LISTING OF EXTENDED ABSTRACT TITLES BY SESSION vii

ABSTRACTS

Monday Orals
- Recent Dev. in the Characterization of Aerosol Microparticles 1
- Computational & Exp. Approaches to Ion Thermochem. & Structure 10
- Mass Spectrometry of Polymers 18
- Electrospray Ionization - Applications 28
- Elemental and Isotopic Analysis 40

Monday Posters
- Ion Molecule Reactions 50
- Ion Sources & Mass Spectrometer Design 96
- Organic Analysis 141
- Environmental Analysis 180
- Spray Ionization 233
- Proteins & Peptides 268

Tuesday Orals
- Mass Spectrometry in Pharmacology & Toxicology 327
- Mass Spectrometry in Environmental Research 337
- Chemistry of Multiply-Charged Ions 347
- Laser Desorption Ionization - Applications 357
- Mechanisms of Ion-Molecule Reactions 367

Tuesday Posters
- Ion Activation and Dissociation 376
- Separations/MS Techniques 422
- Combinatorial Libraries 483
- Toxicology 495
- Drugs and Metabolism 518
- Nucleic Acids and Constituents 579

- Proteins and Peptides 610

Wednesday Orals
- New Approaches to Quantitative Mass Spectrometry 658
- Electrospray Ionization - Fundamentals 667
- Fourier Transform Mass Spectrometry 675
- Laser Desorption Ionization - Fundamentals 683
- Mass Spectrometry and the Earth's Atmosphere 693

Wednesday Posters
- Ion-Molecule Reactions 696
- Computer Applications 717
- Materials Characterization 745
- Inorganic, Elemental & Isotope Ratios 767
- Trapped Ions 782
- Environmental Analysis 815
- Drugs & Metabolism 849
- Spray Ionization 884
- Laser Desorption/Ionization 915

Thursday Orals
- Hydrogen Bonding Interactions 969
- Mass Spectrometry in Immunology 975
- Ion Trap Mass Spectrometry 983
- Time-of-Flight Mass Spectrometry 994
- Energy & Petrochemicals 1005
- Organohalogens: New Issues & Techniques 1015

Thursday Posters
- Fundamental Studies 1025
- Ion Source & Mass Spectrometer Design 1068
- Trapped Ions 1100
- Lipids 1142
- Carbohydrates 1164
- Laser Desorption/Ionization 1204
- Proteins & Peptides 1257

Friday Orals
- Metal Ion Chemistry 1305
- Hyphenated Chromatography/Mass Spectrometry 1311
- Good Laboratory Practices for Mass Spectrometry 1319
- Mass Spectrometry to Study Higher Order Structure 1325
- Surface-Induced Dissociation 1332

INDEX OF AUTHORS 1338

INDEX OF KEY WORDS 1350

WORKSHOP AND INTEREST GROUP MEETING REPORTS
LC/MS Workshop 1356
Ion Trap Workshop 1357
FTMS: "Most Recent Results in FTMS" 1358
Good Laboratory Practices (GLP) Workshop 1359
Elemental: "Comparison of Mass Analyzers for ICP & GD Ion Sources" 1360
Process MS: "On-Line MS for Process Control and Diagnostics: 1361
Desorption/Ionization: "Micro-Electrospray: Can Less Give More?" 1362
Computer Applications: "Validation of MS Data Systems" 1363
TOF: "Progress and Prospects for TOF Mass Spectrometry" 1364
Historical Interest Group 1365
Biomedical Applications: "Probing Biomolecular Non-covalent Interactions: Tricks and Traps" 1366

MINUTES OF THE ASMS BUSINESS MEETING 1367

43rd ASMS Conference on Mass Spectrometry and Allied Topics

INTRODUCTION

This volume represents the official record of the 1995 Annual ASMS Conference and is designated as the Proceedings of the 43rd Annual Conference on Mass Spectrometry and Allied Topics.

The 1995 ASMS Conference was held May 21 - 26, at the Marriott Marquis Hotel in Atlanta, Georgia. The total number of conference attendees was 2,307. There were 1,451 scientific presentations, consisting of 5 plenary lectures, 260 orals, 1,182 posters and 4 tutorial lectures, which were new this year and very well attended. Some of the highlights included the presentation of the 1995 ASMS Award for a Distinguished Contribution in Mass Spectrometry to Prof. Keith R. Jennings of the University of Warwick for his discovery of collision-induced dissociation. In addition, the 1995 ASMS and Corporate Donor Awards were presented to Prof. Kermit K. Murray of Emory University and to Prof. Lee Sunderlin of Northern Illinois University. The plenary lectures were all unique, thought-provoking and spanned a broad range of topics relevant to our science, from mass spectrometric drug testing of Olympic athletes to the "geek factor" of science in the media.

This volume contains extended abstracts that provide brief descriptions of the research presented at the conference. In addition, reports from workshops, interest groups and the annual ASMS business meeting are included.

Special thanks go to Veronica Bierbaum for arranging the excellent scientific program and to Judith Sjoberg and her staff of Professional Association Management for coordinating the printing and distribution of the Proceedings.

Mark M. Ross
Editor and Member-at-Large
ASMS Board of Directors

CITATION NOTICE

This volume contains the extended abstracts of papers presented at the 43rd ASMS Conference on Mass Spectrometry and Allied Topics. The material is not copyrighted and appearance of material in this volume does not jeopardize the author's right to publish the information in scientific journals.

Reference to individual abstracts contained in this volume should be cited as follows:

Author(s); title; *Proceedings of the 43RD ASMS Conference on Mass Spectrometry and* Allied Topics, Atlanta, Georgia, May 21 - 26, 1995.

ASMS BOARD OF DIRECTORS 1994 - 95

President	Christie G Enke University of New Mexico Albuquerque, NM
Vice President for Programs	Veronica M. Bierbaum University of Colorado Boulder, CO
Vice President for Arrangements	Brian Musselman JEOL USA, Inc. Peabody, MA
Secretary	Thomas A Baillie Merck Research Labs West Point, PA
Treasurer	Charles A. Evans Charles Evans & Assoc. Redwood City, CA
Member at Large	Mark M Ross Naval Research Lab Washington, DC
Member at Large	Robert K Boyd Nat'l Research Council Halifax, Canada
Member at Large	Sharon G. Lias NIST Gaithersburg, MD
Past President	Henry M. Fales NIH Bethesda, MD
Executive Director	Judith A. Sjoberg ASMS 1201 Don Diego Avenue Santa Fe, NM 87505 (505) 989-4517
Staff	Cindi Lilly Michele Davenport Kim Leibman

INTEREST GROUP COORDINATORS

Automated MS	Mark F Beam SmithKline Beecham
Biomedical Applications	Pamela F Crain University of Utah
Computer Applications	David D. Stranz Fisons Instruments
Desorption Ionization	Richard B. Cole Univ of New Orleans
Elemental Analysis	Douglas C. Duckworth Oak Ridge Nat'l. Lab
Energy & Petrochemicals	Dean V Davis Unocal Science & Tech
Environmental Applications	M. Judith Charles Univ of North Carolina
FTMS	Carlito Lebrilla Univ of California (Davis)
Fundamentals	John Bartmess University of Tennessee
History of MS	Lawrence R. Phillips National Cancer Inst
Ion Trap MS	Gary L Glish Univ of North Carolina
Isotopic Applications	John Wacker Battelle Northwest Labs
Laboratory Managers	Andrew N Tyler Harvard University
LC/MS & Related Topics	ThomasCovey Sciex, Inc.
Metal Ion Coord. Chem	Jennifer Brodbelt University of Texas
Polymeric Materials	Phil Savickas Dow Chemical Company
Quantitation	Susan T. Weintraub University of Texas
Surface Science	Frasier Reich Charles Evans & Assoc
Time-of-Flight MS	Robert J. Cotter Johns Hopkins Univ
Young Mass Spectrometrists	David Dearden Brigham Young Univ

ASMS COMMITTEES

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Monday Orals
Recent Developments in the Characterization of Aerosol Microparticles

Ambient Aerosol Analysis Using Aerosol Time-of-Flight Mass Spectrometry; *Prather, Kimberly; Fergensen, David; Morrical, Bradley; Noble, Christopher; Nordmeyer, Trent; Salt.. 1
Rapid Single-Particle Mass Spectrometry of Aerosols and Aerosol Reactions; *Johnston, Murray; Carson, Peter; Mansoori, Bashir; Wexler, Anthony. 2
Tandem Mass Spectrometry of Airborne Particles; Yang, Mo; Whitten, William; *Ramsey, Michael. 3
Detection and Characterization of Ultrafine Particles; *Reents, William. 4
Sulfur Speciation of Single Aerosol Particles; *Neubauer, Kenneth; Johnston, Murray; Wexler, Anthony 5
Laser Microprobe Mass Spectrometry of Soot and Soot Precursor Particles; *Fletcher, Robert; Dobbins, Richard; Lu, Weining 6
Effects of MALDI and Solution Parameters on Aerosol MALDI Ion Signal; *Beeson, Michelle D.; Wei, Xiaona; Russell, David H. 7
Application of Two-Step Laser Mass Spectrometry to Kerogen; *Zhan, Qiao; Zenobi, Renato; Knochenmuss, Richard; Buseck, R. Peter. 8
A Reversed Geometry Organic Ion Microprobe; *Todd, Peter; Short, Rober.t 9

Monday Orals
Computational & Experimental Approaches to Ion Thermochemistry & Structure

A Computational Approach to Gas-Phase Ion Chemistry; *Radom, Leo 10
Recent Experimental Investigations of Gaseous Ion Thermochemistry; *McMahon, Terry. 11
Structure and Reactivity Of A Cyclopropyl Anion: Experiment and Theory; Baschky, Michael; Peterson, Kent; *Kass, Steven. 12
Neutral and ionic heats of formation; measurement and reliability; *Holmes, John L. 13
4-Member Cyclic Halonium Ions in Intramolecular 1,3-Fluoride Transfer; *Morton, Thomas Hellman 14
Theoretical Studies of Proton Transfer Potential Energy Surfaces.; *Gronert, Scott; Kimura, Cliff; Sadoun, Aladin. 15
Metal-Ligand Thermochemistry by Guided Ion Beam Mass Spectrometry; *Armentrout, Peter 16
Experimental and Ab Initio Studies of Second Row Radicals; *Turecek, Frantisek; Shaffer, Scott; Gu, Ming; Hop, Corneli. 17

Monday Orals - Mass Spectrometry of Polymers

Characterisation of synthetic polymer formulations using MALDI; *Scrivens, Jim; Yates, Hilary; Segal , John; Jackson, Tony; Taylor, Mike; Critchley, Glen; Maisey, Ann 18
Matrix-Assisted Laser Desorption Investigations of Industrial Polymers; *Hanton, Scott; Parees, David; **Goldschmidt, Robert; King, Richard; Owens, Kevin. 19
High Mass Resolution Imaging TOF-SIMS Analysis of Polymer Surfaces; *Reichlmaier, Stefan. 20
REVERSE ENGINEERING OF INDUSTRIAL POLYMER FORMULATIONS BY MALDI-MS; *Tang, X.; Vertes, Akos; **Dreifuss, Peter; Hull, Clifford, Dutton, Walter. 21
MALDI in Polymer Chem: Rapid Analysis of Chemical Modifications on Polymers; *Whittal, Randy M.; Li, Liang. 22
MW Determination of Synthetic Polymers from ESI & MALDI Mass Spectra; McEwen, Charles; Jackson, Christian; *Larsen, Barbara. 23
Mass Spectrometry of Otherwise Fragile Polymers by End Group REMPI; Anex, Deon S.; Hunziker, Heinrich E.; *de Vries, Mattanjah S. 24
A Polymer Library By In-Source Direct Pyrolysis Mass Spectrometry; *Qian, Kuangnan; Killinger, William E. 25
Polymer Analysis Using a Radio Frequency Glow Discharge Mass Spectrometer; *DePalma, Jr., Patrick; Shick, Jr., Charles, Marcus, R Kenneth.. 26
FD-MS Studies of Samarium-based Oligomerization of Ethylene; *Greaves, John; DeCoster, Donna M., Evans, William J. 27

Monday Orals - Electrospray Ionization-Applications

Protein & Peptide Analysis by A Low-Flow, High Sensitivity MicroES Source; *Wilm, Matthias; Mann, Matthias. 28
Biochemical Characterization of EGF Receptor-SRC SH2 Interactions; *Lombardo, Christian; Consler, Thomas; Luther, Michael; Kassel, Daniel. 29
RECEPTOR PEPTOID LIGANDS IN COMBINATORIAL MIXTURES: AFFINITY SELECTION ESMS; *Kaur, Surinder; Huebner, Vreni; Dollinger, Gavin; Tang, Dazhi; McGuire, Lisa 30
Proteins Associated with Cardiomyocyte Hypertrophy: 2D PAGE, LCMS AND MS/MS; *Arnott, David; King, Kathy; Bier, Mark; Land, Adrian; Stults, John. 31
Amino Acid Transformations during Oxidation of Peptides and Proteins; *Chowdhury, Swapan; Eshraghi, Jamshid, Wolfe, Henry; Forde, Diane; Hlavac, Allan; Johnston, David. 32
Identifying Proteins by Nanoelectrospray Tandem MS & Peptide Sequence Tags; M. Mann.; M Wilm; A Shevchenko; G Neubauer. 33

MALDI and ESI MS of Covalent Peptide-Oligonucleotide Hybrids; *Jensen, Ole N.; Kulkarni, Sandhya; Aldrich, Jane V.; Bennett, Samuel E.; Mosbaugh, Dale W.; Barofsky, Douglas F. 34
Studying Noncovalent Protein-Peptide Interactions by ESI Mass Spectrometry; *Loo, Joseph A.; Hu, Peifeng; Thanabal, Venkataraman 35
Mass Spectrometry in the Development of Recombinant Protein Drugs; Kubis, Alan; Chen, Tom; Ghosh, Kris; Natale, David; Nigam, Somesh; *Labdon, James 36
Application of Micro-ES/MS/MS for Monitoring the Effects of Drugs of Abuse; *Emmett, Mark R.; Caprioli, Richard M. 37
Sequencing Nucleotides (n>50) by Tandem Mass Spectrometry; *Little, Daniel P.; McLafferty, Fred W. 38
Searching Chemical Diversity for Molecular Recognition by ESI-MS; *Smith, Richard D.; Bruce, James E.; Chen, Ruidan; Cheng, Xueheng; Schwartz, Brenda L.; Anderson, Gordon A.; Hofstadler, Steven A.; Gale, David C. 39

Monday Orals - Elemental and Isotopic Analysis

Direct Connection of an ICP and an Ion Trap MS; *Barinaga, Charles J.; Eiden, Gregory C.; Koppenaal, David W. 40
Glow Discharge Ion Trap Mass Spectrometry Employing Filtered Noise Fields; *Duckworth, Douglas C.; Smith, David H.; Goeringer, Douglas E.; McLuckey, Scott A. 41
TIME-OF-FLIGHT MASS SPECTROMETRY WITH A PULSED GLOW DISCHARGE ION SOURCE; King, Fred; *Steiner, Robert. 42
Anodic Stripping Voltammetry Coupled On-line with ICP-MS; *Van Berkel, Gary; Zhou, Feimeng; Duckworth, Douglas; Morton, Shelby. 43
Laser Ablation ICP/MS Analysis of Real World Samples.; *Kahr, Michael; Brink, Christopher; Figg, Deborah. 44
Analysis of Nominally Flat Samples by Radio Frequency Powered GDMS.; *Shick, Jr., Charles R.; Marcus, R. Kenneth. 45
High Precision Continuous Flow D/H Measurement from Hydrogen Gas and Water; *Tobias, Herbert J.; Goodman, Keith J.; Blacken, Craig E.; Brenna, J. Thomas. 46
A Field Mass Spectrometric System for Isotopic Analysis of Actinides.; *Kahr, Michael; Olivares, Jose; Abney, Kent; Kinkead, Scott. 47
Nuclear Isotope Measurement in the Hanford Environment; *Stoffel(s), J. J.; Kelley, J. M.; Bond, L. A.; Kiddy, R. A.; Brauer, F. P. 48
High-sensitivity Thermal Ionization Cavity Source for Mass Spectrometry; *Olivares, Jose A.; Chamberlin, Edwin P.; Duan, Yixiang 49

Monday Posters - Ion Molecule Reactions

Thermochemical Studies of Halocarbenes and Halosilylenes; *Poutsma, John; Paulino, Jose; Squires, Robert. 50
Calculated and Measured Double-ionization Energies of Carbon Tetrachloride; *GRANT, RUSSELL. P.; HARRIS, FRANK M ; **ANDREWS, STUART. R.; PARRY, DAVID. E. 51
DETERMINATION OF Se-H BOND ENERGY OF BENZENESELENOL; Leeck, Diane T.; *Li, Ruomei; Chyall, Leonard; Kenttamaa, Hilkka I. 52
Alkali Metal Ion - Crown Ether Bond Strengths by FTICR Threshold CID ; *Pope, Marshall; Dearden, David. 53
Cation Affinities of Pyridine Bases: Steric Effects; *Isbell, John; Brodbelt, Jennifer. 54
Charge Repulsion in Peptides and Basicities of Different Charge States.; *Kaltashov, Igor; Fenselau, Catherine. 55
Polyatomic Cations Affinities of Pyridines Determined by the Kinetic Method; *Sheng S. Yang, ; Guodong Chen, ; Philip Wong, ; Shuguang Ma, , R. Graham Cooks, , **Fabio C Gozzo, ; Marcos Eberlin 56
Acidities of long chain diols: problems with the kinetic method; *Higgins, Priscilla; Bartmess, John. 57
Reactivity and Thermochemistry of Quadricyclane Anion; *Lee, Hack Sung; Bierbaum, Veronica M. 58
Temperature dependence of radiative association rates; *Ryzhov, Victor; Dunbar, Robert C. 59
A REACTION WINDOW IN CROSS-SECTIONS FOR DOUBLE ELECTRON CAPTURE REACTIONS.; *Griffiths, William; Langford, Marian; Harris, Frank. 60
Reactions and Laser Photofragmentation Processes of SiF2(2+) and SiF3(2+); **Lee, Yin-Yu; *Leone, Stephen R. 61
Partially Chlorinated Hydrocarbons: Gas-Phase Anion-Molecule Reactions ; *Grabowski, Joseph J.; Braun, Jennifer A. 62
Regioselectivity of oxygen addition on PCBs and DDT in ECNCI; *Lépine, François; **Mamer, Orval A.; Milot, Sylvain. 63
Dissociative Attachment in Sulfonate and Carboxylate Compounds; *Andrews, Kim; Bartmess, John; Sorensen, Daniel; Crowder, Cathy. 64
Experimental and Theoretical Characterization of the Gas-Phase SO2N- Anion; Morgon, Nelson H.; Linnert, Harrald V.; *Riveros, José M. 65
A NEGATIVE ION STUDY OF THE ISOMERS OF DINITROBENZENE USING A ASGDI SOURCE; Mo, Wenjun; Langford, Marian, L; Franklin, Anthony, M; *Todd, John, F. J. 66
Investigation of van der Waals clusters by a novel technique for ICR; *Garbade, Klaus ; Wanczek, Karl Peter. 67

Consecutive reactions of conjugated dienes; Rappmund, Andreas; *Wanczek, Karl Peter....68
Bulk Polymerization and Ion Chemistry of Crotonaldehyde, Studied with ICR; *Harder, Andreas; Spiess, Iris, Wanczek, Karl Peter....69
Reactivity of Ionized Carbonyl Compounds and Distonic and Enol Isomers; *Byrd, Michelle; Castro, Lori, Hwang, Thomas; Smith, Rebecca; Leeck, Diane; Kenttamaa, Hilkka....70
Generation and Reactivity of Charged Phenyl Radicals; *Smith, Rebecca; Kenttamaa, Hilkka....71
CHARGE TRANSFER REACTIONS OF THE CYCLOPROPENYL CATION; *Watkins, Layle; Rich, Jennifer; Frank, Samantha ; Hanson, Curtiss....72
Selective ion-molecule reactions of benzoyl ions in a quadrupole ion trap; Creaser, Colin; *Williamson, Brian; **Stockton, Brian....73
Gas-phase Ion-molecule Reactions of Methyl Tertbutyl Ether (MTBE); *Peterman, Scott; Rich, Michaela; Hanson, Curtiss....74
Ion/Molecule Reactions with Polyethylene Glycoles and PEG Ethers; *Onigbinde, Adebayo; Ridge, D. P., Munson, Burnaby, Zhang, Tianlan....75
GC/CIMS of Lipids with Benzene and Carbon Disulfide; *Evans, Jason, Nicol, Gordon; Munson, Burnaby....76
Gas-Phase Ion-Molecule Reactions of Amines with Carbonyl Compounds; Pykäläinen, Mika; *Vainiotalo, Pirjo....77
In-situ Investigation of Soot Formation; *Egsgaard, Helge....78
An Ion Trap MS/MS Study of [C14H10]+,[C10H10]+, and [C10H8]+ Ions.; *Wang, Xiaomin; **March, Raymond E., Hopkinson, Alan C.; Bohme, Diethard K....79
Isomeric Forms of the Products of Ion-Molecule Association Reactions; *Kerr, Kelly E.; Adams, Nigel G....80
Competitive SNi/SN2 from epimeric 1-2 hydroxyether and diether 1-2 indanes.; Christel , Bourhis; Vincent , Gervat; Marie-Claude, Perlat; Françoise, Fournier; *Acher, Mandelbaum; **Jean-Claude , Tabet....81
Ion-Molecule Reactions with Alkyl Cation Transfer by Electrospray FTICR-MS; *Burton, Richard; Watson, Cliff; Katritzky, Alan; Eyler, John....82
Association and Bimolecular Ion-Molecule Reactions of Sulfur Ring Systems; *James, Mary A.; Gidden, Jennifer; Peschke, Michael; Illies, Andreas J....83
ION/MOLECULE REACTIONS OF ALLYL CHLORIDE IN THE ION TRAP MASS SPECTROMETER; Mo, Wenjun; Franklin, Anthony, M; *Todd, John. F. J....84
Mechanism of H/D Exchange in the Reaction of BH2+ and Deuterium; *Hankin, Joseph; Davico, Gustavo; DePuy, Charles, Damrauer, Robert....85
Isotope Effects in the Dissociation of Aniline and Protonated Aniline; *Ranasinghe, Yasmin A.; Glish, Gary L....86
Hydrogen/Deuterium Exchange of Multiply-Protonated Cytochrome c Ions; *Wood, Troy D.; Guan, Ziqiang, Chorush, Russell A ; McLafferty, Fred W....87
Resolvation of Electrospray Ions in a Time of Flight Mass Spectrometer *Lasater, M. A.; Laude, D. A....88

Influence of Water and Structure on Coulomb Energy in Multiply Charged Ions; *Gross, Deborah S.; Rodriguez-Cruz, Sandra E ; Williams, Evan R....89
Acid/Base effect on FAB ionization process * L. Amado, Francisco; N. Domingues, Pedro ; O. Marques, M. Graa; Ferrer Correia, A. J....90
Ion/Molecule Reactions for Improved Effective Mass Resolution in ES/MS; McLuckey, Scott; *Goeringer, Douglas....91
Structure Elucidation of Peptides by Two-Dimensional FT-ICR MS; **Solouki, Touradj; *Ross III, Charles; Pasa-Tolic, Ljiljana; Marshall, Alan G....92
FT-ICR Observation of Metabolic Intermediates for Nephrotoxic Chloroalkenes; *Zhang, Tian-lan; Wang, Liping; Hahsmi, Mazzaz; Anders, M. W.; Thorpe, Colin; Ridge, Douglas....93
Study of Ion-Molecule Chiral Recognition by Amine Exchange Equilibria Dejsupa, Chadin; Liang, Yongjiang; *Dearden, David....94
Chiral Recognition in Molecular Host-Guest Complexations using FABMS; *Sawada, Masami; Takai, Yoshio; Yamada, Hitoshi; Hirayama, Shigeki, Kamada, Kimiko, Hirose, Keiji; Tobe, Yoshito; **Naemura, Koichiro....95

Monday Posters - Ion Sources & Mass Spectrometer Design

SFC/MS using a glow discharge ionization source; *Carazzato, Daniel; B langer, Patrick, Carrier, Alain; Bertrand, Michel J....96
A NOVEL LOW-POWER RF GLOW DISCHARGE ION SOURCE; *Langford, Marian L.; Povey, William T ; Todd, John F. J....97
Micro-electrospray on a Magnetic Sector Mass Spectrometer; *Woolfitt, Adrian; Bateman, Robert; Bordoli, Robert....98
ATMOSPHERIC PRESSURE CHEMICAL IONIZATION BY CORONA DISCHARGE.; *Andrien, Jr., Bruce; Dresch, Tomas; Haren, Patrick, Whitehouse, Craig, Shen, Shida....99
A New Atmospheric Presure MIP Ionization Source for Mass Spectrometry; *Moini, Mehdi, Xia, Ming; Hofmann, Bernhard, Mathews, Kimberly, Holbert, Anthony....100
MULTI-VACUUM STAGE HEXAPOLE ION GUIDE FOR ESI/MS INTERFACE; *Gulcicek, Erol E.; Whitehouse, Craig M....101
Ion Transmission Through Glass and Metal Tubes; *Cao, Jian-Ru; Rosell, Joan; Fenn, John....102
Design of a Composite Liquid-Junction/Electrospray Interface for CE/MS; *Wachs, Timothy; **Sheppard, Robin; Henion, Jack....103
A Versatile, Stable CE-ESI Source; *Kirby, Daniel P....104
Real Time UV Detection with On-Line CE-ESI-MS; *Foret, Frantisek; Muller, Odilo; Goetzinger, Wolfgang; Thorne, Jacqueline; Karger, Barry L.; Vouros, Paul; Kirby, Daniel P....105

Advanced Liquid Ionization Mass Spectrometry for Analysis of a Mixture; *Inoue, Masayuki; Kaneko, Takeo; Li, Yaming; Tsuchiya, Masahiko, **Niwa, Yoshio 106
Electric evaporation of ions from liquid in channels of polymer films; Balakin, A; Dodonov, A; Novikova, L; *Talrose, V; Yakovlev, B. 107
Molecular Weight Enhancement in GC-MS with Supersonic Molecular Beams; *Dagan, Shai; Amirav, Aviv. 108
Soft Ionization via Electron Impact on Free-Jet Clusters; *Wang, Dingneng; Evans, Robert. 109
Concentration Enrichment in High Pressure Ion Sources, Part II.; Williamson, D H.; *Knighton, W.B.; Grimsrud, E.P. 110
A Portable Mass Spectrometer to Measure Surface Contamination; *Gregg, Hugh; Meltzer, Michael; Lindsey, Jean; Edberg, Heather 111
Conversion of HP-5985 GC/MS to Automated, High-Volume ES-MS; *Kiesel, Jennifer R ; Jackson, Alan K.; Depperman, Kevin L.; Hileman, Fred D.; Duffin, Kevin L. 112
Improving Sensitivity in the HP MSD Mass Spectrometers; *Manura, John; Overton, Santford; Baker, Chris 113
Modification of an HP 5972 MSD to Accept a Direct Insertion Membrane Probe; *Bauer, Scott; 114
TWO QUADRUPOLE MASS SPECTROMETERS MODIFIED FOR PYROLYSIS-MS; *Wilkes, Jon G. ; **Voorhees, Kent J.; Lay, Jackson O. ; Volmer, Dietrich A. 115
EXAMINATION OF SEVERAL SHEET MATERIALS FOR USE AS MEMBRANES IN MI/MS; *Maden, Amy J , Hayward, Mark J 116
Optimal Design of a MALDI Time-of-Flight Instrument for MS/MS of Peptides; *Hoyes, John; Curbishley, Steve; Bateman, Robert. 117
Modulated Sample, Membrane Inlet MS: Theory and Practice; *Liu, Fei; Davenport, Michael, Enke, Christie G. 118
Ion storage study for a segmented-ring ion trap source for TOF-MS; *Ji, Qinchung; Davenport, Michael R.; Holland, John F. ; Enke, Christie G. 119
A new design of Ion Storage Accelerator for Time-of-Flight MS; Kraft, Andreas; *Wollnik, Hermann; Laiko, Victor; **Dodonov, Alexander. 120
A new MALDI Tandem QUISTOR Time-of-Flight Mass Spectrometer; *Stoeckli, Markus; Kofel, Peter, Krause, Joern, Schlunegger, Urs P 121
A New LC Electrospray Ion Trap Time-of-Flight Mass Spectrometer; *Mordehai, Alex; Karnicky, Joseph F., Limbek, Belá; Buttrill, Jr., S. E. 122
MALDI TOF/TOF of peptides: Past, Present and Future.; *Cordero, Marcela M.; Cornish, Timothy J.; Cotter, Robert J. 123
Progress in the design of a continuous flow - MALDI interface of a TOF - MS; *Grigorean, Gabriela; Wronka, John; Martin, Charles; Amster , I. Jonathan 124
An Inverted Perfectron Electrospray/Orthogonal TOF Mass Spectrometer; *Gao, Q ; Rockwood, A. L.; Udseth, H. R.; Follansbee, J. C.; Smith, R. D. 125

Collisional Focusing of Ions in the Electrospray TOF Mass Spectrometer; *Krutchinsky, A.N.; Chernushevich, I.V.; Ens, W.; Spicer, V , Standing, K.G. 126
The Laser Ionization GC-TOF/MS Analysis of Organometallics; *COLBY, STEVEN; HANSER, KENT; HARRIS, WILLIAM; REILLY, JAMES. 127
A new GC-TOF mass analyzer; Scherer, Stefan; Dormagen, Jonas; Horvath, Thomas; *Wollnik, Hermann. 128
Design of a GC/TOF MS System for the Analysis of Breath Components; *Miyares, Paul H.; Enke, Christie G. 129
Time-of-flight mirrors with ideal time-focusing in tandem mass-spectrometry; *Makarov, Alexander; Raptakis, Emmanuel; Derrick, Peter. 130
High Voltage Deflectors for Mass Selection on a Wire-Guide MALDI/TOF; *Bolanos, B. J.; Robinson, J. M.; Laude, D. A. 131
Improved Space-Focusing Using Non-linear Ion Acceleration Fields in TOFMS; *Gardner, Ben; **Artaev, Viatcheslav; Holland, John. 132
Design Optimization for Coaxial, Curved-Field Reflectron Time-of-Flight MS; *Cornish, Timothy J.; Cotter, Robert J 133
An Interleaved-Comb Ion Deflection Gate; *Beussman, Douglas J.; Vlasak, Paul R.; **Erickson, Tina A ; Davenport, Michael R.; Enke, Christie G 134
Ion Selection in TOF using a Bi-polar Pulsed Electrostatic Particle Guide; *Adams, Nathan; Just, Craig; Hanson, Curtiss. 135
Comparison of Ion Detectors for MALDI TOFMS; *King, Richard; Owens, Kevin; **Hanton, Scott. 136
Tandem MS Utilizing an Orthogonal Acceleration Time of Flight MS as MS-II; *Cerny, Ronald L , Wulser, Kurt W ; Smith, David L ; **Bateman, Robert H 137
MS & High Energy CID MS/MS of ESI & MALDI Ions on a Sector-TOF Instrument; *Bateman, Robert; Green, Martin; Scott, Gary. 138
A HYBRID TANDEM MASS SPECTROMETER III; *Duhr, Alexander; Stracke, Patric; Stadlmann, Jens; Wollnik, Hermann. 139
A new 2-D / 3-D-TOF MS; Linden, H. Bernhard; *Bamberg, Michael 140

Monday Posters - Organic Analysis

The Evaluation of a Comprehensive MS Reference Library; **Zaikin, Vladimir, Ausloos, Pierre; Lias, Sharon; Clifton, Carol; Mikaya, Anzor; *Stein, Stephen. 141
Odor analysis by GC/MS/FTIR using substructure based spectral libraries.; *Nikiforov, Alex; Remberg, Barbara; Buchbauer, Gerhard; Jirovetz, Leopold; Körnig , Stefan. 142
The Development of an Automated System for Routine MS Analysis; *Fink, Saul, W., Thompson, William, L.; Slayback, John, R. B. 143
Spectral Resolution of Isomeric Alkanes: A Process MS Application; *Haddix, Martin; Cook, Kelsey 144
Distinguishing between Isomeric C3H5 Moieties Using Daughter Ion Spectra; *Green, John Glass. 145

Structure Elucidation Using a Multi-Disciplinary Analytical Approach; *Russell, David J.; Fink, Saul W.; Mallis, Larry M.; Slayback, John R. B. 146
Practical Applications using Automated Mass Spectrometry in Drug Discovery; *Schaffter, L. M.; Spreen, R. C.; Morris, F. X.; Cureton, G. H. 147
Diversity Profiling: Rapid Pharmaceutical Development Based on ESI/MS; *Lee, Mike; Kerns, Edward; Hail, Mark; Rourick, Robyn; Starrett, Anne; Taylor, Susan; Thompson, William; Whitney, Jeffrey. 148
Changes in Volatile Organic Composition in Milk over Time; *Overton, Santford ; Manura, John. 149
Monitoring a Chemical Synthesis Using Flow Injection Mass Spectrometry; *Sheppard, Robin; **Hayward, Mark; Henion, Jack. 150
MI/MS USED IN SUPPORT OF THE MANUFACTURE OF QUINOLINEDICARBOXYLIC ACID; Lopata, Ronald J.; *Hayward, Mark J.; Thomson, Michael L.; Ruiz, Migdalia; Lafontaine, Felix; Marrero, Carlos. 151
On-line monitoring of an Organic Photochemical Reaction By MIMS; *Srinivasan, N.; Wong, P.; Kasthurikrishna, N.; Cooks, R. G.; **Grossert, S ; Pincock, J. A.; Wedge, P. 152
Analysis of Organic Analytes in Organic Matrices by Reverse Phase MIMS; *Bauer, Scott; Bauer, Jan. 153
Potential of the MAB ion source for routine analysis of organic compounds; *Faubert, Denis; Mireault, Pascal; Bertrand, Michel J. 154
UV Laser-Induced Selective Dissociation of Nitro Groups in Nitrocellulose; *Yang, Mo; Ramsey, J. Michael. 155
MS of Prepolymers 1,10-Undecadiyne & 1,2,10,11-C13-1,10-Undecadiyne; *Robbins, Ronny; Berg, Fred. 156
THE TMS-ESTERS OF DECENOIC ACID ISOMERS; DOUBLE BOND POSITION & GEOMETRY; *Jalonen, Jorma; **Mäkelä, Mauri; Hassila, Heikki; Haapaniemi, Esa; Joensuu, Päivi. 157
Development of GC-MS Determination of Nicotinic Acid and Nicotinamide; Dame, Amy D.; Wiberg, Karin; Jacobson, Myron K.; *Pyrek, Jan St. 158
Identifying Polyol Borate Ester Complexes by Negative Ion ESI MS/MS; *Shay, Brian J.; Falk, Nancy; Kalinoski, Henry T. 159
Electrospray / Ion Trap MSn for Structure Elucidation Of Cationics; *Strife, Robert; **Schwartz, Jae; Bier, Mark; Zhou, Joe. 160
Characterization of Monoazo Dyes by Chemical Ionization MS/MS.; *Wang, Jia-shen. 161
Analysis of Dibenzofuran and Dibenzo-p-dioxin in Diphenyl Oxide; *Sherman, Paul; Hileman, Fred; Wendling, Jay. 162
LC/TSP-MS of Hydroxy Compounds After Precolumn Derivatization with IMMC; *Phillips, Lawrence R.; Supko, Jeffrey G.; Wolfe, Tracy L.; Malspeis, Louis. 163
Specific Structural Features which Promote Cluster Formation in FAB-MS; *Sharp, T.R. 164

Study of Cobalt Complexes with Tetradentate Shiff Bases by IS- And FAB-MS; *Raffaelli, Andrea; Pucci, Sergio; Di Sacco, Sonia; Isola, Mauro. 165
Quantitative Analysis of ECF Derivatives of Non-protein Amino Acids; *Moini, Mehdi; Cao, Ping. 166
A Direct Method to Quantitate Fatty Acids in Complex Mixtures; *Ai, Jiu. 167
A NEGATIVE ION STUDY OF INDOLE AND QUINOLINE USING AN ASGDI SOURCE; *Cairns, Stuart N.; Langford, Marian L.; Todd, John F.J. 168
FAB-MS of Protected Steroids and Bile Acids Using Alkali Metal Addition; Aggarwal, Suresht K.; Pogue, Robert T.; *Pyrek, Jan St. 169
M[alkali metal]+ Ions in FAB Spectra of Protected Bile Acid Glucosides; Aggarwal, Suresht K.; Pogue, Robert T.; *Pyrek, Jan St. 170
Fragmentation of 1,5-dialkyl-3,7-diphenylbispidones under electron impact; *Tretyakova, Natalia; Vatsadze, Sergey; **Lebedev, Albert; Zyk, Nikolay; Zefirov, Nikolay; Hass, J. Ronald. 171
Trace Analysis of Degraded Antibiotics by ESI-LC/MS; *Yoo, Jong Shin; Kim, Jin Young; **Kim, Sung Ho. 172
Semi-Quantitative Analysis of Pharmaceutical Product Impurities by API/LCMS; *Wakefield, Michael; Sanders, Mark; Mylchreest, Iain. 173
Predictive Impurity Profiling of Pharmaceuticals Using LC/MS *Thompson, William L.; Venesky, John S.; Volk, Kevin (2); Klohr, Steven E. (2); Kerns, Edward H. (2); Lee, Mike S (3). 174
The Role of Mass Spectrometry in Stress-Testing of Pharmaceuticals; *Kemp, Craig; Cooke, Gary. 175
PROFILING SOTALOL IMPURITIES AND DEGRADANTS USING A STANDARD LC/MS METHOD *Volk, Kevin J.; Kerns, Edward H.; Hill, Susan E.; Wilson, Terry, Behme, Robert; Brooke, Dana; Lee, Mike S. 176
Identification of unknowns compounds in topiramate tablet by IC-ESI-MS; *Xiang, Xinzhen Jane; Ko, Chan Y. ; Guh, H. Y.; 177
Pharmaceutical Applications of IonSpray LC/MS for Cyclodextrin Analysis; *Visentini, Josie; Filosa, Angelo; Rousseau, Caroline; Winters, Conrad. 178
OLIGOMER DISTRIBUTION in PHOTOFRIN® PORFIMER SODIUM; *Siegel, Marshall; Tabei, Keiko; Berkenkamp, Stefan; **Hillenkamp, Franz; Tsao, Rushung; Ingedoh, Arnd; Pastel, Michael 179

Monday Posters - Environmental Analysis

Use of MS Coupled with a Solids Insertion Probe to Pre-Screen Soil Samples; *Check, Catherine E.; Bach, Stephan B.H. 180
Analysis of Soils - Part I: Soil Dynamics and Climatic Change; *Howald, Markus; Schuerch, Stefan; Schlunegger, Urs P. 181
Analysis of Soils - Part II: Determination of Saccharides by MALDI-TOF-MS; *Schuerch, Stefan; Howald, Markus; Schlunegger, Urs P. 182

