_2 + X^{-} \qquad (4b)$$

MECHANISM OF REACTION OF Fe^+ WITH ORGANOSILANES. GENERATION AND CHARACTERIZATION OF TRANSITION METAL-SILYLENE AND -SILENE CATIONIC COMPLEXES IN THE GAS PHASE

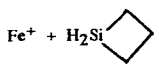
R. Bakhtiar and D. B. Jacobson

Department of Chemistry, North Dakota State University
Fargo, North Dakota 58105-5516

Transition metal-silylene complexes ($L_nM{=}SiR_2$) are postulated intermediates in a number of transition metal-mediated transformations, including Rochow's direct process, catalytic redistribution of silanes, various silylene-transfer reactions, and in dehydrogenative coupling reactions of silanes with transition metals [1] Although transition metal-carbene, germylene, -stannylene, and -plumbylene complexes are well known, the corresponding -silylene species have been synthetically elusive in solution with silylene-metal complexes only recently generated and characterized. The related transition metal-silene complexes ($L_nM(R_2Si{=}CR_2)$) have been proposed as intermediates in metal-mediated rearrangement of organosilicon ligands, including β-hydrogen transfer of a bound silyl group.[2] *Stable transition metal-silene complexes have recently been synthesized and characterized.*[3] The difficulty in synthesizing stable metal-silylene and -silene complexes has prevented detailed studies concerning their involvement in organosilicon chemistry. The mechanism of reaction of Fe^+ with organosilanes was studied in the gas phase by using Fourier transform mass spectrometry (FTMS). The structures of the resulting products were probed by specific ion/molecule reactions (isotopically labeled ethene) with isomeric iron-silylene and -silene cationic complexes ($FeSiCH_4^+$ and $FeSiC_2H_6^+$) characterized.[4]

The predominant reaction channel for reaction of Fe^+ with ethenylmethylsilane and silacyclobutane is loss of ethene, reactions 1 and 2. Reaction of 1 and 2 with isotopically labeled ethene indicates that 1 is an iron-silylene

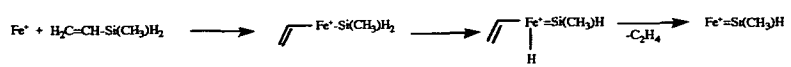
$$Fe^+ + CH_2{=}CH\text{-}Si(CH_3)H_2 \longrightarrow \underset{1}{FeSiCH_4^+} + C_2H_4 \qquad (1)$$



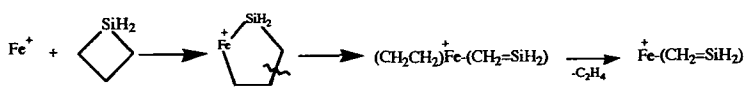
$$Fe^+ + H_2Si \longrightarrow \underset{2}{FeSiCH_4^+} + C_2H_4 \qquad (2)$$

complex ($Fe^+{=}(CH_3)H$) and that 2 is an iron-silene species ($Fe^+(CH_2{=}SiH_2)$). A mechanism for reaction 1 is proposed in Scheme I and involves initial vinyl C-Si insertion. A mechanism for reaction 2 is postulated in Scheme II and involves initial insertion into the strain weakened Si-C bond.

Scheme I

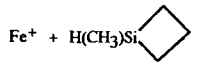


Scheme II



Fe^+ reacts with dimethylsilane to yield exclusive dehydrogenation whereas 1-methylsilacyclobutane gives exclusive loss of ethene, reactions 3 and 4. Structural studies indicate that 3 consists of the silylene complex,

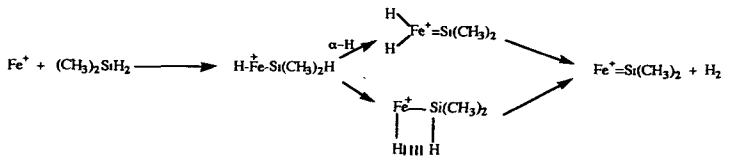
$$Fe^+ + (CH_3)_2SiH_2 \longrightarrow \underset{3}{FeSiC_2H_6^+} + H_2 \qquad (3)$$



$$Fe^+ + H(CH_3)Si \longrightarrow \underset{4}{FeSiC_2H_6^+} + C_2H_4 \qquad (4)$$

$Fe^+{=}Si(CH_3)_2$, while 4 is the silene complex, $Fe^+\text{-}(CH_2{=}Si(CH_3)H)$. A mechanism for reaction 3 is proposed in Scheme III and involves 1,1-dehydrogenation from silicon. Reaction 4 presumably proceeds by a mechanism

Scheme III



analogous to that in Scheme II.

Fe^+ reacts with $(CH_3)_3SiH$ to yield both demethanation and dehydrogenation, reaction 5.

$$Fe^+ + (CH_3)_3SiH \longrightarrow FeSiC_2H_6^+ + CH_4 \qquad (5a)$$

$$Fe^+ + (CH_3)_3SiH \longrightarrow FeSiC_3H_8^+ + H_2 \qquad (5b)$$

Structural studies indicate that the product of reaction 5a is an iron-silylene complex ($Fe^+{=}Si(CH_3)_2$) and the structure of the product of reaction 5b is an iron-silene complex ($Fe^+\text{-}(CH_2{=}Si(CH_3)_2)$. A mechanism for reaction 5 is presented in Scheme IV and involves initial Si-H bond insertion.

Scheme IV

SELECTIVE ION-MOLECULE REACTIONS OF LACTAMS WITH DIMETHYL ETHER IONS

Tracy Donovan McCarley and Jennifer Brodbelt, Department of Chemistry, University of Texas, Austin, TX 78712-1167

A variety of molecules containing a lactam ring system are essential in the polymer and pharmaceutical industries. In this study, the selectivity of ion-molecule reactions of four- to seven-membered ring lactams, both unsubstituted and with methyl substituents in various positions, with dimethyl ether ions was characterized to correlate reactivity with ring size and substitution pattern. The ion-molecule reaction products of the lactams with dimethyl ether reagent ions in the ion trap are summarized in Table 1. All of the lactams were protonated by dimethyl ether reagent ions and formed $(M + 15)^+$ product ions by methyl cation transfer, and most of the lactams formed $(M + 45)^+$ adduct ions. Other products formed include $(M + 3)^+$, $(M + 13)^+$, and $(M + 16)^+$ ions.

Although simple protonation or formation of $(M + 15)^+$ products shows no dependence on ring size or substituent position, formation of the $(M + 13)^+$ and $(M + 16)^+$ products appears to be highly selective. For instance, of the five, six, and seven membered ring systems, the $(M + 13)^+$ and $(M + 16)^+$ products were formed *only* by lactams which do not have a methyl substituent on the nitrogen atom. For the lactams with an *N*-methyl substituent, neither $(M + 13)^+$ nor $(M + 16)^+$ adducts were formed.

Unlike the $(M + 13)^+$ and $(M + 15)^+$ products, the formation of the $(M + 16)^+$ ion by dissociation of an $(M + 45)^+$ adduct has not been reported prior to this study. To assist in the elucidation of the structure of this intriguing $(M + 16)^+$ adduct, the $(M + 16)^+$ adduct of each lactam was collisionally activated and compared to the spectra of lactone analogs. For example, the CAD spectrum of the $(M + 16)^+$ adduct of 2-pyrrolidinone shows a base peak at m/z 59 and less abundant ions at m/z 55 and 83 (Figure 1a). This spectrum is strikingly similar to the CAD spectrum of the $(M + 15)^+$ adduct of γ-butyrolactone (see Figure 1b). Based on this observation, the structures of the lactam $(M + 16)^+$ products and the lactone $(M + 15)^+$ products are presumed to be identical.

A mechanism showing the formation of the 5-methyl-2-pyrrolidinone $(M + 16)^+$ adduct is proposed in Scheme I. Such a mechanism also accounts for the absence of an $(M + 16)^+$ product in the ion-molecule reaction spectra of the lactams which have a methyl substituted nitrogen atom. If the $(M + 45)^+$ adducts of these *N*-methyl compounds dissociate according to the mechanism shown in Scheme I, the neutral eliminated would be $CH_2{=}N{-}CH_3$, a

loss of 43 amu, rather than $CH_2{=}NH$, and the resulting final product would be observed at $(M + 45 - 43)^+$, or $(M + 2)^+$. In fact, collisional activation of the $(M + 45)^+$ adduct of each of the nitrogen-substituted lactams produces an ion at $(M + 2)^+$, which offers additional support for this unusual process.

The ion-molecule reactions of lactams with dimethyl ether ions show a high degree of selectivity that was not observed in the ion-molecule reactions of lactones or amides with dimethyl ether ions. All of the lactams were protonated by dimethyl ether ions, but the formation of additional adduct ions shows selectivity based upon ring size and the presence or absence of a methyl substituent on the lactam nitrogen atom. Each protonated lactam exhibits a unique set of dissociation pathways and product ions, making the discrimination of structural isomers possible.

APPLICATION OF SITE-SELECTIVE ION-MOLECULE REACTIONS TO THE IDENTIFICATION OF ALKALOIDS

Erika Eichmann and Jennifer S. Brodbelt, Department of Chemistry, University of Texas, Austin, TX 78712-1167

The alkaloids quinine and quinidine, along with cinchonine, cinchonidine, have been widely used in medicine longer than many modern drugs. Cinchonidine (**1**), cinchonine (**2**), quinine (**3**), and quinidine (**4**), all exhibit similar antimicrobial activity (See Figure 1). These compounds can be viewed as α,β-amino alcohols with aromatic substituents and tertiary amino groups. The major difference within each pair of stereoisomers (**1/2** and **3/4**) is the distance separating the hydroxyl group from the vinyl group. The interaction between the hydroxyl and vinyl groups in quinidine (**4**) and cinchonine (**2**) has long been recognized, and thus reagent ions which selectively target either the vinyl group or the hydroxyl group may be affected by the degree of interaction between them. In this study, we have examined structurally-selective ion-molecule reactions between (DME) dimethyl ether ions **5** and **6** and the cinchona alkaloids in a quadrupole ion trap mass spectrometer.

The product spectra for reactions of **1**, **2**, **3**, and **4** with DME ions are qualitatively similar to each other (Table 1). Each molecule yields an abundant $(M + 1)^+$ ion, as well as $(M + 13)^+$, $(M + 15)^+$ and $(M + 45)^+$ products. Also present in each spectrum is an ion at m/z = 136, which is due to cleavage of the vinylquinuclidine group from the molecular ion. The two pairs of stereochemically similar pairs (**1/3** and **2/4**) show moderate differences in the $136^+/(M + 45)^+$ and $(M + 1)^+/(M + 45)^+$ ratios and especially in the relative formation of $(M + 13)^+$ and $(M + 15)^+$ ions. The $(M + 13)^+$ product is known from previous studies to form only at sites with available protons that can be donated in the necessary elimination of methanol. This rules out any of the potential reaction sites except the aromatic carbon atoms, the vinyl group, and the hydroxyl group. The fact that some selectivity is observed in reactions of these compounds with DME ions indicates that the interaction between these two functional groups is involved in determining the outcome of the DME/alkaloid ion-molecule reactions, as discussed later.

The DME ions $CH_3OCH_2^+$ and $(CH_3OCH_3)H^+$ were each selectively reacted with the neutral alkaloids. Reaction of the alkaloids with $(CH_3OCH_3)H^+$ yields only the protonated species. Reaction with $CH_3OCH_2^+$ results in formation of $(M + 45)^+$ adducts as well as the $(M + 13)^+$ and $(M + 15)^+$ product ions. The products result via elimination of CH_2O or CH_3OH from the $(M + 45)^+$ precursor.

$$M + (CH_3OCH_3)H^+ \longrightarrow (M + H)^+$$

$$M + CH_3OCH_2^+ \longrightarrow (M + 13)^+,\ (M + 15)^+,\ (M + 45)^+$$

The $(M + 45)^+$ adduct is the precursor for both the $(M + 13^+)$ and $(M + 15^+)$ product ions; however, in all cases, activation of the $(M + 45)^+$ adduct yields predominantly the $(M + 13)^+$ ion via loss of methanol. A representative CID spectrum is shown for the cinchonidine $(M + CH_3OCH_2^+)$ ion in Figure 2. Interestingly, the fact that activation of the $(M + 45)^+$ adducts does not result in formation of $(M + 15)^+$ ions suggests either that the stable $(M + 45)^+$ adduct is not the appropriate structural precursor for the $(M + 15)^+$ ions or that the elimination of CH_3OH to form $(M + 13)^+$ ions is substantially kinetically favored over the elimination of CH_2O to form $(M + 15)^+$ ions.

The reactivities of the individual functional groups within the complex alkaloids are modelled by examination of smaller sub-units of the molecules (Figure 3) in order to understand the reactivity and intramolecular interactions of the complete molecule, and to predicting site-

selectivity. Reaction of the alkenol compounds **7**, **8** and **9** with DME ions yields proton-bound $(M + 47)^+$ adducts and $(M + 13)^+$ products. Additionally, it was determined that both the vinyl groups and the hydroxyl groups are necessary for the reactions of alkenols with DME to proceed in the ion trap. None of the tertiary amine compounds give $(M + 13)^+$ product ions, except *N,N*-dimethylethanolamine (**14**). For all of the tertiary amines, there is no way of forming the $(M + 13)^+$ ions because there is no accessible proton attached to the nitrogen atom. *N,N*-dimethylethanolamine (**14**) produces $(M + 13)^+$ ions, rather than $(M + 15)^+$ ions because of the presence of a reactive hydroxyl group. Naphthalene **16** and 2-methoxynaphthalene **17**, unlike their nitrogen-containing counterparts **10** and **11**, forms $(M + 13)^+$ ions instead of $(M + 15)^+$ ions. The reactions of these models show that methylation is only favored when a tertiary nitrogen atom is present and no other reactive heteroatom site is available. Additionally, the formation of $(M + 13)^+$ ions is kinetically favored.

With respect to the alkaloids, these model studies suggest that methylation occurs at the quinoline nitrogen position, whereas formation of $(M + 13)^+$ ions occurs at the hydroxyl group, with assistance by a second functional group, such as the vinyl group. The fact that the formation of $(M + 15)^+$ ions is preferred for cinchonidine and quinine but the formation of $(M + 13)^+$ ions is favored for cinchonine and quinidine suggests that the functional group interaction between the hydroxyl group and vinyl group plays a significant role in determining the selectivity of the ion-molecule reactions of the cinchona alkaloids.

ION-MOLECULE REACTIONS AND DISSOCIATION OF GLYCOLS IN A QUADRUPOLE ION TRAP: EVIDENCE OF INTRAMOLECULAR INTERACTIONS

Erika Eichmann and Jennifer S. Brodbelt, Department of Chemistry, University of Texas, Austin, TX 78712-1167.

Polyethylene glycols serve as important precursors in the polymer industry and as models in the field of host-guest chemistry. In general, glycols of different chain lengths are not easily distinguished by mass spectrometric methods because they yield similar fragmentation patterns. Glycols have the special ability to participate in multi-site binding of ions. In our quest for obtaining a more detailed understanding of the significance of functional group interactions in mediating gas-phase ion-molecule reactions, we have examined the selective reactions of the methoxymethylene cation, $CH_3OCH_2^+$, with a homologous series of glycols. It was of additional interest to determine the analytical value of derivatizing the glycols through ion-molecule reactions in the gas phase in order to promote greater differentiation of the glycol chain length.

Ion/molecule reactions were examined by using a Finnigan quadrupole ion trap mass spectrometer (ITMS). Collisional activation involved the application of an ac voltage of 0.3 - 1.0 V_{p-p} at the axial frequency of motion of the ion of interest (i.e. 120 kHz at q = 0.3). The dimethyl ether (DME) pressure was nominally 1 x 10^{-5} torr, and the helium buffer gas pressure was 0.8 mtorr. Reaction of the $CH_3OCH_2^+$ cations with each of the glycols resulted in formation of $(M + 13)^+$ product ions. The $(M + 13)^+$ ions likely result from formation of short-lived $(M + CH_3OCH_2)^+$ intermediates which spontaneously dissociate by loss of CH_3OH (Scheme I). Although the terminal hydroxyl groups of the glycols are separated by from five to fifteen atoms, several nucleophilic ether oxygen atoms are present within the chain of the molecule, and this structural feature may offer alternative routes towards stabilization of the necessary $(M + CH_3OCH_2)^+$ complex (Scheme 1).

Multi-stage CAD techniques were used to characterize the structures of the $(M + 13)^+$ ions and their protonated counterparts $(M + H)^+$ (see Figure 1). In contrast to the CAD spectra of the $(M + H)^+$ ions, the CAD spectra of the $(M + 13)^+$ ions show a much richer and more structurally diagnostic variety of fragments (see Table 2). Four major fragmentation routes are observed, each involving elimination of a small neutral molecules in conjunction with losses of C_2H_4O units. The most straight forward pathway involves elimination of $(CH_2O + nC_2H_4O)$.

One type of dissociation process that is observed only for the triethylene glycol and tetraethylene glycol $(M + 13)^+$ ions involves the elimination of $(HCOCH_2OH + nC_2H_4O)$ (n = 0 or 1). Initial hydride transfer from a methylene carbon of the glycol adduct to the positively polarized methylene end group results in an oxonium ion. The elimination of $HCOCH_2OH$ occurs after C-O bond cleavage and may then be followed by loss of a C_2H_4O unit.

Each of the final dissociation routes involves cyclization of the $(M + 13)^+$ ions, followed by intramolecular hydride transfer. The ion may undergo direct cleavage of CH_3OH, followed by elimination of zero, one or two C_2H_4O units. The losses of C_2H_4O units are increasingly favored as the length of the polyether chain increases. Alternatively, the cyclization of the $(M + 13)^+$ ion is followed by a hydride transfer reaction and rearrangement in which an ether oxygen abstracts a proton from a β-carbon atom. Then C-O bond cleavage occurs, resulting in the net loss of $C_3H_6O_2$ (86 u). Because this process does not occur in conjunction with losses of ethylene oxide units, it uniquely identifies the size of the glycol polyether chain.

The perdeuterated reagent CD_3OCD_3 was used to assist in elucidation of reaction and dissociation mechanisms and to determine the extent of rearrangment in the glycol ions. The reaction of tetraglycol, triglycol, and diethylene glycol with $CD_3OCD_2^+$ ions led exclusively to

formation of $(M + 15)^+$ ions, assigned as $(M + CD_3OCD_2^+ - CD_3OH)$. The absence of $(M + 13)^+$, $(M + 14)^+$ and $(M + 16)^+$ ions demonstrates that interchange between deuterium and hydrogen atoms does not occur, and thus the reaction of interest proceeds by attachment of $CD_3OCD_2^+$ to the glycol, followed specifically by loss of CD_3OH (see Scheme 1).

CONCLUSIONS

Polyethylene glycols afford a useful set of model structures for the further examination of functional group participation in ion-molecule reactions. On the basis of the specific fragmentation pathways described in this report, it is apparent that the glycols may undergo intramolecular cyclization upon formation and dissociation of the $(M + 13)^+$ ions. Furthermore, the deuterium labelling experiments demonstrate that the intramolecular cyclization and rearrangements do not result in scrambling of atoms. This study has also provided an example of how derivatization of an organic substrate by selective ion-molecule reactions may offer supplementary structural information to that provided by the spectra of protonated analogs. In the present case, the substitution of a methylene cation for a proton results in modified glycols that undergo many more rearrangements upon collisional activation. For the glycols with longer carbon chain lengths, the loss of 86 amu ($C_3H_6O_2$) from the $(M + 13)^+$ ion is a structurally specific elimination that does not occur in conjunction with C_2H_4O losses, and thus unambiguously identifies the glycol chain size.

ISOMER DISTINCTION IN A QUADRUPOLE ION TRAP: FUNCTIONAL GROUP INTERACTIONS OF DICARBOXYLIC ACIDS AND ESTERS.

***John J. Isbell, Jeff Liou, and Jennifer S. Brodbelt, Department of Chemistry, University of Texas, Austin, Texas 78712.**

Functional group interactions are among the most important classes of substituent effects in both solution and gas phase chemistry[1-6] The term "intramolecular catalysis" has been used to describe those types of functional group interactions which facilitate specific reaction or dissociation channels [7]. Such effects have been observed for a variety of difunctional molecules, including diols and amino alcohols [2,3].

Some of the most striking functional group interactions have been observed for dicarboxylic acids. The ability of the functional groups to interact can be correlated with distinctive fragmentation patterns upon electron ionization [1] or with the extent of dehydration of the diacids upon chemical ionization [6,9]. Similar results have been reported for related esters [8,9] and fatty acids [10]. Low-energy CAD of the protonated diethyl esters of fumaric and maleic acids resulted in stereospecific dissociation pathways: the protonated cis isomer eliminated ethanol, while the trans diester lost one or two molecules of ethylene [11].

The primary goal of our systematic study of functional group interactions is to gain a better understanding of structure/reactivity relationships in gas-phase ion molecule reactions. As with our earlier work, we are particularly interested in the chemistry of complex biomolecules. By studying diacids and their corresponding dimethyl esters, the effect of methyl substitution on isomer distinction can be determined and the extent of functional group interactions can be evaluated. Dimethyl ether was used as a chemical ionization reagent because of its proven selectivity towards certain functional groups and its capability for probing functional group interactions [12,13].

A Finnigan Ion Trap Mass Spectrometer was operated in the positive ion mode at a typical temperature of 100-120°C. Samples were introduced using a solids probe heated to 80-100°C or through a leak valve at a pressure of 1×10^{-6} torr. Dimethyl ether served as a chemical ionization reagent gas and was introduced at a pressure of $1\text{-}2 \times 10^{-5}$ torr. Helium was added as a buffer gas and was added to increase the pressure to the millitorr regime.

For comparison, results were also obtained using a Finnigan Triple Stage Quadrupole (TSQ). Adducts were formed with dimethyl ether by introducing it at 1.2 torr. Argon served as a collision gas and was introduced into the quadrupole at 1.5 millitorr. Electron ionization was performed using nominally 70 eV electrons and the collision energy was typically 10 V.

Reactions of Acids with Dimethyl Ether Ions in an Ion Trap

Using dimethyl ether as a reagent gas, one can easily distinguish between fumaric acid and maleic acid in an ion trap. Fumaric acid produces $(M+13)^+$ ions while maleic acid forms $(M+15)^+$ ions. The postulated mechanism for the $(M+13)^+$ product formation is given in FIGURE I, while that for $(M+15)^+$ is given in FIGURE II.

Not surprisingly, succinic acid adopts a conformation that is somewhat similar to that of maleic acid, presumably to take advantage of the additional electrostatic interaction of the second carboxylic acid to lower the energy of the product ion. It is interesting to note that succinic acid also forms an $(M+45)^+$ adduct while the other two diacids do not. This suggests that flexibility plays an important role in adduct formation and that models of functional group interactions should be chosen carefully.

CAD of Product Ions in an Ion Trap

It is also interesting to examine the nature of fragment ions formed upon collisional activation of the various product ions and the effect of structural rigidity of the acids. After activation of the rigid protonated diacids, dehydration, followed by a subsequent loss of carbon monoxide is observed. The low CAD yield of protonated fumaric acid supports the high-energy, symmetry-forbidden proton transfer.

Protonated succinic acid loses only water. This difference is attributed to the inability of functional group interaction in fumaric acid, and the increase in strain of maleic acid for functional group interaction. It is the increased flexibility of the protonated succinic acid which enables it to lose water and then cyclize to stabilize the resulting fragment ion.

The methylated product ions $(M+15)^+$ predominantly dissociate by elimination of water. The analogous loss of methanol does not occur. This result is especially intriguing with respect to the trans isomer for which a functional group interaction to allow the necessary proton migration would not be expected to be favored.

Reactions of Acids with Dimethyl Ether Ions in a Conventional CI Source and CAD

Reactions between the acids and dimethyl ether ions in a conventional chemical ionization source afford qualitatively similar product spectra. Products are observed for $(2M+H)^+$, $(M+H+DME)^+$, $(M+45)^+$, $(M+15)^+$ and $(M+H)^+$ for both fumaric and maleic acids. CAD of many of the products ions are qualitatively identical; however, the CAD spectra of the $(M+45)^+$ adducts are strikingly different. The $(M+45)^+$ adduct for maleic acid dissociates to the $(M+15)^+$ ion by elimination of formaldehyde, whereas the $(M+45)^+$ adduct for fumaric acid dissociates to the $(M+13)^+$ ions by loss of methanol. This dissociation behavior mimics the initial product formation observed in the ion trap environment.

The formation and dissociation of dimethyl ether adducts of diacids and diesters is dependent on functional group interactions within the adducts. These effects are most apparent for the competitive formation of the $(M+13)^+$ and $(M+15)^+$ ions of fumaric and maleic acid. Only those substrates with two functional groups that may interact preferentially undergo the methylation reaction.

Isomer Distinction of Disubstituted Benzenes in a Quadrupole Ion Trap.

***Niloo Asgharian and Jennifer Brodbelt, Department of Chemistry, University of Texas, Austin, Texas 78712.**

Theoretical calculations[1] have been used extensively to predict the possible stable isomers of $C_2H_3O^+$ composition. It was determined that the lowest energy $C_2H_3O^+$ isomer is the acetyl cation $CH_3C{\equiv}\overset{+}{O}$. The next stable structure was predicted to be protonated ketene, $CH_2{=}C{=}\overset{+}{O}H$ which lies 181 kJ/mol above the acetyl ion. More recently, Cooks et al.[2] determined the structures and reactions of isomeric $C_2H_3O^+$ ions through ion-molecule reactions in a pentaquadrupole mass spectrometer where MS^3 could be achieved. Their results showed that the major $C_2H_3O^+$ isomer formed from acetic anhydride as well as methyl acetate, acetone, and acetaldehyde is the more stable acetyl ion, which formed $(M + 43)^+$ products upon reaction with isoprene and various aromatic substrates.

What led us to continue the investigation of $C_2H_3O^+$ ions was the intriguing observation that of all the precursors of type CH_3COR, only acetic anhydride led to the formation of $(M + 43)^+$ product ions upon reaction with neutral aromatic substrates in a quadrupole ion trap. All the others such as acetaldehyde, 2,3-butadione, acetone, and methylacetate only promoted formation of $(M + H)^+$ protonated substrates. In order to understand the contrasting results obtained in a quadrupole ion trap environment, we undertook a detailed study of reactions of $C_2H_3O^+$ isomers with monosubstituted aromatics and isoprene. A Finnigan Ion Trap Mass Spectrometer (ITMS)[3,4] was used for all experiments. Samples were introduced through a heated leak valve system, and typical pressures used were 2×10^{-6} torr Helium buffer gas was admitted at 1 mtorr. All spectra were recorded at the same manifold temperatures of 45°C and 150°C. The $C_2H_3O^+$ (43^+) ions were generated by 70 eV electron ionization and allowed to react with the neutral sample vapor.

In all cases where isoprene was used as the analyte substrate, both $(M + 43)^+$ and $(M + H)^+$ product ions are formed for all $C_2H_3O^+$ ions. This result replicates the results obtained in a previous study.[2] However, for the reactions of the aromatic substrates with various $C_2H_3O^+$ ions, the $(M + 43)^+$ products are only formed when the $C_2H_3O^+$ ions are generated from acetic anhydride. Figure 3 shows a typical product spectrum for the reaction of $C_2H_3O^+$ ions produced from acetic anyhdride with a neutral substrate, in this case isoprene. According to Cooks and coworkers,[2] there was no difference between $C_2H_3O^+$ ions originating from acetic anydride or other precursors of CH_3COR type. They reported that all of these produced the more stable acetyl isomer as the major structure. The replication of the test substrate used in the previous report[2] (isoprene) duplicated the expected behavior for the CH_3COR precursors in the quadrupole ion trap at ambient temperature. However, the $C_2H_3O^+$ ion generated from acetic anhydride remained unique in its ability to produce $(M + 43)^+$ ions for isoprene at higher temperatures and for aromatic substrates at all temperatures.

There are several possibilities for explaining these discrepancies. Firstly, the translational energy of the $C_2H_3O^+$ ions may be different when generated from different precursors in the ion trap, even if the structures are the same. However, translational energization of each $C_2H_3O^+$ ion by application of a supplementary ac voltage to the ion trap failed to promote changes in the reactive behavior of the ions. The internal energies of the $C_2H_3O^+$ ions could also vary upon formation from

different precursors. Thus the internal energies were varied systematically by increasing and decreasing the helium pressure and by increasing the "cooling" time for $C_2H_3O^+$ relaxation. These efforts caused no change in the reactions of the $C_2H_3O^+$ ions in the ion trap. Structural differences in the $C_2H_3O^+$ isomers are the most obvious reason for differences in reactivity. Yet, CID experiments did not yield structurally distinctive information about the $C_2H_3O^+$ isomers. Translational excitation also failed to induce isomerization of the various $C_2H_3O^+$ ions to more or less reactive forms.

The puzzle that remains is why the precursors respond differently in the ion trap compared to a conventional ion source. In a multiquadrupole instrument, all ionizaton processes occur in an ionization source separate from the mass analyzers. On the other hand in an ion trap, formation of ions and their analysis both occur in one place, the trapping volume. The typical pressure in an electron ionization source is around 10^{-5} to 10^{-7} torr, corresponding to a nearly collision-free environment. In an ion trap, the pressure is around 10^{-3} torr, consistent with a collision frequency of 30 collisions/ms. Thus in the conventional source, the $C_2H_3O^+$ ions undergo no further collisions after formation, whereas the ions may undergo many collisions and thus rearrange in the ion trap. In the pentaquadrupole the collision energy is nearly 0 eV for ion-molecule reactions. In a quadrupole ion trap, ion temperatures have been estimated as 1000 K - 3000K.[5] Thus the average kinetic energy of an ion stored in an ion trap may range from 0.1 - 0.3 eV. All of these factors suggest that the environment of the ion trap is more conducive for promoting isomerization or rearrangement of reactant ions. Moreover, the fact that the formation of $(M + 43)^+$ product ions is temperature dependent in the ion trap supports the idea that the relative extent of isomerization of the $C_2H_3O^+$ ions plays an important role in the outcomes of the reactions.

In light of the consistent discrepancies in the reactive behavior, it seems most plausible that at least two different $C_2H_3O^+$ structures are generated from the different precursors, and these do not intraconvert under any conditions in the ion trap. From our results, it appears that ionization of acetic anhydride results in protonated ketene, whereas all the other precursors generate the more stable acetyl ion.

INTRODUCTION

The solution chemistry of simple organophosphorus compounds is a well studied topic, but relatively few studies of gas phase ion chemistry of protonated and alkylated organophosphorus compounds have been reported.

The condensed phase studies of organophosphorus compounds in strongly ionizing media have shown that phosphates and thiophosphates are protonated on the phosphoryl oxygen and thiophosphoryl sulphur. Trivalent phosphorus compounds, phosphites are protonated on the phosphorus atom.

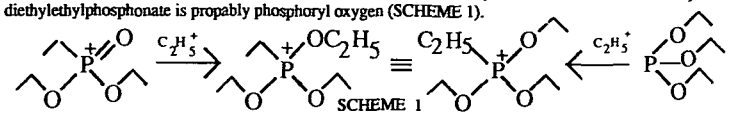
In this study methane chemical ionization (CH_4/CD_4) was used for generation of substrate ions. In addition to the protonation products, $[MH]^+$ or $[MD]^+$, adduct ions, $[M\ C_2H_5]^+$ or $[M\ C_2D_5]^+$, were included for low energy collision activated (CAD) MS/MS analysis.

The site of protonation vs alkylation and dissociation behaviour of products of triethylphosphate, triethylthiophosphate, triethyltetrathiophosphate, diethylethylphosphonate, triethylphosphite, diethylphosphonate, diethylethylphosphonate, dimethylethylthiophosphonate and O-methyl, S-methylethylphosphonothiolate were studied by collision activated dissociation tandem mass spectrometry.

RESULTS

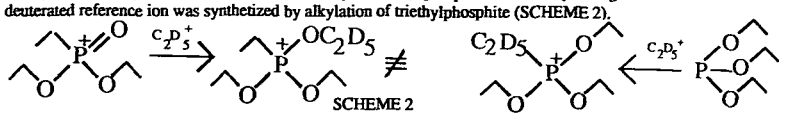
The $[MH]^+$ ions of triethylphosphate and triethylthiophosphate dissociates by loosing C_2H_4 consecutively producing m/z 155^+, m/z 127^+, m/z 99^+ and m/z 171^+, 143^+, m/z 115^+ respectively. The product ion spectrum of $[M\ C_2D_5]^+$ of triethylphosphate shows loss of 3 x C_2H_4 and C_2D_4. These results indicates that C_2D_5 group has become equivalent with the C_2H_5 groups originally present in the substrate molecule. The adduct ion $[M\ C_2D_5]^+$ of triethylthiophosphate shows fragmentation where C_2H_4 is lost three times, but C_2D_5 group bonded to thiophosphoryl sulphur do not show any significant fragmentation under 10 eV collision energy. The dissociation behaviour of triethyltetratiophosphate shows different fragmentation behaviour than triethylphosphate and triethylthiophosphate. The main fragmentation channel is loss of C_2H_5SH which supports ester sulphur protonation. ERMS of MH^+ shows loss of C_2H_4 in the second step when CIE >10 eV. The protonated diethylethylphosphonate dissociates by fragmenting C_2H_4 and C_2H_4. The adduct ions $[M\ C_2H_5]^+$ and $[M\ C_2D_5]^+$ show in the CAD fragmentation that all three ethoxy groups have become equivalent. Dissociation of $[MH]^+$ of triethylphosphite shows loss of C_2H_4 three times as main fragmentation channel which indicates phosphorus protonation. Also the ion corresponding loss of C_2H_5OH is present, which supports the oxygen protonation.

For confirmation of ion structures some reference ions were synthetized. The site of alkylation by $[C_2H_5]^+$ at diethylethylphosphonate is propably phosphoryl oxygen (SCHEME 1).



SCHEME 1

The product phosphonium ion contains three equal ethoxy groups . The corresponding deuterated reference ion was synthetized by alkylation of triethylphosphite (SCHEME 2).



SCHEME 2

The main site for reaction is trivalent phosphorus. The reaction products using $[C_2D_5]^+$ -ion as alkylating agent have not any more the same ion structures as the CAD spectra confirm. Dimethylethylthiophosphonate is bifunctional for protonation reaction. The $[MD]^+$ gives as fragment ion m/z 123, which corresponds to loss of CH_3OD. The ion $[MC_2D_5]^+$ fragments by giving losses C_2D_4 and $CH_3OC_2D_5$. This supports two alkylation sites for thiophosphoryl sulphur and methoxy oxygen.

O-methyl, S-metylethylphosphonotiolate is a three-functional compound for alkylation reaction. The adduct ion $[MC_2D_5]^+$ gives two primary fragment ions; m/z 156 and m/z 107, corresponding to losses of C_2D_4 and $CH_3SC_2D_5$. The fragmentation indicates phosphoryl oxygen and thiomethoxy sulphur alkylation.

CONCLUSION

The protonation and alkylation products of several organophosphorus compounds were synthetized in conventional CI-source. The structures of reaction products and sites of protonation and alkylation were studied by low energy tandem mass spectrometry. The results show that phosphates and thiophosphates alkylates mainly at phosphoryl oxygen and thiophosphoryl sulphur, respectively. Tetrathiophosphates alkylates mainly at ether sulphur. The main reaction site of phosphites is the trivalent phosphorus atom and as minor site ether oxygen. Multifunctional thiophosphonates give mixture of ions, where reaction sites have been phosphoryl and thiophosphoryl groups and also ether oxygen and thioether sulphur.

Ion-Molecule Reactions of Dicoordinated Boron Cations With Alcohols

Thilini D. Ranatunga and Hilkka I. Kenttämaa
Department of Chemistry, Purdue University, West Lafayette, IN 47907

Dicoordinated boron cations are proposed to exist as transient intermediates in solution reactions. Condensed phase studies of these highly electrophilic species are limited to ions with bulky substituents which are strongly π- back bonded to boron. On the other hand, dicoordinated boron cations are easily generated in the gas phase upon electron ionization of boron compounds. Therefore, mass spectrometric methods are useful in the study of the properties and reactivity of highly reactive boron cations, such as $CH_3BCH_3^+$ and $CH_3OBOCH_3^+$. Our earlier studies on the reaction of these boron cations with organic ethers revealed that $CH_3BCH_3^+$ and $CH_3OBOCH_3^+$ dehydrate ethers by stepwise elimination of two alkene molecules from a proton bound intermediate.[1] An adduct of a neutral alcohol and the boron cation is expected to occur as an intermediate in the reaction. Therefore, reactions of alcohols with the boron cations have been studied.

The boron cations $CH_3BCH_3^+$ and $CH_3OBOCH_3^+$ undergo very fast reactions with alcohols, most of which occur by abstraction of a water molecule from the alcohol, leading to elimination of an alkene from a proton bound intermediate **b** (Scheme 1). The proton affinity (PA) of $(CH_3O)_2BOH$, determined by proton affinity bracketing experiments to be 198 kcal/mol at OCH_3 and 178 kcal/mol at OH, is greater than that of $CH_2{=}CH_2$. Thus the proton is more strongly bound to $(CH_3O)_2BOH$. This results in elimination of ethylene from the proton bound adduct, resulting in $(CH_3O)_2B(OH_2)^+$ (m/z 91) as the major product. The product ion of m/z 91 is proposed to rearrange to a more stable form $(CH_3O)(OH)B(HOCH_3)^+$ via intramolecular 1,3-hydrogen transfer. Support for the proposed mechanism was obtained from several experimental approaches, such as CAD, deuterium labeling and reactions with several other alcohols. Alcohols such as methanol that cannot lose an alkene molecule are not dehydrated by boron cations. Reaction of $CH_3OBOCH_3^+$ with d_4-methanol yields product ions $CH_3OBOCD_3^+$ (m/z 76) and $CD_3OBOCD_3^+$ (m/z 79), showing that an intramolecular 1,3-hydrogen transfer occurs in boron cations of type **c** in Scheme 1. The ion $CH_3OBOCH_3^+$ reacts with neopentyl alcohol by abstraction of water which rules out the possibility of the reaction proceeding via a four membered transition state. The secondary products from the reaction of $CH_3OBOCH_3^+$ with ethanol are proposed to arise from replacement of methanol with ethanol as shown in Scheme 1.

In addition to elimination of a water molecule from the alcohols, a facile abstraction of OH was observed upon reaction of the ions $CH_3BCH_3^+$ and $CH_3OBOCH_3^+$ with certain alcohols. For example, $CH_3BCH_3^+$ abstracts OH from n-propanol while $CH_3OBOCH_3^+$ abstracts OH from cyclohexanol and n-pentanol. Abstraction of OH is proposed to occur via the same proton bound intermediate which occurs during water elimination reaction. The relative extent of the water and

OH abstraction reactions depends on the relative exothermicities of the reactions, which is determined by the relative stability of the alkyl ion formed. The formation of the very strong B-O bond is likely to be the driving force for all these reactions.

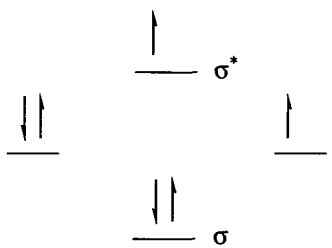
Two-Center Three-Electron Sulfur-Sulfur Bond Energies in Gas-Phase $[(Me)_2S\therefore S(Me)_2]^+$ and $[(Et)_2S\therefore S(Et)_2]^+$.

Andreas Illies, Mary A. James, Michael Peschke, and Ying Deng
Department of Chemistry,
Auburn University,
Auburn, Al 36849.

The sulfur-sulfur bonds in $[Me_2S\therefore SMe_2]^+$ and $[Et_2S\therefore SEt_2]^+$ are examples of two-center three-electron (2c-3e or a $2\sigma/1\sigma^*$) bonds; these 2c-3e bonds were first described in 1931 by Linus Pauling.[1] A simple molecular-orbital representation of this form of bonding is shown by the potential-energy diagram.



Here we present a thorough study of the experimental sulfur-sulfur bond energies for $[Me_2S\therefore SMe]^+$ and $[Et_2S\therefore SEt]^+$. The goals of our studies are to determine ΔG°_{rxn} from equilibrium studies and, hence, the bond enthalpy (ΔH°_{bond}) from the temperature dependence. For an association reaction, the bond enthalpy (ΔH°_{bond}) is the negative of the reaction enthalpy (ΔH°_{rxn}), and the values of the bond enthalpy and bond energy are nearly the same. The gas-phase ion-molecule reactions:

$$[Me_2S]^+ + SMe_2 + M \Leftrightarrow [Me_2S\therefore SMe_2]^+ + M$$

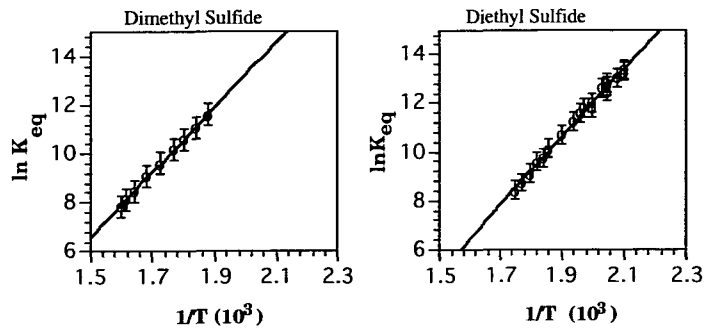
$$[Et_2S]^+ + SEt_2 + M \Leftrightarrow [Et_2S\therefore SEt_2]^+ + M$$

were studied in SF_4 and CF_4 bath gases as a function of temperature. The reaction enthalpies and entropies, were determined from the van't Hoff equation;

(1) Pauling, L. *J. Am. Chem. Soc.* **1931**, *53*, 3225.

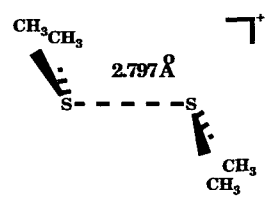
$$\ln Kp = -\Delta H^\circ_{rxn}/RT + \Delta S^\circ_{rxn}/R$$

The van't Hoff plots for the two reactions are shown.



The reaction enthalpies and entropies determined from our data are ΔH°_{rxn} = -26.5 kcal/mol and ΔS°_{rxn} = - 26 cal/mol K for $[Me_2S\therefore SMe_2]^+$ and ΔH°_{rxn} = -27.6 kcal/mol and ΔS°_{rxn} = - 31.4 cal/mol K for $[Et_2S\therefore SEt_2]^+$. The bond enthalpy is the negative of the bond reaction enthalpy and is ≈ 40% of an ordinary two-center two-electron (2c-2e) S-S bond.

Ab initio calculations predict a bond energy of 27.4 kcal/mol and the geometry shown for the $[Me_2S\therefore SMe_2]^+$ molecule. *Ab initio* calculations on $[Et_2S\therefore SEt_2]^+$ are in progress.



The S-S$^+$ bond enthalpies reported here are about 40% of that for an average S-S 2c-2e covalent interaction. These data represent the first reliable gas-phase measurement for a sulfur-sulfur 2c-3e bond in an organic molecule. Research on other S∴S$^+$ interactions are in progress.

PRODUCT FORMATION AND FRAGMENTATION PATHWAY FOR THE REACTION OF BENZENE AND *N*-METHYLIMIDAZOLE

A.B. Whitehill, M. George, D. Giblin, and M.L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304.

Mass spectrometry has been used extensively to study gas-phase ion-molecule reactions. This is due in part to the ability of mass spectrometers to generate ionic species and to carry out controlled reactions with neutral species. This study deals with gas-phase ion-molecule reactions between polyaromatic hydrocarbon (PAH) radical cations and *N*-methylimidazole.

Radical cations are known to take part in biological chemistry, often occurring as intermediates in metabolic pathways. These radical cations are thus necessary to living species. However, it has been proposed by Cavalieri and coworkers that enzymatically created radical cations of PAH's such as benzo[*a*]pyrene and 7,12-dimethylbenz[*a*]anthracene may be the ultimate carcinogens derived from these species. If radical cations of PAH's are of biological significance, then mass spectrometry could play an important role in understanding the reactivity of these species. It is also for these reasons that the current investigation involving the reactions of benzene, as the simplest member of the PAH's, was initiated.

This study was initiated as a starting point for evaluating the gas-phase reactivity of radical cations derived from PAH's toward model biological nucleophiles. Now that this simple system is understood we can extend this study to a series of PAH's ranging from non-carcinogenic to carcinogenic. Once a series of PAH's have been analyzed it can be determined of the gas-phase reactivity of radical cations correlates with their biological activity.

Chemical ionization (CI), fast atom bombardment (FAB) and MS/MS experiments were performed on a Kratos MS-50 triple analyzer equipped with a MACH3 data system. CI experiments were performed at a source pressure of approximately 0.1 torr. Activation was achieved in the third field-free region (between magnet and second ESA) with helium as the collision gas at 50% beam reduction.

To enhance the metastable decomposition of some ions preheating of the FAB ions was accomplished by collisional excitation in the first field-free region (between source and first ESA). Helium was employed as the collision gas at pressures sufficient for 50-80% beam reduction. To select the collisionally activated ions, the outer member of the beta slits (after the first ESA) was used to eliminate the uncollided ions, which occur at higher energy, The 'hot' precursor ions were then transmitted to the third field-free region for metastable and CA experiments.

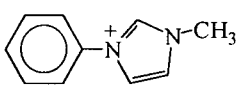
FTMS (Fourier transform mass spectrometry) experiments were performed on a custom-built instrument equipped with a cell capable of RF-only mode experiments. During the RF-only experiments, helium was used as the bath gas.

Early CI experiments showed that an adduct of *m/z* 160 formed in an ionized mixture of benzene and *N*-methylimidazole. FTMS experiments proved that the *N*-methylimidazole radical cation and neutral benzene were the reactants.

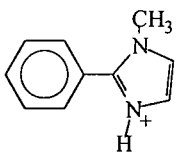
Once the reactants were established, the structure of the adduct ion was pursued. CAD spectra of the adduct provided little information as the fragment ions were mainly reactants; however, hydrogen atom loss was shown to occur to produce an even-electron ion of *m/z* 159. Experiments with d_6-benzene proved that the hydrogen atom loss was from the benzene moiety.

Because the CAD spectrum of the *m/z* 160 adduct provides little information, the structure of the even-electron ion at *m/z* 159 was pursued. The hydrogen atom loss allows us to postulate the *m/z* 159 ion as the C_6H_5 moiety attached to the imidazole ring. With this in mind, three reference compounds were synthesized for comparison. Their structures are shown below.

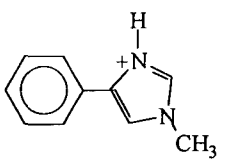
Standard *1*



Standard *2*

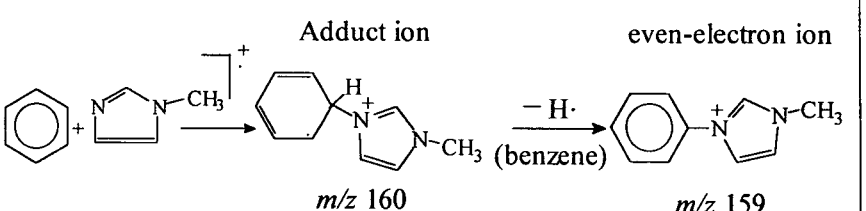


Standard *3*



Comparison of metastable and CAD spectra of the adduct and the three standards allowed us to rule out standard *3* as a possibility. Standards *1* and *2* have similar spectra to each other and the CI adduct which does not allow differentiation.

To differentiate between standards *1* and *2* , the methyl groups in both were substituted with a CD_3 group. For comparison, benzene was reacted with *N*-CD_3-imidazole to produce a radical cation at *m/z* 163. In a MS3 experiment, this ion produced one at *m/z* 162 via CAD. The daughter ion at *m/z* 162 was then CAD analyzed for comparison. After analysis it was determined that the *m/z* 159 CI ion closely resembled standard *3*. This information is summarized in the scheme shown below.



Investigation of Electrophile/Nucleophile Reactions of Polyheteroatomic Organic Cations with Allylic Molecules in Q2 of a Triple Quadrupole Mass Spectrometer

Introduction

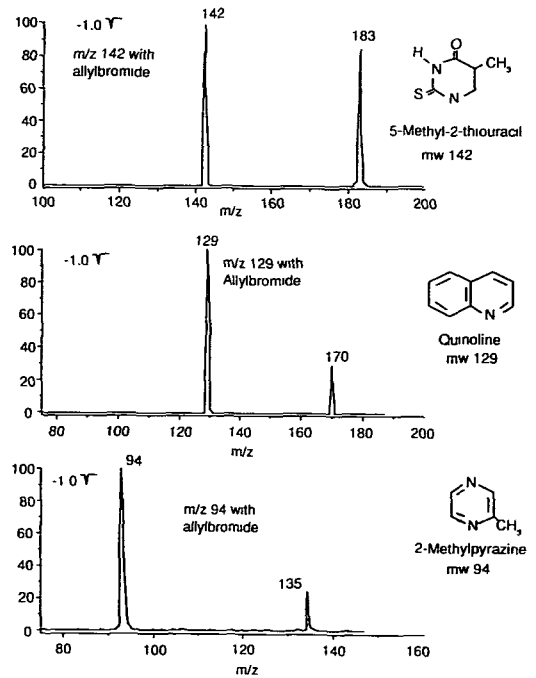
An ever increasing need exists to characterize chemical contaminants in complex environmental samples for those chemicals that are potential mutagens and/or carcinogens. Analyte specific detection must be rapid, sensitive, and cost effective. Our approach to this problem was to evaluate the use of mass selective ion-molecule reactions in the center quadrupole of a triple quadrupole mass spectrometer (1,2). Chemicals containing a nucleophilic heteroatomic center (N,S,O) which represents biomolecules such as DNA or protein are introduced into the ion source. Unknown environmental contaminants, electrophiles which may covalently react with biochemicals, are introduced into Q2 via a direct line or GC column. Analytes reacting with model nucleophilic cations are characterized by scanning Q3.

Experimental

All experiments were conducted on a Finnigan-MAT TSQ-70 triple quadrupole mass spectrometer. Neutral compounds were introduced into Q2 via the CIO transfer line. A sample introduction probe was constructed to provide introduction of liquid samples from the right side of the ion source. Analyses were conducted by Q3MS or Daughter ion experiments where Q1 was used to focus on an ion, Q2 passed all ions, and Q3 scanned for reaction products.

Results and Discussion

Compounds selected as model nucleophiles for this study were low molecular weight N and S containing cyclic compounds. Model electrophiles included a series of allylic compounds with greatly different chemical reactivity and mutagenic potential (3), as well as twelve different epoxides. Two reaction processes were observed, charge transfer and electrophilic addition/elimination. Associative reaction product spectra of three typical model nucleophiles, 5-menthyl-2-thiouracil, quinoline and 2-methylpyrazine are shown in figure 1. In each case, the radical cation molecular ion of the heterocycle was generated in the ion source and allowed to react with allyl bromide in Q2. The spectra show the reaction product 41 daltons greater than the m/z value of the nucleophilic reagent This increase was from the addition of the allyl moiety of allylbromide and loss of bromine.



Conclusion

It has been shown that gas-phase ion-molecule reactions in Q2 of a tandem quadruple mass spectrometer may be used to produce reaction products similar to solution phase chemistry. The interaction of ions of N and S containing compounds, which are model compounds for biomolecules such as DNA and protein, with neutral electrophilic reagents can predict in vivo endpoints such as mutagenesis.

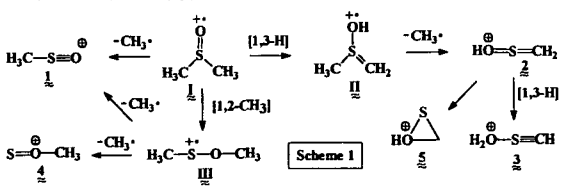
An Experimental and Theoretical Study on the Existence of the $H_3C—S\equiv O^+$ Ion as a Stable Gas Phase Species.

*Fábio Cesar Gozzo and *Marcos N. Eberlin*
Universidade Estadual de Campinas, Instituto de Química, CP 6154 Campinas, SP 13081-970 Brazil

Acylium ions are important and stable ionic species both in solution and gas phase. The acetyl cation, $H_3C—C\equiv O^+$, is one of the most important and simplest acylium ions and the most stable among the $C_2H_3O^+$ isomers. One of its sulfur analogs, the thioacetyl cation, $H_3C—C\equiv S^+$, is also a stable and well characterized gas phase species. There is, however, no clear evidence for the existence of $H_3C—S\equiv O^+$ (**1**), another possible sulfur analog of the acetyl cation. Gas phase generation of ion **1** could in principle be easily achieved by loss of methyl from ionized dimethyl sulfoxide but a further loss of water from ion m/z 63 has been interpreted as evidence for generation of the $H_2C=S=OH^+$ isomer (**2**). Recently,[1] the $CH_3—S\equiv O^-$ anion was characterized as a stable gas phase species. This finding opens the possibility that the corresponding cation **1**, as well as many other members of this potentially important class of sulfur analogs of acylium ions, can be also observed as stable gas phase species. Toward this end, this present experimental and theoretical study was undertaken.

Routes to m/z 63 formation from ionized dimethyl sulphoxide. Methyl loss from ionized DMSO could occur by three alternative routes, as shown in Scheme 1. Ion **1** should be formed in case no rearrangement takes place (**I**). A [1,3-H] shift would lead to **II** which upon methyl loss should yield ion **2**. A [1,2-CH_3] shift would lead to **III**, an ion that bears two non equivalent methyl groups and therefore could fragment to ions **4** and/or **1**. Ab initio calculations (Table 1) show that both rearrangements lead to more stable ions, the [1,2-CH_3] shift being the most thermodinamically favored process. The calculations show also that the O-CH_3 group would be lost preferentially from **III**. Therefore, formation of ion **1** is predicted either from **I** or from the more stable isomer, **III**. To evaluate the occurence of a further isomerization of ion **1**, the relative stabilities of ten CH_3SO^+ ions were estimated (Table 1). Among them, only ions **2-4** have the same C-S-O connectivity as that of ion **1**. Isomerization to ions **6-10** would change this connectivity and likely require the participation of the cyclic ion **5** as the intermediate. However, the calculations show that ion **5** does not lie in a potential well, ring opening without barrier to **2**. This makes the isomerizations to **5-10** unlikely, although some of these ions are more stable than **1**. Ion **1** is considerably less stable than **2**, and so the isomerization **1→2** has to be considered. However, transition state calculations show a relative high energy barrier (54.2 Kcal/mol) for this interconversion. Thus, the ab initio calculations indicate ion **1** as the most likely constituent of the m/z 63 population from ionized DMSO.



CID decomposition of ion m/z 63. Both high and low energy CID spectra of ion m/z 63 show fragmentation to occur mainly by loss of H_2O, S and SO. The latter fragmentation is no doubt a strong evidence for the presence of ion **1**, since the isomerization **2→1** should not occur (Table 1). The fragmentation by loss of water could be interpreted as presence of ion **2**, but its formation from isomerization of ion **1** induced by collision in the CID cell can not be dismissed.

Ion/Molecule reaction of m/z 63. Recently,[2] ion/molecule reactions with 1,3-dioxolanes were demonstrated to be a general approach for gas phase identification of acylium and thioacylium ions. The acetyl cation reacts to form a very abundant "oxirane addition" product at m/z 87, while its isomers, the oxarinyl cation and the $H_2C=C=OH^+$ cation, react mainly by proton tranfer. Ion m/z 63 from ionized dimethyl sulfoxide reacts with 1,3-dioxolane (Scheme 2) forming an abundant oxirane addition product ion at m/z 107. This , in analogy with the results for the $C_2H_3O^+$ isomers, indicates that the ionic beam consists mainly of ions **1**. The MS^3 spectrum of m/z 107 (Figure 1) shows fragmentation mainly to CH_3SO^+, as expected from the CID behavior of analog ions.

The Rich Gas Phase Ion/Molecule Chemistry of The Distonic Radical Cation $^{\cdot}CH_2$—O—CH_2^+ Revealed By Multiple Stage (MS^2 and MS^3) Mass Spectrometry Experiments.

Marcos N. Eberlin Universidade Estadual de Campinas, Instituto de Química, CP 6154 Campinas, SP 13081-970 Brazil

Distonic radical cations are chemically fascinating species since they possess, in a formal sense, spatially separated positively charged and radical sites and therefore could display a diverse and rich reactivity induced by both of these sites. The $^{\cdot}$CH2—O—CH2$^+$ ion (**1**) is one of the simplest distonic radical cations, displaying a peculiar ion/molecule reactivity characterized mainly by net $CH_2^{+\cdot}$ (sometimes net CH^+) transfer. No ion/molecule reaction where both the potentially reactive sites of ion **1** participate has yet been observed. In this study, reactions of the mass selected, pure ion **1** with several neutral compounds are investigated by multiple stage mass spectrometry (MS^2 and MS^3) experiments performed in the versatile pentaquadrupole instrument.[1] Two unprecedent reactions are observed and several structures of ion/molecule reaction products are determined.

The bydented character of ion 1. Reactions with Benzene and Anisole: The MS^2 product spectra for reaction with these two compounds reveal an interesting ion/molecule reaction in which both of the reactive sites of ion **1** participate. The ions observed at m/z 121 and m/z 151, respectively, are the products of a reaction occuring by net $C_2H_3O^+$ transfer, or in other words, proceeding by loss of a hydrogen atom from the intact adducts. Formation of ions **3** are determined by MS^3 experiments (Figure 1) and supported by high level ab initio calculations. The proposed mechanism (Scheme 1) involves an initial electrophilic attack of the positively charged site of ion **1**, followed by a [1,4-H] shift promoted by the radical site which is now incorporated into the adduct structure. This hydrogen shift regenerates the ring aromaticity and leads to formation of the ionized benzyl methyl ether **2**. Further loss from **2** of an hydrogen atom forms **3**. No rearrangement of **3** to the tropylium ion **4** or, alternatively, of ions **2** to the ionized cycloheptatriene **5**, are noted.

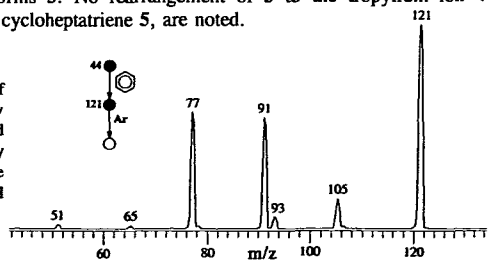

Figure 1- MS^3 sequential product spectrum of ion m/z 121 (assigned as **3**) formed by ion/molecule reaction between mass-selected ion **1** and benzene. This spectrum is very similar to the MS^2 CID spectrum of the authentic ion produced from ionized benzyl methyl ether.

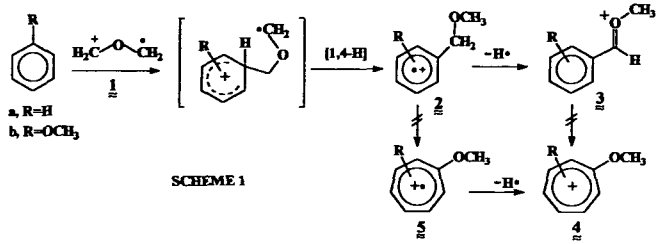

SCHEME 1

A "hole-catalysed"[2] 1,3-dipolar cycloaddition to Ketones: Ion m/z 99 is by far the main product of the ion/molecule reaction between ion **1** and cyclopentanone (Figure 2). This reaction corresponds to net addition of 15u, best assigned to loss of 29u from the intact adduct. Abundant products from similar reactions are also observed for other ketones, i.e. acetone, 2-butanone and 3-pentanone. This reactivity can be accounted for by addition of ion **1** to the carbonyl group (Scheme 2) yielding the ionized 4,4-disubstituted dioxolane intermediates **6**. **1** is the ionized form of the simplest carbonyl ylid $^{\cdot}CH_2$-O-CH_2^+ and by using the terminology introduced by Bauld,[2] this reaction can be classified as a "hole-catalysed" 1,3-dipolar cycloaddition, an unprecedent gas phase reaction. The cycloadducts **6** fragment completely to the cyclic oxonium ions **7** by loss of one of the 4-substituents. Only loss of methyl for acetone and ethyl for 3-pentanone are observed, while 2-butanone shows losses of both methyl and ethyl, the latter being largely predominant. The intermediate for cyclopentanone would be the ionized spiro compound **6d**. This radical cation, in analogy to the fragmentation behavior of 1,4-dioxospiro[4,5]-decane and several analog ions is expected to fragment mainly by loss of ethyl to form m/z 99 and also by loss of a neutral molecule of C_3H_6 to form m/z 86 (Scheme 3), as indeed observed. Formation of ions **7** are also supported by MS^3 experiments and high level ab initio calculations. A stepwise mechanism similar to that presented in Scheme 2 has been proposed for the ionized methylene transfer reaction of the distonic ion $^{\cdot}CH_2CH_2$—O-CH_2^+ to acetonitrile.[3]

Figure 2- MS^2 product spectrum of ion/molecule reactions between mass-selected ion **1** and cyclopentanone, showing product ions corresponding to net CH^+ (m/z 97) and $CH_2^{+\cdot}$ (m/z 98) transfers and the ones assigned to the products of a "hole-catalysed" 1,3-dipolar cycloaddition (m/z 99 and m/z 86).

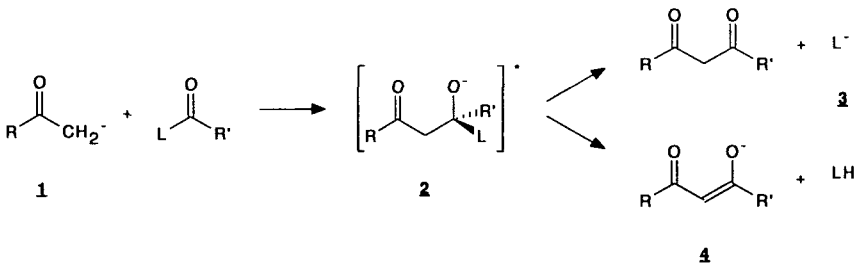
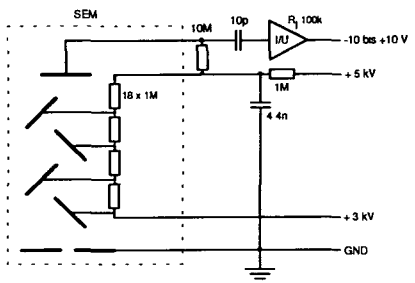
Gas Phase Addition / Elimination Reactions of Carbanions with Carbonyl Groups measured on the Quadrupole, Quistor, Quadrupole Tandem Mass Spectrometer

M. Stöckli, P. Kofel and U. P. Schlunegger
Institute of Organic Chemistry, University of Bern, Freiestr. 3, CH-3012 Bern, Switzerland

Nucleophilic addition of carbanions **1** to carbonyl groups is of considerable importance in organic chemistry. In the general form, the reaction proceeds by a tetrahedral intermediate. The tetrahedral intermediate **2** has been found in a few cases in solution. However, since such addition ions are formed with excess energy, they either revert to reactants or fragment to different products in the absence of stabilising collisions, which is typical for the low pressure conditions used in gas phase ion chemistry. In the presence of a good leaving group L this group is eliminated from the intermediate **2**. Depending on the proton affinity of the leaving group a proton is transfered to the leaving group, and correspondingly either the leaving group anion **3** or the deprotonated addition / elimination product anion **4** is observed [1,2]:



For the study of such reactions a purpose built quadrupole, quistor, quadrupole tandem mass spectrometer [3] was modified for operation in negative ion mode.
Primary ions were generated in a differentially pumped external ion source under negative CI conditions with ammonia, mass selected by a first quadrupole mass filter and injected into a quistor. After a variable storage period in the quistor for reaction the product ions were extracted and analysed by a second quadrupole mass filter. Experimental parameters were: pressure differential 30'000 (between source and quistor chambers); ionization / injection time 10 ms; nominal injection energy 1 ... 2 eV; helium pressure 10^{-3} mbar; reagent pressure $1\ 10^{-6}$ ... $2\ 10^{-5}$ mbar; reaction time 10 ms ... 1 s; quistor radius 1 cm; radiofrequency 1.3 MHz; rf amplitude 370 V (exclusion limit *m/z* 24).
For the detection of negative ions with a secondary electron multiplier the electron current collector has to be floated at a high voltage potential (typically + 5 kV). For operation of the amplifier and recording electronics close to ground potential the electron current was decoupled by a high voltage capacitor. This simple solution could be chosen because the ion currents arrive as a pulse during the extraction event of the pulse sequence:



The following reactions were studied and their rate constants determined:

Reagent	Anion **1** ****	Anion **3**	PA Anion **3** / [kJ/mole]	Anion **4**	Rate constant / [cm^3/s/mol.]
2,2,2-Trifluor-ethyl acetate	$CHOCH_2^-$	$\{CF_3CH_2O^-\}$	1551	$CHOCH{=}COCH_3^-$	$5\ 10^{-11}$ *
Vinyl acetate	$CHOCH_2^-$	$\{CH_2{=}CHO^-\}$	1531	$CHOCH{=}COCH_3^-$	$1.4\ 10^{-11}$
Chloral	$CHOCH_2^-$	CCl_3^- **	1494	$\{CHOCH{=}CHO^-\}$	$7\ 10^{-10}$
Ethanoyl chloride	$CHOCH_2^-$	Cl^-	1393	$\{CHOCH{=}COCH_3^-\}$	$2\ 10^{-9}$
Vinyl acetate	$CHOC(CH_3)_2^-$	$CH_2{=}CHO^-$	1531	***	$3\ 10^{-10}$

{ } Corresponding m/z not observed.
* Compares to $1.25\ 10^{-10}$ cm^3/s/mol. obtained in an ICR study [1].
** A second major product ion $CHOCCl_2^-$ (Cl^+ transfer) has been observed, too.
*** Possibly O^--attack, β-dicarbonyl product contains no α-hydrogens.
**** $CHOCH_2^-$ was produced from acetaldehyde and $CHOC(CH_3)_2^-$ from isobutyraldehyde.

These results are consistent with the mechanism given above. The addition / elimination product is only observed as an ion if the leaving group has a high proton affinity. The measurement of the pressure in the quistor has to be improved in the future to remove the large uncertainty in the measured rate constants.

METHANE LOSS IN DIMETHYL AND TRIMETHYL OXONIUM IONS

H. E. Audier,(1) D. Berthomieu (2) and T. B. Mc Mahon (3)

(1) DCMR, Ecole Polytechnique, Route de Saclay, 91128 PALAISEAU Cedex - FRANCE
(2) LPCR, Centre Universitaire d'Orsay, 91405 ORSAY Cedex - FRANCE
(3) University of Waterloo, Waterloo, Ontario, CANADA N2L 3G1

Dimethyl and trimethyl oxonium ions, **1** and **2**, eliminate CH_4 to yield CH_2OH^+ and $CH_3OCH_2^+$ respectively. On the basis of threshold collision induced decomposition studies, Wang, Squires and Farcasiu[1] have previously proposed that the fragmentation of $(CH_3)_3O^+$ "occurs by a heterolytic cleavage mechanism, with the critical transition state strongly resembling a $CH_3^+/(CH_3)_2O$ complex." Farcasin and Pancirov[2] have also studied the unimolecular dissociation of labelled $(CH_3)_3O$ but have cautioned than in their studies they" are not sure that the mixture of ions have reached equilibrium." In the present study several different complementary approaches have been used to probe the mechanism of CH_3^+/CH_3OH and $CH_3^+/(CH_3)_2O$ reactions.

Unimolecular Dissociation in a Reverse-Geometry Mass Spectrometer

Ions **1** and **2** were generated in the ion source of a VG ZAB-2F mass spectrometer by reaction of CH_3X(X=OH or I) with either methanol or dimethyl ether using H_2O as the chemical ionization reagent gas and their subsequent fragmentation examined in the 2nd field free region.

(1) The similar behaviour of $C_2H_4D_3O^+$ ions generated from either CD_3OH/CH_3I, CD_3OH/CH_3OH or CH_3OH/CD_3I mixtures shows that these reagents all yield the protonated dimethyl ether, $CH_3OHCD_3^+$.

(2) This $CH_3OHCD_3^+$ ion subsequently eliminates either CHD_3 or CH_3D in a ratio of 45:55. Similarly generated $(CH_2D)_2OH^+$ loses CH_3D or CH_2D_2 in a ratio of 63:37, revealing the existence of an important secondary isotope effect and a minimal primary isotope effect. These data can be rationalized either by the intermediacy of a $[CH_3^+{\cdot}CH_3OH]$ complex or by a concerted asynchronous process in which the transition state closely resembles such an ion-neutral complex.

(3) In the case of labelled trimethyloxonium ions, similar experiments lead to the conclusion that the primary isotope effect is more important that in the preceding, dimethyloxonium, case and the secondary isotope effect remains significant, indicating that the elongation of the C-O bond plays a determinant role in the mechanism.

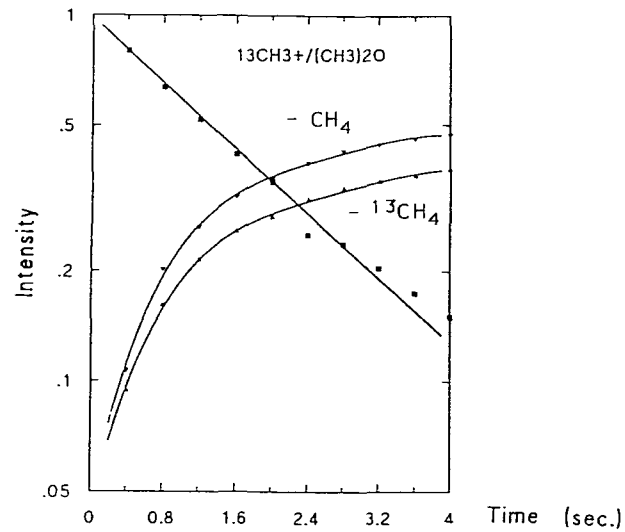
Bimolecular Ion-Molecule reactions in a FT-ICR Cell

The ion-molecule reactions between various isotopically labelled methyl cations, generated in an external ion source, and labelled neutral methanols and dimethyl ethers have been studied in the FT-ICR

cell of a Bruker CMS-47X spectrometer Such experiments clearly demonstrate that two competitive processes occur under ICR conditions: (i) the formation of an oxonium ion intermediate which dissociates *via* loss of methane, and (ii) a direct reaction in which the initial methyl cation abstracts a hydride from a methyl group of the neutral molecule.

(1) The reaction of CD_3^+ with CH_3OH leads to CHD_3 and CH_3D losses in a ratio of 59:41, while in the reaction of CH_3+ with CD_3OH these same neutrals are lost in a ratio of 46:54.

(2) $^{13}CH_3^+$ reacts with $(CH_3)_2O$ to yield CH_4 and $^{13}CH_4$ in a ratio of 56:44 whereas a mechanism involving statistical losses from a trimethyloxonium ion intermediate would yield a ratio of 2:1.



Ab Initio Calculations

Ab initio calculations have been carried out on $(CH_3)_2OH^+$ wich indicate that CH_4 loss may occur *via* a concerted process involving a transition state which has the structure of a $[CH_3^+,CH_3OH]$ complex. For the moment, although no minimum corresponding to a stable ion-neutral complex has been located on the potential energy surface, it cannot be definitively stated that such complexes are not present. On the opposite a $[CH_4,CH_2OH^+]$ complex has been shown to be a stable structure.

DEPROTONATION OF $^{\bullet}CH_2(CH_2)_nXH_2^+$ DISTONIC IONS ($n = 0, 1$; $X = OH, OCH_3, NH_2$)

H.E. Audier[1], D. Leblanc[1], P. Mourgues[1] and S. Hammerum[2]
1 D.C.M.R. Ecole Polytechnique, 91128 Palaiseau Cedex, France
2 University of Copenhagen, DK 2100 Denmark

Is there a significant difference between the Proton Affinities (PA) of the radicals $^{\bullet}CH_2(CH_2)nXH$ (X = O ; NH) and those of the corresponding alcohols or amines ? In order to answer this question we have determined the acidity of the α and β-distonic radical cations $^{\bullet}CH_2XH^+$ and $^{\bullet}CH_2CH_2XH^+$ (X = OH, OCH_3, NH_2) by studying the proton transfer from these ions to a serie of neutral molecules of known proton affinities; this allows us to bracket the proton affinities of the corresponding radicals.

α-Distonic radical cations

$^{\bullet}CH_2OH_2^+$

This ion does not protonate CS_2, CH_3Br and water. On the opposite, protonation of CF_3COOH, CF_3CD_2OD and CH_3I is observed.

These results show that the proton affinity of hydroxymethyl radical, $^{\bullet}CH_2OH$ is between that of H_2O and that of CF_3COOH. Based on the proton affinities recently published, we suggest that PA($^{\bullet}CH_2OH$) is 166 ± 2 kcal.mol^{-1}. By comparison, the PA of methanol is 182 kcal.mol^{-1}.

$^{\bullet}CH_2NH_3^+$

This ion does not protonate acetone-d_6 nor tetrahydrofuran-d_8, while C_6H_5CDO, and NH_3 are protonated.

These results for $^{\bullet}CH_2NH_3^+$ allow us to derive a proton affinity of 199 ± 2 kcal.mol^{-1} for $^{\bullet}CH_2NH_2$. By comparison, the PA of methylamine is 214 kcal.mol^{-1}.

Our results show that the hydroxymethyl and the aminomethyl radicals are considerably less basic in the gas phase than methanol and methylamine, which agrees well with measurements reported for these and related species in condensed phase.

β-Distonic radical cations

$^{\bullet}CH_2CH_2OHCH_3^+$

The PA of $^{\bullet}CH_2CH_2OHCH_3$ lies between that of acetonitrile and that of dimethyl ether; slow proton transfer is observed to toluene-d_8 and to acetic acid. This leads us to suggest that PA ($^{\bullet}CH_2CH_2OCH_3$) is 191 + 1 kcal.mol^{-1}. By comparison, the PA of methyl ethyl ether is 196 kcal.mol^{-1}.

$^{\bullet}CH_2CH_2NH_3^+$

This ion protonates methylamine (rapidly) and dimethyl sulfoxide (more slowly), which leads us to propose that PA ($^{\bullet}CH_2CH_2NH_2$) is 212 + 2 kcal mol^{-1}. PA(ethylamine) is 217 kcal mol^{-1}.

Our results indicate that the proton affinities of β-aminoalkyl and β-hydroxyalkyl radicals are lower than those of the corresponding even-electron molecules. The difference is, however, not nearly as pronounced as for the α-substituted radicals.

Studies of the proton transfer reactions of β-distonic ions are frequently complicated by rapid, competing reactions, such as charge exchange and transfer of ethylene$^{+\cdot}$. Furthermore, a number of very recent observations suggest that the reactions of α- and β-distonic ions with neutral species of similar acidity may be accompanied by isomerization. If substantiated by further studies, this phenomenon may require reinterpretation of some of the present results.

REACTION OF TERT-$C_4H_9^+$ CATION WITH ARENES : INTERMEDIACY OF Π-COMPLEXES

D Berthomieu[1], V Brenner[2], G. Ohanessian[1], J P. Denhez[1], P. Millié[2] and H E Audier[1]

(1) D C M R. Ecole Polytechnique, 91128 Palaiseau Cedex, France

(2) C E A.-C E Saclay, 91191 Gif-sur-Yvette, France

Introduction

The intermediacy of π-complexes in the fragmentation of metastable protonated alkylbenzenes has been suggested for three reactions :

1. The production of a tert-alkyl fragment from protonated n (or sec)-alkylbenzene (1)

   C_6H_6-n-$C_nH_{2n+1}^+ \rightarrow [C_6H_6, \text{n-}C_nH_{2n+1}^+] \rightarrow [C_6H_6, \text{tert-}C_nH_{2n+1}^+]$

2. The H-exchange preceding the dissociation of C_6H_6-iso-$C_3H_7^+$ (2)

   $C_6H_6\text{-iso-}C_3H_7^+ \leftrightarrow [C_6H_6, \text{iso-}C_3H_7^+] \leftrightarrow [C_6H_7^+, C_3H_6]$

3. The isobutane elimination from protonated tert-butyl alkylbenzenes (3)

   $[\text{tert-}C_4H_9\text{-}C_6H_5\text{-}C_2H_5^+ \rightarrow [\text{tert-}C_4H_9^+, C_6H_5C_2H_5] \rightarrow C_6H_5CH^+CH_3 + C_4H_{10}$

Reactions of tert-$C_4H_9^+$ with arenes

These reactions were performed in the ion-source of a VG-ZAB-2F mass spectrometer (B/E) and the decompositions of the adduct were studied in the 2nd FFR.

1. When the encumbrance is small (Ar = benzene or toluene), there is no difference between the MIKE spectrum of the adduct (tert-$C_4H_9^+$+ arene) and that of the isomeric protonated alkyl arene.

2. On the opposite, it has been shown by radiolytic technique that tert-$C_4H_9^+$ does not react with paraxylene by C-C bond formation.

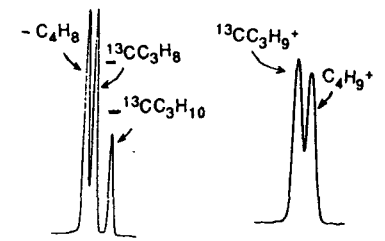
The adduct (paraxylene + tert-$C_4H_9^+$) leads predominantly (90 %) to a benzylic ion through isobutane loss while the protonated tert-butyl paraxylene leads to tert-$C_4H_9^+$ and to the protonated xylene by the way of isobutene loss. We therefore conclude that the adduct essentially corresponds to a π-complex which is the precursor of the isobutane elimination.

3. The adduct (4-tert-butyl toluene + tert-$^{13}CC_3H_9^+$) yields to i) tert-$C_4H_9^+$ and tert-$^{13}CC_3H_9^+$ (50/50) ii) C_4H_8 and $^{13}CC_3H_8$ losses (50/50) iii) only to tert-$^{13}CC_3H_{10}$ elimination (no C_4H_{10} elimination).

This result proves that the adduct corresponds in this case to two structures

i) The covalently bonded structure which is the precursor of tert-$C_4H_9^+$ and of the isobutene loss

ii) The π-structure which leads to a benzylic ion with elimination of a labeled isobutane molecule.



MIKE spectrum of the adduct

Calculations

The results clearly show that the π-complexes are stable enough to survive from the ion source to the 2nd FFR.

Ab-initio and simulated annealing calculations confirm that π-complexes correspond to local minima on the potentiel energy surface. Electrostatic and dispersion energies represent the more important contribution to their stabilization energies. This stabilization energy is calculated to be 11.6 kcal.mol^{-1} for the [benzene, tert-$C_4H_9^+$] complex.

Selective Identification of Benzyl and p-Tolyl Ions in the Mixture of C_7H_7+ Ions By Ion/Molecule Reactions

Tomas Vaisar
Inst. Org.Chem.Biochem., Prague Czech Republic
Present address: Molecumetics Ltd., Bellevue, WA

Ion/molecule reactions represent one possible route to identification of isomeric ions. Herein, gas-phase reaction of C_7H_7+ isomeric ions with anisole is presented.Reactivity of each isomer differs, while tropylium ion is nonreactive and benzyl and p-tolyl ions for adduct ions at the same m/z, however with different structure as is visualised by CID spectra.

Anisole as a reagent combines two possible reactive sites, etheric oxygen, where tolyl ions are supposed to react[1], analogy to dimethylehter, and phenyl ring where reactivity of benzyl ions should be directed[2], analogy to toluene.

For the reaction individual isomers were generated from source compounds as mixtures of isomers where one isomer prevails. Tolyl ions were generated from p-nitrotoluene, benzyl from bibenzyl or from benzylbromide by EI (70 eV). Thermal degradation of tropyliumtetrafluoroborate at approx. 220 oC gave tropylium ion.

For the observation of the reaction anisole vapours (giving ion source pressure 3 x 10^{-6} bar) were mixed in the ions source with vapours of source compounds to give the overall pressure 3-4 x 10^{-5} bar. EI spectra of these reaction mixtures showed for both benzyl and tolyl ions peak at m/z 199 corresponding to addition of the ion to anisole molecule, while for tropylium no such ion was observed. CID spectra of this ion from the field free region between magnetic and electrostatic analyzers obtained by scanning ESA show strikingly different features for both reacting isomers. For tolyl the most abundant ion at m/z 184 corresponds to methyl loss with weak peaks at m/z 91 and 121 probably from benzyl ion impurities (fig 1b). the structure of oxonium ion is suggested for this adduct ion. For the reaction of benzyl there are only these peaks at m/z 121 and 91 from losses of benzene from benzyl moiety (as proved by use of d8-toluene as C7D7+ source) and from reversed association reaction,respectively. Structure of the adduct in this case can be described as an intermediate of Friedel-Crafts alkylation of anisole, where benzyl is attached either to o- or p- position. Surprisingly, the ion corresponding to methyl loss was also observed in the CID spectrum of the adduct when toluene was used as C7H7+ ions source. Thus from the adduct of anisole with C7D7+ ions identity of lost benzene molecule was determined (vide supra) as well as it was shown that the methyl radical lost comes from anisole.

This reaction seems to be easy prove for isomeric identity of the ions studied and can be possibly transffered in to the collison cell of triple stage quadrupole mass spectrometer for more easy use.

Electron Impact Induced Self-Protonation and Self-Condensation of Allenic Ketones

*Chung-Ping Yu, Elisa Rambo, and Jack K. Crandall, Chemistry Department, Indiana University, Bloomington, IN 47405

INTRODUCTION Gas phase ion-molecule reactions of allene (C_3H_4)[1] and various carbonyl compounds (n-propyl acetate[2] and benzyl acetate[3]) have been studied using CIMS, MIKE, and CAD techniques. In the earlier reports formation of allene dimer $[2M-H]^+$ ions and protonated acetate dimer $[2M+H]^+$ ions are observed via [2+2] cycloaddition and nucleophilic addition, respectively. To further study these dimerization processes, we investigated several allenic ketones using the conventional electron impact method. The results of these experiments provide evidence for the competition between nucleophilic addition and [2+2] cycloaddition in the allenic ketone system.

EXPERIMENT The EI experiments were performed with a Kratos MS80 mass spectrometer at 30 eV in a high pressure EI/CI source ($5X10^{-5}$ ~ $1X10^{-4}$ Torr) with the source temperature at 40-50 °C. Samples were introduced into the instrument via direct insertion probe. All mass spectral data presented herein are single scans and are representative of several scans recorded during each experiment.

RESULTS AND DISCUSSION The EI mass spectra of allenic ketones **1-6** (Table1) show a prominent $[M+H]^+$ peak as compared to $[M]^+$ peak, indicating the occurrence of self-protonation in the ion source. The predominant fragmentation of $[M+H]^+$ is loss of 16 and 44 u, except for compound **2**, possibly due to elimination of CH_4 and CO as shown in the Scheme 1 (Scheme 1 is not a representative mechanism of **2**). The mass spectra of compounds **1-4** also display an intense signal for the ion $[2M+H]^+$ peak corresponding to possible structure **a** formed from nucleophilic addition of one M molecule to the $[M+H]^+$ ion and/or proton-bond dimer **b**. The proposed structure **a** is supported by the sequentially analogous loss of 16 and 44 u. Investigation of mass spectra of compounds **5** and **6** leads to an interesting phenomena observed for increasing formation of $[M]^+$ and $[2M]^+$ ions. It is believed that [2+2] cycloaddition corresponds to the appearance of the $[2M]^+$ ion. This is rationalized by consideration of decreasing intramolecular interaction between carbonyl group and allenic double bond with increasing distance between these two groups to produce both "independent" functions.

CONCLUSION In this preliminary work, we report that with decreasing carbon chain length increases abundance of $[M+1]^+$ and $[2M+1]^+$ ions in the EI mass spectrometry under high pressure conditions. A possible dimerization mechanism is proposed on the basis of fragmentation patterns of protonated dimers. Self-protonation of allenic ketones is believed to be responsible for the formation of $[M+1]^+$ ions following nucleophilic addition, rather than [2+2] cycloaddition.

Differentiation of Isomers through Energy-Resolved CID and Ion/Molecule Reactions in an Ion Trap Mass Spectrometer

*Brad I. Coopersmith and Richard A. Yost, University of Florida
Gainesville, FL. 32611

The quadrupole ion trap mass spectrometer (QITMS) has several features which make it an ideal instrument for allowing comparisons between gas-phase and solution-phase reaction mechanisms. Being tandem-in-time, the QITMS can act as a reaction vessel to form reaction products and is able to perform MS^n (n>2) on these products. This latter ability has been used to determine product ion structures based upon the fragment ions (and their abundances) formed following resonant excitation collision-induced dissociation (CID)[1]. However, the use of fragment ion formation for isomer structure differentiation is limited, because in many instances the isomers will yield identical fragment ions. An alternative method for isomer differentiation is the use of selective ion/molecule reactions, as has been employed in the identification of $C_7H_7^+$ isomers [2]. We have investigated the use of a combination of energy-resolved CID (ER-CID) with selective ion/molecule reactions to differentiate between several even-electron secondary and tertiary carbocation isomers.

In the QITMS, CID is thought to occur in a stepwise manner, meaning that energy deposition into the ion occurs through successive low-energy collisions rather than through a single high-energy collision. As a result, the time between collisions allows the deposited energy to be distributed throughout the ion. Therefore, isomer ions which yield the same fragment ions are believed to pass through a common transition state before fragmenting. This mechanism limits the ability of CID to distinguish between isomers based solely upon the fragment ions formed.

ER-CID is shown conceptually in the reaction coordinate in Figure 1. If the isomer ions have different ground state energies, the activation energies (E_{a1} and E_{a2}) required for each isomer to reach the common transition state should also be different. The difference is based on the assumption that the energy barrier to isomerization, E_I, is not exceeded during ion formation. If E_I is exceeded, the ions will be able to isomerize to assume the lower energy conformation. Once the common transition state is achieved, each isomer will fragment at the same rate with respect to the amount of energy deposited. Figure 2 shows the two cases. When E_I is not exceeded during ion formation the activation energies are different and each isomer has a crossover point at a different energy. When E_I is exceeded, there is only one isomeric structure, therefore both isomers have the same crossover energy.

The effects of the mass isolation and the CI reagent ion used were examined. Of the two mass isolation methods studied, apex isolation was found to impart less energy into the ion as compared to two-step isolation. Using a gentle protonating reagent ion, the m/z 57 ion from isobutane, the two-step mass isolated ions had lower crossover energies than the apex isolated ions. Since the same CI reagent ion was used, the only other factor which could impart energy into the ion was the isolation method. The lower crossover energy indicates that the two-step mass isolated ion must have a higher initial energy, which could only occur if two-step mass isolation is more energetic than apex isolation. Two-step isolation was not found to be energetic enough to cause isomerization. On the other hand, it was found that the use of a stronger protonating reagent ion, for example the $C_2H_5^+$ ion from methane, can cause isomerization.

Another method of isomer differentiation examined was the use of selective ion/molecule

reactions. The concept of selective ion/molecule reactions is to use a reactant (ion or neutral) which will only react with the desired component (neutral or ion) of the system under analysis. Based upon previous studies [3], *tert*-butanol was chosen as the neutral reactant to distinguish between secondary and tertiary carbocations using the proposed scheme shown in Figure 3. When *tert*-butanol reacts with a secondary carbocation, the basic oxygen can remove the hydrogen from the carbocation center resulting in the formation of an $[A+56]^+$ product ion. Tertiary carbocations have no hydrogens at the carbocation center, thus the driving force for this reaction is removed and there should be no reaction. This method was found to be effective for both sets of isomers investigated.

Further Investigations of Nucleophile/ElectrophileIon/Molecule Reactions in an Ion Trap Mass Spectrometer

*Brad I. Coopersmith and Richard A. Yost, University of Florida
Gainesville, FL 32611
Douglas W. Kuehl, U.S. Environmental Protection Agency,
Duluth, MN 55804

Gas-phase ion/molecule reactions between potential carcinogens and mutagens (electrophiles) and model DNA bases (nucleophiles) in a tandem mass spectrometer can be analytically useful as an environmental screening technique. Previous work in our laboratory [1] investigating such reactions of carcinogenic allyl halides with piperidine and pyridine on a triple quadrupole mass spectrometer (TQMS) showed good correlation with the Ames Test, a bioassay used to determine mutagenicity. The inability to obtain MS/MS structural information on the product ions formed in the TQMS collision cell led to the use of a tandem-in-time instrument, the quadrupole ion trap mass spectrometer (QITMS) [2]. However, the lack of spatial separation allowed side reactions, especially the self-protonation of the nucleophile, to dominate the product spectra for all nucleophiles investigated.

The desired reaction with the allyl halides (EX), is the addition of the allyl group (E) to the nucleophile ion ($N^{+\cdot}$, m/z N) through an S_N2' mechanism to form a product ion (NE^+) at m/z [N+41]. It became evident that the only method to prevent unwanted side reactions would be to prevent any neutral nucleophile from being present during the reaction period. This goal could be accomplished through two methods, either spatial separation or temporal separation of the nucleophile from the reaction region. The QITMS chamber was modified as shown in Figure 1 for temporal separation using pulsed valve introduction of the nucleophile. The timing required for temporal separation is shown in Figure 2. After pulsing the valve open and closed, the nucleophile is ionized to produce the largest number of nucleophile ions possible. After ionization, the nucleophile ions are isolated as the neutral nucleophile pressure drops back to its base pressure. At that point, the partial pressure of the electrophile will be higher than that of the nucleophile and the reactions due to the neutral nucleophile should be minimized. Using a timing sequence similar to that in Figure 2, the spectrum shown in Figure 3 was obtained for the reaction of pyridine ions (m/z 79) with allyl iodide neutrals. The unwanted side reactions leading to the formation of product ions at m/z 80 and m/z 285 have been minimized while the desired reactions with the allyl iodide leading to the production of ions at m/z 120 (NE^+) and m/z 206 dominate the spectrum. This spectrum indicates that almost all of the pyridine neutrals have been removed prior to the reaction period, thus allowing the pyridine ions to react primarily with the allyl iodide.

To model the DNA/carcinogen reactions in the gas-phase more effectively, nucleophiles with more than one possible site of reaction need to be examined. Three multi-functional nucleophiles were investigated. Their names and structures are shown in Table 1. The information from MS^4 experiments for the reactions of these nucleophile ions with allyl bromide was used to determine the site of reaction. The fragmentations suggest that the allyl group bonds to the sulfur atom as opposed to the nitrogen atom for both the 2-thiohydantoin and the ω-thiocaprolactam $N^{+\cdot}$ ions. For the case of 2-imidazolidinethione, it was not possible to determine to which atom the allyl group is bonded. The hard-soft acid-base (HSAB) theory was used to explain all of the

electrophile/nucleophile ion/molecule results obtained thus far.

Sample Ion/Sample Molecule Reactions in Chemical Ionization Mass Spectrometry

Burnaby Munson, Adebayo Onigbinde, and Gordon Nicol
Department of Chemistry and Biochemistry
University of Delaware
Newark, DE 19716

The electron ionization (EI) mass spectra of oligomeric polyethylene glycols (PEG's) are very similar. The base peak is at m/z 45 and there are virtually no detectable $M^{+\cdot}$ ions in the spectra. The majority of the fragment ions are at low molecular weight and are not helpful for structure identification or confirmation.

The CH_4 CI (chemical ionization) mass spectra are somewhat more useful than the EI spectra for identification of the PEG's. The base peak is at m/z 45 and there are structurally useful fragment ions. There are two series of ions corresponding to $(C_2H_4O)_nH^+$ and $(M-(C_2H_4O)_o)^+$. With the larger PEG's an additional series corresponding to $HO(C_2H_4O)_nH_2^+$ becomes significant. There are low relative abundances of MH^+ ions and the relative abundances of the MH^+ ions do not obviously increase with increasing molecular weights of these oligomers. Interpretation of any molecular weight dependence in the relative abundance of MH^+ ions is hampered by the dependence of the abundance of MH^+ on sample size.

The relative abundances of the MH^+ ions increase dramatically with increasing sample size because of sample ion/sample molecule reactions. These sample ion/sample molecule reactions can be easily detected and studied in GC/CIMS studies. For somewhat larger than usual samples, one can record many (20 - 30) spectra for each chromatographic peak and note the relative abundances of the major ions in the spectra as the sample size varies throughout the chromatographic peak. The extent of conversion, $\Sigma I_i(\text{Sample})/\Sigma I_i(\text{Total})$, is proportional to the concentration of the sample in each spectrum.

Plots of relative abundance vs extent of conversion clearly show the products of sample ion/sample molecule reactions. Sample ions whose relative abundances decrease with increasing extent of reaction (sample concentration) are clearly reacting to form those ions whose relative abundances increase with increasing extent of reaction. For the polyethylene glycols the major reactions are the proton transfer reactions,

$$C_2H_5O^+ + PEG \rightarrow PEGH^+ + C_2H_4O$$

Small amounts of the proton-bound dimers, PEG_2H^+, are also observed. Little evidence is observed for adduct ions.

Similar observations were made for the dimethyl ethers of the polyethylene glycols. The EI spectra of these compounds are quite similar and contain virtually no detectable M^+ ions, and have a base peak at m/z 59. Most of the fragment ions occur at low mass and are not useful for structure determination.

Presented at the 41st ASMS Conference on Mass Spectrometry

The CH_4 CI mass spectra of the dimethyl ethers of the polyethylene glycols also contain m/z 59 as the base peak. There are low abundances of MH^+ ions and structurally useful higher mass fragment ions in two major series, $(C_2H_4O)_nCH_3^+$ and $(C_2H_4O)_nH^+$. The relative abundances of the MH^+ ions do not obviously increase with increasing molecular weights of these oligomers. The relative abundances of the MH^+ ions increase dramatically with increasing sample concentration.

GC/CIMS studies on the di-methyl ethers of polyethylene glycols, like those mentioned above for the PEG's, clearly show reacting sample ions and ions which are products of sample ion/sample molecule reactions. For these compounds, the major new product ion is MH^+. The reaction sequence is somewhat more complex for these compounds. GC/CIMS studies with ethylene glycol di-methyl ether suggest that $C_2H_5O^+$ reacts to form $C_3H_7O^+$ at m/z 59 and perhaps MH^+. $C_3H_7O^+$ also appears to react to form MH^+. FT/ICRMS studies establish this sequence.

Sample ion/sample molecule reactions may occur relatively frequently under commonly used CI conditions, particularly with polar compounds. These reactions are quite useful in forming MH^+ ions for molecular weight determination. These sample ion/sample molecule reactions will not be noticed unless studies are made about the variation of CI mass spectra with sample size. These analytically useful ion/molecule reactions can be recognized and studied in GC/CIMS experiments for complex molecules with only slightly larger samples than are commonly used for analysis.

Evaluation of ion formation of carbamate pesticides in TSP- and ESP MS using different eluent additives and proton affinity calculations

M.Honing[1], D.Barceló[2] and J.Abian[3]; Dept. Environmental[1]- and Neuro[2] Chemistry, CID/CSIC, Jordi Girona 18-26, 08034 Barcelona, Spain.
B.L.M. van Baar[3], R.T.Ghijsen[4], U.A.Th. Brinkman[4]; Dept. Organic[3] and Analytical[4] Chemistry, Free University, de Boelelaan 1083, 1081 HV Amsterdam, The Netherlands.

The carbamate pesticides show in various ionisation techniques a specific fragment ion, $[M+H-CH_3NCO]^+$, which is formed after the loss of methylisocyanaat from the protonated molecular ion. As will be reported [1], addition of ammonium to the eluent in TSP-MS causes the loss of this fragment ion. In this presentation the effect of addition of nicotinic acid and the use of aceton, instead of methanol or acetonitrile, is discussed. For comparison studies, ESP experiments were performed. With both interfaces a list of 19 carbamate pesticides and 12 of their degradation products were investigated.

Results and discussion

Use of Aceton as organic modifier in a 50:50 mixture with water, lead to the formation of the $[M+H]^+$ and the $[M+CH_3COCH_3+H]^+$ ions. Contrary to methanol and acetonitrile, the typical fragment ion, $[M+H-CH_3NCO]^+$, for the N-methyl carbamate pesticides except for dioxacarb and the carbamoyl carbamates, was not observed, as is illustrated in figure1. This difference can be explained by the softening of the ionisation process. Hence the PA of aceton is 825 kJ/mole, whereas the PA of methanol is 761 kJ/mole.
Other studies, using nicotinic acid as additive to 50:50 mixtures of methanol or acetonitrile with water, show the same effect. The abundance of the typical fragment ion is decreased completely. Also the formation of a cluster ion, $[M+\text{nicotinic acid}+H]^+$, was observed. In contrast to ammonium acetate addition, no $[M+H]^+$ ion was present, when nicotinic acid was added to the eluent (see figure 2).
For the metabolites V, VI and VII, of the N-dimethyl carbamate pirimicarb, cluster ions with methanol, acetonitrile and aceton were observed. Decrease of the methyl substitution, on the amine group, lead to a increase of the relative abundance of these cluster ions. This increase of cluster ions can be explained by the decrease of the PA values of these compounds. This is supported by the fact that the effect is also observed for N,N-dimethyl aniline (PA = 935 kJ/mole [2]), N-methyl-aniline (PA = 913 kJ/mole [2]) and aniline (PA = 876 kJ/mole [2]). In Contrast to these clusters ions, no cluster ions with ammonia or nicotinic acid were observed for the metabolites and the aniline compounds.
Additionally electrospray experiments with the carbamate pesticides were performed. With this ionisation technique all carbamate pesticides form $[M+H]^+$ or $[M+Na]^+$ ions, whereas no fragment ions, except for methomyl, are observed.

Conclusion

Use of aceton as organic modifier and nicotinic acid as additive suppresses the formation of fragment ions for N-methyl carbamate pesticides. The abundance of cluster ion of the metabolites V-VII is dependent on their PA values.

Fate of Selected Negative Ions Following Electron Capture at Atmospheric Pressure.

J.A. Culbertson and E.P. Grimsrud, Department of Chemistry and Biochemistry, Montana State University, Bozeman, MT 59717

Many previous studies have focused on the determination of rate coefficients and the ionic products of electron capture (EC) reactions. However, one point which has received very little attention but can be important to the response of an EC transducer is the fate of the negative ion following EC. At atmospheric pressure the dominant mechanism by which ions are destroyed is ion-ion recombination (IIR). Therefore, if a molecular anion formed by resonance EC is regenerated upon IIR (reaction 1a), the EC transducer response will be enhanced relative to the case in which IIR produces neutral fragments of the parent compound that do not attach electrons (reaction 1b).

$$M + e \rightarrow M^- \xrightarrow{p^+} M + \text{neutrals} \quad (1a)$$

$$M + e \rightarrow M^- \xrightarrow{p^+} Z + \text{neutrals} \quad (1b)$$

In this work an experiment has been devised to determine the amount of parent neutral remaining after an electron capturing species has been passed through an ionizing cell at atmospheric pressure. From these measurements, the extent to which the molecular anions are converted back to the original molecule upon IIR has been determined.

The apparatus used in this experiment is shown in Figure 1. It consists of a Hewlett Packard 5890A gas chromatograph (GC) equipped with an ECD. Housed within the GC oven is a stainless steel block which contains two cylindrical cells with a volume of 1.5 cm^3 each. The first cell, or ionizing cell, contains a 13 mCi ^{63}Ni-on-Ni foil which forms its cylindrical wall, while the second, or dummy cell has a non-radioactive Ni foil. The cell temperature was maintained at 120°C by the use of a temperature controller equipped with a heater cartridge and a thermocouple feedback control. A gas flow of 32 cm^3/min of argon-10% methane measured at the ECD exhaust was typically used.

All nitrobenzene (NB) samples were prepared in toluene, while gaseous samples of perfluoromethylcyclohexane (C_7F_{14}), SF_6, and $CHCl_3$ were prepared in pressurized glass carboys. An 18m x 0.53mm SE-54 capillary column (liquid samples) or stainless steel packed column (gaseous samples) were used to introduce the compounds into the cell, and a 12m capillary was used to transport the cell effluent to the ECD.

The results of a typical experiment are shown in Figure 2a and 2b. Figure 2a and 2b are the chromatograms for meta-dinitrobenzene (m-NO_2NB) when it is passed through the dummy cell and ionizing cell respectively. The decrease in response to m-NO_2NB when it is passed through the ionizing cell can be related to the amount of m-NO_2NB being regenerated by IIR in the ionizing cell by Equation 2

$$\alpha = (1-\chi)\beta = \frac{F}{N_e}(H_1/H_2 - 1) \quad (2)$$

where χ is the fraction of recombination events occurring by reaction 1a, β is the EC rate coefficient of M, F is the gas flow through the cell, N_e is the average number of electrons in the ionizing cell and H_1 and H_2 are the peak heights of M when it is passed through the dummy and ionizing cell, respectively. The term $(1 - \chi)\beta = \alpha$ is the experimentally determined quantity. By comparing α to known values of β, the magnitude of χ can be determined from $\chi = 1 - \alpha/\beta$. Listed in Table 1 are values of α, β, H_1/H_2, and χ for the compounds studied in this research.

Compound	α (cm^3/sec)	β (cm^3/sec)	H_1/H_2	χ
NB	1.2×10^{-9}	2.6×10^{-8}	1.4	0.95
o-NO_2NB	5.3×10^{-8}	1.3×10^{-7}	16.1	0.59
m-NO_2NB	2.4×10^{-9}	2.2×10^{-8}	1.7	0.89
p-NO_2NB	8.9×10^{-8}	1.4×10^{-7}	25.0	0.37
p-FNB	5.7×10^{-9}	3.5×10^{-8}	1.4	0.84
C_7F_{14}	1.5×10^{-8}	1.1×10^{-7}	5.2	0.86
SF_6	0.0	3.8×10^{-7}	0.0	0.0

Table 1. Values for α, β, H_1/H_2, and χ for compounds studied.

Values of β for the nitrobenzenes at 4 Torr are from reference 2 while that of C_7F_{14} and SF_6 at 1 Torr are from references 3 and 4. Table 1 demonstrates the varying degree to which the parent molecule is regenerated by IIR following EC. For example, SF_6^- is completely destroyed by IIR and proceeds solely by reaction 1b. On the other hand, NB^- proceeds almost completely by reaction 1a to regenerate NB.

ATMOSPHERIC PRESSURE CHEMICAL IONIZATION (APCI) USING PHOTOIONIZATION

Glenn E. Spangler

Environmental Technologies Group, Inc.
1400 Taylor Avenue
Baltimore, MD 21284-9840

INTRODUCTION - Alternate approaches to ionizing sample using atmospheric pressure chemical ionization (APCI) mass spectrometry were investigated. The approach being reported here is photoionization in combination with acetone reagent chemistry.

EXPERIMENTAL - The design of the ionization source is shown in Figure 1. An EG&G XFX-480 flashlamp (2 atmospheres krypton sealed with a magnesium fluoride window) was side-mounted to a ceramic reaction chamber. Fired onto the walls of the chamber was a thick film resistor across which was applied an extraction electric field. Sample was introduced into the chamber through a membrane (1 mil microporous Teflon impregnated with OV101) inlet using purified laboratory air ($\leq$ 2 ppm H_2O) for sample and carrier gases. The sample was further diluted by a purified laboratory air diluent gas ($\leq$ 2 ppm H_2O), which also served as a curtain gas flowing across the 25 micron ion sampling pinhole leading into an EXTREL CM-50 quadrupole mass spectrometer. Diffusion tube generators were used to supply known concentrations of DMMP and methyl salicylate to the membrane inlet. The reactor temperature was nominally 50° C.

A second configuration for the source is shown in Figure 2 where the addition of a ^{63}Ni radioactive source "up-field" from the photoionization flashlamp was used.

RESULTS - DMMP was inefficiently ionized without acetone. After 36-58 ppm of acetone was added to the reactor, Figures 3 and 4 show that the reactant ions are $(Ac)_nH^+(N_2)_m$ and the product ions are $(Ac)H^+(DMMP)$ and $(DMMP)_2H^+$. The results were similar with and without the radioactive source. After addition of acetone, the photoionization technique appeared to be as sensitive as the radioactive source without photoionization. For photoionization unassisted by ionization from the radioactive source, the reactant ions are formed by the following reactions:

$$Ac + h\nu\ (>9.69\ eV) \rightarrow Ac^+ + e^-$$
$$Ac^+ + Ac \rightleftharpoons AcH^+$$
$$AcH^+ + Ac \rightleftharpoons Ac_2H^+$$

The product ions are formed from the ion/molecule reactions:

$$Ac_2H^+ + DMMP \rightleftharpoons (Ac)H^+(DMMP)$$
$$(Ac)H^+(DMMP) + DMMP \rightleftharpoons (DMMP)_2H^+$$

Methyl salicylate could not be ionized using photoionization alone (even with acetone). Figure 5 shows the negative ionization of methyl salicylate in the presence of the radioactive source with the flashlamp off. The product ions are $(MS)_nO_2^-(N_2)_m$. When the flashlamp irradiated these product ions, the results of Figure 6 were obtained. The reactant ions are $(AC)_nCO_3^-(N_2)_m$ which did not ionize methyl salicylate. The CO_3^- ions are formed from:

$$O_2^-(H_2O) + CO_2 \xrightarrow{h\nu} CO_3^- + H_2O_2$$

This reaction is endothermic by 23.4 kcal/mole ($\approx$ 1 eV).

Philip B.W. Smith, GEO-CENTERS, INC., Gunpowder Br., P.O. Box 68, Aberdeen Proving Ground, MD 21010-0068 and
Gary A. Eiceman, New Mexico State University, Las Cruces, NM 88003-0003

Phenol and polychlorinated phenols are environmentally significant compounds that are used in vast quantities in the manufacture of resins, polymers, bacteriocides and wood preservatives. Phenol is one of the top 50 chemicals produced, and as water pollutants, phenol and chlorophenols are among the most widespread. Rapid field screening and laboratory analysis techniques are required for this important class of materials. The compounds are amenable to negative ion atmospheric pressure ionization (API) and were subjected to exhaustive studies using API-tandem mass spectrometry (MS/MS) and ion mobility spectrometry/mass spectrometry (IMS/MS). In addition to the $(M\text{-}H)^-$, Sciex API III MS/MS and PCP IMS/MS systems delineated various ions for the title compounds, including MO_2^-, $M_2O_2^-$, $(MO_2\text{-}H_2O)^-$, $(MO_2\text{-}OH)^-$ and $(M\text{-}H+H_2O)^-$ (Figures 1, 2; Table 1). Collision-induced dissociation analyses suggested other peaks in the API mass spectra to be benzoperoxide and orthobenzoquinone. Tuned ion IMS/MS provided evidence that neutral phenol adducts with the phenoxide, chloride and oxygen ions (Figure 3). Information on the mechanisms of ionization, ion-molecule reactions, and collision induced dissociation processes has provided significant insights into the behavior of phenolic type ions, including identification of isomers by MS/MS.

INTRODUCTION. The gas phase ion chemistry of polynuclear aromatic hydrocarbons (PAHs) has been investigated extensively, owing to their biological and environmental importance.[1] However, the differentiation of isomeric structures by mass spectrometry (MS) has met with limited success.[2] Basic research into fundamental gas phase ion-chemistry has stimulated interest in the use of unusual reagent gases for greater selectivity and sensitivity analysis. Chemical ionization (CI) can be used for the differentiation of isomeric compounds on the basis of their reactive behaviour. The use of dimethyl ether (DME) as a reagent gas, has been examined for some PAHs,[3] mono- and bi-substituted oxiaromatic compounds[4] and a group of isomeric polysubstituted nitrobenzenes[5], were found to exhibit isomer-specific DME CI spectra.

EXPERIMENTAL. All experiments were performed on a VG Analytical ZAB-2FQ mass spectrometer of BEqQ configuration. Using the following conditions: ionizing electron energy 50 eV, ion source temperature 250°C, and accelerating voltage 6 kV. The ion of interest was mass-selected by the magnetic sector at 6 keV kinetic energy, with He as collision gas in collision cell 2 (CC_2). The ionic fragmentation products were mass-analyzed according to their kinetic energy-to-charge ratio by scanning the electric sector, with detection of the ions following the electric sector; in the absence of collision gas, this process is referred to as the Mass-analyzed Ion Kinetic Energy Spectrometry (MIKES) technique.

RESULTS AND DISCUSSION.

1. DME-CI SPECTRA. In the CI spectra of PAHs obtained with reagent DME, there are a number of ion species that can be attributed to ion/molecule reactions; these species are: $[M]^+$, $[M+1]^+$, $[M+13]^+$, $[M+15]^+$, and $[M+45]^+$. Production of these ions can be associated with charge transfer, proton transfer, and adduct formation. The ion/molecule reactions appear to involve an electrophilic addition reaction. DME-CI mass spectra show only small differences of the $[M+1]^+/M^+$ ratio. On the other hand, these spectra indicate different spectral patterns of the relative abundances of $[M+13]^+$, $[M+15]^+$ and $[M+45]^+$. The relative abundances of ion species

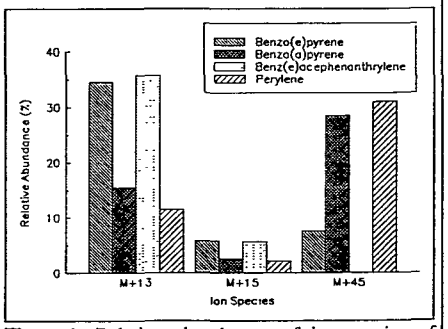

Figure 1. Relative abundances of ion species of PAH isomers of $C_{20}H_{12}$ in DME-CI mass spectra.

from PAH isomers of $C_{20}H_{12}$ are shown in Fig. 1. In the case of $[M+13]^+$ and $[M+45]^+$ are produced more abundantly in perylene and benzo(a)pyrene than the other isomers, benzo(e)pyrene and benz(e)acephenanthrylene.

2. MIKE AND CID-MIKE SPECTRA. The unimolecular metastable decomposition of $[M+45]^{+\bullet}$ to form $[M+13]^+$ is common to such adducts. In some cases, metastable decay led to observation of $[M+15]^+$ and M^+. Similarly, collision-induced dissociation of $[M+45]^+$ results in fragments at $[M+13]^+$, $[M+15]^+$ and M^+, suggesting that the adduct exists as a bound complex involving formation of covalent bonds. A potentially interesting comparison is provided by the MIKE spectra of $[M+45]^+$ ions from heterocyclic PAH isomers containing nitrogen. The $[M+45]^+$ ion of 5,6-benzoquinoline preferentially loses CH_2O, while that of acridine loses CH_2O, CH_3OH and CH_3OCH_2 with comparable intensities. The MIKE spectrum of $[M+45]^+$ from 7,8-benzoquinoline is dominated by the loss of CH_3OH with only a trace due to loss CH_2O. The observed kinetic energy releases, $T_{0.5}$, for loss of CH_3OH and CH_2O from $[M+45]^{+\bullet}$ ions were small, and indicate clearly that these fragmentation reactions involve but a small kinetic shift and reverse activation energy.

CONCLUSION. This study of the reactivity of various types of PAHs with DME has revealed that all of them exhibit $[M]^+$, $[M+1]^+$, and $[M+13]^+$ while some of them exhibit $[M+45]^+$ and $[M+15]^+$ product ions. The relative abundances of these product ions indicate that the PAHs differ in their reactivity with DME. Variation in reactivity is likely due to the topology of PAHs toward electrophilic aromatic addition. The loss of CH_3OH has been shown to be the dominant neutral expulsion reaction of most of the $[M+45]^{+\bullet}$ ions studied. Furthermore, metastable decomposition $[M+45]^{+\bullet}$ of nitrogen-containing compounds were highly individualistic which readily facilitated the isomer differentiation. The KER measurements have provided circumstantial evidence supporting the molecular elimination mechanism.

NICI of Selected PCB Congeners : Moderating Gas, Temperature, and Contamination Effects.

Rob O'Brien, Roger Guevremont, & K.W.M. Siu.
Institute for Environmental Chemistry
National Research Council of Canada
Ottawa, Ontario, Canada. K1A 0R6

Introduction :

The utilisation of NICI has been limited because of an inherent reproducibility problem. Electron Capture based processes would appear to represent the simplest case, however, even under these conditions, complex and poorly understood reaction mechanisms are required to explain common structural features.

Subsets of PCB congeners have been examined using different gases and conditions to provide insight into both the EC-NICI mechanisms and PCB structure-reactivity relationships. It is expected that well constructed PCB structure-reactivity relationships will lead to the development of congener selective analysis.

Experimental Methodology :

All PCB's congeners were obtained from Ultra Scientific (Kingstown, RI), with the exception of BZ203 and BZ116 which were obtained from AccuStandard Inc. (New Haven, CT). Samples were introduced into the VG ZAB 2F ion source using the solids probe. Sample flux was restricted by sealing home made vials (containing sample and glass wool) around a fused silica capillary (5-30μm id). All ports to the source with the exception of the probe and septum inlet were blocked. Nitrogen (UHP) and Carbon Dioxide (Bone Dry) were purchased from Liquid Carbonic, Methane (UHP) from Matheson, and Acetylene (Industrial Grade) from Air Products. All gases were used without further purification. Gas pressure was measured at the source ion gauge typically 1×10^{-5} torr. Temperature by a thermal couple connected to the ion block. The instrument was operated in the CI -ve mode, emission current .2 ma, electron energy 150V, and resolution ~1000. Tetracyanoquinodimethane (TCNQ) was obtained from Aldrich. TCNQ, used to indicate the relative radical concentration and reactions[1,2], was introduced using an open vial packed with glass wool.

Observations and Discussion :

As reported previously[3], PCB's of higher chlorination tended to produce sets of [M-nCl+nH] clusters which decreased in relative abundance at higher source temperatures (fig. 1a,b). Some radical addition reactions in the TCNQ spectra also decreased with higher source temperatures (fig. 2a,b). These observations indicate these reactions could be occurring on the source walls, supporting the mechanism presented by Grimsrud et al[4].

PCB's of lower chlorination tended to yield [Cl]- as the base ion. Changing moderator gas influenced the ratio of parent ion [M]- to [Cl]-. This effect could be directly related to the complexity and thus the internal degrees of freedom in the moderator gas.

CHARACTERIZATION OF NOVEL CHEMICAL IONIZATION REAGENTS BY QUADRUPOLE ION TRAP MASS SPECTROMETRY

*Erwin J. Alvarez, Jin Duan, Aubrey McIntosh and Jennifer S. Brodbelt; Department of Chemistry and Biochemistry; The University of Texas at Austin; Austin, Texas 78712.

INTRODUCTION

The search for alternative means to differentiate classes of compounds and the increase in the fundamental knowledge and understanding of selective ion/molecule reactions have provoked interest in the evaluation of new chemical ionization reagents. Structurally diagnostic information can be obtained from certain types of chemical ionization processes that may derivatize analytes into characteristic adducts. We have begun an extensive systematic evaluation of many promising new chemical ionization reagents as selective probes of several classes of compounds. A Finnigan MAT Quadrupole Ion Trap Mass Spectrometer (ITMS) has been used to investigate the chemical ionization capabilities of reagents such as 1,1-difluoroethylene, 2,3-butanedione, dimethyl sulfoxide, and ethylene oxide with analytes such as lactones, diols, amines, and aminoalcohols. Our long term goal is to develop ways to distinguish isomeric biomolecules and to elucidate the structures of newly synthesized or isolated compounds, including pharmaceutically active quinine alkaloids and glucuronolactones, through the use of selective ion molecule reactions.

EXPERIMENTAL TECHNIQUES

A Finnigan MAT Quadrupole Ion Trap Mass Spectrometer (ITMS) equipped with a Hitachi/Teledyne HST-1000 filtered noise field accesory device for optimization of ion isolation was used to study the ion/molecule reaction processes. The typical reagent gas pressure used was nominally ~1-1.5 x 10^{-5} torr as measured by an ionization gauge positioned in the vacuum chamber; the reagent gas was introduced through a leak valve. The organic analytes were introduced via leak valve or by a heated solids' probe to about 1-2 x 10^{-6} torr.

After its introduction into the trap, the reagent gas was ionized with a short electron ionization pulse. The ions formed were then allowed to undergo ion/molecule reactions with the organic neutrals for a period of about 50-500 ms. Alternatively, a reagent gas ion was isolated by using the appropriate application of DC and RF voltages and allowed to undergo ion/molecule reactions with the organic neutrals for a period of 10-500 ms. This latter method was used to identify reaction pathways.

Collision activated dissociation (CAD) experiments were performed on each isolated adduct ion after completion of the ion/molecule reactions. Collisional activation was performed by the application of an ac voltage of 0.3-0.4 V_{p-p} at the axial frequency of motion of the ion of interest; activation times were typically 10-20 ms. The mass-selective instability mode was used to eject the fragment ions from the trap onto an electron multiplier for detection.

SELECTIVE PRODUCT FORMATION

For this study, eleven organic molecules with simple functional groups were chosen as representative substrates: 1-butanol, 1,3-propanediol, 3-amino-1-propanol, 1-propylamine, 1-pentene, benzene, butyraldehyde, cyclohexanone, γ-butyrolactone, ethylacetate and diethylether. Ten different chemical ionization reagent gases were used: dimethyl ether, dimethyl sulfide, dimethyl sulfoxide, ethylene, propene, 1,1-difluoroethylene, ethylene oxide, ethylene sulfide, 2,3-butanedione and acetone. Dimethyl sulfoxide, ethylene sulfide and acetone reagent ions proved to be unreactive with most of the organic analytes, and generally only resulted in formation of $(M+H)^+$ products. 1,1-difluoroethylene showed initial promise as a selective reagent for the identification of aromatic compounds; it reacts with benzene to form $(M+45)^+$ and $(M+25)^+$ adducts. However, it failed to be useful for substituted aromatic compounds. Substrates with either electron donating or electron withdrawing groups show less reactivity than benzene for the electrophilic adduct formation. For compounds with electron donating groups, only $(M+25)^+$ adducts were seen with less than 1% of the total ion current. For compounds with electron withdrawing groups

no adducts were observed. Results for chemical reagent gases that showed selectivity towards particular functional groups are presented below.

$(M+41)^+$ FROM ETHYLENE

Ethylene can form selective $(M+41)^+$ adducts for carbonyl containing compounds which do not contain an α-hydrogen like ketones, lactones and esters. Among them, the relative abundances of the $(M+41)^+$ adducts are highest for ketones (~40% of the total ion counts) whereas for lactones and esters the $(M+41)^+$ ions are less than 15% of the total ion counts. This difference may be due to the oxygen atom adjacent to the carbonyl group which enhances the basicity of the analyte and thus promotes proton transfer from the intermediate $(M+41)^+$ ion. The allyl cation is also selective for alcohols, whose $(M+41)^+$ adducts constitute less than 15% of the total ion counts. No stable formation of $(M+41)^+$ ions was observed for ethers and aldehydes, which instead form mainly $(M-1)^+$ ions due to hydride abstraction.

$(M+45)^+$ FROM ETHYLENE OXIDE

Ethylene oxide shows special ring-size selectivity for lactones. It can induce $(M+27)^+$ adducts for four-membered ring lactones, $(M+45)^+$ adducts for five-membered ring lactones and mainly $(M+1)^+$ adducts for six-membered ring lactones. The reactions may involve a loose hydrogen-bond intermediate which can subsequently undergo different reactions for four, five or six-membered (proton transfer only) ring lactones, partially based on the basicity of the lactone relative to ethylene oxide. For the smallest rings, the spontaneous dehydration of the intermediate $(M+45)^+$ adduct is favored, resulting in stable $(M+27)^+$ ions. For the five-membered rings the dehydration process is not spontaneous, resulting in intact $(M+45)^+$ adducts.

$(M+25)^+$, $(M+43)^+$ AND $(M+87-18)^+$ FROM 2,3-BUTANEDIONE

Both reagent ions from 2,3-butanedione, $(C_2H_3O)^+$ m/z=43 and $(M+1)^+$ m/z=87, react with hydroxyl containing compounds to form characteristic adducts. $(M+43)^+$ acetylation adducts are observed for alcohols whereas $(M+25)^+$ products are observed for diols. The intact $(M+43)^+$ adduct formed by acetylation was not observed for diols because spontaneous dehydration following acetylation ocurred, resulting in $(M+25)^+$ ions. The m/z=87 ion from 2,3-butanedione is selective for both alcohols and diols by forming $(M+87-18)^+$ adducts. The reaction leading to the $(M+87-18)^+$ ion was found to be favored for small molecular weight compounds with decreasing conversion efficiency as the size (molecular weight) increases.

CONCLUSIONS

This systematic survey of ten novel chemical ionization reagents has shown that there is great promise for the development of alternative chemical ionization reagents for specific applications. Those reagents which show characteristic reactivities with certain classes of compounds, such as ethylene oxide with lactones, are preferable to those which show non-specific reactivities, like acetone and ethylene sulfide. Finally, selective chemical ionization in conjunction with collision activated dissociation for detailed structural elucidation provides a powerful means of characterizing analytes and should prove to be particularly advantageous for distinguishing complex molecules that contain several types of functional groups.

Fragmentation and Ion-Molecule Reactions of Ethanolamine Using FTMS

Sung-Seen Choi and Hun-Young So
Division of Chemistry and Radiation
Korea Research Institute of Standards and Science
P.O.Box 3, Taedok Science Town, Taejon 305-606, Korea

A FT/ICR spectrometer was used to study fragmentation path and ion-molecule reactions of ethanolamine. The reaction between product ions and neutral molecule were studied by varying experimental conditions such as electron impact energy, pressure, and ion trapping time. The major fragment ions observed under 70 eV energy were $C_2H_6N^+$, $C_2H_4N^+$, CH_4N^+, CH_2N^+, $C_2H_3O^+$, CH_3O^+, and CHO^+. The nitrogen containing fragment ions were found more abundant than oxygen containing ones. By comparing the heats of fragmentation reactions calculated by AM1 semiempirical calculations, it was found that formations of nitrogen containing fragment ions are more favorable than those of oxygen containing fragment ions.

The experimental results of SWIFT ejection technique showed that $C_2H_6N^+$ and $C_2H_5O^+$ ions are formed from protonated molecules while CH_4N^+ and CH_3O^+ ions are formed from all three precursors, $M^{+\cdot}$, $[M+H]^+$, and $[M-H]^+$.

The decrease of fragment ions under longer ion trapping time is considered due to dissipation of internal energies by collisions and to the proton transfer reactions. All fragment ions are decreased at a longer ion trapping time while the intensity of the protonated molecules increase. The rate constants for proton transfer reactions between neutral molecules and fragment ions are listed in Table 1.

Table 1. Rate constants for proton transfer reactions

Fragment Ion	k (X $10^{-9}cm^3molec^{-1}s^{-1}$)
$C_2H_6N^+$	1.56
$C_2H_4N^+$	3.43
CH_4N^+	2.70
CH_2N^+	3.84
$C_2H_5O^+$	1.66
$C_2H_3O^+$	2.91
CH_3O^+	3.53
CHO^+	4.26

The mass peaks of $C_2H_7N^{+\cdot}$ (m/z 45) and $C_2H_9NO^{+\cdot}$ (m/z 63) are appeared by changing ion trapping time from 10 ms to 200 ms as shown in Figure 1(a). From thermodynamic parameters, the structure of these two ions could be postulated as $\dot{C}H_2CH_2\overset{+}{N}H_3$ and

$H_2\dot{O}CH_2CH_2\overset{+}{N}H_3$, respectively. The $\dot{C}H_2CH_2\overset{+}{N}H_3$ is found to be formed from $H_2\dot{O}CH_2CH_2\overset{+}{N}H_3$ by oxygen-carbon bond breaking and loss of H_2O. According to calculational results, the distonic ion $\dot{C}H_2CH_2\overset{+}{N}H_3$ is more stable than its isomer $CH_3CH_2NH_2^{+\cdot}$ by 38 kJ/mol.

Product ions larger than molecular ion are also observed. They are considered as ion-molecule reaction products. We could observe $H_2C{=}\overset{+}{N}H_2$ and protonated molecules as the most abundant ion with short and long ion trapping time. This made us to consider the ion-molecule reactions between $H_2C{=}\overset{+}{N}H_2$ (or protonated molecule) and neutral molecule important. The product ion $H_2NCH_2CH_2\overset{+}{N}H{=}CH_2$ (m/z 74) was observed in mass spectrum, as shwon in Figure 1(a). This ion is generated by ion-molecule reaction between $H_2C{=}\overset{+}{N}H_2$ and neutral ethanolamine and subsequent loss of NH_3.

There are three ion-molecule reactions between protonated ethanolamine and its neutrals. They are the formations of $(H_2NCH_2CH_2OH)_2{\cdot}H^+$ (m/z 123), $HOCH_2CH_2\overset{+}{N}H{=}CHCH_3$ (m/z 88), and $HOCH_2CH_2\overset{+}{N}H_2CH_3$ (m/z 76) as shown in Figure 1(b). Among the three product ions, the $(H_2NCH_2CH_2OH)_2{\cdot}H^+$ is the most abundant ion and the next is HOCH2CH2$\overset{+}{N}$H=CHCH3. The $HOCH_2CH_2\overset{+}{N}H{=}CHCH_3$ ion can be formed by loss of H_2O and NH_3, while the $HOCH_2CH_2\overset{+}{N}H_2CH_3$ ion can be formed by loss of NH_3 and $H_2C{=}OH$.

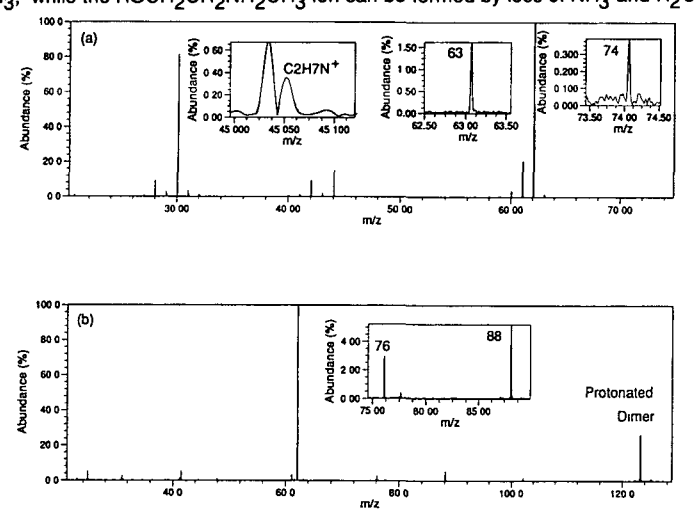

Figure 1. Electron impact ionization mass spectra of ethanolamine with 70 eV of electron impact energy. The pressure and ion trapping time are (a) 2.4 x 10^{-7} Torr and 50 ms and (b) 3.5 x 10^{-7} Torr and 10 s.

The ion chemistry of nitrosamide

Helge Egsgaard[a] and Lars Carlsen[b]

[a]Department of Combustion Research, Risø National Laboratory
DK-4000 Roskilde, Denmark
[b]National Environmental Research Institute,
Department of Environmental Chemistry, DK-4000 Roskilde, Denmark

The nitrosamide, NH_2NO, apparently is the key intermediate in the reaction between amidogen, NH_2, and NO, which is crucial in the highly effective processes developed to remove NO from flue gases [1]. However, the reaction between NH_2 and NO leaves NH_2NO in a highly excited state, causing a rapid decomposition of the latter. The NH_2 + NO has until recently been assumed as the only route to the elusive NH_2NO molecule. Thus, despite its importance, the chemistry of NH_2NO is virtually unknown. However, very recently the nitrosamide has by neutralization-reionization mass spectrometry been demonstrated to be a viable molecule in the dilute gas phase [2]. The isoelectronic CH_3NO_n (n=1,2) system is, on the other hand, one of the most widely studied and a comparison with the general fragmentation of $NH_2NO_n^{+\bullet}$ (n=1,2) appears appropriate.

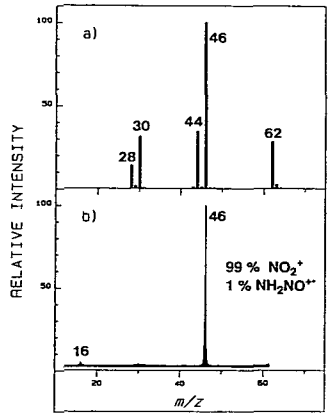

Figure 1. EI mass spectrum of nitramide a) and the collision induced spectrum of the $NH_2NO_2^{+\bullet}$ ($M^{+\bullet}$) b).

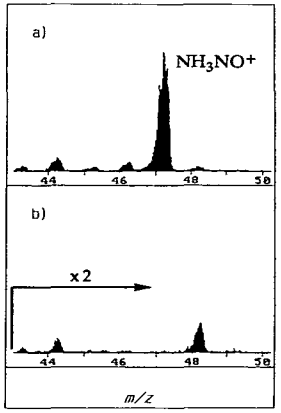

Figure 2. Partiel mass spectrum of a NO^+ plasma following addition of NH_3 a) and the background spectrum b).

The electron impact mass spectrum of nitramide and the collision induced spectrum of the molecular ion, $NH_2NO_2^{+\bullet}$, are given in Figure 1. The nitromethane radical cation shows in

addition to the the simple cleavage concurrent fragmentation via the *aci*- and methylnitrite isomers [3]. In contrast to this, the collision induced fragmentation of nitramide gives rise only to the simple cleavage without any indication of isomerization, possibly resulting in elimination of, e.g. H_2O. The observed m/z 44 ($N_2O^{+\bullet}$) in the electron impact spectrum (cf. Figure 1a) is, owing to the apparent absence of the analogous ion in the collision induced spectrum, assigned to a surface promoted decomposition within the ion source of the relatively labile molecule prior to ionization. The virtual absence of isomerization of $NH_2NO_2^{+\bullet}$ was unexpected since the substitution of CH_3 to NH_2 should make the isomerization processes energetically more favourable. However, the introduction of the relatively weak N-N bond may account for the observed differences. This assumption is, however, somewhat contradicted by the fragmentation of $MeNO^{+\bullet}$ and $NH_2NO^{+\bullet}$; both ions fragmenting by simple cleavages exclusively. On this background it is worthwhile to consider the excited $CH_3NO_2^{+\bullet}$ ion as being described as a methyl cation complexed to a NO_2 radical, thus, giving the nitromethane system unique properties [4].

We have searched for alternative routes to the "NH_2NO" system. Thus, it appears that the NH_3NO^+ is generated through a reaction between NO^+ and ammonia under CI conditions. This ionic reaction constitutes an interesting counterpart to the well-established radical route in the thermal DeNOx process. The reaction may in addition have some implications in heterogeneous processes since NO form complexes with the NO-ligand formally ionized with a number transition metals.

MO calculations strongly support the formation of N-protonated nitrosamide; the reaction being exothermic by 31 kcal/mol [5]. A high energy barrier (86 kcal/mol) prevents the isomerization of NH_3NO^+ to NH_2NOH^+ [5]. The partial CI mass spectra given in Figure 2 demonstrate that the protonated nitrosamide is the primary product of the reaction between ammonia and NO^+. The elemental composition was verified by using ND_3 and $^{15}NH_3$, the protonated nitrosamide being shifted accordingly.

The intensity was found to be very depended on the ammonia pressure, i.e. ammonia acts as a highly effecient sink in the proton transfer from NH_3NO^+ which leaves the elusive nitrosamide. This may be regarded as a novel route to NH_2NO opening up for spectroscopic studies of the parent nitrosamide - the apparent key to the DeNOx chemistry.

Accurate Mass Measurements in Desorption Chemical Ionization (DCI) Mode

S.A. Pergantis, L.L. Madilao, C.A. Emond and G.K. Eigendorf
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Z1

INTRODUCTION

Desorption Chemical Ionization (DCI) is a mass spectrometric technique capable of providing molecular weight as well as structural information on a variety of compounds not amenable to EI-MS. Depending on the structural features of the analyte a variety of reagent gases can be used. We have found ammonia to be a very effective reagent gas in DCI, particularly for the analysis of oxygen containing compounds such as esters, ethers, and hydroxylated compounds. Under these conditions abundant $(M+H)^+$ and/or $(M+NH_4)^+$ pseudo-molecular ions, along with structurally informative fragment ions, are observed.[1] Under ammonia DCI conditions none of the normally used mass deficient reference standards, such as, heptacosafluorotri-N-butylamine, perfluorokerosene (PFK), or tris(perfluoroheptyl)-S-triazine, gave adequate mass spectra. However, PFK has been successfully used with methane in the CI[2] and DCI mode. Others[3,4] have reported the use of mass sufficient compounds (esters, carbowax) as reference materials in high resolution CI/DCI MS.

In this work we have demonstrated the successful use of PFK as a reference standard with a gas mixture of methane and ammonia. This procedure allows for accurate mass measurements in the full scan and peak matching modes for a variety of compounds. Polyperfluoropropylene oxide (Fomblin) was also used as a reference standard either with iso-butane, methane or ammonia. This allowed for the routine accurate mass measurement of higher molecular weight compounds, up to 1730 amu, in DCI mode.

INSTRUMENTATION

Low resolution DCI measurements were carried out on a quadrupole mass spectrometer (Delsi-Nermag R10-10C / Technivent PC Data system). Both low and high resolution (10,000) DCI measurements were carried out on double focusing mass spectrometers (Kratos Concept II H (Q) / Dart Data system, and Kratos MS 80 RFA / DS 55 Data system). Three reagent gases were used: i-butane, methane and ammonia. Figure 1 shows the Negretti SS-Needle Valve system used to introduce gas mixtures into the ion source. During the high resolution measurements the reference compound (PFK, Fomblin) and sample are introduced simultaneously.

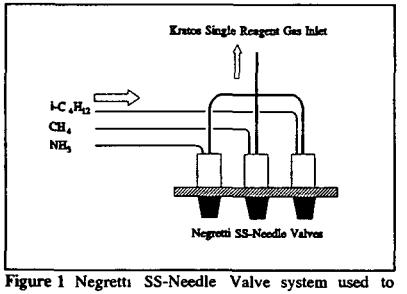

Figure 1 Negretti SS-Needle Valve system used to introduce gas mixtures.

RESULTS

The spectrum obtained for PFK using a mixture of NH_3 and CH_4 gases is presented in Figure 2, the reagent gas ion ratios used are presented in Table 1. The gas ratios could be adjusted using the Negretti SS-Needle Valve system (Fig. 1).

A number of compounds have been analyzed using NH_3 and CH_4 gas mixtures with PFK and

Fomblin as references, the results obtained are presented in Table 2.

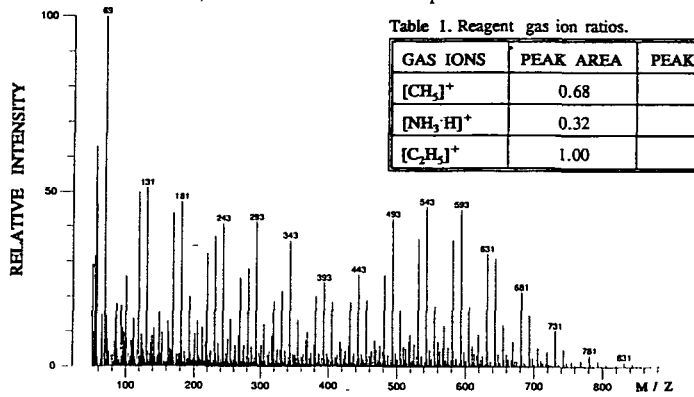

Figure 2. CI spectrum of PFK with ammonia and methane gas mixture.

Table 1. Reagent gas ion ratios.

GAS IONS	PEAK AREA	PEAK HEIGHT
$[CH_5]^+$	0.68	0.86
$[NH_3 \cdot H]^+$	0.32	0.43
$[C_2H_5]^+$	1.00	1.00

Table 2. Accurate mass measurements of compounds from several compound classes

Compound / Formula	Reference / Reagent gas	$[M+Gas]^+$ / $[M+H]+$	Theoretical m/z	Measured m/z	Error, ppm
Disaccharide / $C_{24}H_{33}FO_{15}$	PFK / NH_3 & CH_4	$[M+NH_4]^+$	598.21472	598.21173	5.00
Terpene Precursor / $C_{25}H_{44}O_5SSi_4$	PFK / NH_3 & CH_4	$[M+NH_4]^+$	588.24869	588.24851	0.31
Monosaccharide / $C_{18}H_{26}O_{12}$	Fomblin / NH_3	$[M+NH_4]^+$	452.1768	452.17699	0.43
Organoarsenical / $C_5H_{11}O_2As$	PFK / NH_3 & CH_4	$[M+H]^+$	179.00533	179.0046	3.91
Hemicarcerand / $C_{97}H_{95}O_8N_3$	Fomblin / i-C_4H_{12}	$[M+H]^+$	1430.71974	1430.72006	0.29

CONCLUSIONS

Data presented in this study indicate that mass deficient calibration reference compounds such as PFK and Fomblin can be used in conjunction with a number of reagent gases for high resolution accurate mass measurements in positive DCI (CI) mode. These compounds are generally preferred as reference materials because of their good volatility compared to other compounds reported in the literature.[4,5] We have demonstrated that a gas mixture of NH_3 and CH_4 can be successfully used with PFK, while Fomblin can be used with either i-C_4H_{12}, NH_3 or CH_4. Experiments are under way to evaluate perfluorinated mass deficient reference compounds under negative DCI (CI) conditions.

ALKALI METAL CATIONIZATION OF SOME AROMATIC AMIDES

Yu Cao, Kenneth L. Busch, and John Haseltine
School of Chemistry and Biochemistry
Georgia Institute of Technology, Atlanta GA 30332

A series of organic aromatic pyrrolidine compounds has been used as model compounds to study the cationization of group I alkali metal ions in liquid SIMS. Since the pyrrolidine molecules are relatively small, only a few possible sites are available for interaction with metal ions. We hope that the study of mechanism for cationization of these compounds will facilitate the application of cationization for determination of molecular weights for other organic or biological compounds.

All liquid SIMS mass spectra were recorded in m-NBA matrix doped with four alkali metal (Na, K, Rb, Cs) salts in equimolar ratio. Immediately before the mass spectra were measured, the sample and solvent matrix were mixed together on the probe tip in solutions with a constant molar ratio.

Cationization in SIMS and in EI:

Cationization is strongly affected by the number of pyrrolidine amide groups on the benzene ring. The trend of affinities for alkali metals to the target molecules is *mono* < *bis* < *tris*. The increased cation affinity is due to the increased number of carbonyl functionality groups. Larger cations are more favorably attached than smaller cations for those precursor molecules that have multi-functional (carbonyl) groups. It is possible that larger cations can bind to these compounds more effectively than the smaller ones due to the spatial organization of the carbonyls in these molecules.

Cationization of these same model compounds has also been studied by EI with a direct exposure probe. Alkali cations and precursor molecule both appear in the mass spectra, but no cationization has been observed for any precursor molecules, which indicates that cation adduction occurs in the condensed phase rather than through gas phase ion/molecule reactions.