Rapid Analysis of Fast GC Effluents by Time-of-Flight MS; *Borgerding, Anthony J.; Wilkerson, Charles W. 183
A STUDY OF AMBIENT AIR BY AEROSOL-TIME-OF-FLIGHT MASS SPECTROMETRY; *Lloyd, Patrick; Nordmeyer, Trent, Prather, Kimberly 184
Analysis of Single Inorganic Salt Particles Using TOF MS; *Salt, Kimberly; Prather, Kimberly. 185
Particle Size Analysis By Light Scattering and Aerodynamic Sizing Methods; *Noble, Christopher; Salt, Kimberly; Prather, Kimberly. 186
On-Line Single Particle Analysis of Environmental Tobacco Smoke; *Morrical, Bradley; Prather, Kimberly. 187
Gas-phase Modeling of Scrap Tire Pyrolysis Reactions; *Burrell, Tim; Phillips, Eugene; Rich, Michaela; Hanson, Curtiss. 188
Analysis of Carbonyls: Intermediates of Chemical Oxidation Reactions; *Feinberg, Thomas N.; Charles, M. Judith 189
A Study of the Oxidation of Heterocyclic Compounds using GC-MS Techniques; *Morris, Jackie; Clench, Malcolm; Allen, David. 190
A MEMBRANE INLET SYSTEM FOR MONITORING TRACE ENVIRONMENTAL POLLUTANTS; *Clarke, Nigel J.; Todd, John F.J. 191
Solid Phase Microextraction (SPME)-GC/MS of Proliferation Compounds; *Alcaraz, Armando; Andresen, Brian D. 192
The Detection of TNT and TNT Metabolites by Electrospray Mass Spectrometry; *Carlson, Joel; Vouros, Paul; Kaplan, David. 193
Environmental Analysis by Flow-injection Tandem Mass Spectrometry; *Filigenzi, Michael; Larson, Michael 194
Comparison of HPLC-MS Interfaces in the Determination of Heterocyclic PACs; *Thomas, Darren; Sim, P. Greig; **Benoit, Frank M. 195
Use of Two SPE-GC/MS Methods for Field Isolation and Quantitation of PAH; *Furlong, Edward T. ; Koleis, Janece C. ; Gates, Paul M. 196
VARIOUS MASS SPECTRAL TECHNIQUES FOR THE ANALYSIS OF NITRO-PAH; *Miles, Walter; Chiu, Chung; 197
Determination of Nitrated Polycyclic Aromatic Hydrocarbons in Tree Bark; *Clench, Malcolm; Douce, David; Pragnell, Charlton; Cooke, Michael. 198
Factors Effecting the Analysis of Organic Pollutants by Particle Beam LC-MS; *Clench, Malcolm, Leathard, David; **White, John; Brown, Richard. 199
Environmental Genotoxins by LC/TSP/MS of DNA-Adducts Formed In Vitro.; *Kuehl, Douglas; Serrano, Jose 200
Analysis of Serum PAHs and PAH Adducts by LC/MS; *McClure, P. Cheryl, Barr, John R.; Maggio, Vincent L.; Sirimanne, Sarath; Ma, Li; Patterson, Jr., Donald G. 201
MS Analysis of Pesticides by Combined On-line Photodegradation and LC-MS; *Volmer, Dietrich A ; Wilkes, Jon G. 202
Multiresidue Analysis of Pesticides by Electrospray LC-MS and LC-MS/MS; *Volmer, Dietrich A.; Wilkes, Jon G. 203

Determination of Carbendazim by Immunoaffinity Extraction and LC/LC/MS/MS; *Bean, Karen; Henion, Jack 204
Limitations and Challenges in LC/MS for the Analysis of Carbofuran; *Honing, M.; Barcelo, D.; van Baar, B. L. M.; Brinkman, U.A.Th. 205
Analysis of organophosphates using a trochoidal electron monochromator MS; *Mazurkiewicz, Paul; Laramee, Dr. James, Eichinger, Dr. Peter; Deinzer, Dr. Max. 206
Analysis of Soil Metabolites Utilizing Narrow Bore LC/MS/MS Techniques; *McGown, Steven; Delgado, Nelson 207
LC/MS of Atrazine and its Hydroxylation Metabolite Using Electrospray; *Cai, Zongwei; Cerny, Ronald; Spalding, Roy. 208
Determination of Atrazine and Metabolites Using GC/MS/MS.; *Heikes, David 209
Identification of Biodegradation Products of Carbazole by Mass Spectrometry; *Jayasimhulu, Koka, Schneider, Joanne; Xue, Weiling; Grosser, Robert; Warshawsky, David 210
Analysis of Carbamate and Phenylurea Pesticides by Particle Beam LC-MS.; *Ramesh, Rao. 211
Trace Determination of Sulfonyl Ureas in Soil.; *Li, Lily Y.T.; Campbell, Dale, Henion, Jack. 212
Comparison of Electrospray and Thermospray for the Analysis of Herbicides; *Lamaat, Shalaby, Robert, Croes; Michael, Wadsley; Debbie, Armbrust. 213
Determination of Myclobutanil by GC/MS, GC/HRMS, and MS/MS; Eitzer, Brian; Pylypiw Jr., Harry; **Moore, Colin; *Mattina, Mary Jane 214
NEGATIVE-ION UNIMOLECULAR DISSOCIATION OF ESTERS OF A HERBICIDE ACID; HEADLEY, JOHN V.; *PERU, KERRY M. 215
Determination of Hydrolysis Degradates of Cloransulam-Methyl by ESI LC/MS; *Balcer, Jesse L.; Brown, Stephen M.; Lewer, Paul. 216
The Dissipation of Cloransulam-Methyl in Soil as Determined by ESI LC/MS/MS; *Brown, Stephen M., Balcer, Jesse L.; Duebelbeis, Dennis, Thomas, Angela 217
GC/MS Analysis of Alkyl Methylphosphonic Acids; *Rohrbaugh, Dennis 218
DETERMINATION OF TRIADIMEFON AND IMIDACLOPRID IN WHITE PINE BY GC/MS; *MacDonald, Linda,M.; Rainbird, B.J.; Meyer, Timothy,R. 219
Determination of Triclopyr/Metabolites in Environmental Matrices by GC/MSD; *Olberding, Edward L.; Harnick, Barry J.; Foster, Dale R.; **McNett, Debra A. 220
Determination of Clopyralid in Water With Solid-Phase Extraction and GC/MSD; *Harnick, Barry; Olberding, Edward 221
Evaluation of a Benchtop API LC/MS/MS System for Environmental Analysis; *Bethem, Robert; **Sakuma, Takeo; Shushan, Bori 222
Analysis of Pyrethoid Insecticides by Ion Trap GC/MS/MS; *Bauerle, Gerald; Ray, Kenneth; Brodbelt, Jennifer. 223

Compounds Produced by Motor Burnouts of Refrigeration Systems; *Koester, Carolyn; Hawley-Fedder, Ruth; Foiles, Linda....224
Collisionally-Induced Fragmentation of Chlorinated n-Paraffins.; *Tomy, Gregg; Westmore, John; **Muir, Derek; Stern, Gary....225
LC-MS/MS identification of the major human urinary metabolite of alachlor.; *Driskell, William J.; Hill, Robert H.; Shealy, Dana B.; Hull, R. Delon....226
Structural Characterization of Toxaphene Congeners by GC/MS; *Benoit, Frank M.; Driega, Alex; **Malaiyandi, Murugan....227
Characterization of Major Clorinated Bornanes in Ring Seal Blubber; **Loewen, Mark; *Stern, Gary; Muir, Derek; Westmore, John; Parlar, H....228
Where in the Great Lakes is Toxaphene Going?; *Howdeshell, Mıchael; Glassmeyer, Susan; Myers, Tanya; Hites, Ronald....229
Optimal Ion Trap MS/MS Parameters for the Analysis of Dioxins and Furans; *Plomley, Jeffry B.; **Mercer, Roger S.; March, Raymond E....230
Elemental Compositions from Mass Peak Profiles of M, M+1 and M+2 Ions; *Grange, Andrew H., Donnelly, Joseph R.; **Sovocool, G. Wayne; Brumley, William C....231
Development of a Modernized HRMS Environmental Method for PCBs; *Donnelly, Joseph R.; Grange, Andrew H.; Nichol, Greg; Herron, Nelson; **Brumley, William C....232

Monday Posters - Spray Ionization

Validation of an HPLC-APCI-MS/MS Procedure for Diclofenac in Human Plasma; *Thomas, Darren; Draper, Sally; Hill, Howard; Richard, Martin; Robson, John....233
Effect of Solution Additives and Denaturants on Peptide and Protein ESI-MS *Smelyanskiy, Yanina; **Ogorzalek Loo, Rachel R.; Andrews, Philip C....234
Desolvation of Noncovalently-Bound Complex Ions for ESI-MS Analysis; *Loo, Joseph A.; **Ogorzalek Loo, Rachel R....235
Noncovalent Complex Formation of Cyclodextrins studied by ESI MS; *Penn, Sharron G.; Goodall, David M.; Monnig, Curtis A.; Loran, John S....236
Non-Covalent Complexes formed between Acyl CoA Binding Protein and CoAs; * Robinson, Carol ; Kragelund, Birthe; Knudsen, Jen; Aplin , Robin; Poulsen , Fleming; Dobson, Christopher....237
Source of the Ion at M/Z 622 in "TFA-Fix"; **Ijames , Carl F.; Markey, Sanford P ; Dutky , Robert C ; *Fales, Henry M....238
Electrospray of Borane Salts; High Molecular Weight Clusters and Reactions; *Hop, Cornelis E.C.A.; Saulys, Dovas A.; Gaines, Donald F....239
Comparison of ESI and LSI MS/MS in the Analysis of Newborn Blood Spots; *Chace, Donald; Hillman, Steven; Millington, David; Stevens, Robert....240
Monitoring reactions of nitric oxide with peptides and proteins by ESI-MS; *Mirza , Urooj A.; Lander , Harry M ; Chait, Brian T....241

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Paired Ion ESI of Borane Neutron Capture Agents; *Singh, Padma; Swenson, David; **Schweingruber, Hans; Laine, Roger....242
Negative ESI/MS Enhancement of Primary Amines with TFA/TFE Derivatization; *Fujiwara, Hideji; Nadeau, Ronn G.; Chott, Robert C.; Solsten, R. Thomas....243
Selectivity and Binding Mode of DNA Interacting Molecules Studied by ESI-MS; *Gale, David C.; Camp II, David G.; Smith, Richard D....244
Characterization of Large Glycoproteins Using HPLC/ES-MS; *Huang, Lee; Paiva, Tony; Ramadas, Bhat; Wong, Mel....245
Fragmentation and CID Electrospray Spectra of Antineoplastic Agents.; *Roboz, John; Yu, Qitao....246
Factors Affecting ESI-MS of Nucleobases and Nucleosides; *Yen, Ten-Yang; Voyksner, Robert D.; Charles, M. Juidth....247
New Approach to Determine Modifications in DNA: CZE/MS of Oligonucleotides; Janning, P.; Schrader, W.; Pesch, R.; **Muenster, H.; *Linscheid, M....248
Structure Elucidation of Oligonucleotides Using CZE/ESI MS and Skimer CID; Siethoff, C.; Schrader, W.; Pesch, R.; **Muenster, H.; *Linscheid, M....249
Thermodynamical studies of metal self-assembled complexes by ES-MS *Dupont , Annick; Leize, Emmanuelle, Marquis-Rigault, Annie; Krmer, Roland; Funeriu, Daniel; Lehn, Jean-Marie; Van Dorsselaer, Alain....250
Ion Labeling Study of Self-assembled Supramolecular Species by ESMS *Leize, Emmanuelle; Russell, K.C ; Lehn, Jean-Marie; Van Dorsselaer, Alain....251
Retrospective Analysis of Hyperphenylalaninemias by LSI and ESI MS/MS; *Chace, Donald; Hillman, Steven; Sakuma, Takeo; LeBlanc, Yves; **Shushan, Bori....252
Electrospray Ionization Mass Spectrometric Study of Host-Guest Complexes; *Ramanathan, Ragulan; **Prokai, Laszlo....253
On-line Electrochemistry/Electrospray MS: Study of Oxidation of PAHs; *Xu, Xiaoming; Lu, Wenzhe; Suleiman, Ahmad A.; Cole, Richard B....254
Effects of Anion Encapsulation by Katapinates on Electrospray Mass Spectra; *Giordani, Anne B....255
PROBING THE OLIGOMERIC STRUCTURE OF 4OT USING "NATIVE" ESI-TOFMS; *Fitzgerald, Michael C.; **Chernushevich, Igor; Whitman, Chrıstian P.; Kent, Steven B.H....256
Investigation of Cyclodextrin-Metal Cation Complexes using ESI and FTICR MS; *Kage , David; Watson, Clıff; Prokai, Laszlo; Eyler, John....257
HPLC - Electrospray Mass Spectrometry of Flavonol Glycosides in Hops; *Saegesser, Martin; Deinzer, Max L....258
SULFATED OLIGOSACCHARIDES ANALYSIS : POTENTIALITY OF ESI-MS vs MALDI-TOF MS; *UZABIAGA, Françoise; MONTEIRO, Candida; PETITOU, Maurice; **PROME, Jean-Claude; PICARD, Claudine....259

Detection of Photosubstitution Intermediates of Ru(II) Diimine Complexes; *Arakawa, Ryuichi; Tachiyashiki, Satoshi, Matsuo, Takekiyo. 260
Complexes of Angiotensin II and Transition-Metal (II) Ions Formed By ESI; *Sullards, Cameron, Adams, Jeanette. 261
Amino Acid Coordination to Cu(II)-diimines: Structures and CAD Mechanisms; *Gatlin, Christine, L.; Turecek, Frantisek; Vaisar, Tomas. 262
Peptide Coordination to Cu(II)-diimines: Structures and CAD Mechanisms; *Gatlin, Christine L.; Turecek, Frantisek; Vaisar, Tomas. 263
Analysis of Metal Chelates by Electrospray Ionization Mass Spectrometry; *Wahl, Karen; Stromatt, Robert; Blanchard, David. 264
Production of Coordinated 3d Transition Metal Ions by ESMS; *Xu, Yaodong, Zhang, Xin; Yergey, Alfred L. 265
Characterization of Organometallic Complexes by ESI/Sector MS; *Tong, Huayi; Ng, Ken; Rodebaugh, Ron; Kuell, Chris; Shum, Sai; Pastor, Steve 266
Accurate Mass Measurement of Peptide Ions with a Magnetic Sector Instrument; *D'Agostino, Paul A.; Hancock, James R.; Provost, Lionel R. 267

Monday Posters - Proteins & Peptides

Some Important Effects of MALDI of Small Proteins and Peptides; *Zhu, Y. F.; Lee, K. L.; Tang, K.; Allman, S. L.; Taranenko, N. I.; Chen, C. H. 268
Matrix Solution Effects on the MALDI-MS of Peptides and Proteins; *Cohen, Steven L.; Chait, Brian T. 269
Study of Oxidation Reactions of Selenomethionyl Peptides by MS; *Wang, Rong, Mirza, Urooj A.; Birken, Steven; Chait, Brian T 270
Mapping of B-Amyloid Peptide using Gelatinase.; *Woods, Amina; Cotter, Robert; Ball, M.J.; Roher, Alex 271
Electrospray Mass Spectrometric Studies on Brain Delivery of Neuropeptides; *Prokai, Laszlo; Kim, Ho-Seung; Prokai-Tatrai, Katalin; Bodor, Nicholas 272
Characterization of Iron-binding Siderphores from M. tuberculosis; *Gibson, Bradford; Moore, Christopher; Wong, Diane; Gobin, Jovana; Reeve, Jr., Joseph; Horwitz, Marcus 273
HEMORPHINS IN BLOOD AND BRAIN STUDIED BY MICRODIALYSIS/ES/MS; *Andren, Per E.; Sandersson, Katarina; Caprioli, Richard M.; Nyberg, Fred 274
MS Detection of a new beta-Endorphin-containing Protein in Bovine Pituitary; *Desiderio, Dominic; Yan, Lin; Tseng, Jih-Lie. 275
A Quantitative LC/ESI/MS/MS Method for a Bioactive Peptide in Human Plasma; *White, Robert J.; Oglesby, Thomas D.; Taylor, Paul A.; Florance, James; Wilhelm, Jeffrey A.; Schwartz, Jae C.; Uhrich, Mark D. 276
Mass spectrometric analysis of impurities in peptide synthesis; Chao, Betty; Jiang, Kate; *Papayannopoulos, Ioannis A. 277

Analysis of Crude Synthetic Peptide Mixtures by IonSpray Mass Spectrometry; *Nuwaysir, Lydia; McCandless, Jacqueline; Noble, Dick; Banda, Phil; Chen, Ling; McLean, Matthew. 278
Tandem Mass Spectrometry of Metal-Peptide Complexes.; *Summerfield, Scott; Dale, Vanessa; Despeyroux, Dominique; Jennings, Keith. 279
Loss of the C-Terminal Amino Acid from Transition Metal-Peptide Complexes; *Reiter, Alex; Adams, Jeanette. 280
Intrinsic Coordination between Co(II) and Ni(II) and Histidine Peptides; *Reiter, Alex; Adams, Jeanette. 281
Peptide Adsorption at Gas-Liquid Interfaces Probed by FAB Mass Spectrometry; *van Breemen, Richard B.; Powers, Daniel D.; Kilpatrick, Peter K.; Carbonell, Ruben G. 282
FAB MS of Oxytocin, Deaminooxytocin and Arginine Vasopressin; *Pokrovskiy, Valeriy; Galagan, Natalia, Ostrovskaya, Galina; Rybal'chenko, Vladimir. 283
Processing of Dynorphin A (1-17) in Human and Monkey Blood Studied by MS; *Yu, Jim; **Butelman, Eduardo; Woods, James ; Kreek, Mary Jeanne ; Chait, Brian T 284
Analysis of heterogenous peptide mixtures with MALDI-MS and LC/MS; *Raida, Manfred; Heine, Gaby; Neitz, Susanne; Forssmann, Wolf-Georg. 285
MALDI MS as a Tool in the Characterization of E. Coli RNA Polymerase; *Fenyö, David; Severinov, Konstantin; Severinova, Elena; Darst, Seth; Chait, Brian T.; et al. 286
Pepetide Mapping and MS/MS Analysis of IgG2b containing 2H-Labeled Leucine; *Hirayama, Kazuo; Akashi, Satoko; Noguchi, Kazuyoshi; Yuji, Reiko, Tagami, Uno; Kato, Koichi; Shimada, Ichio; Arata, Yoji. 287
Structural Characterization of IgG Carrying Allotype-j; *Akashi, Satoko; Noguchi, Kazuyoshi; Yuji, Reiko; Tagami, Uno; Kato, Koichi; Shimada, Ichio; Arata, Yoji; Hirayama, Kazuo. 288
Monitoring Antibody Catalyzed Reactions and Interactions; *Siuzdak, Gary; Krebs, Joseph F. ; Benkovic, Stephen J.; Stewart, Jon D ; Strupp, Christian; Hilvert, Don; Dyson, H. Jane. 289
Investigation of Mouse Urinary Proteins Using Electrospray Ionization; *Cox, Kathleen A.; Gaskell, Simon J.; Robertson, Duncan H.L.; Beynon, Robert J. 290
Analysis of a Therapeutic Monoclonal Antibody by HPLC, MALDI-TOF and ESI/MS; *Chan, Stephen; Park, SungAe; Burinsky, David 291
Identifying Human Tear Cytokines by Immunoaffinity Chromatography/MALDI-TOF; *A. , Brockmann; S., Hirsh; R. , Kaswan; R. , Orlando 292
Characterization of Recombinant Human Interferon Alpha-2 by ESI LC/MS; *Heimark, L.; Huang, E.; Pramanik, B.; Nagabhushan, T.L. 293

Mass Spectrometric Characterization of the rhM-CSF Receptor Binding Site; Kalkum, Markus; Yamamoto, Ralph; Schreurs, Jolanda; Deinzer, Max L., *Glocker, Michael O ... 294
Comparison of the Crystallins from Normal and Cataractous Human Lenses; *S., He; S., Pan, K., Wu; R. , Orlando ... 295
Identification of Modified Human Water Insoluble Lens Crystallins by MS.; *Lund, Anders L ; Smith , Jean B.; Smith , David L. ... 296
Problems and Solutions in Sequencing a Mussel Foot Protein from M. edulis.; *Papov, Vladimir; Biemann, Klaus ... 297
Mass Spectrometry of Marine Biomolecules; *Ross, Mark; Waite, Herb; Taylor, Steven. ... 298
Structure elucidation of the sex-differentiation protein in Crustacea by MS; Martin, Gilbert, Sorokine, Odile; Moniatte, Marc; *Van Dorsselaer, Alain. ... 299
Sequence Characterization of a Spider Silk Protein by Electrospray MS/MS; *Yeung, Bernice; Vouros, Paul; **Mello, Charlene M.; Kaplan, David L. ... 300
Processing of avian sarcoma and leukemia virus precursor polyprotein.; *Papayannopoulos, Ioannis A.; Pepinsky, R. Blake; Chow, E. Pingchang; **Vogt, Volker M ... 301
PHOSPHORYLATION SITE IDENTIFICATION BY LC/MS/MS WITH AN ION TRAP MS; *Gillece-Castro, Beth; Arnott, David; Bier, Mark; Land, Adrian; Stults, John ... 302
Electrospray Ionization Mass Spectra of Recombinant Hirudin Byproducts.; *Lango, Jozsef; **Roboz, John; Salat, Janos; Yu, Qitao; Barta, Istvan; Ott, Istvan; Ambrus, Gabor; Simay, Antal. ... 303
Mapping of Brain Proteins Using MALDI/TOF-MS Combined with HPLC; *Ingendoh, Arnd; Seta, Kazuo, Kanai, Michiko; Nakayama, Hiroshi, Uchida, Kazuhisa; **Isobe, Toshiaki; Okuyama, Tsuneo. ... 304
Mass Determination of Large Proteins Exceeding 200 kDa by MALDI/TOF-MS; *Ingendoh, Arnd; Seta, Kazuo; Kanai, Michiko; Yamakawa, Yoshio, Omori-Satoh, Tamotsu; **Isobe, Toshiaki; Okuyama, Tsuneo. ... 305
CHARACTERIZATION and SEMI-QUANTITATION of CHONDROITINASE (MW 111 & 112 kDa); *Siegel, Marshall; Tabei, Keiko; Berkenkamp, Stefan; **Hillenkamp, Franz; Khandke, Kiran. ... 306
Dist. & Loading of Calicheamicin Derivatives Conjugated to Monoclonal...; Siegel, M; Keiko, T; Kunz, A; Berkenkamp, S; Hillenkamp, F. ... 307
MS Analysis of FILAMENTOUS HEMAGGLUTININ and MoAb-CALICHEAMICIN CONJUGATES; *SIEGEL, MARSHALL Ass; TABEI, KEIKO; KUNZ, ARTHUR; BERKENKAMP, STEFEN; **HILLENKAMP, FRANZ. ... 308
Observation of holoprotein molecular ions of several ferredoxins by ESI-MS; Ptillot, Yves; *Forest, Eric; Meyer, Jacques; Moulis, Jean-Marc; ... 309
PROTEOLYTIC PEPTIDES OF RHODOPSIN ANALYZED BY MALDI-TOF; *Barnidge, D. R.; Dratz, E. A.; Sunner, J.; Jesaitis, A. J. ... 310

Analysis of Hydrophobic Peptides and Proteins using ESI- and APCI-MS; *Pellascio, Bernhard; Schlunegger, Urs P.; Schaller, Johann, Kaesermann , Donald. ... 311
Heregulin/Epidermal Growth Factor Chimeras: A Structural Study; *Rosnack, Kenneth; Guarino, Bradley; Singleton, David; Barbacci, Elsa; Moyer, James; Andrews, Glenn; Stroh, Justin. ... 312
LC-MS peptide map of hirudin by using the unspecific protease thermolysin; *Zilg, Harald A.; **Schultz, Birgit. ... 313
Advances in Peptide Mapping by MALDI-TOF-MS; *Vorm, Ole; **Roepstorff, Peter; Mann, Matthias, Houthaeve, Tony ... 314
Use of ESMS for the study of the mechanism of resistance to beta-lactams; *Burlet-Schiltz, Odile; Saves, Isabelle; Samama, Jean-Pierre; Masson, Jean-Michel; Prom, Jean-Claude. ... 315
Analysis of Bovine Insulin (SBI) and Reduced SBI in Glucose Film by PDMS; *Song, Siqing; Cockrill, Steve; Macfarlane, Ronald, D. ... 316
Molecular Recognition in Drug Discovery; *Bell, David; West, Andrew. ... 317
ESI-MS/MS for the Identification of Modifications in Intact Proteins; Busman, M.; Wilcox, M. D.; McIntire, W. E.; Hamm, H. E.; Hildebrandt, J. D.; *Schey, K. L. ... 318
Mass Spectrometric Analysis of Recombinant Stromelysin and Collagenase; *Bauer, M.D.; Sun, Y., Anastasio, M.B., Snider, C.E. ... 319
Characterization of Recombinant NMDA Receptor Regions with ESIMS; *Eckart, Klaus; Koepke, Andreas K. E., Spiess, Joachim. ... 320
Enhanced Nucleophilicity of the N-terminal Proline in a Protease; *Yu, Zhonghua; Craik, Charles; **Jones, Patrick; Burlingame, Alma. ... 321
SEQUENCE AND Ca2+ BINDING PROPERTIES OF FROG (Rana tegrinka) PARVALBUMIN; *Hu, Peifeng; Buckel, Scott; Whitton, Margie; Loo, Joseph A. ... 322
Determination of the Sites of Non-Labile HNE-Adduction to Proteins; *Bolgar, Mark S.; Gaskell, Simon J. ... 323
Protease-catalyzed Incorporation of 18O into Protein Fragments; Schnolzer, Martina; Jedrzejewski, Paul; **Lehmann, Wolf ... 324
Methodology to Identify Proteins using LC-Ion Trap Mass Spectrometry; *Yates, John; Eng, Jimmy; Schieltz, David; Link, Andrew. ... 325
Cross linking of native protein complexes by organic mustards; *Hathout, Yetrib; Fenselau, Catherine. ... 326

Tuesday Orals
Mass Spectrometry in Pharmacology & Toxicology

Applications of MS/MS to the Study of S-Linked Conjugates of Isocyanates; *Davis, Margaret R.; Baillie, Thomas A ... 327
Strategies for Analyses of Drug Metabolite Mixtures by CE-MS and CE-MS/MS; *Naylor, Stephen; Benson, Linda M ; Tomlinson, Andy J. ... 328

Probing the Regioselectivity of Gas Phase Alkylation of Biomolecules; *O'Hair, Richard A.J ; Freitas, Michael A.; Gronert, Scott; Schmidt, Joseph A. R.; Williams, Todd D 329
Determination of ß-Agonists in Bovine Retina Using LC-APCI/MS and MS/MS; *Doerge, Daniel R., Bajic, Steve; Churchwell, Mona I. 330
The Use of GC-MS Techniques to Evaluate Biological Lipid Peroxidation; *Mathews, W. Rodney; Guido, David; McKenna, Rosemary; Laskey, Rachel.... 331
Macrolide Antibiotic Residues in Distiller's Grain and Milk by ESI LC/MS; *Flurer, Rick; Tomlinson, John; Satzger, Duane. 332
Isoprostane Families Following Free Radical Oxidation of Arachidonic Acid; *Waugh, Russell J.; Murphy, Robert C. 333
Beclomethasone Dipropionate and Metabolites in Plasma via HPLC-APCI/MS/MS; *Bryant, Matthew S.; Korfmacher, Walter A.; Nardo, Cymbelene L , Lapiguera, Amelia P.; Lin, Chin-Chung; **Langevin, Carolyn N.; Oglesby, Thomas D. 334
Column-switching sample preparation for quantitative analysis by LC-MS; *Hopfgartner, Gerard; Zell, Manfred; Husser, Christophe; Lausecker, Berthold.... 335
Direct Measurement of Steroid Glucuronides and Sulfates with HPLC/MS; Sanaullah, , *Bowers, Larry 336

Tuesday Orals - Mass Spectrometry in Environmental Research

Haloacetic Acid Drinking Water Disinfection By-Products; *Budde, William L.; Munch, Jean W.; Kryak, David D.; Behymer, Thomas D 337
Investigating Oxidation Reactions in Environmental Systems; *Charles, M Judith; Feinberg, Thomas N.; Richardson, Susan. 338
High Speed Analysis of TTHM Content in Drinking Water using MIMS; *Bauer, Scott, Bauer, Jan. 339
Chemistry and Toxicology of Poultry Chiller Water; *Haddon, William F., Binder, R.G., Harden, Leslie A., Wong, R Y , Stevens, K.L 340
Measurement of Verrucarol, a Product of Satratoxin, in Urine by APCI-MS/MS; *Schurz, Helen, Hill, Robert. 341
HPLC/MS & HPLC/MS/MS Analysis of Explosives in Environmental Samples; Gates, Paul M.; *Furlong, Edward T.; Lindley, Chris E.; Burkhardt, Mark R. 342
MS/MS CID FRAGMENTATION PROCESSES IN SOME PESTICIDES; *Yinon, Jehuda. 343
Quantification of Non-Persistent Pesticides in Human Serum; *Barr, John R.; Patterson, Donald G.; Jr.; Maggio, Vincent L.; McClure, P. Cheryl; Turner, Wayman E.; Newman, Carolyn M.; Needham, Larry L. 344
ESI MS/MS Determination of a New Cationic Surfactant in River Water; *Mertens, Thomas R.; Dunphy, Jocelyn C., Kershner, Karen M.; Morris, III, Samuel J. .. 345

Advantages and Applications of Mass Peak Profiles Plotted from SIR Data; *Grange, Andrew H.; Donnelly, Joseph R.; **Sovocool, G. Wayne, Brumley, William C. 346

Tuesday Orals - Chemistry of Multiply-Charged Ions

Protein Desalting via Gas-Phase Ion-Molecule Chemistry; *Pope, Marshall; Hofstadler, Steven; Dejsupa, Chadin; Dearden, David. .. 347
Importance of Charge-Separation Reactions in ESI/MS-MS; *Adams, Jeanette, Strobel, Fred; Reiter, Alex. .348
The Correlation of Fragmentation and Structure of a Protein; *Wu, Qinyuan ; Van Orden, Steven; Cheng, Xueheng; Bakhtiar, Ray; Smith, Richard D. .349
Quadrupole Ion Trap Study of Ion-Ion Chemistry of Multiply-Charged Ions; *Herron, William, J.; Goeringer, Douglas, E ; McLuckey, Scott, A. 350
Isomeric Structures for Ubiquitin Ions Produced by Electrospray FTMS; *Cassady, Carolyn J.; Ewing, Nigel. .351
Electrostatic Forces in Multiply Protonated Gas-Phase Ions; *Williams, Evan R ; Gross, Deborah S ; Schnier, Paul S , Rodrigez-Cruz, Sandra; Fagerquist, Clifton K. . 352
SID of Multiply-Charged and N-Terminal Fixed-Charge Derivatized Peptides; *Dongre, Ashok; Somogyi, Arpad; Wysocki, Vicki. .353
Deprotonation Reactions of Small Peptide Ions Produced by Electrospray; *Carr, Scott R.; Cassady, Carolyn J. .354
Characterization of Carbonic Anhydrase-Inhibitor Noncovalent Complexes; Cheng, Xueheng, *Chen, Ruidan, Bruce, James E , Schwartz, Brenda L , Anderson, Gordon A.; Hofstadler, Steven A.; Gale, David C.; Smith, Richard D . 355
Compounds That Elude FAB Analysis: It All Begins in Solution!; Noon, Kate; *Allison, John. ..356

Tuesday Orals - Laser Desorption Ionization-Applications

MALDI-MS in the Infrared: A critical evaluation; *Hillenkamp, Franz; Karas, Michael; Berkenkamp, Stefan. . 357
Sequencing Electroblotted Proteins by Tandem Mass Spectrometry; *Fabris, Dan; Vestling, Martha M.; **Cordero, Marcela M ; Doroshenko, Vladimir M ; Cotter, Robert J.; Fenselau, Catherine. 358
MALDI AND PSD CHARACTERIZATION OF RELEASED CARBOHYDRATES FROM GLYCOPROTEINS; *Rouse, Jason C.; Vath, James E.; Scoble, Hubert A. .359
MASS SPECTROMETRY IN PROTEIN AND GLYCOPROTEIN STRUCTURE ELUCIDATION.; Morris, Howard R.; Dell, Anne, Panico, Maria; *McDowell, Roy A. 360
Nucleotide analogs increase the stability of DNA for MALDI-MS analysis; *Schneider, Klaus; Chait, Brian T. 361

Molecular Diagnostics Via Mass Spectrometry of PCR-Amplified DNA Products; *Buchanan, Michelle V.; Doktycz, Mitchell J.; Hurst, Gregory B.; McLuckey, Scott A.; Habibi-Goudarzi, S. 362
Analysis of DNA and Modified Proteins with Resolution Improvements in MALDI; *COLBY, STEVEN; ARNOLD, RANDY; CHRISTIAN, NOAH, HOUSTON, CHRIS; REILLY, JAMES. 363
Applications of High Resolution MALDI TOF to Oligonucleotide Problems; *Juhasz, Peter; Vestal, Marvin; Martin, Stephen; Takach, Ed; Haff, Lawrence; Roskey, Mark; Smirnoff, Igor. 364
Applications of MALDI/TOF in Polymer Chemistry; *Danis, Paul O.; Huby, Francois. 365
Polymer Characterization: A Comparison of MALDI vs Direct Laser Desorption; *Weil, David A.; Jacoby, Cliffton B 366

Tuesday Orals - Mechanisms of Ion-Molecule Reactions

Chemical Reactions vs Collision-Induced Dissociation to Cleave Amide Bonds; *Williams, Tracie L.; Stephenson, James L.; Yost, Richard A. 367
Neutral Products From Ion-Molecule Reactions: F- + 5-Chloro-1,3-Pentadiene; Baschky, Michael; *Kass, Steven; Kass, Steven. 368
Ion-Molecule Reactions of Trimethylenemethane Radical Cation; *Chou, Phillip; Painter, Sherry; Blackstock, Silas; Kenttamaa, Hilkka. 369
Reactions of Small Carbon Clusters with Nitrogen Containing Compounds; *Dunbar, Robert C.; Pozniak, Boguslav P. 370
Ion-Molecule Reactions of 18-Crown-6 With its Fragment Ions Shen, Nanzhu; *Dejsupa, Chadin; Pope, Marshall; Dearden, David. 371
Reactions and Rearrangements of TMS Dimer Radical Cation.; *Peschke, Michael; Mckee, Michael; Illies, Andreas. 372
Ion Molecule Reactions of Organophosphorus Compounds; *Wensing, Michael W.; Snyder, A. Peter; Harden, Charles S. 373
State-selected reactions between N2+ molecular ions and atoms and molecules; *de Gouw, Joost A.; Ding, Li N.; Kato, Shuji; Bierbaum , Veronica M.; Leone , Stephen R. 374
Symmety Induced Kinetic Isotope Effects in the Formation of Ar¥CO2+; *Gellene, Gregory; Yoo, Ryong 375

Tuesday Posters - Ion Activation & Dissociation

Structural Aspects of Metal-Oligonucleotide Binding Studied by ESI-CID-MS *Cheng, Xueheng; Wu, Qinyuan; Gao, Quanyin; Hofstadler, Steven A.; Smith, Richard D.; 376
Gas Phase Chemistry of MX+ Ions (X= H, Na, Cu) from Glycine and Arginine; *Beranova, Sarka; Cerda, Blas; Wesdemiotis, Chrys 377
ESI MS-MS Using B/E vs MIKES Scans; *Sullards, Cameron; Adams, Jeanette. 378

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Electrospray MS of Multiple Alkali Ion Complexes of Proteins and Peptides; Wang, Jianyao; Ke, Fu; Guevremont, Roger; *Siu, K.W.Michael. 379
INFLUENCE OF 2ND STRUCTURE ON PEPTIDE ION DISSOCIATION IN A TANDEM TOFMS; *Gimon-Kinsel, Mary; Russell, David. 380
Intra-ionic Acid/Base Interactions in the CID of Protonated Peptides; *Cox, Kathleen A.; Whiting, Andrew; Gaskell, Simon J. 381
A Multistep Pathway Leading to Peptide wn Ions Confirmed by MS3 and MS4; *Ballard, Kevin; Orkiszewski, Ralph; **Gaskell, Simon. 382
WHY ARE B IONS STABLE SPECIES IN PEPTIDE SPECTRA?; *Yalcin, Talat; Harrison, Alex. G. 383
Gas Phase Reactions of Protonated Biologically Active Peptides.; *MOSELY, JACKIE A; DERRICK, PETER J; GALLAGHER, RICHARD T; COOPER , HELEN J; CRAIG, ANTHONY G 384
Correlation of Energy Losses from CID with Observed Peptide Fragments; *Vachet, Richard W.; Winders, Andrew; Glish, Gary L. 385
Peptide Sequencing Using a Hybrid Magnetic Sector oa-TOF Mass Spectrometer; *Sun, Y.; Bauer, M.D.; Lacey, M.P.; Keough, T. 386
Peptide Fragment Mass Spectra: Comparison of PSD and CID spectra.; *Hines, Wade; Peltier, John; Hsieh, Frank; Martin, Steve. 387
CAD and Photodissociation of Multiply Charged Ions; *Watson, Clifford; Yang, Yarjing; Nawrocki, Joe; Eyler, John. 388
Impulsive Excitation of Ions during Surface-Induced Dissociation; Burroughs, John A.; *Wainhaus, Samuel B.; Hanley, Luke. 389
Electrospray Mass Spectra of Simple Aliphatic Diamines and Methiodides; *Zhang, X. Kate; **Fales, Henry M. 390
Thermal Radiation Induced Dissociation of Tetraethylsilane Cation; *Lin, Chuan-Yuan; Dunbar, Robert C. 391
Some More C3H6O2 Distonic Radical Cations; *An, Yan, Holmes, John L. 392
The Fragmentation of Geometric Isomer, Ionized Maleic and Fumaric Acids; *Chen, Hongwen; Holmes, John L. 393
Characterization of small, oxygen-rich ions.; *Aubry, Christiane; Holmes, John L. 394
The Identification of C3H6O+. from 2-Methoxyethanol.; *Polce, Michael J.; Wesdemiotis, Chrys. 395
N-substituted Benzisothiazolinons: Oxygen Rearrangement on Electron Impact.; *Lango, Jozsef. 396
Unimolecular Dissociation of Acetophenone by Thermal Radiation; Sena, Marcelo; *Riveros, José M. 397
Hyperthermal Surface Ionization of Organic Molecules: Alkyl Alcohols; *Kishi, Hiroshi; **Fujii, Toshihiro. 398
The Unimolecular Dissociation of Energy Selected 2, 5-Dihydrofuran; *Teklehaimanot, Bibi; Meisels, Gerry. 399

Influence of Substituents on Propene Loss from Aryl n-Propyl Ether Ions; *Matimba, Henri E. K.; Ingemann, Steen; Nibbering, Nico M M 400
Angle/Energy-Resolved CID of CS2+ ions at 8-35 eV Collision Energy; Shukla, Anil K.; *Tosh, R.E.; Futrell, Jean H. 401
Tandem crossed beam collision induced dissociation of CO2+; *Chawla, Rahul; Krishnamurthy, M.; Shukla, A. K. ; Futrell, J. H. 402
Investigation of Kinetic Trans Effect in Bis(platinum) Complexes by SID; *Schaaff, Thomas; Qu, Yun; Farrell, Nicholas; Wysocki, Vicki. 403
NI FAB and DCI-MS of Sulfonylurea Herbicides; CAD Spectra of (M-H)- Ions; *Winnik, Witold; Betowski, Leon; Brumley, William 404
DEP/CI-MS/MS Characterization of Sulfonylurea Herbicides; *Johnson, Jodie V.; Yost, Richard A. 405
Measurement of phosphonate proton affinities by using the kinetic method.; **Aline, Leroy; Françoise , Fournier; Jacquy, Dissard; Isabelle, Daoust-Maleval; André, Tambuté; *Jean-Claude, Tabet. 406
CID Studies of Inorganic Species Released During Biomass Combustion; *Dayton, David; Wang, Dingneng. 407
Photodissociation of Electrosprayed Ions in a Quadrupole Ion Trap; *Boue, Stephen M.; Stephenson, James L., Yost, Richard A 408
Pulsed Pressure Quadrupole Ion Trap for Tandem MS of Peptides; *Doroshenko, Vladimir M.; Cotter, Robert J. 409
Thermal Activation of Stored Ions in a Quadrupole Ion Trap; *Herron, William J.; Goeringer, Douglas E.; McLuckey, Scott A. 410
The Analytical Utility of Photodissociation in Tandem Mass Spectrometry; *Beussman, Douglas J.; Erickson, Tina A., Enke, Christie G. 411
SMIKES: A New Scan to Determine the Origin of Artefact Peaks in MIKE Scans.; *Mouget, Yves; Bertrand, Michel J. 412
Mapping Metastable Decays in a TOF MS with a Single-stage Ion Mirror; *Brinkmalm, Gunnar; HŒkansson, Per; Sundqvist, Bo U.R.; **Barofsky, Douglas F. 413
Tandem Mass Spectrometry Utilizing the Advantages of Both MALDI and FTMS; *Castoro, John; Shew, Sandy; Stout, Howard; Winger, Brian; Campana, Joseph 414
MS/MS Studies Using a Hybrid Magnetic Sector oa-TOF Mass Spectrometer; *Keough, T.; Lacey, M.P.; Bauer, M.D.; Sun, Y. 415
Surface Induced Dissociation of Biomolecules and Polymers by MALDI-FTMS; *Pastor, Salvador J.; Yao, Jie; Wilkins, Charles L. 416
Identifying Possible Sources of Ion Neutralization at SAM Surfaces; *Kane, Thomas; Angelico, Vincent; Nair, Hari; Somogyi, Arpad; Wysocki, Vicki. 417
Hydrogen-addition Reactivity of Ions on Odd vs Even Chain Alkanethiol SAMS; *Franklin, Rebecca; Zhong, Wenquing; Somogyi, Arpad; Wysocki, Vicki. 418
Derivatization Reactions for FAB, LSIMS, and Electrospray Ionization; *Carlson, Rich; Busch, Kenneth L. 419

EFFECT OF A MATRIX ON LSIMS-INDUCED FRAGMENTATION OF PHOSPHATE ESTER BOND; *Dass, Chhabil. 420
Parent Resolution in FFR1 MS/MS: Revelations from Ion Intensity Plots; *Ballard, Kevin; **Vachet, Richard; Orkiszewski, Ralph; Glish, Gary, Vrbanac, James; Gaskell, Simon 421

Tuesday Posters - Separations/MS Techniques

Identification of fullerenes in natural flames by APCI/LCMS; *Taghizadeh, Koli; Nauman, David; Lafleur, Arthur; Howard, Jack 422
Effect of Mobile Phase Buffers on Sensitivity in Negative APCI LC/MS; *Schaefer, William; Dixon, Frank, Jr 423
Analysis Of Selected Pharmacueticals Using Different API Techniques; *Goodley, Paul C.; Fischer, Steven. 424
Oscillating Capillary Nebulizer Interfacing with Mass Spectrometers; *Ho, Z. Stacy; Drew, Barry; Browner, Richard. 425
EVALUATION AND APPLICATION OF NEGATIVE ION ATTACHMENT LC/MS; *Norwood, Daniel; Fisher, Dixie, Mullis, James. 426
ANALYSIS OF CEFTIOFUR AND ITS METABOLITES IN MILK BY LC/API-MS; Voyksner, Robert; *Keevers, Jeff. 427
Electrospray Liquid Chromatography/Mass Spectrometry of Ginsenosides; van Breemen, Richard B.; *Huang, Chao-Ran; Rimando, Agnes; Lu, Zhi-Zhen, Fitzloff, John F. 428
Electrospray Liquid Chromatography/Mass Spectrometry of Carotenoids; *van Breemen, Richard B. 429
Multi-residue method of §-agonists by immunoaffinity extraction-LC/LC/MS/MS; *Cai, Jianyi, Henion, Jack. 430
An LC/MS Method Using Non-volatile Mobile Phases with Ionspray Ionization; *Mallis, Larry M.; Slayback, John R. B. 431
A Rapid Universal LC/ESI-MS Method for Profiling Drug Metabolites; Taylor, Susan; *Starrett, Anne, DiDonato, Gerald; Lee, Michael. 432
Electrospray LC/MS Profiling in Evolving Pharmaceutical R&D Strategies; *Kerns, Edward H.; Volk, Kevin J.; Klohr, Steven E.; Rourick, Robyn A., Thompson, William L.; Whitney, Jeffrey L.; Lee, Mike S. 433
Examination of Chiral Purity by HPLC-MS; Davidson, Susan; Pullen, Frank; *Richards, Don, Wright, Adrian 434
Quantitative Aspects of HPLC Peak Purity Determination by ESI/MS.; *Bryant, Duncan 435
Data Dependent Automated MS/MS Switching Methods for Routine LC/MS/MS; *Mylchreest, Iain; Campbell, Clay; Wheeler, Kevin; Wakefield, Michael. 436
Electrospray vs. Thermospray LC/MS for Analysis of Small Molecules; *Creasy, William R. 437

Enhanced Sensitivity LC/MS Using Low Resolution Quadrupole Mass Analysis; *Dodsworth, David W.; Alexander, Anthony J.; Blackledge, James A. 438
Electrospray Interface for Submicroliter LC/MS Analyses; *Davis, Michael T.; Lee, Terry D. 439
Separation and Analysis of Human Lens Alpha-Crystallins by LC-ESIMS *Lin, Peiping; Smith, Jean B., Smith, David L. 440
Preparative Applications of Microcapillary HPLC for Mass Spectrometry; *Hackett, Murray; Hendrickson, Ronald C.; Falchetto, Rocco; Walker, Carthene B.; Shabanowitz, Jeffrey; Hunt, Donald F. 441
Multi-Dimensional LC-MS and LC-MS/MS for Protein Sequencing and Mapping; *Hsieh, Frank, Elicone, Chris; Wang, HangQi; Tarr, George; Regnier, Fred; Martin, Stephen 442
Peptide Sensitivity by LC-ESI/MS as a Function of Column Diameter; *Ackermann, Bradley; Fields, Steven; Regg, Brian; **Dourdeville, Theodore. 443
ENHANCING API-MS PERFORMANCE THROUGH CHROMATOGRAPHY; *Voyksner, Robert; Keever, Jeff. 444
Effects of Salts and Trifluoroacetic Acid on Aerosol MALDI Ion Signal *Beeson, Michelle D.; Wei, Xiaona; Russell, David H. 445
Application of LC/IT/reTOF MS to Peptide Mapping and Drug Analysis; *Qian, Mark G , Liang, Li, He, Ling, Lubman, David M. 446
Continuous Flow MALDI MS in an Ion Trap/reTOF Mass Spectrometer; *Liang, Li; He, Ling; Chien, Benjamin; Lubman, David. 447
Structures of Bioploymers; A Combined MALDI - Ion Chromatography Approach; von Helden, G.; Wyttenbach, T.; Lee, S.; *Bowers, M.T. 448
CITP ESI-FTICR for the Study of X-Irradiation Damaged Tetranucleotides; *Hofstadler, Steven A; Zhao, Zhongxi, Bruce, James E; Smith, Richard D; Budzinski, Ed; Dawidski, Jean; Gobey, Jason, **Box, Harold. 449
Complex Mixture Analysis by using Liquid Chromatography Coupled with FTMS; *Winger, Brian, Castoro, John. 450
MALDI-TOF-MS of Organometallic Species: Comparison to FAB and ESI; *Grimm, Deborah A.; Baba, Aaron I ; Yongwu, Liang; Simon, Jerald; Schmehl, Russell H. 451
ATMOSPHERIC PRESSURE CHEMICAL IONIZATION FOR CE/MS; *Takada, Yasuaki; Sakairi, Minoru; Koizumi, Hideaki 452
DETERMINATION OF AMINO ACIDS BY ON-LINE CAPILLARY ELECTROPHORESIS - ESI/MS; *Lu, Wenzhe; Yang, George; Cole, Richard B. 453
CE-Ionspray-MS Analyses of Tryptic Peptides using a Benchtop Quadrupole MS; *Anacleto, Joseph F.; Allen, Mark. 454
CE/ES/MS of Peptides and Proteins Using A New Sheath-flow Probe; *Banks, J. Fred; Whitehouse, Craig M. 455
Analysis of Peptides, and Proteins Using CE/ESI/MS; *Moini, Mehdi; Cao, Ping; Ray, Kenneth; Holbert, Anthony. 456

On-line Characterization of Peroxidation Intermediates of NAD by CE-ESI-MS; *Zhao, Zhongxi (Zack); Udseth, Harold R.; Smith, Richard D. 457
Electrospray CZE/MS and LC/MS With An Ion Trap Mass Spectrometer; *Stacey, Catherine; Schubert, Michael; **Banks, J.Fred. 458
Direct Analysis of Cellular Proteins by Capillary Electrophoresis FTICR-MS; *Hofstadler, Steven A.; Swanek, Frank D.; Gale, David c.; Zhao, Zhongxi; Bruce, James E.; Ewing, Andrew , Smith, Richard D. 459
CE/ITMS: Achieving Ultra-low Detection Limits; *Ramsey, Roswitha S.; Goeringer, Doug E ; Van Berkel, Gary J.; McLuckey, Scott A. 460
A new setup for on-line CE-MS; *Li, Xuhui; Wu, Jingtao; Li, Hongwei; Lubman, David. 461
OFF-LINE COUPLING OF CAPILLARY ELECTROPHORESIS AND MALDI-TOF MS.; *Walker, Kathleen L.; Chiu, Rick W.; Monnig, Curtis A. ; Wilkins, Charles L. 462
Influence of the Source geometry on the Ion formation in LC/TSP-MS; *Honing, Maarten; Barcel, Damia; Abian, Joaquin; Gelp', Emilio; **Volmer, Dietrich; Levsen, Karsten. 463
Determination of Steroids by HPLC/UV-VIS/Particle Beam Mass Spectrometry; *Mesmer, Mantai; Satzger, R. Duane. 464
LC Particle Beam MS with Massive Cluster Impact; *Wang, T.-C. L.; Cornio, L J.; Markey, S.P. 465
Particle Beam LC/MS using a Glow Discharge Ionization Source; *DePalma Jr., Patrick; You, Jianzhang; Marcus, R. Kenneth; Willoughby, Ross C. 466
LC/MS for Identification of N-Nitrosamines in Cosmetic Raw Materials; *Billedeau, Stanley M ; Wilkes, Jon G ; Thompson, Harold C. 467
SFC/MS: Development and Problem Solving; *Pinkston, J. David; Smith, Claudia A.; Hentschel, Rosemary T.; Bowling, Donald J. 468
Separation and Identification of meso-substituted tetraphenylphorphyrins *M. Domingues, M. Rosario ; O. S. Marques, M. Gra a; Ferrer Correia, A. J. 469
Quantitative Analysis of Abscisic Acid in Plant Tissue Using LC/MS/MS; *Hogge, Lawrence; Abrams, Suzanne; Abrams, Garth; Bock, Cheryl; Dunstan, David; Olson, Douglas, Shaw, Angela. 470
Evaluation of GCMS and FABMS for Analysis of Fungicidal DTTT Degradation; Teesch, Lynn, Thorne, Peter S., *Subramanian, Periyasamy. 471
Pentafluorobenzyl Chloroformate as a Derivatization Reagent for NCI/MS *Simpson, J.T.; Torok, D.S.; Markey, S P. 472
Thermal Study of Glycyrrhizic Acid by On-line Thermogravimetry/GC/MS; *Chung, Henry; Aldridge, John; Dull, Gary; Shu, Chi-Kuen. 473
Characterization of Aromatized Biomarkers by GC/MS/MS with CI; *Hsu, Chang Samuel; Dechert, Gary J.; **Schaps, Marlene E., Hieshima, Glenn B. 474
Structure Elucidation of Trace Components in Pharmaceuticals Using GC/MSn; *Schachterle, Steve. 475
Isotopically Labeled Internal Standards Analysis Using Ion Trap GC/MS/MS; *Bolton, Barbara A.; Schachterle, Steve 476

Reproducibility Study of GC/MS/MS with an Ion Trap Mass Spectrometer; *Bolton, Barbara A.; Schachterle, Steve 477
High Speed Method Optimization For Routine GC/MS/MS In An Ion Trap; Wells, Greg; *Huston, Chuck. 478
Dual Oven Multidimensional Fast GC with Spectral Detection; *Sasaki, Tania A.; Wilkins, Charles L. 479
High-Speed GC/MS Using a Quadrupole Mass Filter; *Grimm, Casey; Lloyd, Steven; **Munchausen, Linda. 480
HIGH-SPEED GC/MS WITH A FAST DOUBLE-FOCUSSING MASS SPECTROMETER; Van Ysacker, Peter G.; Brown, Jeff; Phillips, Andy; Janssen, Hans-Gerd; *Leclercq, Piet A. 481
Fast, Very Fast and Ultra Fast GC-MS in Supersonic Molecular Beams; *Amirav, Aviv, Dagan, Shai. 482

Tuesday Posters - Combinatorial Libraries

Non-Peptide Libraries: Structure Determination by LC/MS/MS.; *Issakova, Olga; Ma, Nina; Kocis, Petr; Sepetov, Nikolai. 483
Optimization of MALDI Sequencing of Support-Bound Combinatorial Libraries; Youngquist, R. Scott; Fuentes, Gary R., Miller, Cathy M.; Ridder, Gregg M.; Lacey, Martin P.; *Keough, Thomas 484
Characterization of Small Molecules by ESI and APCI; *McKay, Richard; McEwen, Charles; Larsen, Barbara. 485
MS/MS of Thiazolidinones: Applications of MS in Combinatorial Chemistry; *Fitch, William, Shah, Nikhil, Holmes, Christopher, Look, Gary, Ni, Zhi-Jie. 486
Characterization of Complex Chemical Libraries Using LC/MS/MS; *Nugent, Kerry; Baldwin, Samuel W.; Land, Adrian P. **; Bier, Mark E. **; Wheeler, Kevin **; **Spear, Kerry L.; Figliozzi, Gianine M.; Zuckerman, Ronald N. 487
MS Analysis of Chemical Libraries Employing a Novel Photocleavable Linker; *Wagner, David; Geysen, H. Mario; Brown, Bradley 488
LC/MS Strategy for the Rapid Profiling of Solid Phase Synthetic Products *Rourick, Robyn, A.; Whitney, Jeffrey, L.; Klohr, Steven, E.; Volk, Kevin, J.; Kerns, Edward, H.; Lee, Mike, S. 489
MALDI-TOF-PSD Analysis of Peptides on Polymeric Beads; *Griffin, Patrick; Konteatis, Zenon; Klatt, Tracey. 490
Characterization of a Benzodiazepine Combinatorial Library By IAE/LC/MS/MS; *Nedved, Michael L.; **Ganem, Bruce; Henion, Jack D. 491
Analysis of Non-peptide, Bead-bound Combinatorial Libraries by MS; *Hemling, Mark; Hertzberg, Robert; Johnson, Walter; Mentzer, Mary; **Roberts, Gerald; Taylor, Paul; Weinsotck, Joseph; Carr, Steven. 492
Determination of the Diversity of Small-Molecule Libraries by ESI-MS; *Dunayevskiy, Yuriy; Vouros, Paul; Carell, Thomas; Wintner, Edward A.; Rebek, Julius Jr. 493

Mapping Chemical-Space: Application and Prediction Within LC/MS; Samuel, Mitrovich; *Willoughby, Ross. 494

Tuesday Posters - Toxicology

Alkylation of E. coli Thioredoxin by S-(2-chloroethyl)glutathione; *Erve, John, Barofsky, Lilo; Barofsky, Douglas; Deinzer, Max; Reed, Don. 495
Optimization of Instrumental Parameters used in HRMS of DNA Adducts; *Scheller, Nova; Ranasinghe, Asoka; Wu, Kuen Yuh; Swenberg, James A. 496
Quantitative Analysis of DNA Adducts by Using HPLC/ESI-MS; *Yen, Ten-Yang; Christova-Gueor, Nadia I ; Scheller, Nova, Swenberg, James A.; Charles, M. Judith. 497
Fragmentation of Thioether Conjugates by ESI and Low-Energy CID; *Oberth, C.H.; Jones, A.D. 498
ESI-LC-MS analysis of heterocyclic aromatic amines and their conjugates; *Stillwell, W. G.; Wishnok, J. S.; Kidd, L. R.; Tannenbaum, S. R.; **Turesky, R. J. 499
Characterization of Heterocyclic Amine Metabolites by Electrospray MS; *Eades, Donald; Malfatti, Michael; Felton, James. 500
Determination of Nitrosamines by ESI with Photochemical Enhancement; *Vollmer, David, Lay, Jack. 501
MS/MS Criteria for a Confirmatory Method for Sarafloxacin in Catfish Tissue; *Cepa, Steven; **Menacherry, Stanley; Bavda, Lalit. 502
ANALYSIS OF BREVETOXINS IN "RED TIDE" ALGAE BY ON-LINE LC - ELECTROSPRAY/MS; *Hua, Yousheng; Lu, Wenzhe; Henry, Michael S ; Pierce, Richard H., Cole, Richard B. 503
DIFFERENTIATION OF PACIFIC AND CARIBBEAN CIGUATOXINS BY APCI/LC/MS; *Musser, Steven M.; Grande, H. Ray; **Dickey, Robert. 504
Characterization 3,4-Dichloro-1-butene Metabolites in Rat by LC-MS-MS; Lam, Zamas; *Brach, Frank; Keller, Douglas; Carpenter, Stephen. 505
Preliminary Screen for Biodegradation of Xenobiotics; *Ottinger, Sean E.; Bach, Stephan B.H ; Guentzel, M. Neal. 506
Identification of Tamoxifen Metabolites in Patients; *Poon, G.K.; Lonning, P.E.; Phillips, D.H.; Jarman, M. 507
Biotransformation of 2,4-Dipyrrolidinylpyrimidine (2,4-DPP) In Vitro.; **Streeper, Rob; Pearson, Paul; Zhao, Zhiyang; *Vrbanac, James. 508
ANALYSIS OF PAHS IN HUMAN SERUM USING CLOUD POINT EXTRACTION AND LC/MS; *Sirimanne, Sarath R.; Ma, Li; McClure, P. Cheryl; Barr, John R., Patterson; Jr., Donald G. 509
HPLC-APCI-MS/MS for the Analysis of PAP Biotransformation Products; *Benson, Linda M ; Mayeno, Arthur N.; Gleich, Gerald J.; Naylor, Stephen. 510
GC-MS Analysis of Hydroxytestosterones to Measure Cytochrome P-450 Activity; *Purdon, Michael P.; Lehman-McKeeman, Lois D.; Caudill, Doug. 511

Determination of Clenbuterol in Retinal Tissue by Electrospray LC/MS/MS; *Tomlinson, John, Flurer, Rick; Satzger, R. Duane. 512
High Energy CID Spectra of Melphalan or Chlorambucil Adducted Peptides; *Zaia, Joseph; Fenselau, Catherine . .. .513
FAB-MS and MS-MS Studies of Extracts from Pinus Ponderosa; *Teesch, Lynn; Lamb, Diane; Al-Mahmoud, M. S., Rosazza, J. P. N. 514
Integrated Mass Spectrometric / Yeast Bioassay for Genotoxin Detection.; *Serrano, Jose; Kuehl, Douglas..... 515
MONITORING ACID- AND BASE-INDUCED "LIPID A" DEGRADATION BY ELECTROSPRAY MS; *Cole, Richard B ; Wang, Yan. 516
HPLC/IonSpray/MS/MS Analysis of Common and Illicit Drugs in Case Samples; *Picotte, Pierre; Sanchez, Gabriel; Shushan, Bori; **Sakuma, Takeo 517

Tuesday Posters - Drugs & Metabolism

IN VIVO METABOLISM OF PEPTIDE E IN RAT BRAIN BY MICRODIALYSIS/ES/MS; *Andren, Per E.; Emmett, Mark R.; Capriolí, Richard M 518
Characterization of Metabolites of a CCK Ligand on an Ion-Trap MS; *Moseley, Arthur; Tippin, Tim; Walsh, John; **Schwartz, Jay; Uhrich, Mark..... .. .. .519
Investigation of the Interactions Between Bicyclomycin and Rho Protein; *Cox, Kathleen A.; Gaskell, Simon J., Moon, Hong-sik; Park, Hyeung-geun; Widger, William R., Kohn, Harold. 520
Characterization of Limonene Metabolites in Advanced Human Cancer; **Vigushin, D ; Coombes, R.C.; *Somani, H.; Jarman, M.; Poon, G.K..... 521
An Electrospray Mass Spectrometric Study of the Gold Drug Myochrysine.; Lock, Colin J.L ; Howard-Lock, Helen E.; LeBlanc, Daren J.; *Smith, Richard W 522
IDENTIFICATION OF DIPHENHYDRAMINE METABOLITES USING DEUTERATED DCIMS; Heinze, T.M ; *Hansen, Jr., E.B.; Deck, J., Cerniglia, C.E. 523
LC/MS/MS detection of GSH-glucuronide conjugates of 2,4-diene VPA in rats; *Tang, Wei; Abbott, Frank..... 524
Characterization of a Novel Metabolic Reaction: The Metabolism of LY315535; *Gillespie, Todd; Goodwin, Mike; Catlow, John, Swanson, Steve. 525
Structural Elucidation of Bisbenzylisoquinoline Alkaloids by Ionspray MS/MS; *Wu, Wu-Nan; Moyer, Michael D. 526
Structures of Human Urinary Metabolites of Mazapertine by IonSpray MS/MS; *Wu, Wu-Nan; Gisclon, Lee G.; McKown, Linda A. 527
ANALYSIS OF TAMOXIFEN METABOLITES BY ON-LINE CE-ESMS USING NONAQUEOUS MEDIA; *Lu, Wenzhe; **Poon, Grace K ; Cole, Richard B. 528
Identification of Lotatadine Metabolites from Human Liver Microsomes.; *Cyr, Terry; Dawson, Brian; Ethier, Jean; Jurima-Romet, Malle; Menzies, Allan; Whitehouse, Larry.... 529
Biomarkers of OH radical formation in rat brain by microdialysis with MPP+; Ste-Marie, Line, **Vachon, Luc; Boismenu, Daniel, *Montgomery, Jane..... ... .530

2K3MVA Is Not An Obligate Intermediate Between Isoleucine & Allo-isoleucine; *Mamer, Orval A.; **Lepine, Francois L 531
Characterization of reactive drug intermediates by ESI Mass Spectrometry; *Lim, H.K.; Bhavsar, J. H ; Chan, K.; Sisenwine, S. 532
Capillary HPLC / CF-LSIMS Characterization of LTD4 Antagonist Metabolites; *Yergey, James; Nicoll-Griffith, Deborah, Chauret, Nathalie, Trimble, Laird. . . .. .533
CE-ES-MS Analysis of Drug Metabolites in Urine.; *Ashcroft, Alison E, Major, Hilary J; Lowes, Stephen; **Wilson, Ian D. 534
Analysis of B-Agonists Using Solid Phase Extraction and LC/APcI/MS/MS; *Preece, Steve, **van Vyncht, Gery. .... .535
Analysis of Cytochrome P-450 Metabolites of Arachidonic Acid by LC/MS/MS; *Garner, Carlos O.; Belas, Frank J.; Blair, Ian A. . .. .536
Characterization of Acylcarnitines by GC/MS/MS; *Carlson, Shannan; Johnson, Jodie; **Borum, Peggy; Bernier, Ulrich; Yost, Richard.. ... .537
Identification of in vitro and in vivo metabolites of Bosentan by LC-MS/MS; *Hopfgartner, Gerard, Zell, Manfred; Lausecker, Berthold; Husser, Christophe; Viger-Chougnet, Antoinette; Haas, Ruth..... 538
Mechanisms of Leukotriene B4 Metabolism: Negative ion ESI MS/MS analysis; *Wheelan, Pat; Murphy, Robert, C 539
Characterization of Acidic Triterpenes by HPLC/ESI/MS; *Weintraub, Susan T.; **Streeper, Robert T.; Satsangi, Neera; Stavinoha, William B 540
Microbore HPLC/MS/MS of CP-166,572 metabolites in the rat; *Avery, Michael; Ballinger, William; Zembrowski, William, Inskeep, Phil; Mylari, Larry, Fouda, Hassan 541
HPLC/ESI MS/MS for the Identification of in vitro Metabolites of CP-118,954; *Cui, Donghui; Prakash, Chandra..... 542
Inhibition of Aldehyde Dehydrogenase by Disulfiram and Metabolites; *Veverka, Karen A.; Johnson, Kenneth L.; Mays, Dennis C.; Lipsky, James J ; Naylor, Stephen. 543
A Study of the Metabolism of Rifabutin Using ESI-MS and Tandem MS; *Thompson, Toni; Vouros , Paul; Koudrikova, Tatiana; Gerber, Nicholas. 544
LC/IonSpray/MS/MS Analysis of Bile Acids; *LePage, Guy; Yousef, Ibrahim; Sanchez, Gabriel; Shushan, Bori; **Sakuma, Takeo..... 545
Detection of Trypanothione Conjugates in Cell Cultures by ESI Tandem MS; *Bolgar, Mark S ; Gaskell, Simon J.; Douglas, Kenneth T.; Wilton, Amanda N. 546
Characterization of Hemiketals of MDL 101146 by Normal Phase LC/ESI/MS; *Brown, Paul W. , Emary, W. Bart; Akbari, Nisar..... ... .547
Analysis of secondary metabolites in crude plant extracts by electrospray; *Wolfender, Jean Luc; Hostettmann, Kurt; **Wagner-Redeker, Winfried. .... .548
Angiotensin II Receptor Antagonist Metabolite Identification by MS/MS; *DeMaio, William; Morton, George. 549

In vitro metabolism of FK 506 (Tacrolimus) using MALDI mass spectrometry; *Gusev, Arkady I.; Muddiman, David C.; Proctor, Andrew; Hercules, David M.; Tata, Prasad; Venkataramanan, Raman. 550
Identification of levodopa and its metabolites by HPLC-Ion Spray-MS; *Koupai-Abyazani, Mohammed R.; Esaw, Barbara; Laviolette, Barbara. 551
Identification of the urinary metabolites of Brivudin in the rat *Triolo, Antonio; Agostara, Giuseppina; Bonelli, Fabio; Crea, Attilio; Freude, H.-Gerhard; Monteagudo, Edith. 552
Metabolism of the neuromuscular blocker NIMBEX by LC-RAM-API-MS; *Pleasance, Stephen; Dear, Gordon; Jones, Anne. 553
A Sensitive LC/ESI/MS/MS Assay for the Antineoplastic Agent Ifosfamide; *Goldthwaite, Charles A.; Belas, Frank J.; Phillips, Mark A.; Anthony, Lowell; Blair, Ian A 554
Identification and Quantitation of Cyclophosphamide Using LC/ESI/MS/MS.; *Belas, Frank J., Goldthwaite, Charles A.; Anthony, Lowell; Blair, Ian A. 555
Strategies for the Quantitative Analysis of Opioid Peptides in Plasma; *Streeper, Robert T., Weintraub, Susan T.; Marquez, Cristina D.; Smith, Philip C. 556
Electrospray LC/MS and LC/MS/MS of Ecdysteroids; *GRANT, RUSSELL P.; GAMES, DAVID.E.; **WILSON, IAN D.; MORGAN, E.D.; LAFONT, R. 557
HPLC/ESI-MS/MS Studies on the Metabolism of an Atherosclerosis Combatant; *Luther, Elbridge; Boyer, Scott; Cole, Mark; Fouda, Hassan; Destito, Rosalina; Liston, Theodore. 558
HPLC/APCI-MS/MS Method for Quantitation of a Cholesterol Absorption Inhibit; *Gauthier, Jeffrey, Butala, Pranay, Luther, Elbridge, Fouda, Hassan, Cole, Mark.. 559
HPLC/ESI-MS/MS of a LTB4 Receptor Antagonist; Glucuronide Acyl Migration; *Cole, Mark; Luther, Elbridge; Fouda, Hassan; Gauthier, Jeffrey; Destito, Rosalina; Liston, Theodore... 560
HPLC/MS/MS Determination of CP-118,954 in Human Serum; *Avery, Michael, Needham, Shane; Fouda, Hassan. 561
HPLC/DAD/ESI-MS/MS Studies on the Metabolic Fate of a Novel PDE4 Inhibitor; *Gauthier, Jeffrey; Bachert, Elizabeth; Liston, Theodore; Cole, Mark; Cole, Mark. 562
Characterization of metabolites of Ziprasidone in human by LC-MS/MS.; *Prakash, Chandra; Kamel, Amin; Anderson, Wayne; Wilner, Keith. 563
PRECLINICAL DRUG SELECTION - APPLICATION OF IONSPRAY LC-MS AND LC-MS/MS; *Kelly, Michele A.; Xiao, Guang; Greenberg, Gerald E., Kuzmich, Sandra; Robertson, Philmore... 564
In vivo and in vitro Metabolism of Immunomodulators by TOF-MS; *Muddiman, David C; Gusev, Arkady I; Proctor, Andrew; Hercules, David M; Venkataramanan, Raman; Tata, Prasad; Diven, Warren 565

Drug Metabolism Studies That Avoid the Use of Radioisotopes; *Hsieh, Feng-Yin; Goldthwaite, Charles A.; Nobes, Brian J.; Mayol, Robert F.; Klunk , Lewis J.; Chaudhary, A K. ; Blair, Ian A. 566
Orifice Voltage Dependent Oxidation of Dihydrolevobunolol to Levobunolol; *Luo, Wendy; Tang-Liu, Diane; Breau, Alan. 567
Metabolic Profiling Using LC/MS/MS With On-line Microdialysis Sampling; *Rourick, Robyn A.; Kerns, Edward H.; Volk, Kevin J.; Whitney, Jeffrey L.; Lee, Mike S. 568
Automated HPLC/MS/MS Approaches for Rapid Identification of Metabolites; *Cole, Mark; Gauthier, Jeffrey; Luther, Elbridge; Fouda, Hassan; Destito, Rosalina; Liston, Theodore. 569
Analysis of diuretics in urine by HPLC/APCI/MS; Yuan-Ping, Yang; *Jentaie, Shiea. 570
The Detection of Concealed Drugs by Field Portable IMS and GC/MS; *Fetterolf, Dean; Donnelly, Brian ; Jourdan, Thomas. 571
ANALYSIS OF "ECSTASY" AND OTHER DESIGNER DRUGS USING HPLC/APCI/MS; *Hansen, Jr , E B ; Churchwell, M.I.; Clark, C.R.; DeRuiter, J ; Noggle, F T , Doerge, D.R. 572
Immunoaffinity Extraction-LC/LC/MS/MS for analysis of LSD Analogs in Urine; *Cai, Jianyi; van Soest, Remco; Henion, Jack. 573
Identification of Previously Unreported Metabolites of LSD in Human Urine; *Nelson, Chad C.; Slawson, Matt H.; Reuschel, Scott A.; Foltz, Rodger L., **Brenneisen, Rudolf. 574
A Method for the Detection of Fluoxymesterone and metabolites by GC/ECNI; * Xu, Naxing; Watson, J. Throck. 575
Ion Trap GC/MS and GC/MS/MS Measurement of Cocaine and its Metabolites; *Bowers, Larry; Fregien, Kelly.. 576
Selected Ion Storage and Tandem Mass Spectrometry of Anabolic Steroids; *Bowers, Larry. 577
Quantification of the phosophodiesterase inhibitor CP-80,633 in human serum; *Kamel, Amin; Schneider, Rick; Navetta, Kim; Luther, El; Fouda, Hassan 578

Tuesday Posters - Nucleic Acids & Constituents

Protocols for DNA Mapping and Screening by MALDI MS; *Bai , Jian; Liu , Yan-Hui; Liang, Xiaoli; Qian, Mark G; Lubman, David M. 579
MALDI of Synthetic Oligonucleotides; *Bentzley, Catherine; **Larsen, Barbara; Johnston, Murray. 580
Improving Mass Resolution in MALDI/TOF Analysis of DNA; *Tang, Kai; **Worrall, Timothy; Cotter, Robert ; Koster, Hubert. 581
Probing the Stability of Phosphorothioate Oligonucleotides by MALDI-TOFMS; *Wang, Bing; Bourque, Andre; Belenky, Alexi; Cohen, Aharon. 582

6-Aza-2-Thiothymine: A Good Matrix for the Analysis of Oligonucleotides; *Lecchi, Paolo; Le, Han; Pannell, Lewis. 583
MALDI-MS - a New Tool to Monitor the Activ. of Nucl. Acid Modifying Enzymes; *Nordhoff, E.; **Cramer, R.; Kirpekar, F.; Hahner, S.; Roepstorff, P.; Haglund,Jr., R.F.; Hillenkamp, F. 584
Study of PAH-DNA adducts by CF-FABMS; *Plante, Sylvie; Bertrand, Michel, J. 585
MALDI-TOF Analysis of PAH-modified DNA Adducts at the Femtomole Level; *Gooden, Jonathon; Gross, Michael. 586
Tandem MS/MS for Determining Structural Isomers of PAH-DNA Adducts; *Byun, Jaeman; Vidavsky, Ilan; Gross, Michael; Mulder, Patrick; Li, Kai-Ming; Cavalieri, Ercole. 587
DNA Adduct and Probe Detection by Electrophore Mass Spectrometry; *Giese, Roger W ; Abushamaa, Amir; Naim, Abdul; Murugaiah, Veeravagu; Xu, Linxiao; Magiera, Daniel; Graner, Helena; Ismail, Yasser. 588
Analysis of Hydroxyl Radical Modification of DNA using LC/MS/MS; *Kowalski, E.M ; Chaudhary, A.K.; Blair, I.A. 589
The Application of CE/ESI/MS/MS for Detection of IQ Adducts of DNA; *Rindgen, Diane; Vouros, Paul; Turesky, Robert J. 590
GC/MS Quantitation of DNA Oxidation Products; Oh, Chang-Hwan; *Iden, Charles R. 591
Capillary Isotachophoresis-Mass Spectrometric Determination of DNA Damage; *Zhao, Zhongxi (Zack); Fuciarelli, Alfred F.; Smith, Richard D 592
Analysis of DNA base modifications in oligonucleotides using LC/ES MS.; *Chaudhary, A. K.; Reddy, G R., Compton, J. L.; Marnett, L. J.; Blair, I. A. 593
Micro electrospray MS/MS for the analysis of modified oligoribonucleotides; *Wolter, M. A.; **Wilm, M. S.; Mann, M.; Engels, J. W. 594
ESMS of oligonucleotides and non covalent interactions studies; *Potier, Noelle; Bischoff, Rainer; Van Dorsselaer, Alain. 595
Non-Covalent Associations of Metal Complexes with DNA Duplexes by ESI-MS; *Harms, Amy C.; Smith, Richard D., Jenkins, Yonchu; Barton, Jacqueline K. 596
Correlation Between ESI-MS, CID Data, and DNA Duplex Melting Temperature; *Gale, David C.; Morris, A. Kirk; Harms, Amy C.; Camp II, David G., Sisk, Ellen C.; Fusciarelli, Al F.; Udseth, Harold R.; Smith, Richard D.. 597
Characterization of oligonucleotide-peptide hybrids by MALDI and ESI MS; *Sochacki, Marek; Bergmann, Frank; Tam, Steve; Michel, Hanspeter. 598
Routine FAB Mass Spectra of Oliognucleotides: Enhancement by Crown Ethers; *Le, Han; Lecchi, Paolo; Sayer, Jane; Jerina, Donald; Pannell, Lewis. 599
Fragmentation of Multiply-Charged Oligonucleotides in Triple Quadrupoles; *Pomerantz, Steven C.; McCloskey, James A. 600
A New Approach for DNA Sequencing and Mutation Detection with ESI-MS; *Terunuma, Hideya; Naito, Yasuhiro; Tsuneyoshi, Toshihiro; Arakawa, Ryuichi; Ishikawa, Keiichiro; Koga, Yoshinori; Prockop, Darwin. 601

ESI-MS on a sector instrument for the analysis of oligonucleotides; *Wolter, M. A.; Engels, J W.; Montanarella, L ; Facchetti, S. 602
FAB/MS Confirmation of Modified Deoxynucleotides in Small Oligomers; Rieger, Robert A.; *Iden, Charles R. 603
The LCMS of Synthetic Oligonucleotides; Bothner, Brian; Chatman, Kelly, Sarkisian, Molly; *Siuzdak, Gary. 604
Analysis of DNA Analogues in Pharmaceutical Applications Using ESI-MS; *Chen, Ling, **Fearon, Karen; Nuwaysir, Lydia; McLean, Matthew. 605
Detection of Imidazoleacetic Acid Riboside by FAB/MS and ESI/MS; Rieger, Robert A. (1); Reddy, D. Meghanath(1); Thomas, Boban (2); Prell , George D (2); *Iden , Charles R. (1). 606
Characterization of 1,2,3,4-diepoxybutane purine adducts using LC/ESI/MS/MS; *Kambouris, S. J.; Chaudhary, A. K.; Blair, I. A. 607
A Study of Metal Ion Interactions With Nucleosides by LSIMS; *Paul, G. J. C.; Theophanides, T ; Anastassopoulou, J ; **Marcotte, I.; Bertrand, M. J. 608
Gas-Phase Chemistry of Metal(II)-Ion-Complexes of Monophosphates; *Adams, Jeanette; Hamilton, Jill. 609

Tuesday Posters - Proteins & Peptides

In situ digestion procedures and analysis of the digest by HPLC/ESI/MS *Falchetto , Rocco; Shabanowitz, Jeffrey; Owens, Gary; Hunt, Donald F. 610
Enzymatic fragmentation with immobilized enzymes and LC/MS analysis; *Raida, Manfred; Forssmann, Wolf-Georg. 611
Sepn/Manipulation of Proteins using Polymeric µ-HPLC On-line with ESI/MS *Hail, Mark; Warrack, Bethanne; Taylor, Susan; Baldwin, Sam; Stoney, Ken, Lee, Mike. 612
Comparison of a TSQ MS to a Reflectron TOF MS with Electrospray Ionization; *Verentchikov, Analoti; Hsieh, Frank; Tomany, Michael, Gabeler, Stephen; Vestal, Marvin; Martin, Stephen. 613
Peptide Mapping on a Nitrocellulose Membrane with Analysis by MALDI MS; *Bai, Jian; Qian, Mark G; Liu, Yan-Hui; Liang, Xiaoli; Lubman, David M. 614
Rapid Identification of Variant Enzymes from Commercial Detergent Products; *Lacey, M.P.; Keough, T.; Sun, Y.; Bauer, M.D.; Grant, R.A.; Bennett, C.B. 615
HPLC-ESI Ion Trap MS/MS Analysis of Proteins Separated by 2D-PAGE; *Kanai, Michiko, Seta, Kazuo; Land, Adrian; Bier, Mark; **Nakayama, Hiroshi; Isobe, Toshiaki; Okuyama, Tsuneo. 616
STRATEGIES FOR IDENTIFICATION OF 2D GEL PROTEINS BY MASS SPECTROMETRY; *Clauser, Karl R.; Hall, Steven C.; Andrews, Lori E.; Smith, Diana M.; Matsui, Neil; Tran, Huu M.; Epstein, Lois B.; Burlingame, Alma L 617
Mass Spectrometry of Proteins Directly Isolated from SDS Gels; *Schuhmacher, Martina; Wunderlin, Markus; Przybylski, Michael 618