Double Cationizations:

In many instances, multiply cationized ions can occur through multiple proton-alkali metal exchange, leading to ions of the type $[M+nCat-(n-1)H]^+$. In the current study, doubly cationized ions $[M+2Cat]^+$ have been observed for 3-nitro-isophthalic pyrrolidine amide without intervention of the proton exchange or creation of a doubly-charged species (Figure 1). The doubly cationized ions with all four cation combinations have been observed. However, the ions containing cesium are relatively more abundant than those ions with other alkali cation combinations. A CID MS/MS study has been performed for the doubly cationized molecules. One striking feature of product ion spectra for the doubly cationized ions is that the major fragments of dissociation are the doubly cationized NO_2 ions, viz m/z 312 ($[NO_2Cs_2]^+$, Figure 2) and m/z 264 ($[NO_2CsRb]^+$) respectively. However, under similar experimental conditions, (same collision cell pressure and similar collision energy) the dissociation for the singly cationized ion is predominantly through alkali cation loss. Double cationization reactions has also been observed for m-NBA doped with alkali cations. Again, those double-cationized ions containing cesium are of higher intensities. Our study shows the nitro group is the initial site of attachment for at least one of the alkali cations.

Cluster Ion Formation in Liquid Secondary Ion Mass Spectra of Diquaternary Pyridinium Oxime Salts

Gary J. Kunkel and Kenneth L. Busch
School of Chemistry and Biochemistry, Georgia Institute of Technology,
Atlanta, Georgia 30332-0400, USA

Alkyl phosphates, used as insecticides, cause inhibition of acetylcholinesterase, an enzyme needed for the propagation of nerve impulses. Diquaternary pyridinium oxime salts are effective reactivators of the enzyme and thus effective antidotes for organophosphate intoxication. In our studies of these compounds using Liquid SIMS, extensive cluster ion formation has been noted. These cluster ions are ascribed to interactions between positive ions from the sample and the liquid matrix. We have used Liquid SIMS to acquire mass spectra for several diquaternary pyridinium oxime salts in the high mass range to study adduct formation reactions.

When glycerol was used as the matrix, no sample related high mass clusters were seen. However, when CSA (camphorsulfonic acid) was added to the glycerol solvent, a multitude of high mass cluster ions are observed. An explanation of these ions is given in Figure 1 for the mass spectrum of AB-8.

Figure 2 is the mass spectrum of AB-13 when NBA (m-nitrobenzyl alcohol) is used. The counter anion is observed for several cluster ions in the mass spectrum. If CSA is added, chlorine-containing adducts are no longer observed. Apparently, the chloride preferentially reacts with CSA and is no longer able to participate in cluster formation. However, a large number of CSA-containing clusters are observed.

When thioglycerol is used, the number of different high mass ions decreases dramatically because fragment ions apparently do not participate extensively in cluster ion formation. The anion is present in many of the cluster ions observed.

Sample were the gift of A. Vincze from the Israel Institute of Biological Research.

INVESTIGATION OF THE PENNING IONIZATION PROCESS USING THE RARE-GAS METASTABLE BEAM SOURCE

D. Faubert, G.J.C. Paul and M.J. Bertrand
Regional Center for Mass Spectrometry, Department of Chemistry,
University of Montreal, Montreal, Canada, H3C 3J7

Penning ionization (PI) involves the electrophilic reaction of a metastable atom (A*) with an analyte (BC) resulting in an ionic state of the analyte (BC^+), the ground state of the atom (A) and the ejected electron in a continuum state (e^-).

$$A^* + BC \rightarrow A + BC^+ + e^- \quad (PI) \quad (1)$$
$$A + B + C^+ + e^- \quad (PI) \quad (2)$$

Reaction (2) occurs if the excitation energy transferred to the analyte is high enough to effect bond breakage within it. Experimental evidence suggests that Penning ionization is the major ionization process which takes place in the ion source where the metastables are formed through a corona discharge.[1] The apparatus employed consists of a metastable beam source and single quadrupole mass spectrometer. Equipment and working conditions are similar to that reported previously[1] except for the initiator. A high voltage pulse (-6 kV), superposed on the DC voltage of the cathode, between the cathode and the auxiliary electrode was used to initiate the discharge. This new modification makes ignition of the discharge easier and prevents arcing in the source housing. The metastable beam source was obtained from Dephy Technology (Que., Canada). The same analyte partial pressure was used in each experiment.

In this study the utility of the metastable beam source has been extended to the investigation of over fifty organic compounds including substituted aromatics, ketones, aldehydes, alkanes, alkenes, esters, ethers, alcohols, nitriles, amines and fullerene. All compounds were analyzed by the five rare-gas metastables with varying excitation energies (Table 1). Upon collision with Xe*, it has been observed that all molecules which yield a signal generate only the molecular ion. For Kr*, aromatics do not give fragment but all aliphatics give at least one fragment with low intensity. As you go up to Ar*, Ne*, He*, fragmentation increase greatly reflecting the higher energy transfer. Higher fragmentation is observed for aliphatics relative to aromatics which is a consequence of lower APs for aliphatics and, possibly, a faster rate of decomposition of excited aliphatic molecular ions to their characteristic fragments. Exception is fullerene where the only ions present in the mass spectrum of C_{60} with He* are the molecular ion ($M^{+\cdot}$) and the doubly charged ion ($M^{2+\cdot}$). These results show that the second ionization potential of C_{60} is lower than 20.61eV. Lifshitz et al. have previously given a second ionization value of 19.85eV for C_{60} which is consistent with our observations.[2] By varying rare-gases, both hard and soft EI-like fragmentation was achieved yielding molecular weight and structural information.

The metastable beam source pressure greatly influences the metastable beam density and consequetly the TICs (Total Ion Currents) obtained. An exemple of pressure study is shown in Figure 1, for each gas an optimum pressure exists for maximum sensitivity. As each gas gives a similar TIC curve, the shape of those curves is probably explained by the same phenomena. At low pressure, either the metastable production is weaker due to the low density of rare-gas atoms or the metastable transport is less effective at the lower differential pressure. At high pressure, the mean free path is much smaller for the metastable atoms as well as ions formed in the ion source and the sensitivity decreases.

A comparison was made of the TICs for various organic analytes to gain information on the proportion of the two metastable states for xenon ($^3P_0$, $^3P_2$) present in the ion source (Table 1). Two classes of compounds are shown in the Table 2, one with ionization potentials lower than

both metastable states and the other with IPs between the excitation energies of the metastables. As only the highest energy xenon metastable can ionize the compounds with IPs between both metastables, the small TICs for this class of compounds reflects (Table 2) the small proportion of the highest metastable in the source. The same phenomenon is observed for the krypton metastables. These observations mean either the production of the highest energy metastable ($^3P_2$) is weak or their lifetime are short relative to the lower energy states.

The TICs detected for aromatic and saturated molecules upon collision with the krypton metastable are shown in Table 3. These results are of interest as they provide insight into the Penning ionization process for molecules of different structures. It is important to mention that all IPs for molecules in Table 3 are lower than both krypton metastables. The TICs for aromatic molecules are at least a factor of five greater than that for saturated molecules. These observations can be explained in terms of electron distributions for the relevant molecular orbitals of the analyte. For the unsatured aromatic molecules, the spacially extended π-orbitals are expected to have higher electron densities on the molecular surface than the spatially limited σ-orbitals for saturated molecules.[3] Hence, the possibility of electron transfer from the analyte to the metastable atom is greater for aromatic molecules than saturated molecules, as shows by the TIC values in Table 3. The number of unsaturated bond in a molecule also affects the sensitivity of the analyte upon interaction with Kr*. The TIC increases from cyclooctane (saturated bonds) to cyclooctatetraene (4 double bonds), as shown in Table 4.

CHARACTERIZATION OF Ar/CH_4 GLOW DISCHARGE PLASMAS

L. R. Meadows and F. L. King
Department of Chemistry, West Virginia University
Morgantown, West Virginia 26506, U.S.A.

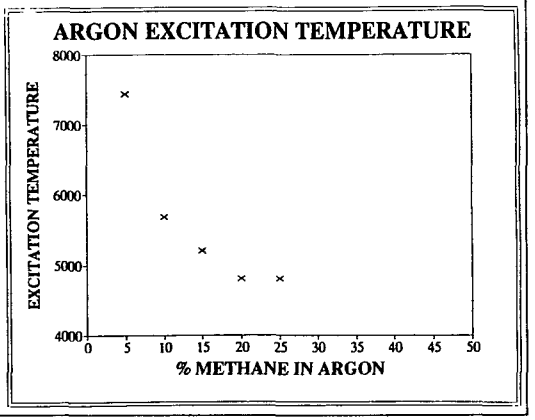
INTRODUCTION

Plasmas sustained in mixtures of methane with a rare gas diluent are employed in the deposition of thin diamond films. Such plasma enhanced chemical vapor deposition affords the ability to deposit films on temperature sensitive substrates because the energy required to promote film growth is imparted to gas phase precursor species through collisions within the plasma. A key limitation to the widespread application of plasma based deposition methods is the poor reproducibility of films obtained from this procedure. This problem is a direct consequence of an inadequate understanding of plasma chemistry and the dependence of this chemistry on plasma operating parameters. Investigations were undertaken to characterize these reactive plasmas. The production of various hydrocarbon species within the plasma was correlated with two observables, plasma energy content and precursor internal energy, derived from mass spectrometric measurements. The long term goal of this work is the correlation of such observables with film quality to permit intelligent control of plasma processing systems.

RESULTS AND DISCUSSION

Two methods were employed in the assessment of plasma energy content. Atomic emission measurements of argon lines in the wavelength range from 425 nm to 435 nm provided data from which argon excitation temperatures were determined. As the plasma composition was varied from 95% argon and 5 % methane to 75% argon and 25% methane, the argon excitation temperature dropped from 7500° to 4700°, Figure 1. Relative argon

Figure 1



ionization temperatures were obtained from the ratio of mass spectrometry signal intensities, (singly-charged argon species)/(doubly-charged argon species). These values exhibited the same trend as observed for the excitation temperatures. It is important to note that although these are not absolutely quantitative values they do provide qualitative measures of the change in plasma energy content. The production of ions corresponding to methyl fragments and the products of condensation of those fragments decreased with decreasing argon excitation and ionization temperatures.

Figure 2

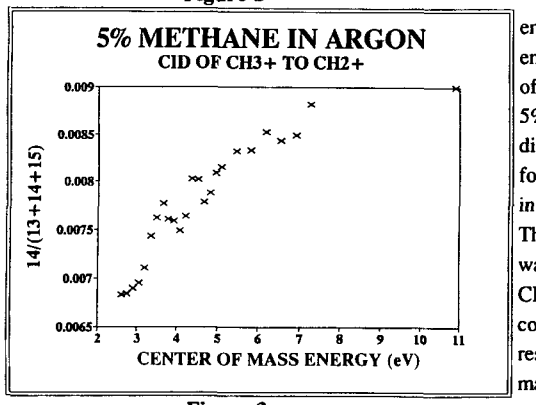


Figure 3

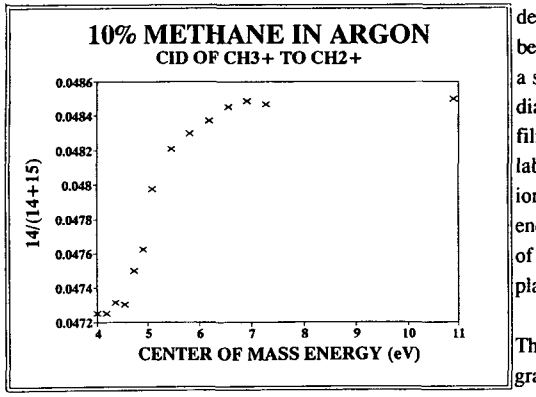

Tandem MS experiments were employed to probe the internal energy of CH_3^+ species as a function of discharge gas composition. With 5% methane the threshold for the dissociation of CH_3^+ to CH_2^+ was found to correspond to a maximum internal energy of 2.2 eV, Figure 2. The same maximum internal energy was found for the dissociation of CH_3^+ to CH^+. Increasing the concentration of methane to 10% resulted in a decrease in the maximum internal energy to 0.5 eV, Figure 3. The ability to track the internal energy of species in these deposition plasmas is important because precursor molecules require a specific internal energy to produce diamond films rather than graphite films. Future investigations in our laboratory seek to correlate argon ion temperatures and internal energies with the diamond character of thin films deposited from these plasmas.

REARRANGEMENT OF α-SILYL-SUBSTITUTED CARBENIUM IONS IN THE GAS PHASE. AN INVESTIGATION OF RELATIVE MIGRATORY APTITUDES

R. Bakhtiar and D. B. Jacobson

Department of Chemistry, North Dakota State University
Fargo, North Dakota 58105-5516

The rearrangement of carbenium ions by 1,2-migration is ubiquitous in organic chemistry with a rich body of information concerning the relative migratory aptitude of various groups [1] α-Silyl-substituted carbenium ions ($R_3Si\text{-}CH_2^+$) have been implicated in rearrangements involving 1,2-group migration in α-functionalized silanes in solution (e.g., reaction 1), however, there is virtually no information regarding the relative migratory aptitude of

$$(CH_3)_3SiCH_2Cl \xrightarrow{AlCl_3} (CH_3)_2ClSi\text{-}CH_2CH_3 \qquad (1)$$

various groups [2,3] This is a consequence of the instability of organosilylenium ions (R_3Si^+) in solution under conditions where analogous carbenium ions are long lived [4] We have initiated studies involving 1,2-group migration of α-silyl-substituted carbenium ions in the gas phase by using Fourier transform mass spectrometry (FTMS) [5]

Nascent α-silyl-substituted carbenium ions are generated from the corresponding (chloromethyl)silane by either protonolysis with CH_5^+ or by chloride abstraction with $Si(CH_3)_3^+$. For example, protonolysis of $(CH_3)_2HSiCH_2Cl$ by CH_5^+ yields primarily HCl loss, reaction 2 The incipient carbenium ion (1) subsequently

$$(CH_3)HSiCH_2Cl + CH_5^+ \longrightarrow (CH_3)HSi\text{-}CH_2^+ + HCl + CH_4 \qquad (2)$$

1

rearranges to thermodynamically more stable silylenium ions by either 1,2-hydrogen or 1,2-methyl group migration, reaction 3. Theory has revealed that there is essentially no barrier for the highly exothermic (ca. 40 kcal/mol) 1,2-

$$(CH_3)_2HSi\text{-}CH_2^+ \xrightarrow{H} Si(CH_3)_3^+ \qquad (3a)$$

$$(CH_3)_2HSi\text{-}CH_2^+ \xrightarrow{CH_3} SiH(CH_3)(C_2H_5)^+ \qquad (3b)$$

hydrogen migration for $H_3Si\text{-}CH_2^+$ to yield $H_2Si(CH_3)^+$ [6] In addition, 1,2-methyl migration for $(CH_3)_3Si\text{-}CH^+\text{-}CH_3$ to yield $(CH_3)_2Si^+\text{-}CH(CH_3)_2$ is highly exothermic (ca. 32 kcal/mol) and has little or no barrier [7] These results suggest that both 1,2-hydrogen and 1,2-methyl migration are accessible processes for carbenium ion **1**

Probing the rearrangement channels for carbenium ion 1 (reaction 3) requires that the two distinct silylenium ions be distinguished. Although CAD does not discern silylenium ion structural isomers, specific ion/molecule reactions with methanol and isotopically labeled ethene readily differentiates these isomers. For example, methanol reacts with *authentic* $Si(CH_3)_3^+$ to yield exclusive loss of CH_4 whereas $SiH(CH_3)(C_2H_5)^+$ yields competitive elimination of H_2 (0.49), CH_4(0.23), and C_2H_6(0.28). In addition, ethene-$^{13}C_2$ reacts with silylenium ions containing a two carbon or longer alkyl chain by elimination of the corresponding olefin, reaction 4.

$$(CH_3)_2Si(C_nH_{2n+1})^+ + {}^{13}C_2H_4 \longrightarrow (CH_3)_2Si(^{13}C_2H_5)^+ + C_nH_{2n} \qquad (4)$$

For the two $SiC_3H_9^+$ isomers, $Si(CH_3)_3^+$ is inert with ethene-$^{13}C_2$, whereas, $SiH(CH_3)(C_2H_5)^+$ yields clean elimination of unlabeled ethene (i.e., m/z 73 goes to m/z 75 cleanly). By combining these two specific ion/molecule reaction probes, nearly any silylenium ion structural isomers can be distinguished.

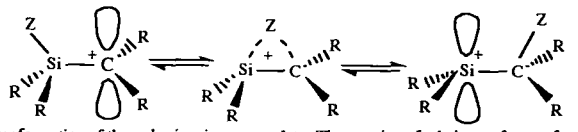
We have generated a host of nascent α-silyl-substituted carbenium ions and studied the relative migratory aptitude of various groups. These include $(CH_3)_2HSi\text{-}CH_2^+$ (1), $(CH_3)_3Si\text{-}CH_2^+$ (2), $(CH_3)_2(C_2H_5)Si\text{-}CH_2^+$ (3), $(CH_3)_2(CH{\equiv}C)SiCH_2^+$ (4), $(CH_3)_2(CH_2{=}CH)Si\text{-}CH_2^+$ (5), and $(C_6H_5)(CH_3)HSi\text{-}CH_2^+$ (6). **1** yields *exclusive* 1,2-hydrogen migration to give $Si(CH_3)_3^+$, **2** undergoes 1,2-methyl migration to yield $Si(CH_3)_2(C_2H_5)^+$, **3** gives roughly 65% 1,2-methyl migration to form $Si(CH_3)(C_2H_5)_2^+$ and 35% 1,2-ethyl migration to give $Si(CH_3)_2(C_3H_7)^+$, **4** yields *exclusive* 1,2-ethynyl migration to give $Si(CH_3)_2(CH_2C{\equiv}CH)^+$, **5** gives *exclusive* 1,2-ethenyl migration to generate $Si(CH_3)_2(CH_2CH{=}CH_2)^+$, and **6** yields both 1,2-phenyl migration to yield $SiH(CH_3)(CH_2C_6H_5)^+$ (94%) and 1,2-hydrogen migration to form $Si(CH_3)_2(C_6H_5)^+$ (6%). The results for **2** and **3** suggest that methyl and ethyl groups have similar relative migratory aptitudes. **1** clearly indicates that hydrogen has a much higher migratory aptitude than a methyl group. **4** and **5** indicate that the migratory aptitude of ethynyl and ethenyl groups is much greater than that for a methyl group Finally, **6** indicates that the migratory aptitude of a phenyl group exceeds that of hydrogen. These results suggest the following relative group migratory aptitudes:

Aryl > hydrogen >> methyl ~ ethyl

ethynyl >> methyl

ethenyl >> methyl

The preferred orientation for 1,2-group migration is presumably coplanarity of the empty p orbital of the carbenium ion center with the sigma orbital of the migrating group (Z) with the transition state involving a three-center, two-electron bond. 1,2-Group migration may be concerted with formation of the carbocation center or may



proceed after formation of the carbenium ion is complete. The question of relative preference for migration of different groups, "migratory aptitude", is a complex one, and there is no absolute order. The preference for migration of groups containing pi systems may be due to initial interaction of the pi electrons with the developing empty 2p orbital on the carbon atom This would yield a structure in which the unsaturated group is coplanar with the empty 2p orbital of the carbenium ion and, consequently, is predisposed to migration.

The relative migratory aptitude of hydrogen to that of ethynyl and ethenyl is under investigation as well as the relative migratory aptitude of ethynyl, ethenyl, and phenyl groups.

AN EXPERIMENTAL AND THEORETICAL STUDY OF THE HYDROGEN-BRIDGED RADICAL CATION $[CH_3C{=}O{\cdots}H{\cdots}O{=}CH_2]^{+\bullet}$

Jaana M.H. Pakarinen,[1] Krista M. Stirk,[2] Pirjo Vainiotalo,[1] Tapani A. Pakkanen[1] and Hilkka I. Kenttämaa[2]

[1]Department of Chemistry, University of Joensuu, SF-80101 Joensuu, Finland
[2]Department of Chemistry, Purdue University, West Lafayette, Indiana 47907, USA

During the past ten years, hydrogen-bridged radical cations have been frequently proposed as intermediates in the dissociation/isomerization pathways of a wide range of radical cations. Although high-level *ab initio* molecular orbital calculations indicate that many hydrogen-bridged -O···H···O-, -C···H···O- and -N···H···O- radical cations correspond to an energy minimum, not much experimental evidence exists to support the existence of such long-lived species.

From the combination of mass spectrometry experiments and *ab initio* calculations, we suggest that the hydrogen-bridged radical cation $[CH_3C{=}O{\cdots}H{\cdots}O{=}CH_2]^{+\bullet}$ is formed from the long-lived and low-energy molecular ion of ionized hydroxyacetone, $[CH_3C(O)CH_2OH]^{+\bullet}$. The isomerization occurs via a [1,4]-hydrogen shift, accompanied by a C-C bond cleavage. The experiments were performed in a differentially pumped dual-cell Fourier-transform ion cyclotron resonance mass spectrometer (FT/ICR) in a magnetic field produced by a 2.3 T superconducting magnet. Aldehydes, ketones and alcohols react with ionized hydroxyacetone by replacement of $CH_3CO\bullet$. For example, propanal replaces $CH_3CO\bullet$ in the ion $[CH_3C{=}O\ \ H\ \ O{=}CH_2]^{+\bullet}$ to form the ion $[CH_3CH_2C(H)O{\cdots}H{\cdots}O{=}CH_2]^{+}$. This product ion reacts by a further replacement of CH_2O with propanal, giving rise to $[CH_3CH_2C(H)O{\cdots}H{\cdots}OC(H)CH_2CH_3]^{+}$ (Figure 1). These results strongly suggest that the long-lived molecular ion of hydroxyacetone partially isomerizes to the hydrogen-bridged radical cation $[CH_3C{=}O{\cdots}H\ {\cdot}{\cdot}O{=}CH_2]^{+\bullet}$

The formation of another hydrogen-bridged ion, $[CH_3C(H){=}O{\cdots}H{\cdots}O{=}CH]^{+\bullet}$, by a [1,5]-hydrogen shift in the ion $[CH_3C{=}O{\cdot}{\cdot}\ H\ {\cdot}{\cdot}O{=}CH_2]^{+\bullet}$, can occur for some of the molecular ions under certain conditions. Ethyl iodide, D5-ethyl iodide, allyl iodide and dimethyl disulfide react by replacement of formyl radical •CHO, in addition to charge exchange. These findings suggest that some of the ions of $[CH_3C{=}O{\cdots}H{\cdots}O{=}CH_2]^{+\bullet}$ rearrange to the structure $[CH_3C(H){=}O{\cdots}H{\cdots}O{=}CH]^{+\bullet}$ prior to or during the reaction.

High-level *ab initio* molecular orbital calculations were performed up to the MP2/6-31G**// 6-31G**+ZPVE level of theory. The hydrogen-bridged species $[CH_3C{=}O{\cdots}H{\cdots}O{=}CH_2]^{+\bullet}$ and $[CH_3C(H){=}O{\cdots}H{\cdots}O{=}CH]^{+\bullet}$ were found to be more stable by 10.2 kcal/mol and 13.5 kcal/mol, respectively, than the covalently bonded, ionized hydroxyacetone. The two enol isomers of ionized hydroxyacetone, $[CH_3C(OH){=}CHOH]^{+\bullet}$ and $[CH_2{=}C(OH)CH_2OH]^{+\bullet}$, which were not observed experimentally, were calculated to be the most stable structures (by 41.2 kcal/mol and 22.3 kcal/mol relative to the covalently bonded, ionized hydroxyacetone).

The Gas Phase H/D Exchange Kinetics of Protonated Amino Acids: Trends Within the Alkyl Side Chain Series

Eric Gard *, Jennifer Bregar, Dale Willard, Carlito B. Lebrilla,
Chemistry Department,
University of California, Davis California 95616

The gas phase H/D exchange kinetics of protonated amino acids with organic deuterium sources (e.g. CH_3OD) are studied using an external source Fourier transform mass spectrometer. The amino acids studied are those containing simple alkyl side chains and trends within this group are examined. Rate constants for the H/D exchange of hydrogen atoms associated with specific functional groups are determined within a given compound and compared to analogous rates associated with hydrogen atoms in other amino acids within this series. The trends in rate constants are compared with known gas phase proton affinities differences between the deuterium source and the amino acid.

Both the forward and reverse exchange experiments were carried out using glycine and no kinetic isotope shift is discernible. Comparison of glycine, alanine, and their methyl esters shows the acid hydrogen is exchanged most rapidly. This holds true for the entire series.

Table 2 shows the approximate rates for the hydrogens on both the acid and amino positions within each amino acid. The acid exchange rate has a small dependence on basicity. In contrast, the amino position shows a clear trend with Proton Affinity (PA) difference. The exchange rate at the amino position becomes slower with increasing P.A. difference. This trend is consistent with previous literature information.

The most basic site in these molecules is the amino group which is also the site of protonation in the molecule. It is interesting that the acid hydrogen exchanges when the protonation site is rather far removed from its location. More work in this area will help determine the mechanism for the exchange process.

SPONTANEOUS UNIMOLECULAR DISSOCIATION OF WEAKLY BOUND IONIC CLUSTERS UNDER LOW-PRESSURE CONDITIONS

Detlef Thölmann and Terrance B. McMahon

Department of Chemistry, University of Waterloo, Waterloo, Ontario N2L 3G1

Gaseous ions trapped under low-pressure conditions, e.g. in an ICR cell, usually are regarded as stable species which exchange energy mainly by collisions. The time between collisions in an ICR cell at typical background pressures of 10^{-9} mbar lies in the range of 10 s to 40 s. Metastable ions, on the other hand, usually have lifetimes of 10^{-4} to 10^{-5} s. This is much shorter than the trapping time of an ICR mass spectrometer. Even for large oligosaccharide molecular ions metastable ion lifetimes do not exceed 2 ms[1].

We generated various ionic cluster ions of the type L_nH^+ and L_nCl^- (n = 1–5) in the home-built high-pressure external ion source of our Bruker Spectrospin CMS 47 FT-ICR mass spectrometer and trapped them in the ICR cell for up to 500 s During the trapping time a spontaneous unimolecular dissociation with loss of one or two ligands was observed. The unimolecular dissociation rate constants varied from 2.4×10^{-3} to 0.83 s^{-1} (see Table 1). This is much slower than any metastable dissociation. For a similar cluster ion, the proton-bound dimer of diethyl ether formed in an association reaction, Fisher and McMahon[2] found a metastable dissociation rate of 550 s^{-1}.

The energy required for the dissociation process, the bond dissociation energy, is 20 to 37 times R·T (T = 298 K), i.e. it is considerable larger than thermal energy. In an exchange of energy with the walls of the ICR cell via black-body radiation, however, the high-energy part of the Boltzmann distribution may continuously be re-populated, yielding some ions with energies above threshold. From preliminary RRKM calculations we estimate the minimum dissociation rate constant for a cluster ion at threshold energy to be on the order of 10^2 to 10^3 s^{-1}. This is at the same order of magnitude as metastable dissociation rate constants and very fast compared to the observed unimolecular rates. Therefore the rate of energization of the cluster ions must be rate determining.

Presented at the 41st ASMS Conference on Mass Spectrometry

Table 1. Unimolecular rate constants k_{uni} and thermodynamical data for the loss of a ligand from cluster ions (**W**: H_2O; **E**: $(CH_3)_2O$)

reaction	k_{uni} [s^{-1}]	ΔH°_{298} [kcal·mol^{-1}]	ΔG°_{298} [kcal·mol^{-1}]	ΔS°_{298} [cal·mol^{-1}K^{-1}]
$W_5H^+ \rightarrow W_4H^+$	0.49±0.01	13.9	5.8	27.2
$W_4H^+ \rightarrow W_3H^+$	$4.6(\pm0.1)\times10^{-3}$	17.4	9.6	26.1
$EW_3H^+ \rightarrow EW_2H^+$	0.23±0.03	12.9	6.1	22.7
$EW_2H^+ \rightarrow EWH^+$	$3.3(\pm0.3)\times10^{-2}$	16.7	7.4	31.1
$E_2W_2H^+ \rightarrow E_2WH^+$	0.44±0.07	14.3	6.2	27.2
$E_2WH^+ \rightarrow E_2H^+$	0.83±0.2	12.4	4.3	27.2
$E_3WH^+ \rightarrow E_2WH^+$	$9.5(\pm1)\times10^{-2}$	21.7	9.3	41.6
$W_3Cl^- \rightarrow W_2Cl^-$	$8.6(\pm1)\times10^{-2}$	11.8	5.1	22.3
$W_2Cl^- \rightarrow WCl^-$	$2.4(\pm0.4)\times10^{-3}$	13.0	6.6	21.4

In order to examine and confirm the supposed mechanism, the pressure and temperature dependence of the observed dissociation rates were investigated. A static pressure of 3×10^{-9} to 1×10^{-6} mbar of CH_4 was used in the ICR cell. A small pressure dependence was observed, originating from some collisional activation. This is **not** due to initial excess kinetic energy of the ions, however, because the bimolecular rate for this process is constant over a time period of 400s at 10^{-6} mbar CH_4. Both unimolecular and bimolecular rates were obtained from rate *vs.* pressure plots. The bimolecular rate of the reaction $W_4H^+ \rightarrow W_3H^+$ with CH_4 as the bath gas is as low as $(6.3\pm0.6)\times10^{-14}$ $cm^3molecule^{-1}s^{-1}$.

The unimolecular dissociation rate constants expectedly show a strong increase with temperature. Heating the ICR cell from 298 K to 320 K increases the unimolecular dissociation rate by about a factor of 2. This shows indeed that the energy required for the dissociation is of thermal origin.

Photodissociation and Relaxation of Gas-Phase Aluminum Cluster Ions

*Brian T. Cooper and Steven W. Buckner
Department of Chemistry, University of Arizona, Tucson, AZ 85721
Denise C. Parent
Chemistry Division/Code 6113, Naval Research Laboratory, Washington, D.C. 20375-5000

Presented here are studies of the oxidation, near-infrared photodissociation and electron photodetachment of the aluminum cluster anions Al_n^-, where $3 \leq n \leq 23$, as well as studies of the relaxation and oxidation of the photoexcited ions. Highly vibrationally excited aluminum cluster anions may be prepared for those clusters that require the absorption of more than one photon to dissociate, and the excited fraction can be estimated from the extent of dissociation using a Poisson distribution. The effects of vibrational excitation on bimolecular reactivity can be used to gain mechanistic insight; conversely, measurements of this kinetic perturbation can be used to determine the internal energy and relaxation rate of the ions.

All experiments were performed with a Fourier transform ion cyclotron resonance mass spectrometer (FT-ICR). The instrument uses a single trapping cell in a 3.0 T magnetic field, and experiments are controlled by an Extrel Odyssey data station. Aluminum cluster anions were formed by direct laser desorption/ionization from an aluminum nitride pellet held on a solids probe, using the unfocussed, Q-switched second harmonic from a Nd:YAG laser. The unfocussed, non-Q-switched, fundamental output pulse of the YAG was used for photoexcitation. Care was taken to ensure the colinearity of the desorption and ion photoexcitation beams. A static Ar background provided collisional cooling for the ions, while for the oxidation reactions O_2 was admitted through a pulsed valve, since oxygen gettering by desorbed aluminum neutrals made it difficult to maintain a static O_2 pressure.

All of the cluster ions studied, with the exception of the "magic number" cluster Al_{13}^-, absorb at 1064 nm. All but n = 3, 6 and 7 (which predominantly photodetach) photodissociate, losing a single aluminum atom. In general, smaller clusters (n < 13) require the absorption of 1 photon to dissociate, and larger clusters require 2. The effects of photoexcitation on the oxidation reactions of Al_{16}^- and Al_{18}^- were investigated; results are given below:

TABLE 1: Kinetic Behavior of Vibrationally Excited Al_n^-

	$Al_n^- + O_2$			Relax		
	k_{therm}/k_{hot}	therm X(n-5)	hot X(n-5)	k_{rad} (s^{-1})	$k_{coll,\ Ar}$ ($cm^3\ s^{-1}$)	eff*
Al_{16}^-	2.5 ± 1.0	0.32 ± 0.04	0.90 ± 0.08	0.47 ± 0.10	(9 ± 2) x 10^{-12}	1.7 ± 0.4
Al_{18}^-	5.0 ± 2.0	1.0	1.0	-	-	-

*k_L for Al_{16}^-/Ar = 4.96×10^{-10} $cm^3\ s^{-1}$.

These clusters react by the following scheme:

$$Al_n^- + O_2 \xrightarrow{-2Al_2O} Al_{n-4}^{-*} \longrightarrow Al_{n-5}^- \text{ or } Al_{n-4}^-$$

These reactions are found to slow down with cluster internal excitation, while preliminary anion experiments and published cation experiments find that the reaction rate increases upon translational excitation. This non-equivalence of different types of energy must mean that vibrational excitation, dispersed throughout the cluster's 3n-6 internal degrees of freedom, does not efficiently couple into the reaction coordinate, while translational excitation can on the other hand be used to overcome an activation barrier (corresponding to dissociative chemisorption) on the entrance channel. The nonstatistical nature of these reactions will be the subject of a future investigation.

The "branching ratio" measurements of Table 1 are not truly branching processes, but rather are sequential. As it is expected that any excess vibrational excitation in the Al_n^- cluster would be largely and proportionally partitioned into the Al_{n-4}^- product, we are justified in using this ratio as a measure of the cluster internal energy. Therefore, it is possible to measure the relaxation rate constants (radiative and collisional), using the experiment of Figure 1, below.

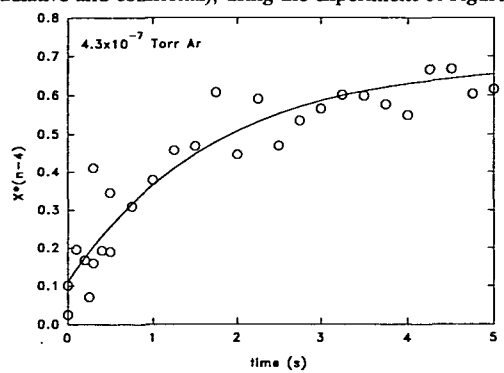

Figure 1. Initial Branching Ratio for the Reaction of Photoexcited Al_{16}^- with O_2 as a Function of Cooling Delay. Open circles: experimental data. Solid line: exponential fit; k_{relax} = 0.60 s^{-1}.

The radiative component of the rate constant measured above, 0.47 s^{-1}, is in the range that would be expected for a typical molecular ion with ~1 eV of excess internal energy, although it is also predicted that this rate constant is *independent* of internal energy, since all vibrational modes are readily populated even at thermal energies. Finally, collisional quenching by Ar is rather inefficient (although this is not unprecedented); more remarkable is that the collisional quenching efficiency for SF_6 is, preliminarily, about the same.

Mass Spectra of Mercury/Alkali and Cadmium/Alkali Clusters and Their Structure

*H. Ito[1], T. Sakurai[1], T. Matsuo[1] and I. Katakuse[2]
[1]Institute of Physics, College of General Education, Osaka Univ. Toyonaka, Osaka, 560 Japan
[2]Department of Earth and Space Science, Faculty of Science, Osaka Univ Toyonaka, Osaka 560 Japan

INTRODUCTION:

Mass spectrometric studies are useful to reveal the size specific properties of micro clusters, such as an electronic shell structure or an atomic shell structure. The structure of cluster ions of group IA, IIA and IIB metal can be explained by the electronic shell structure depending on delocalized electron orbits. That of group 0 rare gas can be explained by the atomic shell structure depending on close-packed atoms (outer form is an icosahedron or a double icosahedron). The cluster size indicating of the specific properties of cluster is called "magic number". In the case of IIB metal cluster ions (Zn, Cd), the total number of valence electrons at their experimental magic numbers differed ±1 from the theoretical shell closing number (2, 8, 20, 34, 40, 58,...)[1]. On the contrary, we expect that in case of IIB/cesium clusters, their total number of valence electrons at experimental magic number could agree with theoretical shell closing number. We report here the investigation of the mass spectra of mercury/cesium, cadmium/cesium and zinc/cesium clusters and discuss the structure of the clusters.

EXPERIMENTAL:

Cluster ions were produced by the bombardment of an appropriate metal sheet with 15keV Cs^+ ions. The primary cesium ions were produced using a thermal ion source. The cluster ions were mass-analyzed using a grand-scale sector mass spectrometer[2]. The identification of clusters was performed using a comparison between high resolution mass spectra at low mass region and calculated isotope patterns. The component of cluster ions at high mass region were determined to be similar pattern as low mass region.

RESULT and DISCUSSION:

We observed the mass spectra of mercury/cesium, cadmium/cesium and zinc/cesium clusters. Figure 1 shows a mass spectrum of zinc/cesium cluster ions. This spectrum is not completely resolved between Zn_nCs^+ and $Zn_{n-2}Cs_2^+$. However, the peak abundance pattern of *zinc/cesium cluster ions can be explained by the electronic shell structure. The abundant cluster* ions, $Zn_{10}Cs^+$ and $Zn_9Cs_2^+$ are attributed by the electronic shell (shell closing number = 20). The abundant cluster ions, $Zn_{20}Cs^+$ and $Zn_{19}Cs_2^+$ is attributed by the electronic shell (shell closing number = 40). Figure 2 shows a mass spectrum of cadmium/cesium cluster ions. The total numbers of valence electrons of Cd_4Cs^+(8), $Cd_{10}Cs^+$(20), $Cd_{17}Cs^+$(34), $Cd_{20}Cs^+$(40) and $Cd_{29}Cs^+$(58) agree with the theoretical shell closing numbers depending on delocalized electron orbits. The electronic shell structure clearly appears in the peak abundance pattern of cadmium/cesium cluster ions. Figure 3 shows a size distribution of Hg_nCs^+. For small clusters, a step-like feature is observed in the abundance distribution. The magic numbers (12, 18, 22, 25, 28 and 31) indicate a symmetrical geometric structure arising from close-packed atoms. For large clusters, a smooth periodic variation is observed. The size distribution of Hg_nCs^+ ions provided information of shell closing effect of neutral mercury clusters, Hg_n^0. The magic numbers (47, 70, 100, 132, 137, 170, 223, 280, 348, 430, 528, 648 and 764), which indicate the stability of neutral clusters, Hg_n^0 depending on the electronic structure, are reflected in the undulated abundance pattern of cluster ions, Hg_nCs^+.

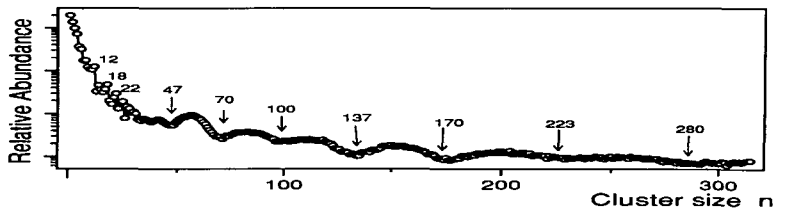

Figure 1. Size distribution of $(Hg)_nCs^+$

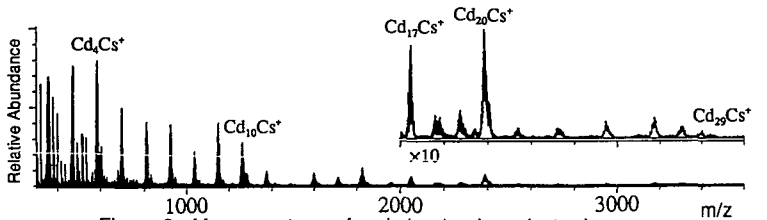

Figure 2. Mass spectrum of cadmium/cesium cluster ions

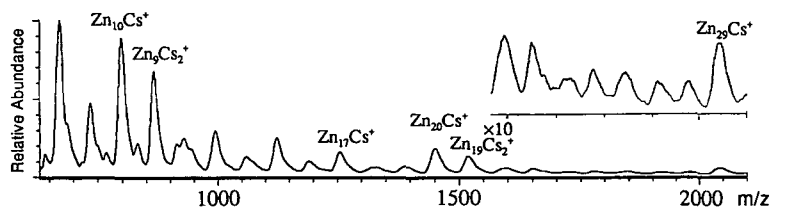

Figure 3. Mass spectrum of zinc/cesium cluster ions

CONCLUSION:

[1] The total number of valence electrons at the magic number of cadmium/cesium and zinc/cesium clusters corresponds to the theoretical electronic shell closing numbers at the low mass region. These clusters are bounded the metallic bonding forces.

[2] The total number of atoms at the magic number of Hg_nCs^+ (n<30) corresponds to the total number of atoms in double icosahedral structure(DIC). Mercury/cesium cluster ions in this region is bounded the van der Waals bonding forces.

[3] The size distribution of Hg_nCs^+ (n>30) ions provides information of the neutral mercury clusters, Hg_n^0. The abundant neutral mercury clusters are originated by the electronic shell structure.

INTRODUCTION

Mass spectrometric techniques have been successfully used to detect and characterize fullerenes since they yield specific molecular information. It should be noted, however, that mass spectrometry can only determine the mass-to-charge ratio of ions which are mass separated, and that mass spectra can not always give accurate information regarding the composition of the material. It is important to confirm whether detected ions are produced directly from the material itself, or produced as secondary products during the ionization process, especially in the case where ion or laser bombardment is used. In order remove such ambiguities, the following procedures are possible:

1. Use different types of ionization methods.
2. Combine mass spectronetry with chromatographic techniques.
3. Measure both positive and negative ion spectra.
4. Measure a purified sample of a single component.

We have taken LC/MS and FD (field desorption) mass spectra of carbon fullerenes and compared and contrasted the results.

EXPERIMENTAL

The fullerene rich carbon soot was prepared by a contact arc method. The separation (purification) was achieved liquid chromatography.

A JEOL SX102A mass spectrometer with a DA7000 data system was used for mass separation and detection. The frit-FAB ion source was coupled on-line to an HPLC system (Yokokawa LC-100). The eluent was ionized on the frit surface using 6keV Xe^0 bombardment. The flow rate was 5µl/min. A syringe pump (Harverd Apparatus Model 22) was also used to infuse the seprated single component into the frit-FAB system. Mass spectra were acquired at every 5 seconds over the mass range m/z 400 to 2200 at 8kV accelerating potential. A carbon emitter (10µm diameter) was used for the field desorption measurements, and the emitter current was increased by at a program rate of 2 mA/min up to 50 mA.

RESULTS AND DISCUSSION

[A] FAB mass spectra of C_{60}, C_{70}, C_{84}

Mass spectra were obtained through LC or direct inlet system. Positive and negative ion mass spectra of C_{84} by direct inlet mode are shown in Figures 1a, 1b respectively.

1. Fragmentation and aggregation phenomena occurred during ionization for purified C_{60}, C_{70} and C_{84} fullerenes. Fullerene-like carbon clusters (C_{2n}^+ n= 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40,41, 42, 43, 44, 45, 46 for C_{84} were produced as gas-phase ions. The intensity of such ions change monotonously according to generation from C_{60}, C_{70} or C_{84}. The intensity at m/z 720 and 840 increase rapidly, which suggests that these peaks are composed of both clusters and fullerenes.
2. Adduct ions (C_{70}+O, C_{70}+CH) were produced.
3. Fragmentation and aggregation were observed less in negative ion mode than in positive ion mode.
4. LC/MS method can distinguish between (1)ions which were produced directly from the material itself and (2)ions which were produced as secondary products during the ionization process,

[B] FD spectra of C_{60}, C_{70} and C_{84}

FD (positive) mass spectra of C_{70} and C_{84} are shown in Figures 2 and 3.

1. Almost no fragmentation or aggregation peaks were observed for C_{60} or C_{70}.
2. Doubly and triple charged ions were observed for C_{60} and C_{70}.
3. For C_{84}, there are some minor components are detected even by FD. This may suggest the purification process for C_{84} was not completed.

Though we can not say definitely whether these peaks are fragment ions or molecular ions of fullerene of these size, we can only say the possibility of latter case is large from the FD mass spectra of C_{60} and C_{70}. In conclusion, (1) LC/MS methds can distingush secondary product ions. (2) FD ionization is more suitable for quantitative analysis of fullerene.

MASS SPECTROMETRIC CHARACTERIZATION OF SYNTHETIC DERIVATIVES OF BUCKMINSTERFULLERENE

J.H. Callahan, M.A. Park, A. Purdy, J.A. Milliken, M.M. Ross, S.W. McElvany, Naval Research Laboratory, Washington, D.C. 20375.

The development of widespread interest in fullerenes since 1990 has led to a wide variety of studies involving C_{60}, including the synthetic derivatization of fullerenes, which may serve as precursors for new materials and polymers. Analysis of these derivatives poses a significant analytical challenge, to which the application of new and established mass spectrometric techniques has proven and should continue to prove useful. We have used mass spectrometric techniques to characterize the products of two types of reactions. In the first, the products of the reaction of catecholborane (CB) with C_{60} are observed by negative desorption chemical ionization (Figure 1). Hydrogenated fullerenes, $C_{60}H_x$, are observed as products of this reaction, with the number of hydrogens (x) exceeding 16 in some cases. Additionally, we have been able to observe intact C_{60}/catecholborane products, $C_{60}CB_n$, where n=1-3. Collision-induced dissociation (CID) of the $C_{60}CB$ product confirms the addition of 120 mass units (corresponding to the addition of CB). The results suggest that the CB reaction may serve as a useful initial step in the synthesis of additional derivatives.

A second reaction of interest is the alkylation of fullerenes with $NaZn(R)_3$ and $Zn(Et)_2$ where R is an alkyl group such as CH_3CH_2 or neo-pentyl (Figure 2). When the reaction mixture in benzene is hydrolyzed with water, DCI analysis shows the resultant products to consist of $C_{60}R_nH_m$, where n=1-15 and m<n. These reactions are similar to those reported by Kahr and coworkers.[1] In general, the lowest molecular weight derivative is $C_{60}RH$, but the addition of a second R group results tends to result in the predominant formation of $C_{60}R_2$, a pattern (even/odd) that continues to higher values of n. CID of the hydrogenated products shows that the alkyl groups are lost preferentially, leaving $C_{60}H_m$- as the products. NMR studies show that thermal dealkylation can similarly occur in solution.

We have also used mass spectrometry to study unusual fullerene derivatives that are formed by reactions of fullerenes with other fullerenes. The products of these reactions are odd-numbered fullerenes with molecular weights corresponding to C_{119} and C_{129}. These are observed in some soots formed by arc-discharge or resistive heating synthesis. They have also been observed in toluene extracts of these soots. We have been able to synthesize these products in solution by ozonolysis, in collaboration with the Huffman group at the University of Arizona.[2] Ozonolysis of C_{60} solutions results in the formation of C_{119}, while ozonolysis of C_{70} solutions results in the formation of C_{139}. Ozonolysis of mixtures of C_{60} and C_{70} result in the formation of a mixed fullerene derivative, C_{129}. Although the mechanism of this reaction is unknown, it is thought to result from the oxidation of C_{60} to C_{59} + CO_2, followed by the reaction of C_{59} with C_{60}.

GENERATION OF FULLERENE-BASED COMPOUNDS AND CHARACTERIZATION BY FTMS*

Changming Jin, Robert Hettich, and Robert Compton
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120

The synthesis and characterization of fullerene-based materials are areas of active research due to the potential applications in areas such as nanotechnology, new organic materials, as well as other novel uses. A variety of fullerene-based compounds have been prepared and subsequently characterized by Fourier transform mass spectrometry (FTMS). These studies have focussed on the synthesis, stabilities, and properties of fullerenes which have been modified by fluorination and coalescence. Charge exchange reactions can be examined in the FTMS to probe the electron affinities (EA) and ionization potentials (IP) of the modified fullerenes to determine how chemical modification affects the properties of the fullerenes.

Fluorinated fullerenes, $C_{60}F_x$ and $C_{70}F_y$ where x=44-48 and y=52-54, have been synthesized by reaction of fullerenes with fluorine gas. Although several theoretical investigations have been directed at predicting the properties of highly fluorinated fullerenes, to date there has been only very limited experimental information about these species. We have used FTMS to investigate charge exchange reactions of these fluorinated fullerenes in order to determine their electron affinities. As listed in Table 1, a variety of charge exchange reagents ranging from phenoxy to rhenium oxide (corresponding EA=2.36 -- 4.46 eV) have been used in these experiments. It was found that fluorination of fullerenes substantially alters the electronic properties of the species. The electron affinities were bracketed to be EA ($C_{60}F_{46}$) = 4.0 +/- 0.25 eV and EA ($C_{70}F_{54}$) = 4.0 +/- 0.25 eV, which is more than 1 eV higher than the corresponding pure fullerenes. Charge exchange reaction results between $C_{60}F_x$ and $C_{70}F_x$ indicated that EA ($C_{60}F_{46}$) is slightly lower than EA ($C_{70}F_{54}$), reminiscent of the fact that EA(C_{60}) < EA (C_{70}).

In an effort to explore alternate methods of generating hydrogenated fullerenes, we have also pioneered a method to generate C_{60} coalescence products in the solid phase (compared with gas phase synthesis). Pure C_{60} films prepared by drying C_{60} toluene solutions were placed on the electrode of a hydrogen plasma discharge chamber. Examination of these samples by FTMS after the hydrogen discharge did not reveal hydrogenated fullerenes, but rather displayed mass peaks corresponding to C_{120}, C_{180}, C_{240}, etc (see Figure 1). These mass peaks were attributed to the coalescence of C_{60} into higher fullerenes under the environment of hydrogen plasma discharge (C_{60} --> C_{120} --> C_{180} --> C_{240}). In the hydrogen rf discharge chamber, C_{60} molecules were bombarded by ions and electrons. This process most likely fragmented some of the C_{60} bonds and allowed bond formation between neighboring C_{60} molecules. Such coalescence reactions between two or more C_{60} molecules are expected to produce fullerenes in the sizes of C_{120}, C_{180}, C_{240} etc. Preliminary experimental results suggested these coalescence products may have the spherical or tubule structures. The coalescence of C_{60} is energetically favorable because larger fullerenes have higher cohesive energy per atom than C_{60}. This discovery may lead to the mass production and isolation of higher fullerenes like C_{120}, C_{180} etc which do not exist as special species in the conventional carbon arc products.

Radial Velocity Distribution Measurement of Ions Ejected by Laser Desorption

**Wenzhu Zhang and Brian T. Chait*
The Rockefeller University, 1230 York Ave. , New York, NY 10021

Matrix-assisted laser desorption mass spectrometry involves the production of gas phase ions by the absorption of laser energy in small organic molecules. Determination of the velocity distribution of ions is of interest to gain an understanding of the fundament physical process. It is also of practical importance in the design of mass spectrometers because the axial velocity distnbution set limits to the achievable resolution and the radial velocity component governs the divergence of ions of interest as they transverse the mass spectrometer.

Previously Beavis and Chait measured the ion axial velocity distribution, demonstrating that the axial ejection velocity of polypeptide ion was essentially independent of the mass. Supersonic expansion was suggested as a model for the matrix assisted laser desorption process.

To measure the radial velocity distribution, we have designed an experimental setup where the position of ions striking a detector could be measured accurately. In the present experiment, it is necessary to use an acceleration field devoid of any radial component that could obscure the intrinsic radial velocity distribution. Such field can be obtained by a series of ring electrodes with appropriate potentials on them. In the setup shown in fig. 1, the ions produced by laser desorption accelerate in acceleration field, transverse the flight tube and impact on a dual microchannel plate detector that allows both the time-of-flight spectrum to be measured and individual impacting ions to be visualized as bright dots on a phosphor screen. A video camera synchronized with the laser pulses records the images of ion impacts from each laser pulse, whereupon the image is transferred to a computer for subsequent analysis. The radial velocity distribution can then derived from the measured position of dots, the physical axial distance that ions travel and the accelerating potential.

Shown in fig. 2, the radial velocity distribution has been measured for the cationic dye brilliant green (MW 386 Da) at various extraction fields (3, 5 and 10 kV across 4.3 cm). The distribution is independent of the applied extraction field and is an intrinsic property of the laser desorption process. The full width at half maximum of the distribution is about 200 m/s. The angular distribution (fig. 3) is also derived using a previously measured value for the mean axial velocity (~750 m/s). The ejected ions are extremely forward peaked, with a half width at half maximum of ~ 13°.

We have designed an experimental setup and measured the radial velocity distribution for brilliant green. The distribution is independent of the extraction field. The extremely forward peaking distribution of the ejected ions supports the supersonic expansion model in the laser desorption process. In future experiments, the radial velocity distribution for peptide ions produced in matrix-assisted laser desorption will be measured.

Gas-Phase Proton Affinity Modifies Molar Response Factors in Fast Atom Bombardment

*Tanya M. Lewis and David H. Russell
Department of Chemistry, Texas A&M, College Station, TX

There have been several studies suggesting that quantitative analysis using fast atom bombardment (FAB) mass spectrometry is subject to discrimination effects that result in signal suppression for some components. Variations in ion yield have been attributed to differences in analyte concentration at the vacuum/surface interface. A direct correlation has been shown between hydrophilicity and signal suppression using glycerol as the matrix. Ionization discrimination has been observed in preliminary studies of mixtures of carboxylic acids using FAB ionization.

In this paper, several mono- and dicarboxylic acids were used as model compounds to determine yields of protonated molecules. We report that ionization discrimination has been observed in both the positive and negative ion mode for equal molar mixtures. Using the surface concentration concept to predict FAB sensitivity the monocarboxylic acid should be preferentially ionized. However, FAB ionization experiments with mono-/dicarboxylic acid mixtures yield exclusively the $[M+H]^+$ of the dicarboxylic acid. These findings are inconsistent with the hypothesis that matrix-acid solubility interactions preferentially ionize hydrophobic compounds. The goal of this study is to determine the nature of ionization discrimination effects of mono- and di-carboxylic acids in FAB.

The experiments discussed here are performed on a modified sector instrument consisting of a Kratos MS-50, as MS-I and a one meter reflectron time-of-flight as MS-II. The Kratos MS-I is operated at an accelerating voltage of 8 KeV with a mass range of 1-2,000 amu. The instrument is equipped with a conventional direct insertion probe source. A variable energy (0-25 KeV) cesium ion gun (Phrasor Scientific) is attached to the ion source housing. The Cs^+ beam is operated continuously at 15 KeV.

We have used metastable ion spectra to bracket the proton affinities of mono- and dicarboxylic acid-glycerol clusters. [Adipic-H^+ (147)] is detected in the metastable spectrum shown in Figure 1. This indicates that the proton affinity of adipic acid is higher than that of glycerol. [Hexanoic-H^+ (117)] is not detected in the spectrum shown in Figure 2. The conclusion is that the proton affinity of glycerol is higher than that of hexanoic acid. Interpretation of these results suggests that gas-phase proton affinity is responsible for the discrimination effects for mixtures of mono- and dicarboxylic acids. Future studies will focus on pulsed-jet/tandem time-of-flight experiments. The application of the principles utilized is being considered for other analyte systems.

THE FORMATION OF NITRIC ACID AND NITRIC ACID COMPLEXES FROM GAS-PHASE AMMONIUM NITRATE CLUSTERS

Robert J. Doyle, Jr., Chemistry Division, Code 6110-D,
Naval Research Laboratory,Washington, DC, 20375-5000.

The sputtering of condensed-phase ammonium nitrate by fast-atom bombardment results in the desorption of ionic ammonium nitrate clusters of the form $(NH_4NO_3)_nNH_4^+$, where n=1,2,3,...,>25, and $(NH_4NO_3)_nNO_3^-$, where n=3,4,5,...,>25. In addition, the well-known nitric acid complexes $(HNO_3)NO_3^-$, $(HNO_3)_2NO_3^-$, and $(HNO_3)_3NO_3^-$ are observed. The absence of anionic ammonium nitrate clusters with n<3 suggests that they are unstable and rapidly decompose to form the observed nitric acid complexes via the reaction:

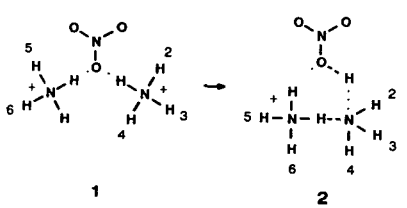
$$(NH_4NO_3)_nNO_3^- \rightarrow (HNO_3)_nNO_3^- + nNH_3,$$

where n=1 or 2. Indeed, these reactions are confirmed by collision-induced dissociation (CID) of much larger clusters where, under multiple collision conditions, the loss of n NH_3 molecules is observed only from product clusters with n<4. The reactions require an unusual rearrangement of central NH_4^+ (which is hydrogen bonded to nitrate anions) that results in the formation of proton bound nitrate anions and enables the loss of NH_3. A proposed reaction schematic, for n=1, is shown in Figure 1.

In contrast, cationic ammonium nitrate clusters with n<7 show the direct loss of a nitric acid molecule via the reaction:

$$(NH_4NO_3)_nNH_4^+ \rightarrow NH_3(NH_4NO_3)_{n-1}NH_4^+ + HNO_3,$$

where n=1,2,3,...,6. CID experiments under multiple collision conditions show that only one nitric acid molecule is lost from a parent ion and further dissociation occurs by losses of NH_4NO_3 molecules only [1,2]. Collisional activation of large clusters, n=25 for example, shows sequential losses of NH_4NO_3 until an n<7 cluster is formed, at which point one nitric acid molecule is lost. A comparison of metastable and CID spectra of $(NH_4NO_3)_nNH_4^+$ ions shows that the loss of nitric acid is predominantly a metastable process. This implies that nitric acid is formed by a rearrangement of the parent ion.



1 2

Figure 1. The rearrangement of $(NH_4NO_3)NO_3^-$ to form $H(NO_3)_2^-$.

The mass spectrum of sputtered ammonium nitrate (cations) establishes that a major stair-step decrease in the ion-abundance distribution occurs at the $(NH_4NO_3)_7NH_4^+$ ion[1]. If the first solvent shell is filled at n = 7, then a cluster-ion core must exist to which NH_4NO_3 molecules are hydrogen bonded to all available hydrogen atoms. The simplest ion configuration that fits this criterion is the first member of the series, $(NH_4NO_3)NH_4^+$, shown in Figure 2. The core ion is fully solvated by the hydrogen bonding of six NH_4NO_3 molecules to the six available hydrogen atoms of the two ammonium ions (indicated by the sites numbered 2-7 in Figure 2). This arrangement results in a structure consisting of seven ammonium nitrate units and an additional ammonium ion which provides the overall positive charge. Ligands are seen to be lost as NH_4NO_3 ion pairs. The ionic mechanism for the formation of nitric acid by proton transfer is through a rearrangement of the core ion through the transition-state structure proposed as Structure **2** in Figure 2 below.

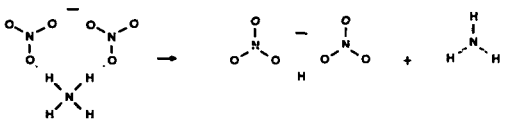


Figure 2. The structure of the core ion (**1**) showing hydrogen-bonding sites and the proposed transition-state (**2**) for rearrangement.

In summary, the experimental evidence established that: (1) the first important structural transition occurs at the $(NH_4NO_3)_7NH_4^+$ ion, (2) only ions with n < 7 dissociate by the direct loss of nitric acid, (3) the loss of nitric acid is predominantly a metastable process, and (4) that a nitric acid molecule is lost only once in the chain of dissociation steps. In conclusion, an ammonium nitrate cationic complex forms and loses nitric acid by an internal rearrangement that is ultimately quenched by the continued addition of ammonium nitrate solvent molecules.

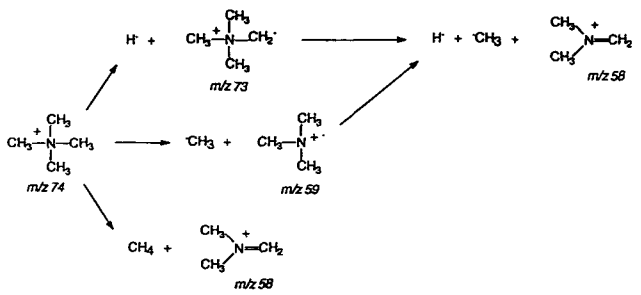
TETRAALKYLAMMONIUM CATIONS AND THEIR NEUTRAL COUNTERPARTS

Šárka Beranová and Chrys Wesdemiotis
Department of Chemistry, The University of Akron, Akron OH 44325-3601.

Tetraalkylammonium cations are simple polyatomic ions, readily accessible by desorption ionization of the corresponding quaternary ammonium salts. Neutralization of these ions provides a route to hypervalent peralkylated ammonium radicals. The present study investigates the unimolecular chemistry of gaseous tetraalkylammonium ions R_4N^+ ($R=CH_3$, CD_3) by metastable (MI) characteristics, collisionally activated dissociation (CAD), and neutralization-reionization mass spectrometry (NRMS).

The tetramethylammonium ion dissociates into two primary fragments, namely $(CH_3)_3N^+$ (m/z 59) and $(CH_3)_2N{=}CH_2^+$ (m/z 58). The MI spectrum of $(CH_3)_4N^+$ (Fig. 1a) indicates that in the metastable time-frame the production of m/z 59 (i.e. loss of a methyl group) dominates. In the CAD spectrum (Fig. 1b), $(CH_3)_2N{=}CH_2^+$ emerges as the most prominent product. This ion can be formed by two mechanisms, a rearrangement elimination of methane and a consecutive loss of $^{\cdot}CH_3$ + $^{\cdot}H$ (Scheme I).



Scheme I.

The B^2/E scans reveal that under MI conditions (Fig. 2a) both $(CH_3)_3N^+$ and $(CH_3)_4N^+$, and to a lesser extent $(CH_3)_3N\text{-}CH_2^{+\cdot}$, are the source of m/z 58. In contrast, upon CAD (Fig. 2b) the predominant portion of $(CH_3)_2N{=}CH_2^+$ arises directly from the molecular ion.

The increase in the abundance of m/z 58 in the spectra of $(CH_3)_4N^+$ is accompanied by substantial peak broadening (Fig. 1b), suggesting that upon CAD, formation of $(CH_3)_2{=}CH_2^+$ proceeds via a process with high reverse activation energy, resulting in a large kinetic energy release. A large reverse activation energy is possible if m/z 58 is reached by CH_4 loss directly out of the molecular ion either in a one step process, or possibly through an ion-molecule complex between $(CH_3)_2N{=}CH_2^+$ and CH_4. Since m/z 59 and 58 compete in the MI frame, the transition state for the concerted CH_4 loss cannot be more than ~50 kJ/mol below the thermochemical limit of the consecutive losses (1025 kJ/mol).

Parallel experimental results obtained for the $(CD_3)_4N^+$ analog support the above findings

Based on the combined MI, CAD, and linked scanning results the conclusions reached here differ from those reported previously (Glish et al., ASMS Conference, San Diego 1985). We find that at internal energies near the dissociation threshold the major decay channels of $(CH_3)_4N^+$ include formation of both $(CH_3)_3N^{+\cdot}$ and $(CH_3)_2N{=}CH_2^+$, the latter ion arising most likely by stepwise direct bond ruptures, as a relatively narrow peak is observed (Fig 1a vs. 1b) The predominant fragmentation pathway of the collisionally activated $(CH_3)_4N^+$ is production of $(CH_3)_2N{=}CH_2^+$ by rearrangement loss of CH_4.

Our first NRMS results on $(CH_3)_4N^+$, showing that its neutralization with trimethylamine yielded a stable $(CH_3)_4N^{\cdot}$ radical, could not be reproduced under various experimental conditions The present study finds that $R_4N^{\cdot}$ ($R=CH_3$, CD_3, CH_2CH_3) decompose fully prior to reionization, primarily via loss of $R^{\cdot}$.

POSITIVE FAB MASS SPECTRA OF SEVERAL COBALT AND CHROMIUM β-DIKETONATES

L. Plaggenborg[a], B. Wenclawiak[a], W. D. Buchannon[b] and J. B. Westmore[b]

[a]*Chemie-Biologie, Universitat-GH-Siegen, W-5900 Siegen, Germany*
[b]*Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2, Canada*

With β-ketoenolate ligands the transition metals chromium and cobalt form kinetically inert, neutral complexes. Metal chelates have been extensively studied under electron ionization (EI) conditions [1]. Since these chelates are soluble in organic solvents, and separable by HPLC, it is apparent that these compounds can be ionized under fast atom bombardment (FAB), i.e. liquid secondary ionization (LSI), conditions.

Chelate complexes of chromium(III) and cobalt(III) with the following ligands were studied: acetylacetone, 1-(2-thienyl)-4,4,4-trifluoro-1,3-butanedione, 1-phenyl-4,4,4-trifluoro-1,3-butanedione, 1-(2-thienyl)-1,3-butanedione, 1-(2-thienyl)-4,4-dimethyl-1,3-pentanedione (Hthdmpd), 1-phenyl-4,4-dimethyl-1,3-pentanedione (Hphdmpd) and 2,2-dimethyl-3,5-hexanedione (Hdmhd).

The FAB mass spectra of samples in a 3-nitrobenzyl alcohol (3-nba) matrix, bombarded by 8 keV xenon atoms, were recorded with a VG 7070E-HF double sector (EB geometry) mass spectrometer, equipped with an 11-250J data system based on a PDP 11/73 microcomputer. Product ion mass spectra of selected collisionally-activated precursor ions were obtained by linked-field scanning (B/E constant). Helium was admitted to the collision cell preceding the electric sector so that the precursor ion current was reduced to about 50% of its original value.

Representative spectra of some of the cobalt complexes are shown in Figs. 1-3. Their characteristic features, together with those of the chromium complexes, can be summarized as follows:

- excellent matrix-free FAB mass spectra of Cr^{III} and Co^{III} chelates are obtained.
- the chromium complexes show protonated molecules and only small yields of polymeric ion species
- the FAB mass spectra of the cobalt complexes, in contrast to the EI mass spectra, show abundant monomeric molecular ions (not protonated molecules), and high yields of the dimeric ion species, $Co_2L_4^+$ and $Co_2L_3^+$
- on CAD the dimeric Co-containing ions decompose to other dimeric ions rather than to mono-Co-containing ions
- a mixture of two different cobalt complexes yields dimeric ions containing mixed ligands

Study of Co(III) Clusters Using FAB Mass Spectrometry

*Chung-Ping Yu, Katerina Dimitrou, and George Christou
Chemistry Department, Indiana University, Bloomington, IN 47405

INTRODUCTION

In conjunction with elemental analysis and NMR spectrometry, we have employed Fast Atom Bombardment mass spectrometry as a routine analysis tool to assist in the identification and structural determination of a series of Co(III) clusters : $[Co_2(OH)_2(OAc)_3(bpy)_2]ClO_4$ (1), $[Co_3O(OH)_3(OAc)_2(bpy)_3](ClO_4)_2$ (2), $[Co_4O_4(OAc)_2(bpy)_4](ClO_4)_2$ (3), $[Co_4O_4(O_2CC_6H_4CH_3)_2(bpy)_4](ClO_4)_2$ (4), and $[Co_4O_4(O_2CC_6H_4CH_3)_2(bpy)_4](ClO_4)_3$ (5); bpy=2,2'-bipyridine and $OAc=O_2CCH_3$. In most cases, X-ray crystallography has confirmed the predicted structure of these compounds

EXPERIMENTAL

FAB mass spectra of complexes 1-5 were obtained with a Kratos MS-80 mass spectrometer that was interfaced with a Kratos DS90 data system. Xenon at 8 KeV was used to produce the primary beam with Ion-Tech saddle field atomic gun. Data for each compound were acquired for 10-20 scans at 10 s/decade. Either 3-Nitrobenzyl alcohol (NBA) or a NBA/DMSO mixture was used as matrix. The syntheses of the Co complexes have been described elsewhere[1]

RESULTS AND DISCUSSION

The FAB mass spectrum of the dinuclear complex 1 shows the formation of $[M-ClO_4^-]^+$, $[M-ClO_4^-\text{-}HOAc]^+$, $[M-ClO_4^-\text{-}2HOAc]^+$, and $[M-ClO_4^-\text{-}2HOAc\text{-}OAc^-]^+$ ions at m/z 641, 581, 521, and 462, respectively The cobalt metal centers appear to retain their formal oxidation state of +3. However, the observation of m/z 462 peak indicates that it is formed by a one-electron reduction which possibly originated from the radiation-damaged matrix[2]. The FAB mass spectrum of the trinuclear complex 2, reveals a number of informative fragments at m/z 929, 869, and 674 which correspond to the ions $[M-ClO_4^-]^+$, $[M-ClO_4^-\text{-}HOAc]^+$, and $[M-2ClO_4^-\text{-}bpy]^+$, respectively. The appearance of m/z 674 peak also indicates the existence of a one-electron reduction; this also agrees with the previous observation.

FABMS studies provided the most powerful evidence that compound 3 is tetranuclear possessing a novel $\{Co_4O_4\}^{4+}$ core, when X-ray quality crystals could not be obtained. That led to the synthesis of compound 4 from 3 via a ligand exchange reaction. The X-ray crystal structure of 4 proved the cubane architecture of this complex. In FABMS the analogous fragmentation paths of complexes 3 and 4 are found to produce ions such as $[M-ClO_4^-]^+$, $[M-ClO_4^-\text{-}bpy]^+$, $[M-2ClO_4^-\text{-}bpy]^+$, $[M-2ClO_4^-\text{-}2bpy]^+$, $[M-2ClO_4^-\text{-}3bpy]^+$, etc.., indicating that complex 3 has the same cubane structure. It is also interesting to note that the ions $[M-2ClO_4^-\text{-}bpy]^+$, $[M-2ClO_4^-\text{-}2bpy]^+$ and $[M-2ClO_4^-\text{-}3bpy]^+$ contain the cobalts in a reduced oxidation state. However no peak was observed for the reduced ion $[M-2ClO_4^-]^+$, where the whole cation would remain intact. This suggests that reduction can be associated with the loss of bpy ligands from the clusters and consequently structural changes in the geometry around the metals. This observation is compatible with the irreversible reduction in cyclic

voltammetry (CV) for both complexes 3 and 4. It is worth noting that these two complexes have a reversible one-electron oxidation in CV studies, and theoretical calculations show this oxidation to be metal based. Compound 5 produced from the electrochemical oxidation of 4 was isolated and analyzed by FABMS. Careful comparison of mass spectra for 4 and 5 reveals that both spectra are superimposable. Thus we believe the reduction of complex 5 back to complex 4 occurs in FABMS.