Sequencing peptides: post-source decay MS without scanning the reflectron.; *Cordero, M.M., Cornish, T.J.; Cotter, R.J. 619
Evaluation of MALDI-PSD and MALDI-CID for Structural Analysis; *Carr, Steven; Hemling, Mark; Roberts, Gerald; Bean, Mark; Annan, Roland; Hilliard, George; **Hoyes, John. 620
Peptide Sequencing: MALDI Time-of-Flight vs Electrospray Triple Quadrupole; Overberg, A.; Ingendoh, A.; *Keane, A.; Sutton, C; Harrison, M.; Cottrell, J. S 621
Deuterated Terminating Agents for Ladder Sequence Analysis by MALDI-TOF MS; Holland, Ricky; *Lay, Jackson, Chiarelli, M. Paul; Vollmer, David. 622
Using ESI to Characterize Protein Sequencing Ladders; *Saha, Sanat; Beavis, Ronald C. 623
Sequence Analysis of C- and N-Terminal Blocked Peptides by PSD-MALDI; *Ingendoh, Arnd; Seta, Kazuo; Kanai, Michiko; **Yamakawa, Yoshio; Omori-Satoh, Tamotsu; Isobe, Toshiaki; Okuyama, Tsuneo 624
An Evaluation of Peptide Fragmentation by MALDI-TOF PSD and MALDI CID MS/MS; *Adams, Gregory W.; Medzihradszky, Katalin F.; Hall, Steven C ; Burlingame, Alma L.; **Bateman, Robert H; Green, Martin R; Maisey, Anne. 625
A Novel N-Terminal Derivative Designed to Simplify Peptide Fragmentation; *Sherman, Nicholas E.; Yates, Nathan A.; Jeffrey, William; Bartlet-Jones, Mike; Shabanowitz, Jeffrey; Hunt, Donald F., Pappin, Darryl. 626
High Energy CID Spectra of Peptides Containing Pyridylethylcysteines; *Wolf, Susan; Biemann , Klaus 627
Surface-Induced Dissociation of Cyclic Peptides; *Dongre, Ashok; Wysocki, Vicki; **Hayward, Mark. 628
Peptide Sequencing at the Low Femtomole Level Using PC-CE-MS/MS; *Tomlinson, Andy J.; Johnson, Kenneth L.; Naylor, Stephen. 629
Controlled fragmentation of derivatized peptides; *Lindh, Ingemar; Griffiths, William; Bergman, Tomas, Sjövall, Jan. 630
Fragmentation of Small Non-polar Peptides Containing NMe-Ala and Pro; *Vaisar, Tomas; Urban, Jan. 631
DETECTION OF PHOSPHORYLATED AND SULFATED PEPTIDES BY LC-ESI-MID; *Jedrzejewski, Paul; Schnolzer, Martina; Lorenz, Peter; Lehmann, Wolf D.; 632
Enzymatic Reactions on Membranes for the MALDI Analysis of Phosphoproteins; *Liao, Pao-Chi; Gage, Douglas A., Allison, John 633
Improved CID Spectra of Peptide Ions Using Stepped Collision Potentials. *Annan, Roland; Carr, Steven. 634
Location of peptide phosphorylation sites by use of (+) and (-)ESI-MS/MS; *Busman, M.; Schey, K. L.; Knapp, D. R. 635
Phosphorylation and N-terminal acetylation of phosrestin I in fly eyes; *Kinumi, Tomoya; Jackson, Kenneth; Kubota, Masayuki, **Ohashi, Mamoru; Matsumoto, Hiroyuki. 636

Electrospray FTICR Mass Spectrometry of Modified Peptides and Proteins; *Nawrocki, Joseph; Watson, Cliff; Eyler, John. 637
Mass Spectrometric Protein Identification in Completely Sequenced Genomes; *Mann, Matthias; Jensen, Ole N.; Vorm, Ole; Houthaeve, Tony; Wilm, Matthias; Mortensen, Peter; Shevshenko, Andrej. 638
Useful Tables of Possible and Probable Peptide Masses; *Mann, Matthias. 639
Analysis of Immunoprecipitated Proteins by Using Tandem Mass Spectrometry; *Schieltz, David M.; Eng, Jimmy K.; Yates, John R. 640
Protein Database Searching with Ion Trap MSn Spectra; *Eng, Jimmy; Yates, John; Schieltz, David. 641
Mass Accuracy Requirements to Map Proteolytic Peptides from a Protein; *Liao, Pao-Chi; Allison, John; Gage, Douglas A. 642
Protein Identification by Database Searching: A Bayesian Algorithm; *Zhang ,Wenzhu ; Chait, Brian T. 643
Applications of a New Algorithm for Deconvolving Multiply Charged Spectra; *Barclay, Victoria; Bonner, Ron; DeNoyer, Lyn; Dodd, Jack. 644
DATABASE FOR MASS SPECTRA OF PROTEINS; *Fenyó, David; **Beavis, Ron C.; Chait, Brian T. 645
Characterization of Protein Digests Using Novel Scanning (Funky Ramps); *Allen, Mark; Anacleto, Joseph; Bonner, Ron; Nuwaysir, Lydia; Bori, Shushan 646
Interpretation of Peptide CID Spectra using Artificial Neural Networks; *Scarberry, R E.; Zhang, Z. ; Knapp, D. R. 647
Peak Matching Techniques for Characterizing Protein Heterogeneity; *Johnson, Kenneth L., Tomlinson, Andy J., Naylor, Stephen 648
Identification of Proteins Using LC/MS/MS on an Ion Trap Mass Spectrometer; *Lane, W.S.; **Land, A.P.; Jardine, I.; Bier, M.E. 649
High Sensitivity Protein Sequencing with ESI-FTMS; *Guan, Ziqiang, Aaserud, David; Valaskovic, Gary; Kelleher, Neil; McLafferty, Fred 650
ESI/FTMS of Enzyme (>40 kDa) Sequence, Heterogeneity, and Inhibition; *Wood, Troy D.; **Kelleher, Neil L.; Little, Daniel P.; Begley, Tadgh P., McLafferty, Fred W., Chen, Lorenzo H.; Borders, Montie; Kenyon, George H. 651
Peptide Mapping by LC/MS/MS Using a Triple Quad or Ion Trap Spectrometer; *Baldwin, Samuel W.; Stoney, Ken; **Land, Adrian P., Bier, Mark E ; Wheeler, Kevin. 652
Protein Molecular Weight Determination on Quadrupole and Ion Trap Systems; *Land, A.P.; Mylchreest, I.C.; Bier, M.E.; Wheeler, K.P. 653
MS/MS in an Ion Trap/reflectron Time-of-flight Mass Spectrometer; *Qian, Mark G.; Zhang, Yu; Bai, Jian; Lubman, David M. 654
MS/MS of Alkali Cationized Peptides Using Quadrupole Ion Trap; *Lin, Tong; Glish, Gary L. 655
Tertiary Structure of Protein Ions in the Gas-Phase; *Fagerquist, Clifton; Schnier, Paul; Gross, Deborah; Rodriguez-Cruz, Sandra; Williams, Evan. 656

Strategies for Accurate Mass API LC-MS Analysis of Complex Mixtures; *Woolfitt, Adrian; Bateman, Robert; Pugh, Jonathon....657

Wednesday Orals
New Approaches to Quantitative Mass Spectrometry

Importance of Desalting Oligonucleotides in Quantitative Electrospray MS; *Greig, Michael J.; Klopchin, Patrick G ; Wheeler, Patrick D., Griffey, Richard H....658
Rapid Quantitation of Eicosanoids in Inflammation Models by ES/MS/MS; *Duffin, Kevin; Margalit, Alon; Isakson, Peter....659
Serum Albumin Determination Using LC/MS with Affinity Chromatography; *Bunk, David; Welch, Michael....660
Quantification of Pranlukast and SB218663 in Plasma Samples Using LC/MS/MS; *Bi, Honggang; Lundberg, David; Pirhalla, Jill; McHugh, Charles; Marchese, Alfredo....661
Application of Ionspray MS/MS Quantification of Beclomethasone Dipropionate; *Schorno, Karl S.; Winslow, L. D....662
Quantitative Analysis of Low Molecular Weight Biomolecules by MALDI-TOF; *Duncan, Mark W.; Lidgard, Ray....663
Quantitative Analysis of Angiotensin II by MALDI/TOF MS; *Nicola, Anthony J. Gusev, Arkady I.; Proctor, Andrew; Hercules, David M.; Jackson, Edwin K....664
Selection of Internal Standards for Quantification by MALDI; *Wilkinson, William R.; Gusev, Arkady I.; Proctor, Andrew; Houalla, Marwan; Hercules, David M....665
Use of Isotopic Surrogates in the Quantitation of Endogenous Analytes; *Alexander, Michael; Abolin, Craig....666

Wednesday Orals - Electrospray Ionization-Fundamentals

Electrochemical Aspects of Electrospray; *Zhou, Feimeng; Van Berkel, Gary....667
High-Frequency Synchronization of Electrospray Current using Pulsed Tension; *Beaugrand, C.; Charbonnier, F.; Rolando, C.; Sablier, M.; Saru, F....668
Characterization and Implementation of Micro-Flow Electrospray Nebulizers; *Covey, Thomas....669
How are electrospray Ions Born Free? - Dole vs. Iribarne Revisited; *Fenn, John B.; Rosell, Joan....670
Is Electrospray Ion Production Concentration Dependent?; *Coopersmith, Brad; Hamilton, Brenda; Abolin, Craig....671
DEPENDENCE OF CHARGE STATE DISTRIBUTION ON ANALYTE CONCENTRATION IN ESI/MS; Wang, Guangdi; *Cole, Richard B....672
PHYSICAL PROCESSES OF ELECTROSPRAY; *Willoughby, Ross; Sheehan, Edward; Mitrovich, Samuel....673
Ion Mobility Spectrometric / Mass Spectrometric Study of Electrospray Ions; *Guevremont, Roger; Siu, K.W.Michael; Wang, Jianyao....674

Wednesday Orals - Fourier Transform Mass Spectrometry

Principles and Design of Ion Traps for FT-ICR Mass Spectrometry *Marshall, Alan G.; Guan, Shenheng....675
Advantages of High Mass Accuracy MALDI-FTMS for Tryptic Mapping; *Stults, John; Li, Yunzhi; McIver, Jr., Robert....676
EVALUATION OF DISSOCIATION TECHNIQUES FOR MALDI-FTMS OF OLIGONUCLEOTIDES; *Hettich, Robert; Stemmler, Elizabeth....677
A Dual Chamber Approach to FT-MS Offering ESI, MALDI, FAB, and EI Sources; *Gard, Eric, Carroll, James; Green, Kirk; Fannin, Steve; Wu, Jiangyue; Camara, Elvira; Lebrilla, Carlito....678
FT-ICR Mass Spectrometry of Very Highly Charged Atomic Ions; *Schweikhard, Lutz; Becker, Stefan; Beiersdorfer, Peter; Beck, Bret; Elliott, Steve....679
ESI/FTMS Instrumentation for Tandem Mass Spectrometry; *O'Connor, Peter B.; Wood, Troy D., Little, Daniel P.; Guan, Ziqiang; Valaskovic, Gary A.; McLafferty, Fred W....680
Fragmentation of Labelled Lysozymes and Derivatives by FT MS; *Robinson, Carol; Miranker , Andrew; Kruppa, Gary; Dobson , Christopher....681
ESI-FTICR Methods for Bioaffinity Characterization Mass Spectrometry; *Bruce, James; Anderson, Gordon; Chen, Ruidan; Cheng, Xueheng; Gale, David, Hofstadler , Steven, Schwartz , Brenda; Smith, Richard....682

Wednesday Orals - Laser Desorption Ionization-Fundamentals

Fast Metastable Ion Fragmentation In MALDI; *Brown, Robert; Reiber, Duane, Lennon, John....683
Delayed Extraction of MALDI Ions in a Reflecting TOF Spectrometer; *Ens, W; Dworschak, R G; Spicer, V; Standing, K G....684
Investigation of Selective Detection in Peptide Mixtures by MALDI MS; *Yu, Wen; Vath, James, Scoble, Hubert....685
Examining MALDI Ion Formation at Various Laser Irradiances; *Campo, Karen K.; Edmondson, Ricky D., Russell, David H....686
Continuous Flow MALDI in an Ion Trap-ReTOF Mass Spectrometer; *He, Ling; Liang, Li; Li, Xuhui; Lubman, David....687
Lanthanide Oxide Cluster Ions Produced by Laser Ablation; *Gibson, John K....688
Role of Solubility in the Preparation of Synthetic Polymer Samples; King, Richard; Goldschmidt, Robert; Xiong, Yansan; *Owens, Kevin; Hanton, Scott....689
Mechanistic Implications of MALDI Ion Signal Profiles; *Kinsel, Gary; Edmondson, Ricky; Russell, David....690
Dissecting MALDI-TOF Mass Spectra; *Allison, John; Liao, Pao-Chi; Lavine, Gary; Hiller, Joseph....691
MALDI Sample Preparation Techniques By X-ray Photoelectron Spectroscopy; *Thompson, Stephen; Jones, David; Robinson, Kevin....692

Wednesday Orals - Mass Spectrometry & the Earth's Atmosphere

Sift Studies of the Reactions of H3O+ with a Series of Sulfides and Thiols; Williams, Ted L.; Babcock, Lucia M.; Adams, Nigel G., Decker, Brian K.; *Nigel Adams 693
The Study of HCFC Radicals Decomposition by NR Mass Spectrometry; *Sadilek, Martin; Turecek , Frantisek 694
Astrophysical Thermochemistry: The Heats of Formation of C3H2 isomers.; *Chyall, Leonard; Squires, Robert 695

Wednesday Posters - Ion-Molecule Reactions

Oxidation Reactions of Cationic Vanadium Clusters; *Rodgers, M. T., Griffin, J. B., Armentrout, P. B. 696
Chemisorption of Hydrogen Molecules on Vanadium Cluster Cations; **Dietrich, G.; Dasgupta, K. ; Kluge, H.-J.; Lindinger, M.; Lützenkirchen, K. ; *Schweikhard, L. ; Ziegler, J. 697
Metal Ion/Molecule Chemistry using a Radio Frequency Glow Discharge Source; *Eanes, Ritchie C ; Christopher, Steven J ; Marcus, R. Kenneth 698
GENERATION AND CHARACTERIZATION OF SILACYCLOPENTADIENYL COMPLEXES OF IRON; *Kardash, Dawn; Kloos, Steve; Boudjouk, Phil; Jacobson, Denley 699
Structure & Reactivity of (FeCNC3H5Cl)+ Complexes; Capron, L., Mestdagh, H.; *Rolando, C., Sablier, M. 700
Ethylene Insertion and Hydrogenolysis Rates of [(C5Me4)SiMe2(n-t-Bu)]ZrMe+; *Hayes, T W , Alameddin, N G ; Richardson, D E , Eyler, J R , Watson, C. H. 701
Gas Phase Reactions of +1 and +2 Chlorotitanium Ions With Isobutene; *Kneen, Kurt; Leroi, George E.; Allison, John 702
Electrospray Mass Spectrometry (ESI-MS) of Metal Chelates; *Ross, Andrew R.S , Ikonomou, Michael, G , Orians, Kristin J. 703
Gas-Phase Actinide Ion Chemistry: Reactions of Th+ and U+ with CH4 and C2H6; *Marçalo, Joaquim, Leal, João Paulo, Pires de Matos, António 704
Gas-Phase Reactivity of Transition Metal Cations with Atomic Species; Angeli, C.; Leymarie, N ; Mestdagh, H.; *Rolando, C.; Sablier, M. 705
Organometallic Distonic Ions: +FeC6H4.; *Xu, Young; Lee, Sam; Freiser, Ben, Bauschlicher, Charles 706
Gas-Phase Isomeric Differentiation Study of FeC7H7+; *Xu, Young, Garcia, Edna; Freiser, Ben; Bauschlicher, Charles 707
Experimental and Theoretical Studies on Nb6C7+; *Lee, Samuel; Kan, Steven; Freiser, Ben S. 708
Generation and Reactivity of Yttrium-Carbon Clusters; *Kan, Steven Z.; Lee, Sam A.; Freiser, Ben S 709

FT-ICR Studies of the Structures and Reactivities of Metal-Carbon Clusters; *Byun, Yong G.; Yeh, Chen-Sheng; Afzaal, Sunia; Lee, Samuel A , Kan, Steven Z., Xu, Young; Freiser, Ben S. 710
Gas-Phase Ion-Molecule Reactions of Lanthanide Ions with Crown Ethers; *White, Forest M.; Solouki, Touradj; Xin, Tianpei; Marshall, Alan G. 711
Gas Phase Reactions of Pt+, Au+, and Hg+ with Small Hydrocarbons; *Taylor, William; Rippy, Allyson; **Babcock, Lucia; Linder, Christopher 712
Glow Discharge/SIFT Studies of Some Gas Phase Metal Ion Reactions; *Linder, Christopher; **Taylor, William; Dalton, A. Leigh; Babcock, Lucia. 713
Reactions of singly-charged transition metal ions with cyclopentene; *Ni, Jinsong; **Harrison, Alex. G. 714
C5H8 isomer distinctions by metal ion reactions; *Ni, Jinsong; **Harrison, Alex. G. 715
Radiative association rate and bond strength of metal ion-neutral complexes; *Ho, Yen-Peng; Dunbar , Robert C. 716

Wednesday Posters - Computer Applications

SIMION 3D Version 6.0; *Dahl, David, ... 717
MacSimion past, present and future; *McGilvery, D. C., Morrison, R J S 718
The Practical Application of Data Controlled Mass Spectral Analysis. *Stahl, Douglas C., Swiderek , Kristine M ; Davis, Michael T ; Lee, Terry D. 719
Possible use of a time domain signal inverse algorithm in FTICR-MS; *Gorshkov, Michael V., Kouzes, Richard T. 720
Homologous Series Plots: A New Slice Through the GC/MS Data Set; *Dolnikowski, Gregory, **Smith, Brian 721
The Determination of Elemental Composition by Low Resolution MS/MS.; *Wang, Jia-shen. 722
USE OF PM3 MOPAC TO PREDICT PHOTOINDUCED H+-TRANSFER IN H-BONDED CLUSTERS; *Gimon-Kinsel, Mary; Huang, Yong; Russell, David 723
Application of a Fuzzy Logic peak-finding algorithm for GC/MS Analysis; *Sander, Peter. 724
New Software Tools for the Analysis of High Resolution Mass Spectra; *Price, John M.; Rockwood, Alan W ; Myers, James D.; Van Orden, Steven 725
Processing MALDI-Time-of-Flight Data: A Maximun Entropy Approach; Reynolds, David J., *Gallagher, Richard T.; Scrivener , Elaine, Derrick, Peter J 726
Hybrid Neural Network for Mycobacterial Detection and Speciation by GC-MS; *Herold, Christopher; Fitzgerald, Robert; Herold, David; **Lu, Taiwei, Zhao, Sean; Lerner, Jeremy. 727
Evaluating EI Mass Spectral Library Search Results; *Sparkman, David 728
Substructure Identification by Library Searching; *Stein, Stephen E , Tchekhovskoi, Dmitrii V 729

Sharing Corporate Mass Spectral Databases; *Little, James L.; McSpadden, William M. 730
Artificial Neural Networks for Identifying Components in Mixtures by MS; *Lay, Jackson; **Darsey, Jerry. 731
Design of a Computer Controlled Magnetic Sector Mass Spectrometer; *Cody, R. B. ; Makino, S. ; Asada, T.; **Yoshidome, K. 732
High-Performance FT-ICR Data System; *Senko, Michael W.; Guan, Shenheng; Marshall, Alan G. 733
High Performance Data System for Ion Trap Mass Spectrometry; *Overney, Gregor; **Hart, Kevin; Wise, Marc B.; Enke, Christie G. 734
PROGRAMMING THE TELEDYNE FILTERED NOISE FIELD SYSTEM; *Clarke, Nigel J.; Todd, John F.J ; Hoekman, Don J. 735
A HIGH SPEED DATA ACQUISITION FOR FAST GC-MS; *Gilbert, Anthony; Atherton, Paul; Hanson, Stewart; Lu, Lin; **Preston, Andrew; Smith, Steve. 736
Display and Manipulation of Three-Dimensional Plots of Ion Trap Data; *Li, Rebecca; Hoekman, Don, Wilson, Ray; McHugh, Sean; Karr, Dane. 737
Interactive Setup and Control of Ion Trap Mass Spectrometry Experiments; *Wilson, Ray; Hoekman, Don; McHugh, Sean; Li, Rebecca. 738
Automating Mass Spectrometry with AppleScript and QuickKeys; *Bonner, Ron; Burton, Lyle; **Mann, Matthias; Wilm, Matthias. 739
A New Mass Spectrometry Data Processing Program; *Bonner, Ron; Burton, Lyle. 740
Automating Pharmaceutical API/LC/MS/MS Quantitation; *Wakefield, Michael; Weissenberg, Klaus. 741
A New Multi-Vendor "CLP-Like" Report Generator for GC/MS Data; *Patkin, Adam. 742
Matrix Assisted Laser Desorption for R&D and automated QC applications; *Humphrey, Paul; Dingley, David; Jones, David. 743
Evaluation of TICFILT as a Software used in LC/MS Analysis.; *Carrier, Alain; Zidarov, Dimo; Bertrand, Michel J. 744

Wednesday Posters - Materials Characterization

Mass Spectrometry as a Tool to Study Painted Art.; *Boon, Jaap J.; van der Doelen, Gisela; Pureveen, Jos; van Ocht, J.; van Grevenstein, A. 745
HPLC-FAB-MS and GCMS study of aromatic components of "gum benzoin" resins; *Pastorova, Ivana; de Koster, Chris G.; Boon, Jaap J. 746
GC/MS Analysis of Vegetal Adhesive Material from Archaeological Origin; Delacotte, J.-M.; *Regert, M.; Rolando, C.; Sablier, M. 747
The Effect of the Terminal Group on the TOF-SIMS Spectra of PDMS; *Dong, Xia; Proctor, Andrew; Hercules, David. 748
Application of ESI MS to the Analysis of Polysulfide Polymers; *Buzy, Armelle; Mahon, Andrea, Kemp, Terry; Jennings, Keith. 749

The Analysis of Polymer Additives by Tandem Mass Spectrometry; *Jackson, Tony; Jennings, Keith; Scrivens, Jim. 750
Average Mass and End-Group Information on Polymers Using MALDI and MS/MS.; *Jackson, Tony; Jennings, Keith; Scrivens, Jim. 751
MS Analysis of Alkylated Benzothiophenes...; Budzikiewicz, H; Drabner, G. 752
Characterisation of Cyclic PET Oligomers by LC-MS; *Yates, Hilary; Scrivens, Jim; Hedley, Julie; Taylor, Mike. 753
LC-MS Characterisation of a Surfactant Complex Mixture; *Yates, Hilary; Scrivens, Jim; Hedley, Julie. 754
Mass Spectrometry of Polyoxyalkylene Block Copolymer Surfactants; *Kalinoski, Henry T.; Hargiss, Leonard O., Shay, Brian J.; **Schuyl, P.J.W. 755
Diffusion of argon in K3B polyimide and its carbon fiber laminates*; *Grayson, Michael. 756
The characterisation of commercial lubricant formulations; *Scrivens, Jim; Yates, Hilary; Bunn, Alan; Tayler, Paul; Beckett, Malcolm; Taylor, Mike; Jennings, Richard. 757
Transformation of Feedstock Molecules in FCC Studied by Mass Spectrometry; *Qian, Kuangnan; Harding, Robert H.; Zhao, Xinjin. 758
Quantitative Analysis of Reformulated Gasoline by Mass Spectrometry; *Drinkwater, Donald; Nero, Vince. 759
Characterization of Asphaltenes from Midway Sunset Crude Oil; *Haas, George W.; Ellis, Leroy; Hunt, Jerry E.; Winans, Randall E. 760
Pyrolysis-Photoionization Mass Spectrometry; *Bookwalter, Craig; Zoller, David; Johnston, Murray. 761
The Accuracy of Chemical Type Analysis Using a Dynamic Batch Inlet System; *Roussis, Stilianos, G.; Cameron, Andrew, S. 762
Improving the Reproducibility of Pyrolysis MS Techniques; *Roussis, Stilianos, G.; Fedora, Jim, W. 763
Analysis of Pyrolysis Residues from Poly (vinyl alcohol); *Pogue, Robert; Ackley, Kathryn; Majidi, Vahid 764
TPD MS of Chemically Modified Ultrafine Oxides; *Pokrovskiy, Valeriy 765
Thermogravimetric Analysis-MS with Data Logging on a Teknivent Data System; *Hileman, Fred; Grote, William; Johnson, Deborah; Tria, John; **Norberg, Peter. 766

Wednesday Posters - Inorganic, Elemental & Isotope Rations

Improved Performance of a Quadrupole Based-Glow Discharge Mass Spectrometer; *Valiga, Robert E.; Duckworth, Douglas C.; Smith, David H.; 767
Elemental Quantification Based on Secondary Species in the Glow Discharge; **Goodner, Kevin L.; Eyler, John R.; Barshick, C. M.; Smith, David H. 768
Reduced Mass Range Ion Trap MS for Atomic Ions; *Barinaga, Charles J.; Eiden, Gregory C.; Koppenaal, David W.; **Hemberger, Philip H. 769

Reducing Energy Dispersion in Plasma-Source Sector-Field Mass Spectrometry; *Burgoyne, Thomas; Hieftje, Gary; Hites, Ronald. 770
Insulator Surface Potential Measured by TOF SIMS; *Guo, X. Q.; Short, R. T. 771
Resonant Laser Ablation - Thin Film and Multilayer Analysis; *Allen, T. A ; **Gill, C. G.; Anderson, J. E.; Kelly, P. B.; Nogar, N. S. 772
High sensitivity LC-combustion-IRMS based on a moving belt; *Caimi, Richard J.; Brenna, J. Thomas. 773
LC Combustion Interface for High Precision Isotope Ratio Mass Spectrometry; Brand, Willi; *Dobberstein, Peter. 774
Optical versus Mass Spectrometry: The Race for Fieldable Isotopic Analysis; *Barshick, C.M.; Young, J.P ; Shaw, R.W.; Smith, D.H.; Ramsey, J.M. 775
Alumatrane Revisited: Distribution of Oligomeric Ions in EI, CI, and LSIMS; *Bartlett, Michael; Burns, Scot; Bruce, David; **Busch, Kenneth. 776
Characterization of Supported and Unsupported Transistion Metal Complexes; *Bartlett, Michael; Bruce, David; **Busch, Kenneth; Thomas, Susan; White, Mark, Bertrand, J. Aaron 777
A STUDY OF THE CLUSTER ION DISTRIBUTION FROM METAL NITRATES USING PDMS; *Ferrell, William; Van Stipdonk, Michael, da Silveira, Enio, Schweikert, Emile 778
Electrospray Ionisation of Polyoxoanions of W, Mo and Si in Aqueous Soln.; *Summerfield, Scott; Howarth, Oliver; Jennings, Keith 779
Study of the Stability of Metal Ion-Macrocycle Complexes by ESI-MS/CID/MS; *Znamirovschi, Calin G.; **Frutos, Dinorah; Enke, Christie G. 780
Atmospheric Pressure Chemical Ionization of Novel Bismuth Compounds; *Yhard, G Bradley *, Curtis, Jonathan M ^, Agocs, Lisa *, Burford, Neil * 781

Wednesday Posters - Trapped Ions

Comparison of ICR cells with open geometry for FT-ICR; *Kuhnen, Florian; Spiess, Iris; Wanczek, Karl-Peter. 782
A comparison of fundamental principles and properties of ion traps; Engelmohr, Peter; *Wanczek, Karl Peter 783
A new structure for a FT Ion Trap used in electrical and combined modes; Engelmohr, Peter; *Wanczek, Karl Peter. 784
Characterisation of a multi-purpose open endcap ICR-Cell; *Spiess, Iris; Kuhnen, Florian; Wanczek, Karl-Peter. 785
Examples in Hierarchies of Optimally Triple Frequency Focused FTMS Traps; *Rempel, D. L.; Gross, M. L. 786
Short-Bore Concentric Tube Source for Coupling HPLC to ES/FTICR; *Harper, C. J.; Drader, J. J., Campbell, V. L.; Laude, D. A. 787
Experimental Effects of the Radial Electric Field in Open Cells; *Vartanian, V. H.; Laude, D. A 788

Investigation of Gas Phase Ion-Ion Reactions in an FTICR Trapped Ion Cell; *Torres, T. A., Laude, D A. 789
FTICR/TOF for Measuring Large Ion Populations in Penning Traps; *Schmidt, E. G , Laude, D. A. 790
Improved Ion Injection in a Single Trap Electrode Cell for FTICR; *Anderson, J. S.; Torres, T. A.; Vartanian, V H.; Laude, D. A. 791
Quadrupolar Excitation Efficiency in Non-Ideal FTICR Trapped Ion Cells; *Drader, J. J.; Hendrickson, C. L., Campbell, V. L ; Laude, D. A. 792
MALDI/FTICR Using Quadrupolar Excitation in a Single Trapped Ion Cell; *Anderson, J. S.; Laude, D. A 793
ESI/FTICR Analysis of Protein Conformation; *Campbell, V. L ; Laude, D. A. 794
A New Approach for Stabilizing Ion Radial Motion in FT-ICR; Vartanian, V H., *Laude, D. A. 795
Facile Implementation of Quadrupolar Axialization in FTMS; *Ijames, C. F. 796
Electron Bean Induced Axialization of Ions in FT-ICR; Amster, Jon; *Easterling, Michael. 797
Experimental and Theoretical Studies of Broadband Quad Excite in FT-ICR; *Pitsenberger, Cynthia; Amster, I. Jonathan 798
Quadrupole Excitation Trapping during Electron Beam Events in ICR; Hatcher, Joey; *Bartmess, John. 799
Studies of Large Individual Ions by FTICR Mass Spectrometry; *Chen, Ruidan; Bruce, James E ; Cheng, Xueheng, Dale, Mitchell W., Hofstadler, Steven A.; Anderson, Gordon A.; Smith, Richard D 800
A New Dual Cell for Selective Ion Accumulation and Separation in FTICR/MS; *Chen, Ruidan, Bruce, James E ; Cheng, Xueheng, Hofstadler, Steven A , Anderson, Gordon A.; Rockwood, Alan L , Udseth, Harold R., Smith, Richard D 801
Enhanced Selective Ion Accumulation with Dipolar Magnetron Excitation; *Bruce, James; Anderson, Gordon; Chen, Ruidan; Cheng, Xueheng; Gale, David; Hofstadler, Steven; Schwartz, Brenda; Smith, Richard 802
Selective Ion Excitation and Isolation in Trapped-Ion Mass Spectrometry; *Guan, Shenheng , Marshall, Alan G. 803
A Unified Description of Space Charge Effects in FT - ICR; *Mitchell, Dale W.; Smith, Richard D. 804
Minimization of Frequency Shifts for Improved Mass Accuracy in FT-ICR MS; *Gillig, Kent; Bluhm, Brian; Solouki, Touradj; Russell, David 805
FT-ICR Mass Spectral Analysis of Unevenly-Sampled Biomolecule Data; Guan, Shenheng, *Senko, Michael W.; Huang, Yulin; Marshall, Alan G., McLafferty, Fred W. 806
Optically Detected Electron Spin Resonance of Trapped Mass-Selected Ions; *Li, Guo-Zhong, Guan, Shenheng; **Dalal, Nar S; Marshall, Alan G. 807
A Combined rf Quadrupole/Magnetic Ion Trap for FT-ICR MS; *Huang, Yulin ; Li, Guo-Zhong , Guan, Shenheng , Marshall, Alan G. 808

Delayed Photofragmentation of Size Selected Gold and Silver Cluster Ions; Lindinger, M. ; Dietrich, G.; Kluge, H.-J.; **Lützenkirchen, K. ; *Schweikhard, L. , Walther, C.; Ziegler, J. 809
Instabilities of Ion Motions in Ion Cyclotron Resonance Traps; *Schweikhard, L. ; Ziegler, J. ; Bopp, H. ; **Lützenkirchen, K. 810
Single- and Two-Photon Fragmentation of Stored Gold Cluster Ions; Walther, C ; Becker, St.; Dietrich, G.; Kluge, H.-J., Lindinger, M. ; **Lützenkirchen, K. ; *Schweikhard, L. ; Ziegler, J. 811
Substituent distribution analysis in O-methyl celluloses by MALDI-FT-ICR-MS; *De Koster, Chris G.; Duursma, Marc C.; Arisz, Peter W ; Heeren, Ron M.A.; Boon, Jaap J. 812
Characterisation of electrosprayed polymers with MALDI-FT-ICR-MS; *Heeren, Ron M.A. ; van Rooij, Gerard J.; Duursma, Marc; de Koster, Chris G.; Boon, Jaap J. 813
FT/MS Analysis of Block and Random Polyester-Urethane Polymers; *Ludicky, Robert. 814

Wednesday Posters - Environmental Analysis

Halogenated Aromatic Compounds in Air Particulates SRM 1648 & 1649; *Xu, Ming; **Kim, Hyun Sik; Guan, Shenheng; Marshall, Alan G.; Dougherty, Ralph C. 815
A New Approach for the Analysis of Volatiles in Complex Matrices; *Barshick, Stacy-Ann; Buchanan, Michelle; Guerin, Michael 816
EPA Method 8270 (semivolatiles) using a GC/Ion Trap Spectrometer; *Barshick, Stacy-Ann; Griest, Wayne; Worthy, Suzanne. 817
Factors Affecting Membrane Introduction Mass Spectrometry; *Ohorodnik, Susan; Callahan, John; Anderson, Mark; McElvany, Steve. 818
Direct Sampling Ion Traps vs. GC/MS for Monitoring VOCs in Groundwater*; *Wise, Marcus; Merriweather, Roosevelt; Guerin, Michael. 819
RAPID SAMPLING FOR RAPID ANALYSIS: A NEW METHOD FOR VOCs IN DRINKING WATER; *Gardner, Ben; Johnson, Jennifer; **Artaev, Viatcheslav; Sparkman, O. David; Holland, John. 820
Monthly Variations of Haloacetic Acids in Drinking Water by GC/MS; *Benoit, Frank M.; Williams, David T.; LeBel, Guy L. 821
Determination of Haloacetic Acids in Drinking Water by Electrospray LC/MS; *Kryak, David D.; Behymer, Thomas D. 822
Analysis of VOCs in water at the Parts-per-Quadrillion Level using MIMS; *Bauer, Scott; Bauer, Jan 823
Analysis of Pesticide Residues in Drinking Water using Megaflow ESI; *Rontree, John; Lowes, Steve; Claereboudt , Jan; Ackermans, P.; Van Hoof, F. 824
Formation of Organochlorine Compounds during Water Chlorination; *Lebedev, A.T.; Moshkarina, N.A.; Brodsky, E.S.; Klujev, N.A.; Petrosyan, V.S. 825

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Multispectral Identification of Ozonation By-products in Drinking Water; *Richardson, Susan D.; Thruston, Jr., Alfred D.; Collette, Timothy W.; **Patterson, Kathleen S.; Lykins, Jr.,Benjamin W. 826
Identification of Brominated Organics in Ozonated Drinking Water; *Thruston, Jr., Alfred D.; Richardson, Susan D.; Collette, Timothy W.; **Patterson, Kathleen S.; Lykins, Jr.,Benjamin W. 827
Isotope Ratio Monitoring for Stable Isotope Analysis on CH4 and N2O in Air; *Brand, Willi A.; Seedorf, Ronald. 828
Evaluation the Air-Quality in Mass Spectrometry Labs. by SPTD/GC/MS; Anren, Hu; *Jentaie, Shiea. 829
GC-MS-MS a novel approach for monitoring the bacterial load in air.; *Krahmer, Mark; Fox, Alvin; Fox, Karen. 830
Transfer Line on MS Sampling and Analysis of VOCs in Air; *Thompson, Cyril; Wise, Marcus; Guerin, Michael. 831
MONITORING TRACE CONTAMINANTS IN AIR VIA ION TRAP MASS SPECTROMETRY; *Palmer, Peter T ; **Karr, Dane, Pearson, Richard; Valero, Gustavo; Wong, Carla. 832
Air Analysis for VOCs: Tenax Collection vs. On-Line Membrane Sampling; *Cisper, M.E.; Gill, C.G ; Kok, G.L.; Hemberger, P.H. 833
Characterization of Volatile Organic Compounds by Thermal Desorption-GC-MS; *Ma, Cheng-Yu; Skeen, Todd T ; Dindal, Amy B.; Higgins, Cecil E.; Jenkins, Roger A. 834
Analysis of Air Samples from Polypropylene Film Plants using Thermal Desorp; *Chuang, C.H. William; Arnold, Elizabeth; Roy, Tim 835
Volatile Organic Compound (VOC) Analysis in Blood Using Spray Extraction; *St-Germain, François; Vachon, Benoit; Brunet, Julie; **Mamer, Orval; Des Rosiers, Christine ; Montgomery, Jane. 836
A Study of Semi-Volatile Organic Emissions of Polymer Combustion by GC/MSD; *Carlson, Joel; Dunayevskiy, Yuriy; Atal, Ajay; Panagiotou, Thomai; Vouros, Paul; Levendis, Yiannis. 837
STRATEGIES FOR IDENTIFICATION OF OFFGASSED VOLATILE ORGANIC COMPOUNDS; *Yang, Lily; Leano, Hector; Martin, Millie; Limero, Thomas; James, John. 838
Electrospray Ionization and Tandem Mass Spectrometry of Dyes; *Fencl, Jennifer B.; Glish, Gary L.; **Voyksner, Robert D. 839
Analysis of Surfactants and Their Metabolites by HPLC-IS-MS and MS-MS; *Raffaelli, Andrea; Pucci, Sergio; Campolmi, Laura; Salvadori, Piero 840
Determination Surfactants In Water by LC and LC-MS; *Scullion, Simon; Clench, Malcolm; Cooke, Michael. 841
Biodegradation Kinetics and Pathways; *Morrall, Stephen W.; Lawrence, David L.; Federle, Thomas W. 842

Detection of Adsorbed Atmospheric Contaminants Using Static SIMS; *Groenewold, Gary; Harrison, Evan; Delmore, James; Ingram, Jani; Appelhans, Anthony; Dahl, David. 843
DETERMINATION OF RADIATION STABILITY OF CROWN ETHERS; *CAMPBELL, JAMES A ; GRANT, KAREN E.; WESTER, DENNIS W.; ABASHKIN, V.M.; JOHNSTON, PAUL F. 844
GC/MS Analyses of Hanford Waste Tank Vapors Using SUMMA[a] Canisters; *Lucke, Richard B; McVeety, Bruce D; Klinger, George S; Clauss, Therese W; Fruchter, John S; Goheen, Steve C 845
MASS SPECTROMETRY ANALYSIS OF TANK WASTES AT THE HANFORD SITE; *CAMPBELL, JAMES A.; LUCKE, RICHARD B.; MONG, GARY M.; CLAUSS, SCOTT A. 846
GC/MS Method for the Chemical Speciation of Arsenic and Selenium Compounds; *Cameron, Douglas; Brozovich, Tara; Watts, Heath; Wang, Jin. 847
Organoarsenic and Organotin Speciation by Ionspray-MS-MS and LC-MS-MS; *Corr, Jay J.; Siu, K.W. Michael. 848