CONCLUSION

As we expected, the highest mass observable ions of Co(III) complexes in FABMS are $[M-ClO_4^-]^+$ ions. A series of diagnostic fragment ions resulting from sequential loss of intact ligands are observed and these fragmentation patterns can provide a better understanding of the identity of these complexes. It is also recognized that some of these fragment ions are reduced by one electron in the fragmentation processes.

FRAGMENTATION REACTIONS OF MULTIPLY-PROTONATED PEPTIDES+

*Xue-Jun Tang[1,2], Pierre Thibault[2], Robert K. Boyd[2] ; [1]Albert Einstein College of Medicine, Department of Biochemistry, 1300 Morris Park Av., Bronx, NY 10461, [2]Institute for Marine Biosciences, National Research Council, 1411 Oxford St., Halifax, Nova Scotia Canada B3H 3Z1

Ion evaporation techniques such as ionspray have found application in protein chemistry, not only for precise molecular weight determination (within 0.01% for MW of up to 200 kDa) but also for primary structure characterization. A striking example of this latter application has been demonstrated by Loo *et al* [1] who conducted MS-MS experiments on multiply protonated (up to $(M+49H)^{49+}$) albumins. However, sequence information obtainable from these complex MS-MS spectra is limited by uncertainties in determining the fragment mass (within < 0.5 Da) and corresponding charge states. Practical exploitation of MS-MS for such structural investigations will depend upon further understanding of the dissociation mechanisms and development of sensitive methods for determining charge-states of fragment ions.

Under low-energy CID conditions, the fragmentation of protonated peptides is found to be highly dependent on the number and location of basic residues and more particularly of Arg. In the case of tryptic peptides the initial formation of the doubly-protonated species appears to involve obligatory protonation at the N-terminus while the second proton is conveniently positioned on the side chain of the C-terminus residue [2]. This favorable case yields (b + y") complementary pairs via charge-site initiated fragmentation where the ionizing proton of the y fragment ion is anchored on the side-chain of the basic C-terminus residue. The formation of $(y''')^{2+}$ ions is explained by a charge-site-remote mechanism where an extra proton is located on the C-terminus side of the cleaved bond. Product ion spectra corresponding to dissociation of higher protonated forms of precursors are dominated by cleavages occurring near the middle of the peptide chain. Protonation at mid-chain sites presumably minimize Coulombic repulsions and lead to charge-site initiated fragmentations. For peptides possessing basic residues near the N-terminus, such as angiotensin I and substance P, the product ion spectra of $[M+2H]^{2+}$ and $[M+3H]^{3+}$ are dominated by a and b ions with almost no accompanying y ions. It is proposed that these b_n ions could have a different structure from those observed for tryptic peptides and that a charge-site induced mechanism could account for their formation. An example of this is shown in Figure 1 A, the product ion spectrum of $[M+2H]^{2+}$ from substance P. The unusual stabilities of the doubly-charged fragments $b_{10}'^{2+}$ and $b_9'^{2+}$ were investigated using intermediate ions formed in the orifice-skimmer region of the mass spectrometer (Figure 1 B). The product ion spectra of $b_9'^{2+}$ and $b_{10}'^{2+}$ gave abundant fragment ions corresponding to b_n+57 and b_n+170, respectively. These unusual rearrangement reactions were found to arise from wholesale transfer of one or two residues from the C-terminus end of the doubly-charged b fragment to the side chain of a Lys residue.

The fragment ion spectrum of $[M+2H]^{2+}$ from γ-endorphin, another non-tryptic peptide, is shown in Figure 2. Some of the salient features of this spectrum can be rationalized assuming that one external proton is localized on the Lys sidechain while the second proton can be transferred to amide nitrogens on the N-terminus side of this basic residue. Charge-site initiated fragmentation reactions would favor the formation of (b_j plus y''_{17-j}) complementary pairs for j=3-8. However, if the second ionizing proton is located on the C-terminus side of Lys, the same mechanism will lead to formation of $(b_j')^{2+}$ fragments for j=12-16. The difficulty of obtaining sequence ions from each amide bond was even more evident for peptides possessing a large number of basic residues such as dynorphin1-13 (YGGFLRRIRPKLK). In this latter case the fragment ion spectra of $[M+3H]^{3+}$ and $[M+4H]^{4+}$ yield abundant a_1, y''_1, $(y_{12}''')^{2+}$ and $(y_{12}''')^{3+}$ ions with almost no other structurally informative fragment ions, although intramolecular Coulombic repulsion is likely to be significant. It appears that mobilization of ionizing protons along the peptide backbone must also be possible, in order to promote charge-site initiated dissociation mechanisms, and that low-energy CID is not effective in achieving this if the protons are anchored on highly basic sites.

FRAGMENTATIONS OF DOUBLY-CHARGED ALKALI METAL-PEPTIDE COMPLEXES

Xue-Jun Tang[1,2], Pierre Thibault[2] and Robert K. Boyd[2]; [1]Dept. of Biochemistry, Albert Einstein College of Medicine, 1300 Morris Park Ave., Bronx, NY 10461; [2]Institute for Marine Biosciences, National Research Council, 1411 Oxford St., Halifax, Canada B3H 3Z1.

Electrospray ionization of peptide solutions doped with alkali metal salts X^+Y^- produces abundant doubly-charged ions $(M+H+X)^{2+}$ and $(M+2X)^{2+}$. For X = K, Rb, Cs, CID of these ions yields mainly X^+ plus the charge-separation complement, with increasingly sparse fragmentation as X increases in size. For tryptic peptides M in which the C-terminal residue is Arg, and for X = Li or Na, a major CID fragmentation pathway leads to $(M+X-60)^+$ and/or $(y'+X-60)^+$ ions. This behaviour is specific to peptides containing a C-terminal Arg residue, such as des-Arg[1]-bradykinin (Fig.1), while *e.g.* des-Arg[9]-bradykinin (RPPGFSPF, Arg at N-terminus, not shown) yields no such fragments nor do peptides containing Arg within the sequence. Many peptides which do not contain any Arg residues yield singly-charged $(M+X)^+$ ions which fragment to give abundant $(b+X+OH)^+$ ions (for X = Li, Na) whose origins are now well understood [1]. The present work has concentrated on elucidating the nature of the 60 Da neutral fragment associated with lithiated or sodiated peptides containing an Arg as the C-terminal residue. Typical fragment spectra (low-energy CID, SCIEX API III triple-quadrupole instrument) are shown in Fig.1.

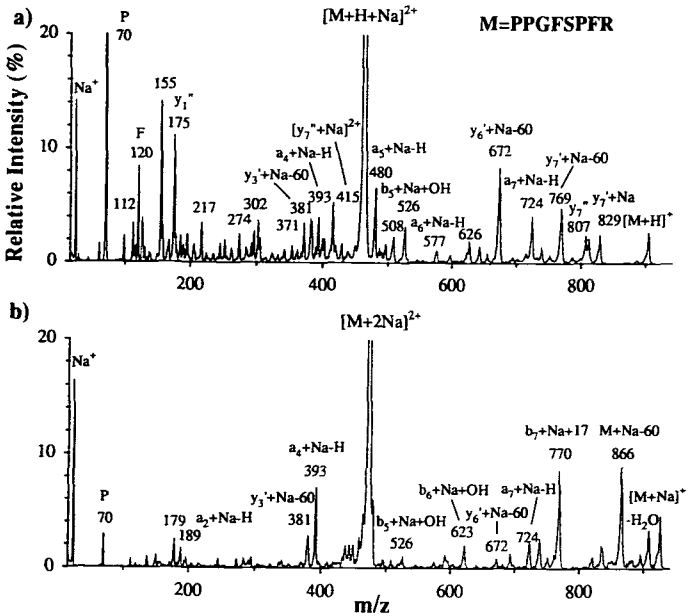

Figure 1. Fragment-ion spectra of (a) $[M+H+Na]^{2+}$ and (b) $[M+2Na]^{2+}$ precursor ions from ionspray ionization of des-Arg[1]-bradykinin.

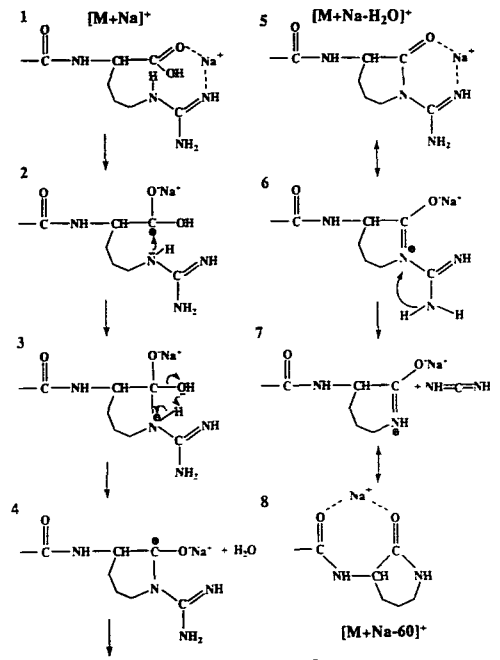
The singly-charged lithiated peptide $(HGLGAR+Li)^+$, produced by LSIMS, was shown previously [2] to yield an intense fragment corresponding to loss of 60 Da, but no attempt was made to characterize this process. Similar CID experiments [3] on the intense $(b_4+Li+OH)^+$ fragment (which has a C-terminal Arg residue) of $(LWMRF+Li)^+$ showed that it readily lost 18 Da followed by a further loss of 42 Da; a mechanism was proposed [3] for the first of these steps (H_2O expulsion).

The present work has extended these earlier findings [2,3] to include both X = Li and Na, to both singly- and doubly-charged precursors, and has elucidated characteristics of the reaction in which a 60 Da neutral fragment is expelled. The main findings may be summarized as follows:

(a) the reaction is restricted to peptide-X^+ complex ions, where X = Li or Na;
(b) the reaction is characteristic of Arg residues, which must be located at the C-terminus;
(c) experiments using D_2O, in which exchangeable hydrogens were replaced by deuterium, showed that the 60 Da neutral fragment contains 4 exchangeable hydrogen atoms;
(d) it was possible to produce the $(M+X-60)^+$ fragments by CID in the post-orifice expansion region; precursor-ion scans showed peaks corresponding to $(M+X)^+$, $(M+2X)^{2+}$, and more interestingly to $(M+X-18)^+$, though this last intermediate ion was of only moderate intensity.



Scheme I

Scheme 1 shows a mechanism proposed to account for findings (a)-(d), drawn for sake of simplicity for a singly-charged precursor; steps 1-5 are slightly modified from those proposed by Grese *et al.*[3] to account for loss of H_2O. The overall loss of 60 Da is thus accounted for by successive losses of H_2O and of a 42 Da fragment from the Arg sidechain, suggested here to be HN=C=NH (isoelectronic with CO_2). The alternative neutral structures are those of diazomethane, *cyc*-(-CH_2-N=N-) (diazirine) and NH_2-CN (carbamonitrile), which are less feasible on both energetic and mechanistic grounds.

GAS-PHASE FRAGMENTATIONS OF ANIONIC COMPLEXES BETWEEN PEPTIDES AND TRANSITION METAL IONS: COMPARISONS WITH ALKALINE EARTH METAL IONS

Hong Zhao, Alex Reiter, and Jeanette Adams, Department of Chemistry, Emory University, Atlanta, GA 30322

We showed previously[1] for gas-phase anionic $(M + Ca^{2+} - 3H)^-$ complexes that Ca^{2+} can bind at two sites in peptide molecules. One site is the deprotonated C-terminal carboxylate and the other is the deprotonated side chain of either the protic amino acid Asp, Glu, His, Tyr, or Trp. Here, our goals are to determine the preferential binding site(s) for the transition metal ions Co^{2+} and Ni^{2+}. CID spectra were acquired of peptide-metal ion complexes desorbed by LSIMS using a VG 70-S, forward geometry mass spectrometer. Spectra of decompositions that occurred in the first field-free region were acquired by using linked scans at a constant ratio of B/E. Twenty-two peptides were studied, which include YGGFL, VAAF, YPFAG, VHLGP, and *N*-acetyl-YGGFL.

CID spectra of complexes between the three metal ions and the simple peptide VAAF, which contains only aprotic (hydrocarbon) side chains, is shown in Figure 1. The spectra show that Ca^{2+} can only bind to the deprotonated C-terminus (C-terminal *y* ions), whereas both Co^{2+} and Ni^{2+} can bind to both the C- and N-termini (*y* ions plus N-terminal *a* and *c* ions). For *N*-acetyl-YGGFL (Figure 2), Ca^{2+} can still bind to the deprotonated Tyr side chain to give an abundant *c* ion[1]. The Co^{2+} can likewise bind to the side chain, but Ni^{2+} now only binds to the C-terminus. More information about the binding can be obtained from the chemistry of peptides that contain Pro. When the N-terminal binding site is disrupted (Figure 3), Ca^{2+} still can bind to the N-terminal deprotonated Tyr side chain, but Co^{2+} and Ni^{2+} can only bind to the C-terminus. When the C-terminal binding site is disrupted (Figure 4), Ca^{2+} can still bind to the C-terminus, whereas Co^{2+} and Ni^{2+} can only bind to the N-terminus.

From these data, important conclusions can be drawn about the metal ion-peptide complexes Formation of the complexes requires the metal ion to first "anchor" or bind to a specific site in the peptide. Following anchoring, catalytic deprotonation of the amides occurs to form the final $(M + Cat^{2+} - 3H)^-$ complex. For Ca^{2+}, the primary anchoring sites for YGGFL are either the deprotonated C-terminus or the deprotonated Tyr side chain. The N-terminal amine is not an anchoring site. The anchoring of Ca^{2+} to a deprotonated C-terminus as observed here in the gas phase is also known to occur in aqueous solution.[2] For Co^{2+}, there are no preferential anchoring sites: Anchoring can occur at either the N-terminal amine, at the deprotonated C-terminus, or at the deprotonated Tyr side chain. Anchoring either to the amine or to the C-terminus has also been observed in aqueous solution.[2] For Ni^{2+}, the most important anchoring site is the N-terminal amine. To a much lesser extent, the deprotonated C-terminus can also serve as anchor. The deprotonated Tyr side chain is not an anchoring site. The strong preference of Ni^{2+} for an anchoring N-terminal amine also occurs in aqueous solution.[2]

Another important conclusion can be drawn about geometric constraints on metal ion complexation. For Ca^{2+}, there are little or no constraints on complex formation. The gas-phase results are analogous to those in aqueous solution.[3] For Co^{2+} and Ni^{2+}, however, two adjacent deprotonated amides are required for complex formation. The gas-phase results are similar to those in aqueous solution.[2]

The gas-phase and aqueous-phase chemistry of Ca^{2+}, Co^{2+}, and Ni^{2+} is thus fundamentally the same. The differences that are observed in aqueous solution result from acid-base equilibria that are imposed on the system by the solvent. Weakly acidic sites, such as amides or side chain hydroxyl groups, cannot be deprotonated in water without precipitation of the metal ion as its hydroxide. One could envision that without such equilibria, the intrinsic, gas-phase chemistry would be precisely mimicked in aqueous solution.

STRUCTURAL DETERMINATION OF PRECURSOR IONS IN THE COLLISION-INDUCED DECOMPOSITION OF Ca^{2+}-SPECIFIC PEPTIDES BY MOLECULAR MODELING

Alex Reiter, Hong Zhao, and Jeanette Adams, Department of Chemistry, Emory University, Atlanta, GA 30322.

We have previously studied the gas-phase chemistry of anionic complexes between alkaline earth metal ions (Mg^{2+}, Ca^{2+}, and Ba^{2+}) and peptides.[1,2] It was found that fragmentations of the complexes are the same, but product ion abundances change. The relative abundances of fragment ions increase with increasing size of metal ion.

To determine whether there is a relationship between the gas-phase fragmentation chemistry and known solution chemistry, this work was extend to Ca^{2+}-specific peptides. The Ca^{2+}-specific peptide sequences of -Asp-Val-Pro- (-DVP-) and -Tyr-Thr-Pro- (-YTP-) were investigated by CID and molecular mechanical calculations. These two sequences are found in the calcium proteins staphlococcal nuclease and thermolysin, respectively.[3] CID of -YTP- containing peptides, however, fragment to give primarily $(M + Cat^{2+} - 3H - C_2H_4O)^-$ ions,[2] which is a new peptide with the sequence -Tyr-Gly-Pro- (-YGP-).[2] Therefore, this sequence was also studied. The peptides investigated include **ADVPAA**, **AADVPA**, **AYTPAA**, **AAYTPA**, **AYGPAA**, **AAYGPA**, and **YPFAG**.

For **ADVPAA**, the formation of the c_4 product ions, which contain the intact -DVP- sequence, is more abundant when Ca^{2+} is the metal ion. This is in sharp contrast to our previous results.[1] Conversely, the peptide **AADVPA** cannot be cleaved to give a c_4 ion because it would require cleavage of the -DVP-Pro ring. Instead, a c_3 ion is observed even though it involves cleavage of the -DVP- binding site. In this latter case, formation of the c_3 product ion is least abundant when Ca^{2+} is the metal ion. For **AYGPAA** and **AAYGPA**, the trend seen is similiar to that observed for **ADVPAA** and **AADVPA**.

Molecular mechanical calculations were performed to address possible precursor ion structure. The calculations show that for **ADVPAA** (Figure 1), the most favored structures for Mg^{2+} and Ba^{2+} contain the metal ion bound to the Asp deprotonated side chain and to two adjacent deprotonated amides that would be distant from the site of cleavage. Thus, the most abundant precursors do not contain the metal bound in immediate proximity to the bond being cleaved. Therefore, these most abundant precursors decompose to give other product ions. For Ca^{2+}, however, the most favored precursor contains the metal ion in the -DVP- binding site immediately adjacent to the site of cleavage, and thus it decomposes to give highly abundant c_4 ions. The calculations show that for **AADVPA** (Figure 2), the most favored binding site for Ca^{2+} is again the -DVP- sequence. For Mg^{2+} and Ba^{2+}, the most favored binding site is the deprotonated Asp side chain and the two N-terminal amides. (The energy for the Ca^{2+} complexed similarly to Mg^{2+} and Ba^{2+} is shown in brackets, in Figure 2). The most abundant precursor structure for Ca^{2+}-**AADVPA** cannot undergo fragmentation to produce c_3 ions. In contrast for Mg^{2+} and Ba^{2+}, the c_3 ions arise from a high abundance of low energy precursor ions that are shown in Figure 2. Molecular mechanical calculations failed to reveal any useful information for the Tyr-containing peptides because of complications arising from calculated structures that have the Tyr-phenyl ring puckered upon complexation to the metal ions.

COLLISION INDUCED DISSOCIATIONS OF DEPROTONATED PEPTIDES. DIPEPTIDES AND TRIPEPTIDES CONTAINING PROLINE

*Russell J. Waugh[a], John H. Bowie[a] and Michael L. Gross[b]
[a]Department of Organic Chemistry, The University of Adelaide, Adelaide, SA 5001, Australia
[b]Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304, U.S.A.

The presence and position of proline in underivatized di- and tripeptides may be determined from a consideration of the collisional activation mass spectra of the $(M-H)^-$ ions , formed by fast atom bombardment. Product ion and deuterium labelling studies utilizing a Kratos MS 50 TA and a VG ZAB 2HF instrument have been used in an attempt to elucidate fragmentation mechanisms. The fragmentation mechanisms presented have been rationalized by 'anionic processes' based on the basic fragmentations of even-electron anions of simple organic compounds,(1) however in certain cases other reaction types (*e.g.* 'charge remote' processes) may possibly occur.

Deprotonated dipeptides, upon collisional activation, fragment by the characteristic process :- $NH_2CH(R^1)CONHCH(R^2)CO_2^- \rightarrow NH_2C(R^1)CONHCH(R^2)CO_2H \rightarrow {}^-NHCH(R^2)CO_2H + NH_2C(R^1)=C=O$ when R^1 and R^2 = H or alkyl, to identify the C-terminal amino acid.(2) When one α-substituent (R^1 or R^2) is H or alkyl and the other is an alcohol (Ser, Thr),(3) an acid (Asp, Glu),(4) an amide (Asn),(5) aryl (Phe, Tyr),(6) heterocyclic (His, Trp),(6) an amine (Arg, Lys),(5) or is a sulphur group (Cys, Met),(7) three main fragmentation types have been found to occur. Two questions are addressed, viz i) do Pro peptides undergo the usual cleavage shown above, and ii) are there any cleavages characteristic of Pro?

The spectra of five isomeric pairs of Pro dipeptides and the isotopically labelled derivatives where all the acidic hydrogens are exchanged with deuterium have been recorded. The spectra illustrated in Figures 1 and 2 are typical of all deprotonated Pro dipeptides studied where the α-substituent of one amino acid residue is H or alkyl. When Pro is N-terminal, the fragmentation pattern is consistent with that reported previously for simple dipeptides.(2) For example, Figure 1 is dominated by ion peaks formed by the competitive loss of CO_2 and formation of $(Leu - H)^-$ at *m/z* 130 [see above]. In contrast, the spectra of those isomers containing a C-terminal Pro are quite complex [illustrated by $(Leu\text{-}Pro - H)^-$ in Figure 2]. The base peak is always *m/z* 114 $(Pro - H)^-$ formed by the basic peptide cleavage shown in equation (1). An interesting fragmentation worth noting here is the formation of *m/z* 130 $(Leu - H)^-$. This ion formation involves transfer of the carboxyl oxygen to the carbonyl group of the N-terminal amino acid residue. The process is rationalized for the general case in equation (4), involving the attack of HO^- at the carbonyl group of the N-terminal amino acid residue followed by deprotonation within complex (d).

Proline di- and tripeptides are shown to undergo the basic peptide fragmentation given above. Care must be taken when there is a C-terminal Pro, because in addition to the expected Pro^- peak [*i.e.* ${}^-NHCH(R^2)CO_2H$], there is also a peak corresponding to $NH_2CH(R^1)CO_2^-$ formed by nucleophilic attack of HO^-. Also there are no fragmentations of Pro di- and tripeptides, apart from the basic backbone fragmentation shown in equation (1), which specifically identify a Pro residue irrespective of its position in the peptide.

FRAGMENTATION OF PROTONATED PEPTIDES: AGREEMENT BETWEEN SURFACE-INDUCED DISSOCIATION SPECTRA AND QUANTUM CHEMICAL PREDICTIONS

Jennifer L. Jones, Ashok R. Dongré, Árpád Somogyi, and Vicki H. Wysocki
Virginia Commonwealth University
Department of Chemistry
Richmond, Virginia 23284-2006

Protonated peptides can be effectively dissociated by collisions with a surface.[1,2] The goal of the work described here is to combine electrospray ionization (ESI) and liquid SIMS (LSIMS) ionization with surface-induced dissociation (SID)[1] to investigate the energy dependence of peptide fragmentation as a function of SID collision energy. The total internal energy acquired by the peptide during both the ionization and activation steps is reflected by the number and relative abundances of fragment ions in the product ion scan. For a given collision energy, the MH^+ ions formed by electrospray ionization do not fragment as extensively upon collision with a surface as do ions formed by LSIMS. A plausible explanation for this observation is that ESI produces protonated peptides that are "colder" than those produced by LSIMS. For similar fragmentation patterns, arginine-containing peptides formed by ESI require a SID collision energy ≈ 40 eV higher than those formed by LSIMS. If additional energy is imparted to the ions by collisional activation in the ESI capillary-skimmer region before mass selection for SID, more extensive fragmentation is apparent in the SID spectrum.

The great sensitivity of the SID spectra to the ionization method suggests that the low internal energy content of the ions produced by ESI, coupled with the narrow movable internal energy distribution associated with SID, can be used to predict the population of different protonated forms (of the same peptide) that fragment under given conditions. Results presented in Figure 1 show the influence of the number, type and location of basic groups on fragmentation threshold. SID thresholds vary with peptide structure; higher thresholds are observed for peptides with basic residues at the amino terminus. This suggests that the majority of the ion population have a stable H-bridged structure (side-chain...H^+...amino terminus).

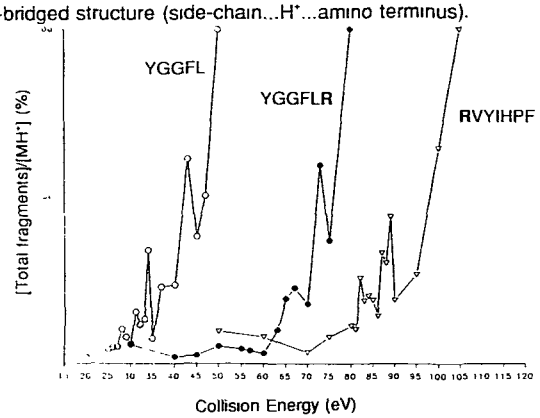

Figure 1

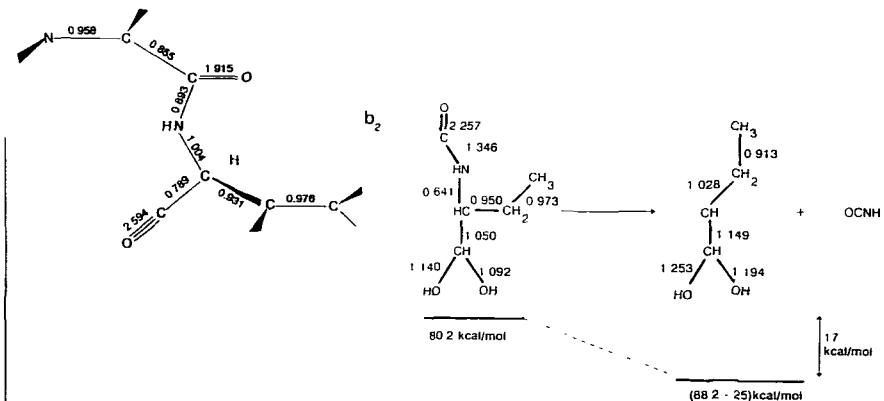
MNDO bond orders have been proved recently to be useful for the description of ion structures and primary fragmentation processes.[2,3] Although bond orders cannot be regarded as direct reactivity indexes, it is generally agreed that smaller bond orders represent weaker bonds. This is illustrated by the bond order values for a $\mathbf{b_2}$ ion (Structure I). Easy loss of CO from **b** ions to produce **a** ions is predicted by experimental results and by the small bond order value (**0.789**) for the C-C≡O bond of Structure I.



Structure I Structure II

Calculations for a number of different protonated forms of model peptides led to the following conclusions: The protonation has a local effect; only the bond orders of the α, β and γ bonds change significantly due to protonation The protonation on the amide nitrogen leads to a significantly weakening (by about 30%) of the amide bond. Accordingly, the cleavage of this bond, which can lead to the formation of ions **b**, **y**, and **a**, is preferred energetically. Protonation on the amide oxygen makes the amide bond stronger, so the formation of the above fragment ions is less likely from this form. Charge-remote backbone cleavages can be modeled by neutral peptides; the weakest bonds in the neutral peptides are the carbon-carbon bonds of the backbone. Charge remote backbone cleavage, followed by side-chain cleavage, is less favorable that the cleavage of the amide bond of a nitrogen-protonated form, in agreement with experimental observations. If the remote charge is located on the carboxy terminus, we propose that cleavage of the same C-C backbone bond, with subsequent loss of HNCO, would lead to a **z+1** ion (the suggested precursor of the **w** side-chain cleavage ions)(Structure II).

Gas-Phase Conformational Studies of Multiply Charged Cytochrome c Ions Using Collisional Activation and Ion-Molecule Reaction

*Rong Feng and Yasuo Konishi, National Research Council of Canada, Biotechnology Research Institute, 6100 Royalmount Avenue, Montreal, Quebec H4P 2R2, Canada

Electrospray-produced multiply charged protein ions usually form one (or more) charge-state distribution in the mass-to-charge ratio (*m/z*) range of 500-2500. The charge-state distributions are sensitive to protein conformational changes in solution. Typically, the ions from a protein having the native conformation form a charge-state distribution in the high *m/z* region because the molecule can carry only a limited number of charges while still maintaining its conformational integrity. On the contrary, an unfolded protein, which is capable of holding more charges, always places its charge-state distribution in the low *m/z* (high charge-state) region. The unfolded protein exposes more of the molecular interior and occupies more space than its native counterpart. It is of fundamental interest whether these two classes of multiply charged protein ions can maintain their conformational differences in the gas phase, where solvent stabilization is absent and increased Coulombic repulsion among the charges may force the coiled polypeptide chain to stretch. In this study we used collisional activation and ion-molecule reactions to probe the gas-phase conformational differences of the multiply charged cytochrome c ions.

A triple quadrupole mass spectrometer (Sciex API III) was used for the protein conformational studies. Horse heart cytochrome c (MW 12,360 Da) that was denatured under acidic condition (10% acetic acid v/v, pH 2.2) produced a low *m/z* charge-state distribution centered around the 16+ charge state (Fig. 1a). In contrast, the native protein that was preserved in a neutral stabilizing buffer (10 mM ammonium acetate, pH 6.7) gave a high *m/z* charge-state distribution centered around 7+ (Fig. 1b).

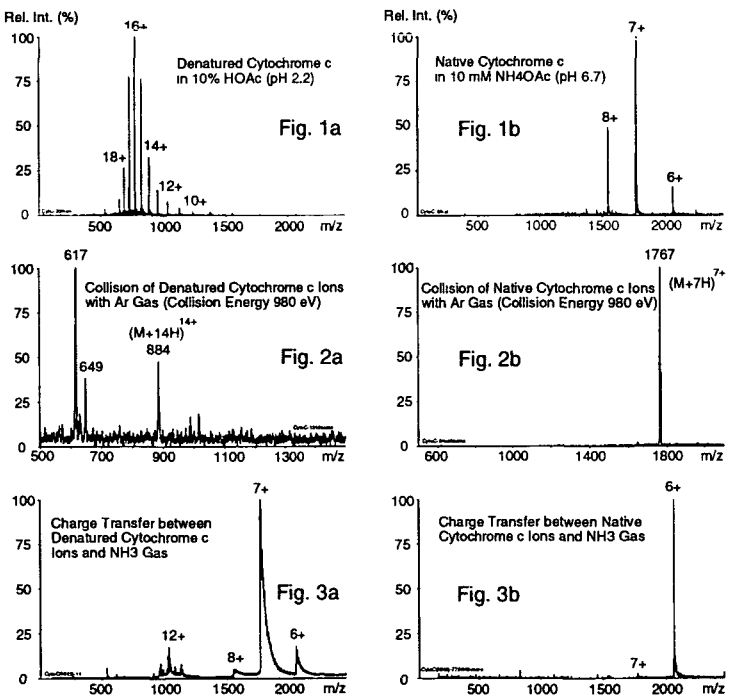
The collisional fragmentation patterns of the cytochrome c ions originated from the denatured and native solution conformations showed sharp differences, which could not be entirely attributed to the charge disparity between them. At the same collision energy (corrected for the charge difference), the former preferentially shed the covalently-bound heme group, producing two intense singly charged fragments at *m/z* 617 and 649 (Fig. 2a), whereas the latter did not dissociate appreciably (Fig. 2b). Thus, it appeared that in the former the heme group was exposed to the impinging argon atoms because the polypeptide chain remained unfolded, while in the latter the heme group was still wrapped in the polypeptide chain and protected from the collisions.

The size difference between the denatured and native cytochrome c molecules in solution appeared to be carried over to the gas phase, as indicated by the collisional scattering cross-section measurements. Under non-dissociative collision conditions and using the same collision gas density, the ions from the denatured solution conformation were more prone to scattering loss than the ions from the native solution conformation. This indicated that in the solvent-free vacuum, the gaseous ions originated from the native cytochrome c in solution still maintained a more compact size, despite the

Coulombic repulsion among the charges.

The multiply charged cytochrome c ions from the denatured and native solution conformations were also subjected to ion-molecule reactions in the gas phase. The former lost protons to ammonia at a rate much higher than the latter (see Figs. 1a and 3a, and Figs. 1b and 3b). In addition to the variations in the charge-transfer energy barrier due to the charge disparities, this large difference in reaction rate also reflected a substantial gas-phase structural difference between these two classes of ions. In the latter, its more compact structure might have restricted the charge-transfer reaction, as the positive charges on the folded protein could be protected by hydrogen-bonding and internal "solvation" from the electron-donating groups.

The above results suggest that, despite multi-charging and lack of solvent stabilization, protein conformational differences still exist in the gas phase; the multiply charged ions from the native conformation in solution appear to retain more folding features in the gas phase than the ones from the denatured conformation in solution.



ROLE OF KINETIC ENERGY IN COLLISION-INDUCED DISSOCIATION OF CS_2^+

YiBai Chen, Kevin Norbash, Ronald Tosh, Anil Shukla* and Jean Futrell
Department of Chemistry and Biochemistry, University of Delaware,
Newark, DE 19716

INTRODUCTION

CID of CS_2^+ ions has been a subject of ongoing controversy since first studied by angle-resolved mass spectrometry [1]. The relative abundances of fragment ions CS^+ and S^+ showed two crossovers when monitored as a function of scattering angle. It was suggested that this behavior results from the excitation of CS_2^+ ions into higher electronic states which dissociate independently. Later studies at low energies using crossed-beam [2] and at high energy using z-deflection [3] showed only one crossover which was also reproduced by theoretical calculations of relative abundances based upon kinetic energy release [4]. The low energy experiments showed that relative intensity of CS^+ increased with collision energy but decreased with scattering angle. Since ions with higher internal excitation on collision are scattered at larger angles, it was suggested that collisional excitation results in specific electronic states of CS_2^+ which are associated with unique dissociation behavior. All these studies, however, did not measure the kinetic energy of fragment ions and based their conclusions on the variation of relative abundances only. We have therefore studied the low energy CID of CS_2^+ ions using our tandem crossed-beam mass spectrometer where we can measure kinetic energy of fragment ions also.

RESULTS AND DISCUSSION

S^+: CM velocity contour diagrams for S^+ measured at 7.7, 17.2 and 34.5 eV collision energies show a single peak centered at non-zero scattering angles. Figure 1 shows such a contour diagram at 17.2 eV energy. The energy transfer for this dissociation process, determined by integrating these contour diagrams over all scattering angles, is close to thermochemical threshold of 4.8 eV. Since, energy transfer is nearly constant at all energies, there is no change in the collisional activation and dissociation process.

CS^+: CM velocity contour diagrams for CS^+ show quite a different behavior. Although, the threshold for this process is 5.7 eV, we could not get enough fragmentation at and slightly above this energy. At the lowest energy of 8.6 eV, we found a very broad peak with most probable energy transfer of 8 eV. As the collision energy was increased, energy transfer for this process also increased. At 12.4 and 17.2 eV, the energy transfer into internal modes corresponded to nearly 11.5 eV. At 17.2 eV we also notice a shoulder which corresponds to 5.7 eV energy transfer as shown in Figure 2. At further higher energies, this low energy process again disappears.

Since CS^+ is the high energy process, there may be a competitive shift associated with this process resulting in transfer of higher energy for dissociation. The energy depositions of 8 and 11.5 eV suggest that dissociation proceeds from higher excited state(s) and probably results in excited fragment ions. We suggest from known and speculated potential energy diagrams that CS^+ is formed in excited A and C states respectively at 8.6 and 17.2 eV collision energy.

CONCLUSIONS

These results suggest that CID of CS_2^+ to CS^+ follows a complex pathway that is strongly dependent upon ion's kinetic energy and results in excited fragment ions. Dissociation to S^+, however, proceeds via lowest energy pathway at all energies.

Fundamental Studies Of Molecular Ion-Surface Collisions: Pyridine Ions on Self-Assembled Monolayers

Sam Wainhaus, John A. Burroughs, Qinyuan Wu, and *Luke Hanley,
Department of Chemistry, m/c 111, University of Illinois at Chicago,
Chicago, IL 60607-7061.

Self-assembled monolayer covered gold surfaces have been used as collision targets for surface induced dissociation (SID) of molecular ions since they can be reproducibly prepared outside of vacuum using wet chemical methods [1,2]. Furthermore, the low sticking coefficients of self-assembled monolayers to most vapors allow these collision targets to remain clean on the molecular level, regardless of the atmospheric or vacuum environment in which they are placed. However, the constant bombardment of such monolayers by energetic molecular ions during SID experiments is likely to lead to their chemical modification.

We compare here the SID spectra of pyridine ion scattering off the simplest self-assembled monolayer film, methyl thiolate (MeS) adsorbed on a clean single crystal of silver, Ag(111), with the ion beam damage of same. These experiments are performed in a tandem mass spectrometer which is coupled to an ultrahigh vacuum surface analysis chamber [3]. This apparatus is also equipped with thermal desorption MS and infrared reflection absorption spectroscopy (IRAS) for monitoring the MeS coverage on the Ag(111) surface. The MeS monolayer is prepared by gaseous dosing of dimethyl disulfide.

Figure 1 displays the vibrational spectrum of MeS/Ag(111) recorded by IRAS. By measuring the 2912 cm^{-1} (symmetric C-H stretch of the methyl group) IRAS peak area following ion bombardment of the surface, we have determined the MeS coverage remaining on the surface after a 5 ± 2 nA/cm^2 pyridine ion exposure at 55° off the surface normal:

Beam Energy	Exposure Time	MeS Remaining
32 eV	30 min	76 %
32	60	65
64	30	62
64	60	49

Figure 2 shows SID spectra of $C_5H_5N^+$ scattered off a monolayer of MeS/Ag(111) at 32 and 64 eV. Both spectra display strong MH^+ (80 m/z) and $[M-CN]^+$ (53 m/z) peaks. In addition, the 32 eV spectra displays a $[MCH_3]^+$ peak (94 m/z) which results from reactive scattering off the MeS monolayer. At 64 eV, reactive scattering does not occur but more extensive fragmentation of the incident ion is observed.

We have also monitored individual scattered ion peaks as a function of incident ion exposure time. Although all scattered ion signals slowly increase over 60 min as the methyl groups on the surface are sputtered away by the incident beam, these peaks each increase at the same rate. Therefore, even though the self-assembled monolayer has been significantly damaged by the ion beam, the SID spectra are not affected. These results further indicate that self-assembled monolayers are excellent targets for SID experiments since they give reproducible spectra even after continual ion beam exposure.

Surface-Induced Dissociation of Ferrocene at Self-Assembled Monolayer and Single Crystal Surfaces

S.A. Miller, D.E. Riederer, Jr., and R.G. Cooks
Department of Chemistry, Purdue University, West Lafayette, IN 47907, USA
W.R. Cho, H.W. Lee, and H. Kang
Department of Chemistry, Pohang Institute of Science and Technology, Pohang, Korea 790-600

Comparative studies are reported for surface-induced dissociation (SID) of ferrocene molecular ions performed on a hybrid BEEQ tandem mass spectrometer and a Wien filter/quadrupole (WQ) combination. Ferrocene molecular ions (m/z 186) undergo dissociation upon collisions at Si(100) and alkylthiol self-assembled monolayer surfaces (SAMs) and the resulting SID mass spectra compare well between the two different instruments. Energy resolved mass spectrometric (ERMS) studies were completed on a perfluorinated alkylthiol (F surface) and a perdeuterated alkylthiol (D surface) SAM surface, while a similar study was done on a clean Si(100) single crystal surface. The Si(100) and the D surface had remarkably similar ERMS curves while the F surface indicated a larger internal energy deposition (Figure 1). Ferrocene was used as a thermometer ion[1] to probe the translational to vibrational (T-V) energy conversion efficiency on the F and D surfaces. T-V energy conversion efficiencies of 15% and 24% for the D and F-surface, respectively, were estimated by a method previously described[1]. These efficiencies are reasonable with previous results for other systems in which the T-V energy conversion is greater for the F surface (19%) than the D surface (13%).[2] The larger T-V energy conversion for the F surface is attributed to the larger effective mass and rigidity of the surface compared to the D surface. The similarity between the Si(100) and the D surface suggest that the effective mass of these collision partners is nearly the same.

Ferrocene has also proven to be a model ion for SID in three respects; i) simple fragmentation patterns (ii) relatively large secondary ion survival probability and iii) lack of ion/surface reactions. This study as well as others[3,4] have shown the main fragmentation pathway of ferrocene to be the loss of one cyclopentadienyl radical followed by a second loss of a cyclopentadienyl radical. Structural assignments were checked by recording SID mass spectra of two ferrocene isotopes (m/z 184 and 186) under identical conditions (Figure 2).

Ferrocene has a relatively low ionization potential and high proton affinity. The low ionization potential accounts for the large secondary ion yield and ion/surface reactions, such as hydrogen (or deuterium) atom pick-up, are also allowed by the high proton affinity. The absence of this reaction suggests that charge exchange is a prerequisite for hydrogen atom transfer in agreement with the mechanism suggested elsewhere.[5] Further insight into this mechanism was obtained by colliding 1,8-bis(dimethylamino)naphthalene (a "proton sponge") on the D surface. The "proton sponge" has a slightly lower ionization potential and a much higher proton affinity than ferrocene. Again, ion/surface reactions did not occur despite the very large proton affinity of the compound.

COLLISIONS OF PERFLUOROPROPYLENE IONS WITH SOLID SURFACES

T. Ast, D.E. Riederer, Jr, S.A. Miller, M. Morris and R.G. Cooks, Department of Chemistry, Purdue University, West Lafayette, IN 47907

The perfluoropropylene molecular ion $C_3F_6^{+\cdot}$ (m/z 150) yields two fragment ions of similar appearance energies: $C_3F_5^+$ (m/z 131, AE 14.8 eV) and CF_3^+ (m/z 69, AE 15.0 eV). However, depending on the activation method employed, these two ions can be formed in vastly different proportions. In particular, $C_3F_5^+$ is observed only in methods involving a significant degree of electronic excitation (e.g. electron impact, high energy CID, charge exchange), while it is absent, or formed in very low abundance, in methods proceeding predominantly through vibrational excitation (e.g. low energy CID). These observations were rationalized invoking an isolated electronic state of $C_3F_6^{+\cdot}$ which fragments preferentially and directly to $C_3F_5^+$, and which can be populated only by an electronic excitation mechanism.[1,2]

Early attempts to study the surface induced dissociation (SID) of $C_3F_6^{+\cdot}$ were not successful; collisions at an adsorbate covered stainless steel surface gave no projectile fragments and only beam neutralization and chemical sputtering were observed.[3] These experiments have now been repeated on a newly constructed hybrid BEEQ tandem mass spectrometer[4], which, among other features, provides a 100-fold better vacuum in the target region (4×10^{-9} torr). The performance of a stainless steel, as well as of three self-assembled monolayer surfaces, has been examined: $CH_3(CH_2)_{15}SH$ (the H surface), $CD_3(CD_2)_{15}SH$ (the D surface) and $CF_3(CF_2)_{11}(CH_2)_2SH$ (the F surface). The yields of m/z 69 and m/z 131 from the molecular ion have been studied over the collision energy range 20-70 eV for all four surfaces and the results are shown in Figure 1. At low collision energies, H and D surfaces (Figure 1a) yield predominantly the m/z 131 ion, pointing to the prevalence of electronic excitation. As the collision energy is increased, the m/z 131/69 ratio is reversed, suggesting a change over to fragmentation from a vibrationally excited state. These results support the conclusions of Futrell et al. reached in a similar CID study.[5] This effect is much less pronounced for the SS and F surfaces (Figure 1b); the m/z 69 ion now dominates at all collision energies, implying that the main mode of activation leads to vibrational excitation.

The behavior of other major ions generated from C_3F_6 has also been examined. As an example, Figure 2 shows the product ion spectra obtained upon 50 eV collisions of $C_2F_4^+$ at all four surfaces. The F surface provides largest energy deposition; only slightly smaller is observed for the SS surface, in which surface adsorbate sputtering is also evident. The H and the D surfaces are least efficient in energy transfer, as manifested by the presence of the reflected projectile ion at m/z 100. On the other hand, a significant amount of chemical sputtering is observed for both the latter surfaces, reminiscent of the earlier study.[3] The extent of chemical sputtering shows a large dependence on the nature of the projectile; this should be born in mind when assessing the surface cleanliness on the basis of the sputtering experiment. Thus, most organic ions exhibit no or little sputtering upon collisions at the H and D self-assembled monolayer surfaces[6]; as opposed to this, organofluorine ions, CH_3I^+, I^+, I_2^+, and Xe^+ are some examples of ions that induce intense sputtering off these surfaces under identical experimental conditions.

Reactions of Organosilanes with Self-Assembled Monolayers

Ashok R Dongré, Árpád Somogyi, and Vicki H. Wysocki
Department of Chemistry, Virginia Commonwealth University,Richmond, VA 23284-2006

Introduction

Collision of mass-selected projectile ions with chemically-modified surfaces leads to extensive fragmentation. In addition to fragmentation, other processes, like ion- surface reactions, chemical sputtering and neutralization, are observed.[1] Several ion-surface reactions have recently been observed between small organic ions (benzene,[2] pyrazine[3]) and self-assembled monolayer surfaces.

The aim of this investigation to study the reactions of silicon containing ions with various self-assembled monolayer surfaces. Given the preferred formation of Si-F and Si-O bonds over Si-C bonds, the reaction peaks observed for CF_3 and OH terminated surfaces could, expectedly, be more intense than those detected for CH_3 terminated surfaces.

Experimental

The instrument used in this investigation is a tandem quadrupole instrument in a 90° arrangement with the surface intersecting the ion optical path at 45°.[4] The self-assembled monolayers are prepared by immersing plasma-cleaned vapor deposited gold in 1mM ethanol solution of the given thiol. The monolayer surfaces used in this investigation were prepared from 2-(perfluorooctyl)-ethanethiol, octadecanethiol, perdeuteroeicosanethiol, and 1-hydroxyundecanethiol. The silicon containing ions selected to collide with the organic monolayer surfaces were $(CH_3)_3Si^{37}Cl^+$ m/z 110, $(CH_3)_2Si^{37}Cl^+$ m/z 95, and $(CH_3)_3Si^+$m/z 73.

Results and Discussion

The silicon-containing ions react with the fluorinated alkanethiol monolayer. Several reaction peaks are observed for all the three selected ions. Reaction products at m/z 47(SiF^+) and m/z 49 (H_2SiF^+) are fairly intense peaks in the spectra (eg. see Figure 1). The reaction peak at m/z 47 is the base peak at collision energy of 80 eV for m/z 95. The breakdown curve for m/z 95 shows that the peak at m/z 47 is 17-18% of the total ion abundance. No appreciable reaction products are observed when the ion is collided with the n-alkanethiol monolayer surfaces. Silicon also reacts with the hydroxy-terminated surface but reactions are not as enhanced as those observed on the fluorinated surface. A peak at m/z 75 is observed which could be due to the formation of a $(CH_3)_2SiOH^+$ adduct. The absence of the m/z 75 peak in spectra obtained with n-alkanethiolate and fluorinated alkanethiolate monolayers indicates that m/z 75 is formed via reaction with the hydroxy group and not by fragmentation of the selected ion. Peaks at m/z 45 ($SiOH^+$) and m/z 47(H_2SiOH^+) are more intense than those observed on alkanethiolate monolayer surfaces, which indicates that a fraction of the ion intensity results from the reaction and the rest from the fragmentation of the precursor ion.

Comparison of the selected silicon-containing ions with carbon analogues ($(CH_3)_3C^+$ and $(CH_3)_2CCl^+$; generated from *terc*-C_4H_9-Cl) suggests that the d orbitals of silicon play a role in the reactivity of silicon compounds with fluorinated alkanethiolate monolayers.

Reactions of Immonium Ions with Self-assembled Monolayer Films

*Rebecca L. Franklin, Árpád Somogyi and Vicki H. Wysocki, Virginia Commonwealth University, 1001 West Main Street, Richmond, VA 23284

Several processes can occur when a polyatomic ion collides with a surface. These processes include (i) surface-induced dissociation (SID), (ii) ion/surface reactions, (iii) charge exchange (i.e. chemical sputtering) and (iv) neutralization. Recently, self-assembled monolayer (SAM) films of alkanethiolates on gold were shown[1,2] to be effective surfaces for the study of ion/surface interactions.[3] Monolayers used in this investigation include 2-(perfluorooctyl)-ethanethiol, 1-octadecanethiol, and 1-eicosane-d_{41}-thiol covalently bonded to vapor-deposited gold. Here we compare the ion/surface collision products formed by collision of various even-electron immonium ions (e.g. $CH_2{=}NH_2^+$) and their methyl, deuterium, and oxygen analogues with fluorinated alkanethiolate and alkanethiolate films.

Spectra of immonium ions studied exhibit SID, ion/surface reactions, and chemical sputtering, as a function of laboratory collision energy and surface film type. SID of $CH_2{=}NH_2^+$ leads to CH_2^+ and NH_2^+ with some NH_4^+ produced Similarly, SID of $C_2H_4^+$ produces CH_2^+ and CH_3^+. All ions studied exhibited peaks at m/z 69 on the fluorinated surface; this ion corresponds to the chemical sputtering of CF_3^+ from the surface. Typical sputtering peaks from the 1-octadecanethiol surface include m/z 39, 41, and 43.

Chemical reactions of the ions studied include addition of F or CH_3 followed by H and H_2 losses to produce mainly even-electron ions. The reaction product of F addition to $CH_2{=}NH_2^+$ is observed at m/z 46. When $CH_2{=}ND_2^+$ is the projectile ion, the reaction product is detected at m/z 47 (see scheme 1 and figure 1). When the m/z 58$^+$ immonium ion formed from tertiary butylamine is collided with the fluorinated surface, m/z 46 is one of the products formed. This ion (m/z 46) corresponds to the product peak for fluorine addition to $CH_2{=}NH_2^+$. The ion CH_2OD^+ also reacts with the fluorinated surface to add fluorine with loss of HD and H to form FCO^+.

Surface-Induced Dissociation Spectra of Ketones

Árpád Somogyi, Thomas E. Kane, Vicki H. Wysocki
Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284-2006

Introduction Surface-induced dissociation (SID)[1] is a promising ion-activation technique. Recent studies[2-4] proved the advantages of self-assembled monolayer films for ion-surface collisions. These monolayers can be easily prepared by the spontaneous assembly of 1-alkanethiols and their derivatives on gold. The monolayers can reduce the neutralization of the projectile ions which leads to higher scattered ion abundance. They also can improve the energy transfer to the projectile, to date, fluorinated alkanethiolates proved to be the most effective monolayers for high kinetic energy - internal energy conversion.[1, 1-4] Chemical reactions between the projectile ions and the monolayers have also been described.[1-4] These reactions, together with the measurement of the total ion current at the detector and the current at the surface, make the SID method unique for the characterization of the self-assembled monolayers in vacuum.

As a continuation of our recent work,[4] we present here the SID spectra of simple ketones (acetone, acetophenone, and benzophenone). The main fragmentation processes of these molecular ions are well known, and acetophenone was also a subject of a recent SID study of Cooks et al [3] Therefore, the main aim of this study is not the description of the fragmentation of these simple ketones but rather the investigation of the effect of different monolayers and collision energies on the fragmentation and ion-surface reactions.

Experimental The instrument used in this investigation consists of two quadrupoles (Extrel, Pittsburgh, PA) arranged in a 90° geometry, with a surface placed to intersect the ion optical path of each quadrupole.[5] The covalently bound monolayers were prepared by the spontaneous assembly of octadecanethiol (C_{18} surface), perdeuteroeicosanethiol (CD_3 surface), and 2-(perfluorooctyl)-ethanethiol (fluorinated surface) on plasma-cleaned vapor-deposited gold. 70 eV electron impact ionization was used to form the molecular ions of acetone, acetone-d_6, acetophenone, acetophenone-methyl-d_3, acetophenone-ring-d_5, and benzophenone.

Results and Discussion

Breakdown curves and energy deposition

The breakdown curves obtained for the acetophenone molecular ion on the fluorinated surface are shown in Figure 1. Similar sharp curves were obtained for the acetone molecular ion, and for the selected acetyl cation (m/z 43). The breakdown curves obtained on the C_{18} and CD_3 surfaces are not as sharp as those on the fluorinated surface and they are shifted to higher collision energies. For example, in the case of the acetyl cation (m/z 43), to get a similar [m/z 15]/[m/z 43] ratio, higher collision energy was required for the alkanethiolate (C_{18} and CD_3) surfaces (by about 10 eV) than for the fluorinated surface. These results support the narrow and relatively high internal energy distribution associated with fluorinated alkanethiolate surfaces, as has been reported e.g., for $W(CO)_6$.[3]

Ion-surface reactions

i) H(D) addition In contrast with benzene molecular ion,[3,4c] the H(D) addition to the ketone molecular ions is estimated to be slightly exothermic. Accordingly, in the low-energy SID spectra (10-30 eV) of these ions with alkanethiolate surfaces $[M+H(D)]^+$ peaks are observed, and molecular ions are of very low intensity. In addition, acetone molecular ion proved to be a sensitive probe to detect *trace* H-containing contaminants on the fluorinated surface. The appearance and pressure dependence of the $[M+D]^+$ peak in the SID spectrum of acetone-d_6 with the fluorinated surface

indicate that the acetone is also physisorbed to the monolayer surface.

ii) $CH_3(CD_3)$ addition The 25 eV SID spectra of acetophenone molecular ion with the C_{18} and CD_3 surfaces are shown in Figure 2. In contrast with benzene,[3,4c] intact adduct ions are observed, together with the $[M+CH_3-H_2]^+$ and $[M+CD_3-HD]^+$ peaks. For acetone molecular ion, the adduct ion peak is dominant in the reaction region of the SID spectra. Results for the molecular ions of acetophenone, acetophenone-methyl-d_3 and acetophenone-ring-d_5, suggest that two different methyl adducts may be formed: an O-adduct and a ring-adduct Preliminary MNDO and *ab initio* quantum chemical calculations predict the O-adduct more stable than the ring(ipso)-adduct.

Determination of Bond Energies by Collisional Dissociation of Electrospray Ions in Free Jet Expansions

S.D. Fuerstenau* and **J.B. Fenn** *Dept. of Chemical Engineering*
Yale University, New Haven, CT 06520

We present a method for measuring bond dissociation energies of ions which fragment due to collisions in the nozzle-skimmer region of an electrospray ion source. The approach is applicable to any differentially pumped, atmospheric pressure ion source. We consider the multi-collisional excitation of the ion in the jet to be essentially a heating process in which the extent of excitation, or temperature, is directly proportional to the applied voltage. When properly normalized , plots of ion current vs. voltage are interpreted as the result of a unimolecular decomposition. We relate the extent of decompositon to the voltage with an Arrhenius rate expression to arrive at an activation energy for the fragmentation process.

J. French and co-workers observed twenty years ago that the focusing potential applied between the nozzle and skimmer of a high pressure ion source could lead to desolvation of analyte ions. More recently, researchers in R.D. Smith's laboratory found that thermal excitation in the jet region aided in subsequent CID of large peptides in tandem MS experiments. R.Voyksner has demonstrated that at higher voltages covalent bonds may be broken with this CID technique that is both efficient (> 90% yield) and reproducible.

In contrast to single collision CID, ions accelerated in low pressure jets are subjected to hundreds or thousands of energetic collisions over a short time period (10 µs.) During this time the temperature and density of the surrounding gas drop drastically along the ion's path of travel through the jet. At first glance the energetics of this process appear to be hopelessly complex and undefined. Jarrold has pointed out, however, that the product of many collsions, each with a broadly distributed excitation probability, can result in a very narrow distribution of internal energies in the excited ions. We proceed with the problem by making the following simplifying assumptions:

- The amount of energy deposited into an ion, due to the sum of all collisions may be represented by a temperature, Tp, and is proportional to the applied voltage, ie,

$$Tp = \Omega(Vn-Vs)$$

  where Ω is a source dependent constant of calibration.

- The amount of decomposition occurring during and after excitation may be treated as the result of a unimolecular reaction occuring at a single temperature, **Teff**, which we assume scales with voltage.

$$dC/dt = -kC \;\text{--->}\; C(t)/Co = \exp\{-k(Teff)t\} \qquad (1)$$

- The flight time, t*, between excitation and sampling at the quadrupole entrance is fixed but unspecified, and is the same for all ions of similar mass at a given skimmer potential. It follows that:

$$-\mathrm{Ln}\,(C(t^*)/Co) = kt^*$$

Assuming that the rate constant k follows an Arrhenius form, we may express the extent of decomposition as :

$$\mathrm{Ln}\,(C(t^*)/Co) = At^* \exp(-Ea/RTeff) \qquad (2)$$

Taking the log and substituting ΩV fot Teff we get

$$\mathrm{Ln}\,(-\mathrm{Ln}(C/Co)) = \mathrm{Ln}\,At^* - Ea/R\Omega V \qquad (3)$$

A plot of Ln(- Ln(C/Co)) vs. 1/V will have a slope of - Ea/RΩ . The constant Ω can be found by using a calibration compound with a known Ea of dissociation.

Normalization of Ion Currents

It follows from (3) that a plot of C/Co vs. V should have the form

$$C/Co = \exp(-At^* \exp(-Ea/R\Omega V)) \qquad (4)$$

This is an S shaped function which starts at one and decays to zero.

Unfortunately the response of the parent ion vs voltage rarely has this shape. Typical response curves show a rise due to focusing and then a decay attributed to fragmentation. We postulate that the response of a parent ion , Ip , may be represented as the product of two functions of nozzle-skimmer voltage. These are a focusing transfer function, T(V), and a loss function, L(V), which follows the extent of decompositon. Because focusing and decay can occur simultaneously, the function of interest , L , cannot be separated without some additional information. This is provided by the response of the daughter ions which, it may be reasonably argued, follow the same focusing function of the parents. Assuming the disappearance of one parent ion results in the appearance of one daughter ion, we may write a mass balance:

$$Ip = TL$$
$$Id = T(1-L) \;\text{-->}\; L = Ip/(Ip+Id) \qquad (5)$$

Note that T is never specified explicitly. Eqs. (5) represent the algebraic basis for extracting L(V) functions from more complicated systems.

Experimental

The system used in this study employed three stages of pumping with a VG 1200 micromass quadrupole. The pressure in front of the first skimmer was about 1 torr and that in the second pumping stage 1 millitorr. The nozzle to skimmer distance was 3mm with fields in the jet region as high as 50,000 V/M. The ions explored here were SF6-, WCO6+ and MCO6+, all generated by corona discharge in the atmospheric pressure region of the source. ES ions studied were clusters of the amino acid Arginine and metal cations solvated with Acetonitrile. Literature values are available for the gas phase dissociation of all ions except Arginine. Responses were typically recorded with the mass resolution set to its minimum value to minimize discrimination effects.

DISSOCIATION PROCESS	SLOPE	REPORTED Ea	Ω (^{0}K/V
$SF_6^- \text{--->} SF_5^-$	-173	1.05 eV (ref. 1)	70
$WCO_6^+ \text{--->} WCO_5^+$	-207	1.39 eV (ref. 2)	77
$MoCO_6^+ \text{--->} MoCO_5^+$	-152	0.97 eV (ref. 2)	73
$Na^+(ACN)_2 \text{--->} Na^+(ACN)$	-157	1.06 eV (ref. 3)	78

THE EFFECT OF CHARGE ON ION STABILITY A QUANTITATIVE COMPARISON. Sohrab Habibi-Goudarzi, Kevin J. Hart and Scott A. McLuckey, Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6365.

Multiply-charged biopolymers derived from electrospray have yielded useful structural information upon collision-induced dissociation [1] It has been noted that more highly charged species tend to fragment more readily due, presumably, to the additional strain associated with a high coulombic field. A quantitative comparison of the threshold for dissociation of gaseous multiply-charged ions as a function of charge in an MS/MS experiment, however, has not yet been reported. We have been evaluating collisional activation in the quadrupole ion trap for studying the threshold behavior of singly-charged parent ions[2] and have extended this work to multiply-charged biopolymers.

Specifically, we have studied in detail the behavior of the oligonucleotide anions $d(A_pA_pA_pA)^{3-}$ and $d(A_pA_pA_pA)^{2-}$. The former anion fragments exclusively through loss of A^- upon resonant excitation whereas the latter fragments mostly via loss of neutral adenine (Figure 1). We have employed a kinetic method[3] to determine the difference in the threshold resonance excitation amplitudes which can be correlated to literature E_o values based on the calibration curve developed in reference 2. The kinetic method for each of the two parent anions involves the following steps. First, the parent ion is isolated and subjected to collision-induced dissociation at constant resonant excitation amplitude (tickle voltage) and varying excitation duration (tickle time). The rate of decay of the parent anion (k_v) is the slope of the linear region of $-\ln(P_t/P_0)$ vs. tickle time curve. Second, the time dependent decay experiment is then repeated at all other pertinent excitation amplitudes. Finally, the k_v data obtained from each of the above experiments are plotted against the excitation amplitudes.

Ideally, the threshold resonance excitation amplitude is obtained by extrapolating to zero k_v the initial, non-linear region of the k_v vs. tickle voltage curve. Since we are interested in the difference between the two cases (i.e. the triply and the doubly charged anions), and since more data points are need to make accurate estimations, we extrapolated the linear region of the latter curve (Figure 2). The values obtained for each case are then converted to their equivalent literature E_0 values according to the equation TREA= 92.58 + 288.13*[log(E_0)], where TREA is the threshold resonance excitation amplitude in mV (see reference 2). The $d(A_pA_pA_pA)^{3-}$ anion had a threshold resonance excitation amplitude of 187 mV or E_0 of 2.14 eV and the $d(A_pA_pA_pA)^{2-}$ anion 207 mV or 2 50 eV. This suggests that the difference in the threshold energies of these parent anions is about 0.4 eV. The procedure we used to obtain these values should provide an upper limit to the difference in critical energies The results of this work, which should correlate with CID cross-section on beam-type instruments, illustrate the important role that coulombic repulsion plays in the ability to fragment multiply charged ions. For this reason, this case study may have relevance in a variety of electrospray ionization mass spectrometry applications.

Photodissociation of Solvated Ions

*Y.J. Yang, D.M. Peiris and J.R. Eyler
Department of Chemistry, University of Florida, Gainesville, FL 32611-2046.

Several methods have been used to measure the binding energies of solvated ions, including equilibrium measurements in both high pressure[1,2] and ICR[3] mass spectrometers and photodissociation measurements in a TOF mass spectrometer[4]. An alternate way to study ion/neutral binding energies is photodetachment measurement in ICR mass spectrometry. By measuring the depletion of the parent ion as a function of photon energy, the threshold of photodetachment, related directly to the binding strength of solvated ions, can be determined. Since the electron affinities of the halides are well known, bonding in halide solvates can be studied by using UV-visible photodetachment. The initial stages of work in which the 266 nm 4th harmonic output of a Nd:YAG laser was used to induce photodetachment of alcohol solvated halides are presented here.

The experiment was performed in a FT ICR mass spectrometer with a data system which includes an external trigger option. Thus the Nd:YAG laser was synchronized with the mass spectrometer through the use of a photodiode. Laser energy at 266 nm was *ca.* 17-25 mJ/pulse. The solvated halides were formed by the ion-molecule reactions:

$$ClCO_2C_2H_5 + e^- \rightarrow CO_2Cl^- + C_2H_5$$
$$CO_2Cl^- + CH_3OH \rightarrow \mathbf{CH_3OHCl^-} + CO_2$$
$$CO_2Cl^- + C_2H_5OH \rightarrow \mathbf{C_2H_5OHCl^-} + CO_2$$

where the pressure of $ClCO_2C_2H_5$ was about 4×10^{-7} torr and the total pressure maintained at 1×10^{-6} torr. The chloride donors were formed using an electron beam pulse, followed by a period for ion-molecule reaction formation of the solvated chlorides and relaxation of internal energy before firing of the laser.

Figures 1 and 2 show mass spectra of CH_3OHCl^- and $C_2H_5OHCl^-$ under identical conditions with and without laser irradiation of the ions. By measuring the disappearance of the parent ions, the extent of photodetachment was found to be 49% and 59% for CH_3OHCl^- and $C_2H_5OHCl^-$, respectively (Figs.3 and 4). No increase in the intensity of chloride ion was seen upon laser irradiation for either solvate, which means no photodissociation channel is involved.

Generally one would expect the relative binding strength of the solvent-halide ion to be substantially greater than that in the solvent-halogen. Also, the structure of the neutral solvates may change so that the equilibrium internuclear distance increases compared to that of the solvated ions. Given that the EA of chlorine is 3.62 eV and that we observed photodetachment at 266 nm (4.6 eV),

an upper limit of 1.0 eV can be placed on the difference between ion and neutral solvation energies. To obtain more information on the binding energies and structures of halides solvated by different solvents, we plan to use a doubled dye laser to find the photodetachment threshold and also carry out *ab* initio calculations to understand the structure of both neutral and ion solvates. The binding energies obtained from gas phase equilibrium and photodetachment studies will be compared. The shifts of the binding energies for solvated anions will be also determined, giving a clue as to the structures and bonding interactions in these species.

Infrared Multiple Photon Dissociation Spectra of Solvated Ions

D. M. Peiris, J. M. Riveros[1] and J. R. Eyler
Department of Chemistry, University of Florida
Gainesville, FL 32611-2046
[1]Inst. of Chemistry, University of Sao Paulo, Sao Paulo, Brazil

There have been a number of studies of gas-phase ions solvated with single neutral molecules to begin following the transition from gas to solution phase ionic behavior. In particular, solvated halide ions have been studied (1) due to their structural simplicity and their existence in solution. In past work we have used CO_2 lasers to excite gaseous ions and photodissociate them. Fortunately, the C-O stretching band of methanol at ν = 1034 cm^{-1} overlaps the CO_2 laser spectrum. Thus, methanol serves as a good solvent candidate for infrared photodissociation studies of solvated ions.

In the past, we have utilized the technique of infrared multiple photon dissociation (IRMPD) in a Fourier transform ion cyclotron resonance mass spectrometer (FTICR) to obtain spectra of gaseous ions (2). A similar approach was used in this study to obtain spectra of halide ions solvated by methanol and deuterated methanol (CH_3OHX^- and CH_3ODX^-, where the halide X is F or Cl).

Experimental apparatus associated with FTICR and its modifications for the IRMPD technique have been previously discussed in detail (2). The background pressure was maintained at 5 x 10^{-9} Torr. CF_4 *or* $ClCO_2C_2H_5$ was admitted in up to 5.5 x 10^{-7} Torr and CH_3OH *or* CH_3OD was then admitted in up to a total pressure of 1.1 x 10^{-6} Torr. The anion of interest was isolated by a series of ejection pulses and then irradiated with the unfocused output of a line-tunable pulsed CO_2 laser. The photoproduct X^- was ejected during the laser pulse in order to prevent it from reacting with excess solvent molecules present in the cell. *The IRMPD spectra of the halide solvated anions were obtained by monitoring the depletion* of the parent ion as a function of a laser wavelength with constant laser energy. CH_3OHX^- and CH_3ODX^- were generated by the reaction sequences shown in reactions 1 through 8.

Methanol solvates of the **fluoride** ion:

$CF_4 + e^- \longrightarrow CF_3 + F^-$ (1)
$F^- + HCO_2CH_3 \longrightarrow CH_3OHF^- + CO$ (2)

Deuterated methanol solvates of the **fluoride** ion:

$CF_4 + e^- \longrightarrow CF_3 + F^-$ (3)
$F^- + DCO_2CH_3 \longrightarrow CH_3ODF^- + CO$ (4)

Methanol solvates of the **chloride** ion:

$ClCO_2C_2H_5 + e^- \longrightarrow ClCO_2^- + C_2H_5$ (5)
$ClCO_2^- + CH_3OH \longrightarrow CH_3OHCl^- + CO_2$ (6)

Deuterated methanol solvates of the **chloride** ion:

$ClCO_2C_2H_5 + e^- \longrightarrow ClCO_2^- + C_2H_5$ (7)
$ClCO_2^- + CH_3OD \longrightarrow CH_3ODCl^- + CO_2$ (8)

Irradiation of CH_3OHX^- and CH_3ODX^- ions results in photodissociation via reaction 9

$CH_3O(H,D)X^- + nh\nu_{ir} \longrightarrow F^- + CH_3O(H,D)$ (9)

IRMPD spectra of CH_3OHX^- and CH_3ODX^- in the 920 - 1060 cm^{-1} region (10.6μm - 9.6 μm P and R branches of the CO_2 laser) are presented in Figures 1a, 1b, 1c, and 1d. Comparison of IRMPD and neutral IR spectra must be done with care due to limitations in resolution and spectral coverage in the IRMPD experiments. Furthermore, peaks seen in the IRMPD spectra will be the result of coincidences between sharp absorption bands and the sharp laser lines.

All IRMPD peaks are red shifted when compared with the neutral. Peaks in the neutral spectra range from 975 - 1075 cm^{-1} whereas IRMPD spectral peaks range from 945 - 1050 cm^{-1} Unfortunately, there is no structural information available for the CH_3OHX^- species (except one isolated study of CH_3OHF^- (3); the spectrum from that study differs somewhat from ours) for comparison with our results At this point, it is difficult to compare the shifts in either CH_3ODX^- or CH_3OHX^- peaks with the respective neutral peaks.

In this study, we have successfully utilized the technique of IRMPD in a FTICR mass spectrometer to obtain spectral information for solvated halide ions. Theoretical calculations and further studies are ongoing to assist in unambiguous assignment of these peaks.

Future experiments include probing the OH stretching modes of these solvated halide ions. In this study we will employ the probe-pump technique which has been proved in our *early experiments* (2). A Nd: YAG *laser with a newly-installed ir extension package in* conjunction with a cw CO_2 laser will be used for these experiments.

Obtaining Structural Information on the Aglycones of Macrolide and Azalide Antibiotics by ESI-Tandem Mass Spectrometry of Lithium-Attachment Ions

Mark J. Cole

Drug Metabolism Department, Central Research Division, Pfizer Inc, Groton, CT 06340.