Wednesday Posters - Drug & Metabolism

Quantitation of a CCK Ligand Using LC/MS/MS on Traps and Quadrupoles *Moseley, Arthur, Tippin, Tim, Hart, Robert; St. Claire, Bob; **Schwartz, Jay, Uhrich, Mark. 849
Concomitant Detection of Tazarotene and Three Metabolites from Human Urine; *Luo, Wendy; Matsumoto, Richard; Tang-Liu, Diane; Breau, Alan. 850
Quantification of Dofetilide and its N-desmethyl metabolite in Human Serum *Schneider, Rick, Fouda, Hassan. 851
Measurement of CO2 Exchange Rates in Transferrin by Mass Spectrometry; *Brown, Todd; Hileman, Fred; **Harris, Wes. 852
Analysis of 2-Butoxyethanol and Metabolites in Human Urine by GC & ESI/MS; *Markham, Dan A ; Bartels, Micheal J.; Corley, Richard A.; **Rettenmeier, Albert W. 853
Evaluation of Nalmefene Metabolism in Rats and Dogs Using Thermospray LC/MS; *Mathur, Chandra; Murthy, Satya S ; Kvalo, Loretta T.; Wilhelm, Jeffrey A 854
Quantitation of Ritalin and Ritalinic Acid in Human Plasma by API LC/MS/MS; Cassidy, Ken C.; *Matassa, Luca C. 855
Automated LC/ESI/MS/MS Quantitation of a Phospholipid Drug in Human Plasma; *Hamilton, Brenda; Graham, Elizabeth, Abolin, Craig; **White, Robert, Oglesby, Thomas. 856
Ultra Trace LC/MS/MS Determination of Reserpine in Plasma.; **Anderson, Melissa; *Wachs, Timothy; Henion, Jack. 857
Lovastatin and Hydroxy-acid Lovastatin in Dog Plasma via LC-APCI/MS/MS; *Korfmacher, Walter A.; Lapiguera, Amelia P.; Lin, Chin-Chung; **Langevin, Carolyn N.; Oglesby, Thomas D. 858

LC/MS/MS QUANT. OF LOVASTATIN & ITS HYDROXY ACID IN MOUSE & RAT PLASMA; *Wu, Henry, Y, Henion, Jack , Zhao, Jamie; Korfmacher, Walter A ; Lin, C.C. 859
QUANTITATION OF LTE4 IN HUMAN URINE BY ION SPRAY LC/MS/MS; *Wu, Henry Y.; Li, Lily Y.-T ; Henion, Jack; Krol, George J. 860
Automation of Rapid, High Sensitivity Pharmacokinetic Assays by LC/MS/MS; *Stoney, Ken; Nugent, Kerry; **Land, Adrian P., Bier, Mark E.; Schwartz, Jae, Wheeler, Kevin. 861
Semi-automated Electrospray LC/MS/MS Quantitation of CGS 20286A in Plasma; *Hayes, Michael J.; Joshi, Jill C.; Carlsen, Steve; Powell, Mark L. 862
Quantitation of Cefoxitin in plasma by LC/MS Negative Ion Electrospray; *Zamecnik, Jiri; Florio, Eugene. 863
Determination of Novel Thrombin Inhibitors in Animal Plasma by LC/API-MS; *White, Dineen J.; Russell, John W.; Wang-Iverson, David. 864
LC/MS/MS Method for the Determination of Nicotine & Cotinine in Plasma; *Xu, Allan; Havel, Jim; Petersen, Mary; Hulse, James. 865
Tetracyclines in Honey, Eggs and Animal Tissues by ESI MS and MS/MS.; Snider, Neil S ; *Malis, Greg M 866
Determination of a 4-Azasteroid in Serum Using Negative Ion APCI LC/MS *Halm, Kathy; Lloyd, Thomas, Moss, M. Lee. 867
Determination of a 5-HT receptor agonist by LC-APCI-MS-MS; *Pleasance, Stephen; Fraser, Ian; Allanson, John; Jones, Anne. 868
Quantitative Analysis of Tirilazad Mesylate in Plasma by APCI/MS-MS.; *Hauer, Michael J.; Moore, Theresa A.; Steenwyk, Rick C.; Bombardt, Paul A , Pearson, Paul G 869
GC/MS and LC/MS Confirmation of Malachite Green Metabolites in Catfish; *Turnipseed, Sherri; Roybal, Jose; Hurlbut, Jeff; Long, Austin. 870
ESI-MS Analysis of Bioactive Isoleukotrienes; *Harrison, Kathleen; Murphy, Robert C. 871
LC-ESI-MS/MS of polyamines and basic amino acids.; *Feistner, Gottfried J 872
LC/LC/MS/MS ANALYSIS OF HUMAN PLASMA FOR A "STICKY" PEPTIDE; *Li, Lily Y.-T., Zhao, Jamie, Henion, Jack; Newman, Michael 873
Detection of the Endogen NO Gas from Living Animals by Mass Spectrometry; Delacotte, J -M.; Faye, T.; *Regert, M.; Rolando, C.; Sablier, M 874
MACROMOLECULE ISOTOPE-RATIO MEASUREMENTS WITH HPLC/CRIMS; *Osborn, Blaire L.; Abramson, Fred P. 875
QUANTITATIVE ASPECTS OF MASS SPECTROMETRIC IMMUNOASSAY; *Nelson, Randall W.; Krone, Jennifer R.; Lewis, J. Kathleen; Williams, Peter 876
The Analysis of Flunixin Residues in Animal Tissues by NICI-GC-MS; *Kwok, David; Chow, Pauline; Young, Larry; Mori, Brian. 877
GC/MS Determination of Perillyl Alcohol Metabolism After Oral Dose in Dog; *Phillips, Lawrence R , Supko, Jeffrey G.; Malspeis, Louis 878

Positive chemical ionisation GC-MS analysis of nicotine and continine; *Loftus, Neil; Skarping, Gunnar; Dalene, Marianne; Speakman , Alison ; Bukowski, Nick... 879
Analysis of anagrelide in human plasma by GC/ECNCI MS.; *Yeola, Suresh N.; Saleh, Samir A.; Sanchez, Stephanie C.; Kambouris, Sara J.; Chaudhary, Ajai K.; Migdalof, Bruce H.; Blair, Ian A... 880
QUANTITATIVE DETERMINATION OF ZK 118372 IN HUMAN PLASMA USING NCI-GC/MS; *BRUDNY-KLOEPPEL, Margarete; GUENTHER, Clemens; WEISS, Christian... 881
Quantitation of Odd-Numbered Long Chain Fatty Acids in Red Cell Membranes; *Giordano, G.; Burlina, A., Magarotto, M.; Edini, C.; Zacchello, F. ... 882
A Novel Approach for Analysis of Fadrozole Pseudoracemates in Human Plasma; *Iannucci, Robert; Linberg, Leonid; Powell, Mark... 883

Wednesday Posters - Spray Ionization

Sonic Spray Ionization Method for API Mass Spectrometry; *Hirabayashi, Atsumu, Sakairi, Minoru; Takada, Yasuaki; Koizumi, Hideaki ... 884
Electrospray LC/MS With Orthogonal TOFMS and Ion Trap TOFMS *Purves, Randy; Li, Liang... 885
Sensitivity Advances In Electrospray FTMS; *Kruppa, Gary; Stacey, Catherine; Speir, J. Paul; **Whitehouse, Craig; Laukien, Frank... 886
High Sensitivity Electrospray With A Fourier Transform Mass Spectrometer; *Stacey, Catherine; Kruppa, Gary; Spier, J. Paul; **Mann, Matthias... 886
Characterization of in vitro Metabolites of Ziprasidone by Mass Specrometry; *Kamel, Amin; Prakash, Chandra... 887
Reduction of Ambient Air Contaminants; Aebi, Beat; *Henion, Jack... 888
Pulsing Electrospray and Selecting Ions from Electrospray by Ion Mobility; **Li, Guo-Zhong; Wang, Weimin; Kim, Tamen; *Moore, Robert B... 889
Achieving High Sensitivity LC/MS with an API-Ion Trap Mass Spectrometer; *Habibi-Goudarzi, Sohrab; Henion, Jack; **Duffin, Kevin, L.; Hileman, Fred D.;... 890
Capillary, Multicapillaries or Porous Tube for Electrospray Ion Sources; *Beaugrand, C.; Charbonnier, F.; Rolando, C.; Sablier, M.; Saru, F... 891
Transport of Electrospray Particles through the Interfaces; *Bondarenko, Pavel; Macfarlane, Ronald... 892
Ion Distribution of Electrospray and Efficiency of Transferring Ions; Wang, Weimin; **Li, Guo-Zhong; Kim, Tamen; *Moore, Robert B... 893
Stability of a Liquid Jet Emerging from an Electrospray Cone-Jet; *Sheehan, Edward; **Willoughby, Ross... 894
Secondary Droplet and Ion Formation in Electrospray: The Teardrop Model; *Sheehan, Edward; **Willoughby, Ross... 895
Role of Peptide Structure in the Production of Ions from Charged Droplets; *Downard, Kevin; Biemann, Klaus... 896

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Tuning Parameters: Their Dominant Role in Electrospray Ion Intensities; *Cunniff, John; Vouros, Paul... 897
The Characterization of m/z Deviates and Molecular Mass Uncertainty; *Juneau, Paul L.; Giordani, Anne B., Pyne, David A... 898
Chemical Redox Reactions in ES-MS: Study of Electrode Reactions; *Zhou, Feimeng; Van Berkel, Gary... 899
Electrochemistry Combined On-line with Electrospray Mass Spectrometry; *Van Berkel, Gary; Zhou, Feimeng... 900
Formation of Protonated Ions from Acidic Species at High pH in Electrospray; *Smith, Richard W... 901
Electrospray Ionization, Maximum Charge States to Multiplexing; *Schnier, Paul D.; Williams, Evan R... 902
Protein Cations from Basic Solutions with an API III and an API 100.; *Le Blanc, J.C. Yves; Shushan, Bori; **Siu, K.W. Michael; Guevremont, Roger... 903
Effects of Organic Solvents on Aerosol MALDI Ion Signal *Beeson, Michelle D ; Wei, Xiaona; Russell, David H... 904
Analyzing Thermally Labile Compounds in ESI Sources with Heated Capillaries; *Kleintop, Brent; Lim, H.K.; **Oglesby, Thomas; Chan, Kelvin; Sisenwine, Samuel... 905
Peptide Mixture Analysis by Combining Electrospray-CID-MS and Chemometrics; *Cusworth, III, William; Turecek, Frantisek... 906
Ion Solvation in Electrospray Generated SDS Clusters; *Gao, Q; Zhang, J; Harms, A. C.; Udseth, H. R.; Rockwood, A. L ; Sherman, M. G.; Smith, R. D... 907
Rapid Molecular Weight Determination Using Electrospray Ionization; *Gedamke, Rich; DiDonato, Gerald; Hail, Mark; Lee, Mike... 908
Adventures in the Positive Ion ESIMS of Acids and Neutral Molecules; *Shah, Nikhil; Fitch, William... 909
Electrospray Ionization of Neutral Complexes from Non-Polar Solvents; *Cheng, Xueheng; Gao, Quanyin; Smith, Richard D.; Simanek, Eric E.; Mammen, Mathai; Whitesides, George M... 910
Electrospray Mass Spectra of Less Polar Compound Dissolved in n-Hexane; Wang, Wen-shyang; Huang, S-wan ; *Shiea, Jentaie... 911
Low Temperature Electrospray Mass Spctra of Thermally Unstable Compound; Wen-Shyang, Wang; Chin-Hsiung, Wang; *Jentaie, Shiea... 912
Multi-channel ESI source for directly coupling to HPLC; Chinghsiung , Wang, *Jentaie, Shiea... 913
Negative ESI Mechanism of TFA/TFE Derivatives of Glyphosate and AMPA; *Fujiwara, Hideji; Singh, Rajendra. K.; Nadeau, Ronn; Chott, Robert C... 914

Wednesday Posters - Laser Desorption/Ionization

MALDI of Non-Covalently Bound Complexes.; *Woods, A.S.; Buchsbaum, J.C., Berg, J.M.; Cotter, R.J. 915
Primary Structure of Proteins Determined by MALDI Mass Spectrometry; Yang, Hou-Jun; Amft, Matthias; Grundwuermer, Johann M.; Li, Yiao-Ling, *Grotemeyer, Juergen. 916
MALDI/TOF/MS and Recombinant HIV Protein Expression; *Parker, Carol; Papac, Damon; Tomer, Kenneth. 917
MALDI-TOF Analysis of Peptide Digestion Mixtures with Detergents; *Gharahdaghi, Farzin, Fernandez, Joseph; Mische, Sheenah, M. 918
Sample Preparation for Protein Fingerprinting of Bacteria Using MALDI MS; *Liang, Xiaoli; Cain, Teresa C.; Bai, Jian, Liu, Yan-Hui; Lubman, David M. 919
MALDI Combined with Chemical Reaction Methods for Studying Protein Folding; *Zhang, Jian; Wang, Yajun; Edmondson, Rick; Gillig, Kent; Hayes, Timothy; Russell, David 920
Carboxyl-Terminal Ladder Sequencing of Peptides and Proteins; *Wang, Rong; Chait, Brian T 921
PROTEIN CONFORMATION, HYDROGEN BONDING, AND ENERGY TRANSFER IN MALDI; Bencsura, Akos; *Vertes, Akos. 922
Mass Tracer Methods based on MALDI; *Whittal, Randy M.; Schriemer, Dave C.; Li, Liang 923
MALDI Mass Spectrometry of Tissue Extracts ; *Ogorzalek Loo, Rachel R , Andrews, Philip C 924
Evaluation of Maldi.MS For Agricultural Applications; *Shalaby, Lamaat; Hubbard, Natalie; Stahl, Bernt; Hillenkamp, Franz; Zeng, Jianru. 925
CID studies of MALDI generated peptide ions by RETOF MS; *Holle, Armin; Köster, Claus. 926
Effective Methods for Characterization of Membrane Proteins by MALDI-MS; *Shyong, Bao-Jen, Mitchell, Charles; Andrews, Philip 927
Assessment of Photoaffinity Crosslinking of Macromolecules by MALD MS; *Farmer, Terry B.; Caprioli, Richard M. 928
DESALTING PROCEDURE FOR HIGH SENSITIVITY ANALYSIS OF PEPTIDES BY MALDI-MS; *Zhang, Haiying; Caprioli, Richard M. 929
DIFFERENTIATION OF MULTIMERIC ANTIGENS BY MSIA AND ENZYMATIC MODIFICATION; *Nelson, Randall W.; Krone, Jennifer R.; Dogruel, David; Lewis, J. Kathleen; Williams, Peter 930
Sequence Specific Fragmentation Generated by MALDI in Ion Trap/reTOF; *Lee, Heewon; Lubman, David. 931
Strategy to Locate Cysteine Residues by Specific Cleavage and MALDI-TOF MS; *Wu, Jiang; Gage, Douglas A ; Watson, J Throck. 932

MALDI-MS of Proteins Electroblotted onto Membranes after 2D-PAGE Separation; *Strupat, Kerstin, **Eckerskorn, Christoph; Karas, Michael; Hillenkamp, Franz. 933
Oligonucleotide And Protein Analyses Using Membranes And MALDI-MS; *Stevenson, Tracy I ; Loo, Joseph A. 934
LDMS for Fast DNA Analysis and Disease Diagnosis; *Chen, C. H.; Taranenko, N I.; Allman, S. L.; Tang, K ; Matteson, K. J.; Ch'ang, L. Y. 935
Oligonucleotide Analysis by MALDI MS via Ion Trap/reTOF MS; *Liu, Yan-Hui; Bai, Jian; Qian, Mark G.; Liang, Xiaoli; Lubman, David M. 936
Synthesis and MALDI Characterization of Electrophore-Labeled DNA; *Hurst, Gregory B.; Britt, Phillip F.; Buchanan, Michelle V 937
Use of a Polymeric Substrate in MALDI MS for DNA Mapping and Screening; *Liu , Yan-Hui; Bai, Jian, Liang, Xiaoli; Lubman, David M 938
The Effect of Impurities on the Analysis of Oligodeoxynucleotides by MALDI; *Shaler, Thomas; Wu, Kuang Jen; Wickham, Juanita; Becker, Christopher 939
Analysis of DNA Dideoxy-Sequencing Reaction Products by MALDI-TOFMS; *Shaler, Thomas; Wu, Kuang Jen, Sannes, Kristin; Becker, Christopher. 940
Protocols for improved laser ejection/ionization TOFMS of oligonucleotides; *Srinivasan , Jannavi, R.; Levis, Robert, J., Narayanaswami, Gowri. 941
IMPROVEMENT IN OLIGONUCLEOTIDE ANALYSIS BY ADDUCT FORMATION; *Tang, Xiaodong, **Callahan, John; Zhou, Ping; Hayes, Joe; Vertes, Akos*1-1. 942
MALDI Post-Source Decay of Oligonucleotides; *Deterding, Leesa; Tomer, Kenneth. 943
NEW INSTRUMENTAL APPROACHES TO TOF MASS SPECTROMETRY OF DNA; *Dogruel, David; Nelson, Randall W.; Williams, Peter. 944
PROGRESS IN DNA SEQUENCING AND FUNDAMENTAL STUDIES USING MALDI-TOFMS; *Chou, Chau-Wen; Nelson, Randall W.; Williams, Peter. 945
MALDI of Drug Compounds from Intact Biological Tissue; *Reddick, Christopher, Yost, Richard. 946
Application of MALDI TOFMS for Quantitative Analysis; *Hensel, Russell; King, Richard, Owens, Kevin. 947
Analysis of Synthetic Polymers and Copolymers by MALDI-MS; *Schaer, Martin. 948
Characterization of Polyesters by Transesterification Using MALDI TOF MS; *Williams, John B.; Gusev, Arkady I.; Hercules, David M. 949
Accuracy of MALDI for Mol. Weight Characterisation of Synthetic Polymers; *Overberg, A.; Ingendoh, A., Keane, A.; Sutton, C ; Cottrell, J S. 950
High Resolution MALDI Studies of Polymer Mixtures and Copolymers; *Schriemer, Dave C; Li, Liang. 951
Analysis of GPC Standards by Matrix-Assisted Laser Desorption/Ionization; Hanley, Brian; Parees, David; *Hanton, Scott; **King, Richard; Owens, Kevin. 952

Structural Determination of Azo Dyes by Photoionisation Mass Spectrometry; *Wright, Scott; Dale, Michael; Jones, Anita; Langridge-Smith, Patrick. 953
Two Step Laser Mass Spectrometry of Copolymerised Indole Derivatives; *Mackintosh, J. Gordon; Mount, Andrew; Wright, Scott; Redpath, Craig; Dale , Michael; Langridge-Smith, Patrick. 954
Molecular Analysis From Organic Substrates Using Laser Mass Spectrometry; *Dale, Michael; Langridge-Smith, Patrick; **Zhan, Qaio; Zenobi, Renato; Costello, Kevin. 955
Wavelength Dependent Photo-ionization of some Amines at Metal Surfaces; *Goldschmidt, Robert; Owens, Kevin. 956
Enhanced Detection Limits of High Molecular Weight PAHs Using LD-TOF MS; *Soloveytchik, Boriana; **Miller, John; Vertes, Akos. 957
Real-Time Monitoring of Aerosol Reactions; *Carson, Peter; Johnston, Murray; Wexler, Anthony. 958
Laser Desorption/FTMS For Polymer Microstructure Characterization; *Qian, Kuangnan; Tianlan, Zhang; Ridge, Douglas P. 959
The electronic spectroscopy of some p-alkylphenols and catechols *Grace, Louis I.*; Barstis, Toni L.O.**; Lubman, David M.; Dunn, Thomas M. 960
Laser Desorption/Ionization of Size-Resolved Liquid Microdroplets; *Mansoori, Bashir; Johnston, Murray; Wexler, Anthony. 961
Laser Desorption Mass Spectrometry of Hydroxy-Nitro-PAHs; *Bezabeh, Dawit; Jones, A. Daniel; Kelly, Peter B. 962
Infrared spectroscopy of methanol attached to gold tetramer cluster ions; **Dietrich, G.; Walther, C.; Kluge, H.-J.; Lützenkirchen, K. ; *Schweikhard, L. ; Ziegler, J. 963
Laser Desorption/Resonant Laser Ablation - Trace Analysis of Solid Matrices; *Gill, C. G.; Earl, W. L. ; Garrett, A. W.; Nogar, N. S.; Hemberger, P. H. 964
Lanthanide, Thorium, and Uranium Oxide Clusters Formed by DLV/FTICR; *Pires de Matos, António; Marçalo, Joaquim; Leal, João Paulo. 965
Photolabalisation of Fe Bound Phosphine Ligands: Laser Desorption FTI CR MS; *Aplin, Robin; Davies, Stephen; McMarthy, Tom; Watkins, Carl; Evard, Dwight. 966
Laser ablation mass spectrometry of sodium penetrated petroleum cokes; *Willett, Gary; Hopwood, Femia; Fisher, Keith; **Greenhill, Paul. 967
Laser Mass Spectrometry of Synthetic Linear and Dendritic Polymers.; *Mowat, Ian; Donovan, Robert; Bruce, Morag; **Monaghan, John. 968

Thursday Orals - Hydrogen Bonding Interactions

Effects of Protonation on Structure and Entropy of Bifunctional Molecules; Szulejko, Jan; *McMahon, Terry; **Audier, Henn; Milliet, Ariel. 969
Detection and Characterization of Gas Phase Cyclodextrin Complexes Dejsupa, Chadin; Dearden, David. 970
Probing Hydrogen-Bonding Interactions in an Ion Trap; *Brodbelt, Jennifer; Colorado, Armando; Vartanian, Victor; Chen, Jim. 971
Studies of Photoinduced Proton Transfer Reaction in H-Bonded Clusters; *Huang, Yong; Russell, David H. 972
Protonated Dimethyltartrate Dimer Decomposition Chirality Effects in FTMS; *Nikolaev, Eugene; McMahon, Terry. 973
In Search of Non-Classical Ethyl Cation Stabilized by Organic Molecules.; *Zagorevski, Dmitri; Holmes, John L. 974

Thursday Orals - Mass Spectrometry in Immunology

Schistosome Surface Oligosaccharides Modulate Immune Response; *Reinhold, Vernon N.; Reinhold, Bruce B.; Velupillai, Palanivel; Harn, Donald A. 975
Identification of a Graft-vs-Host Disease Associated Human Minor Antigen; *Sherman, Nicholas E.; den Haan, Joke M.M.; Hunt, Donald F.; Shabanowitz, Jeffrey; Engelhard, Victor H.; Goulmy, Els. 976
CE-MS and MS-MS analyses of lipopolysaccharides from Pseudomonas aeruginosa; Auriola, Seppo I-1; *Thibault, Pierre; Sadovskaya, Irina I-2; Masoud, Hussein I-2; Altman, Elenora I-2; Richards, James I-2. 977
A Human Melanoma Antigen which Results from Post-Translational Modification; *Hendrickson, Ronald C.; Skipper , Jonathan A.; Gulden, Pamela H.; Shabanowitz, Jeffrey; Chen, Y.; Slingluff, C. L.; Englehard, V H.; Hunt, Donald F. 978
Tandem Mass Spectrometry & Data Analysis of Immunological Peptide Mixtures; *Yates, John R. III; McCormack, Ashley L.; Eng, Jimmy K.; DeRoos, Paul C.; Rudensky, Alexander Y. 979
ES and MALDI MS Analysis of Glycosylation-Engineered a-1 Acid Glycoprotein; *Bean, Mark; Huddleston, Michael; O'Shannessy, Daniel; Carr, Steven. 980
Epitope Determination by Mass Spectrometry: HIV p24; *Tomer, Kenneth; Papac, Damon; Parker, Carol. 981
Probing the antibody-antigen interaction by affinity-mass spectrometry; *Zhao, Yingming; Muir, Tom; Kent, Stephen H.B.; Chait, Brian T. 982

Thursday Orals - Ion Trap Mass Spectrometry

Resonant Excitation of Injected Atomic Ions in an Ion Trap MS; *Eiden, Gregory C.; Barinaga, Charles J.; Koppenaal, David W 983
Ion Remeasurement in the RF Quadrupole Ion Trap; *Goeringer, Douglas; McLuckey, Scott; Crutcher, Richard. 984
Buffer Gas and q-eject Effects on the Performance of an Ion Trap; *Lammert, Stephen A.; Wells, J. Mitchell. 985
Effect of Ion population Upon MS/MS Parameters in a Quadrupole Ion Trap; *Griffin, Timothy; Yost, Richard. 986
Fragmentation of Peptides by MicroES/ Quadrupole Ion Storage (QUISTOR) MS; Kšrner, Roman; *Wilm, Matthias; Mann, Matthias; Houthaeve, Tony. 987
Peptide Sequencing Using Fast MS and MS/MS Scans on a Quadrupole Ion Trap; *Bier, Mark E ; Schwartz, Jae C.; Zhou, Joe; Taylor, Dennis; Syka, John; Fies, Bill; Borchers, Torsten; James, Mike. 988
Practical Matrix-Assisted Laser Desorption Ion trap MS for Peptide Analysis; *Qin, Jun; Chait, Brian T 989
Analyzing Mixtures With a Hybrid Quadrupole/Ion Trap Mass Spectrometer; *Jonscher, Karen R.; Yates, John R. 990
A Portable Atmospheric Sampling QUISTOR/reTOF- MS for Air Monitoring; *Grace, Louis I.; Chambers, David M.; Thomas, Stan W.; Andresen, Brian D. 991
Identification of in vitro Bupropion Metabolites by APCI LC-Ion Trap MS; *Taylor, Lester; Singh, Romi, Chang, Sai; Johnson, Robert, Schwartz, Jae; Barber, Michael. 992
Analytical Protocols for Environmental Substances using an Ion Trap; Plomley, Jeffry B , Koester, Carolyn J., Lausevic, Mila, Xuewu, Jiang, *March, Raymond E.; Londry, Frank A. 993

Thursday Orals - Time of Flight Mass Spectrometry

Time-of-Flight (TOF) Mass Spectrometry--Nearing the Half Century; * Standing, K. G. 994
Organic Secondary Ion Imaging by Time-of-Flight Secondary Ion MS (TOF-SIMS); *Lindley, Patricia M.; Reich, Fraser. 995
Important Aspects Concerning the Quantification of Biomolecules by TOF-SIMS; *Muddiman, David C; Nicola, Anthony J, Proctor, Andrew; Hercules, David M. 996
Peptide Sequencing by Carboxypeptidase Digestion Coupled with MALDI-TOF; *Patterson, Dale; Tarr, George; Martin, Stephen; Regnier, Fred. 997
MALDI electrostatic analyzer TOF mass spectrometry studies of biopolymers; *Wu, Kuang Jen; Marsh, Eugene; Odom, Robert. 998
A Mass Analyzer for High Speed Liquid Chromatography; Andrien, Jr., Bruce; Boyle, James, Banks, Fred; *Dresch, Thomas; Haren, Patrick, Whitehouse, Craig. 999

ACHIEVING LINEAR DETECTOR RESPONSE IN TOF-MS; *Stresau, Dick, Hunter, Kevin; Gray, John 1000
A Time Focusing Equation and a Classical Uncertainty Relation in TOFMS; *Stein, Ronald. 1001
Analytical Form of Position Focusing in the Parabolic Electrostatic Field; *Stein, Ronald. 1002
Space-Velocity Correlation Focusing; COLBY, STEVEN; *REILLY, JAMES; 1003
Tandem Mass Spectrometry on a Triple-ESA Time-of-Flight SIMS Instrument; *Kristo, Michael; Odom, Robert. 1004

Thursday Orals - Energy & Petrochemicals

Mass Spectrometric Studies on Porphyrins and Geoporphyrins; *Quirke, J. Martin E.; Yost, Richard A.; Van Berkel, Gary J. 1005
Mass Spectrometry of Porphyrins: Ionization and Appearance Energies; *Ferguson, James A.; Quirke, J. Martin E ; Johnson, Jodie V., Yost, Richard A. 1006
Heavy Resid Characterization using High Resolution and Laser Desorption MS; *Hunt, Jerry E.; Kim, Yeonhee; Winans, Randall E.; Anderson, Ken B , Miller, Jeffery. 1007
The New EPA GC/MS Method for Total Aromatics in Reformulated Gasoline; *Drinkwater, Donald, Nero, Vince. 1008
Analysis of Gasoline for Aromatic Hydrocarbons by GC/MS and by Low eV-HR/MS; *Grigsby, Ronald D.; McWilliams, Ted B. 1009
Hydrocarbon Analysis Using An Ion Trap/MS With External Ionization; *Teng, Siu. 1010
Industrial Applications of FTMS: A Present and Future Prospectus; *Campana, Joseph. 1011
The Identification of Zinc Dialkyldithiophosphates in Lubricating Oils; *Nero, Vincent; Drinkwater, Donald. 1012
FLUID CATALYTIC CRACKING PRODUCTS CHARACTERIZED BY GCMS; *Cheng, Michael, Hudson, James. 1013
Coupling FI-MS with LC for the Characterization of Heavy Sat'd Hydrocarbons; Liang, Zhenmin, *Hsu, Chang Samuel, Blum, Saul, Robbins, Winston; Grosshans, Peter. 1014

Thursday Orals - Organohalogens:New Issues & Techniques

Why Do We Still Care about Dioxins?; *Hites, R.A., Brzuzy, L., ... 1015
Ultrasensitive and Very Fast Analysis of Halogenated Toxicants; *Patterson, Donald G.; Jr; Liu, Zaiyou; Green, Vaughn E., Barr, John R 1016
Inventories of Toxic Organochlorine Compounds in the Great Lakes' Sediments; *Swackhamer, Deborah L., Pearson, Roger; Eisenreich, Steven J ; Long, David T. 1017

Characterization of Major Taxophene Components in Lake Sediments & Aquatic; *Stern, G.A.; Lowen, M.; **Miskimmin, B.M.; Muir, D.C.G.; Parlar, H.; Schindler, D.W.; Westmore, J.B. 1018
Dioxin and Furan Analysis by Ion Trap, Triple Quadrupole MS/MS, and HRMS; *Mercer, Roger S.; Plomley, Jeffry B.; Townsend, Jennifer A.; Waddell, Dave S.; Plomley, Jeffry B.; March, Raymond E. 1019
An Isotope Dilution Method for the Analysis of Chlorinated Diphenyl Ethers; *Ralitsch, Milan; Gottschalk, Russell; Birkholz, Detlef. 1020
Photoelectron Capture Negative Ion Mass Spectrometry of Organohalogens; *COLBY, STEVEN; HARRIS, WILLIAM; HANSER, KENT; REILLY, JAMES. 1021
Determination of Pesticides on Agricultural Samples by Static SIMS Analysis; *Ingram, Jani; Groenewold, Gary; Appelhans, Tony; Miller, David; Delmore, James. 1022
Real-time Analysis of Breath for Carbon Tetrachloride and its Metabolites; *Kenny, Donald; Thrall, Karla; Callahan, Patrick. 1023
TUNABLE ENERGY (0.03-60 eV) ELECTRON CAPTURE NEGATIVE ION SPECTROMETRY; *Laramee, James; Deinzer, Max. 1024

Thursday Posters - Fundamental Studies

STRUCTURES AND ELECTRONIC PROPERTIES OF FULLERENE-RELATED COMPOUNDS; *Hettich, Robert; Ying, Z. Charles; Compton, Robert. 1025
Reactions of Fullerene Oxides in a FT-Mass Spectrometer; *Holliman, Christopher; McElvany, Stephen 1026
Collision experiments with fullerene ions and molecular gases; *Cooper, Helen J; Gallagher, Richard T; Derrick, Peter J; Vulpius, Tore. 1027
Intermolecular Nitrile Oxide Transfer in Fullerene Isoxazolines; *Pogue, Robert; Meier, Mark; Thomas, Craig; Majidi, Vahid 1028
Ion Mobilities from FT-ICR Mass Spectral Peak Widths; *Pasa-Tolic, Ljiljana; Guan, Shenheng; Marshall, Alan G. 1029
Gas Phase Protonation of Aniline; *Nold, Michael ; Wesdemiotis, Chrys. 1030
Synthesis and Characterization of the 3,5-dehydrophenyl Anion; *Hu, Jun; Squires, Robert. 1031
Reactions of Radical Anions Having Formally Distinct Radical & Anion Sites; *Grabowski, Joseph J.; Owusu, Daniel. 1032
Photodetachment of Solvated Ions; *Yang, Yarjing; Peiris, Dil; Riveros, Jose M.; Eyler, John R. 1033
Advances in Applications of the Kinetic Method; *Cooks, R. Graham; Horn, Lynn; Chen, Guodong; Yang, Sheng; Patrick, Jeffrey. 1034
Gas Phase Ion Chemistry of Sulfonate Anions. *Smith, Jacob D.; O'Hair, Richard A.J.; Schmidt, Joseph A.R.; Williams, Todd D. 1035
Bond-Selective Photodissociation: Mechanisms and Applications; *Bookwalter, Craig; Ross, Philip; Johnston, Murray. 1036

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Collision Spectroscopy Involving Charge Permutation and Light Emission; *Wesdemiotis, Chrys; Beranova, Sarka; Polce, Michael J.; Wiedmann , Fred A. 1037
Collisionally Induced Emission Spectroscopy; *Wiedmann, Fred; Wesdemiotis, Chrys. 1038
Matrix Isolation of Mass-Selected Ions for Analysis by FTIR Spectroscopy; *Allison, John; Halasinski, Thomas; Godbout, Jerry; Leroi, George E. 1039
Spectroscopic Studies of the Electron Recombination of Several Small Ions; *Foley, B. Lachele; Adams, Nigel G.; Babcock, Lucia M.; Butler, Jeffery M.; Drucker, Mark B. 1040
Ab Initio Calculations of the Ar¥CO2+ Cluster Ion; *Gellene, Gregory 1041
Symmetry Breaking and Electron Correlation in (O2)-, O2, and (O2)+; Chandrasekher, Charu A., *Griffith, Kelly S.; **Gellene, Gregory I. 1042
Accurate Ionization Energies And Heats of Formation of Simple Enols; *Turecek, Frantisek. 1043
Theoretical Study of the Ring Closure of the 1,7-Octadiyne Cation; *Robbins, Ronny; Jensen, James; Berg, Fred. 1044
The Presence of Hydrogen Trioxide in the Gas Phase; *Fujii, Toshihiro; **Kishi, Hiroshi. 1045
Structure of isomeric Gly-Pro b2 ions calculated by ab-initio methods; *Eckart, Klaus; Holthausen, Max C., Koch, Wolfram; Spiess, Joachim. 1046
Fragmentation of Benzalacetones: Theory and Experiment; Heinicke, Ralf; Moritz, Fritz; *Grotemeyer, Juergen. 1047
Ion Pair Formation and Fragmentation in EIMS of Methyl Octadecanoate; *TAKAYAMA, Mitsuo; HIRAOKA, Kenzo; NAKATA, Hisao. 1048
Gas Phase Decomposition of Dimethyl(hydroxy)silyl Radical; *Nguyen, Viet; Shaffer, Scott, A; Hop, Marcel, C.E.C.A; Turecek, Frantisek. 1049
Evolution of the m/z91:92 ratio during CAD of Butylbenzene Molecular Cation; Beaugrand, C ; Rolando, C.; *Sablier, M. 1050
Can Protonated Peptides Fragment from Their Triplet States?; *Somogyi, Arpad; Wysocki, Vicki; **Mayer, Istvan. 1051
Study Of MS Decomposition Mechanisms In 2,3-Difluoro-dimethyl Succinates; *Parees, David. 1052
Energy Resolved Mass Spectrometry of Organophosphonates; *Wensing, Michael W.; Forch, Brad E.; Fifer , Robert A.; Snyder, A. Peter; Harden, Charles S. 1053
Energy Resolved Mass Spectrometry of Organophosphorus Esters; *Wensing, Michael W.; Forch, Brad E.; Fifer, Robert A.; Snyder, A. Peter; Harden, Charles S. 1054
Effect of Collision Gas on FAB-MS/MS Spectra from Calibration Point Method; *Lemire, Sharon; Busch, Kenneth. 1055
Considerations about the FAB ionization process of a-aminoacids *N. Domingues, Pedro ; L. Amado, Francisco ; F.Barros, Cristina; O. S. Marques, M. Graa; Ferrer Correia, A. J. 1056

PDMS Analysis of Frozen Cycloalkenes Betts, Robert; **da Silveira, Enio; *Schweikert, Emile. 1057
Biomolecular Cluster Formation in PDMS; *Demirev, Plamen; Eriksson, Jan; Hkansson, Per; Papaleo, Ricardo, Sundqvist, Bo; Zubarev, Roman. 1058
252Cf-PDMS of New Pyrazole Derivatives; Ponciano, Cassia; Lin, Whei; Pereira, Neila; Freitas, Antonio; Barrelro, Eliezer; *da Silveira, Enio. 1059
Matrix Effects on the Fragmentation of Vitamin B12 in PDMS *Blankenship, James; Van Stipdonk, Michael; Schweikert, Emile 1060
DESORPTION OF PEPTIDE IONS USING MALDI MATRICES IN CONJUNCTION WITH PDMS; *Van Stipdonk, Michael; Blankenship, James; Schweikert, Emile. 1061
Evaluation of Solvent Effects on MALDI Matrix Crystal Formation; *Sumner, Lloyd W.; Edmondson, Ricky D.; Campo, Karen K.; Russell, David H 1062
Infrared Matrix-Ass. Laser Des./Ion. (IR-MALDI) using a Free-Electron Laser; *Cramer, Rainer; **Haglund, Jr., Richard F.; Hillenkamp, Franz. 1063
Effect of analyte hydrophobicity on beam-induced dehalogenation in LSIMS; *Th berge, Roger; Bertrand, Michel, J 1064
Cluster Ion Formation in LSIMS for a Series of Quaternary Ammonium Salts; *Paul, G. J. C.; Anastassopoulou, J., Arkas, M.; Paleos, C. M., **Marcotte, I , Bertrand, M. 1065
Organic Secondary Ion Emission from Solids and Liquids; *McMahon, John; Todd, Peter, Caimi, Richard; **Brenna, Thomas 1066
Mechanistic Studies of High Valent Iron Catalysts; *Weintraub, Susan T.; Bartos, Michael J , Gordon-Wylie, Scott, Wright, L James, Noon, Kathleen R.; Collins, Terrence J. 1067

Thursday Posters - Ion Source & Mass Spectrometer Design

New Axial Energy Analyzer For Secondary Ion Mass Spectrometry; *Wei, Jian; Schaeffer, Richard 1068
Resolution and Transmission of Quadrupoles: RF-DC and RF-Only Operation; *Pedder, Randall E.; Schaeffer, Richard A. 1069
Quadrupole Mass Spectrometry Using the Second Mathieu Stability Region; *Pedder, Randall E.; Schaeffer, Richard A. 1070
A.M. versus F.M. Quadrupole Mass Spectrometer; *Beaugrand, C.; Rolando, C.; Sablier, M.; Simonneau, G. 1071
Influence of a Low Frequency Component on the Standard RF of a Quadrupole; Beaugrand, C.; Poisson, L.; *Rolando, C.; Sablier, M. 1072
CHARACTERISTICS OF A HIGH-PRESSURE QUADRUPOLE COLLISION CELL; *Thibault , Pierre ; Whalen, Kevin I-1; Boyd, Robert I-1; **Shushan, Bori , Sakuma, Takeo I-2; 1073
A New Detector for Magnetic Sector Instruments Based on a Scanning CCD; *Finch, Jeffrey W.; Musselman, Brian D.; Sims, Gary R., **Kunihiro, Fumio. 1074