Macrolides are a class of antibiotics containing an amino sugar, a nitrogen-free sugar, and a 14- or 16-membered lactone. Azalides are similarly glycosylated and contain a 15-membered azalide ring. The tandem mass spectra of protonated macrolide and azalide antibiotics provides almost no information on the structures of the aglycone moiety (Figure 1). Only the localization of a substituent to the aglycone can be inferred from a CAD spectrum. This is true for both high and low-energy CAD conditions (1). Intense $[M+Li]^+$ ions of the macrolides and azalides are produced by adding lithium to the samples and increasing the sampling orifice voltage. The $[M+Li]^+$ ions dissociate during low-energy (≈ 50 eV) CAD to produce a wealth of structural information about their aglycones. An example of macrolide dissociation is shown in Figure 2. Most of the dissociation occurs through two major pathways, which are distinct for the azalide and macrolide classes. Product ion structural assignments for the azalides were facilitated by comparison of CAD spectra from analogs containing aglycone substitutions. Collisionally-activated dissociation can be induced in the skimmer region by increasing the voltage applied to the skimmer cone. The spectra obtained are composed of CAD product ions from both protonated molecules and lithium-adduct ions, as well as some ions from the chemical background. Skimmer-induced CAD provides much of the same information as CAD in the second quadrupole region, but the process is not as efficient. A comparison of azithromycin $[M+Li]^+$ CAD spectra obtained from both CAD regions is shown in Figure 3.

A Study of Air Sensitive Compounds Containing Low Coordinate Cationic Phosphenium and Arsenium Centres by Electrospray Mass Spectrometry.

*Jonathan M.Curtis[1], Pearl Blay[1], Neil Burford[2], Trenton M. Parks[2] and Simon Mason[2].
[1]*Institute for Marine Biosciences, National Research Council, Halifax, Canada B3H 3Z1.*
[2]*Department of Chemistry, Dalhousie University, Halifax, Canada. B3H 4J3*

Several salts of the arsolidinium cation (**1**) have recently been isolated. These are novel examples of arsenium centers, a Group 15 analogue of a carbene [1]. The X-ray crystal structures of these compounds have revealed that they exist as the weakly bound dimers $(\mathbf{1})_{2a}$ and $(\mathbf{1})_{2b}$ in the solid state. In solution, the conclusions drawn from NMR studies are that the dimeric species $(\mathbf{1})_2$ either exist as monomers or that the dimer is fluxional. Since these compounds are ionic, analysis by electrospray mass spectrometry was attempted to shed some light on the nature of the species existing in solution. However, the compounds are also extremely sensitive towards moisture and oxygen, so there are a number of challenges involved in their handling and introduction into the mass spectrometer.

Electrospray mass spectrometry used a SCIEX API-III mass spectrometer in the ionspray mode of operation. The nebuliser gas used was ultra-pure nitrogen, and the exhaust gases from the sealed spray chamber were pumped away to ensure a dry atmosphere. Dry, distilled dichloromethane only was used both as the solvent to dissolve the samples and for electrospray. Sample concentrations were in the millimolar range. The API-III was operated with potentials which minimise source fragmentation. The sample solution in an evacuated flask was introduced into a nitrogen filled glove bag. A portion of the solution was tipped into a second flask via a bridge, and withdrawn through a septum into a syringe. Sample introduction into the API-III was by means of a syringe-driver housed within the glove bag. A background spectrum of the solvent could be obtained using the flow from the LC pump before starting the flow of sample solution.

The electrospray spectrum of $[(\mathbf{1})_{2b}(GaCl_4)_2]$ in 100% dichloromethane is given in the figure which illustrates the complexity of the situation. The dication $(\mathbf{1})_{2b}$ is not seen but in addition to the monocation **1b** (the base peak, *m/z* 167), a monocation at twice the molecular mass of **1b** is observed (*m/z* 334) which may be the dimer $(\mathbf{1})_{2b}^{+\cdot}$. Some of the other peaks can be interpreted as fragments of the solid-state structure (eg *m/z* 259 is loss of As), but many are not easily identified. The glove-bag atmosphere is seen to be sufficiently pure, since 90 minutes after first exposing the sample to it, both monomeric and dimeric forms were still observed, although some hydrolysis products became evident. The electrospray spectrum of the aza-dimer $(\mathbf{1})_{2a}$ gives a prominent ion at *m/z* 161, corresponding to the monomer (not shown). Again, no evidence for the dimeric dication was seen. Similar results have also been obtained for the phosphorus analogue of **1a** (a phospholidinium gallate salt) which does not have a dimeric structure in the solid state.

In the present experimental arrangement, poor reproducibility is the major obstacle despite the apparently adequate sample handling procedures. This is mainly due to erratic liquid flow through the capillary. Blockages may be a result of undissolved material in suspension, but filtering the solutions is not trivial given their reactivity. Also, the use of dichloromethane creates additional problems since, for example, it is reactive towards a number of polymeric components used in coupling tubing etc. Nonetheless, it has been demonstrated that the dimeric arsolidinium cations $(\mathbf{1})_2$ are dissociated in solution.

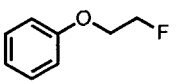
SELECTIVE MULTIPHOTON IONIZATION STUDIES OF DEUTERIUM-SUBSTITUTED β-FLUOROPHENETOLES

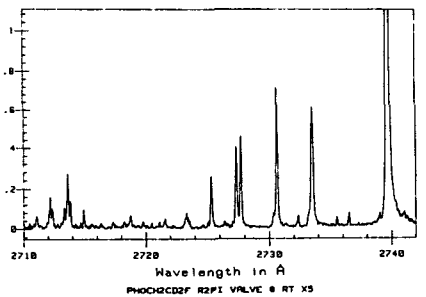
Timothy K. Shin, Thomas A. Shaler, Bryan E. Kohler & Thomas H. Morton
Department of Chemistry, University of California, Riverside, CA 92521

β–Fluorophenetole exists predominantly as a mixture of two conformational isomers, *anti* (which should have Cs symmetry) and *gauche* .[1]



β-Fluorophenetole
MW = 140

Because it is crystalline, it can be prepared in high purity, and supersonic jet expansion followed by laser induced, resonance excitation multiphoton ionization (REMPI) allows selective ionization of individual conformers. From the S_1 vibrational progression as a function of laser wavelength in a one-color experiment, analysis of the excitation spectra of the unlabeled compound and its deuterated analogues $PhOCD_2CH_2F$, $PhOCH_2CH_2F$, $PhOCH_2CD_2F$ and $PhOCH_2CHDF$ allows the assignment of the longest wavelength band (which happens also to be the most intense absorption) at 274 nm to the *gauche* and a band 82 cm^{-1} to the blue to the *anti*.



In part this assignment is based on two small peaks between these, 41 cm^{-1} and 56 cm^{-1} to the blue of the *gauche* (0,0) band in $PhOCD_2CH_2F$, which can be correlated with the calculated lowest-frequency torsions (3-21G) of the ground-state, unlabeled molecule (58 and 78 cm^{-1}), as contrasted to the calculated lowest torsional frequencies for the anti, 26 and 52 cm^{-1}. Other vibrational progressions can also be assigned on the basis of the *ab initio* calculation for the ground state.

Two-photon absorption in the 260-274 nm range leads only to formation of molecular ions, while three photon absorption leads to fragmentation (in addition to the molecular ions). The predominant fragmentation pathway in one color experiments is expulsion of vinyl fluoride to produce phenol$^{+\bullet}$ ions, and the ratios of $PhOD^{+\bullet}$ to $PhOH^{+\bullet}$ from the deuterated compounds are very nearly the same as those seen in the 70 eV source mass spectra. Measurements of the ratios of those two fragment ions as a function of laser wavelength permit assessment as to whether the mass spectrum is significantly affected by changes in photon energy or by the conformation of the neutral parent molecule. No significant effect is obserbed.

Mean $PhOH^{+\bullet}$ / $PhOD^{+\bullet}$ (94/95) RATIO

	MPI	70 eV EI
	1.3	1.3
	1.0	1.0

The total energy of two 274 nm photons is 9.06 eV which is 0.56 eV higher than the ionization potential of β–Fluorophenetole (8.5 eV). Any *anti-gauche* interconversion has to happen after the molecule has absorbed a second photon. In order to confirm this process two color experiments are in progress.

Excited State Dynamics of 2,2'-Bithienyl Studied by Resonance-Enhanced 2-Photon Ionization

Wybren Jan Buma, Bryan E. Kohler, and Thomas A. Shaler
Department of Chemiistry, University of California, Riverside California, 92521

Conjugated organic polymers like the polyacetylenes and polythiophenes are currently the subject of intensive investigation as a result of their ability to conduct electricity under certain conditions as well as for their nonlinear optical properties.[1] In the course of our continuing spectroscopic investigations of the electronic states in simple polyenes, the molecule 2,2'-bithienyl (bithiophene) has been studied. Previous high resolution spectroscopic studies of bithiophene in our laboratory have shown that in hydrocarbon matrices at liquid helium temperatures the lowest excited singlet state of bithiophene is the 1B state[2]. Here we report a study of the excited states of bithiophene under isolated conditions in a supersonic expansion by the technique of resonance-enhanced multiphoton ionization.

Our apparatus and techniques for obtaining one- and two-color high resolution electronic excitation spectra of jet-cooled molecules have been described in detail previously.[3] The bithiophene used in these experiments was commercially available material that was purchased from Aldrich and used without further purification. In one-color experiments, the frequency-doubled output of DCM dye provided frequencies appropriate for excitation of bithiophene to S_1 with subsequent ionization by a second photon of the same color. Two-color experiments used in addition, 193 nm pulses of light from an ArF excimer laser.

The origin of the electronic transition from the ground state to S_1 in jet-cooled, isolated bithiophene was found to be at 321.42 nm (31,112 cm^{-1}). The excitation spectrum has been measured up to 1700 cm^{-1} above the S_1 origin. An almost identical spectrum has also been obtained in our laboratory by fluorescence excitation in a free jet. During the early part of these studies it was noticed that the relative intensities of certain peaks in the spectrum were sensitive to the expansion conditions that were used. A thorough study by fluorescence techniques subsequently confirmed that two conformers of bithiophene, s-cis and s-trans were frozen out in the expansion, and careful temperature dependence studies allowed the relative excited state stabilities and interconversion barrier to be estimated.[4] An expanded view of the one color [1+1] MPI spectrum is presented in Figure 1, showing the relative locations of the origins of the s-trans and s-cis spectra.

Another interesting observation made in one color [1+1] MPI scans was a laser intensity-induced splitting of the more intense lines in the spectrum as shown in Figures 2a and 2b. Similar intensity-induced line splittings in MPI spectroscopy have been reported by Syage and co-workers for methyl iodide.[5] Those results were explained as being due to excited methyl iodide's undergoing predissociation. Although the same process is unlikely in bithiophene, the key to observing the splitting is a transformation of the initially formed excited state to a non-ionizable species. This is possible in bithiophene by either internal conversion back to S_0, or by intersystem crossing into the triplet manifold. It was found that the dip in the line was absent when using 193 nm light to perform the ionization, as shown in Figure 2c.

The lifetime of the S_1 state in bithiophene is much shorter than the 10 nsec pulses that were used in attempting to measure it by fluorescence, as expected for such a strongly allowed transition. When the decay of the excitation was measured by 2-color MPI at the s-trans origin, the profile shown in Figure 3 was obtained. From simply considering the shape of the the decay, qualitative conclusions about the excited state dynamics of bithiophene can be deduced. The early part of the decay curve is characterized by an unexpectedly slow rise time. The maximum ion intensity is not reached until about 200 nsec after the signal begins to increase. Since the S_1 state had decayed away by very early time delays, this slow rise time must be coming from some state other than S_1. Additionally, since the intensity continues to increase for delay times up to 200 nsec, yet a third state must be giving rise to the ion signal, and it must further be the case that this third state has a much larger ionization cross section than either of the other states. Further work is underway to attempt to identify the species involved and to determine the rates and cross sections of the various proceesses in the excited state dynamics of bithiophene.

These results therefore support the conclusion that bithiophene excited to the zero point vibrational level of its first excited singlet state undergoes intersystem crossing or internal conversion rapidly to form an intermediate excited state. The intermediate state undergoes a slower conversion or crossing to form a state that has an ionization cross section much larger than the other states involved, and which has a relatively long lifetime.

Base Pair Formation of Free Nucleobases and Mononucleosides in the Gas Phase

M. Dey, J. Grotemeyer*, E.W. Schlag**

* Institut für Physikalische Chemie, Universität Würzburg, Marcusstr. 9/11, 8700 Würzburg, Germany
** Institut für Physikalische Chemie, TU München, Lichtenbergstr. 4, 8046 Garching, Germany

The famous Watson-Crick structure of the double-stranded helix of nucleic acids now celebrates its 40th annivesary. The forces causing the double-stranded structure of the DNA are hydrogen bonds between bases of the strand, hydrophobic forces between each strand and interactions between the phosphate ions and solvent molecules. The famous specific interactions A-T and C-G may be a result of of these forces or of specific affinities of the nucleic acid bases.
To examine the partial contribution of the nature bases to form definite base pairs we investigated the pure base interactions in the gas phase. We used the pure bases without derivatization or solvation in order to exclude solvent and side group interactions.

In order to examine the dimer formation behaviour we desorbed mixtures of two bases at the same time. The mass spectra of all 10 possible base combinations have been observed.The base pairs are formed during the desorption of the nucleobases into the jet. In the jet the translational velocities of all molecules are very similar due to the multiple collisions between jet gas atoms and sample molecules. Therefore also weak bonded dimers can be formed by collision of two base molecules. Due to the multiple collisions the equilibrium of the dimer formation is reached faster than the desorption time of about 100 µs As the excess energy deposited in the molecular ion is rather small for MUPI (less than 1.7 eV), these dimers can be observed in the RETOF mass spectrometer.
As seen from the mass spectra below, specific clusters of adenine and thymine as well as cytosine and guanine are formed in the supersonic jet prior ionization.
Association constants are calculated with the assumption that we have the following equilibrium

$$B_1 + B_2 \rightleftharpoons (B_1\text{-}B_2)$$

$$K = [B_1\text{-}B_2]/([B_1]x[B_2])$$

with $[B_1]$, $[B_2]$ and $[B_1\text{-}B_2]$ being the corresponding peak intensities (see table 1).
As can be seen clearly from these results, the base pairing in the gas phase is base specific. A-C, C-T and G-T hetero dimers are not formed . Thus stacking or π-complexes of the bases has little contribution in stabilizing the dimers in the gas phase.

The double hydrogen bonded A-T as well as the triple bonded G-C base pair in the DNA are not only formed because of sterical reasons due to the phophate-sugar chain but show themselves a natural affinity already in the gas phase. Similar results have been obtained for the nucleosides.

Nanosecond and Femtosecond Multiphoton Ionisation - Comparison of Fragmentation Behaviour

Using commercially available ns-laser systems MUPI has become a very useful and generally accepted ionisation technique in mass spectrometry in the last few years. However, recent experiments have shown that the ionisation efficiency of MUPI and other techniques decresases rapidly with the mass of the investegated samples [1]. Therefore this ionisation techniques are rather unsatisfactory for high masses like large proteins or enzymes. A recent theory [1] proposes an increase in the mass range accesible to cation radical formation by using fs- instead of ns-laser pulses.

Femtosecond laser systems provide a convenient way of increasing the laser intensity by at least three orders of magnitude. Conventional ns-Laser systems like excimer or YAG pumped dye lasers have intensities of about 10^4-10^5 W/cm^2, whereas our fs-dye laser provides intensities of about 10^8 W/cm^2.

In order to investigate the effects of laser intensity on the ionisation process as well as on the fragmentation behaviour we compared the results of nanosecond (YAG pumped dye laser with a pulsewidth of 6-7 ns; output energy about 40 µJ) and femtosecond (tuneable fs-laser with a pulsewidth of 500 fs; output energy 8 µJ) laser pulse ionisation for samples up to 1900 Dalton. The experimental setup has been described in detail elsewhere [3]. The samples are desorbed by a CO_2-laser and transfered into the ionisation chamber by a pulsed argon jet. Liquid samples are mixed with the argon and the mixture is expanded through the jet valve into the desorption chamber. A Reflectron-Time-of-Flight mass spectrometer (Bruker TOF-1) is used for recording the mass spectra.

In order to compare ns- and fs-laser ionisation it is essential to produce the ions under similar conditions. Thus the ns- and the fs-pulses are adjusted such a way that both pulses hit the stream of neutrals nearly at the same point in the ionisation chamber.

First we investigated the resonant (λ=259 nm) and non resonant (λ=260.5 nm) ionisation of "cold" (jet-cooled) and "hot" (effusive inlet) benzene.

In the resonant case no difference is observed between ns- and fs-laser pulse ionisation for "cold" benzene. Applying a non resonant wavelength the same result is observed for "hot" benzene. Using a non resonant wavelength and "cold" benzene, however, ionisation is only observed for the fs laser pulse.

These results can be explained as follows. Using a resonant wavelength the same long-lived intermediate state is populated both for "hot" and "cold" benzene. Thus the time between absorption of the first (population of the excited state) and the second photon (ionisation) is not critical. In the non resonant case for "cold" benzene ionisation takes place through a virtual state. Thus the ionisation efficiency depends strongly on the laser intensity, and ions are observed only for fs-pulses delivering much higher intensities. In "hot" benzene due to the higher temperature higher rovibrational states of the electronic ground state are populated allowing for ionisation through hot bands. Therefore, a long-lived intermediate state is reachable and ionisation is again possible by both ns- and fs-pulses.

Comparing ns- and fs-ionisation for tryptophan one can see that due to the other ionisation mechanism (autoionisation ladder instead of ladder switching) fragmentation is more intense for fs-pulses.

Furthermore the determination of the threshold energies for ns- and fs-ionisation (λ=260.5 nm) of β-carotene, gramicidin s and gramicidin d shows that fs-pulses are about 40 times more "efficient" in ionisation than ns-pulses.

Eventually it is shown that the unique features of MUPI (easy change between "hard" and "soft" ionisation; molecular ion being the base peak in the mass spectrum) are also valid for femtosecond pulse ionisation. Figure 1 shows the "hard" and "soft" mass spectra of gramicidine d.

$[M-2H]^{+\cdot}$ Formation in the FD-MS Analysis of Hydrocarbons

C. E. Heine and M. M. Geddes
Exxon Research and Development Laboratories
P.O. Box 2226, Baton Rouge, LA 70821

Intense $[M-2H]^{+\cdot}$ signals have been noted in FD-MS analyses of various compounds. High-boiling hydrocarbon molecules, such as long-chain n-alkanes and squalane, may give rise to particularly abundant $[M-2H]^{+\cdot}$ ions (1). This phenomenon complicates the interpretation of FD-MS data obtained from waxes (2) and other hydrocarbon mixtures, especially when the exclusive formation of molecular ions (M^+) is assumed. The present study compares the magnitude of $[M-2H]^+$ formation in the FD-MS analysis of several pure hydrocarbon standards, including saturated and aromatic compounds. Key experimental parameters are then investigated with respect to their influence on this phenomenon. These parameters include the emitter current program, electric field strength, and quantity of sample loaded onto the emitter.

All experiments were performed on a Kratos MS50 (EB) mass spectrometer equipped with a DS55 data system. Data comparison took place after the individual mass spectra obtained in each FD-MS analysis were summed. The 10 micron tungsten emitters used were activated in our laboratory The activation procedure (using indene) was controlled by a Linden Emitter Activator Samples were applied to the emitter from hexane or methylene chloride solutions by the "syringe technique". The FD anode voltage (+8 kV) also served as the ion acceleration voltage. The cathode voltage (applied to the source block) was -2 kV in normal operation, but varied between -2 and +4 kV for experiments involving alteration of the electric field strength. The standard emitter current program incorporated a current ramp of 1 2 mA/min

The compounds analyzed in this study are shown in Table 1 The intensity of the $[M-2H]^+$ signal relative to the M^+ signal (from the summed mass spectrum) is listed next to each structure, along with the sample quantity loaded onto the emitter. Table 1 shows that equal quantities of C30, C33, and C36 n-alkanes (analyzed separately) gave rise to $[M-2H]^+$ formation which increased with the length of the alkyl chain. Comparison of results obtained from a branched C30 alkane (squalane) and a linear C30 alkane reveal increased $[M-2H]^+$ formation for the branched compound An aromatic ring, however, strongly suppressed $[M-2H]^+$ formation in n-heptadecylbenzene relative to that observed from its saturated analogue (n-heptadecylcyclohexane) in another interesting comparison None of the aromatic compounds tested in this study provided evidence of significant $[M-2H]^+$ formation. Analyses of compounds which did give rise to abundant $[M-2H]^+$ ions indicate that the $[M-2H]^+$ desorption profiles track those of the M^+ ions as a function of emitter heating current

Figure 1 displays the dependence of $[M-2H]^+$ formation for squalane on the potential difference between the FD anode and cathode. 20 nmols of squalane were used in each analysis represented in Figure 1. The data reveal a pronounced diminution in $[M-2H]^+$ signal intensity (relative to the M^+ signal) as the applied potential difference is reduced. Since the electric field strength is linearly related to the applied potential difference (3), $[M-2H]^+$ formation exhibits a strong field dependence. In contrast, no thermal dependence (investigated by widely varying the emitter current program) was documented for this phenomenon

Another experimental parameter shown to influence the magnitude of $[M-2H]^+$ formation is the amount of sample initially loaded onto the FD emitter. Figure 2 shows that $[M-2H]^{+\cdot}$ formation (relative to M^+ formation) decreases as the sample quantity of squalane decreases. Both the field dependence (illustrated in Figure 1) and the sample quantity dependence (illustrated in Figure 2) were confirmed by

similar experiments conducted with the C36 n-alkane.

In summary, this study suggests that $[M-2H]^+$ formation in hydrocarbon molecules may be minimized by appropriate choice of the applied potential difference (hence, field strength) and the amount of sample loaded onto the emitter in the FD-MS analysis Of course, practical limits exist for each of these approaches. In our experiments, when the potential difference between anode and cathode was reduced to 4-5 kV, a significant decrease in ionization efficiency resulted in a serious loss in sensitivity. Likewise, a loss in signal accompanies the practice of loading less sample onto the emitter Yet, FD-MS results of high quality (with misleading $[M-2H]^+$ signals essentially eliminated) were obtained for all compounds analyzed in this work by manipulating these two experimental parameters. The nature of the $[M-2H]^+$ ions is unclear at the present time. They may be formed by converting the alkyl chain into a cyclic or olefinic structure in a field-dependent process. The trends of increased $[M-2H]^+$ formation documented for saturated molecules of increasing chain length and branchiness may implicate a cyclic structure. This issue may be clarified by MS/MS experiments conducted with suitable standard compounds

Infrared Spectroscopy of Matrix-isolated Products Following Charge Exchange Ionization of Dihalomethanes with Ar

X.K.Zhang* J.M.Parnis and R.E.March
Chemistry Department Trent University Peterborough ON Canada K9J 7B8
* *Registered at Queen's University Kingston ON Canada K7L 3N6*

INTRODUCTION The ionization, fragmentation and isomerization processes of dihalomethanes CH_2X_2 (X=Cl,Br) following charge-exchange (CE) ionization with Ar has been investigated. The various ionic and neutral products of CH_2X_2 generated were characterized through a combination of matrix-isolation infrared spectroscopy and mass spectrometry.

EXPERIMENT The experimental arrangement consists of a modified EI ionization device inside a vacuum chamber containing a closed-cycle helium cryostat system (Fig.1). A stream of CH_2X_2 and Ar was subjected to ionization directly above the surface of a cold CsI matrix window, where the product species condensed subsequently with the excess neutral precursors at 12 K. Vibrational spectra of matrix-isolated species were obtained with a FTIR Spectrometer.

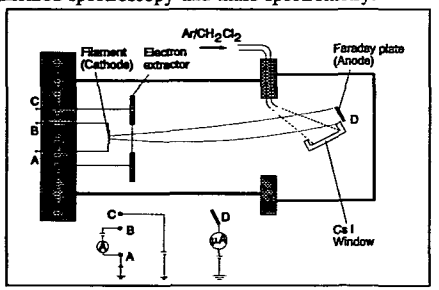

Figure 1 Diagram of EI device and cryostat assembly

RESULTS Various products, such as $HCCl_2^+$, $HCCl_2$, CCl_2^+, and Ar_nH^+, were identified in the spectrum of Matrix-isolated species following CE ionization of CH_2Cl_2 with Ar. Of most interest, a group of strong absorption features was observed, which corresponded to the fundamental absorptions of isodichloromethane H_2CCl-Cl,[1] and showed great photosensitivity to irradiation in the 590-1000 nm range (Fig.2); The ionization of an equimolar mixture of CH_2Cl_2/CH_2Br_2 revealed no scrambled product, *i.e.* H_2CCl-Br, was observed, though the isomers of each were clearly identified (Fig.3).

The MIKE and CID experiments of $CH_2X_2^{+\cdot}$ showed that the expulsion of CH_2 to form X_2^+ is mainly, though not exclusively, a collision-activated decomposition process since the intensity is proportional to the pressure of collision gas in the cell. NRMS experiments showed that no significant amounts of neutral or ionic species having structures other than tetrahedral existed in the gas phase.

Three experiments were carried out by exposing the neutral Ar/CH_2Cl_2 matrix to resonant emissions of excited Ar, Kr and Xe formed by EI. The contribution to isomerization from the resonant emission of excited Ar atoms was found to be less than ca. 10% of that contributed by CE ionization.

DISCUSSION The generation of isodihalomethanes through CE ionization with Ar could be explained by three mechanisms:

1) Molecular ions having structures other than tetrahedral and of diminished stability are created during the ionization process in the gas phase, and are neutralized during the condensation process.

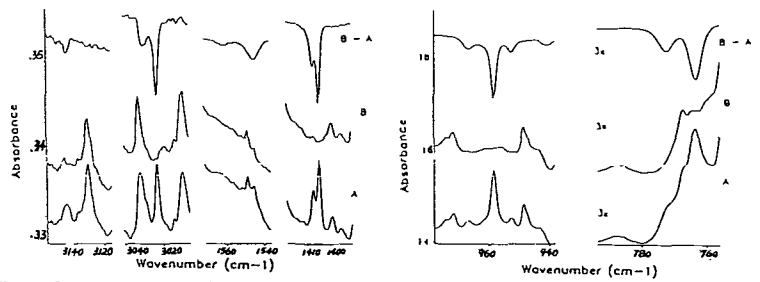

Figure 2. A: spectrum after deposition; B: spectrum after exposing the matrix to irradiation of red light; B-A: difference spectrum of B and A.

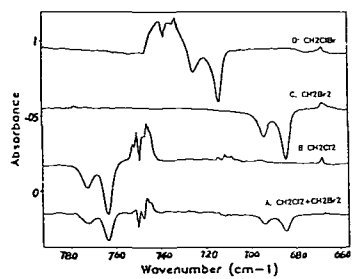

Figure 3. Comparison of CH_2 wagging mode of isodihalomethanes. Spectra shown are the net difference spectra after irradiation with red light.

2) Molecular ions having a tetrahedral structure are neutralized, and these energetic neutral species undergo isomerization during the matrix trapping process. The mass spectrum obtained by reionization of neutralized molecular ions showed a slight increase in intensity of Cl_2^+, which may indicate that some of the isomer are generated in the neutralization process.

3) The isomers are products of fragment recombination. This mechanism is not plausible due to lack of the observation of scrambled H_2CCl-Br product when a mixture of CH_2Cl_2 and CH_2Br_2 was subjected to CE ionization.

CONCLUSION The isodihalomethanes H_2CX-Y (X,Y=Cl, Br) have been generated through CE reaction of CH_2X_2 with Ar, and their back-isomerization upon irradiation with red light has been observed also. The formation of the isomers may be evidence for the existence of molecular ions which have structures other than tetrahedral, and have a diminished stability.

Ultra Small Volume and Flow Rate Electrospray Ionization / Mass Spectrometry with a Sheathless Source

David C. Gale, Charles G. Edmonds, and Richard D. Smith
Chemical Sciences Department
Pacific Northwest Laboratory
Richland, WA 99352

The co-axial liquid sheath electrospray ionization (ESI) source is widely used and has advantages for CE and LC interfacing. However, the use of a co-axial sheath liquid has several disadvantages. The sheath liquid contributes additional ionic and neutral species that compete in the ESI process for available charge, and depending on the mixing of the analyte and sheath streams, lowers the maximum sensitivity obtainable. Past experience from our laboratory has also shown that stable signals from sheath type sources can in certain applications be difficult to obtain for extended periods of time.

A new low volume sheathless ESI source (Figure 1), utilizing an etched tip small diameter fused silica capillary (5 to 20 μm), has been developed. This sheathless source for pressure infusion applications is constructed from a 25 μL gas-tight syringe and a modified 1/16 in. bored-through stainless steel reducer. ESI-MS data from both sheathless and sheath sources were acquired on a modified triple-quadrupole mass spectrometer (Sciex TAGA 6000E). Samples were pressure infused at set flow rates with a Harvard Syringe pump. For the sheath source, methanol, at a flow rate of 2.5 μL/min, was used as the sheath liquid. Horse heart myoglobin (M_r = 16951) in 5% acetic acid, 5'-dCCTCTCCTCCCT-3' oligonucleotide (M_r = 3470) in distilled H_2O and oxidized bovine A-chain insulin (M_r = 2532) in 10 mM ammonium acetate were used in this study.

Shown in Table 1 are data acquired with the methanol sheath and sheathless sources respectively. *Identical samples were used to compare the sheathless and sheath* source designs. In obtaining the data shown in Table 1, a 50 μm capillary was used in the sheath source. An HF etched 20 μm capillary was used in the sheathless source. Sample flow rates of 0.50 μL/min and 0.20 μL/min were used for the sheath and sheathless sources respectively. A total of 500 scans (time = 17.2 minutes, scan range = 10 *m/z*) were acquired over the most intense peak in the electrospray mass spectra to obtain the average intensity and % RSD.

Several tentative conclusions can be drawn from the data given in Table 1. First, the sheathless source requires a significantly lower potential to generate a stable electrospray. Second, the signal intensity for the sheathless source ranges from 3.0 to 7.4 times greater than that observed for the methanol sheath source from a flow rate 2.5 times smaller. Third, the percent relative standard deviation of the measured ion currents is substantially lower for the sheathless source, indicating that it is more stable.

The total amount of sample consumed during the mass spectrometric analysis with the sheathless source can be quite low. Shown in Figure 2 is an electrospray mass spectrum of 5'-dCCTCTCCTCCCT-3' acquired with a 5 μm etched tip capillary. The flow rate used for this analysis was 50 nL/min. The mass spectrum represents the consumption of 20 nL of sample, corresponding to 50 femtomoles of the oligonucleotide. Thus, the new

sheathless ESI source is more sensitive and stable compared to the sheath source design and has the ability to operate at lower flow rates and with lower overall sample consumption.

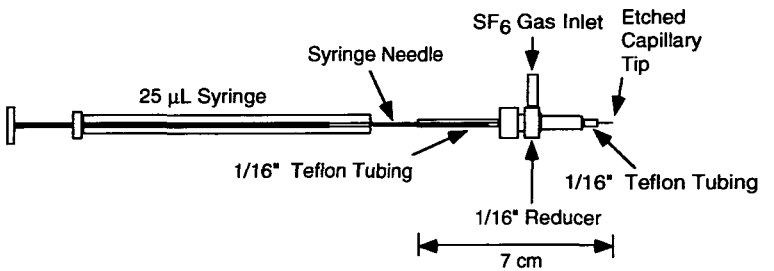

Figure 1

TABLE 1	ESI Potential	Relative Intensity	% RSD
POSITIVE ESI - horse heart myoglobin (0.5 mg/mL)			
Myoglobin - Sheath Source	+ 4.0 kV	1.167×10^6	9.5%

OPTIMIZATION AND EVALUATION OF A CAPILLARY ELECTROPHORESIS - ELECTROSPRAY MASS SPECTROMETRY INTERFACE EMPLOYING OPPOSITE POLARITIES AT THE INJECTOR AND ION SOURCE

Johnson Varghese and Richard B. Cole*

Department of Chemistry, University of New Orleans, Lakefront Campus, New Orleans, LA 70148

A capillary electrophoresis - electrospray mass spectrometry (CE-ESMS) interface coupling a Dionex CE System I unit to a Vestec 201 electrospray mass spectrometer has been constructed. The interface design utilizes the sheath liquid electrode approach [1]. Components of the constructed interface were taken through systematic optimization procedures defining the placement of the fused silica CE capillary exit relative to stainless steel electrospray needles. Maximum sensitivity conditions were found to be rather different from maximum stability conditions. Optimum sensitivities were obtained with the CE capillary tip protruding 0.1 to 0.2 mm outside the electrospray needle. Despite some loss in sensitivity, placement of the capillary tip about 1 mm inside the needle afforded increased ruggedness to the interface and stability to generated signals. Under these conditions, fluctuations in the applied voltages or variations in buffer properties did not degrade electrical contact at the interface.

The combined instrumentation has been used to evaluate the purity of cationic and anionic laser dyes. Solutions of organic dyes are used in laser sources to enable laser operation over a continuum of wavelengths (from the near-UV to the near-IR). The purity of the laser dye can profoundly affect the laser efficiency and the usable lifetime of the dye. Secondary products contained in laser dyes are quite likely to be of inferior efficiency. Impurities may quench laser activity at variable rates, leading to a deterioration of laser power. Assessment of laser dye purity can thus be of high importance to dye laser users.

For on-line analysis of anions, positive CE voltages were used in combination with negative ESMS potentials. On-line cation analysis was performed using a surfactant buffer additive, cetyltrimethylammonium chloride, and negative CE voltages in conjunction with positive ion ESMS Using opposite polarities at the CE source vial and the electrospray needle enabled electroosmotic flow towards the detector in each case. Successful separations of impurities contained in the cationic laser dye Rhodamine 6G were demonstrated. These included isomeric impurities as well as structural analogs which were deficient in an ethyl substituent. Negative ion ES in conjunction with normal polarity CE (positive potential at source vial) proved to be the most difficult due to intrinsic difficulties associated with negative ion ESMS. The anionic laser dye Eosin Y (containing four bromine atoms) was first analyzed by direct infusion (Fig. 1). A major impurity corresponding to a three bromine analog was detected in the sample. This impurity was separated from Eosin Y using positive voltage CE-selected negative ion monitoring ESMS (Fig. 2). Peptide mixtures were also successfully analyzed by negative voltage CE-positive ion ESMS.

Improved Microbore HPLC Electrospray Mass Spectrometry Interface.

**Igor A. Kaltashov and Catherine Fenselau*
Department of Chemistry and Biochemistry,
University of Maryland Baltimore County, Baltimore, MD 21228.

On-line high performance liquid chromatography (HPLC)/electrospray ionization mass spectrometry (ESIMS) offers a great number of advantages. Since electrospray is a very "soft" ionization technique, it forms molecular ions predominantly, making the corresponding mass spectra easy to interpret. The combined technique also allows identification of analytes that are not completely separated by chromatography. Electrospray ionization permits analysis of heavy molecules by multiply charging them, in which case a deconvolution procedure can be used to calculate the molecular weight of the analyte.

Microbore reversed phase HPLC columns can be operated at very low flow rates (below 50 μL/min.), which are easily adopted by ESIMS without post-column splitting. This increases the overall sensitivity of the system as all injected material is directed to the ion source. In the present work, an on-line microbore reversed-phase HPLC/ESIMS system has been developed to interface a thermally assisted electrospray source and a quadrupole mass analyzer.

In our experiments an ISCO (Lincoln, NE) μLC-10 system equipped with two 100DM syringe pumps and a Synchrom (Lafayette, IN) C18 1.0x15.0 mm column was used. To achieve stable low flow rates through the column, both pumps were operated at relatively high flow rates and, after mixing, the flow of eluent was split (see Fig.1). Use of a second C18 column of larger diameter as a ballast column allowed a constant splitting ratio to be maintained across the gradient. The typical flow rate through the working column was 20 μL/min. The mobile phase consisted of (A) 0.25 % acetic acid in water and (B) 0.25 % acetic acid in acetonitrile. All eluent coming out of the UV flowcell was directed into the electrospray ion source through a piece of fused silica (0.1 mm ID). A Hewlett Packard (Palo Alto, CA) quadrupole 5988A mass spectrometer equipped with a Vestec (Houston, TX) electrospray ion source and a Phasor (Duarte,CA) ion multiplier was used. All mass spectral data was collected and processed by a Vector II data system from Technivent Corp. (Maryland Heights, MO).

To evaluate the performance of the system and to estimate its limit of detection, a mixture of synthetic peptides and proteins was used. The UV-chromatogram and the mass spectrum of positive ions in a 200-1400 amu mass range were recorded simultaneously. Comparison of a UV-chromatogram with total ion current (TIC) chromatogram and reconstructed ion chromatograms for particular ions shows that chromatographic fidelity was maintained when the eluent flow was directed to the ES ion source. We were able to detect all the compounds of the mixture by ESIMS (using reconstructed ion chromatograms) when the mixture was diluted so that only 10 pmol of each component was injected into the column. At that point only half of the mixture compounds had been seen by the UV detector at 215 nm.

The developed system was also employed for peptide mapping. A tryptic digest of melphalan-treated metallothionein (total concentration of material ca. 50 μM, injection volume 2μL) and *S. aureus V8* protease-digested microsomal glutathione S transferase were analyzed by the HPLC/ESIMS system. Mass spectrometry provided information on the molecular weights of digest fragments and allowed identification of species that were not clearly separated by chromatography.

The system has been also evaluated for on-line identification of drug-related components of a rat bile extract. Fig. 2 shows a UV-chromatogram and mass spectra of each UV-peak. The presence of fragment ions in each spectrum helps to identify the analytes. In addition to these two species detected by their absorption, mass spectrometry allowed us to detect 6 more compounds, which lack chromophores.

A Performance Evaluation of Several Ion Introduction Techniques Used For Electrospray Ionization.

*Steven M. Musser and James A. Sphon.

Division of General Scientific Support, CFSAN, U.S. Food and Drug Administration, Washington, DC 20204.

Electrospray is now used routinely in HPLC/MS analysis for ionization of a variety of compounds, primarily large biomolecules. Since the introduction of electrospray and its complementary process, ionspray, a variety of methods have been presented for desolvating and transporting ions from atmospheric pressure to high vacuum. The three most common methods are direct introduction of the electrosprayed droplets into the mass spectrometer via a small orifice ; desolvation at atmospheric pressure followed by transport into the analyzer via a quartz tube; and transport/desolvation of the ions through a stainless steel capillary. Although all three ion introduction techniques have been used successfully to obtain mass spectra of both high and low mass compounds, a direct comparison of the techniques has not been reported. Because of the variety of electrospray interfaces now available commercially, and the increasing importance of electrospray to the analytical laboratory, this investigation was undertaken to determine the effect of each ion introduction technique on the mass spectra obtained for both small and large molecules.

A Vestec Model 201A quadrupole mass spectrometer with a Teknivent Vector2 data system was used for all experiments. A standard Vestec electrospray ion source was modified for direct ion introduction (figure 1). Additional modifications of the inlet tube permitted various capillary tubes to be used for heated capillary ion introduction (figure 2). For all experiments the ion source was held at 125 °C and a 2.9 kV needle voltage used. Sample solutions were pumped to the needle tip at a rate of 5 µl/min using a Sage Instruments syringe pump. A 500 ml/min coaxial flow of air over the needle was used for nebulizer assisted electrospray. An Aalborg Instruments flow meter was used to measure all gas flow rates. For direct ion introduction experiments a 0.40 mm orifice was used which resulted in a flow of air through the orifice of ≈ 23.5 ml/sec. To simulate a quartz tube type of interface, a glass lined stainless steel capillary (GLT) having an i.d. of 0.70 mm and a length of 20 cm was used. This configuration resulted in an air flow through the GLT tube of ≈ 26.3 ml/min. When an uncoated stainless steel (SS) capillary having an i.d. of 0.76 mm and a length of 20 cm was used the resulting air flow through the tube was ≈ 30 ml/sec. Capillary tube temperatures for both GLT and SS were operated in the range of 105 - 120 °C.

While the charge distribution for myoglobin and an amine test mixture remained constant regardless of which introduction technique was used, the sensitivity was higher with the direct introduction method, despite similar air sampling rates. Comparison of the absolute sensitivities of the transfer tubes with the direct introduction method showed that use of the GLT transfer tube resulted in a 4-5 fold loss in sensitivity for both myoglobin and low mass compounds (< m.w. 500). Conversely, use of the stainless steel transfer tube resulted in a 5-6 fold decrease in sensitivity for myoglobin and approximately an order of magnitude decrease in sensitivity for low mass compounds. These results show that no significant advantage other than sensitivity is gained by using any of the three ion introduction methods. Additionally, low mass sensitivity using stainless steel tube interfaces can be improved by replacing them with similar inner diameter glass lined stainless steel tubing.

NEGATIVE ION FORMATION IN ELECTROSPRAY MASS SPECTROMETRY

Rolf F. Straub and Robert D. Voyksner, Analytical and Chemical Sciences, Research Triangle Institute, P. O. Box 12194, Research Triangle Park, NC 27709

INTRODUCTION

Electrospray (ES) ionization is rapidly developing as a method to produce gas-phase ions from analyte species in solution for subsequent analysis by mass spectrometry (MS). It is a soft ionization method capable of providing positive ions of many synthetic drugs, dyes, natural products, high molecular weight biopolymers and a variety of other compounds. In contrast to this, only a few examples have been reported so far using negative ions for the characterization of compounds with acidic functionalities such as carboxylic, phosphoric, and sulfonic acid groups.

One crucial reason for this is the fact that, for otherwise equivalent conditions, an electric (corona) discharge occurs, presumably caused by electrons emanating from the sharp edges of the electrospray needle held at a few thousand volts negative relative to a counter electrode. For aqueous or highly conductive solutions, it becomes even more difficult to maintain stable electrospray in the case of negative polarities because, generally, higher voltage is necessary to electrospray the liquid. This situation makes negative-ion mode ES-MS more difficult than ES-MS in the positive-ion mode. This paper describes negative-ion ES-MS operation on a single quadrupole mass spectrometer and compares the results to some positive-ion operations. Also, the ability of common chromatographic solvents to stabilize ES current and to promote intense analyte signals was determined.

EXPERIMENTAL

Sample Introduction:	Flow injection at 4 µL/min for indicated solvent systems and samples.
Electrospray:	Analytica of Branford designed for an HP 5989 operated for the formation and transmission of negative ions.
Mass Spectrometer:	Hewlett Packard 5989 operated in negative ion detection mode.

RESULTS AND DISCUSSION

Optimizing the Generation of Negative Ion in ES

The three layered electrospray needle used consisted of a 50 µm i.d. stainless steel inner tube to deliver solvent, and a 125 µm i.d. second layer tube to deliver an additional solvent as a sheath flow to enhance ES negative ion operation, especially when using high percentages of water. The third and outer tube was used to coaxially add gas to aid in nebulization. In negative-ion operation, oxygen was generally used as an electron scavenger gas.

An evaluation of eight representative chromatographic solvents (methanol, ethanol, 2-propanol, methoxyethanol, acetone, tetrahydrofuran, chloroform and acetonitrile) indicated that 2-propanol (IPA) added with oxygen in the electrospray bath gas is best-suited to suppress electrical (corona) discharge phenomena in negative-ion operation while aiding in solution nebulization, desolvation and transfer of ions in solution to the gas phase. For positive-ion mode no such precaution was necessary. The use of 2-propanol leads to the most abundant $[M - H]^-$ ion with few background ions in the electrospray spectrum of 37 ng/µL adenosine-5-

monophosphate (AMP). Therefore, IPA is an ideal choice as a mobile phase additive in negative-ion ES-MS operation. Also, AMP dissolved in methanol or 2-methoxyethanol exhibits an abundant $[M - H]^-$ ion, few fragment ions, and a low background. Less suitable solvents such as chloroform, acetone and acetonitrile produce higher background throughout the mass range, but in particular at lower m/z ratios. The nucleotide dissolved in ethanol or tetrahydorfuran yielded a low abundance $[M - H]^-$ ion and comparatively abundant background ions.

Application of Negative Ion ES-MS for the Detection of Various Compounds

Negative ions with varying degrees of solvation and structurally relevant fragments can be obtained from a variety of solute species including β-lactam antibiotics, aminoglycosides, aminocyclitols, tetracyclines, sulfonamides, nucleotides, peptides and explosives. No fragmentation of parent species, except those from some labile explosives, was observed as low potential differences were applied between the capillary and the first skimmer, and electrical discharge was avoided in the gas phase. An increase of the capillary voltage resulted in collision induced decomposition to produce structurally relevant fragment ions in both operation modes. Negative-ion electrospray offers the advantage of providing complementary structural information to help in characterization of an unknown compound or to confirm a certain tentatively proposed structure. Nucleotides and explosives were best characterized in negative-ion mode owing to the ease with which they form anions in solution; they could be detected down to the 1 pg/µL level. Other compounds (antibiotics and peptides) were more sensitive by positive ion detection, particularly when no acid sites were present on the molecule to form an anion. Compounds that had both basic and acidic sites (β-lactams) resulted in ion currents within a factor of 2-3 between positive ion (low pH solution) and negative ion (high pH solution) detection. Conditions that promote the formation of anions in solution usually improved the electrospray ion current for negative ion detection. Therefore, the best ion currents for all the conditions evaluated were obtained at solvent pH values of 9-10 (pH adjusted with ammonium hydroxide).

CONCLUSIONS

Negative-ion electrospray mass spectrometry provides a means to characterize a wide variety of compounds such as antibiotics, synthetic drugs, nucleotides, peptides, and explosives. Conditions which promote the formation of anions in solution (high pH with NH_4OH) usually improve ES response. Also, an appropriate choice of the solvent (isopropanol) or the sheath fluid has a substantial effect on the stability of the current produced by the electrospray and the intensities of the recorded signals. This can be attributed to enhancements in the nebulization and desolvation processes resulting in higher ion evaporation yields.

Comparison of Buffer Systems in Capillary Electrophoresis - Electrospray Ionization / Mass Spectrometry

Jon H. Wahl, David C. Gale, Steven A. Hofstadler, Harold R. Udseth, and Richard D. Smith
Chemical Sciences Department
Pacific Northwest Laboratory
Richland, WA 99352

The combination of capillary electrophoresis (CE) with electrospray ionization mass spectrometry (ESI/MS) is becoming a powerful technique for the study of biomolecules. In general, a wide selection of buffer systems are used for CE separations. In CE-ESI/MS, however, volatile buffer systems, which are at the lowest practical concentration and ionic strength, generally produce the best detector response. Consequently, a balance must be achieved between a high buffer concentration that degrades solute detectability in ESI/MS and a low buffer concentration that causes solute zone broadening due to conductivity differences.

A variety of ESI approaches are used for interfacing CE with MS. For example in the coaxial sheath flow design, a small flow of liquid serves to establish the electrical contact. Several disadvantages, however, exist with this interface design; for example, the coaxial liquid invariably provides additional electrolyte to the ESI source that may decrease the analyte response and will contribute to the chemical background. Presently, our laboratory is re-examining a sheathless CE-ESI interface approach using a conductive capillary terminus. These two different ESI interface designs are compared and their dependence on solute detectability for three different buffer systems at three different concentrations are examined for capillary i.d.'s of 100 and 10 µm.

The experimental system for these initial studies consists of a modified Sciex TAGA 6000E mass spectrometer and an in-house built capillary electrophoresis system. The coaxial electrospray design used a 75% MeOH / 24% H_2O / 1% HOAc as the sheath fluid, and the sheathless design used a conductive coating at the analytical capillary terminus to establish electrical contact with the CE effluent. In all studies, aminopropylsilane treated fused-silica capillaries of various inner diameters (i.d.) are used. The buffer systems examined are HOAc, NH_4OAc/HOAc, and Na_2HPO_4 at concentrations of 1, 10, and 100 mM and ranged in pH from 3.0 to 6.0. The solute chosen for these experiments is Methionine(M)-Lysine(K)-Bradykinin (1320 Da) at a concentration of 1 µM in all buffer systems used. The solute was electroosmotically infused at ~ -275V cm^{-1} in all studies to approximate the actual conditions in a CE-ESI/MS experiment.

The results for the 3^+ charge state of M-K-Bradykinin obtained using the NH_4OAc/HOAc buffer systems (pH = 4.7) are summarized in Figure 1 where the signal-to-background (S/B) is shown as a function of buffer concentration for both a sheath and sheathless ESI interface. The lighter and darker shaded bars represent the results obtained using 100 µm and 10 µm i.d. capillaries, respectively. From Figure 1 several important observations are made: 1) analyte signal intensity decreases with increasing buffer concentration and ionic strength, as commonly known, 2) the use of smaller i.d. capillaries does not degrade analyte detectability and in some cases enhances detectability (cf. the 10 mM case), and 3) the sheathless interface appears to offer better analyte detectability for this buffer system (cf. the 1 mM case).

Shown in Figure 2 are the total ion electropherograms obtained from a tryptic digest of *Candida krusei* cytochrome *c* when 10 mM HOAc (pH 3.4), 10 mM NH_4OAc/HOAc (pH 4.7), and 1 mM Na_2HPO_4 (pH 6.0) are used.; in addition, the mass spectra acquired for the solute zones 2 and 8 while using 10 mM NH_4OAc/HOAc are also shown. The separations are performed in a 20 µm i.d. capillary at -270 Vcm^{-1} with a sheathless ESI interface. The mass spectrometer in each case was scanned from *m/z* 400–1100 in 2 *m/z* steps at 1 s/scan. As noted previously, and as

can be seen in Figure 2 from the relative intensities, the analyte response decreases as the concentration and ionic strength increases for a buffer system. Still, the S/B is sufficient to allow detection of the tryptic fragments with the three buffer systems.

We have examined and demonstrated that a variety of buffer systems may be utilized for CE-ESI/MS. Moreover, in many cases where a buffer system has a high ionic strength the combination of small i.d. capillaries, which provides a simple method to reduce the effluent mass flow entering the electrospray interface and enhances the overall ionization efficiency, and a sheathless ESI interface server to provide significantly better analyte detectability.

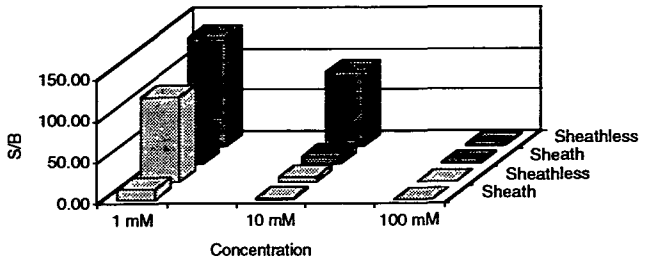

Figure 1 The signal-to-background (S/B) results for the 3^+ charge state of M-K-Bradykinin using the NH_4OAc/HOAc buffer systems. Legend: 100 µm i.d. ▒ 10 µm i.d. ■

On-Capillary Isotachophoresis for Sample Clean-Up and Loadability Enhancement in Capillary Zone Electrophoresis/ Electrospray Mass Spectrometry

M.H. Lamoree[1], N.J. Reinhoud[1], U.R. Tjaden[1], W.M.A. Niessen[1] and J. van der Greef[1,2]

1. Division of Analytical Chemistry, Leiden Amsterdam Center for Drug Research, P.O. Box 9502, 2300 RA Leiden, The Netherlands
2. TNO-CSIA, P.O. Box 360, 3700 AJ Zeist, The Netherlands

Introduction

The coupling of capillary zone electrophoresis (CZE) to mass spectrometry (MS) provides an analytical technique that combines the high separation efficiency characteristic of CZE with the high selectivity of mass spectrometric detection. A major drawback of CZE is the limited loadability, resulting in poor concentration detection limits. An increase in sample loadability can be achieved by electrophoretic analyte focusing procedures such as isotachophoresis (ITP) and stacking. On-line ITP-CZE-MS in a dual capillary system for improvement of detection limits in CZE-electrospray-MS has been presented at this conference last year. In this presentation, an ITP-CZE procedure in a single capillary prior to electrospray MS analysis is described. The applicability of ITP-CZE-MS as a trace analysis technique is illustrated for some β-agonists. The ITP-CZE-MS approach is applied to the analysis of β-agonists in calf urine.

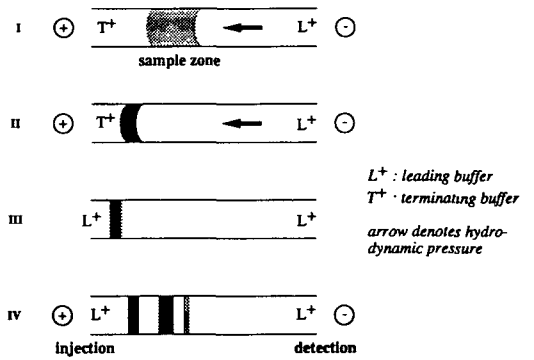
Experimental

A Finnigan MAT SSQ 710 mass spectrometer, equipped with an electrospray interface and operated in the positive ion mode, was used.
ITP analyte focusing and CZE were carried out in a 740 mm x 100 µm I.D. fused-silica capillary. The capillary inlet served as the anodic end, while the electrospray needle was at ground potential. Buffer systems: CZE buffer: 80% methanol in 50 mmol/l ammonium acetate (also ITP leading buffer), ITP terminating buffer: 80% methanol in 50 mM β-alanine (pH 4.8).

ITP-CZE

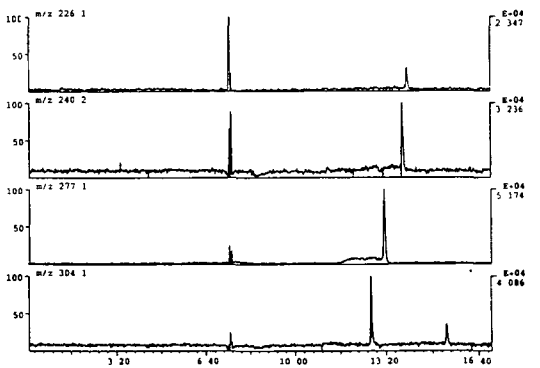
The procedure of single-capillary ITP-CZE consists of 4 steps (see Figure):

1. injection of the sample between leading and terminating buffer, starting isotachophoresis with hydrodynamic pressure from detector side (via height difference, Δh) to counteract both the electroosmotic flow and the electrophoretic migration.
2. hydrodynamic mobilization of sample zone towards the inlet side, removal of terminating buffer, sample cleanup by removal of slowly migrating ionic constituents.
3. *replacement of terminating by leading buffer.*
4. separation of analytes by zone electrophoresis and detection by electrospray mass spectrometry.



ITP-CZE-MS

In ITP-CZE-MS it is important to have identical composition of leading buffer and sheath flow to allow application of hydrodynamic pressure in the ITP step without disturbing the continuity of the buffer system.



Injection of 870 nl of a 80 ppb test mixture containing all β-agonist (injected amount 70 pg of each analyte); ITP conditions: 5 kV, 600 s, Δh=100 mm

Conclusions

Enhancement of sample loadability by ITP leads to a 100-fold improvement in concentration detection limits for the β-agonists. On-capillary ITP shows to be a promising approach for loadability enhancement in CZE-MS. Further optimization of the system is currently under investigation.

Design and Construction of a Thermospray-type Interface for On-line Capillary LC/MS.

Alain carrier and Michel J. Bertrand, Regional Center for Mass Spectrometry, Department of Chemistry, University of Montréal, Montréal, Canada, H3C 3J7.

The development of techniques allowing the introduction of liquid samples into the ion source of a mass spectrometer has considerably increased the range of compounds that can be analysed by mass spectrometry. Previous work (1) in our laboratory has lead to the development of a simple and inexpensive DLI system that uses a conventional GC/MS interface. Experiments conducted with this system have demonstrated that it is extremely stable, reproducible and allows picogram range sensitivity for low molecular weight compounds. However, this interface has limitations for the analysis of polar compounds. In order to allow the analysis of thermally labile or involatile compounds the design and the construction of a capillary thermospray-type interface such as that developed by Vestal and coworkers (2) was undertaken. The capillary thermospray-type interface developped is schematicaly shown in Figure 1. The interface consists of a fused-silica capillary tubing (10µm) which is introduced directly into a CI source throught the solid probe inlet and is oriented in the beam axis. The heating of the interface is provided by the ion source and ionization is achieved using external mode ionization (filament-on mode). In order to evaluate the system and to determine its optimum operating conditions, the influence of several parameters that are known to have an effect on the overall performance was studied.

The effect of the temperature of the interface, which is provided by the heating of the ion source, was studied. As it can be seen from Figure 2, which shows the intensities of the solvent ions versus the source temperature, all ions reached a maximum intensity in the same region (140-160 ºC). This region was found to provide extremely stable operating conditions. Partial to severe instability was encountered on both sides of this temperature range. Another factor that was found to have an effect on the stability is the flow rate. The flow rate in the system has an effect on the ion source pressure which can affect the composition of the plasma and therefore the ionization characteristics of the system. Result indicates that the range of flows corresponding to stable conditions is found to be between 2 and 6 µL/min. Experiments were also conducted at

different distance between the orifice of the interface and the ion exit slit to determine its effect on the overall performance. It has been found that the ion intensities increase with the sampling distance up to a certain point (12,5 mm) at wich a drop in intensities occurs. In order to evaluate the potential of the interface for the characterization of organic compounds several experiments have been conducted. Mass spectra obtained for a series of test compounds were found to be in all points comparable to those obtained under typical thermospray conditions as shown in Figure 3. Good sensitivity was obtained with the interface developped. Detections limit of 5 to 30 pg were obtained for caffeine, adenosine and chloramphenicol in single ion monitoring. The performance of the capillary thermospray-type interface developped is satisfactory. It is easy to operate and provides reliable results.

Design of Electrospray Interfaces for Finnigan-MAT TSQ-70 and VG-ZAB MS

Sharon Jackett, Longfei Jiang, Mehdi Moini
Department of Chemistry and Biochemistry, University of Texas at Austin, TX 78712

The design of an electrospray interface for the Finnigan-MAT TSQ-70 and VG-ZAB mass spectrometers is described.

A. The thermospray (TS) ionization feature of a Finnigan-MAT TSQ-70 mass spectrometer was converted to electrospray ionization (ESI) utilizing the existing source, pumping capacity (using only one mechanical pump), flanges and temperature controller of the TSQ-70 TS feature with a few minor modifications.

The solid-probe design of the ESI interface (Figure 1) produced the pressure required in the first stage of pumping to obtain adequate signal intensity, resolution, and peak shapes. The adequacy of this design in terms of pressure is demonstrated using gramicidin S as the analyte. The doubly charged gramicidin S produced a very strong signal at 572 m/z at picomole level. The optimum signal intensity, resolution, and peak shape were obtained by adjusting the distance between the end of the heated capillary tube and the skimmer. At a distance of ca 4 mm, the pressure in the first stage of the vacuum system was ca 3-5 torr. This pressure along with the existence of a 0.5 mm orifice between the first and second stage, produced vacuum conditions identical to the normal operating conditions of the MS in the chemical ionization mode.

Overall quality of the ESI-generated spectrum is shown in the spectrum of cytochrome C from horse heart (Mw 12,361 Da) in methanol+water+acetic acid (Figure 2). This spectrum is similar to spectra of cytochrome C reported in previously published literature, but shorter scan rates are used in the present experiment The high signal-to-noise ratio of this spectrum allows much faster scan rates. At a scan rate of 1 scan/sec, a signal to noise ratio of approximately 3:1 was observed. Fast scan times (< 1 s) are especially useful when ESI is combined with separation techniques such as capillary zone electrophoresis in which chromatographic peak widths are only a few seconds

In summary, we attribute this enhanced sensitivity and greater ease of operation to the alignment of the ion optics, use of a single mechanical pump, and the mounting of the system on a solid probe. Conversion of the commercial TS option to a simple and economically viable ES option, has made the analysis of large biomolecules possible without expensive upgrades. Mass spectrometric results of low and high molecular weight biomolecules, the mass accuracy, sensitivity, and charge states of the observed ions are comparable to existing published results by other laboratories.

B. The electrospray interface for the VG-ZAB double focusing mass spectrometer is as follows: The electrospray needle is held at a potential of +5 kV relative to the potential of the heated stainless steel capilary tubing. The charged droplets enter the stainless-steel heated capillary tube which is held at a potentail of ca. 4200 V, through which they are transported into the ESI source. The electrospray source consists of two pumping stages. The region between the heated capillary and the first skimmer defines the first stage and is pumped by a mechanical pump to a pressure of ca. 20 torr. This pressure is advantageous because it is too high to sustain an electric discharge. The second stage of pumping, the region between the

first and second skimmers, is pumped by a small diffusion pump to pressures at which molecular flow predominates (<10^{-3} torr). The use of the two pumping stages held at these pressures allows overstepping of the discharge zone, and thus there is no need to float pumps. The other focusing elements of the source are those of the commercial FAB source of the ZAB mass spectrometer. The entire source including heated capillary, skimmers and lens elements are mounted on the source flange, and all voltages are provided by the existing VG power supplies. This feature makes it possible to quickly change from ES to other ionization modes. The system is also capable of operating in counter flow of heated gas modes of desolvation. Figure 3 shows our preliminary results of ES ionization of gramicidin S.

Linear Calibration curves using Particle Beam LC/MS.

***Thomas C. Marecic, Ross C. Willoughby, Stephen M. Penn , Millipore/Extrel Mass Spectrometry, 575 Epsilon Drive , Pittsburgh, PA 15065**

Introduction: It has been reported that, as a quantitative tool particle beam is hindered by non-linear calibration curves. Linearity has been achieved through the coelution of a compound with an excess of its isotopically labeled analog[2]. In our laboratory we have demonstrated linear calibration curves for benzidine and caffeine using a particle beam LC/MS system without the use of coeluting compounds. These data support a Band Pass model which relates analytical response with transmission efficiency of the interface.

Band Pass Model: The Band Pass model correlates analytical response to mass transport efficiency of a particle beam LC/MS interface. Figure 1 shows analytical response curves from the model. The ideal curve shows the upper limit of response assuming 100% transport of the analyte through the interface. The band pass limit curve shows three distinct regions of response. There are two non-linear regions at the ends of the curve with a linear one in the middle. A transmission curve can be constructed from the analytical curve (figure 2) using the following equation for transmission efficiency of particles through the interface.(ε_{trans}),

$$\varepsilon_{trans} \propto \text{Intensity/concentration}$$

From this band pass curve it is evident that as long as the interface is operating in the linear region, transmission of analyte is independent of particle size, hence a linear analytical curve. On the other hand, if the analytical region of interest is in the lower region of the curve, response of the analyte is particle size dependent, and the resulting curve will be non-linear. It has also been demonstrated[2] that an interface can be operated in the lower concentration region of the Band Pass curve and give linear response. This is provided there is a carrier compound to increase the particle size into the region of constant transmission efficiency. It is worth nothing that the shape of the Band Pass curve is interface dependent.

Experimental: The linearity data was run on an Extrel **benchmark** LC/MS using a prototype particle beam interface. The HPLC system was a WATERS 600ms. The mobile phase was a 50:50 mixture of water and acetonitrile flowing at 0.5ml/min.

Results: Plotted in figure 3 are the analytical curves for benzidine on two different interfaces. Over the concentration range shown the data from the Extrel interface is linear to ≈ 5ng. This concentration range is near the limit of detection for benzidine on this instrument, while the data from reference 2 is curved with lowest data point at 18 ng.
The linearity of the Extrel data can be attributed to the interface operating in the flat region near the volatility/dispersion loss end of the Band Pass curve, while the other interface is apparently operating in volatility/dispersion loss region of the Band Pass curve. Plotted in Figure 4 are the transmission efficiency curves for both interfaces. The curve for the Extrel interface shows a flat region where ε_{trans} is independent of particle size and hence concentration. For the interface used in reference 2 it appears that there is a dependence of ε_{trans} on particle size over the specified concentration range.

Conclusion: The Band Pass model can be use to explain both linear and non-linear particle beam data based on the dependence of the transmission efficiency on particle size . On the Band Pass curve there are regions where transmission is independent of particle and hence the analytical curves tend to be linear. With the new Extrel particle beam interface it is possible to quantitate linearly close to the detection limits of the mass spectrometer.

Hydrogen /Deuterium Exchange in Electrospray Ionization Mass Spectrometry as a Practical Tool for Structure Elucidation

James J. Conboy, Mark F. Bean, Mark E. Hemling, and Steven A. Carr,
Department of Physical and Structural Chemistry,
SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

Measurement of the number of active hydrogens in a molecule by various types of hydrogen/deuterium exchange experiments has for a number of years proven useful in the elucidation of compounds of unknown structure, in the determination of the mechanism of chemical or biological reactions, and in the interpretation of fragmentation pathways in mass spectra [J. A. McCloskey, *Methods in Enzymology*, **193**, 329 (1990)]. Various means for making such measurements have been developed for nearly every ionization/sample introduction method that has been widely used including EI, CI, FAB, thermospray, particle beam, GC/MS, and LC/MS. Recent work in the analysis of protein conformation by ESIMS has made use of both solution phase and gas phase (atmospheric pressure or *in vacuo*) hydrogen/deuterium exchange methods. The gas phase exchange experiments were performed either on FTMS instrumentation to achieve the long residence times required for exchange or with a heated dual-capillary inlet reactor interface for desolvation and then exchange of the sample molecules. We have implemented methods for hydrogen/deuterium exchange which require only simple changes to the plumbing of our Sciex API-III Ionspray source. Effective exchange of active hydrogens may be achieved by replacing either all of the nebulizer gas or part of the curtain gas or both with a deuterated exchange agent such as ND_3. These methods provide for essentially complete exchange of all active hydrogens on the types of small molecules (e.g., alkaloids, glycosides, etc.) for which H/D exchange has been of proven utility in structure elucidation work; larger molecules, or at least those with a large number of potentially exchangeable hydrogens, proved to be more challenging particularly in regard to completeness of exchange. These methods also appear to work without the need for dissolving the sample in deuterated or aprotic solvents. A simple ESIMS H/D exchange experiment is a useful addition to the mass spectrometrist's armamentarium for the elucidation of unknown structures. With it, H/D exchange is now extended to classes of compounds not amenable to FAB or DCI, especially in cases where sample is limited.

EXPERIMENTAL Nebulizer Exchange: Samples were dissolved in elution solvent (50/50 CH_3OH/H_2O with 0.2% HCOOH; or 50/50 CH_3CN/H_2O, 95/5 CH_3CN/H_2O, or 90/10 $CHCl_3/CH_3OH$ with 5 mM NH_4OAc) and introduced by loop injection (2-3 µL/min) into the ion spray interface. Nebulizer gas (30-35 psi) was toggled from zero air to ND_3 (29-30 psi) after the signal maximized and then back to zero air after ~10 scans. Residual gas was removed from the interface region by the exhaust fan.

Curtain Exchange: Samples were introduced as described above. ND_3 exchange gas was added to the N_2 curtain by a flow controller (1--10 %curtain flow) with simultaneous increase of the declustering potential (OR - R0 = 120--220 V) to reduce clustering and adduction and to increase the extent of exchange. Residual gas was removed completely only after a recycle of the cryopumping system.

General: All components used in the modifications to the interface plumbing were selected to be compatible with ND_3, e.g., stainless steel, indium, Teflon, and glass. ND_3 was obtained from Isotec (99+%; Miamisburg, OH) or Cambridge Isotopes (99%, Woburn, MA).

RESULTS/DISCUSSION Nebulizer Exchange: During flow injection of a sample, H/D exchange is readily effected by switching the nebulizer flow from air to ND_3 for several scans, then switching back to air, thereby providing both normal and exchanged data in a single experiment. For some compounds this leads to noticeable suppression or enhancement of ionization which can be useful for selecting scans for analysis. The exchange is effected very quickly which can be important for reducing gas consumption -- the nebulizer method uses ~0.7 L/min of ND_3. Effective exchange can be observed for most of the molecules tested (Table I) including exchange of amides on the smaller peptides.

Curtain Exchange: H/D exchange can also be effected by introducing ND_3 as a portion (1-10%) of the curtain gas. It was thought that H/D exchange at the atmosphere/vacuum interface would be a way to reduce possible back exchange and to decouple the exchange reaction from any effect the ND_3 gas might have on the desorption/ionization process. Introduction of ND_3 in this region can cause significant clustering $[n(ND_3) + ND_4^+]$ and adduction $[(M + D)^+ + n(ND_3)]$ to be observed. Increasing the declustering potential helps to eliminate the clustering and reduces the adduction. If increased too much, fragmentation may also be induced as evidenced by the water loss ($-D_2O$) peak observed. Increased

declustering potential can also be used in combination with increased curtain ND_3 concentration to drive the exchange process toward completion for the more refractory molecules. Curtain H/D exchange is effective for small molecules with "active" hydrogens. The larger molecules are more difficult to exchange effectively as were the peptides which contain less active amide hydrogens. Notable exceptions to this are the nucleotides which were both exchanged nearly completely in the negative ion mode.

Curtain H/D exchange suffers from residual gas effects, particularly when the plenum is configured with a Teflon/Viton O-ring seal rather than the Macor/indium configuration used in most of the experiments. Residual ND_3 can be observed to exert its effects for several hours after the gas has been turned off. Nevertheless, the reduced gas consumption (1-10% vs. nebulizer exchange experiments) makes this method suitable for cases where prolonged lifetimes of exchanged species are required, e.g., MS/MS experiments; if done at the end of the day, the instrument is completely recovered by the next morning. Other ways of introducing the ND_3 to the orifice more directly may reduce the recovery time.