Secondary electron multiplier operating at forvacuum pressure; *Makarov, Alexander; **Yablokov, Michail 1075
The Direct Imaging of Ions Using a Charge Injection Device (CID) Detector; *Christopher, Steven J.; Parker , Mark A., Marcus, R. Kenneth. 1076
Development of an Hybrid Mass Spectrometer for Ion Investigations.; Mueller, Matthias; Wilhelm, Ulf; Aicher, Klaus-Peter; *Grotemeyer, Juergen. 1077
An API-Quistor-Quadrupole Mass Spectrometer for Ambient-Air Analysis; *Gaelli, Markus; Schlunegger, Urs P. 1078
Applications of Notched Broadband Waveforms in Ion Trap Mass Spectrometry; *Karr, Dane; Hoekman, Don, Koski, Alice. 1079
Design of a High Field FTICR for MALDI and LD/CI Studies; *Pitsenberger, Cynthia; Lei, Qing Paula; Easterling, Michael; Amster, I. Jonathan. 1080
Construction of a New External Source FTMS Instrument; *Carroll, James; Fannin, Steve, Wu, Jiangyue; Lebrilla, Carlito 1081
In-Cylindrical-Cell Maldi with FT ICR Spectrometer; *Knobeler, Markus, Wanczek, Karl Peter; Laukien, Frank. 1082
An Electrostatic Ion Guide Interface for Electrospray FTMS; *Tang, Liang; Buchanan, Michelle V , Hettich, Robert L ; Hurst, Gregory B 1083
Interchangeable Electrospray Source for Study of Biomolecules using FTMS *Green, M. Kirk; Gard, Eric; Camara, Elvira; Penn, Sharon G., Lebrilla, Carlito B. 1084
High-Field Electrospray FT-ICR Mass Spectrometer for Biopolymer Analysis; *Pasa-Tolic, Ljiljana; Marto, Jarrod A., Senko, Michael W , White, Forest M.; Guan, Shenheng; Marshall, Alan G 1085
The Design and Performance of an In-Field ESI-FTICR Instrument; *Wu, Qinyuan , Udseth, Harold R , Anderson, Gordon A , Van Orden, Steven, Sherman, Michael G. ; Chen, Ruidan ; Hofstadler, Steven A.; Smith, Richard D 1086
Performance of an External Cluster Ion Source and Electrostatic Ion Guide; *DeSantolo, Anthony M.; Mandich, Mary L., Reents , William D 1087
Construction of an ICP-FTICR Mass Spectrometer; *Milgram, Eric; Watson, Cliff; Eyler, John. 1088
Characterisation of a Novel Ion-Emitter for FT-ICR; *Spiess, Iris, Maass, Imke, Görtler, Bernd, Glasmachers, Albrecht; Wanczek, Karl Peter 1089
Fluorescence and Absorption Spectra of Mass-Selected Trapped Ions; *Jackson, George S.; Huang, Yulin; Guan, Shenheng; Kim, Hyun Sik; Marshall, Alan G. 1090
FTICR Performance of a 5.3 Tesla Split-Pair Magnet; *Reents, William; Mandich, Mary, DeSantolo, Anthony. 1091
Performance of a small Low-field FT/ICR Mass Spectrometer; *Perez, James; Leeck, Diane; Beasley, Brandon; Kenttamaa, Hilkka. 1092
Low Noise FTICR Detection Electronics *Anderson, Gordon; Bruce, James; Hofstadler, Steven, Rockwood, Alan; Smith, Richard. 1093

Improved Performance of a LabVIEW-Based FTICR Data Station; *Drader, J. J.; Hendrickson, C. L.; Laude, D. A 1094
A New ICR-Cell for Simultaneous Trapping of Positive and Negative Ions; *Malek, Robert; Wanczek, Karl-Peter. 1095
A scheme for feedback excitation in FTICR-MS based on multielectrode trap; *Gorshkov, Michael V.; Kouzes, Richard T. 1096
Hypercube: ICR Ion Trap Optimized for Excitation, Detection, and Trapping; *Jackson , George S.; Guan, Shenheng; Marshall, Alan G 1097
Extending the Functionality of Ion Trap Spectrometers; *McHugh, Sean; Hoekman, Don; Bradshaw, Stephen; Wilson, Ray, Li, Rebecca... 1098
Performance Enhancement of the HP 5971/5972; *Roy, Laura; Jehnsen, Chris; Hamerly, Thomas; Graves, Peter. 1099

Thursday Posters - Trapped Ions

Matrix-Assisted Laser Desorption Ion Trap Tandem MS of Peptides; *Qin, Jun; Chait, Brian T. 1100
Filtered Noise Fields in a Paul Ion Trap for Multiple MS Analyses; *Karr, Dane; Kelley, Paul; Bradshaw, Steve; Louris, John..... 1101
Advanced SWIFT Technique for MALDI/Quadrupole Ion Trap Mass Spectrometer; *Doroshenko, Vladimir M.; Cotter, Robert J.... 1102
Application of Tailored Waveform Generation to the Quadrupole Ion Trap; *Taylor, Dennis; Schwartz, Jae; Zhou, Joe; James, Mike; Bier, Mark; Korsak, Andy; Stafford, George. 1103
Selective Ion Accumulation in an ICP/ITMS using a Filtered Noise Field *Eiden, Gregory C.; Barinaga, Charles J.; Koppenaal, David W..... 1104
AUTOMATED RESONANCE EJECTION IN A QUADRUPOLE ION-TRAP MASS SPECTROMETER.; Murrell, Jason; *Todd, John F.J.; Watts, Peter. 1105
Enhancement of Ion Trapping Efficiency in an Ion Trap with a Pulsed Valve; *Wang, Yang; Schubert, Michael; Franzen, Jochen. 1106
New Method for Signal Generation; **Schubert, Michael; Nagel, Marcus; Wang, Yang; *Franzen, Jochen. 1107
Ion Cloud Structure In A Quadrupole Ion Trap; *Bach, Gloria A.; Dynin, Efim A.; Kirchner, Nicholas J. 1108
A Field-Portable Ion Trap for the Detection of Chemical Weapons Compounds; *Lammert, Stephen A.; Merriweather, Roosevelt; **Sarver, Emory W.; Wasserman, Michael B..... 1109
Ion Traps as Chemical Sensors; *Hart, Kevin J. 1110
Electron-Capture by Ions in a Quadrupole Ion Trap; *Vachet, Richard W.; Clark, Steven D.; Glish, Gary L. 1111
Experimental Studies of Space Charge Effects in an Ion Trap MS; *Shaffer, Barrie A.; Karnicky, Joseph F.; Buttrill Jr., S. E. 1112

Negative Ion Electrospray / Ion Trap MSn For Structure Elucidation; *Strife, Robert; **Schwartz, Jae; Bier, Mark; Zhou, Joe;. 1113
Technological Aspects of a New LC/MSn Quadrupole Ion Trap; *Schwartz, Jae; Bier, Mark; Taylor, Dennis; Zhou, Joe; Syka, John; James, Mike; Stafford, George; Stafford, George. 1114
Novel Technologies and Enhanced Features for GC/MS/MS; *Johnson , Eric, Schwartz, Jae; Taylor, Dennis; Bier, Mark; Ragsdale, John. 1115
Quadrupole Ion Trap Control Language - Power in the Hands of Researchers; *Zhou, Joe; Schwartz, Jae. 1116
Ion Optics and Design Considerations for a New LC/Quadrupole Ion Trap; *Bier, Mark E.; Schwartz, Jae C.; Zhou, Joe; Taylor, Dennis; Stafford, George; Syka, John; James, Mike; Borchers, Torsten. 1117
Particle Resonances in "Monopole" and Quadrupole Electric Ion Traps; *Wuerker, Ralph; **Kelley, Paul; Louris, John. 1118
Implications of Ion Population for GC/MS/MS on a Quadrupole Ion Trap; *Quarmby, Scott T.; Yost, Richard A. 1119
Investigations of Mass Shifts in the Ion Trap Mass Spectrometer; *DeGnore, Jon P.; Yost, Richard A. 1120
Effect of Scan Direction on Mass Resolution in Stretched & Compressed Traps; *Wang, Mingda. 1121
High Resolution Selective Ion Monitoring In An Ion Trap; *Wells, Greg; Huston, Chuck. 1122
Field Modulated Selective Ion Storage In An Ion Trap; *Wells, Greg; Huston, Chuck. 1123
Mass Displacements Measured in a Quadrupole Ion Trap; *Londry, F.A.; March, R.E. 1124
Collisional cooling effects on the ion relaxations in an ITMS instrument.; Philippe, Lière; Stephane, Bouchonnet; Thierry, Blasco; **Ray , March; *Jean-Claude , Tabet. 1125
QIT/TOF Analysis of Space Charge Effects in a Quadrupole Ion Trap; *Ventura, M. C.; Laude, D. A. 1126
OPTICAL TOMOGRAPHY INSIDE QUADRUPOLE ION TRAPS; *Garrett, Aaron; Nogar , Nicholas; Hemberger, Philip; **Cleven, Curtis; Cooks, R. Graham..... 1127
Ion Trap MS: Variations in Electrode Size and RF Drive Frequency; *Garrett, Aaron W.; Hemberger, Philip H.... 1128
New Modes of Operation in an Ion Trap Mass Spectrometer; *Cleven, C.D.; Frankevich, V.; Horn, L., Nappi, M.; Soni, M.H., Weil, C.; Cooks, R.G.; **Garrett, A.W.; Hemberger, P.H.; Amy, J., Stafford, G. 1129
Calculation of Parametric Resonance For Non-Linear Ion Trap; *Dynin, Efim A.; Kirchner, Nicholas J. 1130
The Use of Ion Trap Mass Spectrometry with FNF Waveforms for MS of Drugs; *Miller, Mark L. 1131

BIOMARKER DETECTION LIMITS USING A PRYOLYSIS-QUADRUPOLE ION TRAP SYSTEM; *Basile, Franco; Mowry, Curtis; Voorhees, Kent. 1132
Reactions of NO+ in a QITMS: Implications for Biological Metabolic Studies; *Silverton, Susan F.; Basic, Cecilia; **Johnson, Jodie V.; Yost, Richard A. 1133
Barbiturate Analysis In A Quadrupole Ion Trap:Borinium Adduct Ion Formation; *Colorado, Armando; Brodbelt, Jennifer..... 1134
Measurement Of Critical Energies In A Quadrupole Ion Trap.; *Colorado, Armando; Brodbelt, Jennifer. 1135
Gas-Phase Basicities and Metal Ion Affinities of Quinones in a QIT; *Hall, Brad; Brodbelt, Jennifer. 1136
Metal Complexation of Quinolone Antibiotics in a Quadrupole Ion Trap; *Alvarez, Erwin J.; Tang, Ming; Brodbelt, Jennifer S.; Vartanian, Victor. 1137
The QUISTOR as a Pulsed-Extraction Source for TOF-MS of VOCs in Air; *Chambers, David M.; Thomas, Stan W.; Grace, Louis I.; Andresen, Brian D. 1138
Oxidation of Azo Dyes: Gas Phase Reactions in an Ion Trap MS; *Voyksner, Robert ; **Betowski, L. Don. 1139
Developments in Explosives Vapor Detection by Glow Discharge/Ion Trap MS; *Asano, Keiji; Vaidyanathan, Gopalakrishnan, Goeringer, Douglas; McLuckey, Scott. 1140
CAD Spectra of PAHs by Ion Trap and Triple Quadrupole Mass Spectrometry; *Winnik, Witold; Betowski, Leon; Pyle, Steven; Marcus, Alvin; Brittain, Robert. 1141

Thursday Posters - Lipids

FRAGMENTATION PATHWAYS OF TRIACYLGLYCEROLS DEDUCED FROM MODEL COMPOUNDS; **STROOBANT, Vincent; *DE HOFFMANN, Edmond; 1142
Ag-phase HPLC-MS of tri acyl glycerides; *Schuyl, P.J W.; Joode, T. de, Duchateau, G.S.M.J.E.; Vasconcellos, M.A 1143
Characterization of a Family of Brain Lipids with Sleep-Inducing Potential; *Siuzdak, Gary; Cravatt, Benjamin F.; Prospero-Garcia, Oscar, Henrikson, Steven J , Boger, Dale L., Lerner, Richard A 1144
EI Mass spectra of Monounsaturated w3 Fatty Acid Nicotinates and SQMGs.; Keusgen, Michael; *Curtis, Jonathan M.; Ayer, Stephen W. 1145
Identiification of Eicosanoids Using Electrospray Mass Spectrometry; *Kerwin, James; Ericsson, Lowell. 1146
ESI-MS Analysis of PAF Precursors in Human Keratinocytes and Cell Line; *Harrison, Kathleen; **Travers, Jeffrey; Murphy, Robert C. 1147
IDENTIFICATION OF 20-HETE IN RAT KIDNEY PHOSPHATIDYLINOSITOL; *Zhu, Ying; McGiff, John C.; Balazy, Michael. 1148
Phospholipid Analysis by MALDI FT-ICR MS/MS; *Marto, Jarrod A.; White, Forest M., Marshall, Alan G. 1149

Detection of Phospholipid Molecular Species in U937 Cells using CF-LSIMS; *Li, Chun; Yergey, James. 1150
Analysis for Analogs of Phospholipids by FAB Mass Spectrometry; *Yu, Chungping; Huang, Jianxing; Widlanski, Theodore S. 1151
Analysis of Polyunsaturated Phospholipid Turnover by Electrospray LC/MS; *Ma, Yee-Chung; Ward, Glen; Wang, Tao-Chin; Salem, Jr, Norman; Kim, Hee-Yong. 1152
Isolation and Identification of Phospholipids in Lipid Extracts by ES/MS/MS; *Duffin, Kevin; Obukowicz, Mark; Shieh, J.J. 1153
Massie Cluster Impact Ionization of Phospholipids; *Dookeran, Nyla; Todd, Peter. 1154
Formation of the [M-H]+ Ion in the LSIMS Mass Spectrum of Sphingosine; *Chevis, Eddie A.; Busch, Kenneth L. 1155
Characterization of GS-15 and Biomarkers of the Helderberg Formation; *Ospina, Maria; Powell, David, Yost, Richard, **Channell, James 1156
PY/MS FAME EXTRACT PROFILING OF PATHOGENIC MICROORGANISMS; *Basile, Franco; **Hadfield, Ted L.; Sickenberger, Dave W.; Voorhees, Kent J. 1157
SPECIES DIFFERENTIATION OF BEESWAXES USING PYROLYSIS MASS SPECTROMETRY; **Beverly, Michael, Kay, Paul, *Voorhees, Kent J. 1158
GC-MS TECHNIQUES USED IN EVALUATING ALCOHOL AFFECTS ON LIPID METABOLISM; *Pawlosky, Robert, Salem, Norman 1159
A COMPARISON OF HIGH- AND LOW- ENERGY CID OF DERIVATIZED LIPIDS; *Griffiths, William; Yang, Yang, Zhang, Jie; Lindgren, Jan Åke; Sjövall, Jan 1160
Electron Capture MS Analysis of Lipid Peroxidation Products; *Grimsrud, A.J., van Kuijk, F J.G.M. ; Thomas, D.W., Sears, L J 1161
Analysis of Neurosteroids by Liquid Chromatography/Mass Spectrometry; *Kim, Hee-Yong; Romeo, Elena; Ma, Yee-Chung 1162
MS/MS Study of PBN Spin Adducts from Rat liver Microsomal Dispersions; *Sang, Hong, Janzen, Edward, G; Arimura, Masana; Kotake, Yashige; DuBose, Coit M ; Poyer, J Lee 1163

Thursday Posters - Carbohydrates

Characterisation of Glycosylation Sites in Recombinant Proteins by ES-MS/MS; Truong, Long; Eng, Marian; Canova-Davis, Eleanor, *Ling, Victor. 1164
Determination of glycosylation in external invertase by MALDI-TOF MS; *Zeng, Chenhui; Biemann, Klaus 1165
Characterizing the N-Glycosylation of CRF-Binding Protein; *Craig, A. G., Sutton, S. W., Vaughan, J.; Koerber, S.C.; Fischer, W.H. 1166
Characterization of a Plasminogen Activator with LC, CE, ESI-MS and MALDI; Apffel, A.; *Chakel, J ; Hancock, W S ; Holloway, B.; Swedberg, S ; Udiavar, S ; Pungor Jr , E., Souders, C. 1167

Analysis of parotid gland oligosaccharides by MALDI mass spectrometry; Wing, David R.; O'Donnell, Niall; Naven, Thomas J P.; *Harvey, David J. 1168
Analysis of the N-linked oligosaccharides of human C1s using ESI-MS; **Ptillot, Yves; *Thibault, Pierre; Thilens, Nicole; Rossi, Vronique; Lacroix, Monique; Coddeville, Bernadette; Spik, Genevive, Schumaker, Verne. 1169
GLYCOSYLATED END-PRODUCTS OF Beta-2-MICROGLOBULIN IN SERUM BY MALDI-MS; *Dreifuss, Peter; Vertes, Akos; **Tang, X; Braatz, James; Hull, Clifford. 1170
Characterization of human Chorionic Gonadotropin Using HPLC/MS; Liu, Chuanliang; *Bowers, Larry. 1171
Glycosylation Site Mapping by MALDI-TOF; *Yang, Y.; Orlando, R. 1172
Characterizing the Carbohydrate Moieties of EPGs and PGIPs by MALDI-TOF; *Kolli, V.S.K.; Bergmann, C.; Mohn, C.; Albersheim, P.; Darvill, A.; Orlando, R. 1173
Characterization of the Nodulation Factors Produced by Bradyrhizobium; *Kolli, V.S.K.; Carlson, R.W ; Peters, N.K.; Orlando, R. 1174
FAB and ESIMS of Acidic Glycosphingolipids—Lex- and Lea-derivatives; *Ohashi, Yoko; Ii, Tadashi; Kurono, Sadamu; Ogawa, Tomoya; Nagai, Yoshitaka. 1175
MALDI-MS ANALYSIS OF GANGLIOSIDES FROM HUMAN GRANULOCYTES; *Peter-Katalinic, Jasna; **Stahl, Bernd; Karas, Michael; Hillenkamp, Franz; Hanisch, Franz-Georg; Egge, Heinz; Muething, Johannes; Spanbroek, Rainer. 1176
SIALYLATION OF GANGLIOSIDES FROM DEVELOPING CHICKEN BRAIN BY ES-MS; *Peter-Katalinic, Jasna; Ashcroft, Alison; Green, Brian; Hanisch, Franz-Georg; Muething, Johannes. 1177
ESI-MS and ESI-CID-MS/MS of Complex neoLacto-Series Glycosphingolipids; *Levery, Steven B.; **Salyan, Mary Ellen K.; Stroud, Mark R. 1178
GLYCOSPHINGOLIPIDS FROM BOVINE RED BLOOD CELLS AND FOETAL CALF BRAIN; *Perreault, Helene; Koul, Omanand; Street, Jacqueline; McCluer, Robert; **Costello, Catherine. 1179
Detailed Characterization of Glycosphingolipids by ES-MS-CID-MS; *Reinhold, Bruce B.; Song, Ye; Reinhold, Vernon; Brigande, John V.; Seyfreid, Thomas, N. 1180
Determination of the Glycosylation Position in Mono-O-glycosyl Flavonoids; Li, Qimin; Van den Heuvel, Hilde; *Claeys, Magda. 1181
Mass Spectrometry and LC/MS of Polyphenols; *Williams, Jon; **Belanger, Ronald; Cohen, Gerald. 1182
Low-energy Fragmentation of Protonated Glycoalkaloids and Related Aglycones; *Claeys, Magda; Van den Heuvel, Hilde; Chen, Su; Derrick, Peter J.; Mellon, Fred A.; Price, Keith R. 1183
MALDI-MS of Bacterial Glucans; *Stahl, Bernd; **Talaga, Philippe; Zeng, Jianru; Karas, Michael; Steup, Martin; Hillenkamp, Franz; Bohin, Jean-Pierre 1184

Examination of Chitin-Metal Interactions by ESI and MALDI Mass Spectrometry; *Callahan, John H.; Shahgholi, Mona; Ross, Mark M. 1185
FAB-MS/MS of Immunoreactive Tetrasaccharides from Chondroitin Sulfate; *Ohashi, Mamoru; Ii, Tadashi; Kubota, Masayuki; Hirano, Takashi; Yoshida, Keiichi; Suzuki, Sakaru. 1186
Mass Spectromeric Characterisation of Sulfated Oligosaccharides.; *Watson, Eric; Termin, Andreas; Shah, Bhavana; Bhide, Anjali; Zamborelli, Tom; Venot , Andre. 1187
ES-MS of Heparin-Derived Glycosaminoglycan Disaccharides.; *Watson, Eric; Yao, Flora. 1188
CE/MALDI-MS of Mixtures of Heparin Derived Oligosaccharides; *Rhomberg, Andrew; Juhasz, Peter; Biemann, Klaus. 1189
Ionspray (lc-)ms of synthetic sulphated oligosaccharides; *Jacobs, Peter L.; Westerduin, Pieter; **Silvestro, Luigi; 1190
Massive Cluster Impact Ionization of Saccharides; *Dookeran, Nyla; Todd, Peter. 1191
LC-ESIMS and in-source CID of derivatized oligosaccharides.; *Aduru, Subhodaya; **Faull, Kym F. 1192
Improved MS Analysis of Oligosaccharides as Fluorinated Glycosylamines; *Huang, Zhi-Heng; Gage, Douglas A. 1193
MALDI and ESI mass spectrometry of cationic oligosaccharide derivatives; *Naven, Thomas J. P.; Harvey, David J. 1194
MALDI/FTMS of Oligosaccharides; *Fannin, Steve; Wu, Jiangyue; Carroll, James; Lebrilla, Carlito. 1195
MALDI-MS Applications on Carbohydrates; *Börnsen, Klaus Olaf ; Mohr, Martin; Widmer, H. Michael. 1196
ANOMERIC CONFIGURATION OF SUGAR NUCLEOTIDES BY FAB/MS/MS; WOLUCKA, B. A.; *de HOFFMANN, E. 1197
LC-MS/MS of Carbohydrates with Post Column Addition of Metal Salts; *Kohler, Martin; Leary, Julie, A. 1198
KER of Oligosaccharide/Metal/Ligand Isomers Using FAB and ES Ionization; Smith, Glenn; Bott, Geoffrey; *Leary, Julie, A. 1199
ESI-MS/MS Study of Co, Zn, Mn, Cu, Ca and Mg Complexes of Oligosaccharides; *Sible, Emily, M.; Brimmer, Steven, P.; Leary, Julie, A. 1200
Post-source decay fragmentation of oligosaccharides ionized by MALDI; *Maisey, E. Anne; **Harvey, David J. 1201
Oligosaccharide Structure Determination On An Ion Trap.; *Asam, Michael; Glish, Gary. 1202

Thursday Posters - Laser Desorption/Ionization

Using Aerosols for MALDI Liquid Introduction; Wei, Gang; Fei, Xun; He, Lin; *Murray, Kermit K. ... 1204
Design parameters of a gridless ion mirror for post source decay analysis; *Zeng, Jianru, Karas, Michael; Hillenkamp, Franz ... 1205
A Method for Acquiring Daughter-Ion Spectra in a Reflecting TOF Instrument; *Westmacott, G R; Ens, W; Standing, K G. ... 1206
Time of Flight PSD measurements with pre-cursor ion selection; *Kowalski, Paul; Hauer, Charles; Cornett, DS; Park, Melvin; Stack, Robert; Wronka, John. ... 1207
High Resolution Precurson Ion Selection for Post Source Decay Experiments; *Holle, Armin; Park, Melvin; Detlev , Suckau. ... 1208
Probing the Outer Limits of Performance for MALDI-TOF MS and MS-MS; *Vestal, Marvin, Juhasz, Peter; Blakley, Calvin, Martin, Stephen. ... 1209
HIGH RESOLUTION LINEAR MALDI-TOFMS OF PEPTIDES AND OLIGONUCLEOTIDES; **WEINBERGER, SCOT; KENNY, JAMES; *KORNFELD, RICH. ... 1210
Strategies for LDI/MALDI on a Sector Instrument; *Lennon, III, John D.; Shinn, David; Vachet, Richard W., Glish, Gary L. ... 1211
High Resolution Array Detection of the Ions Formed by MALDI; *Itagaki, Yasuhiro; Fujita, Tsuyoshi; Naoki, Hideo; Nakajima, Terumi ... 1212
Accurate Mass Determination in MALDI/FTMS using Internal Standards; *wu, Jiangyue; Fannin, Steve; Franklin, Melanie A. ; Molinski, Tadeusz F. ; Lebtrilla, Carilto. ... 1213
Ion Coupling in High-Resolution MALDI FT-ICR Mass Spectra of Biopolymers; *Pasa-Tolic, Ljiljana, Guan, Shenheng, Huang, Yulin, Jackson, George S.; Kim, Hyun Sik ; Marshall, Alan G. ... 1214
Peptide Mapping and Sequence Analysis of Proteins by MALDI FT-ICR MS *Solouki, Touradj; Pasa-Tolic, Ljiljana; Jackson, George S.; Guan, Shenheng; Marshall, Alan G. ... 1215
Femtomole Biomolecule Detection by Remeasured MALDI FT-ICR MS; *Solouki, Touradj; Guan, Shenheng; Marto, Jarrod A.; White, Forest M.; Marshall, Alan G. ... 1216
HIGH MASS ANALYSIS IN FOURIER TRANSFORM MASS SPECTROMETRY; *Yao, Jie; Pastor, Salvador J ; Wilkins, Charles L. ... 1217
Further Improvement of Mass Accuracy in MALDI reTOF MS of Peptides; *Vorm, Ole, Mortensen, Peter; Mann, Matthias. ... 1218
Orthogonal-Injection MALDI; *Dworschak, R G, Ens, W; Spicer, V; Standing, K G; Verentchikov, A V ... 1219
A Charge Detector for High Mass MALDI Ions; *Lautz, Carsten; Bahr, Ute, Roehling, Ulrich; Hillenkamp, Franz ... 1220

Application of Maximum Entropy to MALDI; *Zhang, X Kate; **Ferrige, Anthony G., Fales, Henry M. ... 1221
SEM as a Tool to Investigate Sample Morphology Effects in MALDI MS; *Westman, Ann; Barofsky, Elisabeth. ... 1222
Nanoscale Sample Manipulation and Preparation Method for MALDI MS; *Golding, Rafael E ; Whittal, Randy M.; Li, Liang. ... 1223
Methods for Modifying the MALDI Process; *Bai, Jian; Liang, Xiaoli; Liu, Yan-Hui; Lubman, David M. ... 1224
Novel Sample Preparation for MALDI; *Kochling, Heinrich; Biemann, Klaus. ... 1225
Investigation of Sample/Matrix Preparation in MALDI by Confocal Microscopy; *Li, Liang; Whittal, Randy M.; Dai, Yuqin. ... 1226
Influence of Sample Preparation on Time-Dependent MALDI MS of Proteins; *Lavine, Gary; Allison, John. ... 1227
Dependence of Resolution on Laser Power in MALDI-TOF MS; *Liao, Pao-Chi; Allison, John. ... 1228
Big Spot MALDI - Advantages of Irradiating Large Portions of the Target; *Hiller, Joseph; Szekely, Gabriella; Allison, John ... 1229
The Behavior of Peptide Mixtures in MALDI-MS; *Hiller, Joseph F , Lavine, Gary; Micke, Mel; Szekely, Gabriella, Allison, John ... 1230
MALDI Calibration and the Effect of Layered Sample and Standard; *Zhou, Jie; Lee, Terry D ... 1231
Charge State Distribution Shifting of Protein Ions Observed in MALDI; *Zhou, Jie; Lee, Terry D. ... 1232
Optical Characterization of the MALDI Plume; *Hurst, Gregory B. ... 1233
Optoacoustical Monitoring of Laser Absorption of MALDI Matrices; *Taranenko, N. I , Golovlev, V V.; Puretzky, A A.; Allman, S. L.; Chen, C. H ... 1234
The Wavelength Dependance of MALDI in the Range 350-450 nm; *Chen, Xiangjun; Beavis, Ronald C ... 1235
Influence of esterification and target preparation in MALDI of polyesters; *Joëlle, Guittard, Martine, Tessier; **Jean-Claude , Blais, Gérard, Bolbach, Laurence, Rozes; Alain, Brunot; Ernest, Maréchal; Jean-Claude, Tabet. ... 1236
Cationization Mechanism of Synthetic Polymers by Alkali Metals in MALDI; *King, Richard; Goldschmidt, Robert; Xiong, Yansan; Owens, Kevin ... 1237
Separation of the Desorption and Ionization Events in the MALDI Experiment; King, Richard, *Owens, Kevin, **Hanton, Scott. ... 1238
Evaluation the matrices used in MALDI by their FAB mass spectra; Hsing-Long, Chei; *Jentaie, Shiea. ... 1239
Comparisons of Proton Transfer Reactions of MALDI Matrices; *Kinsel, Gary, Land, Mark; Li, Nan. ... 1240
SEMI-EMPIRICAL STUDY OF PROTON TRANSFER IN MALDI-MS OF SMALL PEPTIDES; *Sadeghialavijeh, Mehrnoosh; Vertes, Akos ... 1241
INTERNAL ENERGIES OF IONS FORMED BY MALDI; *Gimon-Kinsel, Mary; Gillig, Kent; Sumner, Lloyd; Edmondson, Ricky; Russell, David. ... 1242

Factors influencing metastable fragmentation in MALDI TOF/MS; COLBY, STEVEN; Houston, Chris; Christian, Noah; Arnold, Randy; *REILLY, JAMES.....1243
Ion Formation and Photodissociation in MALDI-Mass Spectrometry; Amft, Matthias; Grundwuermer, Johann M.; Yang, Hou-Jun; *Grotemeyer, Juergen. 1244
Photochemical versus Thermal Mechanism for MALDI; Ehring, Hanno; Costa, Cesar; *Demirev, Plamen; Sundqvist, Bo. 1245
Probing The Dynamics of MALDI Ion Formation; *Edmondson, Ricky D.; Campo, Karen K.; Russell, David H. 1246
Water as a Matrix in Infrared MALDI-MS; *Berkenkamp, Stefan; Karas, Michael; Hillenkamp, Franz. 1247
Inorganic Matrix uses for MALDI - TOF - MS; *Tanaka, Koichi; Kawabata, Shin-ichirou; Resch, Martin; Paulus, Gert; **Humphrey, Paul; Dingley, David.....1248
Hydroxy Benzophenones: A New Class Of MALDI Matrices For Proteins/Peptides; *Reiber, Duane; Brown, Robert. 1249
Synthesis of MALDI Matrices and Correlation with Ion/Neutral populations; *Sumner, Lloyd W.; Hipp, Travis L.; Edmondson, Ricky; Gimon-Kinsel, Mary; Russell, David H. 1250
New matrices for Matrix-Assisted Laser Desorption/Ionization (MALDI) MS *Krause, Joem L.; Schlunegger, Urs P. 1251
Amino Acid Composition and Wavelength Effect on MALDI-MS of Small Peptides; *Olumee, Zohra; Vertes, Akos. 1252
Investigation of Selective Peptide Ionization with Various MALDI Matrices; *Blackledge, James A.; Alexander, Anthony J.; Dodsworth, David W. 1253
Effects of Substrates on the Ion Yields for Mixture Analysis by MALDI MS; *Liang, Xiaoli; Bai, Jian; Liu, Yan-Hui; Lubman, David M 1254
Surface Modification of Active Substrate Applied in MALDI MS; *Liu , Yan-Hui; Bai, Jian; Liang, Xiaoli; Lubman, David M 1255
Polymers as a Probe Element for Surface Enhanced Neat Desorption (SEND); *Bardel, Patrick; Hutchens, T.William 1256

Thursday Posters - Proteins & Peptides

Conformation of cytochrome c2 mutants studied by H/D exchanges using ESIMS; Halgand, Frdric; Jaquinod, Michel; Caffrey, Michael; Fitch, John; Cusanovitch, Michael; *Forest, Eric. 1257
Probing Conformation and Dimerization in Yeast Hexokinase with ESIMS; *Eckart, Klaus; Spiess, Joachim. 1258
ESI-TOF-MS Studies of Refolding and Assembly of Soybean Agglutinin; *Tang, Xue-jun; Saha, Sanat; Brewer, C. Fred; Chernushevich, Igor; Standing, Kenneth G. 1259
Rapid Deuterium Exchange-in Time for Probing Protein Conformational Change; *Dharmasiri, Kuruppu; Smith, David L. 1260

ESI-MS of Protein Noncovalent Tetrameric Associations at High m/z; *Schwartz, Brenda L.; Gale, David C.; Smith, Richard D., Chilkoti, Ashutosh; Stayton, Patrick S.; Smith, Virginia F.; Randall, Linda L. 1261
ESI-MS Analysis of the Transthyretin Tetramer & Some Non-Covalent Adducts.; *Green, Brian N.; **Oliver, Ronald W.A. 1262
Conformational Changes of Proteins Detected by MALDI-MS; Yang, Hou-Jun; Li, Xia-Ling; *Grotemeyer, Jürgen. 1263
Unusually Strong Binding of A Noncovalent Spermine-Peptide Complex; *Feng, Rong. 1264
Conformation of Chaperone Bound Ligands Probed by ESI MS; *Robinson, Carol; Gross, Michael; Dobson, Christopher; Radford, Sheena. 1265
Studies of H/D exchange of peptides and proteins by using aerosol MALDI *Wei, Xiaona; Beeson, Michelle D.; Russell, David H. 1266
Probing High Order Structure of Proteins by H/D Exchange/ESI-MS; *Maier, Claudia S.; Kim, Ok-Hee; Deinzer, Max L. 1267
Studies of Partially Folded Proteins by H/D Exchange and ESI-MS; *Tang, Xue-jun; Wang, Fang; 1268
Disulfide bridges assignments of homologous vegetable proteins; Guy, Philippe; Gagnon, Jean; Marion, Didier; *Forest, Eric. 1269
Characterization and Location of Disulfide Bonds in Proteins with ABD-F; *Rajamani, Umamaheswari; Pannell, Lewis; Sackett, Danny; Le, Han; Lecchi, Paolo. 1270
Determination of Disulfide Bonds in Proteins from AIDS Related Research; *Pannell, Lewis; Rajamani, Umamaheswari; Le, Han; Lecchi, Paolo. 1271
Identification of Cross-Linking Peptides Using ESI and MALDI-TOF MS *Le, John C.; Haniu, Mitsuru; Horan, Thomas; Katta, Viswanatham; Arakawa, Tsutomu; Rohde, Michael. 1272
Synthesis of Disulfide Linked B-Actin Peptides.; *Bencsath, F. Aladar; Shartava, Archil; Monteiro, Carlos A.; **Goodman, Steven R. 1273
DETERMINATION OF THE LOCATION OF CYS IN PEPTIDES BY TANDEM MS/MS; *NEMIROVSKIY, OLGA; GROSS, MICHAEL. 1274
Identification of a Cysteine Substitution in GCSF by Peptide Mapping-ESI-MS; *Yeh, Che-Hung; Tedeschi, Nicole; Herman, Alan. 1275
The Location of S-S Bonds in Proteins by Partial Acid Hydrolysis and MS; *Aplin, Robin; Anderson, Kerry. 1276
Disulfide Structure Study of EGF domain of Neu Differntiation Factor (NDF); *Katta, Viswanatham; Liu, Naili; Meng, Shi-Yuan; Zamborelli, Tom; Mayer, John; Lu, Hsieng; Hara, Shinichi. 1277
Identification of Venomous Snakes using Electrospray Mass Spectrometry. *Perkins, John R.; Despeyroux, Dominique; Gallagher, Richard T.; Derrick, Peter J.; Jennings, Keith R.; Newton, Russell P. 1278
MS Investigation of the Molecular Mechanism of Action of Cytotoxin B; *Wilm, Matthias; Just, Ingo; Selzer, J; Aktories, Klaus; Mann, Matthias. 1279

Tandem Mass Spectrometry of Cyanobacterial Toxins; Dale , Vanessa, *Jennings, Keith. 1280
Structural Analysis of Conotoxins by Mass Spectrometry; *Nakamura, Takemichi; Fainzilber, Michael; Zlotkin, Eliahu; Burlingame, A. L. 1281
STRUCTURE-FRAGMENTATION CORRELATIONS OF PROTONATED ACTINOMYCINS; *Thomas, Darren; Morris, Michael; Curtis, Jonathan; Boyd, Robert. 1282
Characterization of Recombinant Forms of Adenylate Cyclase Toxin, CyaA; *Hackett, Murray; Walker, Carthene B.; Shabanowitz, Jeffrey; Sebo, Peter; Guo, Lin; Hewlett, Erik L.; Hunt, Donald F. 1283
Identification of Post-translational Modifications for Cytochrome P450lin; *Huang, Rong; Ghosh, Dipak; Gunsalus, Irwin ; Rinehart, Kenneth. 1284
An ESI MS Study of the Soluble Methane Monooxygenase Enzyme System; *Buzy, Armelle; Jennings, Keith; Amarbalita, Marvy; Wilkins, Pat; Dalton, Howard. 1285
ES-MS analysis of resorcinol suicide substrate binding to cyt c peroxidase.; *Doerge, Daniel R; Divi, Rao L; **Hutton, Therese. 1286
Characterizing Peptides Isolated from Conus Venoms by Ionspray HPLC/MS & MS; *Jones, Alun; Bingham, Jon-Paul; **Lewis, Richard J.; Alewood, Paul F 1287
ANALYSIS of CYTOMEGALOVIRUS (CMV) PROTEASE (MW 28 kDa); *Siegel, Marshall; Tabei, Keiko; Berkenkamp, Stefan; **Hillenkamp, Franz; Bebernitz, Geraldine; Ding, Wie-Dong, Baum, Ellen. 1288
Effects of pH on the MALDI MS of Class I MHC Peptide Antigens.; *Woods, A S.; Huang, A Y.; Cotter, R.J.; Pardoll, D.; Jaffee, E.M. 1289
Identification of Peptides Associated with Class II MHC Molecules; *Addona, Theresa A.; Shabanowitz, Jeffrey, Hunt, Donald F. 1290
Characterization of the Major Peptide Components in Subcellular Fractions; *McCormack, Ashley L.; Eng, Jimmy K., DeRoos, Paul C., Rudensky, Alexander Y.; Yates, John R. III. 1291

Ambient Aerosol Analysis Using Aerosol-Time-of-Flight Mass Spectrometry

*Kimberly A. Prather, C Noble, K. Salt, T Nordmeyer, D Fergenson, and B. Morrical,
Department of Chemistry, Riverside, CA 92521

Particulate pollution is an area of growing concern in light of recent studies which suggest a link between high concentrations of ambient PM_{10} (particles with diameters equal to or less than 10 μm) and adverse health effects ranging from respiratory ailments to premature death. However, analytical chemistry techniques aimed at sampling and analysis of atmospheric aerosols are extremely limited in comparison to the number of methods that exist for studying gas phase smog components. As a result, current government regulations for levels of ambient particulates are necessarily general, lacking any chemical specificity

We have recently developed a technique, Aerosol-Time-of-Flight Mass Spectrometry (ATOFMS), which is capable of real-time determination of the size and chemical composition of individual aerosol particles [1-3] In order to obtain such information, the techniques of aerodynamic particle sizing and time-of-flight mass spectrometry are combined in a single instrument In one of the aerosol studies being performed in our laboratory, this instrument is being used for the direct analysis of ambient aerosols with the goal of establishing correlations between particle size and chemical composition. To date, we have observed very distinct size/composition correlations for organic and inorganic particles Two type of particles representative of the more common chemical classes of particles we observe are shown in Figures 1 and 2. Figure 1 shows an example of a single particle spectrum of a 2 2 micrometer particle of marine origin Figure 2 shows a single particle spectrum of a 2 9 micrometer particle we classify as organic soot The majority of particles in both of these chemical classifications fall in very distinct particle size ranges

Current measurements are being made to establish potential links between the presence of particular types of particles with such factors as the time of day, weather conditions, and concentration levels of gaseous smog components such as NO_x and ozone This data will allow a better understanding of tropospheric gas-aerosol processes to be established. Clearly, if one begins to establish links between chemical species in different particles for a particular size range, this will contribute significantly to our understanding fundamental atmospheric mechanisms. In addition, such information will yield information of potential sources of aerosols of biological and environmental concern Accurate characterization of the sources of particles is a necessary step in efforts towards the establishment of adequate pollution control strategies

RAPID SINGLE-PARTICLE MASS SPECTROMETRY OF AEROSOLS AND AEROSOL REACTIONS

M.V Johnston, P.G. Carson, and B A. Mansoori, Department of Chemistry and Biochemistry
A.S. Wexler, Department of Mechanical Engineering
University of Delaware, Newark, DE 19716

Many applications in aerosol science and technology require on-line, real-time chemical characterization of individual particles. Although several techniques are available for off-line single particle analysis, suitable on-line methods have been developed only recently. In our work, individual aerosol particles are analyzed by rapid single-particle mass spectrometry (RSMS) The experimental apparatus is shown in Figure 1. Particles are sampled directly into the source region of a time-of-flight mass spectrometer through a nozzle which forms a tight particle beam. Individual particles in the beam are detected by the light scattered from a continuous laser beam The particle size can be determined from the intensity and/or width of the scatter peak. The scattered radiation also triggers an excimer laser which performs laser desorption/ionization (LDI) of the particle in-flight. Ions generated from the particle are mass analyzed, and its chemical composition is determined from the mass spectrum. Thus, both size and composition are obtained for each particle. Since the total time between sampling and analysis is approximately one millisecond, chemical transformation by reaction, condensation, evaporation, or phase change is minimized.