General: ESI gas phase H/D exchange compares favorably with our experiences with DCI and FAB H/D exchange results. Both of these other methods work well for small molecules or molecules with few exchangeable hydrogens. ND_3-DCI seems to be limited mainly by the type and size of molecules that are amenable to DCI; however, it can be a more vigorous process, exchanging hydrogens on carbons which are activated by other substituents. FAB exchange experiments seem to be limited by more basic problems including possibly slow exchange, back exchange, reduction processes, radiation damage related processes, etc. Our initial experiments with ESI solution phase H/D exchange showed relatively poor exchange. This may have been due to back exchange problems or poor initial exchange conditions; we have not yet attempted to pinpoint the source of the incomplete exchange results

CONCLUSION ESIMS gas phase H/D exchange is an effective way to determine the number of exchangeable hydrogens on small molecules and to exchange many of the active hydrogens on larger molecules. For compounds containing more than a few active hydrogens, ESI gas phase exchange via the nebulizer is, in practice, simpler and more efficient than FAB H/D exchange. Improvements to the curtain exchange experiment to improve the effectiveness of the exchange process and combination of one or both of the gas phase experiments with an optimized solution exchange technique may provide a universal method for complete and effective exchange of molecules of all types and sizes.

ACKNOWLEDGEMENT The authors wish to thank M. Mentzer for providing the DCI measurements and for assaying the ND_3 gas prior to use

Ion Source Effects on β-Lactam and Macrolide ESI Mass Spectra

*Y. Shida[1] and K. O'Hara[2], Depts. of Chemical Analysis[1] and Microbiology[2], Tokyo College of Pharmacy, Tokyo, Japan, and
C.E. Parker and K.B. Tomer, Laboratory of Molecular Biophysics, N.I.E.H.S., P.O. Box 12233, Research Triangle Park, NC 27709

Penicillins, cephems, and macrolides are important antibiotics for both human and animal use. As part of a study on the utility of electrospray mass spectrometry for the structure determination of the β-lactams and macrolides, ESI/MS spectra of a series of these compounds were obtained on a VG 12-250 mass spectrometer equipped with a Vestec electrospray source and controller, using skimmer voltages of +10V to 40V. ESI/MS and ESI/MS/MS spectra of the same compounds were obtained on a Finnigan/MAT TSQ700 triple quadrupole mass spectrometer using argon as the collision gas, and a series of collision energies from 0 eV to -40 eV.

Vestec skimmer-induced CID ESI/MS spectra of penicillins and macrolides were in good agreement with ESI/MS/MS spectra obtained on a triple-quadrupole mass spectrometer. There was no selection of the parent ion in the single quadrupole, however, so a composite spectrum resulting from CID on all of the ions present in the source was observed.

Because the Vestec skimmer also functions as a repeller, it is not possible to obtain spectra with zero skimmer voltage or zero collision energy. While this effect may not be as apparent on larger molecules, such as proteins, it leads to some CID contribution to the ESI/MS mass spectra of easily-fragmented molecules.

Thus, while we were able to closely match the TSQ MS/MS spectra with the Vestec CID spectra, we found that we were unable to duplicate the TSQ ESI/MS spectra on the VG 12-250 with the Vestec source. In general, the Vestec ESI spectra most closely matched the TSQ spectra obtained at ~5-10 V higher collision energies (Figure 1).

An additional effect noted was that the sodiated species were often of higher relative abundance in the TSQ700 mass spectra. In some cases, this effect was so pronounced that CID and MS/MS spectra could not be obtained from the same parent ion in both instruments.

TYROSINASE-CATALYZED HYDROXYLATION OF LEUCINE ENKEPHALIN: ELECTROSPRAY IONIZATION MASS SPECTROMETRIC IDENTIFICATION OF THE REACTION PRODUCTS

Véronique Larsimont, Günther Hochhaus and Laszlo Prokai,
Department of Pharmaceutics and Center for Drug Discovery,
University of Florida, Gainesville FL 32610

The enzyme tyrosinase catalyses the ortho-hydroxylation of phenols and the subsequent oxidation of the resulting catechols to o-quinones It is common throughout nature and plays a central role in the biosynthesis of both norepinephrine and melanin. In addition, our group and others have shown that tyrosinase will react with tyrosine-containing peptides, including enkephalins, to give hydroxylated products [1-4]. It is known that enkephalins are deactivated and metabolised in vivo by aminopeptidases, carboxy-peptidases and enkephalinases [5]. However, since enkephalins and tyrosinase have been found in the same brain regions in some species [6, 7], our goal was to determine the exact nature of the products formed when tyrosinase reacted with leucine enkephalin (LE). Subsequently, as it is known that the integrity of the Tyr[1] residue in enkephalins is essential for interaction with opioid receptors [8, 9], we wished to compare the affinity of these products and leucine enkephalin itself to opioid receptors in rat brain homogenate.

The reaction between LE and mushroom tyrosinase was carried out under the following conditions: 1 mM LE, 50 mM ascorbic acid, 0.1 M potassium phosphate buffer (pH 7), 32 mg/ml mushroom tyrosinase at room temperature with constant shaking. The reaction was stopped after 1 hour by adding 66 ml of 1 M HCl per ml of incubation solution.

Chromatograpic separation of LE and the reaction products was realized using a Partisil 5 ODS-3 125 x 4.6 mm column (Whatman), a mobile phase of 12 5% acetonitrile (v/v) in citrate/dipotassium phosphate buffer (pH 5) at a flow rate of 1ml/min, and UV detection at 254 nm. In a control run, ascorbic acid was seen to elute in a large solvent front at 1 4 minutes and LE eluted with a retention time of 9 5 minutes. When the incubation mixture was applied to the system, two distinct additional peaks were seen on the chromatogram with retention times of 5 7 minutes and 7 3 minutes respectively.

For the isolation of the reaction products, aliquots of the incubation solution described above were applied to the HPLC system and the product peaks were collected and pooled according to their retention times The collected peaks were concentrated under a stream of nitrogen and purified using a Sep-Pak C_{18} cartridge prior to mass spectrometric analysis

A Vestec 200ES instrument (single quadrupole, 2000 Da mass range, Technivent VECTOR/ONE Data System) was used to obtain ESI mass spectra under the following conditions: Flat-tipped hypodermic needle (0 005 in i.d. x 0.010 in o d. x 0 75 in long) at 2.4 kV potential, spraying solvent of 3% AcOH in MeOH/H_2O (7/3 v/v), source block temperature of 250°C, spray chamber temperature of 50-65°C and repeller voltage at 18V for normal ESI and 50V for CID [10]. Electrospray ionization mass spectrometry provided intact molecular ions of LE and the products of the enzyme reaction and selective fragments were obtained by collision induced dissociation. The identification of the hydroxylated products of LE was achieved by comparing the ESI mass spectra obtained to those of the parent peptide The mono-hydroxylated enkephalin ([HO-Tyr[1]]-LE) gave molecular ions at *m/z* 572 and 594 for

$[M+H]^+$ and $[M+Na]^+$, respectively (Fig 1) compared to *m/z* 556 and 578 for the corresponding molecular ions in the parent enkephalin Under CID conditions (Fig 2), a 16 Da increase was also observed in the *m/z* value of the a and b sequence ions, starting with the a_1 ion of the series (*m/z* 152). On the other hand, the internal fragments *m/z* 120 and 177 are not affected. This is evidence that the phenylalanine moiety has not been modified. Therefore, the oxygen was incorporated, as expected, into the [Tyr[1]] residue. The ESI mass spectra recorded from the second product of the enzymatic reaction ([$(HO)_2$-Tyr[1]]-LE) have indicated, based on the 32 Da increment in *m/z* of the molecular ions as well as the a and b sequence ions when compared to the parent enkephalin, that additional hydroxylation also took place at the N-terminal tyrosine. The relative intensity of the peaks obtained from mass spectrometric analysis showed that [$(HO)_2$-Tyr[1]]-LE was a minor product and therefore, sufficient quantities could not be collected for use in receptor binding studies. The results of the binding studies indicated that the hydroxylation of LE by tyrosinase reduces its affinity to receptors in rat brain homogenate by a factor of 17.

Analysis of Mureidomycin Antibiotics by Ionspray Mass Spectrometry.

Duncan K. Bryant (1), Catherine S.V. Frydrych (2), and Gerald Risbridger (2).
SmithKline Beecham Pharmaceuticals, (1) Old Powder Mills, Tonbridge, Kent TN11 9AN, United Kingdom, (2)Brockham Park, Betchworth, Surrey RH3 7AJ, United Kingdom.

Atmospheric Pressure Ionisation Mass Spectrometry (API/MS) is proving to be a versatile ionisation technique for the analysis of a wide range of pharmaceutical compounds[1]. API/MS has been successfully applied here to the study of a class of antibiotic compounds called mureidomycins (1). These compounds, isolated as metabolites from a culture and purified by HPLC, were found to give a positive response to a translocase inhibitor screen. The structure contains m-tyrosine residues at both the N- and C-termini in addition two highly modified residues in-between. Firstly there is an unusual N-methylated diamino acid with an enamine-sugar uracil or dihydrouracil group as the side chain. Then moving towards the C-terminus there is a methionine residue that is reversed with its nitrogen linked to the C-terminal tyrosine residue via a ureido bond.

Ionspray proves ideal for providing rapid and unambiguous molecular weight data for challenging samples. The high sensitivity of the technique is also important for the analysis of culture metabolites that are often only available on the nanomole scale. Fast atom bombardment (FAB) can also be used to obtain spectra[1] although the sensitivity is considerably lower.

Ionspray Mass Spectrometry was performed on a Sciex API-III triple quadrupole mass spectrometer (Toronto, Canada). About 10-100pmol of sample was used for analysis. The eluant used for both positive and negative ion modes was generally 50% MeCN/50% 1%HOAc(aq) flowing at 20mL min^{-1}. In positive ion mode the ionspray voltage was 5kV and the orifice voltage was set at 70V. In negative ion mode the ionspray voltage was -4.5kV and the orifice voltage was varied between -70 and -120V. CID MS/MS was performed using argon as the collision gas at a thickness of $6x10^{14}$ atoms cm^{-2}.

The positive ion mode MS/MS ionspray spectrum of mureidomycin B is shown in Figure 1. A protonated molecule is observed at 843Da indicating a molecular weight of 842Da. It can be seen that there is extensive fragmentation of the backbone of the molecule that is analogous to the behaviour observed with peptides when subjected to low energy CID in triple quadrupoles[2]. However, unlike peptides, mureidomycins appear to exhibit sidechain fragmentation. The enamine-sugar-dihydrouracil moiety undergoes considerable fragmentation upon collision induced dissociation. Similar fragmentation patterns are observed for other members of the mureidomycin family. In negative ion mode ionspray of mureidomycin B a deprotonated molecule of 841Da is observed giving an unambiguous molecular weight assignment of 842Da.

The fragmentation of mureidomycins observed in both positive and negative ion modes is, as stated previously, analogous to that of peptides. Table 1 summarises the wide variety of fragment ion types observed in positive ion mode MS/MS including a, b, c, x, and y ions along with imminium ions and sidechain fragment ions. With acidic residues at both termini there is no preference for N- or C-terminal ions.

Fragmentation can also be induced by in-source CID, performed by increasing the orifice voltage. The optimum voltage for in-source CID can be found by ramping the orifice voltage from 20-250V. The optimum value for mureidomycins appears to about 150V that is much higher than the value observed for organic molecules[3] (80-120V).

Extracted ion chromatograms can also be used to observe the onset of CID in the tandem MS/MS experiment. By varying the argon collision gas thickness, one can observe the onset of decomposition of the pseudo-molecular ion. It was found that optimal fragment ion formation occurs at a gas thickness of about $4.5x10^{14}$ atoms cm^{-2}. This is somewhat higher than that observed for organic molecules[3].

The Use of Electrospary-Mass Spectrometry for the Analysis of Pharmaceuticals, Proteins and Peptides

Paul C. Goodley and Steve Fischer, The Hewlett-Packard Co., Scientific Instruments, Palo Alto, CA, 94304

Electrospray ionization (ES) has not only expanded the mass range of conventional mass spectrometers (ms) by a factor of 40 It has also increased the applicability and sensitivity by the same factor For compounds which were either difficult or nearly impossible to analyze by ms a short year ago, can now be easily analyzed in a few minutes by ES-MS Experimental drugs and pharmaceuticals such as antibiotics and anticancer or tumor treating drugs can be analyzed directly using ES-MS

Compounds such as Taxol, Taxol metabolites, Vinblastine, and antitumor alkaloids and metabolites can be analyzed by ES-MS within minutes of collection or purification. Antibiotics such as Lincomycin, Erythromycin, Tobramycin, Penicillin G, Hydrogromycin B and Tetracycline can easily be analyzed from crude extracts by ES-MS The data from these compounds may be quantified using internal standards as references to less than five percent (5%) relative standard deviations (RSDs) For small proteins and peptides, be they natural or synthetic, and having mass less than 10,000 Daltons (DA), the same techniques may be applied to yield excellent quantitative data having RSDs less than eight percent without using internal standards When internal standards are used, the RSDs will drop below five percent

The low RSDs are a result of the ion source design where-by the electrospray chamber, which is at atmosphere pressure, is isolated from the high vacuum system and the ion lens system The pressure of the exiting gases and ions is held very stable. Figure 1 shows the detailed ion source The ions are generated in the Electrospray Chamber and transfered to the Capillary Exit region near the CID Supersonic Zone of Silence as shown in Figure 1 below.

Fig. 1

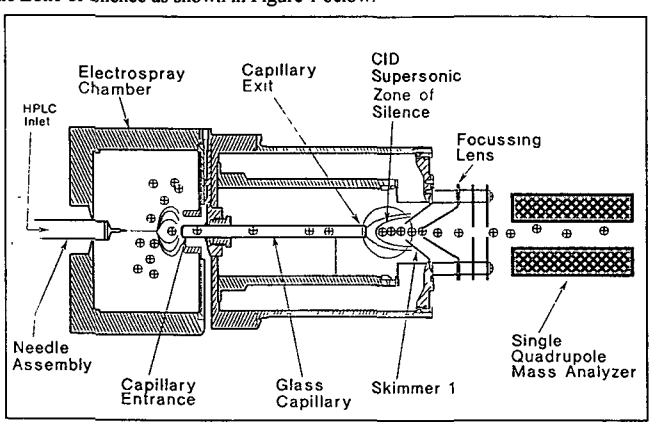

Figure 2 below shows three examples of using ES-MS with an untrasound droplet generator using the antibiotic, Lincomycin. Three sets of examples are shown. The top example set shows the extracted parent molecular adduct ion of Lincomycin at m/z 408, followed by its' full scan mass spectrum. The top trace in each set is a flow injection in which the peak elutes in 10 seconds or less. Each subsequent sets of data are similar, but the concentrations decrease from 100 nanograms per injection to 100 picograms for the last set of data. Detection levels are obvious for the full scan mode at ca 100pg.

USE OF AN ON-LINE LIQUID CHROMATOGRAPHY TRAPPING COLUMN FOR ELECTROSPRAY MASS SPECTROMETRIC ANALYSIS OF CYTOKINE MEDIATORS INVOLVED IN INFLAMMATORY SKIN DISORDERS.

*I. Kay, M. Judge, A.I. Mallet and M.W. Greaves, St John's Institute of Dermatology, UMDS, University of London, St Thomas' Hospital, London SE1 7EH, England.

INTRODUCTION

We are currently investigating the use of ESI-MS for the identification, at the molecular level, of a family (chemokine) of cytokines with pro-inflammatory activities. These cytokines are characteristically basic, heparin binding, range from 8-10 kDa in molecular weight and have been implicated as mediators involved in inflammatory skin disorders.

The isolation procedures used in the extraction of cytokines, from biological matrices, give rise to samples which can contain a number of non-peptide components such as salts, ion-pairing reagents, detergents or preservatives. It is accepted that the efficiency of electrospray ionisation is affected by these substances. We describe here a method which circumvents this problem.

METHODS

Electrospray Mass Spectrometry

ESI-MS analysis was performed on a VG Masslab Trio 2, fitted with a VG Biotech ESI source (Fisons Instruments, UK). Peptide samples were introduced into the ESI-MS source in 50:49:1 acetonitrile/water/acetic acid v/v/v, containing 1 pmol/µl gramicidin S (ESI running solvent). An Isco model SFC-500 micro flow pump (Jones Chromatography, UK) was used to deliver the solvent at a flow rate of 7.5 µl/min. Gramicidin S was used to tune the instrument. The electrospray needle was held at 4 kV relative to the source and a cone voltage of 65 was applied. Ubiquitin was used as a calibrant. Unless otherwise stated ubiquitin, cytochrome C, and myoglobin were monitored using selected ion recording (SIR) at m/z 857, 824, and 893 respectively.

LC Trapping Column

The trapping column system (Figure 1) comprised a Rheodyne (model 8125) injection valve with 500 µl loop, a Rheodyne (model 7000) 6-way switching valve, and a microbore column (1 x 50 mm) packed (in house) with porous poly(styrene/divinylbenzene) PLRP-S (8 µm particle size, 300 °A pore size). Samples, diluted with water, if necessary, were loaded onto the column via the 500 µl injection loop. The column was washed for 3 minutes with acetonitrile/water/acetic acid 15:84:1 (v/v/v) using a Waters model 501 pump (500 µl/min). The 6-way valve was then switched and bound material was eluted off the column with ESI running solvent.

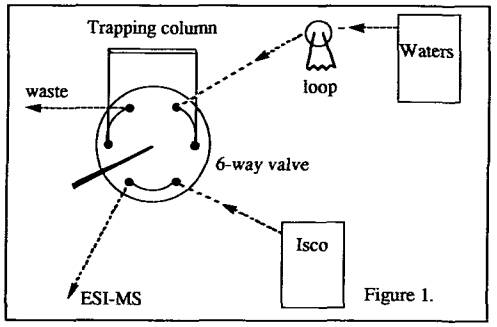

Figure 1.

Reagents Studied

The effects of various reagents (Table 1) on the efficiency of electrospray ionisation of three model peptides, ubiquitin, cytochrome C, and myoglobin were assessed directly and in conjunction with the on-line trapping column.

Extraction of chemokine peptides

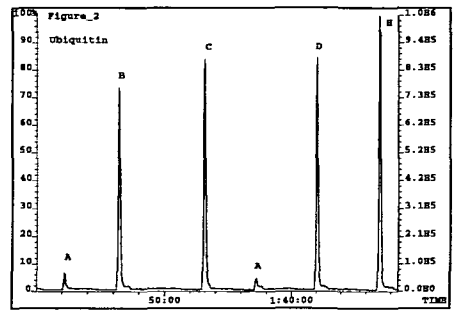
Stratum corneum samples from healthy individuals and skin scale samples from Psoriatic patients were homogenised in 0.1 % TFA in a glass homogeniser, and centrifuged at 12,000 x g for 15 min. Supernatants from skin extracts were filtered (0.45 µm), concentrated, and applied to heparin affinity columns in 50 mM tris buffer (pH 8). The column was washed in buffer and bound material was eluted in buffer suplemented with 0.65 M NaCl. This material was chromatographed on Aquapore RP-8 and resultant HPLC fractions were analysed using the trapping column.

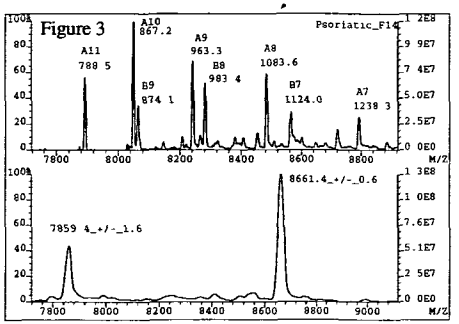
RESULTS

The effect of reagents (Table 1) on the efficiency of electrospray ionisation of ubiquitin, cytochrome C and myoglobin was determined using duplicate injections (10µl) for each peptide in the absence and in the presence of reagent. The results, presented in Table 1, are expressed as the % decrease in ESI signal intensity observed when peptides were analysed in the presence of reagent. The ability of the trapping column to remove ionisation suppressing reagents from ubiquitin (20 pmol) samples prior to ESI-MS is shown in Figure 2. A, Blank; B, Pure peptide; C, 0.1% TFA; D, 100mM phosphate; E, 0.2% Na azide containing samples. Similar results (not shown) were obtained with cytochrome C and myoglobin. The trapping column system has been used in the analysis of HPLC fractions derived from psoriatic scale extractions. An example is shown in Figure 3.

Table 1

Reagent	Conc. (%)	Peptide	Reduction(%)
TFA	0.01	Ubiquitin	93
		Cyto. C	90
		Myoglobin	62
Phosphate	10 mM	Ubiquitin	76
		Cyto. C	71
		Myoglobin	73
Na azide	0.02	Ubiquitin	58
		Cyto. C	68
PEG	0.005	Ubiquitin	66
SDS	0.01	Cyto. C	54





DISCUSSION AND CONCLUSIONS

We have demonstrated that the presence of salts, ion-pairing reagents, preservatives, or detergents can be detrimental to the efficiency of electrospray ionisation of peptides. This confirms the work of several other groups of workers. We have successfully circumvented this problem by using a trapping column which allows the removal of ionisation suppressing reagents from peptide samples prior to their analysis. Furthermore cytokines have a propensity to adsorb onto surfaces, particularly when taken to dryness. The trapping column system eliminates the requirement for samples to be taken to dryness as repeated injections onto the column enable peptides to be concentrated prior to ESI-MS. We are currently attempting to identify chemokine peptides in biological matrices with on-line LC trapping ESI-MS.

Analysis of Synthetic Peptide Impurities Using Capillary Electrophoresis/Electrospray Mass Spectrometry

Kenneth J. Rosnack, Justin G. Stroh
Glenn C. Andrews and David H. Singleton
Pfizer Inc, Groton CT 06340

We have constructed a CE/MS system based on experimental designs found in the literature.[1-3] We present several examples where so called single components were isolated by HPLC but were confirmed as mixtures by CE and CE/MS.

A mixture of Bradykinin and Magainin Spacer Peptide was run to test the performance & reliability of our CE/MS system. The CE/UV, reconstructed total ion electropherogram, and the averaged mass spectra for each component confirmed a working system. The HPLC/UV chromatogram of an isolated synthetic peptide Ac-C(Acm)PNEFTGDRC(Acm)QNYVM-NH_2 indicated a single component sample (99.3% by UV area). Direct infusion ESI/MS analysis of the sample indicated a mixture of desired peptide and a dehydration product. One could question whether the dehydration product is due to fragmentation of the peptide or whether it is indeed an impurity in the sample. The CE/UV and reconstructed total ion electropherograms of the Ac-C(Acm)PNEFTGDRC(Acm)QNYVM-NH_2 peptide sample are presented in Figure 1. The averaged mass spectrum of peak 1 indicated a doubly charged ion *m/z* 971.1 Da. Assuming that the peak is related to the synthesized peptide, the experimental mass of the component is 1941.6 Da, corresponding to dehydration of the intact peptide. The mass spectrum of peak 2 indicated the intact peptide. See Figure 2.

While analyzing a synthetic peptide MVII-C, we observed severe adsorption of the sample to the untreated fused silica. By analyzing the sample on a linear polyacrylamide coated column[4-5], we had virtually eliminated adsorption of this peptide. Coated columns were therefore used in all future experiments.

An HPLC/UV chromatogram of an isolated synthetic peptide, Heregulin-α, indicated a single peptide component at approximately 16 minutes. A CE/UV electropherogram, using a citrate buffer, of Heregulin-α (pI 9.3) also indicated a fairly clean sample. Because the pH of the citrate buffer was much lower than the pI of Heregulin-α and that sodium citrate was not compatible with ESI/MS, a buffer of 20mM ε-amino-n-caproic acid[6] (EACA) pH 4.6 was used. The averaged mass spectra of peaks 1 and 2 gave the same mass indicating the presence of isomers or perhaps, within mass accuracy, a deamidation product. Further analysis with isolation of the components would be required to evaluate the mixture.

We have demonstrated that CE and CE/MS are techniques that can solve practical problems encountered in the daily operations of a peptide synthesis laboratory. We have also found that the purity of HPLC isolated peptide samples can be confirmed through the use of CE and CE/MS. Coated fused silica capillary columns virtually eliminated compound adsorption resulting in better resolution and increased sensitivity as determined in our experiments.

Practical Considerations in the Capillary Electrophoresis - Electrospray Mass Spectrometry of Proteins

by Toni J. Thompson, Frantisek Foret, Daniel P. Kirby, Paul Vouros, and Barry L. Karger, Barnett Institute, Department of Chemistry, Northeastern University, Boston, MA 02115.

Capillary zone electrophoresis (CZE) -- electrospray ionization (ESI) mass spectrometry (MS) is a potentially powerful tool for the separation and identification of biomolecules. The CZE separation is affected by the properties of the background electrolyte (BGE), such as pH, concentration, and chemical composition. At the same time, the background noise level in the MS is, in part, determined by the species and concentration of the ions that are detected. This study systematically compares the CZE separation and ESI/MS detection of a protein mixture in several different BGE systems and liquid sheath compositions to develop a more complete understanding of the flexibility of the CZE-ESI/MS combination.

The mass spectrometer in this study was a Finnigan TSQ700 equipped with an electrospray ionization source. Mass spectra were obtained at a rate of one second/scan from *m/z* 600 - *m/z* 2000. The electrospray conditions included the 170°C drying gas (N_2) flowing at ~3000mL/min, and the gas sheath (O_2) flow rate was 190mL/min. The liquid sheath was of varying composition and flowed at 2.5 µL/min. The electrospray voltage was varied to obtain the most stable electrospray. The capillary electrophoresis power supply (Spellman CZE1000R) was operated at 20kV The separation column was 80 cm long X 75 µm i.d. and was coated in house with linear polyacrylamide. Sixty nL of the same sample, which consisted of cytochrome c, myoglobin, α-chymotrypsinogen A, β-lactoglobulin A, ribonuclease A, and β-lactoglobulin B, were introduced into the column by siphon injection for all analyses.

The figures on the following page illustrate some of the effects of the BGE and LS compositions on the separation and S/N. Figure 1 illustrates the separation with 6-aminohexanoic acid adjusted to pH of 4.4 with acetic acid as the BGE and the liquid sheath containing acetic acid. Figure 2 illustrates the effect on the separation when HCl is substituted for acetic acid in the liquid sheath.

A variety of BGE and LS conditions appears to be compatible with CZE-ESI/MS. Successful operation with this combination requires integration of LS, BGE, and ESI/MS. In no case have we seen that the spectra are compromised by these variations. The BGE composition determines the selectivity and CZE separation efficiency. When high selectivity is required, volatile or some non -volatile BGE constituents can be used,such as β-alanine or 6-aminohexanoic acid. Typical non-buffered solutions may be employed in cases where selectivity is sufficient. The liquid sheath composition can also affect the migration of the analytes, due to migration of anions from the LS toward the anode, forming an moving ionic boundary inside the capillary. This may result in a change in pH of the BGE and affect the effective charge on the proteins which can result in a change in their migration order and/or times. The BGE and LS compositions affect not only the migration but also the S/N and electrospray stability. Successful analyses can be obtained with BGE containing some non-volatile constituents and cations other than protons. One may choose to trade better S/N for separation selectivity.

Effect of Gas-Phase Acid Addition on the Electrospray Mass Spectrum of Myoglobin

*Baiwei Lin[a] and Jan Sunner[b]
[a]Lederle Laboratories, American Cyanamide, Pearl River, NY 10965
[b]Department of Chemistry, Montana State University, Bozeman,MT 59717

INTRODUCTION

Addition of acids to the electrospray solution tends to shift the charge distribution of a protein towards lower m/z. At the same time, the protein tends to denatured. Such denaturation will, in general, result in the dissociation of specific non-covalently bonded complexes.

In the case of myoglobin, denaturation is revealed by the accompanying dissociation of heme. The native myoglobin, with the heme, has a molecular weight of 17,566 Da. After the denaturation and the heme loss, the molecular weight is 16,951 Da. We studied the effect of adding acids, not to the ESI solution, but to the gas-phase in the electrospray source. Results from gas-phase are compared with those from addition of acids to the ESI solution. The effect of several different acids added to the gas-phase was also investigated.

EXPERIMENTAL

Figure 1 shows the instrumental set up for electrospray/quadruple mass spectrometer. A home-built electrospray ion source, shown in Figure 2, is interfaced to a quadruple MS (VG-TRIO2). A stainless steel transport capillary (i.d.=0.5mm) connects the electrospray at 1 atmosphere with the intermediate pressure chamber. A wound heater wire was used to control the capillary temperature. Optimum temperatures ranged from 75°C to 85°C.

RESULTS AND DISCUSSIONS

(A) Acidic Addition To Gas-Phase Versus ES Solution. When myoglobin was electrosprayed in pure water, only the native heme-globin complex was detected, as shown in Figure 3(a). The complex had few charges, $<10^+$, and the complex ions had low intensity. With only a small amount of acetic acid added to the protein solution, where pH was 5, an envelope of peaks for the denatured myoglobin appeared, Figure 3(b). In contrast, gas-phase acid addition gave a very different result, Figure 3(c). Only the native heme-globin complex was obtained. The appearance of HOAc in gas-phase significantly increased the charges on the native myoglobin, up to 12^+. More importantly, there was a fifty-fold increase in the signal intensity.

(B) The Effect Of Different Acids In The Gas-Phase. Addition of organic acids into the gas-phase, such as HOAc in Figure 4(a) and p-tolunesulfonic acid in Figure 4(b), gave very similar results. Both spectra show only heme-globin complex with relatively high ion intensities. Therefore no heme dissociation and presumably no denaturation occurred. The increase in the charge state may indicate that the protein conformation loosened with the presence of acid in the gas-phase.

Addition of HCl into the gas-phase had very different effects on the protein spectra. As shown in Figure 4(c), extensive heme dissociation was observed. Further, the signal-to-noise level was seen to be low. At a higher HCl flow rate, no spectra at all could be obtained. Addition of HCl into the gas-phase is seen to suppress the native myoglobin ions.

CONCLUTIONS

Acid addition into the gas-phase of ESI source can enhance the intensities of the native myoglobin ions in the electrospray spectrum since the addition of acetic acid into the gas-phase can only obtain heme-globin complex ions and therefore no heme dissociation occurred. The complex ion intensity was also greatly increased. However, the addition of the same acid into ESI solution resulted in a great denaturation of the myoglobin. The effect of gas-phase acid addition varied considerably between different acids. Some acids, such as HCl, resulted in the extensive denaturation of the protein with no signal improvements. Other acids, such as acetic acids and p-tolunesulfonic acid, provided a good environment for heme-globin complex and promoted native ion intensities.

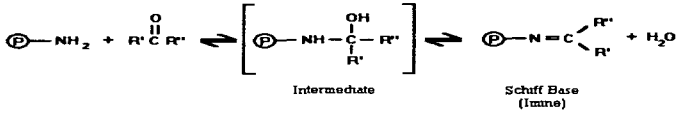
Probing Ketone-Protein Adducts by Means of Electrospray Mass Spectrometry.

J.C.Y. Le Blanc*, K.W.M. Siu and R. Guevremont, Institute for Environmental Chemistry, National Research Council of Canada, Montreal Road, Ottawa (Ontario) Canada K1A 0R6.

In previous work we have shown that multiply charged ion distributions observed in the electrospray (ES) mass spectrum of proteins originate from pre-formed multiply charged protein ions in aqueous solution. An aqueous solution equilibrium model based on the pK_a's of acidic and basic sites on proteins was used to compare the distribution of ions in solution to the shape of the ion abundance profile in the electrospray mass spectrum [1-3]. Since the aqueous solution chemistry of proteins is reflected in their ES mass spectra, aside from the acid/base equilibrium, other types of equilibria taking place in solution may be monitored by ES-MS as well. Aldehydes and ketones are known to react with free amine in proteins to form a Schiff base (reaction 1). This reaction is quite simple and has the advantages of being site specific and with minimal alteration to the charge state.



Reaction 1

When proteins are electrosprayed from solutions containing ketones or aldehydes, two types of distribution are observed: 1) the overall distribution describing the various multiply charged ions present in solution, and 2) for each given charge state, a series of peaks representing the equilibria of successive additions of ketones (or aldehydes) to free amino sites on the protein. Ubiquitin was electrosprayed from a solution containing water:methanol:acetone:piperidine (37:50:10:3 (v:v:v:v)); Figure 1 shows the overall charge distribution of the multiply charged ions, and the clusters of peaks representing the addition of acetone to each charge state. Since acetone can react at more than one site, the addition of acetone may be represented by successive addition steps as represented by the following scheme:

$$Ubiquitin^{-z} + Acetone \rightleftharpoons [Ubiquitin\text{-}Acetone]^{-z} + H_2O$$
$$[Ubiquitin\text{-}Acetone]^{-z} + Acetone \rightleftharpoons [Ubiquitin\text{-}Acetone_2]^{-z} + H_2O$$
$$\ldots\ldots\ldots + \ldots\ldots\ldots \rightleftharpoons \ldots\ldots\ldots + \ldots\ldots\ldots$$
$$[Ubiquitin\text{-}Acetone_{(x-1)}]^{-z} + Acetone \rightleftharpoons [Ubiquitin\text{-}Acetone_x]^{-z} + H_2O$$

The subscript **x** represents the maximum number of acetone that can react with the protein and **z** denotes the charge state of the protein. From the relative intensities of the ions in an ES mass spectrum, the equilibrium constant for each successive addition may be calculated for a given solution condition. Figure 2 shows the calculated equilibrium constant as a function of the number of ketone groups added to ubiquitin based on the results shown in Figure 1.

When water in the solution is gradually replaced with methanol or acetonitrile in the presence of acetone, a gradual increase in the number of imine formed is observed. In other words, the cluster of peaks for a given charge state will shift towards higher m/z values (e.g. see the ubiquitin-acetone ions with z=-7 in Figure 3). The formation of the imine results from the nucleophilic addition of free amine to acetone; in proteins only lysine residues and the N-terminal (if not blocked) may have free amine to react with acetone. By electrospraying two solutions, information on the composition of a protein may be

obtained as follows. The protein is first electrosprayed under regular conditions (water:methanol) to determine its molecular mass. A second protein solution containing acetone and in which the water has been replaced with another solvent (methanol or acetonitrile) is electrosprayed to determine the molecular mass of the protein with all the amino sites modified. From these two mass spectra, the number of lysines and N-terminal groups may be calculated:

$$Total\ Number_{(Lysine\ +\ N\text{-}Terminal)} = \frac{(\ Protein\ Mass_{(Acetone,\ DDW\ free)} - Protein\ Mass_{(Acetone\ free)}\ )}{40.06}$$

The numbers of lysines and N-terminal groups in several proteins were calculated as above and compared with values based on sequence information (Figure 4). The straight line represents a one to one correlation between experimental and expected values; the triangles indicate the experimental values. For all but one protein (β-lactoglobulin) the calculated number of lysines and N-terminal is statistically identical to the expected value. β-Lactoglobulin has one free cysteine group that can act as a nucleophile towards acetone addition thus resulting in too high a total amino number.

Structural Analysis of Lipids by Negative ESI/MS/MS

Stephen Chan and Vernon Reinhold
Department of Nutrition, Harvard University School of Public Health, Boston, MA 02115

The introduction of electrospray ionization (ESI) offers an alterative approach for sensitive analysis of many biomolecules. Thus far, the majority of ESI applications are based on the detection of cations derived from proton or alkaline ion adductions. However, for biomolecules containing strong acidic residues, the formation of anions (through deprotonation) may be more abundant under negative ESI conditions. The formation of anions is especially important for lipophilic molecules such as endotoxic Lipid A and phospholipids because of the acidity of their phosphate groups.

Lipid A serves as the lipophilic membrane anchor for the outer polysaccharide coat of Gram-negative bacteria. It has been linked to many of the pathophysiological effects of the bacteria. The structural information of this class of compounds is extremely important because the toxicity levels of Lipid A different dramatically from structure to structure. For those structures associated with an extreme toxicity, a sensitive technique is needed in order to handle the small biological amount frequently available. Monophosphoryl Lipid A (MLA) moiety obtained from *Salmonella minnesota* Re595 along with several different phosphatidylethanolamines were chosen as models for our structural studies using negative ESI/MS/MS.

All the experiments were performed on a Finnigan TSQ-700 triple stage quadruple mass spectrometer equipped with an Analytica (Bradford, CT) electrospray ionization source. Oxygen is used as a shealth gas for electron scavenging during sample infusions. All the lipid samples were dissolved in a buffer containing a mixture of chloroform and methanol in a ratio of 2:1 (by volume). The pH was maintained at about 10 buffered by NH_4OH. Typically, the infused samples contain 40 μg of lipids in a 100 μl of buffer. The sample infusion rate is 0.75 μl/min and the mass spectrometer is operated at 10 sec/scan. The instrument tuning and calibration are based on a solution containing a mixture of insulin A and a tetra-peptide (MRFA). The solution is made of a mixture of methanol and water in a 7:3 ratio (by volume). Again NH_4OH was used to maintain the pH at 10.5.

The ESI mass spectrum shows the heterogeneity of the Lipid A sample (Figure 1) as was previously reported [1]. The very low noise level detected in the mass spectrum indicates the high sensitivity of the technique. Only singly charged species are observed for the MLA structure identified. In this particular sample, the hexaacyl MLA (m/z = 1716) is the predominant species. Our collision studies reveal that the predominant fragment ions are the loss of the fatty acid acyl groups at different sites. This information allows the acyl groups on MLA to be identified. The mass spectrum of phosphatidylethanolamine shows primarily the $[M-1]^-$ and $[2M-1]^-$ species (Figure 2). The same species were also observed for the phosphatidylethanolamines with mono- and di-methyl amine groups. The collision spectra derived from the $[M-1]^-$ indicate that the main fragment ions are the loss fatty acid acyl chains.

In summary, sensitive detection of lipids have been achieved using negative ESI/MS. Structural information about the acyl residues on the lipids can be revealed by MS/MS.

This studies can certainly be extended to other compound types containing phosphate residues similar to our lipid samples.

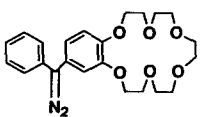
Chemical Properties of Diaryldiazomethane: An Electrospray Ionization Mass Spectrometric Study

Yunhui Wu* and Stephen R. Wilson
Department of Chemistry, New York University
Washington Square, New York, NY 10003

The discovery of the chemistry of diazo compounds was made a century ago. The first synthesis of ethyl diazoacetate in 1883 opened the wide field of diazo chemistry, which even today has not yet been exhausted. Recently, several mono-adducts of C_{60} have been prepared via cycloaddition of diazo compounds with fullerene molecules.[1,2] During this study, we have observed that ESI-MS is very efficient for investigating the chemical properties of diazo compounds. Although chemistry of diazo compounds is well known, direct detection of their adducts and dimers by mass spectrometer is usually not easy.

We have synthesized a crown ether tagged diaryldiazomethane (**1**).[2] With the use of electrospray ionization mass spectrometry, we are able to study the chemical properties of unstable diaryldiazomethane compounds. The reactions of diaryldiazomethane with O2, methanol, carboxylic acids (such as fatty acids and amino acids) and fullerenes are easily followed by this approach.



1

Figure 1 showed the ESI mass spectrum of products formed by mixing **1** with pure methanol at r.t. for 2 hours. Strong signals from the potassium complexes of the dimerized products were seen. In 5% AcOH methanol, however, the major product was the methyl ether derived from acid catalyzed addition of methanol to the diazo molecule (Figure 2). Oxidation products were also observed in both cases.

As an alternative, carboxylic acids can be derivatized and detected in the positive ion mode. Figure 3 is the ESI mass spectrum of the product formed by mixing **1** with N-Boc-l-Trp-OH, and only the corresponding ester was seen. Besides,

compound **1** also reacted with dipolarophile such as fullerenes.

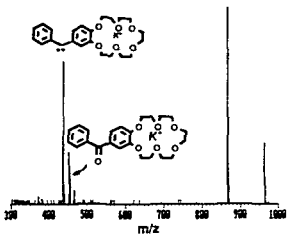


Figure 1 ESI mass spectrum of a solution of **1** in methanol (KOAc was added prior to the analysis The same procedure was used for the whole study)

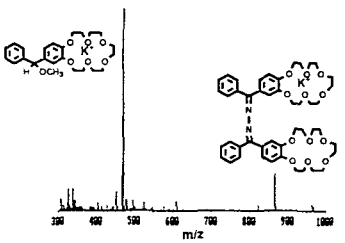

Figure 2 ESI mass spectrum of a solution of **1** in 5%AcOH methanol

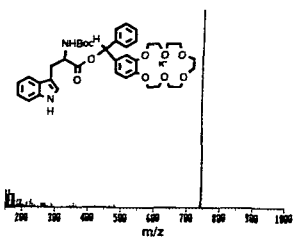

Figure 3 ESI mass spectrum (in KOAc/C_6H_6-MeOH) of the products from the reaction of **1** and Boc-l-Trp-OH

The results shown above have demonstrated that ESI-MS can be used for studying chemical properties of certain type of compounds. ESI-MS has proved itself that it is not only important to the measurement of biopolymers but also useful for the analysis of small organic molecules.

Quantification of a New Aryl Amidine

LTB_4 Antagonist (CGS 25019C) in Human Plasma Using Electrospray LC/MS

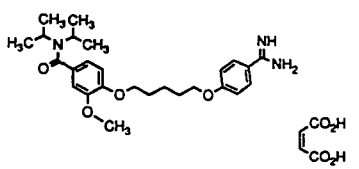
*M. J. Hayes, M. Leal and M. L. Powell,

Clinical Pharmacokinetics and Disposition, Pharmaceutical Div., Ciba-Geigy Corp., Ardsley NY, 10502

An analytical method has been developed for the determination of CGS 25019C (4-[5-[4-(aminoiminomethyl) phenoxy]pentoxy]3-methyoxy)-N,N-bis(1-metylethyl)benzamide (z)-2-Butenedioate (1:1). This compound has been shown to selectively antagonize the human LTB_4 receptor. Elevated LTB_4 levels have been found in psoriatic lesions, in the synovial fluids of patients with rheumatoid arthritis and gout, in arterial blood of asthmatic patients during wheezing attacks, and in rectal dialysate from ulcerative colitis patients.

The method is based on LC/MS and utilizes a structural analog as the internal standard. Samples (1 ml) were extracted with methylene chloride: hexane (60:40) under basic conditions, back extracted into sulfuric acid, and reextracted into methylene chloride:hexane. Separation was accomplished on a 0.32 mm x 5 cm C-18 column. Solvent A was 0.04% formic acid, solvent B was 0.04% formic acid in acetonitrile. A gradient was done from 5-95% B in 5 minutes. The flow rate was 5 ul/min. Mass spectrometry was carried out under positive ion electrospray conditions with selected ion monitoring at m/z 456 and 329 for drug and internal standard, respectively. The limit of quantification (LOQ) is 0.5 ng/ml.

Specificity was demonstrated by the lack of interfering peaks at the retention time of the drug and internal standard. Recovery and reproducibility assessments indiate good accuracy, precision and linearity over the validated concentration range of 0.25 to 50 ng/ml.



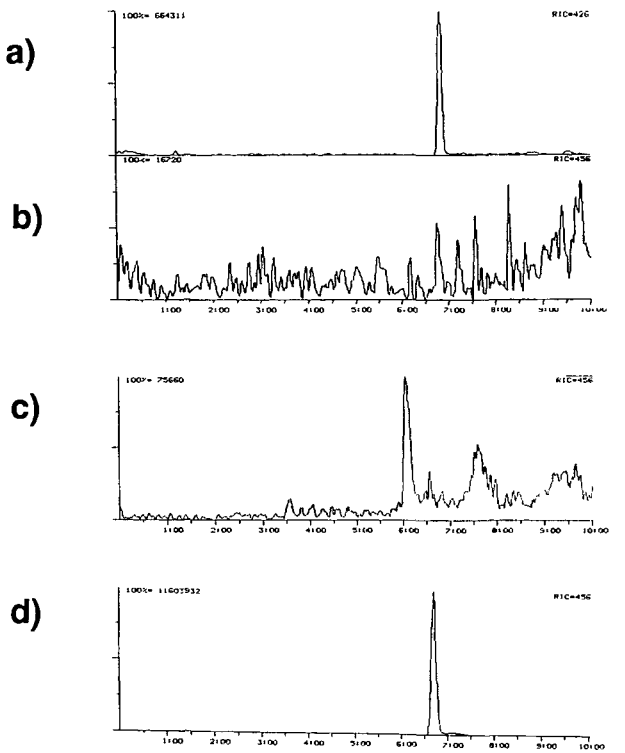


Figure 1 ESI - LC/MS chromatograms of human plasma spiked with internal standard and CGS 25019C: a) internal standard at 10 ng/ml (m/z 426), b) blank plasma, c) 0.25 ng/ml drug, d) 50 ng/ml drug.

Evaluation of Tandem MS vs. API Interface Voltage using Ionspray to Distinguish Isomers of Diarrhetic Shellfish Poisoning Toxins

J.C. Marr[1], and S. Pleasance[2] [1]Fenwick Laboratories Limited, Halifax, N.S., Canada, B3H 4M2, [2]Institute for Marine Biosciences, NRC, Halifax, N.S., Canada, B3H 3Z1 (present address: The Wellcome Foundation Ltd., Beckenham, Kent, U.K.)

The toxins okadaic acid (OA), dinophysistoxin-1 (DTX-1), and dinophysistoxin-2 (DTX-2) belong to a class of polyether compounds that are known to cause diarrhetic shellfish poisoning (DSP). Very little mass spectral data is available for these compounds, although a detailed study of EI and CI mass spectra of OA was been done by Benscath *et al.* (1). Ionspray mass spectrometry (ISP-MS) is a proven method for the detection of DSP toxins in complex samples (2). However, the mass spectra are very simple, the most abundant ions being the protonated molecule, little structural information is provided and the spectra produced by the isomers are identical. To aid in structural elucidation, and/or isomeric characterization, two methods were used to obtain additional fragmentation of the analyte ions. Conventional collision-induced dissociation (CID) using tandem mass spectrometry was compared with CID induced by increasing the API sampling orifice voltage from 40V to 100V. An orifice voltage of 80V produced sufficient fragment ions for characterization.

OA and DTX-2, and DTX-1 and the methylester of OA are isomeric pairs. The OA alcohol was also investigated to help define the nature of the fragment ions. The mass spectra from the five compounds were evaluated and compared to identify characteristic fragment ions that could be used to differentiate the isomers (Figure 1). For OA, DTX-1 and DTX-2, fragment ions which contain the CO_2H group were identified. Confirmation was possible by comparison with the OA methylester spectra (via a corresponding fragment ion 14 amu higher) and the OA alcohol (via a corresponding fragment ion 14 amu lower) (Table 1). Fragment ions that were unique to DTX-1, which contains an additional methyl group at C-35, were also identified (Table 1). The subtle difference between OA and DTX-2 (a methyl group at either C31 or C35) could not be determined, but DTX-1 and its biologically inactive isomer OA methylester can be distinguished.

The protonated molecule of OA was also subjected to conventional MS/MS and the resulting fragment spectrum was compared with mass spectra obtained using MS at increased orifice voltages. Inducing CID via increasing orifice voltage yielded informative fragmentation, with fewer rearrangements than tandem MS, making the spectra easier to interpret, with the disadvantage that the precursor ions were not mass selected. These diagnostic fragment ions will be used in future experiments on DSP toxins using SIM and MRM MS.

Characterization of Case-Associated Compounds in Oils Implicated in the Spanish Toxic Oil Syndrome Using Atmospheric Pressure Ionization Mass Spectrometry

INTRODUCTION

In 1981, an epidemic that would later become known as the toxic oil syndrome (TOS), broke out in Spain affecting approximately 20,000 individuals, several hundred of whom have died. The disease was initially termed "atypical pneumonia", and was characterized in its acute phase by fever, eosinophilia and respiratory insufficiency. It later developed into a chronic phase that included neuropathy, scleroderma, hepatitis and pulmonary hypertension. Many victims of TOS still suffer the chronic effects of the disease. Through epidemiologic studies, the disease was linked to the consumption of food oils that were sold as olive oil in Madrid and its surrounding areas. Investigations showed that the oils actually contained rapeseed oil that had been denatured with aniline.

Even though a great deal of work has been performed on the oil samples since 1981, the etiological agent(s) of the disease have not been identified. Case-associated compounds (fatty acid anilides and aniline) have been detected in case oils. Hampering identification of the causative agent(s) of the disease, however, has been the uncertain history of some of the oils that were collected, and the lack of an animal model for the disease.

As if to magnify the importance of identifying the agent of TOS, in 1989, an epidemic clinically similar to TOS occurred in the United States. That disease, termed eosinophilia myalgia syndrome (EMS), was traced to the ingestion of L-tryptophan. The outbreak resulted in several thousand cases of EMS, and 36 deaths. The failure to identify etiological agents of TOS and EMS suggests that similar outbreaks of this type of disease are possible in the future.

Since the initial studies of TOS and EMS, new and more powerful analytical techniques like electrospray and atmospheric pressure chemical ionization (APCI) have become available as interfaces for liquid chromatography/mass spectrometry. Using a SCIEX API III mass spectrometer, we are designing experiments to quantitate case-associated compounds in the oils (anilino-propane diol and its esters, and fatty acid anilides), and screen for other aniline derived compounds. Presented here are the experiments designed to accomplish that task.

EXPERIMENTAL - Quantitation of Case-Associated Compounds

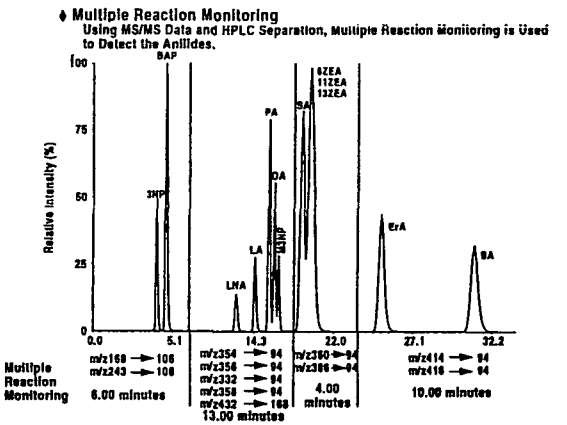
The compounds we are initially investigating are shown in the following figures. Previous analyses by capillary gas-liquid chromatography and high performance liquid chromatography (HPLC) with confirmation by mass spectrometry determined the fatty acid profiles of the oils. Further investigation using HPLC indicated that linolenyl anilide, linoleoyl anilide, palmityl anilide, oleoyl anilide, and stearyl anilide were present in concentrations ranging from 30 ppm to 2,000 ppm. Using HPLC and MS/MS analysis, the above anilides, as well as behenyl anilide, erucyl anilide, 8Z-eicosenyl anilide, 11Z-eicosenyl anilide, 13Z-eicosenyl anilide, bis-anilinopropanol, 3-amino-1,2-propane diol and its esters will be quantitated.

EXPERIMENTAL - Parent Scan Screening for Aniline Derived Compounds

Since the identity of the etiological agent of TOS has not been found, it is wise to assume that not all of the aniline derivatives have been discovered. To this end, we are screening the oils for other possible aniline containing compounds. Those so far studied consistently lose m/z 94, the anilide group. Assuming that other anilide compounds would dissociate under MS/MS conditions in a similar manner, parent scans examining for the loss of aniline could prove to be valuable in identifying other possible compounds to investigate as promoters of disease.

DISCUSSION AND CONCLUSION

The oils present many challenges to the analytical chemist, the primary of these being their age and their complex composition. Significant peroxidation of the oils has occurred since their collection in 1981. It is also likely that alteration or decomposition of many compounds has occurred. Our principle task is to account for all aniline-containing compounds and identify as many of these compounds as possible. Some aniline-containing compounds have shown themselves to be relatively stable, however the stability of the anilino-propane diol and its esters is unknown.



ACKNOWLEDGEMENTS

This work is part of a cooperative agreement to study the Toxic Oil Syndrome between the Centers for Disease Control and Pevention, Atlanta, GA, and Fondo de Investigacion Sanitaria, Instituto Nacional de la Salud, Madrid, Spain.

Use of Crown Ethers to Enhance Electrospray Ionization Mass Spectra of Samples Containing Alkali Metal Salts

Anne B. Giordani, Parke-Davis Pharmaceutical Research, Division of Warner Lambert Company, 2800 Plymouth Road, Ann Arbor MI 48105

Introduction Alkali-metal-salt contaminants from synthesis or isolation steps and samples in alkali-metal-salt form often present analysis problems in electrospray ionization mass spectrometry (ES-MS). For instance, unresolved adducted species cause error in molecular weight determination. At a resolving power of 1000, this puts upper limits on exact molecular weight determinations of 6k, 22k and 38k for lithium, sodium and potassium-contaminated species, respectively. Interpretation of ES spectra is more complicated when the adducted species are formed from more than just a single type of charge carrier. The presence of alkali metal salts in samples analyzed by ES-MS causes a decrease in sensitivity due to dilution of the sample ion current when a multiplicity of adducted species is formed (e.g. $[M + 2H]^{+2}$, $[M + H + Na]^{+2}$ and $[M + 2Na]^{+2}$). In worse cases, no peaks representative of the sample are observed due to ion suppression or because the conductivity of the sample solution disrupts the stability of the electrospray. In addition, sensitivity is poor for alkali-metal-salt forms of acidic organic compounds which only weakly dissociate in solution.

An effective strategy for dealing with alkali-metal-salt contamination is chromatographic removal. Chromatographic "clean up" can be achieved by HPLC/MS, by HPLC-fraction collection or by solid-phase extraction using some of the disposable products which are on the market. Similarly, prior to analysis, alkali-metal-salt forms of acidic organic compounds can be converted to their free acid form by ion exchange chromatography.

Chromatographic approaches are time consuming, can be technically challenging and can result in sample losses due to sample handling, incomplete recovery of sample from the column, etc. Very few simple, non-chromatographic, strategies for dealing with alkali-metal-salt contamination have been reported. Precipitation from ammonium acetate solution has been shown to enhance ES mass spectra by removal of sodium counter ions from synthetic oligodeoxy-nucleotides.[1] Addition of small amounts of crown ethers to peptide samples before fast atom bombardment (FAB) analysis was demonstrated to be a simple and rapid way to remove interferences in FAB mass spectra caused by salt contamination.[2]

Crown ethers are synthetic macrocyclic compounds capable of binding cations.[3] The polyether ring size of 18-crown-6 ether makes it particularly selective for sodium and potassium ion binding in 1:1 complexes.[4] Reported here is the use of 18-crown-6 ether addition to direct infusion solutions prior to ES-MS analysis.

Results and Discussion One to one complexes of 18-crown-6 ether with H^+ (m/z 265), H_3O^+ (m/z 283), Li^+ (m/z 271), Na^+ (m/z 287) and K^+ (m/z 303) were observed by manual (20 µL) loop injection of 18-crown-6 ether in one to one (v:v) acetonitrile/ water, 0.01 M lithium acetate, 0.01 M sodium acetate and 0.01M potassium acetate/acetic acid (pH 2.4) solutions. The base peaks in the respective spectra were from the complexes of 18-crown-6 ether with Li^+, Na^+ and K^+. The proton and hydronium ion complexes of 18-crown-6 ether have relative intensities of less

than 20% in the Na^+ and K^+ spectra, whereas, in the Li^+ spectra their relative intensities are greater than 50%. This observation may be a reflection of the particularly favorable binding of 18-crown-6 ether with sodium and potassium cations compared to lithium cations.

The ES spectra of two synthetic peptide samples which contained significant, but unknown, amounts of sodium had improved signal to noise ratios, and no longer contained Na^+ adducted ions following dilution with a water/1% 18-crown-6 ether in methanol/acetic acid solution (final concentration of the synthetic peptides was approximately half, 18-crown-6 ether ≈ 0.02 M).

The effective removal of sodium adducts from the ES spectra of sodium-contaminated insulin solutions by the addition of 18-crown-6 ether to the analyte solution was demonstrated. The spectra from the solutions containing 18-crown-6 ether had significantly improved signal to noise ratios and prominent peaks representative of 18-crown-6 ether binding to the proton-adducted insulin ions. Sodium adduction seemed to be more favored in lower-charge-state ions compared to higher-charge-state-ions of insulin, whereas, 18-crown-6 ether binding seemed to be more favored in higher-charge-state proton-adducted ions compared to lower-charge-state proton-adducted ions of insulin.

The total ion current and the ion current of the $[M + H]^+$ peak in the ES-MS spectra of leucine enkephalin versus sodium chloride concentration was studied. Sodium chloride caused an erosion in both signal intensity and signal to noise ratio at increasing concentrations. The spectra of solutions containing 18-crown-6 ether had significantly better signal to noise ratios, including that of the $[M + H]^+$ ion. The total ion current of the crown ether-containing solutions increased with the sodium chloride concentration. However there was no concomitant increase in the ion current of the $[M + H]^+$ peak, the increase in total ion current was due to the increase in $[18\text{-crown-6 ether} + Na]^+$ and other crown-ether/sodium chloride related ions.

In the ES spectra of sodium suramin, a compound containing six sodium sulfonic acid groups, peaks representing multiple sodium losses carried more of the total ion current in the spectrum from crown ether solution than in the spectrum from acetonitrile/water solution.

Conclusions 18-Crown-6 ether addition is a simple, nonchromatographic strategy for dealing with alkali-metal contamination of solutions for ES-MS analysis. Addition of 18-crown-6 ether to the electrospray infusion solutions of sodium chloride-containing samples decreases formation of sodium-cationated species, and improves the sensitivity through major increases in the signal-to-noise ratios in ES-MS spectra. This is potentially a useful technique for molecular weight measurement of alkali-metal-contaminated samples by ES-MS. Crown ether binding to alkali-metal ions and to proton-adducted analytes is observable in the ES-MS spectra. The pairs of peaks representing the proton-adducted and the crown ether-proton-adducted ions carry complete molecular weight and charge state information about the analyte.

On-line Accurate Mass Analysis of a Pesticide Mixture by APCI LCMS on a Magnetic Sector Instrument

R.H. Bateman, *P.A. Bott and A.R. Woolfitt
Fisons Plc, VG Analytical, Floats Road, Wythenshawe, Manchester, M23 9LE, England.

Atmospheric Pressure Chemical Ionisation is a powerful technique when coupled to an LC system for the analysis of a wide range of compounds. Although APCI has been utilised as an LCMS interface on quadrupole mass spectrometers for a number of years, it is only recently that this technique has been transferred to magnetic sector mass spectrometers [1]. The obvious application for this is to obtain accurate mass measurements at higher resolving powers, which will assist in obtaining elemental compositions of unknown compounds.

The aim of this work was to investigate the factors which are important for the successful operation of an LCMS interface at high resolution. These include basic sensitivity checks, reproducibility of sample injections, chromatographic integrity and investigation of internal references for calibrating and mass measuring the sample.

Figure 1 shows the UV detector trace and full magnet scanning TIC trace of a mixture of n-methyl carbamate pesticides, chromatographic resolution is maintained through the LCMS interface.

Figure 2 shows the limits of detection for one carbamate pesticide, carbofuran. A detection limit of 150pg compares favourably with the sensitivity obtained on quadrupole instrumentation [2].

Figure 3 shows a spectrum of methanol clusters from a 50% methanol water solvent system, demonstrating a useful internal reference.

Figure 4 shows the accurate mass measurement for carbofuran by a narrow voltage scanning experiment at 3000 resolving power. Utilising the methanol cluster ions as calibrant, good mass measurements can be obtained.

APCI coupled to a magnetic sector mass spectrometer has the potential, in terms of sensitivity and chromatographic reproducibility, of being a useful technique for accurate mass determinations.

Analysis of Venoms Used in Pesticide Research by Electrospray Ionization Mass Spectrometry

Ronald E. Shomo, II* and Charles Webster
FMC Corporation, Agricultural Chemical Group, Analytical Department
Princeton, New Jersey 08543

The use of venoms as pesticides is a novel approach in the agrichemical industry. The concept is simple, identifying a specific agent in a complex venom that is toxic to a particular insect pest and producing this agent on a commercial scale.

The analysis is difficult because of the complexity of these venoms coupled with limited quantities of sample (typically sub nanomoles). Electrospray ionization has the sensitivity to determine the identity of the desired agents in these venoms without consuming large quantities of material.

Figure 1 shows the electrospray results of a HPLC fraction of 62 pmoles of a native spider venom. The molecular weight was determined to be 6371.73 ± 0.9 u. The spectrum clearly indicates that two species are present. These species co-elute by HPLC, but are clearly distinguished by electrospray mass spectrometry. The second species molecular weight was measured at 6398.39 ± 0.4 u.

Figure 2 shows the electrospray data of 3 pmoles of a recombinant spider venom isolated by HPLC. The venom was mass measured at 6372.07 ± 0.9 u with a second component mass measured at 6397.14 ± 2.9 u.

The recombinant and the native spider venoms were thought to be identical in composition; however the HPLC retention times were dramatically different. This phenomenon was attributed to a difference in the way the protein folded.

IONIZATION OF AROMATIC HYDROCARBONS IN SOLUTION FOR ANALYSIS BY ELECTROSPRAY IONIZATION-MASS SPECTROMETRY

Keiji G. Asano and Gary J. Van Berkel
Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge TN 37831-6365

The applicability of electrospray ionization-mass spectrometry (ES-MS) is generally limited to analytes that are ionic in solution or that can be ionized in solution by acid/base chemistry. Neutral, nonpolar analytes such as polycyclic aromatic hydrocarbons (PAH's) are not typically amenable to ES-MS analysis. Furthermore, chemical derivatization aimed at adding an ionic moiety to these molecules is problematic due to the large variation in reactivity with molecule structure and the potential for multiple reaction products. This work presents our investigation of solution-phase electrochemical, chemical, and photochemical means to form cations of these compound types for analysis by ES-MS. The mass spectrometer employed was a modified version of a Finnigan-MAT ion trap mass spectrometer (ITMS) adapted to sample ambient air.[1]

We have previously shown[2] that radical cations of certain analytes may be formed via an electrochemical oxidation inherent in the ES process that occurs at the metal/solution interface in the ES needle. Formation and observation of these electrochemically generated radical cations required the "appropriate" analyte (i.e., easy to oxidize and stable as M^+ in solution) and the "appropriate" solvent system (i.e., inert to reaction with M^+). Radical cations can also be generated electrochemically by placing an electrochemical amperometric flow cell in-line with the ES. For the appropriate analytes, when the voltage difference between the two electrodes in the cell is zero, no ion signal is observed. When the potential between the two electrodes is increased to the proper level to oxidize that compound, the radical cation of the analyte can be observed. Therefore, as demonstrated by the data in Figure 1, variation of the cell potentials allows for selective ionization.

Chemical oxidants, including Brønsted acids, charge-transfer reagents, and Lewis acids can also be used to form cations of highly conjugated and aromatic systems.[3] As an example, the ES mass spectrum of β-carotene ionized in solution by dissolution in TFA is shown in Figure 2. Ionization selectivity is afforded by the use of different chemical oxidants. This is demonstrated in Figure 3 for the simulated elution of PAH's with post-column ionization in solution using a chemical oxidant. The strongest oxidant (SbF_5) affords the least selectivity, but affords the best detectability. The best selectivity is achieved using a weaker oxidant (DDQ/TFA). In such a case detectability for the easily oxidized compounds is still high, but is dramatically reduced for harder to oxidize compounds.

Light can also be used to ionize analytes in solution for analysis by ES-MS. This work made use of a 150 Watt xenon arc lamp that irradiated the solution just entering the ES needle. We found that irradiating the analyte solution with light may ionize a compound directly (or promote the compound to an excited state from which it can transfer an electron to another species in solution) or may ionize the analyte and/or promote reactions between the analyte neutral or ion in solution and other species originally in the solution or created by irradiation (Figure 4). Although not investigated, it is anticipated that various spectral filters or discrete wavelengths might be used to afford ionization selectivity as demonstrated above for electrochemical and chemical oxidation.

In summary electrochemical, chemical, and photochemical means can be used to form cations from analytes in solution for analysis by ES-MS. Variation of voltage gradients in solution, different chemical oxidants, and tunable light may each be used to afford ionization selectively. And finally, these results indicate that ES-MS might be used to probe the ionic products formed in solution during electrochemical, chemical, and photochemical experiments.

Studies of 1,3-Cycloaddition of Fullerene by Electrospray Ionization Mass Spectrometry

Yunhui Wu* and Stephen R. Wilson
Department of Chemistry, New York University
Washington Square, New York, NY 10003

Recently a burst of scientific investigations on fullerenes has occurred due to their unique structures and properties. Among the studies, cycloadditions of fullerenes with dienes and 1,3-dipoles have attracted much attention. Several mono-adducts have been isolated and characterized.[1]

During our studies on the application of electrospray ionization mass spectrometry (ESI-MS) to organic chemistry,[2] we have found that ESI-MS was very useful for studying cycloadditions of fullerenes. Our study started with the known reaction which involved C_{60} and diaryldiazomethane. When a mixture of C_{60} and C_{70} (9 : 1) was reacted with excess crown ether diaryldiazomethane (**1**) for 1 hr at 5-10 °C, up to hexa-adducts were detected by ESI-MS. Figure 1 shows the ESI mass spectrum of the products of this reaction after 3 days. Nitrones such as compound **2** showed similar reactivities under the same conditions.

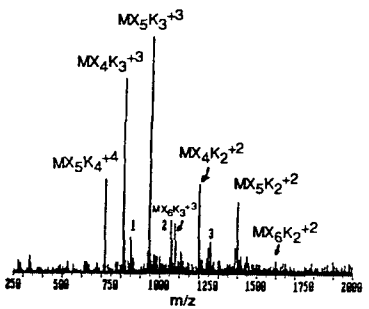

Figure 1. ESI mass spectrum of the products from the reaction of **1** and C_{60}/C_{70} (9 : 1) in benzene-methanol (1 : 1) containing KOAc M = C_{60}, X =

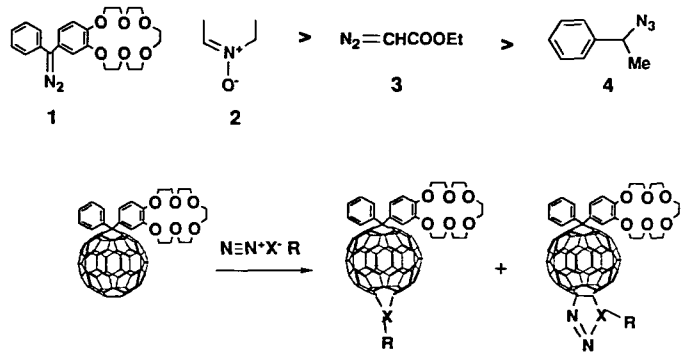
Peaks: 1, $C_{70}X_2K_2^{+2}$; 2, $C_{70}X_3K_2^{+2}$, 3, $C_{70}X_4K_2^{+2}$.

When ethyl diazoacetate (**3**) and α-methylbenzyl azide (**4**) were used, the addition reactions proceeded much slower and more than one type of product formed. The reaction of **3** with C_{60} at r.t. formed five-membered rings as major products. With

increasing temperature, more loss of nitrogen occurred. The least reactive dipole **4** only reacted with C_{60} at higher temperature. Products with losses of nitrogen molecules started to appear at about 100 °C.

Clearly, the nature of the products of 1,3-cycloadditions of C_{60} is both substrate and temperature dependent. Our studies have shown that the relative reactivities of the 1,3-dipoles used are as following:



5-10 °C	X = CPh, R = Ar	Only	
25 °C	X = CH, R = COOEt	Minor	Major
65 °C	X = N, R = CHMePh	Minor	Major

Our results have shown that ESI-MS can be used not only for detection of products, but also for studying relative reactivities and mechanism. Since ESI-MS mainly reflects solution chemistry, we think its future in organic chemistry is bright.

Electrospray Ionization Mass Spectrometry Is a Useful Tool for Studying Fullerene Chemistry

Yunhui Wu* and Stephen R. Wilson
Department of Chemistry, New York University
Washington Square, New York, NY 10003

Mass spectrometry has played a critical role in C_{60} chemistry and indeed in its discovery. While MS is very sensitive, C_{60} derivatives are often fragile and non-volatile, so that great difficulties have been reported with even the mildest ionization methods. FAB-MS and LD-MS are often used for characterizing products from reactions of fullerenes, however, electrospray ionization mass spectrometry (ESI-MS) has been employed only in few cases.[1]

We have recently been exploring of the application of ESI-MS to organic chemistry and have found that ESI-MS is useful for the direct observation of fullerene reactions in solution. Our first observation was that oxyamination products of C_{60} could be detected. For example, the addition of iso-butyl amine and oxygen could be followed by ESI-MS in the positive ion mode (Figure 1). In addition, we have also detected methoxylated fullerene ions in the negative ion mode when fullerenes were treated with NaOMe methanol-toluene solution. Interestingly, only ions with additions of odd numbered methoxyl groups were seen. Deuterated reagents were used for the identification of the ions.

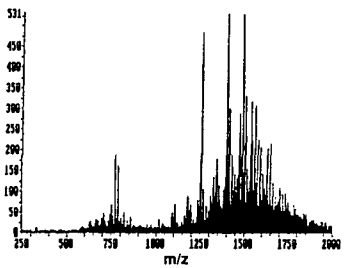

Figure 1. ESI mass spectrum (in 2.5%AcOH/MeOH-PhMe) of the products from the reaction of C_{60} and i-$BuNH_2$ in air at 24 hr

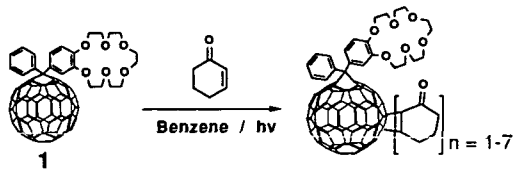
To facilitate the analysis of fullerene derivatives, we have synthesized a crown ether tagged C_{60} (**1**).[2] Based on the fact that this molecule has very similar chemical properties to C_{60} itself, we conducted a search of reactions of C_{60} and utilized ESI-

MS for the analysis of the products. By using this tagged molecule, we have directly observed the products from oxidation, oxyamination, methoxylation (in both positive and negative modes), bromination, hydroboration, Diels-Alder reaction, [2 + 3] cycloaddition and [2 + 2] photocycloaddition. Figure 2 shows ESI mass spectra of photochemical reaction mixtures of **1** and varied concentrations of 3-methyl-2-cyclohexen-1-one. As the concentration of enone increased, more multiple addition products formed.



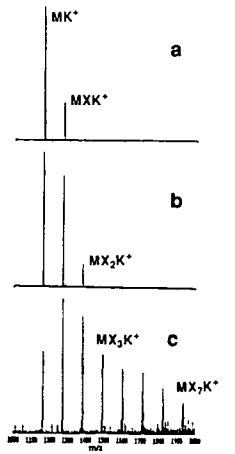


Figure 2 ESI mass spectrum of the products from the reaction of **1** and 3-methyl-2-cyclohexen-1-one in $KOAc/C_6H_6$-MeOH The concentration of the enone was increased by 10 and 100 fold from a to b, c M = compound **1**, X = 3-methyl-2-cyclohexe-1-one

Based on the study with the crown ether tagged C_{60}, we have successfully repeated the same photochemical reaction on C_{60} itself. The mono-adduct was isolated and fully characterized.

We hope that we have shown the great potential of ESI-MS in the field of fullerene chemistry. Although ESI-MS has limitations with regard to type of analyte, it is possible to be used efficiently with suitable strategies.

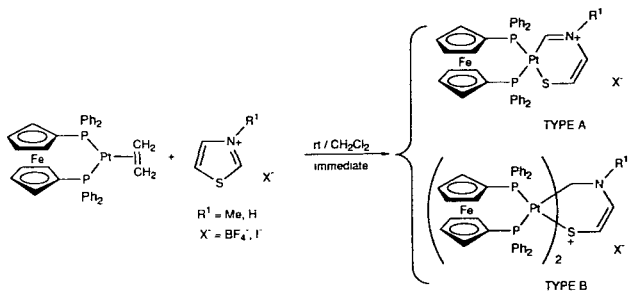
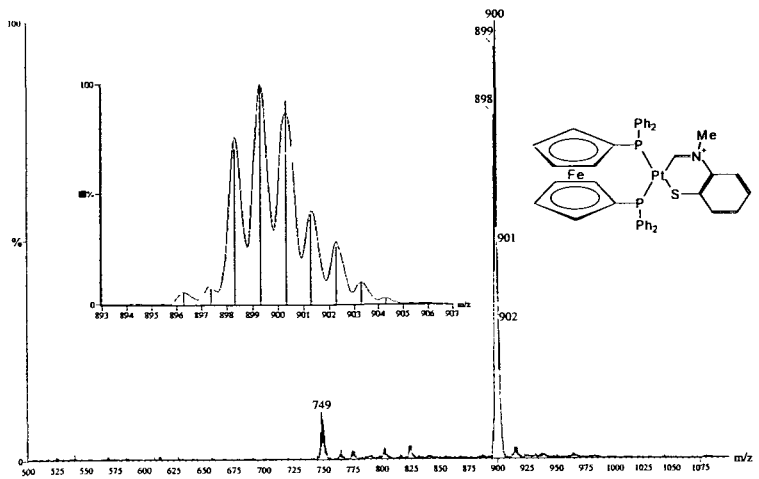
The Characterisation of Novel Ionic Platinum Complexes by Electrospray Ionisation Mass Spectrometry

R T Aplin, C V Robinson, V C M Smith The Dyson Perrins Laboratory, Oxford University, Oxford, U K OX1 3QY and S Lowes VG Biotech, Altrincham, Cheshire, U K. WA14 5RZ

C-S Activation of thiazolium salts and related compounds has been achieved by the reaction of (dppf)PtC_2H_4 and a series of thiazolium and benzothiazolium salts -

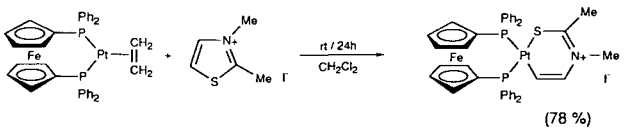


These ionic products are readily characterised by ESI MS where the molecular cation is the only intense peak in the spectrum -

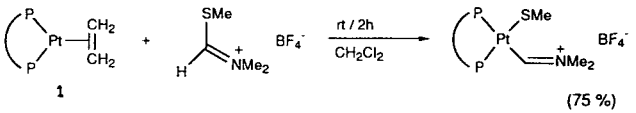


This is in marked contrast to their FAB spectra which are dominated by fragment ions and show evidence for ligand displacement by the FAB matrix N-methylthiazolium and N-methylbenzothiazolium salts afford 1 1 and 2 1 type A and B products -

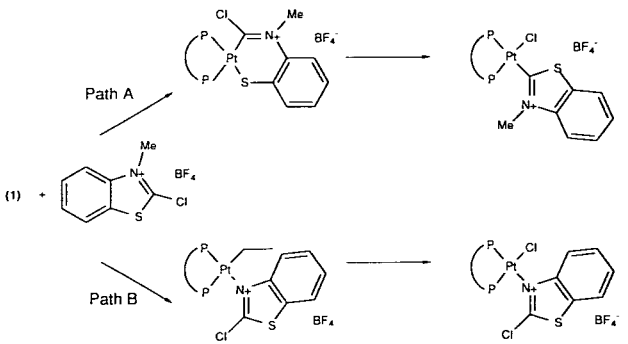
N-methyl-2-methylthiazolium and N-methyl-2-methylbenzothiazolium salts afford type A products with the opposite regiochemistry -



The acyclic analogue S,N,N-trimethylformamidinium tetrafluoroborate similarly affords type A product -



Cationic carbene products were obtained from the reaction of N-methyl-2-chlorobenzothiazolium tetrafluoroborate -



The ESI MS of this product, where the platinum is not part of a metallocycle, shows a low abundance molecular cation Loss of the heterocycle affords the base peak in the spectrum. In all the spectra the observed isotope pattern is in very good agreement with the theoretical pattern

ELECTROSPRAY MASS SPECTROMETRY OF METALLOCENES AND ORGANOMETALLIC SALTS

Xiaoming Xu, Steven P. Nolan, Mark L. Trudell, and Richard B. Cole*

Department of Chemistry, University of New Orleans, Lakefront Campus, New Orleans, LA 70148

An electrospray (ES) mass spectrometer (Vestec 201, Houston, TX) was used to analyze metallocenes $(C_5H_5)_2Fe$, $(C_5H_5)_2Ru$, & $(C_5H_5)_2Os$, and newly synthesized organometallic salts $[(CH_3)_5C_5RuC_6H_6]^+[CF_3SO_3]^-$ & $[(CH_3)_5C_5RuC_8H_7N]^+[CF_3SO_3]^-$. Each of these compound types contains metal-carbon bonds. Under normal ES ionization conditions, the organometallic salts exhibited very stable ionization and high sensitivity for molecular cations (Fig. 1). The isotope distribution patterns for the intact cations were in excellent agreement with those predicted by natural abundances.

The mass spectra of metallocenes (Fig. 2), on the other hand, showed molecular ions corresponding to oxidized forms of the neutral molecules, $[(C_5H_5)_2M]^+$ (M=Fe, Ru, Os). According to the generated isotope distribution patterns, protonated molecules were present in negligible quantities, and no doubly charged species were observed. Ferrocene, which can be ionized under normal ES operating conditions, showed very stable electrospray characteristics and high sensitivity. Ruthenocene and osmocene, however, were far more difficult to ionize. Their molecular ions could only be obtained at higher needle voltages, i.e., very near to corona discharge conditions. This result was attributed to higher $E_{1/2}$ (ox) values and higher ionization energies of ruthenocene and osmocene relative to those of ferrocene. For osmocene, conditions were established whereby protonation was competitive with oxidation, thus creating two pathways of ion formation. The obtained mass spectra demonstrate a clear example of the use of the electrospray instrument as an electrolytic cell [1,2]. Also observed were fragment ions $C_5H_5M^+$ (M = Fe, Ru) generated by collision-induced dissociation of the respective molecular ions.

Solution-phase reaction products of unstable forms of metallicinium ions were also observed in the ES mass spectrum. These products were present in particularly high abundances if the singly charged ion satisfied the 18-electron rule. In methylene chloride solvent, chloride ion was incorporated into the inner sphere of the metallocenes forming Cp_2RuCl^+ and Cp_2OsCl^+ (Fig. 2c) complexes via nucleophilic addition. Other products of nucleophilic addition to Ru(IV) and Os(IV) species (i.e., hydroxide and trifluoroacetate addition) were also produced. No analogous species were observed for ferrocene.

Previously, organometallic species have been characterized using FAB-MS.[1-6] The FAB technique, however, is hindered by secondary processes; such as oxidation and/or reduction of the analyte, adduct formation and other reactions between the analyte and matrix. While ESI-MS has been used extensively for the analysis of peptides and other compounds of biological interest, it has not been routinely used for the analysis of organometallic species.[7] The purpose of this study is to qualitatively compare the FAB-MS and ESI-MS of a series of Ru-, Re- and di-metallic compounds.

All experiments were performed on a Kratos Concept 1H mass spectrometer. For the FAB experiments, the LSIMS source was used, and 3-nitrobenzyl alcohol was the matrix. For the ESI experiments, the buffer solution was 50/50 H_20/MeOH, 1% acetic acid; and the analytes were dissolved in pure MeOH. The acceleration potential was 8kV for FAB and 4kV for ESI. Data were collected in the raw data mode. Each spectrum is the average of 20-50 scans. The organometallic compounds were synthesized, and all other chemicals were acquired from commercial sources.

The compounds studied are outlined in Table 1. An example of the type of spectra obtained is shown in Figure 1. For this discussion, the compounds are grouped by charge states. **A** and **G** did not give any results or expected results and thus are not discussed here. **D, E, G** and **I** have a +2 charge state. **D, E** and **I** show loss of 2 PF_6's with reduction in FAB. Doubly charged ions are also observed at very weak intensities. By ESI, **D, E** and **I** give ions corresponding to loss of PF_6's with no reduction. **B, C** and **F** have a +3 charge state. For all three compounds, loss of 2 PF_6's with reduction is the major peak in the FAB spectra. However, weak doubly charged ions are also observed. These compounds by ESI do not show any reduction and do show a charge distribution that relates to successive loss of PF_6's. **H** and **J** have a charge state of +4. **H** gives no information under our FAB conditions, and **J** gives a very small ion which corresponds to loss of 2 PF_6's and reduction. Both compounds give much more information via ESI, but some reduction is observed with the loss of 3 and 4 PF_6's.

An important feature of FAB spectra is that fragmentation is observed for some compounds. For example, **I** (Fig. 1), shows loss of the ligand. Another feature of the FAB spectra, is that oxidation is observed for some of the compounds. These processes are not observed in ESI.

In conclusion:

1. FAB-MS gives information on organometallic species, but secondary processes such as reduction can complicate the spectrum.
2. ESI-MS is a viable tool for the analysis of organometallic species. It does not appear to be as susceptible to the above secondary processes.
3. FAB-MS loses its effectiveness at higher mass and higher charge state.
4. ESI-MS does not appear to be hindered by higher mass and higher charge state.
5. FAB-MS produces informative fragmentation.
6. ESI-MS does not produce informative fragmentation.

A HEATED CAPILLARY ATMOSPHERIC PRESSURE IONIZATION SOURCE WITH AN ATMOSPHERIC PRESSURE CHEMICAL IONIZATION INTERFACE.

IAIN MYLCHREEST AND MARK HAIL, FINNIGAN MAT, SAN JOSE, CA 95134.

The recent explosion of interest in performing LC/MS analysis with atmospheric ionization techniques has led to the development of a number of ionization sources for both electrospray (ESI) and atmospheric pressure chemical ionization (APCI). A new atmospheric ion source has been developed based upon a heated metal capillary design (1), which allows APCI operation (Fig 1) and high flow ESI, at 1.0 to 1000 ul/ min of LC eluent.

The heated capillary provides a means of efficiently desolvating and transporting ions from ionization techniques such as APCI into a mass analyzer. For APCI operation the heated capillary is typically operated at 150 to 200 C, this provides enough energy to desolvate ions previously formed in the corona discharge region without thermally degrading them, and also assists in the desolvation of larger droplets formed in the APCI nebulizer and vaporizer probe. Liquid flow rates of up 2 ml/min in both normal and reverse phase LC are able to enter the source in APCI operation due to the desolvating ability of the heated capillary, although only a fraction of this flow actually passes through the capillary. The heated capillary allows high LC flow operation, but other features of the source contribute to improved sensitivity and detection limits of a wide range of compounds. The heated capillary in this source is off axis with respect to the the skimmer orifice, this is believed to prevent undesolvated droplets and particulates entering the mass analyzer, this significantly reduces the high background noise commonly seen in these high flow ESI and APCI techniques. This off axis arrangement typically increases the signal to noise by a factor of three to five (Fig 2). The desolvated ions in this off axis region are focussed towards the skimmer orifice axis using a tube lens (2) which enhances the detected ion signal by a factor of five. After passing through the skimmer the ions are focussed using an RF only octapole which efficiently passes the ions in to the mass analyzer. It is this RF only octapole that contributes significantly to the improved sensitivity of this source, providing factors of ten to one hundred fold increase in sensitivity over the same source utilizing a conventional lens system in this area.

APCI typically produces protonated molecular species or adducted molecular ions with little or no structural information. However it is possible to induce fragmentation of ions at different points in the source and create structurally useful information. Controlled thermal fragmentation is possible by raising the heated capillary above 200 C in APCI operation. Fragmentation can also be produced in the capillary-skimmer region by applying an accelerating potential to the capillary exit. The RF only octapole is primarily a focussing device but the application of an offset voltage accelerates ions in this region and allows them to collide with resident gas molecules and induces fragmentation ions identical to those produced in a conventional collision cell, although lacking the specificity of traditional MS/MS.

The analytical performance of this APCI source is demonstrated with the low picogram detection of steroids such as prednimustine (fig 3), boldenone, and testosterone. The potential for qualitative and quantitative analysis in the low picogram range is demonstrated in the selected reaction monitoring and single ion monitoring modes for these types of molecules. The analysis of ethoxylated polymers is shown using this APCI interface, producing molecular ion species of the individual polymer units up to molecular weights of 2000 Daltons. APCI operating in the negative ion mode is also demonstrated for the analysis of phenoxy acid herbicides and prostaglandins.

Development of High Sensitivity Detectors for Mass Spectrometry

*Anthony Bauco and Alan Then,
Galileo Electro-Optics Corporation, Sturbridge, MA 01566

Recent efforts to improve the sensitivity of mass spectrometry systems have begun to focus on the ion detector as the major opportunity for advancement. Until recently, current detectors were more than adequate for the systems since other components, such as the chromatograph, inlet, ion source, and mass analyzer, were the limiting factor in system sensitivity. Now that system sensitivity is pushing the limits of the current detector designs we are able to see the effects of new detector design concepts and technologies.

Most of the improvements have been in the areas of ion optics, electron multiplier material science, and electron multiplier geometry. Improved ion optics have resulted in better collection efficiency through improved coupling between the mass analyzer and electron multiplier. All of our testing was done on a HP5971 MSD which has a quadrupole mass filter. Each quadrupole provides a distinct beam profile and divergence that varies with the physical geometry and operating conditions. A unique detector must be designed for each quadrupole since the optimal ion optics are dependent on the beam profile and divergence. The ion optics of the detector should efficiently couple the mass filter output to the electron multiplier while blocking or avoiding the noise components exiting the mass filter such as photons and neutrals. Ion optics modeling and experimentation enables us to optimize the coupling between the detector and the various types of mass analyzers being used today. Improved material selection has also resulted in lower background noise by filtering or absorbing photons and neutrals. Improvements in multiplier geometry have resulted in lower dark noise generated by ion feedback and improved collection efficiency, defined as the percentage of available ions that are collected by the cone of the Electron Multiplier. Improvements in electron multiplier material science have resulted in greater linear output currents, extended life, and higher conversion efficiency, defined as the number of secondary electrons generated by an ion striking the cone of the Electron Multiplier. By combining greater linear output currents, higher gain, and lower noise we are able to extend the dynamic range of the detector, defined as the maximum linear input divided by the minimum detectable input.

The testing was done on Galileo's standard 4778 detector, supplied as original equipment on the HP5971 MSD, and Galileo's new high sensitivity plug in detector. Our software was HP's DOS chemstation REV A. We used a HP 5890 GC with a HP 7673 Autoinjector. A Deactivated injection port liner (HP5181-3587), 12M X .2mM X .33uM HP Ultra-1 column, and Merlin Microseal septum were used in the GC. All detectors were given a 12 hour test period with equal pumping times. The sample used was 100pg/ul of Methyl Stearate in Methanol with a 1ul injection. The EM voltage was set to Autotune plus 400V. The injection port and MSD interface temperatures were set to 280C. The oven program started at 100C with a 30C/min ramp to 280C, holding for 1min. The purge on time was set to 1 min. The MSD scan range was 45-370 amu, the A/D samples were 2^2, and the threshold was set to zero. We were able to see a decease in background noise by a factor of two to four. It was measured by sitting on mass 400, where there is very little real signal, and calculating the input current to the Electron Multiplier. This noise is not to be confused with the background created by a chromatograph where real signal is received at times it should not be. The following graphs are a plot of mass 298 versus time. The peak abundance, total RMS background noise, and resulting signal

to noise is provided. We were able to see a sensitivity increase of three to five times over the standard product with as much as a factor of ten at higher voltages. The maximum linear output current was well above 20 uA and separate experiments at Galileo have provided linear output currents as high as 100uA and promise even more. The techniques used here can be applied to other quadrupoles as well as other types of mass filters.

Identification of Disease State Associated Antigens Presented to the Immune System by Class I MHC Molecules; Prospects for the Development of Synthetic Vaccines Against Viral Infection and Cancer.

*Wanda M. Bodnar, Donald F. Hunt, Andrea L. Cox, Theresa A. Davis, Hanspeter Michel, and Jeffrey Shabanowitz, Dept. of Chemistry, University of Virginia, Charlottesville, VA 22901; Robert A. Henderson, Craig Slingluff, and Victor H. Engelhard, Dept. of Microbiology and Beirne Carter Center for Immunological Research, University of Virginia School of Medicine, Charlottesville, VA 22901.

Cellular proteins are continually being degraded to nine and ten residue peptides in the cytosol. These fragments become associated with class I glycoprotein molecules that transport them to the cell surface for presentation to cells of the immune system (1). Cytotoxic T lymphocytes (CTL) bind to the class I molecules and check the nature of the peptides being presented. If they are derived from foreign proteins (viruses or tumors), the CTL become activated, multiply, and lyse the diseased cell. If only self peptides are presented, the CTL remain dormant and continue their surveillance of other cells in the neighborhood. Although the above description is somewhat oversimplified, it is clear that presentation of peptides derived from disease state associated proteins plays a critical role in activating an immune response. Sequence analysis of these peptides is a necessary first step in developing vaccines or other agents that modulate the immune response to particular diseases. The task is a challenging one because the peptide fragments characteristic of the disease state will be present in a complex mixture of several thousand peptides derived from normal cellular proteins. The concentration of any individual peptide in the mixture is usually in the range of 10-1,000 fmol/10^8 cells.

We have demonstrated previously that microcapillary HPLC electrospray ionization tandem mass spectrometry is a powerful tool for the sequence analysis of individual peptides present in fmol concentrations within extremely complex mixtures (2-4). Improvements in chromatographic separation should facilitate the identification of antigens from highly complex (>80 peptides) fractions which activate alloreactive, tumor specific, or autoimmune CTL. By subjecting biologically active fractions to a second dimension of chromatography, we effect a different separation of the peptides within the original fraction. Comparison of the peptide signals of biologically active fractions from the first and second dimension separations allows us to pinpoint likely candidates for epitope reconstitution. This methodology has enabled us to characterize a single HLA-A2.1 restricted peptide recognized by the CTL clone AHIII12.2. Characterization of this peptide represents a major analytical breakthrough, as it is only the second such antigen characterized directly from a complex mixture of self peptides (5).

Of particular interest, is the characterization of peptides which specifically activate CTL to kill human melanoma cells. Melanoma tumor

is the most serious form of skin cancer, leading to 6,500 deaths each year. In the U.S. alone, there are over 32,000 new cases reported yearly, with males ages 25-65 at highest risk. The main obstacle we face is the identification of a single activating peptide from within an HPLC fraction containing 50-300 peptides. To address this problem, we have employed the multistage chromatographic separation described above. The major limitation encountered with this protocol, however, was the loss of sample due to adsorption of peptides on the column and container walls. To overcome this problem we have constructed an apparatus that allows multidimension chromatography and both mass analysis and the cytotoxicity assay to be performed on a small fraction (3%) of the material isolated from $3x10^9$ cells. In figure 1, effluent from the microcapillary column is split, and a predetermined amount directed into the electrospray ionization source of the mass spectrometer. The complementary effluent is allowed to flow into individual wells of of a microtiter plate containing medium for biological assay. The end result is a record of the masses of the peptides deposited in each well. By increasing our chromatographic resolution, we are thus better able to pinpoint candidates which activate tumor specific CTL at trace levels.

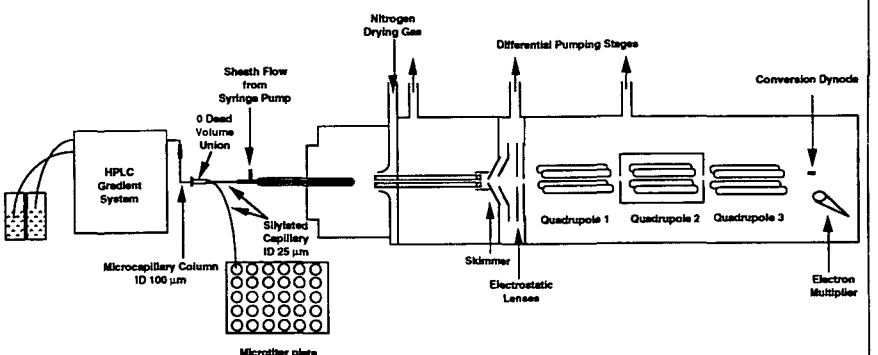

Figure 1. Microcapillary HPLC ESI MS/MS system with splitter to direct the effluent simultaneously to the mass spectrometer and to wells of a microtiter plate

Electrospray/capillary liquid chromatography (ESI/LC) and matrix assisted laser desorption (MALD) mass spectrometry for the analysis of expressed domains of carcinoembryonic antigen (CEA) and anti-CEA antibodies.

John E. Shively, Kristine Swiderek, Stanley Hefta, and Terry D. Lee. Beckman Research Institute of the City of Hope, Duarte, CA 91010.

CEA is a 180 kDa cell surface glycoprotein expressed in a variety of tumors of epithelial cell origin. Antibodies specific to CEA can be used as a serum test in vitro to monitor the recurrence of colon and other cancers, and in vivo for diagnosis and therapy of cancers of the colon, breast, and lung. CEA crossreactive antigens such as NCA (nonspecific crossreacting antigen) and BGP (biliary glycoprotein, also known as NCA-160) may interfere in tumor specific applications since they occur in a variety of normal tissues, including granulocytes. We have used several mass spectrometric techniques to study the structure of CEA, its crossreactive antigens, and engineered antibodies specific to CEA. Measurements of the molecular mass of CEA and NCA by mass spectrometry has been difficult since carbohydrate may comprise 50% of their molecular masses, and their glycosyl moieties, like most glycoproteins is notoriously heterogeneous. However, with the use of MALD/TOF/MS (on a Shimadzu instrument using a neodymium-YAG laser and sinapinic acid as a matrix) as an analytical tool, we have been able to show that CEA and NCA-55 (one of several glycoforms of NCA) have molecular masses of 135,000 and 55,000 (calculated at the maximum peak height). In the case of CEA this mass is substantially lower than that calculated by SDS-gel electrophoresis (180,000 Da), and for NCA agrees well. We have performed a variety of enzymatic and chemical deglycosylation studies on NCA-55 and shown that the loss in mass as analyzed by MALD/TOF/MS agrees well with masses predicted by other studies (**1**). When NCA or mutants lacking one, two, or three of the glycosylation sites in the N-domain (108 amino acids, three glycosylation sites) are expressed in HeLa cells and analyzed by MALD/TOF/MS the masses observed agree well with the calculated masses. The glycosyl deletion mutant studies of NCA demonstrate that the bacterial-lectin binding properties of this glycoprotein are contained within the first two glycosylation sites and probably involve protein as well as carbohydrate determinants. In addition, we have expressed a number of CEA domains and shown that their calculated and observed masses closely agree (**2**). Thus, this approach has been an accurate and sensitive (1-10 picomoles analyzed) method to analyze complex glycoproteins.

In order to study the site-specific structures of the glycosyl moieties of CEA and NCA, the reduced and alkylated forms were digested either with a combination of trypsin and chymotrypsin or pepsin and the glycopeptides purified by a combination of reversed phased and "hydrophilic" phase (polyhydroxylethylaspartamide) HPLC. Since the rather hydrophilic and heterogeneous glycopeptides do not resolve well on reverse phase HPLC, and give hard to interpret mass spectra results unless highly purified, it was necessary to use secondary chromatography approaches. In our hands, the best analytical tool for glycopeptide analysis was SIMS analysis (a Phrasor Instruments cesium ion gun) on a triple quadrupole mass spectrometer (Finnigan TSQ700). CEA has 28 N-glycosylation sites and a C-terminal glycosylphosphatidyl inositol moiety. A glycopeptide isolated from glycosyl site number 1 has the sequence SGREIIYPN*ASLLIQ, where the glycopeptide has a mass of 3738, 1675 of which is due to the peptide moiety (**3**). The SIMS spectrum shows sequential losses of Gal, Gal-GalNAc-Fuc, Gal-GlcNAc(-Fuc)-Man, etc., all the way down to the intact peptide at 1675 (no glycosyl moiety). Although the mass spectra cannot distinguish the structural nature of the sugar moieties, they can be logical assigned based on consensus

structures published for glycoproteins. When the same glycopeptide is analyzed by ESI, a hard to interpret mass spectrum is obtained. We attribute this difficulty to the occurrence of multiply charged fragments ions which include peptide and glycosyl fragments exhibiting no obvious pattern of fragmentation or charging. In comparison to CEA, NCA has 12 glycosylation sites of which a peptide from glycosyl site 1 has the sequence $(Man)_3(GlcNAc)_2Fuc$ as determined by MS/MS SIMS analysis. An indication of the sensitivity of the approach is given by the isolation of NCA-160 (BGP) from granulocytes and digestion with trypsin at the 50 picomole level on a nitrocellulose membrane and isolation of the resulting glycopeptides from capillary liquid chromatography (160 micron ID column). Analysis of 25% of the recovered glycopeptides (about 6 pmoles) by SIMS gave 30% of the sequence of the protein, including significant information about the location and nature of glycosyl residues. One example shown (**4**) predicts an M_7GN_2 glycosyl moiety.

The analysis of engineered antibodies to CEA has also benefited from mass spectral analysis. For the large fragments, including intact immunoglobulin (150,000 Da), we have routinely used MALD/TOF/MS. For the smaller fragments, including single chain antibodies (SCA) (28,000 Da), we have used ESI combined with LC/MS. We have found LC/MS a requirement for these analyses, since the samples are always isolated in bio-compatible buffers which severely interfere with direct infusion ESI. In one example, we have observed a mass of 28,133 for a SCA with a predicted mass of 24,146. Further structural analysis revealed that the SCA had the correct N- and C-terminal amino acid sequence. The SCA gave broad peaks on conventional wide pore C8 reversed phase packings in a capillary column. When the SCA is reduced and S-alkylated (by iodoacetic acid in 6 M guanidinium HCl and 10 mM DTT) the problem becomes so severe as to make analysis by ESI impossible. This problem was solved by using less absorptive polymer resins such as Polymer Labs **PR** packing. In this case, a single sharp peak was observed with a deconvoluted mass agreeing to within 10 mass units of that predicted. The polystyrene packing has other applications, including use in high pH solvent systems such as TEA/TFA. The high pH systems may have applications in negative ion ESI. Recently, we have analyzed strongly anionic macromolecules (carboranyl oligophosphates) and shown that they give excellent negative ion spectra on ESI LC/MS, but otherwise have been difficult to analyze by negative ion SIMS or MALD. We attribute the latter difficulties to the presence of strongly complexed cations which interfere in SIMS or MALD, but are removed during LC/MS, a technique ideally suited to ESI.

We conclude that multiple MS approaches are required to solve the diverse problems encountered in the analysis of protein conjugates of immunological interest.

Structural and Mechanistic Studies of Human Neutrophil Elastase by Mass Spectrometry

P. R. Griffin, T. A. Dickinson, B. G. Green, W. B. Knight, J. Doherty, and R. A. Mumford, Merck Research Laboratories, Rahway, N. J. and Glaxo, Inc. N.C.

Human Neutrophil elastase (HNE; EC 3.4.21.37) is a 220 amino acid serine protease that is present in mM concentrations in the azurophilic granules of polymorphic nuclear monocytes (PMN). HNE has been implicated in a number of inflammatory diseases (cystic fibrosis, bronchitis, emphysema, inflammatory bowel disease and perhaps rheumatoid arthritis). A series of β-lactams have been described by Merck Research Laboratories as mechanism-based inhibitors of elastase. Knowledge of the molecular nature of enzyme-inhibitor (E-I) complexes formed by reaction of HNE with β-lactams can lead to the proposal of a mechanism of inhibition consistent with both chemical and kinetic data. We have utilized capillary-HPLC-ESI-MS and matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) for probing the interaction between HNE and a β-lactam (1) and between HNE and α1-proteinase inhibitor (α1-PI).

Reaction of β-lactams with HNE produces very stable E-I complexes and the stability of these complexes was postulated by Firestone and co-workers (2) to be attributed to a "double hit" mechanism involving both acylation and alkylation of active-site serine and histidine, respectively. This "double hit" mechanism for b-lactams was derived from X-Ray crystallography experiments on cephalosporin inhibitors complexed with elastase. To probe this mechanism of inhibition HNE (25,199 Da as determined by HPLC-MS; see Figure 1) was reacted with L-680,833 (Figure 2) (k_{obs}/k_i = 680,000 $M^{-1}s^{-1}$; M.W. = 467). This reaction yielded an E-I complex with a mass of 25,523 Da (a mass shift of +324 Da; see Figure 2). The observed mass shift is consistant with the β-lactam ring opening followed by the loss of the phenoxy group at C4 and the incorporation of a molecule of water to the complex. The role of histidine in this complex is unclear. However, these results suggests that a "double hit" of active site serine and histidine may not be required to produce a stable E-I complex.

It is interesting to note that only irreversible E-I complexes were observed by HPLC-ESI-MS, ESI-MS using direct infusion in aqueous solutions, and by MALDI-TOF-MS. Reversible tight-binding complexes between HNE and secretory leucoprotease inhibitor (SLPI) were not observed yielding both intact HNE and intact SLPI. In addition, complexes between porcine pancreatic elastase (PPE) and β-lactams were analyzed affording identical results as obtained on HNE. Finally, complexes between HNE and α1-PI were analyzed by MALDI-TOF-MS. As expected, a 70 kDa complex of HLE-α1-PI was present as well as the 4.1 kDa peptide that is cleaved from α1-PI. These results demonstrate that mass spectrometry is a powerful tool to probe the mechanism of inhibition of enzymes by mechanism-based inhibitors.

[1]Dept. of Chemistry, Dalhousie University, Halifax, Canada, B3H 4J3, [2]Institute for Marine Biosciences, NRC, Halifax, Canada,B3H 3Z1, [3]Institute for Biological Sciences, NRC, Ottawa, Canada, K1A 0R6.

Lipopolysaccharides (LPS) are a unique group of biomolecules found on the outer surface of the cell walls of gram negative bacteria (1). LPS typically have endotoxic and O-antigenic properties and have been the subject of much scientific and medical interest. These complex oligosaccharides usually consist of three distinct regions: the O-specific chain, the Core, and the Lipid A. The latter region normally consists of fatty acids and phosphate groups bonded to a disaccharide of two D-glucosamine units, whereas the O-specific chain and the Core are almost exclusively carbohydrate.

Branhamella catarrhalis (*B.cat.*) has recently been recognised as an opportunistic pathogen and is often the sole causative agent of a number of respiratory diseases and acute otitis media (2,3). *Hemophilus influenzae* type b (*Hib*) infection can lead to meningitis in young children (4). In both cases, it is believed that LPS plays an important role in the expression of their virulence. Furthermore, the LPS isolated from these bacteria are unusual in that they lack an O-specific chain.

The separation and characterization of such complex biomolecules by conventional methods is difficult as they are large, polar, labile, and lack a significant UV chromophore. Furthermore, LPS isolated from a given species are typically heterogenous owing to varying degrees of substitution of the basic LPS structure. However, these compounds usually possess ionic functionalities which facilitate their analysis by techniques such as capillary electrophoresis. Successful separation and detection of the O- and N,O-deacylated LPS has been accomplished using capillary electrophoresis coupled with ionspray mass spectrometry (CE-ISP-MS).

The O-deacylated LPS were found to be amenable only to negative ion MS, which is consistent with the fact that these molecules contain acidic moieties but no protonation sites. CE-ISP-MS of O-deacylated LPS from *B.cat* revealed its natural heterogeneity (Fig. 1), which is due mainly to the number of phosphate or phosphoethanolamine groups attached to the principal LPS structure. The N,O-deacylated LPS were amenable to both positive and negative CE-ISP-MS. These two modes of detection permitted identification of the same compounds. Moreover, the principal analytes observed differ only in the number of hexose units they contain. Full mass scan acquisition for the N,O-deacylated LPS was typically carried out on picomole quantities of material. However, the limit of detection in selected ion monitoring mode was in the low femtomole range.

Structural characterization of the O- and N,O- deacylated LPS was achieved using tandem mass spectrometry with low energy CID. The principal fragmentation pathways observed arise from cleavage of the glycosidic bonds leading to sequential loss of the monosaccharide units (Fig. 2). Positive and negative MS-MS spectra of the doubly-charged O- and N,O-deacylated LPS were characterized by intense fragmentations corresponding to the lipid A moiety and its complementary fragment.

STRUCTURAL CHARACTERIZATION OF THE ADJUVANT ACTIVE COMPOUNDS IN *QUILLAJA SAPONARIA* MOLINA EXTRACTS

C. E. Costello[1], K. E. Vogele[2], J. Thurin[2] and B. Morein[3]
[1]Department of Chemistry, Mass. Inst. of Technology, Cambridge, MA 02139
[2]The Wistar Inst., Philadelphia, PA 19104
[3]Royal Veterinary College, Stockholm, Sweden.

The ISCOM adjuvant, Immune Stimulatory Complex, is a 35-nm particle which is formed by mixing a saponin glycoside mixture, Quil-A, with cholesterol and antigen. Quil-A contains a multitude of different compounds, many of which are toxic. Before the adjuvant properties of these extracts can be exploited for human use in vaccines, it is necessary to establish structure-function relationships of the various components. In this study, the adjuvant active compounds in Quil-A have been purified through a series of chromatographic procedures and the active fractions followed by bioassay throughout the isolation procedure. Two compounds have been found to be responsible for most of the adjuvant activity and one is responsible for the formation of the ISCOM particle. Our preliminary data indicate that the isolated compounds are not identical to those previously published which were isolated from the same material (1-3). The The structures of the components of the most abundant adjuvant-active fraction and the core compound(s) obtained from it upon base hydrolysis are presently being determined, using a combination of mass spectrometry and multidimensional NMR. Positive- and negative-ion LSIMS and MS/MS and matrix-assisted laser desorption mass spectrometry have each contributed to the results.

Experimental. LSIMS and MS/MS mass spectra were obtained with a JEOL HX11/HX110 (E_1B_1-E_2B_2) tandem mass spectrometer, operated at +/- 10 kV acceleration. CID took place in a cell located between MS-1 and MS-2, floated at 3 kV *vs.* ground. MALDI mass spectra were obtained on a Vestec VT2000 linear time-of-flight instrument, using an LSI nitrogen laser (337 nm), +30 kV or -25 kV acceleration, and a LeCroy transient digitizer for data acquistion.

Results. LSIMS and MALDI mass spectra have been obtained for the fractions containing the intact saponins and for all of the components obtained by hydrolysis of the active fraction followed by chromatographic separations. The initial mixture was quite heterogeneous, and, indeed, some minor heterogeneity remained in all fractions even after extensive purification. Results from an earlier MS/MS investigation of simpler saponins (4) were helpful in assigning the product ion structures. The availability of hydrolysis products as well as intact saponins in this study helped with elucidation of new pathways. The most abundant components of the intact adjuvant have the apparent molecular weights 2019.2 and 2151.2, and the major hydrolysis product has molecular weight 1674.8. Minor but potentially important components vary in carbohydrate content and in the substitution of the triterpene. Evidence from the MS/MS data indicates that there is variation in all three carbohydrate regions of the structure. CID of fragment ions as well as the molecular species was needed to unravel the heterogeneity in each

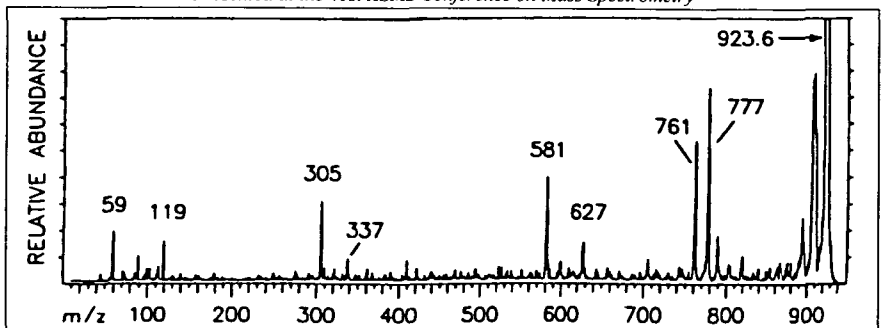

Fig. 1. CID mass spectrum of *m/z* 923.6 in the LSIMS of an active intact saponin fraction.

of these regions. Figure 1 shows the CID mass spectrum obtained for a fragment in the negative-ion LSIMS spectrum of intact acylated saponin that contains, among others, a pair of components differing in mass by 14 u. Scheme 1 shows assignments of the product ions from *m/z* 923. On the basis of the spectra obtained for *m/z* 909 and *m/z* 923, it could be determined that the mass shift occurred at the rhamnose residue. MS/MS was thus very useful to differentiate among the isomers that varied in carbohydrate chain size and branching patterns, whereas NMR was particularly good for distinguishing among the isomeric carbohydrate residues and for establishing linkage positions. MALDI was the fastest, most sensitive and most reliable method for determination of molecular weight heterogeneity.

THE ROLE OF MASS SPECTROMETRY IN THE STRUCTURE DETERMINATION OF MUCINS EXPRESSED BY CARCINOMAS

R. L. Cerny and M. L. Gross, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588 and M. A. Hollingsworth, Eppley Institute for Research in Cancer, University of Nebraska Medical Center, Omaha, NE 68198

The basic cellular processes that regulate O-linked glycosylation of proteins are poorly understood. There is evidence that epithelial cells from different tissues glycosylate different serine and theonine residues on the same core of heavily O-glycosylated proteins such as mucins. Truncated oligosaccharides on mucins produced by tumors in epithelial tissues have been identified as tumor-associated antigens. It has also been postulated that the points of attachment of the oligosaccharides are altered by these tumors, thus exposing tumor associated epitopes on the mucin core regions. These epitopes are currently being evaluated as target antigens for diagnostic reagents and tumor vaccines.

MUC 1 is glycoprotein expressed by a wide variety of human adenocarcinomas and their normal epithelial counterparts. MUC 1 has a core protein consisting of 1272 residues. The central two thirds of the protein sequence consists of identical 20 amino acid tandem repeats. Synthetic peptides (30 residues and 20 residues) corresponding to the tandem repeat sequence were glycosylated *in vitro* using UDP-[^{3}H]GalNAc and N-acetylgalactosaminoyltransferase from pancreatic and breast tumor cell lines, HPAF and MCF7 respectively. The glycopeptides were purified by chromatography on Dowex 1 and P-10 columns, and then reverse phase HPLC on a C-18 column. Analysis of the resulting glycopeptides by mass spectrometry showed that up to three molecules of GalNAc linked to each repeat unit in the peptides (see Figure 1). The protonated 30 residue peptide has an average mass of 2869.6 daltons. Addition of a GalNAc subunit increases the molecular weight by 203 daltons. Fraction A contains glycopeptides incorporating principally 2 GalNAc subunits (but also 1 and 3), fraction B contains a glycopeptide with only one GalNAc subunit, and Fraction C contains the unmodified peptide. Purified glycopeptides were sequenced on a gas phase sequencer and glycosylated positions were determined by measuring the incorporated radioactivity in fractions collected flowing each round of Edman degradation. The results showed that two of three threonine resides and none of two serine residues on the MUC 1 tandem repeat peptides were glycosylated by both HPAF or MCF7 lysates at the following positions: GVTSAPDTRPAPGSTAPPAH (underlined T indicates GalNAc attachment).

Efforts are underway to improve the sensitivity of tandem mass spectrometry for the use in the analysis of clinical specimens, which cannot be studied by the modified Edman assay. Shown in Figure 2 is the CAD spectrum of 1 nanomole of a synthetic glycopeptide that incorporates one GalNAc unit. The spectrum was obtained using a ZAB-T, four sector mass spectrometer with array detection with a mass ratio of 1.21:1. Although the spectrum contains several abundant sequence ions, information on the position of the GalNAc moiety is absent. In fact, elimination of GalNAc is one of the most abundant fragments. Further work must be done to enhance the information obtained from the CAD spectrum.

CHARACTERIZATION OF NATURALLY-OCCURRING AND MODIFIED FULLERENES BY FOURIER TRANSFORM MASS SPECTROMETRY *

Robert L. Hettich, Changming Jin, Rhys Thomas, and Robert N. Compton
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120
and
Peter R. Buseck and Semeon J. Tsipursky
Department of Geology, Arizona State University, Tempe, AZ 85287

Based on the remarkable stability and properties of fullerenes, it was thought that these species may have formed under natural conditions outside the laboratory and may be found in geological samples. Collaborative research between Peter Buseck, Semeon Tsipursky and Robert Hettich resulted in the first evidence of naturally-occurring fullerenes in a carbon-rich terrestrial rock sample from Russia. The natural source of fullerenes in this case was a carbon-rich rock (shungite) from Shunga, Russia. Buseck and Tsipursky noted that, under high resolution transmission electron microscope investigations, certain portions of this rock appeared to be identical to images of synthetic fullerenes. Examination of a few micrograms of this sample by laser desorption (266 Nd:YAG laser) Fourier transform mass spectrometry at ORNL revealed the presence of C_{60} and C_{70}, as shown in Figure 1 laser desorption spectrum. While these initial results were quite encouraging, the experimental parameters for this technique must be carefully controlled to insure that the fullerenes detected were present in the sample and were not created in the mass spectrometer by the laser desorption event. Examination of pure graphite samples indicated that fullerenes were not generated from pure graphite under these low energy laser desorption conditions (10^6 - 10^7 W/cm^2). In addition, thermal desorption of the sample (350 °C) followed by low energy electron capture also indicated the presence of C_{60} in this sample, shown in Figure 1 thermal desorption spectrum (a higher temperature is needed to thermally desorb C_{70} from the probe tip). These experiments were the final proof needed to verify the presence of fullerenes in the sample, because thermal desorption will not generate fullerenes from graphitic material. The origin of the shungite rock is a subject of debate at this time; it may be a product of either a volcanic or organic process. This shungite sample is similar in composition to meta-anthracite rank coals and is jet-black in appearance.

FTMS is useful for examination of the structures and properties of fullerene derivatives as well. For example, hydrogenated fullerenes were generated by exposing solid films of C_{60} to a high pressure of H_2 at elevated temperatures. Experimentally, C_{60} powder was placed in metal capsules (Pd and Au) and exposed to 1000 Bar of H_2 at 700 K for times ranging from 24-96 hours. Figure 2 shows the positive ion mass spectrum of a sample which was contained inside a Pd capsule for 90 hours during the hydrogenation process. Besides the typical pure C_{60} isotopic mass distribution at 720, 721, 722 amu, there is evidence of $C_{60}H_x$ for x up to 24. Identical results were obtained for both Pd and Au capsules, indicating that the metal capsule did not serve as a catalyst for these hydrogenation reactions. To examine whether the protons might be inside or outside the fullerene cage, the following charge exchange reaction was used (pyridine is known to be a stronger base than C_{60}).

$$\text{Pyridine} + C_{60}H_x^+ \text{ ------ } (\text{Pyridine}+H)^+ + C_{60}H_{x-1} \qquad (1)$$

The resulting mass spectrum revealed that the $C_{60}H_x^+$ containing an odd-number of hydrogens would undergo faster proton transfer to the pyridine than the even-numbered hydrogenated species. Further research is in progress to examine these hydrogenated fullerenes with other reagent gases.

Analysis of Fullerene Soot Extracts by Liquid Chromatography-Mass Spectrometry Using Atmospheric Pressure Ionization†

J.F. Anacleto,* Department of Chemistry, Dalhousie University, Halifax, N.S. Canada
M.A. Quilliam and **R.K. Boyd**, Institute for Marine Biosciences, NRCC, Halifax, N.S. Canada

Techniques have been developed for the analysis of fullerenes and related compounds present in materials such as soots produced by resistive heating of graphite in an inert atmosphere and condensates from benzene flames. The minor constituents of three fullerene-rich materials have been characterized by on-line LC-MS techniques using both positive and negative ion mass spectra obtained by atmospheric pressure chemical ionization (APCI). Two of the materials were soots, produced by resistive heating of graphite, from different commercial suppliers: one contained monoxides of the carbon clusters as the principal minor components (e.g., $C_{60}O$ and $C_{70}O$), while the other contained hydrogenated species including $C_{60}H_2$, $C_{60}H_4$, and $C_{70}H_2$ (1). The third material, a condensate from a controlled benzene flame, was shown to contain all of the minor constituents mentioned above as well as significant quantities of compounds that behaved under the APCI/MS conditions as isomers of the C_{60} and C_{70} fullerenes, and which reverted to the latter upon heating (2).

Further characterization of the flame soot extract was performed by LC coupled on-line to ionspray mass spectrometry (3). Charge-transfer complexation, using a post-column addition of either an electron donor or acceptor, was utilized as a pre-ionization technique. The negative ion mode experiments, using TMPD as the electron donor, produced intense $M^{-\cdot}$ ions corresponding to the C_{60} and C_{70} fullerenes, but failed to provide any information regarding the identity of the metastable constituents. Analyses in positive ion mode, using DDQ as the electron acceptor, showed that the metastable compounds yielded mass spectra consistent with their identification as fullerene adducts with highly unsaturated moieties C_nH_{2n-4} with n=5, 6, and 7 (Figure 1). The molecular radical cations of these adduct species were susceptible to facile fragmentation yielding the molecular ions of the corresponding fullerenes. Based on this information, the Diels-Alder adduct of C_{60} and cyclopentadiene has been synthesized and shown to be identical (based on ^{13}C and proton NMR) to the $C_{60}C_5H_6$ adduct (n=5) generated in the benzene flame (4).

The separation of fullerenes on four commercially available reversed-phase columns was also investigated using LC-APCI/MS (5). Three of the octadecylsilica (C_{18}) phases were incapable of adequately separating the fullerenes, present in a trichlorobenzene soot extract, according to carbon number. However, baseline resolution of nearly all the fullerenes (up to at least C_{96}) was achieved with a 2-(1-pyrenyl)ethylsilica phase. This was probably the result of increased π-bond interactions between the stationary phase and the fullerenes.

The resolution of individual fullerene isomers was best accomplished with a polymeric octadecylsilica bonded phase (Figure 2). All of the other stationary phases, monomeric C_{18} and pyrenyl, were very poor in this respect. A proposed mechanism for this unique ability combines the shape selectivity of polymeric phases, previously recognized for planar polycyclic aromatic hydrocarbons, and the "molecular footprints" of the fullerene isomers.

Carbon Cluster Anions: C_5^- to C_{60}^-

Nigel G. Gotts, Gert von Helden, Michael T. Bowers
Department of Chemistry, University of California, Santa Barbara

Introduction:

Ever since the discovery of Buckminsterfullerene, carbon cluster ions have been at the forefront of many research efforts. In particular, the structures adopted by the carbon cluster ions have represented a major field of interest, as manifested by the question "Where do fullerenes come from"?

We recently introduced a novel experimental technique, dubbed "Ion Chromatography"[1], which enables structural analysis to be performed for a mass selected species. The procedure utilizes a high pressure drift cell. Ions passing through the cell are separated according to their collision cross section, and hence their structure. When applied to carbon cations, several structural families are observed. These sequentially manifest themselves in the order, Linear chains, Monocyclic rings, Bicyclic rings, Tricyclic rings, 3-D rings, Fullerenes/Cages, as cluster size increases[2].

Here we report on an extension of the study to include carbon anions. The object, to discern any differences in structural behaviour between the two ion forms.

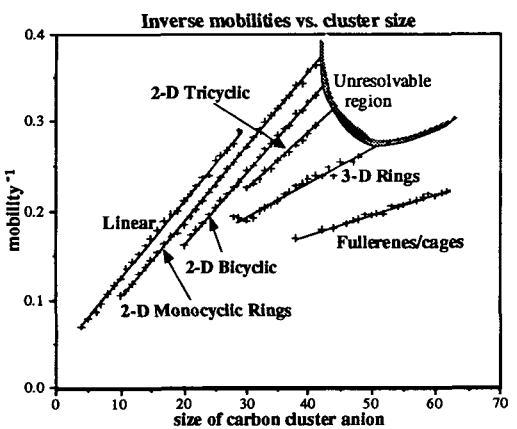

Figure 1

Experimental:

Carbon clusters, ions and neutrals alike, are produced in a typical laser vaporization source. Following supersonic expansion, the chosen ion species are accelerated to 5kV, and subsequently mass selected via a reverse geometry double focussing mass spectrometer. A 5-10 ms packet of the cluster ion of interest is then decelerated and injected into a high pressure drift cell, containing up to 5 Torr of helium. Ions drift through the cell under the action of a weak electric field. Collisions with the helium serve to spatially, and by analogy temporally, separate the different isomers present. Upon exiting the cell the ions are quadrupole mass analysed and detected. Data obtained in this manner is termed an Arrival Time Distribution (ATD). Fitting the

ATD's to obtain the mobilities of the isomers present is routinely performed via a computer peak matching program. Semi-empirical computer modelling procedures are adopted to match an observed mobility with a possible structure. The accuracy in this approach is typically to within a few percent.

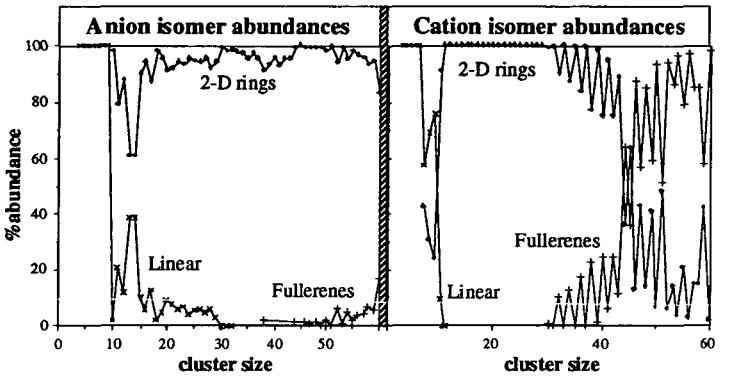

Figure 2

Results and Conclusions:

Figure 1 graphically depicts the observed structures for cluster anions in the range C_5^- to C_{62}^-; plotted as a function of inverse mobility. Note that ions of the same structure fall along a common gradient, and also that the 2-D tricyclic, bicyclic, and monocyclic rings possess similar slopes. Qualitatively these results are identical to those obtained for the cations.

Two notable exceptions occur in the linear and fullerene forms of the anions. In figure 2 we depict the percentage abundances observed for the linear, total 2-D ring (monocyclic+bicyclic+tricyclic), and fullerene systems. It is immediately apparent the linear cations vanish at a cluster size of ten units, while linear anions are still observed at C_{28}^-. Since the anions are probably formed via electron attachment to neutrals, it appears neutral linears may exist to quite large sizes.

For fullerenes an even/odd oscillation in relative abundance is apparent with even being favored. These structures dominate the ATD's of the cations above C_{44}^+, with C_{60}^+ more than 95% fullerene. On the other hand for anions fullerene abundances remain minor components up to and beyond C_{60}^-. For example only 20% of the C_{60}^- species possess the fullerene form, the remainder being planar rings.

What these results suggest is; a) since the same structural families are present for both the anions and cations, the neutrals almost certainly have these families also; linears, planar rings, fullerenes; b) the late development of the fullerene family in the anions probably reflects the rather larger electron affinity of planar ring systems over fullerenes, rather than an inherently greater stability of neutral planar rings over fullerenes.

MASS SPECTROMETRY OF UNUSUAL FULLERENE COALESCENCE PRODUCTS

J.H. Callahan, M.M. Ross and S.W. McElvany
Chemistry Division/Code 6113, Naval Research Laboratory, Washington, DC 20375-5000

L.D. Lamb and D.R. Huffman
Physics Department, University of Arizona, Tucson, AZ 85721

One of the unusual chemical characteristics of fullerenes is their ability to undergo reactions that apparently involve coalescence of smaller fullerenes resulting in larger clusters. Recent studies of this phenomenon have consisted of laser vaporization of pure fullerenes and mass spectrometric analysis of larger all-carbon ions (1,2). The speculation is that following photon-induced damage of the fullerenes, the species formed react to yield the larger clusters, which in all cases to date have been measured to have an even number of carbon atoms.

In a recent study, we detected the large, odd-numbered, pure-carbon clusters C_{119}, C_{129} and C_{139} in toluene extracts of soot produced in a graphite arc (3). Figure 1a shows a narrow-range mass spectrum from the methane negative ion/desorption chemical ionization (NI/DCI) analysis (4) of a soot toluene extract. Between m/z 1350 and 1600 essentially only C_{119}^- and C_{129}^- are observed. However, Figure 1b shows that when positive ion/desorption electron ionization is used extensive fragmentation results. Specifically, lower-mass ions corresponding to C loss, C_{118}^+ and C_{128}^+, and subsequent C_2 losses, C_{116}^+, C_{114}^+ and C_{126}^+, C_{124}^+, from C_{119}^+ and C_{129}^+, respectively, are observed. Collision-induced dissociation experiments proved unsuccessful in fragmenting either C_{119}^- or C_{119}^+ using 200-eV (lab) multiple collisions with xenon in the triple quadrupole instrument.

While it is evident that C_{119}, C_{129} and C_{139} correspond to "dimers" of C_{60}, C_{60}/C_{70} and C_{70} less one carbon atom, respectively; it is not obvious how this reaction might proceed. One possibility would involve oxygen whereby a CO or CO_2 loss could drive the process. To test this idea ozone was bubbled through toluene solutions of pure C_{60}, pure C_{70} and a 1/1 mixture of C_{60} and C_{70}. The NI/DCI analyses of these three samples are shown in Figures 2a, b and c, respectively. The O_3/C_{60} reactions yields predominately C_{119}, O_3/C_{70} yields mostly C_{139} and ozonolysis of the mixture yields C_{119}, C_{139} and C_{129} as the most abundant products.

These results indicate that ozone/fullerene reactions can result in opening of the cage followed by reaction with another fullerene to yield a larger carbon cluster. It appears that similar products can be formed in the graphite arc, also. Although the gas-phase behavior of the odd-numbered clusters is similar to that of fullerenes, the structures of these unusual species are unknown. However, these observations are consistent with reported oxidation-induced opening to fullerene tubes (5).

LASER DESORPTION MASS SPECTROMETRY OF PHOTOPOLYMERIZED C_{60} FILMS

D. S. Cornett*, M. A. Duncan, I. J. Amster
Department of Chemistry, University of Georgia, Athens, Georgia, 30602

A. M. Rao and P. C. Eklund
Center for Applied Energy Research, University of Kentucky, Lexington, Kentucky, 40511

Irradiation of thin films of C_{60} with intense visible or ultraviolet light initiates chemical reactions within the films. The phototransformation process produces films which are no longer soluble in toluene, whereas unirradiated, or pristine, films are readily soluble in this solvent. Based on evidence collected using numerous techniques, we recently proposed that the phototransformed films consisted of polymerized C_{60} molecules.[1] For example, several Raman bands observed for the C_{60} films shift significantly upon phototransformation, and X-ray diffraction shows that the spacing between adjacent cages is smaller after transformation. Laser desorption mass spectrometry provides direct evidence as to the composition of the films, and clearly demonstrates that phototransformed films are composed of cross-linked fullerene molecules.

Experiments are conducted in a linear time-of-flight mass spectrometer operated at 25 kV Laser desorption is accomplished using 337 nm (N_2 laser) light at a fluence of 5-30 mJ cm^{-2}. The restriction on the upper limit for the fluence is dictated by the fact that higher fluences produced a visible plasma at the surface, a condition which has been shown to produce higher fullerenes from C_{60}.[2,3] Also, desorbed ions are sampled directly into the mass spectrometer without the addition of any thermalizing gas which could promote the formation of clusters by condensation. 200 nm thick fullerene films are prepared by vacuum vapor deposition of 99% pure C_{60} directly onto stainless steel mass spectrometry probes. Phototransformation of the films is accomplished by exposure to either a 300 W Hg arc lamp or the 5 W output of an Ar^+ laser (all lines) for 1 to 12 hours. All sample handling is conducted in an inert atmosphere to minimize exposure to O_2. Pristine films are stored and transported in a dark environment to prevent any possible transformation by ambient light.

Because the wavelength of the laser light used for desorption is within the range which can cause transformation, pristine films have been analyzed under the same conditions as the transformed samples, to evaluate the possibility that the desorption laser causes transformation during the desorption process. Figure 1 shows mass spectra of transformed (1a) and pristine (1b) films, desorbed using a laser fluence of approximately 30 mJ cm^{-2}. As seen in Fig. 1a, laser desorption of a transformed film produces a broad distribution of ions extending to 15 kDa which we identify with clusters of cross-linked fullerene molecules, $(C_{60})_N$. The mass spectrum obtained from the pristine film, Fig. 1b, also exhibits a distribution of cluster ions. However, the mass range of this distribution terminates at a much smaller value of N than does the ion distribution shown in Fig. 1a. The insets of the two figures show an expanded view of the mass range encompassing the dimer and trimer ions of C_{60}. Clearly evident is the fact that each cluster peak is composed of a series of ion peaks, each separated by 24 Da. The similar nature of the two insets suggest that

the desorption laser does initiate a small degree of phototransformation. At a laser fluence of ca. 10 mJ cm^{-2}, mass spectra obtained from a transformed film exhibit a cluster distribution extending up to $(C_{60})_{10}$, while a pristine film produces less than 1% of $(C_{60})_2$ relative to C_{60} molecular ion. This data suggests that the cluster ions observed in the phototransformed mass spectrum are indeed being directly sampled from a polymerized film. Higher mass distributions observed at higher fluences indicates that more energy must be deposited into the film in order to disrupt the bonding of larger particles.

DYNAMIC SIMS

R.G. Wilson, Hughes Research Laboratories, Malibu, CA 90265

This review of dynamic SIMS includes discussions of fundamentals, including enhancement of positive secondary ions by using O_2 primary ions, and the enhancement of negative secondary ions by using Cs primary ions, the measurement of RSFs (relative sensitivity factors) for quantification of dynamic SIMS for both positive and negative secondary ions, and the observation of systematics in these RSFs[1-4] for many materials including semiconductors,[1,3,4] insulators,[5] polymers,[6] and metals[7-9], and quantification issues. Ionization efficiencies from 1 to 100% can be achieved for many elements, and, for a sector magnet instrument with about 10% transmission, corresponding useful yields of 10^{-1} to 10^{-3} are achieved for many elements (with low ionization potential or high electron affinity). Exceptions are elements with high ionization potential and low electron affinity. RSFs and quantification can be accurate to within 10 or 20% for limited elements and controlled conditions within one laboratory[10] and within 30% among many laboratories,[11-14] and within 60% for many elements, many analysts, many instruments, and over many years.[4] RFSs (systems) can be determined for many materials within a factor of 5 by preparing and measuring only two standards.[2] The dependence of RSFs on instrument and analysis conditions is considered.[15] Only the position of the analysis spot within the target holder window for sector magnet instruments causes significant error. Approximate detection limits for dynamic SIMS are discussed. Charge compensation using sector magnet instruments is demonstrated, as are high mass resolution, dynamic range, and the use of isotopes and molecular species to enhance dynamic range/detection sensitivity.[4] General applications to depth profiling, bulk analysis, and imaging are distinguished, but imaging is not dealt with here. Specific practical applications to materials growth and device structures are illustrated, including 1% change in stoichiometry, Be- and Si-doped HBTs, stacked multilayer III-V devices, spreading of annealed delta doped layers, nipi structures, quantum wells, In- and As-doped II-VI devices, II-VI superlattices, deep implantation-channeled profiles, and the profiling of Na in insulators. Details of many of these issues can be found in references 4 and 16.

Static SIMS Studies of Alkylmethylphosphonic Acids Adsorbed on Substrates of Environmental Interest

J. C. Ingram, G. S. Groenewold, A. D. Appelhans, and J. E. Delmore, Idaho National Engineering Laboratory, P. O. Box 1625, Idaho Falls, ID 83415-2208

Alkylmethylphosphonic acids (AMPAs) may be detected rapidly and sensitively on environmental and industrial surfaces using static SIMS. The analysis of these compounds is important as they are degradation products of chemical weapons agents. Further, AMPAs are non-volatile and adsorb strongly to some substrates which make them difficult to extract and analyze by standard chromatographic methods.

Detection is achieved using a SIMS instrument equipped with two unique features: a) perrhenate (ReO_4^-) primary ion beam and b) pulsed secondary ion extraction for sample-charge neutralization. The perrhenate ion gun produces a large molecular anion and is operated at ca. 10 keV and 100 picoamps; it is highly efficient for sputtering molecular ions from a sample surface, giving improved sensitivity over conventional atomic ion guns. These features result in abundant secondary ions originating from the top few monolayers of the sample. Pulsed extraction alternately samples positive, then negative ions. By varying the positive/negative ratio, sample surface charging can be minimized. These features allow analysis of insulating samples such as leaves, which are not readily analyzed using conventional SIMS. Moreover, anion and cation spectra are acquired simultaneously. No sample preparation is required.

The AMPAs investigated in this study are listed in Table 1 along with their structures and molecular weights. Nanogram quantities of AMPAs are readily detected on plant leaves, steel, and some polymers.

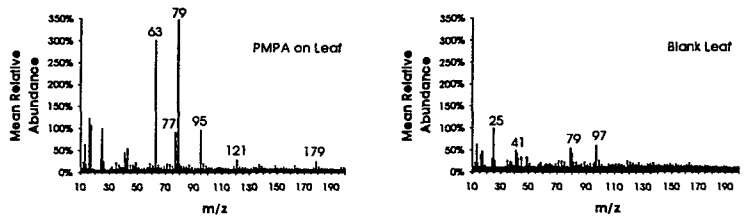
Table 1. AMPAs

Alkylmethylphosphonic Acids	Structure	Acronym	MW (amu)
Ethyl methylphosphonic acid		EMPA	124
Isopropyl methylphosphonic acid		IMPA	138
Pinacolyl methylphosphonic acid		PMPA	180

In these studies, it was found that the anion spectra were more useful than the cation spectra for identification of AMPAs on various substrates. The methylphosphonic acid moiety present in the three molecules studied, shown in

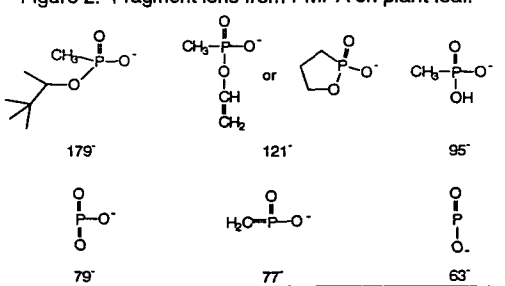
Table 1, is responsible for similar fragmentation chemistries observed in the anion SIM spectra of these molecules. The anion spectrum of PMPA shown in Figure 1 is typical of spectra collected for other AMPAs.

Figure 1. SIM anion spectra of PMPA on a plant leaf and the blank leaf background.



The fragment ions at 179^-, 121^-, 95^-, 79^-, 77^-, and 63^- marked on the PMPA spectra in Figure 1 are identified in Figure 2. The 79^- and 63^- ions are the most abundant ions observed in the anion spectrum and are attributed to PO_3^- and PO_2^-. The 95^- ion is interpreted as the methyl phosphonate ion which would arise from cleavage of the large alkyl groups from the parent molecule. Another fragment ion indicative of the methyl phosphonate moiety is observed at m/z 77^-, which is believed to have the structure presented in Figure 2. It is speculated that 77^- ion is formed by dehydration of the 95^- ion. The ion observed at m/z 121^- in the spectra is the most difficult ion to interpret. This ion would correspond to the loss of C_4H_{10} from $[PMPA - H]^-$. At the present time, the driving force for these eliminations has not been identified other than to surmise that the 121^- ion possesses unusual stability; two structures are proposed in Figure 2. The 179^- ion is identified at $[PMPA - H]^-$.

Figure 2. Fragment ions from PMPA on plant leaf.



Anion spectra of IMPA and EMPA on leaves are similar to the spectrum shown in Figure 1 with the only difference being the m/z of the $[M-H]^-$ peaks.

P.O. Box 2008, Oak Ridge, TN 37831-6365

Use of static SIMS and MS/MS to determine the distribution of biologically important compounds in tissue samples requires development in two areas. First has been development of instrumentation suitable for this purpose; the transmission characteristics of the instrument we have developed approach theoretical limits. Although further improvements in sensitivity through instrumental development are expected, for example, increased secondary ion yield, it is necessary that samples be prepared in such a way that they are amenable to analysis by SIMS. In short, improvements in sample preparation and handling will be crucial for further development and eventual use of the method. In this paper, we report on results obtained from various tissue samples, mainly with the goal of determining what must be done. The areas of consideration include fixing the sample, solving the problems of sample charging, distinguishing analyte-specific ions from the milieu of other secondary ions that are emitted from the sample, and enhancing the images that are created.

Biological tissue samples all contain water at preparation. Static SIMS is a surface analysis method, so that if the samples melt before analysis, surface spreading of analytes destroys their heterogeneity. Consequently, we have found the samples must be prepared frozen and dried under vacuum without ever thawing. Samples prepared in this way tend to be insulators. A charge compensation scheme that employs an electron flood gun and pulsed extraction has been used to solve the problem of sample charging.

Figure 1 shows secondary ion images obtained from two different dried tissue samples. In Fig.1A, a 1 μL spot of acetylcholine solution was deposited onto a liver sample that had been dried previously in vacuum. The localization of the acetylcholine secondary ion emission is the mark of a dried sample. If the surface of the sample is wetted, the analyte is spread rapidly and emission is diffuse. However, preparation of dry samples is problematic. In Fig. 1B, samples were prepared by cryosection of mouse brain, obtained from nude mice that had been plunged into liquid nitrogen. The mottled appearance of Fig. 1B arises because the sample surface is heterogeneous, and tends to peel from the target. The virtually uniform distribution attests to the fact that the samples were kept dry. When samples melt, soluble analytes migrate to the periphery of the sample.

Figure 2A-C, obtained from the liver sample shown in Figure 1A, show the utility, and loss of secondary ion current from using MS/MS for imaging. Fig. 2A shows the same data as Fig. 1A, but in a different presentation format, i.e., the image of m/z 146. The spike of acetylcholine is clearly visible. However, to the right, intense emission of secondary m/z 146 is also evident, where there is no acetylcholine. Fig 2B shows one image based on the intensity of the MS/MS 146->87 transition, characteristic of acetylcholine. Fig. 2C shows the sum of 12 such images, all taken from the same sample under static SIMS conditions. The vast suppression of chemical noise by MS/MS and reduction of electronic noise by signal averaging make it possible to clearly identify the location of the acetylcholine spike.

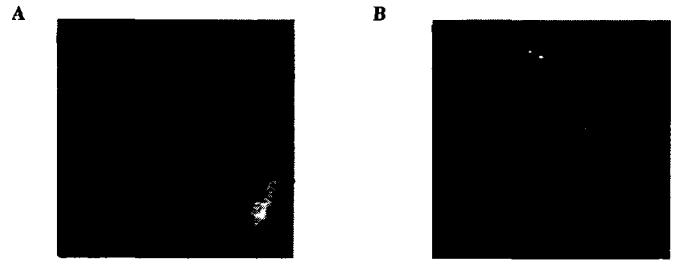

Figure 1. Secondary ion images obtained from dry tissue. In (A), 1 μL of acetylcholine was injected onto the previously dried sample. Because the sample was never wetted after the application, emission of m/z 146 from the acetylcholine is confined to the white spot. The rigorously prepared mouse brain section shown in (B) is an insulator, and tends to "peel".

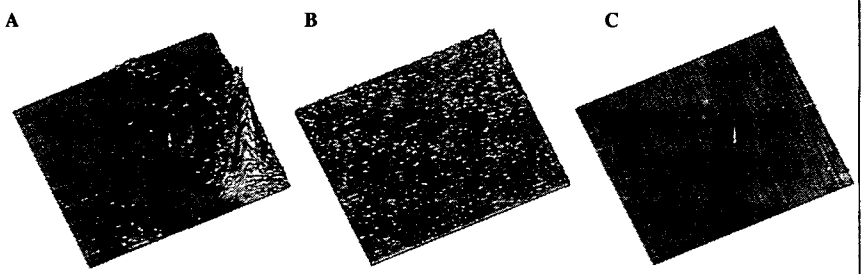

Figure 2. Reduction of Chemical and Electronic Noise. For reference, (A) has been generated from the same data as Fig. 1A., a secondary ion image. In (B), the image based on the intensity of the MS/MS transition m/z 146->87, and shows how electronic noise can replace chemical noise in the image. Electronic noise can be reduced by summing separate images, as shown in (C), which is the summed image of 12 separate MS/MS imaging scans of the sample.