We have used RSMS to study aerosol reactions The basic setup for this application is also shown in Figure 1. Aerosol particles having a known size and composition are generated with a vibrating orifice aerosol generator These particles flow into a reaction chamber where they are exposed to one or more reactive gases. After an adjustable reaction time, the particles are sampled directly into the mass spectrometer. An aerodynamic particle sizer is also available to separately monitor the particle size distribution With this setup, a variety of experiments can be performed to address both the kinetics and thermodynamics of aerosol reactions. Current applications in our laboratory include redox reactions of particulate chromium or sulfur with gaseous oxidizing and reducing agents, chemical equilibria in liquid droplets, and condensation reactions of gases onto particles.

The success of this work is directly related to the analytical capabilities of LDI. Unfortunately, LDI is only a semiquantitative technique owing to shot-to-shot irreproducibilities of the laser pulse energy and beam profile and to complex dependences of the signal intensity on matrix composition and morphology. However, much of the work we do involves liquid droplets and we have found that these samples act as ideal media for LDI. Liquids provide a reproducible local environment around the analyte, the droplet morphology is reproducible and well-defined, and the preparation of calibration aerosols is straight forward.

Since particle-to-particle variations of the signal intensity typically range from 20 to 60% for particles having similar size and composition, quantitative information cannot be obtained from the mass spectrum of a single particle ablated by a single laser pulse. When the aerosol consists of

particles having uniform size and composition, the precision can be improved by averaging the spectra of several particles. For example, inorganic cation and anion concentrations can be determined to better than +/- 10% by averaging the spectra of twenty particles. In each case, the absolute signal intensity of the appropriate quantitation ion in the mass spectrum scales linearly with concentration. When the aerosol consists of particles having different composition, particles are first grouped into classes having similar composition (via discriminant analysis, the classification and regression tree algorithm, etc.) and then the average analyte concentration within each group is determined. Particle size is also an important parameter. Although the relative signal intensities usually do not change significantly with particle size, the absolute signal intensites scale linearly with either surface area or volume depending upon the nature of the analyte and the laser fluence used to obtain the mass spectrum. Thus, quantitation can be achieved, but the mass spectra must be averaged over many "similar" particles and several parameters must be controlled or accounted for over the course of the experiment

Tandem Mass Spectrometry of Airborne Particles

J. Michael Ramsey, Mo Yang, Peter T. Reilly, William B. Whitten
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6142

Most manufacturing or processing activity produces solid emissions in the form of airborne particulates. Low vapor pressure liquids condensed on ambient particulate matter is indicative of the materials and processes being used. Laser Desorption mass spectrometry of single microparticles in an ion trap provides a capability to analyze the airborne particles as well as condensed phase materials on a microparticle surface without any instrument manipulation. On-line, single particle analysis allows detection of microscopic variations in sample compositions in real time. In this experiment, a quadrupole ion trap mass spectrometer coupled with a particle injection system is demonstrated for laser desorption mass spectrometry and MS/MS analysis of single microparticles. The device can be used for detection of controlled substances and investigation of harmful airborne particles such as pollens, fibers, microorganisms, etc.

Chemical analysis of individual microparticles using laser desorption mass spectrometry in our ion trap system has been described elsewhere.[1] Briefly, the particles are introduced into the ion trap by a particle hopper or a particle launcher mounted in the vacuum chamber. When a particle arrives at the center, a YAG laser (532 nm) desorbs and ionizes the molecules adsorbed on the microparticle surface. The ions are trapped and subsequently mass analyzed using the mass-selective instability mode of operation of the ion trap.[2] A detection limit of 0.7 fm per particle was determined for tetraphenyl-phosphonium bromide (TPPB) adsorbed on 100 μm silicon carbide microparticles.[1] Also, direct isotope ratio measurements of nickel particles with a size of 50 μm has been demonstrated using the same method.[1]

For the measurements of MS/MS fragmentation, all masses of ions are expelled except the parent ions. These parent ions are excited with an additional low RF voltage between the two end cap electrode, resulting in dissociation through collision with buffer gas atoms. The fragmented ions dissociated from the parent ions are again mass analyzed. This additional information, which cannot be obtained with a conventional time-of-flight mass spectrometer, enhances the specificity of a chemical determination.

The measured primary mass spectrum of TPPB laser-desorbed from a SiC microparticle and the fragmentation mass spectrum dissociated from the mass selected parent ions of $(C_6H_5)_4P^+$ are displayed in Figure 1 and 2 respectively. While the primary mass spectrum shows a large number of fragmentation peaks and inorganic background peaks with the parent ion peak, the fragmentation mass spectrum exhibit a recognizable fragmentation pattern in which the peaks correspond to the loss of one, two, or three phenyl groups from the parent ions. This measurement may be interpreted by pattern recognition algorithms for chemical determinations. For example, if the fragmentation pattern of an unknown sample demonstrated a similar fragmentation pattern to that in Figure 2, then we would suspect that the sample molecule consists of four phenyl groups surrounding a base block that also may be determined from the fragmentation pattern.

To apply the MS/MS technique to real-time chemical analysis of aerosol particles, an atmospheric particle sampling system and a dual particle detection system were designed and examined with a particle generator that simulates airborne particulates. Figure 3 illustrates the overall systems including the ion trap, particle detector, atmospheric sampling interface, and

particle generator. The fiberoptic particle counter enables one to detect the injected particles and to trigger the desorption laser to intercept the particle. Figure 4 shows the real-time positive ion mass spectrum of 15 μm KNO_3 particles injected directly from the air into the ion trap. The peaks are the isotopes of potassium with a measured ratio of 6.7. The natural abundance ratio is 6.9.

The demonstrated real-time spectra of the KNO_3 particles and MS/MS measurements of the organic chemicals desorbed from a microparticles surface indicates that chemical composition of aerosol particles can be analyzed directly from the air without any sample manipulation. Detailed information about the particle transmission efficiency, minimum detectable particle size, ratio of neutral to charged particles, and mass spectroscopic investigation of various aerosol particles will be available in the near future.

Detection and Characterization of Ultrafine Particles

W. D. Reents, Jr.
AT&T Bell Laboratories, Murray Hill, NJ 07974 USA

Particles present in the environment have significant affects in many areas from personal health due to atmospheric particles to various industrial processes that can be ruined due to particulate contamination such as semiconductor device manufacture and manufacture of sterile health products. The ability to detect deleterious contamination requires appropriate instrumentation to detect these particles. To prevent such contamination, the particle source must be identified by determining the composition of the offending particles.

In a controlled environment, particle contamination often occurs in transients. In order to identify unknown particles, a technique must obtain compositional and size information regardless of particle identity, and perform this analysis in real-time so as to separate "background" particles from those produced in the transient event. Since processes are sensitive to certain particle size regimes and, possibly, compositions, the instrumentation must be designed with these needs in mind. I have developed an instrument, the Ultra-Sensitive Particle Analysis System (USPAS) for situations where ultrafine particles, down to 0.002 micron, are of concern, such as the semiconductor manufacturing industry and the ambient environment.

Particle characterization occurs via pulsed laser ablation/ionization of individual particles with time-of-flight mass spectrometric detection of the created positive ions. Particle composition can be determined only if sufficient information is contained in the ion population; discrimination against elements due to their high ionization potentials reduces compositional information Negative ion detection can be used to compensate for this discrimination, but correlating negative and positive ion intensities to obtain relative abundances is difficult. Instead, by heating the particle to extremely high temperatures, ionization of all elements approaches 100%. This is shown in Figure 1 for NaCl where the relative *positive ion* intensities match the actual elemental ratio present.

Further characterization is obtained from sizing the particle. In some processes, particles smaller than a critical size do not harm the process. In semiconductor device manufacturing, device line widths approaching 0.18-0.35 micron will be affected by particles >0.05 micron whereas gate oxides with thicknesses of 0.002 - 0.08 micron will be affected by correspondingly smaller particles. Since ionization is efficient with the USPAS, the ion signal should correlate with particle mass and, for dense particles, their diameter. This is the case when the cube root of ion signal is plotted vs. particle diameter (see Figure 2). These particles represent not only different sizes, but also different compositions. They are 0.2 micron NaCl, 0.15 micron polystyrene latex spheres, 0.1 micron NaCl, and 0.017 micron silicon particle. Based upon the noise level of the USPAS, the particle size characterization limit is below 0.002 micron.

Detection efficiency and real-time characterization are also very important capabilities. The USPAS detects 3-4% of particles entering the capillary inlet; evaluated using 0.074 nm polystyrene latex spheres and calibrated against a Condensation Particle Counter. All of these characteristics of the USPAS are available during real-time characterizations.

Particle size calibration of USPAS for particles from 0.017 to 0.2 micron in diameter

Sulfur Speciation of Single Aerosol Particles

K.R. Neubauer, S.T. Sum, M.V. Johnston, Department of Chemistry and Biochemistry
A.S. Wexler, Department of Mechanical Engineering
University of Delaware, Newark, DE 19716

Sulfur enters the atmosphere as gaseous species emitted from both natural and anthropogenic sources. These species can undergo a variety of oxidation reactions that ultimately yield hexavalent sulfur aerosols Since the final products play an important role in acid rain production and the earth's energy balance, it is important to distinguish tetravalent and hexavalent sulfur aerosols, as well as differentiate those arising from natural and anthropogenic sources. To attain these goals we chose to examine five target compounds that are present in the atmosphere: sodium sulfate, ammonium sulfate, ammonium sulfite, methanesulfonic acid (MSA), and the sodium salt of hydroxymethanesulfonic acid (NaHMSA). Sodium sulfate is observed in oceanic aerosols, while both ammonium salts are observed over land. MSA is found only in the marine environment and originates solely from natural emissions, while HMSA is formed in urban hazes and primarily arises from anthropogenic sources Thus, MSA and HMSA serve as tracers for distinguishing natural and anthropogenic sulfur emissions.

To differentiate these compounds, we used Rapid Single-Particle Mass Spectrometry (RSMS), a method that allows single particles to be analyzed on-line and in real time. With RSMS, particles are drawn directly into the source region of a reflectron time-of-flight mass spectrometer where they are detected by light scattering of a continuous laser beam and then ablated by an excimer laser pulse. With this sequence of events, each mass spectrum results from a single laser pulse ablating a single particle

Our results indicate that these sulfur compounds can be distinguished on the basis of peak area ratios and threshold laser fluences; the relevant portions of representative spectra are shown in Figure 1 MSA is characterized by $SO_4^-/CH_3SO_3^-$ and $HSO_4^-/CH_3SO_3^-$ area ratios much less than one, while Na_2SO_4 possesses a dominant SO_4^- peak, an HSO_4^-/SO_4^- ratio less than 1, and no $CH_3SO_3^-$ signal. NaHMSA is characterized by a strong SO_2^- peak, weak SO_4^- and HSO_4^- peaks, and, under certain conditions $HOCH_2SO_3^-$ is observed. Ammonium sulfate and ammonium sulfite yield similar spectra, both possessing HSO_4^-/SO_4^- area ratios greater than one. These latter two compounds can only be distinguished on the basis of excimer fluence: ammonium sulfate has a lower threshold for ion production than ammonium sulfite.

Because ambient particles likely contain mixtures of various sulfur species, it is important to distinguish the relative amounts of these compounds in multicomponent particles. To address this issue we produced particles consisting of varying amounts of MSA, Na_2SO_4, NaHMSA, and NaCl and monitored the peak area ratios of ions characteristic of each species. Although the average peak area ratios scale with relative concentration, quantitative information cannot be obtained due to large particle to particle spectral variations.

To improve quantitation, we subjected the sulfur mixtures to classification and regression trees (CART) analysis. CART examines a given data set and decides which variables best distinguish the different classes within the data set. Once CART has been trained, it can then analyze unknown data sets. When the sulfur mixtures were analyzed by CART at least 80% of the particles were correctly classified, with the majority of the errors resulting from classifications in the adjacent concentration ranges The results for the three mixtures analyzed are shown in Figure 2. Thus, CART analysis allows the concentration distribution within a group of particles to be determined.

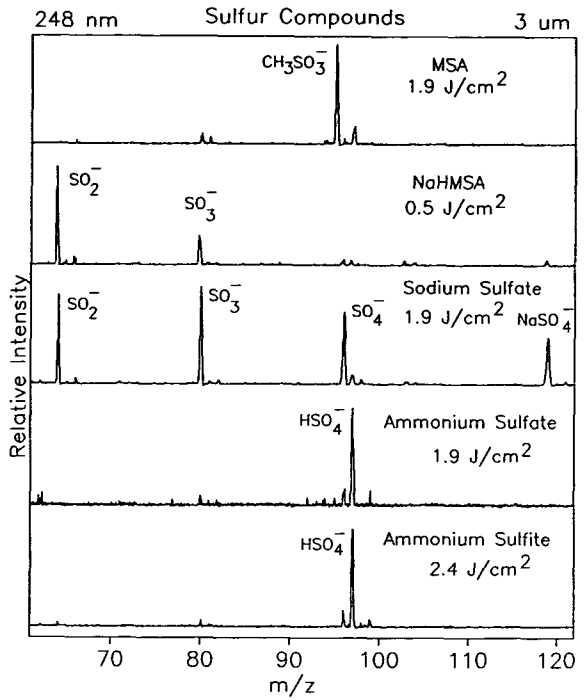

Figure 1

CART Results

Mixture	% MSA or NaHMSA	Number of Variables Used	Number of Spectra (Particles)	Number Correctly Classified	% Correctly Classified
MSA/Na_2SO_4	1.5, 7.3, 14, 23, 33, 39, 50	22	162	140	***83***
50% NaCl MSA/Na_2SO_4	0.1, 1.6, 10, 17, 21, 25	16	120	96	***80***
NaHMSA/ $(NH_4)_2SO_4$	1, 10, 20, 30, 40, 50	17	120	102	***83***

In flame combustion research the study of gas-to-particle conversion and the subsequent aerosol evolution occurring in or above flames is important for providing fundamental understanding of the flame combustion processes and developing control strategies to limit combustion products relevant to health and environmental concerns. Laser microprobe mass spectrometry and transmission electron microscopy (TEM) have been applied to particles collected in the flame to characterize particle chemical composition and morphology.

Brown University developed a quick-collection (~10ms) method, shown in Figure 1, to sample particles at various heights (20, 30, 40, 50, and 70 mm) in an ethene diffusion flame where the temperature and oxidation conditions differ.[1,2] The particles are captured on plasma-etched TEM grids. The precursor particles found low in the flame (20 and 30 mm) have the appearance of individual spherules, approximately 5 nm in diameter, and have low electron opacity when viewed by TEM.[3] Particles collected using the same technique at higher regions in the flame have a distinctly different morphology; they show classic soot aggregation and exhibit higher opacity with respect to the transmitted electron beam. To learn more about the chemical composition of these two types of particles, a commercial transmission laser microprobe mass analyzer having the time-of-flight spectrometer was used in a defocused mode to obtain characteristic mass spectra and to identify chemical differences of samples collected at different heights.[4] The positive ion mass spectra of the precursor particles collected low in the flame (typical spectrum Figure 2a) are characteristic of mid-mass range polycyclic aromatic hydrocarbons (m/z 202 to 302). The hydrogen mole fraction for the precursors is approximately 0.36. Spectra of particles collected high in the flame contain primarily the carbon cluster series, $C_mH_n^+$ where m = 1 to 15 and n = 0 to 2, characteristic of carbonaceous material devoid to a large extent of hydrogen (typical spectrum in Figure 2b). The hydrogen mole fraction based on peak areas corrected for ^{13}C abundance is 0.15. In a small fraction of the spectra, we observed mass peaks that correspond to polycyclic aromatic hydrocarbon-like compounds in the range m/z 418-444 and high mass fullerene-like peaks. At this time, the source of these large ions is not clear - whether they are inherent in the sample or are formed in the laser ablation process. Work is progressing to help determine the source.

The mass spectrometric technique is sensitive to unseparated PAH's as found by Mauney in his analysis of shale oil soot with laser microprobe[5] and more recently by Zare and co-workers in their analysis of meteoritic samples.[6] The peaks that we have identified are the ones predicted by Stein and Fahr to be the most thermodynamically stable (stabilomer) structures possible in the flame under the conditions prevailing in these experiments.[7] The results of our experiments suggest that PAH or PAH-like compounds are formed low in the flame and contribute to the composition of the precursor particles. As the small particles are processed at higher temperatures in the upper regions of the flame, hydrogen is lost and the soot is transformed into a more carbonaceous material.

Effect of MALDI and Solution Parameters on Aerosol MALDI Ion Signal

Michelle D. Beeson, Xiaona Wei, and David H. Russell,
Laboratory for Biological Mass Spectrometry, Department of Chemistry
Texas A&M University, College Station, TX 77843

We have recently described a technique that uses a pneumatic aerosol generator to combine liquid introduction with matrix-assisted laser desorption ionization (MALDI) mass spectrometry.[1] This technique is called aerosol MALDI to differentiate it from the more common surface MALDI experiment. In the aerosol MALDI technique, the matrix and analyte-containing solution is delivered using a syringe pump to a pneumatic aerosol generator and sprayed into the vacuum as an aerosol. The aerosol first passes through a heated drying tube at 500 C to remove solvent and then ionization is performed using 355 nm from a frequency tripled Nd:YAG laser. The ions are orthogonally accelerated at 10 kV, mass separated in a 1.1 m flight tube, and detected with a microchannel plate particle multiplier. The mass spectra are collected by a digital oscilloscope and downloaded to a microcomputer for analysis.[1]

We have examined the effect of several MALDI and solution parameters on the aerosol MALDI ion signal. One of the more interesting observations concerns the effect of analyte concentration on ion signal. The aerosol MALDI ion signal is non-linear in analyte concentration (Figure 1). We attribute this observation to residual solvent in the aerosol particles.[2] We have also examined the effect of adding

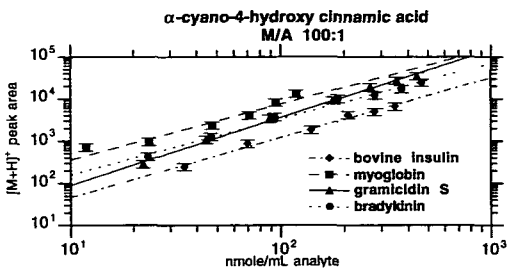

Figure 1. Aerosol MALDI ion signal as a function of analyte concentration.

water to organic solvents (Figure 2). For over 80 % of the analyte/matrix/organic solvents studied, maximum analyte ion signal is obtained from organic solvent/water mixtures. However, the composition of this mixture is not the same for all analytes or all matrices studied. We interpret this to mean that analyte/matrix/solvent interactions within the aerosol particle are important for obtaining optimum aerosol MALDI ion signal.

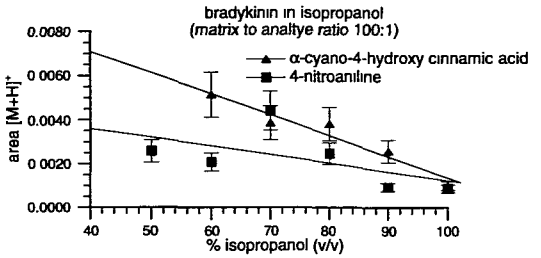

Figure 2. Bradykinin ion signal from solutions of isopropanol and water.

Based on our observations and the work of Browner and co-workers[3] and Cook and co-workers,[4] we have developed a model describing the microphysical aspects of aerosol MALDI. For aerosol particles produced from solutions containing multiple solutes, it is possible for aerosol particle composition to vary with particle size. After initial formation, (Figure 3a) aerosol particles continue to break-up, as depicted in Figure 3c. During the break-up process, small particles are ejected from the surface of the original particle and the composition of these small particles may not be identical to the composition of the initial particle due to aerosol ionic redistribution (AIR).[3,4] AIR can occur in aerosol particles that are inhomogeneous due to the more hydrophobic solutes migrating to the air interface. In the process of AIR, the inhomogeneous aerosol particles break up and form "daughter" aerosol particles. The smaller particles ejected from the surface of the initial aerosol particle are enriched in the *more* hydrophobic species whereas the larger particles are enriched in the *less* hydrophobic species at the center of the initial aerosol particle. This AIR effect may influence the aerosol MALDI ion signal. For example, if the hydrophobicities of the matrix and analyte are not the same, AIR may separate the matrix and analyte into different particles, resulting in reduction or loss of ion signal. Other species in the aerosol particle will also affect the matrix/analyte interactions and thus AIR. For example, when trifluoroacetic acid is present, matrix/analyte interactions are increased, resulting in improved aerosol MALDI ion signal.

Two-step laser mass spectrometry (L2MS) is a modern analytical method that features intact vaporization and efficient soft ionization of high molecular weight compounds. It utilizes a pulsed CO_2 laser for desorption of intact neutral molecules, a pulsed, tunable UV laser for resonance-enchanced multiphoton postionization, and a reflectron time-of-flight mass spectrometer for mass analysis [1]. L2MS is a highly sensitive and optically selective analysis method. It can serve as very powerful tool for the direct chemical analysis of selected compounds in complex sample mixtures, such as tissue, polymers, environmental samples, and geo/cosmochemical materials.

Kerogen is the oldest carbonaceous matter found on Earth. It formed from the residues of biological organisms and land-plant material that degraded into complex carbon-rich structures. During burial, thermal processes progressively convert the organic material into oil, gas, polycyclic aromatic hydrocarbons (PAHs), and ultimately graphite [2]. For conventional analysis methods, e.g., pyrolysis chromatography [3], a time-consuming kerogen acid digestion process is used (several days) In this work we studied Green River, Phosphoria, and Mowry kerogens, all form Wyoming, U.S.A. We recorded the L2MS spectra of digested samples, as well as untreated rock and rock powder directly.

Figure 1 shows the L2MS spectra of a *post-mature* sample (Phosphoria formation). The peak at m/z = 178 results from anthracene, phenanthrene, or both. All spectra show a series of peaks with mass intervals of 14 starting from m/z = 178. They arise from alkyl-substituted 178, e.g., peaks at m/z = 192, 206, and 220 are from methyl-, dimethyl-, or ethyl-178 etc.

Figure 2 shows the L2MS spectra of different forms of an *immature* sample (Green River formation). The series of peaks with mass intervals of 14 starting from m/z = 178 is again observed most strongly in the spectrum of the untreated rock sample. Peaks at m/z = 202 and 228 result from pyrene and chrysene (or their isomers). There are other examples of peak groups, i.e. 274, 288, and 245, 259, etc.

For *post-mature* and *immature* samples, the acid-digested kerogens and the pulverized rock give almost identical L2MS spectra. This similarity demonstrates that acid digestion does not introduce any artifacts, e.g., from chemical alteration of the PAH contents of these samples. It also shows that grinding the rock suffices for sample preparation for L2MS analyses.

In the spectra of the *post-mature* samples (Fig.1), there are only slight differences among the spectra of intact rock, rock powder, and digested samples. Acid treatment or grinding did not liberate the higher mass PAHs from bulk material. But for *immature* samples (Fig. 2), acid treatment or grinding induce a dramatic shift in the mass distribution relative to the intact rock data. We suspect that this difference is related to the lower

molecular weight PAHs that accumulate along fissures or cracks in the material, whereas higher molecular weight molecules stay trapped in the rock matrix.

A REVERSED GEOMETRY ORGANIC ION MICROPROBE

Peter J. Todd, John M. McMahon and Robert T. Short
Chemical & Analytical Sciences Division
Oak Ridge National Laboratory
PO Box 2008, Bldg. 5510A
Oak Ridge, Tennessee 37831-6365

Secondary ion microprobes perform mapping of sample surfaces by measuring the intensity of selected secondary ions while a beam of high energy primary ions are rastered across the sample surface. Transmission of secondary ions through the mass spectrometer depends in part on the careful focus of the secondary ion optics. This focusing requirement limits the size of the sample (i.e., the field of view) that can be mapped to about 100 - 200 μm in diameter. This field of view can be enlarged by use of deflectors inside the secondary ion source. By coordinated operation of deflectors in both the primary and secondary ion sources, fields of view in excess of 1 cm. dia. can be demonstrated. The process of employing coordinated primary and secondary ion deflectors is called dynamic emittance matching (DEM).

With microprobes, only secondary ions from a single point on a sample can be transmitted, regardless of how broad the primary ion beam is. Consequently, if the deflectors of the secondary ion source are operated in the usual DEM mode, but (a) the primary ion beam is defocused and (b), the deflectors of the primary ion beam are disengaged, then a secondary ion image can be created. Figures 1 and 2 demonstrate this capability. Figure 1 shows a secondary ion image of choline (m/z 104) obtained from two spots on a gold sample. It was obtained by using our microprobe in normal fashion. Figure 2 shows the secondary ion image generated by using a defocused Cs+ primary ion beam, with primary deflectors turned off, and only secondary ion deflectors operated. Clearly, there is some loss in spatial resolution in Figure 2, but the image is unmistakably from the same sample as that is Figure 1. The spatial resolution is, in fact, determined by the quality of the secondary ion optics, rather than the primary ion spot size, the latter being the more conventional requirement for spatial resolution. Because the secondary ion optics, rather than the primary ion optics, determine spatial resolution, we call our method, a reversed geometry ion microprobe.

The utility of a reversed geometry microprobe is related to the fact the some primary sources cannot be focussed. These include the traditional fast Xe atom bombardment (FAB) source, and the massive cluster ion impact (MCI) source. The latter cannot be focussed because the cluster ions generated by it possess a broad distribution of mass, kinetic energy and charge states. Unique features of the MCI

as a primary ion source include the ability to generate abundant secondary ions from high molecular weight compounds and such emission persists well beyond the dose known as the static SIMS limit. In short, the MCI gun can be used exactly like a FAB gun except that secondary ions can be emitted from dry samples, including biologic tissue, without sample preparation. By combining the capabilities of the MCI gun with the reversed geometry ion microprobe, characteristic secondary ions can be emitted directly from a specific place on a sample of biologic tissue.

A COMPUTATIONAL APPROACH TO GAS-PHASE ION CHEMISTRY

Leo Radom

Research School of Chemistry, Australian National University, Canberra, ACT 0200, Australia

Ab initio molecular orbital theory today can straightforwardly produce information about the structures and thermochemistry of ions and on the mechanisms of the reactions that they undergo. For small systems, the calculations are now able to provide quantitatively reliable data, that may be used to assist in the interpretation of experimental results and, occasionally, to resolve discrepancies. Particularly useful in this regard are variants of a level of theory called G2 theory, introduced by Pople and co-workers in 1991 with the aim of being able to predict thermochemical data to so-called chemical accuracy: roughly 10 kJ mol^{-1}, 2 kcal mol^{-1} or 0.1 eV.

The first example presented concerns **gas-phase proton affinities** (PAs).[1] The background to the story is the suggestion in 1991 by Mautner and Sieck (MS) and Szulejko and McMahon (SM), on the basis of high quality variable temperature proton-transfer equilibrium measurements, that the standard proton affinity scale of Lias and co-workers (LBLHLM) should be revised. It was of interest to test this challenge theoretically. What we find from a comparison of our calculated G2 proton affinities with the LBLHLM values spanning a range of more than 500 kJ mol^{-1} is that there is generally good agreement, the mean absolute deviation between theory and experiment for 31 comparisons being just 6.2 kJ mol^{-1}. Thus, there is no support for a wholesale revision of the LBLHLM scale. The largest and only serious discrepancy occurs for isobutene where the G2 proton affinity (802 kJ mol^{-1}) lies significantly below the LBLHLM value (820 kJ mol^{-1}). Significantly, isobutene was the molecule chosen as the anchor point in the MS and SM scales!

On the other hand, there *are* a number of significant discrepancies between the G2 proton affinities and the MS values at the upper end of the scale. However, if we examine the proton-transfer enthalpies *directly measured* by MS, we find uniformly good agreement between theory and experiment, including reactions involving the "problem" molecules. The mean absolute error is 2.3 kJ mol^{-1} and the maximum error is 6.9 kJ mol^{-1}. Again, noting that the MS PA scale was derived using the PA of isobutene as an absolute standard, it is of interest to examine the effect of removal of this absolute standard by evaluating the theoretical and experimental proton affinities at the upper end of the scale *relative to isobutene*. The resulting values are all in very good agreement!

Our analysis points us in one obvious direction: virtually all the results can be reconciled if we trust the theoretical predictions and lower the standard proton affinity for isobutene by about 18 kJ mol^{-1} from its current value, i.e. from 820 to 802 kJ mol^{-1}. Our G2 results also suggest that the currently accepted experimental $\Delta H_{f\,298}$ value for *t*-butyl cation may be too low by about 15–20 kJ mol^{-1}.

Subsequent to the completion of our calculations, a new and independent proton affinity scale has been reported by Szulejko and McMahon (SM), and related new measurements have been reported by Traeger. The agreement between our theoretical results and the new experimental data is quite remarkable. The 20 comparisons show a mean absolute deviation of just 2.3 kJ mol^{-1} and a maximum deviation of less than 7 kJ mol^{-1}. But, in particular, the new SM results also suggest a downwards revision in the proton affinity of isobutene to about 802 kJ mol^{-1}. In addition, new experiments by Traeger and by Baer also suggest a proton affinity for isobutene in the vicinity of 802 kJ mol^{-1}.

In addition to calculating proton affinities or proton-transfer enthalpies, theory may be used to calculate **proton-transfer entropies**[2] using standard statistical thermodynamics procedures Comparisons of calculated and experimental absolute entropies reveal excellent agreement, with a mean absolute deviation of 0.3 J mol^{-1} K^{-1}. All values agree to within 0.7 J mol^{-1} K^{-1}, lending confidence to the theoretical predictions in those cases where the experimental information is less precise.

Because absolute entropies are generally not available for ions, it is commonly assumed in the experimental literature that the entropy for the ion is the same as that for an isoelectronic neutral analogue. We have examined this assumption and find that in many cases (e.g. NH_3 vs H_3O^+) that this involves an error of 1–2 J mol^{-1} K^{-1} but in some cases, particularly for those species containing hindered rotors, the error is 5–10 J mol^{-1} K^{-1}, i.e. is unacceptably large.

Examination of entropies for proton-transfer reactions show that there is a significant scatter between experimental measurements from different laboratories, with differences of up to 9 J mol^{-1} K^{-1}. If we take this as representing roughly the sort of accuracy available from such experimental determinations, the agreement between theory and experiment may be considered generally reasonable, but there are a few cases of significant discrepancies. We believe that the determination of reaction entropies may be an area where it is currently more straightforward to obtain precise results from theory than from experiment.

The **tropylium and benzyl cations**[3] have been widely studied by mass spectrometrists but their precise thermochemistry is still uncertain. Our calculated heat of formation for benzyl cation (907 kJ mol^{-1}) is in good agreement with recent experimental results (910 kJ mol^{-1}) but for tropylium cation our $\Delta H_{f\,298}$ (878 kJ mol^{-1}) suggests that experimental re-examination would be desirable. Our best estimate of the energy difference between the two $C_7H_7^+$ isomers is 29 kJ mol^{-1} in favor of tropylium cation.

Recent work from Beauchamp's laboratory on the silicon analogues of the tropylium and benzyl cations has given indirect evidence for the production of both species from the ionization of silatoluene. The experiments also suggested that the stability ordering in the silicon systems is the same as in the $C_7H_7^+$ systems, i.e. silatropylium is more stable than silabenzyl cation. Our calculations do not support this conclusion. We find a clear-cut energy preference of 38 kJ mol^{-1} in favour of silabenzyl cation.[3]

Finally, **nucleophilic substitution reactions**[4] are discussed as an example of the use of theory to study gas-phase ion reactions. Overall barriers for identity S_N2 reactions of X^- with CH_3X (X = F, Cl, Br and I), taking place via backside attack and resulting in inversion of configuration, are found to be small and to lie in a narrow range between -11 (X = F) and +10 (X = Cl) kJ mol^{-1}. In contrast, frontside attack, resulting in retention of configuration, needs to overcome large barriers of between 170 and 195 kJ mol^{-1}. The theoretical results provide an explanation for a second pathway for exchange, observed at about 193 kJ mol^{-1} by Bierbaum and coworkers in the case of X = Cl. The observed barrier is very close to that calculated (195 kJ mol^{-1}) for the frontside attack.

The summary take-home message is that theory can play an important and complementary role to experiment in studying the structure and thermochemistry of gas-phase ions and the mechanism of reactions involving such species.

Recent Experimental Investigations of Gaseous Ion Thermochemistry

T.B. McMahon; Department of Chemistry; The University of Waterloo;
Waterloo, Ontario; CANADA N2L 3G1

Thermochemical data for gas phase ions provide a valuable means for assessing intrinsic stabilities and reactivities of charged species in the absence of complications due to solvation and ion-pair interactions. Pulsed ionization high pressure mass spectrometry (HPMS) is one of the most valuable techniques for obtaining such thermochemical data, through examination of the temperature dependence of ion-molecule equilibrium processes.

For example, from an examination of proton transfer equilibrium, eqn. (1), the *relative* base

$$B_1H^+ + B_2 \rightleftharpoons B_2H^+ + B_1 \qquad (1)$$

strengths of the species B_1 and B_2 can be determined. If the *absolute gas phase basicity* of either B_1 or B_2 is known then the other is automatically determined. Alternatively an absolute basicity may be determined from the free energy change for an association reaction. For example the basicity of methyl *t* butyl ether my be obtained from a measure of the equilibrium constant for association of the *t*-butyl cation with methanol, eqn. (2).

$$t\text{-}C_4H_9^+ + CH_3OH \rightleftharpoons [CH_3Ot\text{-}C_4H_9]H^+ \qquad (2)$$

In recent attempts to carry out such experiments for the association of small organic cations with neutral molecules it was discovered that temperature dependence of the equilibrium constant (van't Hoff plot) revealed the existence of two isomeric forms of the association adducts of *t*-butyl cation and several small organic molecules. For example, the data for methanol (Figure 1.) show an adduct at low temperature characterised by a strong enthalpy of association ($\Delta H°$=-29 kcal/mole) but an unusually unfavourable entropy of association ($\Delta S°$=-54 cal/(mole-K)). In contrast, the adduct formed at high temperature has a much weaker enthalpy of association ($\Delta H°$=-15 kcal/mole) but a less unfavourable entropy of association ($\Delta H°$=-21 cal/(mole-K)). As can be seen from the data summarized in Table 1., this pattern is repeated for a number of other species. The low temperature structures are thought to be covalently bound adducts (*i.e.* protonated methyl *t*-butyl ether in the case of methanol, **I**) while the higher temperature structures are, most probably, weakly hydrogen bonded species in which the proton of a protonated base interacts with the π system of *i*-butene (*i.e.* **II** in the case of methanol). These two types of structure have been found, by *ab initio* calculation, to correspond to stable minima on the potential energy surfaces of several of the adducts. In addition, the data are also consistent with a further stabilizing interaction in the low temperature adducts of ethanol and diethyl ether, in which a hydrogen on the carbon adjacent to the basic oxygen site forms a hydride bridge to the *t*-butyl cation centre. Such an interaction would serve to explain the peak due to protonated acetaldehyde (+ *i*-butane) in the metastable spectrum of ethanol adducts.

Analogous experiments have been carried out involving adducts of transition metal ions generated *via* laser ablation with rare gases and small molecules. For example the data shown in Table 2. for argon adducts reveal a predominantly electrostatic character for such species.

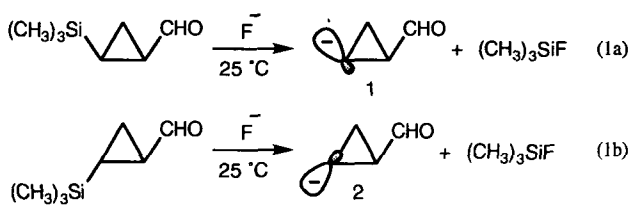
Structure and Reactivity Of A Cyclopropyl Anion: Experiment and Theory

Michael Baschky, Kent Peterson and Steven Kass
Department of Chemistry
University of Minnesota, Minneapolis, MN 55455

Cis and *trans*-2-(trimethylsilyl)formylcyclopropane react in our variable temperature flowing afterglow device at room temperature to afford distinct, noninterconverting, cyclopropyl anions (eq 1).[1] The structure, reactivity and



thermodynamic properties of these homoenolates have been probed experimentally and computationally. For example, the formyl group is found to have a large stabilizing influence (Figure 1).

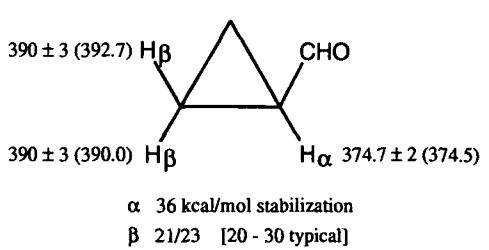


Figure 1. Experimental and calculated (in parentheses) acidities in kcal/mol.

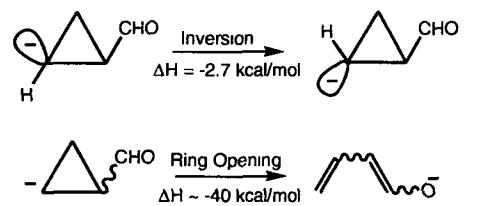
Cyclopropyl anions **1** and **2** isomerize at elevated temperatures; inversion and ring-opening processes take place (eqs 2 and 3). The latter rearrangement can proceed, in principle, via eight different transition states, six of which were found



computationally. The theoretical (Table 1) results are in accord with experiment and indicate that there is a large preference for inward rotation (torquoselectivity) of the *trans* anion and essentially no bias for the *cis* species. These results can readily be explained in terms of orbital and electrostatic interactions.

Table 1. Calculated (MP2/6-31+G(d)) barriers for the ring-openings of *cis* and *trans*-2-formylcyclopropyl anions.[a]

Neutral and Ionic Heats of Formation; Their Measurement and Reliability for Ketenes.

J.L. Holmes, J.K.Terlouw *, C. Aubry and D. Suh *

Chemistry Department, University of Ottawa, Ottawa, Ontario, K1N 6N5, Canada
** Chemistry Department, McMaster University, Hamilton, Ontario, L8S 4M1 Canada*

The heat of formation, $\Delta_f H°$, of ketene, CH_2CO, is an important thermochemical quantity, leading to $\Delta_f H°$ estimates for many substituted ketenes, R_1R_2CCO. $\Delta_f H°[CH_2CO]$ was measured in 1971 from the heat of the reaction $CH_2CO(g) + NaOH(aq) \dashrightarrow CH_3COONa(aq)$ and the resulting value of -11.4 ± 0.4 kcal mol^{-1} has been widely quoted.

There are no data for methyl or dimethyl ketenes and only the former has been investigated by *ab initio* MO theory [1], $\Delta_f H°[CH_3CHCO](calc) = -15.6 \pm 2.4$ kcal mol^{-1}. This value implies a most unusually small (-4 kcal mol^{-1}) $\Delta(\Delta_f H°)$ for methyl substitution, which in olefins and allenes is -8 ± 1 kcal mol^{-1} and in carbonyl compounds -13 ± 1 kcal mol^{-1}.