Surface Characterization by Reactive Collisions of Halide Ions with Self-Assembled Monolayer Surfaces

*Donald E. Riederer, Jr., Scott A. Miller, Mike Morris, Teodor Ast, T. Pradeep and R. Graham Cooks, Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393
Matt Linford and Christopher E.D. Chidsey, Department of Chemistry, Stanford University, Stanford, CA 94305-5080

Ion/surface collisions in which atoms or groups are abstracted from the surface is a developing area in mass spectrometry. Self-assembled monolayers provide well-defined surfaces [1] for the study of these reactions which are (i) of fundamental interest, (ii) have the potential for providing a new method for surface chemical analysis, and (iii) have potential utility for the development of novel materials and chemically modified surfaces.

Detailed studies have been performed in which iodine ions (I^+) and iodine containing molecular ions ($CH_3I^{+\cdot}$, I_2^+) collide with fluorinated self-assembled alkyl surfaces [$CF_3(CF_2)_{11}(CH_2)_2$-Au] at collision energies ranging from 20 to 70 eV. These iodine containing ions are extremely reactive and produce several ion/surface reaction products in good abundance. Bromine and chlorine containing ions produce analogous products but of somewhat lower abundance. This is in sharp contrast to the behavior of hydrocarbon ions which yield few reactive products upon collisions with the fluorinated surface [2,3].

At a kinetic energy of 60 eV, collisions of I^+ with this surface yield as major products IF^+, CFI^+, IF_2^+, ICF_2^+ and $IC_2F_3^+$ (Figure 1) These endothermic reactions require C-C or C-F bond cleavage and are driven by the translational energy of the projectile. For example, collisions of I^+ with the fluorinated surface resulting in the production of IF^+ is estimated to be ≈58 kcal/mol (2.5 eV) endothermic [4] These reactions are distinctive in that they do not occur when the collision partner is a gas phase (rather than surface bound) species. This emphasizes the unique conditions that prevail during ion/surface collisions which allow cleavage of strong covalent bonds and incorporation of groups into the ionic projectile.

Many of the products formed when CH_3I^+ and I_2^+ are used as projectiles (Table 1) are the same as those produced by the I^+ projectile. Furthermore, the abundances of these products with respect to the scattered I^+ ion remain constant as the projectile is changed. This suggests that the iodine containing projectiles react first by fragmenting to yield I^+, followed by abstraction of groups from the surface.

Another process observed is the deposition ("soft-landing") of the primary projectile onto the target surface. These species can be detected by subsequent ion/surface reactions. For example, the ion at m/z 254 in Figure 1 and Table 1 corresponds to I_2^+ resulting from deposition of I atoms onto the fluorinated surface which then react with the primary beam to form I_2^+. Another example of deposition followed by abstraction is shown in Figure 2. The upper portion (Figure 2a) displays ions resulting from collisions of CH_3I^+ with a stainless steel surface. Products include CH_3I^+, $C_2H_4I^+$, and $CH_3ICH_3^+$ which arise from reaction of the primary ion with adventitious hydrocarbons present on the surface. The same projectile and surface are used in Figure 2b, however in this case, the surface was pretreated by exposure to a 5nA/cm^2 beam of $C_3F_6^+$ for a period of 40 min. In addition to the hydrocarbon products, the fluorine containing products IF^+, HIF^+, and CH_3IF^+ are observed as the result of fluorine or fluorocarbon deposition from the $C_3F_6^+$ beam and subsequent reaction with the $CH_3I^{+\cdot}$ projectile. Finally, recent observations indicate that metal ions such as W^+, Cr^+, Mo^+, and Fe^+ can undergo reactions in which several surface atoms are abstracted by a single projectile (Figure 3). Such reactions have potential application for surface analysis and controlled surface

modification for the production of microdevices.

Organic Thin Films on Pd(111) and Ti Foils by TDS, LITD/FTMS, and AES

Ihab M. Abdelrehim, Nick A. Thornburg, Steve Pullins, Johari Sloan, Erika Cleaver, and *Donald P. Land, Department of Chemistry, University of California, Davis, CA 95616.

Transition metals are known to play a role in catalytic processes of organic adsorbates. Both Pd and Ti are of interest as catalysts. Also, the surface composition of Ti biomedical implants is thought to play a major role in the infectious rejection of implants. Molecular identification of species on Ti and TiO surfaces has proven difficult, however. In this study numerous organic species are adsorbed on Ti foils and a Pd(111) single crystal and surface analysis is performed by Auger electron spectroscopy (AES), thermal desorption spectroscopy with FT mass spectrometry (FTTDS), and laser-induced thermal desorption with post-ionization and FT mass spectrometry (LITD/FTMS). Direct comparison is made for the characteristics of desorption for benzene, propene, acetylene, and isopropanol. This is accomplished using a new instrument designed and constructed at UC Davis combining these three technologies.

These studies utilize laser power densities such that organics are desorbed as neutrals and the substrate is not ablated (1064 nm, 5ns, $<10^7$-10^8 W/cm^2). Post-ionization of neutrals is accomplished with a 70 V electron beam. LITD mass spectra were compared with gas-phase electron impact FT mass spectra for all four compounds and both types of spectra were identical in each case. This indicates that LITD, even from catalytic surfaces does not induce decomposition of the adsorbed species.

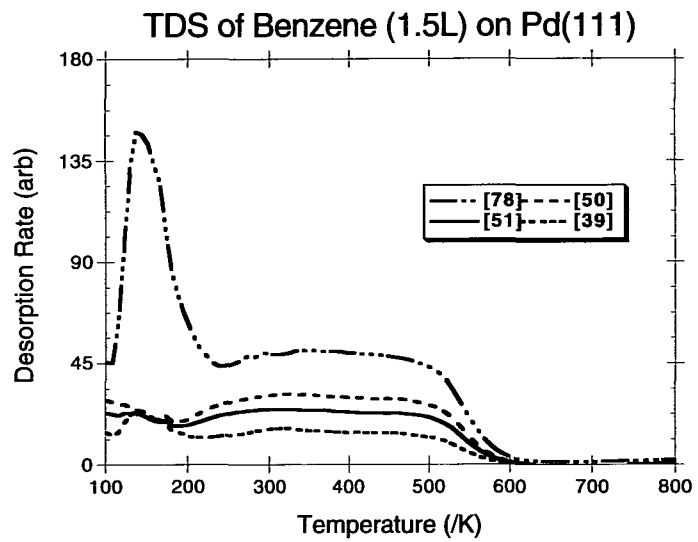
LITD/FTMS often yields the desorption of intact intermediates. Acetylene on Pd, when heated, can desorb or cyclotrimerize to form benzene. In the presence of sulfur, thiophene may be produced. During TDS, the benzene and thiophene thus formed primarily decompose. However, using LITD/FTMS these species are observed in abundance. In addition, we obtained low temperature desorption (100 K) of $C_3H_3^+$ which may be a fragment of a tightly bound C_4H_4 surface species proposed in this system, but as yet unobserved. This peak was not observed using FTTDS. Also, thiophene which appeared to be substantial in the LITD (30% of the base peak) was almost insignificant (<1%) in the TDS profile.

The TDS profile of benzene (Fig. 1) illustrates a true multiplex thermal desorption experiment. A complete mass spectrum is obtained in which different species and fragments can be monitored. Also, for the TDS of acetylene we observed the desorption of thiophene due to trace amounts of sulfur on the surface. This might have been missed if masses to be monitored needed to have been preselected. This demonstrates the importance of having a true multiplex TDS experiment.

The presence of alkali metals lead to direct ionization, flooding the cell, and not allowing the desorbed organics to fill the cell. The use of deflection plates allows us to deflect the alkali metals and facilitate the detection of the organic species. This information is presented by a colleague at the conference.

The use of these surface analysis techniques complement each other and allow for complete analysis of organic adsorbates. In addition to these techniques a FT reflection infrared spectrometer will be coupled to the instrument for vibrational studies.

Figure 1



Shown above is a profile plot of a TDS experiment of benzene. The plot shows benzene (mass 78), and fragments of benzene (mass 39, 50 and 51).

Modern Analysis as the Catalyst for Today's Evolving Polymer Science

R.R.Matheson, Jr.
Marshall Research Laboratory
E.I. Du Pont de Nemours and Co.

Polymer science is concerned with structures on many length scales. The important properties of macromolecular materials can only be understood by reference to structural details that may encompass the local stereochemistry of particular atoms, preferred bond orientations over volumes of many cubic microns, and even the macroscopic proportions of entire articles. Polymer science has achieved considerable success in elucidating the functional consequences of molecular structure in three important limits: the so-called theta condition (1), the perfect crystal (2), and the state of equilibrium orientational order of rodlike molecules (3). Much of modern interpretation proceeds from comparison to one or more of these ideals.

However, several forces are acting to drive macromolecular materials far from these comfortable limits. Molecules of smaller average size dominate many of today's technologies. Mixtures of ever greater complexity appear. Many convenient solvents must be avoided in order to obviate environmental concerns (4). The history of handling and environmental exposure can change polymeric structures and performance in surprising ways that need elucidation (5). Increasingly subtle property differences among macromolecular systems assume economic or intellectual significance. Contemporary polymer science faces a rich array of important phenomena that cannot be readily understood as consequences of large, linear homopolymers in orientationally perfect, crystalline or theta conditions. Biological macromolecules generate much of this phenomenology.

Polymer science is evolving in response. Modern analytical techniques are key to this evolution. For polymer molecules far from one of the three limiting conditions structural details assume greater significance. Indeed, some structural features can determine how rapidly or even how closely macromolecules may approach those limits. End groups obviously make a greater contribution to properties as molecular weights decrease. The exact distribution of functionality (rather than an average amount) dominates configuration and properties under non-theta conditions. Branch points and stereochemical irregularities distort and constrain crystallization. The extremes of either side of a distribution of molecular weights dominate the phase equilibria that depend on orientational order (6). Only with precise and often sophisticated analytical tools can the consequences and interactions of such structural details be understood.

It is convenient to use mass spectrometry as a paradigm for the catalytic role that analyses assume in modern polymer science. One can find it applied to problems of mixtures (characterizing additives, solvents, etc.), of nonlinear structures (7), of new synthetic routes (characterizing end groups, monomer sequences, etc.) and complete molecular weight distributions (8). This is the kind of information that is required for polymer science to advance towards a more complete elucidation of the important properties of macromolecular materials.

Presented at the 41st ASMS Conference on Mass Spectrometry

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI/TOF) has been a technique which has primarily focused on biomolecule analysis. However, the technique has the potential to make significant contributions in the area of polymer analysis. Previous work has shown that water soluble polymers can be analyzed using conditions similar to those of biopolymers.[1] Additionally, MALDI on polyglycols,[2-5] polystyrene,[4] and poly(methyl methacrylate)[4,6,7] have been shown using solvent mixtures and salt addition in the preparation.

We have further refined the technique of MALDI/TOF for polymers. This includes extending the mass range for poly(styrene sulfonic acid) to 400,000 amu as shown in Figure 1. In addition we have developed a simple method for the analysis of non-aqueous polymers. This method utilizes matrices such as sinapinic acid and dihydroxybenzoic acid. We dissolve the polymer of interest and a suitable matrix in an organic solvent and apply this mixture to the probe. We have found the matrices to be completely soluble in organic solvents such as acetone, methanol, and tetrahydrofuran which are common solvents for polymer systems.

Using the above approach to non-polar systems, we have obtained results for such polymers as poly(methyl methacrylate), poly(vinyl acetate), poly(vinyl chloride), poly(carbonate), poly(12-hydroxystearic acid), and poly(N-vinylpyrolidone/vinyl acetate). Figure 2 displays the result we have obtained for a poly(methyl methacrylate) of 59,000 molecular weight. The spectrum shows a singular distribution centered around 60,000 amu.

In addition, the double and triply charged distributions are observed as well as clusters corresponding to the dimer and trimer.

ToF SIMS STUDY OF ADDITIVE MIGRATION ON POLYMER SURFACES

L. Lianos, Tran Minh Duc, CENATS, Claude Bernard University, 43 Bd 11 Novembre 1918, F69622 Villeurbanne, France

S. Reichlmaier, J. Hammond, Physical Electronics Division, Analytical Laboratory, 6509 Flying Cloud Drive, Eden Prairie, MN 55344 USA

Surface migration of additives is an important issue in the polymer industry. Additive "blowout" could modify surface properties and thus induce problems when improved wettability, adhesion, transparency or chemical inertness is needed. The essential capabilities for solving this kind of problems are high surface sensitivity, high mass and spatial resolution, all combined in the ToF Static SIMS method (Figure 1) as well as the possibility of analysing insulating materials "in situ".

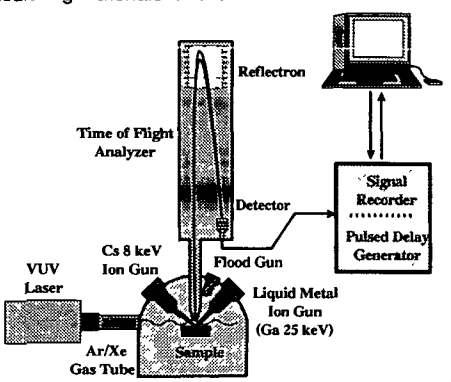

Figure 1. : The ToF SIMS instrument

Our ToF analyser combines high mass resolution and high mass accuracy with an exceptional sensitivity thanks to a parallel and multi ion detection and the absence of dispersion optics. In the performances of the method we could also include the great mass range (up to 15000 D) with a constant high transmission and high signal/noise ratio.

Working with a Cs (t_{pulse} < 1 ns) source allow us to obtain a high mass resolution (10000 M/ΔM at 28 D) in order to separate and unambiguously identify fragments appearing at the same nominal mass. High lateral resolution can also be achieved by employing a micro-focused Ga^+ gun as the primary ion beam. This configuration can provide chemical maps of the surface with a lateral resolution of 200 nm.

Static SIMS spectra were acquired in both positive and negative ion mode for additives belonging to different families : Antioxidants (Irganox 1010, Irganox 1076, Irganox 3114, Ionox 330, Irgafos 168), Acid acceptors (Calcium stearate), Anti-UV (Tinuvin 622), Flame Retardants (Adine 505, Dechlorane 505) and Lubricants (Erucamide).

The high transmission of the ToF analyser permits the detection of the parent ion peaks with a high mass accuracy, of most of the additives analysed here (Figure 2). The fragmentation

pathways of these materials are also investigated. Both the parent ion peak and the fragmentation pattern serve as a fingerprint for the additive and can be used for its identification and further on to the study of its spatial distribution on a polymer surface.

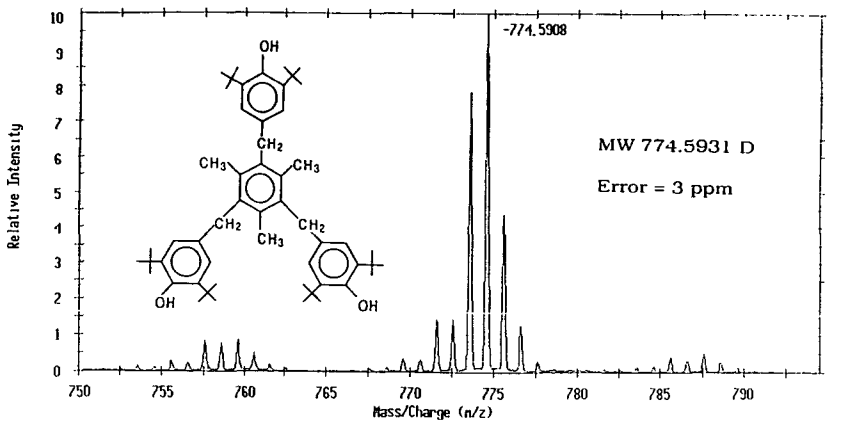

Figure 2. : Static SIMS spectrum of IONOX 330 (Positive Ions, 750 to 800 D)

Studies of additive migration on a polypropylene (PP) pellet surface show that non-organic additives could be detected even at bulk concentrations of the order of 200 ppm. Organic additives could also be identified even through their parent molecule peak but in higher bulk concentrations. Some cases of additive migration on the surface of the polymer are examined by imaging static ToF-SIMS (Erucamide in PP, Glyceryl MonoStearate (GMS) in PP and GMS in PolyEthyleneTerephthalate).

MICROSTRUCTURE OF COPOLYMERS BY STATISTICAL MODELLING OF THEIR MASS SPECTRA

GIORGIO MONTAUDO
Dipartimento di Scienze Chimiche, Universita' di Catania,
Viale Andrea Doria, 6 95125 Catania (Italy)

A novel method for the determination of the microstructure of copolymers is presented. Statistical modeling of the mass spectral intensities of copolymers has been used here to derive information on the distribution of monomers along the copolymer chain, and a procedure to find the composition and the sequence of the copolymers analyzed has been developed. Although polymers often possess molecular dimensions too elevate to be revealed by conventional high resolution mass spectrometers, MS has been successfully used to identify the mixtures of oligomers formed in the partial degradation of synthetic and biological copolymers, or of the oligomers contained in low molecular weight copolymers[1-13]. We have recently found that opportune decoding of the information contained in the mass spectral intensities leads to the determination of composition and microstructure in copolymers, and this represented a significant progress with respect to the past, since only the mass numbers corresponding to MS peaks had been used in previous work on the structural delucidation of copolymers by MS[5-9]. Mass Spectrometry is a powerful and rapid analytical method and, being able to look at the mass of individual molecules in a mixture of homologues, is particularly suitable for the detection of a series of oligomers. However, mass spectra had not been exploited to estimate oligomers distributions, due to the diffuse notion[1,2] that a lack of correlation existed between EI (electron impact) peak intensities and concentration of the oligomers in the mixture. The introduction of soft-ionization techniques, as chemical ionization (CI), fast atom bombardment (FAB), secondary ions mass spectrometry (SIMS), laser desorption (LD, MALDI), field desorption and field ionization (FD and FI), etc., has largely eliminated this problem, and sizeable evidence has been now accumulated showing that, in many cases, peak intensities of molecular ions appearing in mass spectra reflect the relative amounts of oligomers present in the mixture[1-9]. In order to extract quantitative information about the composition and sequence of copolymers, one has to learn how to exploit MS peak intensities, which depend from the relative abundances of the oligomers present in the spectrum and are directly related to the microstucture of the copolymers. The statistical analysis of copolymers makes use of Bernoullian and Markovian models in order to characterize the microstructure of copolymer samples[5-6], and assuming a theoretical distribution and then fitting the calculated oligomer abundances with the experimental MS peak intensities, the copolymer composition can be determined. In our first approach to the problem, we analyzed by FAB-MS some microbial copolyesters having Bernoullian distributions, which were subjected to partial methanolysis in order to reduce their molecular weights, and it was assumed that the chain cleavage agent was producing a non-selective process. This introduced a limitation in our approach, since the intensity of mass peaks actually depends both on the distribution of comonomers along the chain, and on the cleavage process. Furthering our studies we have found that, from the analysis of the mass spectra, it is possible to ascertain if the cleavage of a copolymer chain occurred by a selective or a non-selective process, therefore removing the above ambiguity. Furthermore, we have extended our computations to determine the composition and the microstructure of several copolymers whose mass spectra have been recently reported in the literature[6]. These spectra have been recorded using different ionization techniques as: LD, FAB, FI, EI, and refer both to low molecular weight copolymers (that can analyzed directly without subjecting the copolymer to partial cleavage to reduce their molecular weight), and to high copolymers. The copolymers analyzed are both of the addition and condensation type.

Mass spectra may provide direct composition estimates and we have now derived simple mathematical formulas that allow to estimate the copolymer composition, independent from the statistical calculations, by direct analysis of the mass spectra. This analysis allows also to ascertain if the process used to cleave the copolymer chain has been a selective or an unselective one. Statistical modeling of mass spectra of copolymers has thus reached a certain level of generalization, and it can be used to complement NMR analysis, which has been so far the only technique available for sequencing copolymers. In order to perform numerical calculations, all the formulas have been implemented in a computer program, MACO, written in Standard ANSI Fortran that runs on a Microwax computer. All the mass spectra of copolymers studied have been analyzed employing this program. The present version of the computer program (MACO 4) has proved able to deal with all the cases considered here (both addition and condensation copolymers), independent from the MS ionization technique and from the method by which the partial degradation was performed (methanolysis, aminolysis, ozonolysis photolysis, pyrolysis), and also in the case of low molecular weight copolymers (preformed oligomers).

Direct and Matrix-Assisted Laser Desorption Fourier Transform Mass Spectrometry of Polymers

Charles L. Wilkins, John A. Castoro, and Michael S. Kahr, Department of Chemistry, University of California, Riverside, CA 92521

Characterization of polymers by laser-assisted mass spectrometric methods is of interest for a number of reasons. In the context of high performance ion cyclotron resonance mass spectrometry (FTMS), its demonstrated high mass resolution, excellent mass measurement accuracy, and applicability to highly non-volatile samples are the primary analytical advantages. During the past several years, direct laser desorption FTMS using high power pulsed carbon dioxide (IR) or Nd-YAG (UV) lasers has been shown to be a powerful tool for analysis of polar polymers and polymer additives. In the very recent past, the newer technique of matrix-assisted laser desorption has also been adapted to FTMS for this purpose. Recent results using both methods are discussed in this paper.

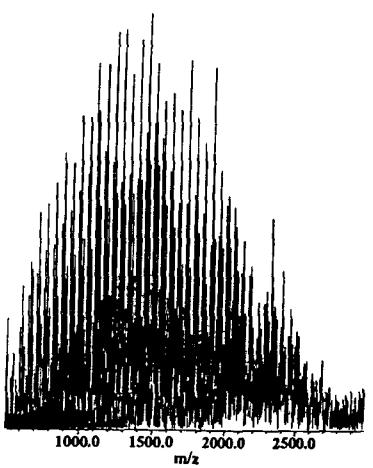

Figure 1 - Laser desorption-silver CI FTMS spectrum of an isobutylene sample.

Experience has shown [1-3] that it is relatively easy to obtain high resolution FTMS spectra of heteroatom-containing polymers with average molecular weights up to about 8,000-10,000 daltons using direct carbon dioxide laser desorption with FTMS detection. In fact, because oligomer ions produced in this way are so abundant, in favorable cases, it is possible to obtain ultrahigh mass resolution [3]. However, for higher mass polar polymers and hydrocarbon polymers, direct carbon dioxide laser desorption FTMS generally fails to produce mass spectra revealing oligomer distributions. Instead, spectra showing predominantly fragment ions are observed.

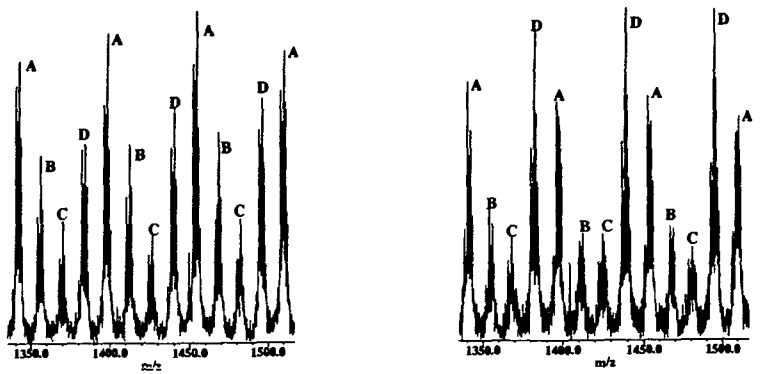

Figure 2 - Partial silver-CI LD-FTMS spectra of two different commercial isobutylene samples.

In this presentation the advantages and disadvantages of laser-assisted FTMS methods for polymer analysis are reviewed, with examples drawn from both polar and non-polar polymer classes. In the latter case, it has recently been shown that a combination of direct carbon dioxide laser desorption combined with chemical ionization methods is efficacious[4]. Figures 1 and 2 show some recent results for polyisobutylene samples. In addition, recent results show that matrix-assisted laser desorption/ionization (MALDI) Fourier transform mass spectrometry has some distinct advantages for high mass polar polymer analysis.

Finally, a number of examples of ultrahigh resolution polymer mass spectra will demonstrate the significantly enhanced analytical performance that is possible with FTMS-MALDI, as compared with more common TOF-MALDI measurements.

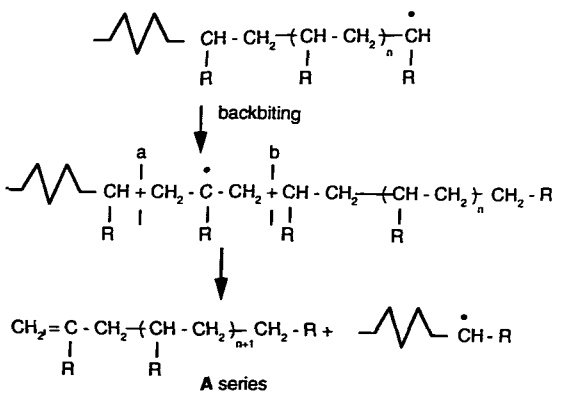
Pyrolysis Field Ionization Mass Spectrometry (Py-FI-MS) of Polyolefins.

Robert P. Lattimer, The BFGoodrich Research and Development Center, Brecksville, Ohio 44141.

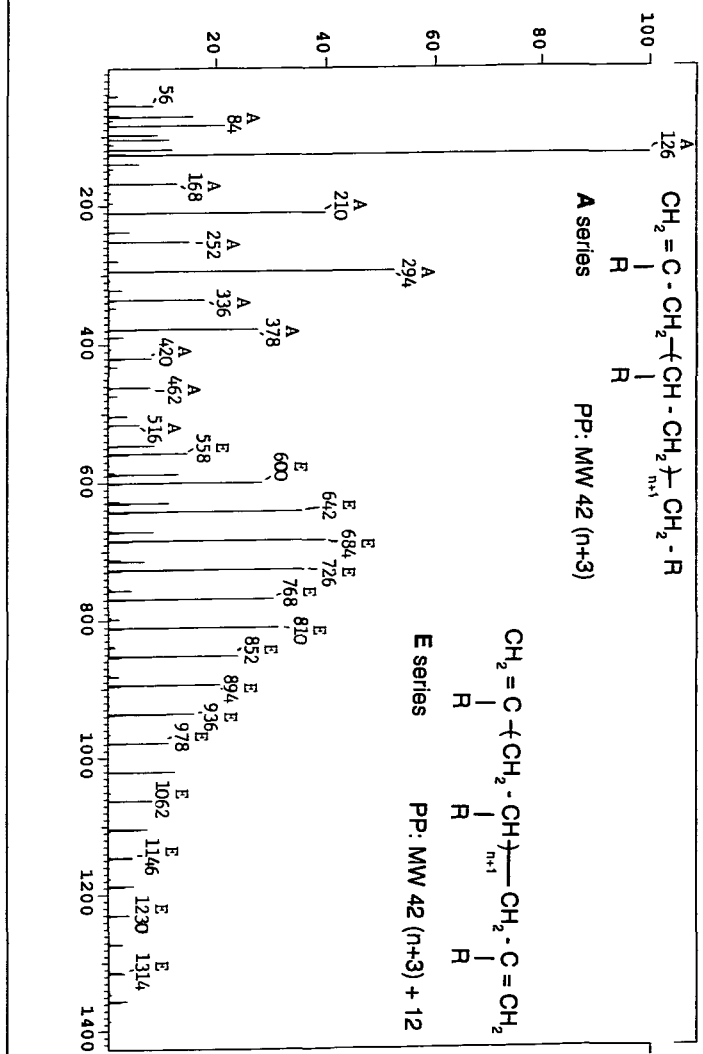
Five high molecular weight polyolefins (saturated hydrocarbon polymers) were examined: Polyethylene (PE), poly(isobutylene) (PIB), polypropylene (PP), poly(1-butene) (P1B), and poly(4-methyl-1-pentene) (P4M1P). Pyrolysis (Py) was carried out by heating the polymers in the direct probe of a Finnigan MAT 95Q mass spectrometer. Volatile hydrocarbons produced at the onset of pyrolysis ($\approx$350-400°C) were examined by field ionization (FI-MS), using standard carbon dendrite emitters. Volatile products were typically observed at every carbon number to masses well above 1000 Da. The distributions of pyrolyzates showed some similarities among the various polymers. For all of the materials, *alkene* oligomers (MW = $x\,n$, where x is the mass of the olefin monomer and n is the oligomer number) were dominant at lower masses. For most of the polymers, *dialkene* oligomers tended to be the most prominent pyrolyzates at higher masses. As an example, a Py-FI mass spectrum for PP is attached. The **A** series oligomers (alkenes) and **E** series oligomers (dienes) are marked.

Degradation mechanisms have been proposed to explain the observed patterns of volatile pyrolyzates. As an example, the dominant mechanism for formation of **A** series oligomers from the alkyl ethylene polymers (PP, P1B, P4M1P) is shown below. The first step is a homolytic main chain cleavage, which produces two free radicals. These may be primary, secondary or tertiary radicals, depending on the polymer structure. The chain-end radicals then undergo "backbiting" processes in which the radical site is transferred along the chain, with concurrent rearrangement of hydrogen atoms. When the formation of both secondary and tertiary internal radicals is possible, the tertiary radicals are strongly preferred. These internal radicals then undergo ß-scission and hydrogen abstraction reactions to yield both volatile and nonvolatile (high polymer) products. The nonvolatile products are terminally unsaturated; these intermediates can undergo further decomposition to yield the diene oligomers that are the dominant higher mass pyrolyzates observed via FI-MS.

Py-FI-MS is perhaps unique in its ability to detect pyrolysis products over such a wide mass range (> 1000 Da). The in-source pyrolysis (with its short transfer distance to the field emitter) and the inherent soft ionization capability of FI-MS combine to make the detection of these higher mass products possible.



Pyrolysis Field Ionization Mass Spectrum (Py-FI-MS) of Polypropylene (isotactic PP).

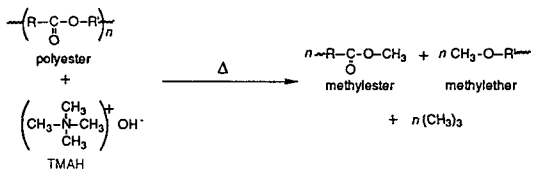


Characterisation of Polyester-based Surface Coatings by Pyrolysis GC/MS and Electrospray MS.

Susan M. Hunt, Malcolm R. Binns and Margaret M. Sheil
Dept. Chemistry, University of Wollongong, Northfields Ave, Wollongong NSW 2522 AUSTRALIA

Polyester resins are used extensively in paints which serve as protective and decorative surface coatings for a range of products including building materials and metal appliances. Polyesters are synthetic polymers that generally contain di-acid and diol monomers formed into polyester chains by a condensation reaction. In paint formulations, the polyester chains are joined together by "cross-linking" agents in a high-temperature reaction process known as "curing" which produces a solid, high molecular weight coating. Chemical characterisation of polyesters is important for the analysis of structural anomolies and degradation products of coatings to aid in the development of coatings with improved durability and performance. Thus we report here the results of an evaluation of several different mass spectrometric techniques for the characterisation of polyesters resins used in surface coatings.

The first method evaluated was a simultaneous-pyrolysis methylation (SPM) technique developed by Challinor[1] in which the polyester is mixed with a methylating reagent, tetramethyl ammonium hydroxide (TMAH) and pyrolysed in the injection port of the GC. On reaching the pyrolysis temperature (770°C), the polyester undergoes the hydrolytic methylation reaction shown below:



Pyrolysis and derivatisation occur simultaneously and the methylated pyrolysis products are analysed immediately by GC/MS. Methylation encourages the formation of larger and less polar fragments compared with direct pyrolysis. Figure 1, shows a typical pyrogram for a polyester and its monomeric components illustrating that the monomers can be readily identified.

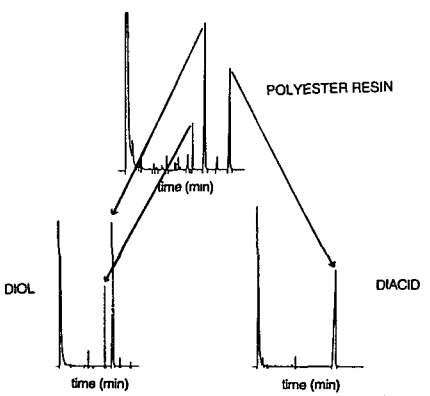


Figure 1: SPM pyrograms for polyester 1 and its component diacid and diol.

Further, the SPM method is extremely versatile, being applicable to a range of different samples including the polyester resins, liquid paints (comprising resin, pigment and crosslinker) and solid (cured) paint coatings.

Secondly, in a novel application of the technique, fourteen polyesters were analysed by electrospray ionisation (ESI). Singly-charged species are produced, as shown in a typical spectrum given in figure 2, so molecular weight distributions of the polyesters can be clearly identified.

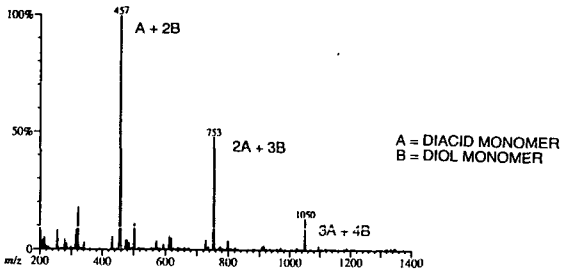

Figure 2. ESI spectrum of polyester 1
(50% CH_3CN, 1% formic acid, 5 µL/min, 2.5 µg/mL polyester)

The ESI spectra enabled indentification of: the range of chemical structures present in each sample; the distribution of acid versus alcohol "end groups" (important in the stability of cross-linked resins) and; any structural anomalies such as those caused by fragmentation of the monomer prior to polymerisation. The identities of the peaks in the ESI spectra were confirmed by ES/MS/MS experiments.

Finally, table 1 shows the number average molecular weights (M_n) determined from ESI compared to the results from other techniques including gel permeation chromatography(GPC), osmometry (VPO) and matrix-assisted laser desorption (MALDI). These data, especially the MALDI, suggest that the M_n's determined by ESI are lower than the true molecular weights of the samples. This is possibly a consequence of the poor solubility of the polyesters in the aqueous acetonitrile solutions used for these analyses being more significant in the case of ESI. We are currently investigating this further by comparing a range of electrospray solvents for the polyesters and water soluble polymers.

Comparison of M_n determined for four polyesters by a range of techniques.

Polyester	ESI	GPC	VPO	MALDI
1	510	773	1400	1356
2	537	842	2050	
3	618	1140	2247	1471
4	610	1419	1933	

Thus SPM and ESI appear to be complimentary techniques for the analysis of polyesters with the former useful for monomer identification and the latter enabling structural characterisation of oligomeric species.

We are grateful to Paul Humphries and Stephen Davis of Kratos Analytical for MALDI spectra.

The Mass-Changing Reaction Between MS and MS

Christie G. Enke
Michigan State University
and
Richard A. Yost
University of Florida

Tandem mass spectrometry (MS/MS) has achieved a very high level of importance in the field of mass spectrometry. In the analysis of targeted compounds in complex mixtures, the first mass analyzer is used to select ions of the targeted compound's mass and the second mass analyzer provides the targeted compound's mass spectrum or detects an m/z value in that spectrum. Much more information concerning the structure of pure compounds is provided by obtaining, with the second mass analyzer, the mass spectrum of each of the m/z values appearing in the mass spectrum from the first mass analyzer. These common conceptualizations and applications of tandem mass spectrometry, and indeed the nomenclature of MS/MS instrumentation itself (BE, QQ, etc.), tends to concentrate on the types of mass analyzers employed and appears to take for granted the essential process occurring between the mass analyzers. It is clear that without some mass changing (or, more rigorously, mass-to-charg-changing) reaction after the first mass analyzer, the MS in the second mass analyzer stands for "more of the same". This presentation reflects on the historical significance of the recognition of low-energy collision-induced dissociation (CID) in the development of the triple-quadrupole mass spectrometer and on the importance and variety of mass-changing reactions in the overall field of tandem mass spectrometry.

Our own entry into mass spectrometry was in pursuit of the goal of creating a computer-controlled analytical instrument which would incorporate both separation and identification stages, and, in which the computer could randomly select the sample components to be identified. In the consideration of quadrupole mass analyzers for each stage of such an instrument, the immediate problem was how to energize the ions selected by the first quadrupole mass analyzer so that the second quadrupole would have a spectrum of m/z values to obtain for compound characterization. In a private conversation, Graham Cooks, who had already recognized the separation and identification processes inherent in mass-analyzed ion kinetic energy spectrometry (MIKES)[1], encouraged us in this work and suggested that high-energy collision-induced dissociation (CID) might be easier than the electron-impact excitation that we were considering. High kinetic energy was considered necessary because, in the MIKES instruments, ion

[1]Cooks, R. Graham, "Collision Spectroscopy," R. Graham Cooks, Editor, Plenum Press, 1978, page 426

fragmentation efficiency was known to fall off dramatically below a few thousand electron volts of ion kinetic energy. In his later angle-resolved MIKES studies, Graham showed the fragmentation losses at lower energy to be due to the larger scattering angle of the products[2].

The Office of Naval Research funded the tandem quadrupole project at Michigan State University (more for the novelty of the data system approach than the soundness of the mass spectrometry). The question of the method of interquadrupole ion excitation remained open at the time of the 1977 ASMS meeting (Washington, DC) when, in a serendipitous meeting with Jim Morrison of La Trobe University, Australia, we mutually recognized that the process that produced the background fragment ions interfering with his tandem quadrupole photon-induced fragmentation studies was exactly the process we needed for our proposed analytical instrument. Experiments performed by Yost on Morrison's instrument resulted in a publication demonstrating the feasibility of an analytical triple-quadrupole mass spectrometer[3] and in a patent on low-energy CID in an rf-only quadrupole on which Morrison is a coinventor. Simulations performed with the now-familiar (but then as yet unpublished) SIMION, developed by Morrison and McGilvery at LaTrobe, proved invaluable in these studies. Our results were confirmed by Hunt and Shabanowitz[4] on a triple quadrupole mass spectrometer they constructed in an incredibly short time, and by Cooks[5] on an equally spontaneous double-quadrupole mass spectrometer while the triple quadrupole in our laboratory was still under construction. Only a little later, our instrument produced data[6] and several studies on the energetics and utility of low-energy CID were performed in our lab and others[7,8]. Computer control and data acquisition for all the MS/MS scans were developed and one of the first instrument command languages for user programming of automated experimental sequences was developed[9,10].

As a mass-changing reaction between mass analyzers, both high-energy and low-energy CID have great and undisputed power and usefullness. MS/MS with CID has been employed in a substantial fraction of the papers presented at this meeting. However, the field is far from mature. We are only approaching the adoption of a common format for MS/MS data and

agreement on a universally useful experimental protocol still seems a long way off. There are few available libraries of MS/MS data and general rules for the structural interpretation of the full MS/MS data set (the product spectra of all significant precursors) are few. What is needed is the development of an expert system despite the lack of codified human expertise to implement. We have worked on a system to discover correlations between chemical substructures and patterns in the MS/MS spectra[11], but a generally useful system has not yet been achieved. All these are areas where further development is needed to bring the applicability of MS/MS to the mature level enjoyed by practitioners of single-stage mass spectrometry.

The inherently low kinetic energy of ions in the triple quadrupole mass spectrometer makes it a natural environment for the observation of ion-molecule reactions. This is a form of mass-changing reaction in which the selected ion reacts with a neutral reactant gas introduced into the center quadrupole collision chamber. This can be called a collisionally-activated reaction (CAR) even though, in practice, the ion-molecule products are favored over the CID products at near-thermal kinetic energies. With our initial triple quadrupole instrument, we observed many interesting products, even with argon as the collision gas. With a deuterated selected ion or reactant molecule, a variety of H-D exchange products were observed. In 1981, Porter, Beynon and Ast[12] called the MS/MS instrument, "a complete chemical laboratory," in which synthesis, purification, reaction, and analysis occur in the source, MS1, collision cell, and MS2 respectively. This concept is still to be fully explored.

The CAR process can provide greater specificity than direct ion fragmentation. In Yost's lab, the cyclopentadiene molecular ion was readily distinguished from the linear 1-pentene-3-yne molecular ion (same m/z and composition) by CAR with isobutane while the CID products of these two ions differed only slightly in their relative ion abundances[13]. Yost's group also developed a "reverse" CAR system in which the effluent from a GC served as the collision gas. When piperidine molecular ion was selected by the first mass analyzer, the formation of product ions is selective for electrophiles (potential carcinogens)[14]. Orlando, Fenselau, and Cotter have demonstrated the efficient production of sequence ions of polypeptides by endothermic proton transfer reactions[15]. A scheme developed in Enke's lab for GC/MS/MS analysis of PCB's depends on the reaction of the selected molecular anion with O_2 reagent in the center quadrupole to produce the oxygen-chlorine

exchange product ion[16]. By cycling through the appropriate precursor/product mass pairs as the chromatogram develops, a separate ion chromatogram can be obtained for each degree of PCB chlorination from 4 through 7. For the study of ion-molecule reactions, the ion trap and Fourier transform mass spectrometers have the advantages that the ion kinetic energy is inherently near-thermal and long and controlled reaction times are readily achieved. For incorporation into an analytical scheme, particularly for chromatographic detection, the triple quadrupole has the advantage that the process in each stage is continuous.

Even though mass-changing reactions have been stressed in this talk, charge-changing reactions between the mass analyzers are also effective. Charge-changing processes that have been used with MS/MS include charge stripping, charge inversion (Cooks), and neutralization-reionization (McLafferty).

Ion fragmentation has also been achieved by processes other than CID. Collision with a surface (SID) introduced in Graham Cooks' lab has been observed, extended, and applied by several others[17]. Another technique of growing significance is photon-induced dissociation (PID). Following early studies by Morrison and Vestal, many others have explored this technique[18]. High-efficiency PID in an interaction region between two time-of-flight mass analyzers has recently been demonstrated in Enke's lab[19]. Fragmentation efficiencies of 10% to 70% have been achieved in an instrument designed to produce ten or more PID product ion spectra per second so that MS/MS data sets can be obtained from chromatographically delivered sample.

The mass-changing reaction has quietly become the main thrust of MS/MS research following an early preoccupation with the hardware of mass analysis. From the examples cited, we can see that it is this process that is at the very heart of the ability of MS/MS to extend the characterizing power of single-stage mass spectrometry. The mass-changing reaction part of the MS/MS story is far from finished. For each of the techniques currently employed, still more work is needed to understand and characterize the fundamentals of the processes and thus apply them more effectively. Techniques for the improvement of the process efficiencies will be very welcome, and much work remains to be done in the development of more techniques that are selective for particular chemical structures or reactivity.

Young Mass Spectrometrists Interest Group
Workshop: Perspectives on Publication from the Inside Sunday, May 30, 7:30-9:00 p.m.

A panel of seven editors representing eight journals addressed several issues related to publication. The editors and their journals were Michael Bowers (J. Am. Chem. Soc., Int. J. Mass Spectrom. Ion Processes), Richard Caprioli (Biol. Mass Spectrom.), Catherine Fenselau (Anal. Chem.), Michael Gross (J. Am. Soc. Mass Spectrom.), Doug Ridge (Org. Mass Spectrom.), Alan Marshall (Rapid Commun. Mass Spectrom.), and Fred McLafferty (Accts. Chem. Res.). During the first hour of the workshop, each panel member presented their thoughts on a single publication related issue. During the last half hour of the workshop, the audience questioned the panel members on a broad range of topics. Approximately 150 people were in attendance, and their participation in the question-and-answer session made this a lively and informative workshop.

Michael Bowers discussed the factors authors should consider in selecting a journal for publishing their work. He divided the journals represented in the workshop into ACS versus non-ACS publications, and pointed out that ACS journals are broader in scope than the non-ACS journals. To decide which category of journal is most appropriate for a paper, the author should consider whether the work in question is technique driven, and therefore better matched with the more narrowly focused non-ACS journals, or directed toward a chemical problem, and therefore suitable for the broader audience of an ACS journal. Bowers also presented his thoughts on the reviewing process, and pointed out that reviewers may miss the point of a paper. In such a case, the editor will usually side with the reviewer, and under these circumstances, it is appropriate and necessary for the author to fight back.

Richard Caprioli advised the audience on the appropriate way to respond to reviewers. Reviews are intended to inform not only the editor, but also the authors. Although reviewers are people, and therefore capable of making mistakes, in his experience, Caprioli finds that papers are improved by the review process. Authors should not take reviews personally, but rather consider them as unbiased, outside evaluations of their work. When rebuttal of a reviewer's comments is required, the author needs to document his arguments with references to published work. Editors are not adversaries in the publication process, and in fact, wish to publish quality science in their journals.

Catherine Fenselau described the manner in which reviewers are selected and their reports interpreted. Editors look for people with a record of objectivity, and who provide informative reviews. Editors try to avoid reviewers that have a conflict-of-interest or that are strong adversaries of the author. A good review will tell the editor if the experiments are well planned, if the interpretation is reasonable, and if there are similar papers in press or that have been published. Fenselau discourages reviewers from focusing on editorial changes, although some may be suggested where minor revision is needed. Major revision of a manuscript is necessary if the structure of the paper needs to be changed, or if additional experiments are required before publication. Although reviewers may suggest additional experiments, the editor must make the difficult decision regarding the necessity of this exercise. Often, the suggested additional experiments are more appropriately the subject of further work and additional papers. Some advice was offered for contributors in interpreting reviews of their papers: if the reviewer misses the point, then it probably needs to be better written! This advice was echoed by several of the panel members.

Michael Gross reminded the audience that as the society's journal, *JASMS* has the broadest scope of all the mass spectrometry journals. In his experience as an editor, the slowest step in the publication process is manuscript revision, which is entirely under an author's control. He then

described the information that should be provided in a cover letter that accompanies a submission. It is not particularly useful to tell the editor why the work is important, as the reviewers will provide this information. It is important for the author to suggest reviewers and to veto reviewers in the cover letter. When submitting a revised manuscript, the cover letter needs to be far more detailed than the letter that accompanied the original submission. Revisions should be itemized, and editors find it useful if the manuscript is "yellow lined" to show the changes that have been made. Gross advised reviewers to ask themselves if they are being overzealous in their critique, and cautions against being overly picky in suggesting changes.

Doug Ridge proposed that mass spectrometry is of wider interest than often credited. He recommended as a general rule for authors to address the widest possible audience, that is, to publish in ACS journals when appropriate. As for selecting a non-ACS journal for publication, he reminded the audience that *Organic Mass Spectrometry* and *International Journal of Mass Spectrometry and Ion Processes* are international journals with wide readerships. *OMS* traditionally publishes chemically oriented papers, while *IJMSIP* is more physically oriented.

Alan Marshall discussed the purpose of publishing work as a communication. This type of publication allows one to stake out a new territory. However, Marshall warned against publishing all work as communications. A communication can be used to publish preliminary results, but a full paper should follow after the completion of more detailed studies. It is generally a bad idea to split up a large piece of work into several smaller pieces. Marshall pointed out that the National Science Foundation was aware of this practice, and has changed their rules for reporting prior work in a proposal by limiting principal investigators to listing only five relevant publications.

Fred McLafferty summarized the ideas that had been presented, and put them into a broader perspective. He divided journals into two categories - primary and review. He implored the audience to learn about the journals in their field by reading them. In preparing a paper, it is important for the author to know the impact of his work. Authors need to make clear in the first paragraph why the reader should go on. It is also important to have a good title and abstract to attract a reader's interest. His advice is to first pick the audience, pick the journal, and then to sell the idea. With regards to the role of the editor, McLafferty pointed out that as the buck stops with the editors, they must make the final decision about the publication of a paper, and that a reviewer's comments are only advisory. Finally, he reminded the audience that it is their duty to provide good reviews, as this keeps up the quality of a journal.

At this point, questions were entertained from the floor. One of the better established young mass spectrometrists, Klaus Biemann, stated that he was aware of a practice by some authors of publishing the same data in more than one journal. The panel agreed that this is an unethical practice, and should be discouraged. The question was raised that good papers are frequently rejected from *Journal of the American Chemical Society* because they do not meet the criterion of "being suitable for publication in *JACS*". Fred McLafferty pointed out that most journals have a page budget which cannot be exceeded, and therefore must at times reject worthy papers. Mike Bowers said that this being the case, he often rejects papers when there is a lack of consensus among the reviewers regarding suitability for the journal. Several other questions were addressed to the panel, and discussed at length. The workshop concluded at 9:00 p.m.

Summary of Workshop on Field/Portable Mass Spectrometry

Organized by John F. Wacker[1] and M.Judith Charles[2]

[1]Pacific Northwest Laboratory, P.O. Box 999, Richland, WA 99352)
[2]Department of Environmental Sciences and Engineering, University of North Carolina, Chapel Hill, NC 27599-7400

The objective of the workshop was to provide information about developments in field/portable mass spectrometry and to stimulate discussion among the speakers and the audience. The following are highlights of the workshop.

Presentations

1. Mitchell D. Erickson, Argonne National Laboratory, Environmental Research Division, "Field Analysis: What do We Need and Why?"

Generic types of fieldable mass spectrometers, ranging from large mobile laboratories to portable instruments capable of *in-situ* measurements were described. Future needs and requirements (*e.g.*, better sample/instrument interfacing, routine implementation, on-the-fly decision making), including the need for regulators to accept field/portable mass spectrometry methods, were discussed.

2. David Koppenaal, Pacific Northwest Laboratory, Atomic and Molecular Chemistry Section, "Needs for Inorganic Mass Spectrometry."

Major application areas for *in-situ* inorganic and isotopic mass spectrometry, such as environmental cleanup, national security, and atmospheric chemistry, were discussed. Target species include toxic metals (As, Cd, Hg, etc.), isotopics of actinides, fission products (*e.g.*, ^{129}I and ^{99}Tc), and atmospheric trace constituents (noble gases, Cl-N-O-H_2O species, etc.). A variety of methods were described, including the use of laser ablation—inductively-coupled plasma mass spectrometry for analyzing radioactive samples.

3. J. Michael Ramsey, Oak Ridge National Laboratory, "Microminiaturized Instrumentation for Chemical Separations."

Described the development of "LC-on-a-chip." Capillary-zone-electrophoresis separation of Sr from Rb (40,000 theoretical plates), using a column (10-μm ID by 10-cm long) etched onto a 0.1 cm^2 area on a glass slide, was demonstrated.

4. Brian Andresen, Lawrence Livermore National Laboratory, Applied Technology Program, "Lawrence Livermore Experiments with Small Mass Spectrometer Systems."

Described the coupling of a microbore gas chromatograph column to an HP 5971A quadrupole mass spectrometer. The system, complete with vacuum pumps and

electronics, weighs 60 lbs, consumes 350 W, fits into a large suitcase, and is capable of achieving ppb sensitivity for many volatile organic compounds.

5. Phil Hemberger, Los Alamos National Laboratory, "Evolution of Transportable Ion Trap Mass Spectrometers at Los Alamos: Macro to Micro."

Described small ion trap mass spectrometers under development, including a gas chromatograph/mass spectrometer that can be used on a truck and an ion trap that fits in a beer can.

6. Neil S. Arnold, Center for Micro Analysis and Reaction Chemistry, The University of Utah, "Man Portable GC/MS for In Situ Field Applications."

The evolution of the instrument developed at the University of Utah was described. The current version is a 60-lb instrument that can easily be carried in a back-pack and can detect 100 ppb of toluene and benzene. Work is underway to produce an instrument that weighs 25 lbs and uses <75 W.

7. Albert Robbat, Trace Measurements Analytical Laboratory, Department of Chemistry, Tufts University, "GC/MS: A cost effective means for conducting site characterization."

The presentation emphasized the poor reproducibility of laboratory measurements for characterizing VOCs at contaminated site, the cost of the analyses, and the inability to characterize a site despite analyzing a large number of samples. A site can be more effectively characterized by analyzing samples in the field, while being faster and less expensive than laboratory analysis.

8. Marc Wise, Oak Ridge National Laboratory, "Field Transportable Ion Trap Mass Spectrometer for Real-Time Environmental Monitoring."

Development of an ion trap mass spectrometer that weighs 120 lbs, consumes 550 W, and can perform analyses by electron or chemical ionization (positive and negative ion detection) was described. The mass spectrometer is capable of detecting ppb- to ppt-levels of VOCs in air and water.

Discussion

The potential commercialization of field/portable mass spectrometers was discussed. Concerns were raised about the cost of the instrumentation and the need to alter regulations to accept methods based on field/portable mass spectrometry. The need for performance-based methods and the willingness for regulatory agencies to accept these methods was discussed.

Isotopic Applications Interest Group Workshop

"Signals and Noise: Measurement Limits in Mass Spectrometry"

The workshop on the final evening of the conference drew an attendance of about fifty persons. The workshop was a tutorial session covering four topics:

- General aspects of measurement and limits
  Dr. John Stein, GE-Vallecitos Nuclear Center
- Faraday cup measurements
  Dr. Karleugen Habfast, Finnigan MAT
- Pulse counting measurements
  Prof. John Hayes, Indiana University
- Data rejection criteria
  Dr. David Smith, Oak Ridge National Laboratory

Dr. Stein's overview answered three questions:

"What is the signal?" Singly charged ions of the sample of interest that give a usable current or pulse from the detector.

"What is the noise?" Unwanted ions (molecular, memory, multiply charged, or metastable) from the source; scattered ions or neutrals from the analyzer; ions from ion pumps and vacuum gauges; detector noise due to cosmic rays, dark current, and electronics.

"What is the detector?" Faraday cup, electron multiplier, Daly detector, or P-N junction and its associated electronics.

Dr. Habfast asserted that a Faraday cup is the most accurate device to measure singly charged ions. It cannot distinguish one multiply charged ion from multiple singly charged ions. It is bias free but does have limited precision. Limitations are due to 1) RC time constant of the electrometer amplifier, 2) linearity of the high-ohm resistor (negligible with today's high quality resistors), 3) electrometer noise, and 4) secondary electron emission from the Faraday cup itself. The latter effect is minimized by making the cup deep (at least 20x the aperture size), by using special coatings and shapes to reduce secondary emission, and by preventing the escape of secondaries with magnetic or electrostatic fields.

Prof. Hayes described the statistical nature of ion arrival at the detector and the effect of counting system deadtime on count losses. The conventional approach to count loss corrects only for first-order coincidences. More accurate approaches consider higher orders of ion coincidence. The optimal approach is to measure an effective deadtime experimentally. Uncertainty in the deadtime places upper limits on the usable count rate as well as the attainable precision. Hence, it is more important to minimize the uncertainty in the deadtime than it is to minimize the deadtime itself.

Pulse counting gives better signal-to-noise at low signal levels, but analog measurement gives higher precision at high signal levels.

Dr. Smith related pulse-counting statistics to the rejection of outliers. Although count data follow a Poisson probability distribution, the ratios of count data do not follow any well-defined probability distribution. The use of normal distribution statistics to reject ratio data and assign confidence intervals is inaccurate, but the inaccuracy becomes negligible for large counts. Quality control can be improved by the use of a two-dimensional control chart instead of a one-dimensional chart. A plot of two parameters, such as concentration vs. isotopic ratio, yields more information and can frequently point to the cause of a problem when one arises.

General discussion followed the presentations.

A brief business meeting followed the workshop. Announcement was made of the second A. O. Nier Symposium on Inorganic Mass Spectrometry to be held in Durango, Colorado, on 10-12 May 1994. The conference will feature invited oral papers and contributed posters on high-sensitivity measurements in isotope geochemistry, nuclear energy, environmental assessment, accelerator mass spectrometry, other areas of inorganic mass spectrometry, and current advances in instrumentation development. Symposium sponsors are the Isotope Science Group of Los Alamos National Laboratory, the Chalk River Nuclear Laboratory of Atomic Energy of Canada, and the Idaho National Engineering Laboratory.

Discussion ensued regarding the competition for attendance between the A. O. Nier Symposium and the 1994 ASMS Conference which will follow only three weeks later. Those present, representing both the Isotopic Applications and Elemental Analysis Interest Groups, expressed a strong preference for the Nier Symposium because of its greater concentration of papers of interest. A few indicated that they would probably attend both the Nier Symposium and the ASMS Conference.

A discussion of topics for workshops or symposia at future ASMS Conferences centered on isotope ratio measurements in biological samples. The use of stable isotopes is increasing in biological studies because of the difficulty of getting approval for the use of radionuclides. The advantages and disadvantages of various ionization methods applied to the elements of interest in these studies would be valuable. A related instrumentation issue is that "many" in the biological field are using mass spectrometers not designed for ratio work to do ratio measurements.

The linking of Elemental Analysis and Isotopic Applications papers in both the oral and poster sessions this year was regarded as a good move.

LABORATORY MANAGERS INTEREST GROUP

WORKSHOP ON AUTOMATION IN THE MASS SPECTROMETRY LABORATORY

The topic of this year's workshop was "Automation in the Mass Spectrometry Laboratory". With the current slow economic growth, many laboratory managers are faced with the not uncommon task of being asked to "do more with less" - less personnel, less financial resources, less capital budget. Automation offers a means of increasing productivity while providing benefits for the end-user.

Mark Bean of SmithKline Beecham discussed automated molecular weight determinations using electrospray on a Sciex API III LC/MS system. Mark reported good results for the analysis of most compounds containing heteroatoms, from the very small up to medium-sized proteins. Either MW or MW plus fragmentation information (via manipulation of orifice potential) was readily obtainable. Other benefits of ESI analysis include the production of simple spectra, which lends itself to automated spectral processing. Automation also allows more time for challenging samples and speeds up the turn-around time for routine analyses.

Chemists submit a predetermined amount of dry sample in an autosampler vial attached to a submission form. The sample is dissolved in the chemists' solvent of choice; however, no acidic solvents are used. DMF and DMSO are generally avoided due to the production of multimeric species in the electrospray spectra. The samples are then sorted into two groups according to elution solvent requirements. Solvent A is used for those samples that elute in acidic aqueous methanol, while solvent B is used for those that will elute in acidic MeCN/MeOH. Each sample is injected twice; once for positive ion mode, and once again for negative ion mode. Solvent blanks and standards are injected for each of the solvent runs, and the solvent lines are washed prior to shutdown.

A translation program resident on the in-house VAX generates the Sciex acquisition batch file from the logged-in samples. The file is then transferred from the VAX to the Sciex MacIntosh computer. A sample tracking sheet is also generated at the same time. The instrument is tuned and calibrated daily, and the new calibration files are read into the acquisition method. Using the scripting feature of MacSpec, spectra are printed, having been adjusted for mass range, number of plot boxes, normalization, etc. The spectra are then distributed to the MS analysts (noted on the tracking sheet) for interpretation.

Ken Matuszak of Abbot Laboratories described an integrated robotics/MS system which utilizes ammonia desorption chemical ionization (DCI) for molecular weight confirmation.

Chemists enter sample information such as ID, solvent, and expected molecular weight, into a microVax oracle data base. Sample and solvent information are transferred to the DECstation. Samples are barcoded, which is then read and sent to the DECstation. A separate program matches the barcode and sample information, and send sample information to a Finnigan SSQ 700, and solvent information to a Zymark robot. The robot then prepares the sample and places it on the probe. The TSQ sets up the appropriate scan range based upon expected molecular weight, performs the analysis, processes the data and prints a hardcopy.

Approximately 8,000 samples are run on an annual basis. The system runs virtually unattended. Maintanance includes replacing the ion source and DCI filaments, recalibration (every three months), ion volume changes and source cleanings, and quadrupole maintenance. The number one problem has been the submission by the chemist of too much sample, which results in a saturated spectrum. Sample overload can also lead to source contamination and carry-over. Sample requirements are for between 0.5 and 1.0 mg. To avoid this problem, samples are reviewed before they are placed in the robot rack. Other minor problems include computer hang up and an occasional mishap from the robot.

Jane Gale of Bristol-Myers Squibb covered the topic of automated analysis of clinical samples for pharmacokinetic and bioavailability studies. Jane reviewed the benefits of automation, including increased productivity, a reduction on the reliance on contract labs (with concomitant cost reduction), maximization of instrument utilization, and improvement in analyst safety (less contact with potentially harmful biological fluids). Automation also helps in the tracking of samples, and can greatly accelerate the drug development process, which relies heavily on clinical studies.

Sample types include drugs, metabolites, and endogenous materials in matrices such as blood, urine, milk, and cerebrospinal fluid. Analytical techniques include GC/MS, LC/MS, and HPLC. Automation currently implemented includes robot-operated extractions, autosampler injections, data acquisition into batch files without operator intervention, and transfer of raw data to spreadsheets or mainframe programs for linear regression and calculation of predicted concentrations.

Jane outlined plans for further development of automation, from sample receipt to sample re-storage. A robot would take clinical sample tubes from an automatic feeder, move the sample across a barcode reader, place the sample in a storage rack and decontaminate in a bleach bath. Robots would then transfer samples to a freezer. Autosampler racks would be prepared robotically and would include standards and QC samples, as well as the study samples. This would be followed by transfer to the various workstations (GC/MS, LC/MS) for analysis. Samples would be subsequently returned to the freezer for storage. Up to 400,000 clinical samples could be analyzed per annum.

Jeff Kiplinger of Pfizer, Inc. concluded the workshop with a slightly different spin by reporting Pfizer's efforts in both the US and UK to establish hands-on mass spectrometry for molecular weight confirmation. Jeff outlined requirements for the system, including liquid introduction, soft ionization to produce MW information, ease of use (idiot proof), and low maintenance. Jeff reminded the workshop audience that users of such a service would have little or not instrumental experience, and that the system would have to be as simple as possible. Use by unsophisticated users means many unanticipated problems!!

Following evaluation of various ionization techniques for MW determinations, including thermospray, electrospray, particle beam/CI, particle beam/EI, and CF-FAB, it was found that particle beam/CI and thermospray produced reliable data in 75-90% of samples. Pfizer-UK installed a Fisons Trio-100 with TSP and PB on two systems, while an HP MS-Engine with ammonia CI PB was installed in the US, where throughput is currently 12,000 samples/quarter. Throughput in the UK lab is at 8,000 samples/quarter.

Jeff discussed the fact that the design and implementation of such a system requires the integration of several non-compatible parts. Vendors have been slow to design hardware/firmware/software with compatibility. Jeff suggested a long-term commitment with one manufacturer may be the best way to approach this problem.

Jeff offered other tips as well, suggesting that the system shouldn't be located too far away from the spectroscopists responsible for it. Sufficient training must be given including both spectral interpretation and instrument operation. Be prepared for user dependency. Finally, automation tends to spur growth in sample submission.

The workshop was well received and generated good discussion and interchange of ideas. Some of the approximately 80 attendees suggested a follow up in a few years, and perhaps having an oral or poster session devoted to laboratory automation.

Respectfully submitted,

Gerry Di Donato

Gerry DiDonato
Workshop Organizer

Workshop: Matching LC with MS; Current and Future Options

The LC/MS Interest Group conducted a spirited workshop on Thursday evening, June 3rd, with ca. 150-200 people attending. The workshop was structured in response to feedback from prior workshops. It was felt that these workshops had been too structured, time being filled with formal presentations and discussion from "gurus". Too few "real questions" were addressed and audience involvement was perceived as minimal. To address these concerns, we had **no structure** to this years workshop. I served only as a facilitator for questions that were posed by the audience. The role of the facilitator was to engage, challenge, and even intimidate the audience in an effort to provoke their involvement. The risk of chaos was well worth it as many excellent topics were discussed. The most encouraging part of the workshop was that almost all attendees got involved in the workshop by either asking, or answering questions.

The following is a summary of some of the questions posed. The audience submitted written questions at the beginning of the workshop. The availability of space prohibits a complete summary of the answers. Hopefully, these will give the flavor of the workshop.

How can LC/MS become as simple to use as traditional HPLC detectors (UV,etc)?
What is the optimal liquid flow rate for electrospray?
Where will Particle Beam LC/MS be in two years?
Where will Thermospray LC/MS be in two years?
Is there a need for a standard reference compound and standard reference spectrum for LC/MS?
Will there ever be a universal LC/MS interface?
What can be done to significantly increase the sensitivity of PB/LC/MS?
Will standard LC equipment meet the needs of present MS inlets or will there be a new generation of LC equipment?
What is the best LC column size for API/LC/MS?
Is it important to confine or restrict LC flow rates for the sake of the MS?
Can ultrasonic assisted electrospray really work at high flow rates, and if so, why is all the work shown at 50 uL?
Is anyone routinely doing accurate mass work with API LC/MS; and if so, what resolution and accuracy are they achieviing?

Based on feedback since this workshop, attendees would prefer this less structured, more interactive format. We will try this again in the future. I would like to thank all the participants for getting involved and contributing to a productive workshop.

Respectfully,

Ross Willoughby

FROM: David D. Stranz, Fisons Instruments

SUBJECT: Summary of discussions at the ASMS meeting

The Computer Interest Group workshop was held on Monday evening, 31 May 1993, at the ASMS annual meeting in San Francisco. The sole topic of that meeting was the status of the AIA Mass Spectrometry Data Interchange effort. Following the workshop, a meeting of vendors participating in the effort was held to develop plans for testing and final release of products implementing the interchange specification. I am pleased to furnish this summary of the workshop and vendors' discussion.

There were approximately 50 attendees present during the workshop, both end users and vendors. Dave Smith (PE-Sciex) welcomed the participants, explained the purpose of the workshop, then introduced me. I gave an overview of the AIA/MS effort and presented the current status and projected testing and release schedule. In brief, the status is that a second release of beta-level documentation and software was made in March 1993, and was distributed to vendors and other implementors at Pittcon. Several vendors have implemented applications using the tool kit, and have begun producing test files in netCDF format.

Following my talk, Don Zakett (Dow Chemical Company) presented his perspective as an end user, and gave some observations as a beta tester of several vendors' preliminary implementations. Slow conversion of large data sets (tens of megabytes) was identified as a potential usage problem. David McLaughlin (Eastman Kodak Company) gave some further views with respect to his use of the MS tool kit in exporting data from Kodak's corporate spectral database into netCDF format for import into a commercial MS data system. Performance on large files and some inadequacies in the implementation for spectral libraries were noted as problems.

During the discussion period, several concerns were raised. First, there was strong interest in using the AIA/MS netCDF files for long-term archival storage of mass spectral data. My answer was that we are also very interested in providing an archival storage mechanism, but the current state of the specification and implementation is too unstable to permit that. It will likely be several years before the specification stabilizes sufficiently. We did agree, however, to provide "version translators" which would update an AIA/MS file from the preceding version to the new in the event we release a new version. This would permit users who do archive data to keep their archives current.

Second, several users expressed concern about our validation of the software. There are three aspects to this: validation of the applications provided by vendors, validation of the AIA/MS tool kit, and validation of the underlying Unidata netCDF tool kit. Vendors are obviously responsible for certifying their own software. Round-robin testing will serve both to validate the files produced by vendors' implementations and the AIA/MS tool kit. I have suggested to the AIA that they become involved in the validation process for the netCDF tool kit, since it has been recommended and is presently serving as the underlying protocol for all AIA data interchange

implementations. The Laboratory Automation Standards Foundation (a non-profit organization assisting in standards development) might be an appropriate body to provide such validation.

Third, we discussed future directions for the MS effort. Three avenues were presented: full integration of the chromatography and mass spectrometry specifications; extension of the MS specification to cover MS/MS, FT/MS, and time-of-flight MS; and extension to cover quantitative and qualitative results and GALP information. By a show of hands, integration of chromatographic information was chosen as most important. Very little interest, other than by vendors themselves, was shown for other MS techniques. There was also some discussion of splitting the MS specification at some point into two parts, one describing experimental data sets, and another specifically tailored for spectral libraries. The current specification enforces a somewhat awkward marriage of these two topics into one.

After the workshop, vendors and interested parties held a brief meeting to discuss status and forward directions. Three issues were discussed: required enhancements and modifications to the beta release before final testing and public release, a formal round-robin testing plan, and projected release dates for products containing the AIA/MS specification.

With respect to modifications: Several individuals expressed interest in incorporating additional information, most of which was within the scope of the existing specification and will be added. In particular, explicit description of selected ion monitoring data (*i.e.* mass groups and monitoring times) was considered important in reconstructing SIM/SIR/MID data sets. There was also a request for some convenience functions to be added to the programming tool kit to make retrieval of TIC and certain other data easier. I agreed to incorporate these changes, and will make a final version of the documents and tool kit available by the end of June.

The vendors agreed that following receipt of the final beta distribution, they would develop applications to both read and write interchange files, and conduct round-robin testing of all major parts of the specification. This testing will be completed by the end of September, at which time we will submit the results to the AIA board for acceptance. I stressed the importance of AIA certification, and set a goal of at least 50% compliance before I could submit the results. Testing will be conducted by exchange of data files among the various vendors and end user beta testers. I will serve as recipient for all files on PC diskette; Jim Watt (PE Nelson) will make these files available via anonymous FTP, and I will furnish diskette copies to testers without network access. I will correlate testing results and notify participants of required changes.

Once testing is complete, I will submit the results to AIA for acceptance. We expect that the AIA will act on the request in time to allow us to make the specification fully public and begin distributing products which contain it by the end of this calendar year.

I will provide full details of the logistics of the round-robin testing plan with the revised distribution at the end of June. In the meantime, if you have not received a copy of the March 1993 beta distribution, please contact me.

The AIA/MS interchange effort is much anticipated by the end user community. Several individuals expressed their pleasure with the progress made to date, and are eagerly anticipating release of products. I would like to thank all of the participants in this long effort for their assistance and cooperation. We are nearing the end of the tunnel, and I am confident we will emerge successful.