To investigate this problem by experiment the AE values for the reactions (1)-(3) were measured using energy selected electrons.

$$CH_3COOC_6H_5 \dashrightarrow C_6H_5OH^+ + CH_2CO \quad (1)$$
$$CH_3CH_2COOC_6H_5 \dashrightarrow C_6H_5OH^+ + CH_3CHCO \quad (2)$$
$$(CH_3)_2CHCOOC_6H_5 \dashrightarrow C_6H_5OH^+ + (CH_3)_2CCO \quad (3)$$

The fragment ion was easily demonstrated to be ionized phenol by its metastable ion and collision induced dissociation behaviour. The three reactions showed very small kinetic energy releases from the metastable ionized phenyl esters. The AE values were 9.83, 9.58 and 9.50 ± 0.05 eV respectively and the $\Delta_f H°$ values for the esters were -66.8, -70.8 and -77.6 kcal mol^{-1} respectively. With $\Delta_f H°[C_6H_5OH^{+\cdot}]$ as 172.3 kcal mol^{-1}, the ketene enthalpies of formation were:

$$\Delta_f H°[CH_2CO] = -12.4 \pm 1.3 \text{ kcal mol}^{-1};$$
$$\Delta_f H°[CH_3CHCO] = -22.2 \pm 1.3 \text{ kcal mol}^{-1},$$
$$\Delta_f H°[(CH_3)_2CCO] = -30.8 \pm 1.3 \text{ kcal mol}^{-1}.$$

The average $\Delta(\Delta_f H°) = -9$ kcal mol^{-1}, the same as for allenes and olefins and so the results of the calculations may be in error.

The neutral heats of formation, combined with the IE values of Bock [2], lead to ionic heats of formation of 211, 185 and 165 kcal mol^{-1} respectively, in excellent agreement with independent values determined from the production of $CH_2CO^{+\cdot}$, $CH_3CHO^{+\cdot}$ and $(CH_3)_2CCO^+$ as fragment ions. The present results therefore appear to be consistent.

4-MEMBER CYCLIC HALONIUM IONS IN INTRAMOLECULAR 1,3-FLUORIDE TRANSFER

Viet Nguyen and Thomas Hellman Morton
Department of Chemistry, University of California, Riverside

When an ion and molecule encounter one another in the gas phase, they do not necessarily fall into a potential well, even if the well is deep and accessible with no energetic obstacle other than the centrifugal barrier. An instance is provided by the reaction of CF_3^+ with C_3H_6O carbonyl compounds. Eyler, Ausloos, and Lias reported the transposition of F^+ for O two decades ago,[1] and our experimental results show that simple metathesis operates regardless of whether the neutral reactant is acetone or propionaldehyde.

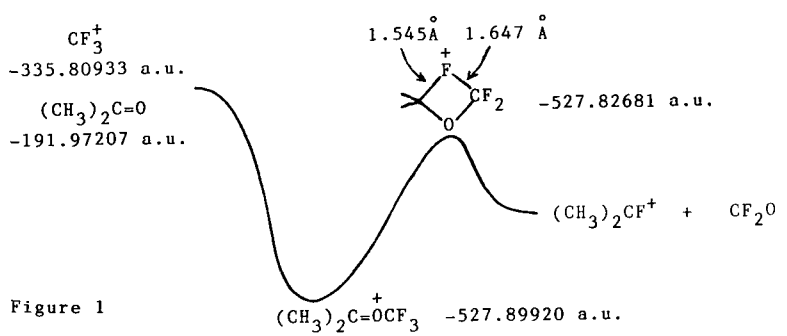

Figure 1

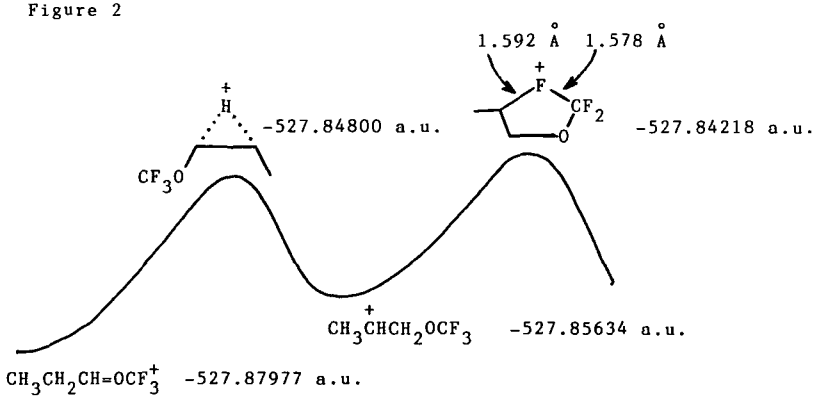
The peculiarity of this outcome can be grasped by first considering the high barrier corresponding to the 4-member cyclic transition state represented in Figure 1 for the reaction of CF_3^+ with acetone. As portrayed by the reaction coordinate diagram above, Hartree-Fock based SCF calculations (6-31G**//6-31G**) indicate that the simple Lewis acid-base adduct has an electronic energy more than 3 eV below that of the isolated reactants (Zero Point Energy correction <0.1 eV). We find no other potential energy minima corresponding to alternative approach geometries. The transition state for F-O metathesis lies nearly 2 eV above the Lewis acid-base adduct.

Does the reaction perforce pass through a Lewis acid-base adduct

Figure 2



en route to the transition state? Consideration of the potential energy surface for CF_3^+ plus propionaldehyde offers a test of that hypothesis. Barriers for rearrangement of $CH_3CH_2CH{=}\overset{+}{O}CF_3$ are considerably lower than the 4-center transition state for F-O metathesis. As the reaction coordinate diagram in Figure 2 depicts, the barrier for a vicinal hydride shift is 1 eV lower than for F-O metathesis. Although the resulting isomeric ion, $CH_3\overset{+}{C}HCH_2OCF_3$, is 0.6 eV higher than the Lewis acid-base adduct, it has a low barrier for subsequent fluorine transposition via a 5-center transition state, 0.3 eV. Therefore the intermediacy of a Lewis acid-base adduct would predict that $(CH_3)_2CF^+$ ought to result from the reaction of propionaldehyde with CF_3^+.

EBFlow experiments show that $(CH_3)_2CF^+$ is produced when CF_3^+ reacts with propionaldehyde,[2] but ^{13}C-labeling reveals that this is not a consequence of the rearrangement portrayed in Figure 2. Instead (as confirmed by a comparison of the CAD fragmentation of the product ion from $CD_3CH_2CH{=}O$ and CF_3^+ with the CAD of authentic $CH_3\overset{+}{C}FCH_3$) simple metathesis occurs followed by (on the msec timescale of the EBFlow experiment) a rearrangement of free $CH_3CH_2CHF^+$ by competing methyl and fluorine shift.

Theoretical Studies of Proton Transfer Potential Energy Surfaces

Scott Gronert, Cliff Kimura, and Aladin Sadoun
Department of Chemistry and Biochemistry,
San Francisco State University, San Francisco, CA 94132

Introduction

Proton transfer plays a critical role in a variety of processes and provides a model for more complicated bond transformations. Gas phase studies can be the most illuminating because the potential energy surface is not perturbed by solvation or ion pairing effects. Although experimental gas phase studies have provided a wealth of thermochemical data, there are critical limitations. For example, the relatively narrow dynamic range of the present mass spectroscopy technology limits the range of activation barriers that can be characterized accurately. As a result, computational studies provide an important complement to experimental studies of gas phase proton transfers. To be useful, the calculations must provide results that are reliable and accurate. In the present contribution, we present a new computational protocol that yields very accurate ΔHacid values for a series of simple acids. In particular, the hydrides of the first and second row non-metals are investigated (CH_4 => FH and SiH_4 => ClH) as well as HCCH and NCH. In addition, a set of high-level calculations are presented for the reactions of these species with their conjugate bases. Transition states as well as ion dipole complexes have been located and the activation barriers have been correlated to the reaction exothermicities *via* a Marcus Theory approach.[1,2]

Results

Radom and Smith[3] have shown that the Pople's G2 approach[4] can reproduce experimental gas phase acidities with good accuracy. For the series in this study, an RMS error of 0.9 kcal/mol is observed; however there are large discrepancies in some cases. For example the acidity of CH_4 is underestimated by 1.8 kcal/mol. In an earlier study, we showed that the errors can be reduced (RMS error = 0.7 kcal/mol) by augmenting the basis sets of the conjugate bases with a set of ghost functions centered at the position of the missing proton.[5] Although successful, this approach suffers from arbitrariness (where to position the ghost functions) and it is difficult to generalize to reaction systems. A preferable approach would be to supplement the basis sets of the heavy atoms with diffuse, atom-centered functions. The exponents of a second set of diffuse sp functions for the first and second row non-metals have been defined in this study by minimizing the calculated proton affinities of the conjugate bases at the MP4/6-311++(+)G(d,p) level (the third '+' refers to the second set of diffuse functions on heavy atoms). The exponents as well as the calculated acidities are given in Table 1. As before, we have adopted a modified version of the G2 protocol. The major differences are the addition of the second set of diffuse sp orbitals on heavy atoms and a single set of diffuse s orbitals on hydrogens. Optimizations are completed at the MP2/6-31+G(d,p) level and energies are corrected for zero-point vibrations (HF scaled by 0.91). Finally, the values are converted to 298 K by the usual methods. Overall, the process gives energies that approximate the QCISD(T)/6-311++(+)G(3df,2p) level.

G2+++ = MP4/6-311++(+)G(2df,p) + ZPE

+ QCISD(T)/6-311++(+)G(d,p) - MP4/6-311++(+)G(d,p)

+ MP2/6-311++(+)G(3df,2p) - MP2/6-311++(+)G(d,p)

Table 1 Exponents for Extra Diffuse Functions and Calculated Gas Phase Acidities.

System	Exponent	ΔHacid(298 K) Exp.	G2+++	G2	Becke3P86
CH_4	0.0142	416.7 ± 0.7	416.6	418.5	417.6

HCCH		378.0 ± 0.6	377.2	377.9	378.8
NCH		351.4 ± 0.5	351.4	350.8	352.5

Energies in kcal/mol. Experimental values from Berkowitz, Ellison, and Gutman, *J. Phys. Chem.* **1994**, *98*, 2744. G2 from Smith and Radom, *J. Phys. Chem.* **1991**, *95*, 10549.

The values in Table 1 indicate that the G2+++ method can give excellent results with a smaller RMS error than the G2 method (0.5 kcal/mol vs. 0.9 kcal/mol). Moreover, none of the errors is greater than 1 kcal/mol. DFT calculations have also been investigated.[6] The best values come from the Becke3P86/6-311++(+)G(3df,2p) level and they are included in Table 1. The RMS error is 0.9 kcal/mol.

Our earlier studies of identity proton transfers[5] have been extended to a series of exothermic proton transfers: OH^- + FH, SH^- + ClH, PH_2^- + SH_2, CH_3^- + H_2, NH_2^- + OH_2, CH_3^- + NH_3, HCC^- + FH, SiH_3^- + PH_3, HCC^- + SiH_4, NH_2^- + H_2, SiH_3^- + FH, and NC^- + SH_2. In most cases, there is no barrier to proton transfer and a stable, hydrogen-bonded complex is formed. For the systems where both reaction partners have significant intrinsic barriers to proton transfer, a double-well potential with a barrier is observed (CH_3^- + H_2, CH_3^- + NH_3, NH_2^- + H_2, HCC^- + SiH_4, SiH_3^- + PH_3, and NC^- + SH_2). The barriers do not correlate with the exothermicity of the reaction or the difference in energy of the reactant and product ion-dipole complexes. Marcus Theory leads to a reasonable correlation for this small data set; however, analysis of the contributions from each of the terms in the Marcus equation indicates that the correlation is somewhat fortuitous and that the Marcus approach can provide no more than a crude description of the potential energy surface.[7]

METAL-LIGAND THERMOCHEMISTRY by GUIDED-ION BEAM MASS SPECTROMETRY

Y.-M. Chen, N. F. Dalleska, S. Goebels, C. Haynes, F. A. Khan, F. Meyer, M. B. More, M. T. Rodgers, R. H. Schultz, M. Sievers, B. L. Tjelta and P. B. Armentrout
Chemistry Department, University of Utah, Salt Lake City, UT 84112

In the last several years, a versatile approach has been developed to determine accurate sequential bond dissociation energies (BDEs) for a multitude of metal-ligand systems. This is accomplished by generating individual ML_x^+ (or ML_x^-) complexes in the gas phase and monitoring reaction (1), collision-induced dissociation (CID), as a function of the kinetic energy of the collision in a mass spectrometer.

$$ML_x^+ + Rg \longrightarrow ML_{x-1}^+ + L + Rg \qquad (1)$$

Such studies can include virtually any metal and ligands ranging from familiar species such as CO,[1,2,3,4,5,6,7] H_2O,[8,9] NO,[4] alkenes,[10,11] and benzene[12,13] to the unusual but potentially important such as N_2,[4] CH_4,[8,14] and other alkanes.[15,16] Most recently, we have begun to examine the interactions of alkali ions with crown ethers,[17] nucleic acid bases and amino acids.[18]

The studies described here have been performed on a guided ion beam tandem mass spectrometer described in detail elsewhere.[19] Cationic transition metal complexes are generated in a high pressure flow tube source,[20] where the ions undergo ~10^5 collisions with the room temperature bath gasses, which provide three-body stabilization and thermalization of the metal-ligand complexes. The ions are then mass analyzed and focused into a collision cell. Here the ions react with a neutral reagent (at sufficiently low pressures that single ion-neutral encounters are the rule) at a kinetic energy, E_T, that can be varied over a wide range (3-4 orders of magnitude). Product ions are analyzed in a second mass spectrometer and detected by single particle counting. Ion intensities are converted to absolute reaction cross sections, $\sigma(E_T)$, a direct measure of the probability of reaction at E_T.

There are several important factors that must be considered in order to extract accurate thermochemistry from threshold CID data. These include complete thermalization of the ions, analysis that explicitly considers the kinetic and internal energy distributions of the reactants, the choice of collision gas (Xe is used almost exclusively in our studies), and the effects of multiple ion-neutral collisions (before analysis, our data are extrapolated to zero neutral pressure, rigorously single collision conditions).[1] In addition, as the metal-ligand complexes become larger, the probability increases that they do not dissociate before detection (a time window of ~10^{-4} s). We account for this effect by using RRKM theory to calculate a dissociation probability as a function of the ion internal energy.[2]

Examples of our CID data are shown in Figure 1 for the case of $Na^+(H_2O)_4$ and Figure 2 for Na^+-Adenine. The first example shows the influence of the internal and kinetic energy distributions. It is obvious that the 0 K threshold (dotted line) of ~0.5 eV differs appreciably from the apparent threshold exhibited by the data (open circles). The threshold determined in this analysis agrees well with an energy derived from equilibrium methods,[21] indicated by the arrow. Figure 2 shows that even complicated ligands yield good quality threshold CID spectra. Interpretation of such systems is in progress.[18]

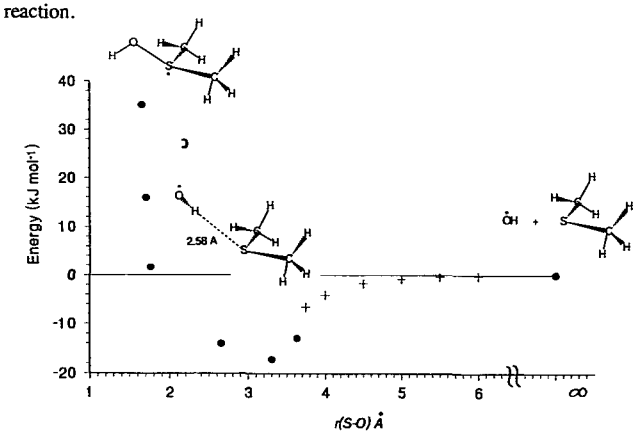
EXPERIMENTAL AND AB INITIO STUDIES OF SECOND ROW RADICALS

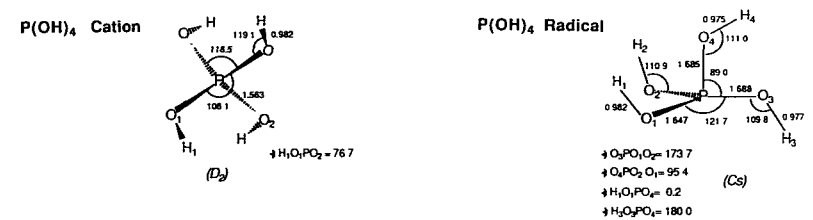
František Tureček, Scott A. Shaffer, Ming Gu and Cornelis E. C. A. Hop
Department of Chemistry, Box 351700, University of Washington, Seattle, WA 98195-1700
Department of Chemistry, University of Wisconsin, Madison

Radicals centered at second-row atoms appear as possible intermediates of several chemical reactions. The $(CH_3)_2S^{\bullet}OH$ radical has been presumed by atmospheric chemists to be formed transiently in the tropospheric oxidation of dimethylsulfide, but it has never been detected *(1)*. Hydroxyl radical attack on phosphines is presumed to involve hydroxylated phosphoranyl radicals that have been studied by theory but eluded detection. We combine neutralization-reionization mass spectrometry with ab initio calculations to investigate the formation of hypervalent sulfuranyl and phosphoranyl radicals by fast electron transfer, and examine their stabilities and unimolecular dissociations.

$(CH_3)_2S^{\bullet}OH$ represents a (9-S-3) hypervalent radical with formally nine electrons at the central sulfur atom. We prepared it transiently by collisional neutralization of its stable cation, $(CH_3)_2S^{+}OH$, which in turn was made by gas-phase protonation of dimethyl sulfoxide with $t\text{-}C_4H_9^{+}$ *(2)*. The sulfuranyl radical was found to decompose completely on the 4.5 μs time scale of the experiment to yield CH_3SOH, $(CH_3)_2S{\rightarrow}O$, and $(CH_3)_2S$, which underwent consecutive dissociations. Ab initio investigations of $(CH_3)_2S^{\bullet}OH$, carried out at the MP2(FULL)/6-31+G(d) level of theory, found no potential energy minimum for the sulfuranyl radical *(3)*. At typical S-O and C-S bond lengths the radical shows large negative gradient for dissociation by S-O bond cleavage. A shallow potential energy minimum of 13-17 kJ mol^{-1} was found at various levels of ab initio theory for a dipole-dipole complex of $(CH_3)_2S$ with $HO^{\bullet}$, in which the hydroxyl hydrogen is oriented toward the sulfur atom. No bonding interaction between S and O was found at various S-O distances. Closer approach of the hydroxyl oxygen atom to the sulfur atom resulted in a substantial increase of potential energy, indicating a large activation barrier (Figure 1). By contrast, we found an activation barrier of only 4 kJ mol^{-1} for the hydrogen abstraction to yield $CH_3SCH_2^{\bullet}$ and water, which is exothermic by 105 kJ mol^{-1} at 298 K *(2)*. Hydrogen abstraction is predicted to be the favored channel in the dimethyl sulfide-hydroxyl radical reaction.



The tetrahydroxyphosphoranyl radical, $P^{\bullet}(OH)_4$, represents a hypervalent (9-P-4) species with formally nine electrons at the central phosphorus atom. The radical was prepared transiently by collisional neutralization of the $P(OH)_4^{+}$ ion, which is a common dissociation product of electron ionization of trialkyl phosphates. The $P^{\bullet}(OH)_4$ radical dissociates completely on the μs time scale. The observed dissociations involve loss of hydrogen atom, and formations of H_2PO_3, HPO_3, HPO_2, PO_2, PO, P, and OH. Isotope effects were found favoring the formation of $P(OD)_3$ and D_2O from $P^{\bullet}(OD)_4$. Ab initio calculations at the MP4(SDQ)/6-31+G(d)//MP2(FULL)/6-31+G(d) level of theory found $P^{\bullet}(OH)_4$ to be metastable with respect to exothermic dissociations by loss of $H^{\bullet}$ ($\Delta H_{f,298}$ = -30 kJ mol^{-1}) and elimination of water ($\Delta H_{f,298}$ = -7 kJ mol^{-1}). The loss of $H^{\bullet}$ overcomes a barrier of 90 kJ mol^{-1}. The optimized geometries of $P(OH)_4^{+}$ and $P^{\bullet}(OH)_4$ greatly differ (Figure 2).



Consequently, vertical electron transfer forms the hypervalent radical with non-relaxed geometry of 129 kJ mol^{-1} internal energy that drives fast dissociation by loss of $H^{\bullet}$. The H_3PO_4 molecules are formed with >160 kJ mol^{-1} internal energy due to the dissociation exothermicity. This and further energy deposition upon reionization drives the loss of $OH^{\bullet}$ from $H_3PO_4^{+\bullet}$, which is only 223 kJ mol^{-1} endothermic. The loss from $P^{\bullet}(OH)_4$ of $OH^{\bullet}$ is 108 kJ mol^{-1} endothermic and requires an activation energy estimated at >160 kJ mol^{-1}. The calculated electron distribution in $H_3PO_4^{+\bullet}$ indicates separation of the radical and charge sites *(5)*. The ion can be viewed as an oxy radical with an adjacent positive charge on the phosphorus atom. This explains the large hydrogen atom affinity of oxygen atoms in phosphate cation-radicals and the ensuing isomerizations by exothermic intramolecular hydrogen transfer.

Relative energies were also calculated for the $P(OH)_3$ and $HPO(OH_2)$ isomers, which were prepared by neutralization of their cations and found to be distinct species. Neutral phosphorous acid is 45 kJ mol^{-1} more stable than trihydroxyphosphine. Collisional activation of the $P(OH)_3$ brings about isomerization to $HPO(OH)_2$, which is calculated to have 225 kJ mol^{-1} activation energy. An opposite order of stabilities is found for the cation-radical of which $P(OH)_3^{+\bullet}$ is 136 kJ mol^{-1} more stable than $HPO(OH)_2^{+\bullet}$. The latter ion dissociates readily by loss of $H^{\bullet}$ which requires only 119 kJ mol^{-1}.

CHARACTERISATION OF SYNTHETIC POLYMER FORMULATIONS USING MALDI

Jim H Scrivens*, Hilary Yates, John Segal, Tony Jackson, Mike Taylor
ICI, Wilton Research Centre, Po Box No 90, Wilton, Cleveland, England, TS90 8JE

Glen Critchley, Ann Maisey
VG Organics, Floats Road, Wythenshawe, Manchester, England

INTRODUCTION

The use of mass spectrometry in the characterisation of synthetic polymer formulations has, until recently, been restricted to the characterisation of monomers, oligomers, additives and performance enhancers. Secondary ion mass spectrometry (SIMS) and field desorption (FD) have been used to characterise synthetic polymers in excess of 10,000 Da but the study of intact polymer systems of commercial interest has been extremely limited. The technique of matrix assisted laser desorption/ ionisation mass spectrometry (MALDI), although initially used almost exclusively in biological applications offers significant potential for the study of synthetic polymer systems.

EXPERIMENTAL

A VG Organics TofSpec MALDI-TOF spectrometry was used in the work. Both linear and reflectron modes were employed with the linear mode using a hybrid microchannel plate/ electron multiplier detector and the reflectron mode a dual channel plate detector. A nitrogen laser (337nm) was employed. Polystyrene spectra were obtained in dithranol with CF_3COO^- Ag^+ added. Polymethylmethacrylate (PMMA) samples were run in indole acrylic acid (IAA) having been dissolved in acetone.

RESULTS

A number of systems have been studied including PMMA with varying end groups, polystyrenes, commercial phenol formaldehyde resins, complex esters used in lubricant formulations and polybutadienes. Considerable care was taken with calibration since a conventional two point external calibration using a compound of different chemical class and with varying experimental conditions such as laser power etc. leads to a mass measurement accuracy of ~ 0.2%. This can be adequate for profile determination or general scouting experiments but is not adequate for the determination of end groups. For this work a multi-point external calibration using either a combined sample of polystyrene 1700, 5050 and 10200, or PMMA 2010, 5270 and 9200 was used. Where possible experimental conditions were maintained. This resulted in mass accuracies of ~ 0.04% for linear operation and ~ 0 025% for reflectron operation. Further accuracy could be obtained using internal standards but this was not always possible or desirable.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

END GROUPS IN PMMA SAMPLES

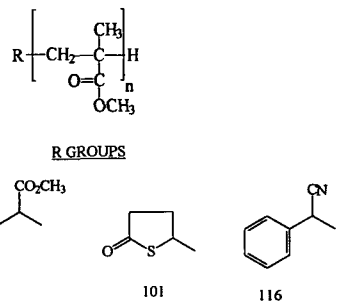

Figure 1

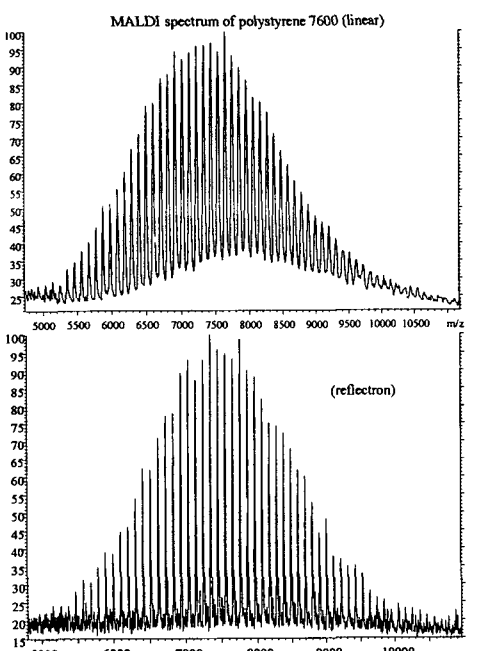

Figure 2

Figure 2 shows the MALDI spectra of a polystyrene 7600 sample in both linear and reflectron modes. The reflectron data gave improved mass accuracy data over the linear. Care needs to be taken with cationised species where the individual species are not always resolved.
The MALDI data have been compared with that obtained by field desorption and give good agreement for polystyrene samples although the obtainable resolution is greater with FD. For many samples however thermal fragmentation is a problem with FD and MALDI gives superior results. MALDI gives promising results for synthetic polymers particularly for those with low polydispersity in the 10-50 KDa region which is of commercial significance Further work is needed to extend the applicability of the approach to other polymer systems and to samples of widely varying dispersity.

Matrix-Assisted Laser Desorption/Ionization Investigations of Industrial Polymers

Scott D. Hanton and David M. Parees,

Department of Chemistry, Drexel University, Philadelphia, PA 19104

Matrix-assisted laser desorption/ionization (MALD/I) mass spectrometry is being applied to measure the chemical structure of industrial polymers.[1] The chemical structure information is used to better understand the structure/property relationships of these materials. MALD/I experiments produce data allowing us to measure the molecular weight distributions, determine the end groups and clearly observe the masses of the oligomer repeat units of individual polymers. MALD/I can analyze some materials that are difficult for more traditional analyses like gel permeation chromatography (GPC), either because of solvent or column incompatibilities. The molecular weight distribution information is used in the verification of synthetic pathways, product comparisons, vendor product specification and quality control of materials.

The successful application of MALD/I analysis to industrial polymers is greatly dependent on the chemical structure of the polymers. Different chemical structures may require significantly different sample preparation. The sample preparation step is perhaps the most important component of a MALD/I experiment. We developed a sample preparation strategy that enables us to analyze a wide range of polymer chemistries. The strategy consists of four primary steps:

* Identify the chemistry of the material,
* Choose an appropriate solvent based on the solubility parameters of the sample,
* Choose an appropriate matrix based on the polarity of the sample,
* Ensure efficient ionization with the addition of an ionization reagent.

To aid in choosing the appropriate matrix, we break the role of the matrix into five components: separation of the individual oligomers, isolation of the oligomers, absorption of the laser radiation, desorption of the oligomers, and ionization of the oligomers. The appropriate matrix does not need to be a single molecule, as long as the matrix role is accomplished. By using combinations of different molecules we can tune the matrix to the sample chemistry. This can provide the flexibility necessary to analyze new sample chemistry.

The new sample preparation strategy has helped us analyze a wide range of polymers, including: isocyanate based prepolymers, formamides, polyesters, acrylates, polyols and silicones. These experiments were completed on a non-commercial, 1-M linear time-of-flight mass spectrometer with 18 kV extraction potential and a nitrogen desorption laser (337 nm). The data were analyzed with a software package developed in-house.

One example, of this work is the analysis of poly(ethenylformamide (PEF). Figure 1 shows a MALD/I mass spectrum of a low molecular weight PEF polymer. In the development of PEF products we need to understand the impact of different synthesis conditions on polymer molecular weight. In this case we measured PEF produced at three different reactor temperatures. Figure 2 shows the average molecular weights for three temperatures. Over the range measured, molecular weight of PEF is linearly dependent on reactor temperature.

High Mass Resolution Imaging TOF-SIMS Analysis of Polymer Surfaces

Stefan Reichlmaier, Physical Electronics Inc.
6509 Flying Cloud Drive, Eden Prairie, MN 55344, USA

Introduction

Industrial polymer surfaces contain a variety of substances including additives, process aids, protective coatings and oligomeric materials. Adhesion, wetability, printing properties and physical properties like friction are affected by these organic and inorganic compounds on the surface of the polymer. Analyzing the spatial distribution of these materials on a solid surface of a polymer is frequently crucial in industrial problem solving Secondary Ion Mass Spectrometry (SIMS) utilizes a finely focused scanned primary ion beam and a Time-of Flight (TOF) mass analyzer offers great opportunities for these challenging analyses.

Imaging of organic compounds on polymer surfaces down to micron sized features has become possible with the recent advances in Time-of-Flight SIMS (TOF-SIMS) [1-4]. Most recently the application of retrospective data analysis for small oligomeric particle analysis has proven to be an important next step in the application of organic imaging with TOF-SIMS [5] These imaging applications, however, suffered from chemical ambiguity due to the low mass resolution mode the instruments had to be operated in when performing TOF-SIMS imaging analysis. With a carefully optimized bunching scheme in the primary ion optical column it is now possible to obtain good spatial resolution and good mass resolution simultaneously. This allows the resolution of mass interference in the fragmentation region (m/z=0-350) most commonly used for organic imaging applications

Experimental

Two different kind of samples were investigated in this study. A poly (ethylene terephthalate) (PET) film coated with a solvent cast glyceryl monostearate (GMS) layer and a polycarbonate bulk material with poly (vinyl alcohol) dots on it. In both cases the samples were cut to size for mounting on a one inch sample mount and then directly analyzed in the mass spectrometer. A PHI 7200 model TOF-SIMS instrument equipped with a Ga liquid metal ion (LMI) gun was used for the analysis This instrument utilizes a double stage reflectron type time-of-flight mass analyzer. A low energy electron flood gun was used for charge compensation during the measurements Images were acquired using the LMI gun in the conventional (low mass resolution) mode and also in the bunched mode of operation (high mass resolution) Utilizing the retrospective analysis of the obtained data (a complete mass spectrum is stored at any image pixel), reconstruction of images of specific mass peaks and recreation of local area mass spectra was carried out after data acquisition was completed.

Results and Discussion

A mass interference at m/z=341 between ions originating from the GMS coating and ions from the PET substrate was found in a previous study [3], but could only be mass resolved using the

instrument in the high mass resolution spectroscopy mode without sufficient spatial resolution. By analyzing this sample utilizing the new high mass resolution imaging capability it was confirmed that the observed GMS islands on the sample surface give rise to a mass peak at m/z=341 31 whereas the exposed PET surface between the islands only showed a peak at m/z=341.07
The PVA dots on polycarbonate were first imaged using a low mass resolution "fingerprint" (peak pattern) of the spectra of the two polymers to locate a PVA dot (figure 1).

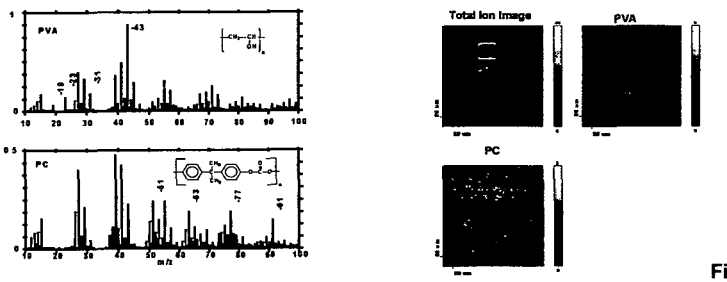

Figure 1.

Using a data set acquired in the high mass resolution imaging mode and reconstructing mass spectra from on and off the PVA dot show an oxygen containing fragment ion clearly resolved from the hydrocarbon peak (figure 2a) The images created using only these two peaks respectively, clearly show the different spatial distribution (figure 2b).

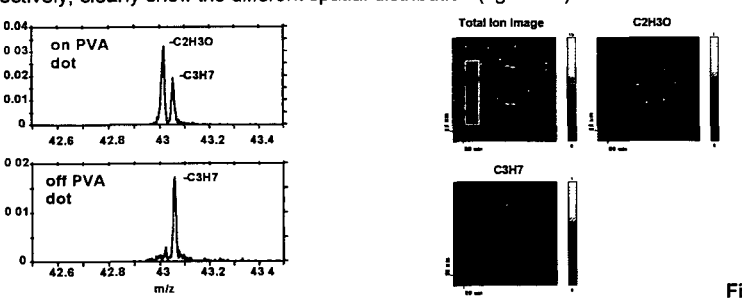

Figure 2.

This new capability resolves previously existing ambiguities in assigning chemical species to the observed mass peaks. The spatially resolved chemical spectroscopy strongly enhances the problem solving capability of the technique for polymer surface chemistry.

REVERSE ENGINEERING OF INDUSTRIAL POLYMER FORMULATIONS BY MALDI-MS

Xiaodong Tang[1]*, Akos Vertes[1], Peter Dreifuss[2], Clifford Hull[2], Walter Dutton[2]
[1] Department of Chemistry, The George Washington University, Washington, D. C. 20052
[2] Washington Research Center, W. R. Grace & Co., 7379 Route 32, Columbia, MD 21044

Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry (MALDI-MS) has recently been viewed as a useful technique for synthetic polymer analysis [1-4]. However, industrial applications are still somewhat limited because operational parameters require further optimization. For this report, we sought to maximize the information obtained by MALDI-MS analysis on polymer standards and applied this to the analysis of actual industrial samples. Variables under investigation included choice of matrix, sample pretreatment and accelerating voltage. We also looked at potential interferences from polymer mixtures. Experiments were carried out on a linear time-of-flight mass spectrometer equipped with a compact nitrogen laser.

Choice of Matrix: Over 15 potential matrices were tested; 9-anthracenecarboxylic acid (9-ACA) was found to be particularly sensitive both to polar and to some non-polar polymers. Good quality spectra were readily obtained from the following polymer standards: PEG 610, 3300, 5000, 8000, 10225, 10730, 15000; PPG 450, 1000, 1200, 2000, 5000; PMMA 2000, 6000, 12000; Jeffamine 2000; polybutadiene 1000; and polydimethyl siloxane (PDMS) 1500. Additional experiments were carried out using matrix mixtures of varying composition. Excellent results could be obtained from a composite matrix ("super" 9-ACA) of 9-ACA and 5-methoxysalicylic acid (molar ratio 5:2) (see Figure 1a).

Sample Pretreatment: The presence of both sodium and potassium cationized ions results in an apparent loss of resolution in a MALDI analysis. To overcome this problem, two sample pretreatments were found to be useful: (a) both analyte and matrix solutions were purified by ion-exchange, followed by addition of a controlled amount of sodium or potassium ions to the matrix. This resulted in homogeneously cationized polymer ions; (b) To remove some of the cations, 18-crown-6 was added to the matrix/analyte solution on the probe. This method often resulted in better mass resolution. The concentration of the crown ether depended on the amount of alkali impurity in the matrix/analyte mixture.

Accelerating Voltage: In MALDI-MS analysis, the detector efficiency is known to fall off with decreasing velocity of the ions, especially for high mass particles. Figure 1 shows a comparison of the mass spectra of PPG 5000 in "super" 9-ACA matrix at 30 kV and 15 kV accelerating voltages. We observed that decreasing the accelerating voltage decreased the ion intensity by a factor of 5, decreased the mass resolution from 275 to 125 (at m/z 5078) and truncated the high mass end of the spectrum.

Polymer Mixtures: The MALDI spectrum of a PPG 2000/PEG 3300 mixture in 9-ACA matrix is shown in Figure 2. Both polymers are readily recognized by repeating mass differences of m/z 58 and m/z 44, derived from the repeating PPG [$-OCH_2CH(CH_3)-$] and PEG [$-OCH_2CH_2-$] monomers, respectively. No fragmentation or interaction between these two samples were observed, indicating the potential of MALDI for the analysis of synthetic polymer mixtures.

Applications on Industrial Samples: Based on the above studies, we investigated the use of MALDI-MS for problem solving, as well as for characterization and quality control of industrial polymers. Information could be obtained by MALDI-MS on samples that were not well characterized, but for which corroborating analytical data was available, including GPC, FTIR, NMR, and electron ionization, APCI and K^+IDS MS.

Figure 3 shows an example of MALDI-MS analysis of an unknown polyurethane component in a commercial product isolated by HPLC. From GPC measurements, only one component with average MW 6,000 could be readily discerned. In the MALDI spectrum, we observed two components with

averages centered at m/z 5,300 and m/z 8,000. The peaks in the 4,000 to 6,000 mass range were sufficiently resolved to indicate PPG bonded to a single toluene diisocyanate. Despite various attempts, the higher mass component centered at m/z 8,000 is not sufficiently resolved to be able to determine its composition. The solution to these challenges is still required.

MALDI in Polymer Chemistry: Rapid Analysis of Chemical Modifications on Polymers

Randy M. Whittal and Liang Li
Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada
T6G 2G2

Chemical modification of polymers is a common practice in polymer chemistry. Assessing the success of a chosen chemical modification usually requires several analytical methods for unambiguous assignment. Among these analytical tools, matrix-assisted laser desorption ionization (MALDI) mass spectrometry can provide strong evidence of structural modification. The objective of this work is to assess the feasibility of analyzing end-group modified polymers with MALDI in our linear time-lag focusing time-of-flight (TOF) instrument [1].

A linear TOF mass spectrometer, combined with time-lag focusing, provides mass resolution in the range of 3000-6000 fwhm for peptides up to 3000 Da [1]. In this technique, MALDI ions are generated in a field-free source and then pulsed out of the source after a 280 ns delay. For polymer analysis, a sample preparation method capable of providing good external mass accuracy, reproducibility, resolution and uniform analyte distribution is necessary.

The matrix 2-(4-hydroxyphenylazo)benzoic acid (HABA) introduced by Juhasz et al. [2] is found to provide the best external mass accuracy, highest resolution and reproducibility of the molecular weight distribution. HABA is dissolved in 1,4-dioxane at a concentration of 0.05 M. Polyethylene glycol and modified polymers are dissolved in methanol ($\approx 10^{-3}$ M). The polymer solution and HABA solution are premixed to provide a final polymer concentration of 10^{-4} M. To 100 μL of polymer/HABA solution, 1.0 μL of 0.02 M NaCl is added. 1.0 μL of this mixture is added to the sample probe and allowed to dry. The HABA crystals formed from the 1,4-dioxane solution are small (1 to 3 μm) and uniform. The analyte is evenly distributed throughout.

Figure 1A is the MALDI mass spectrum of PEG 3350 using a pulse voltage of 1.80 kV. This is the optimal pulse voltage for ions of ≈3300 Da. The resolution for the polymer ions in this spectrum is 950 to 1050 fwhm across the whole distribution. This resolution is limited by the isotope peaks of the polymer at this mass. The kinetic energy of MALDI generated ions increases with mass. It is thus necessary to increase the pulse voltage to focus ions of higher mass at the detector plane. Figure 1B shows the mass spectrum of PEG 3350 using a pulse voltage of 2.19 kV. This pulse voltage is appropriate for focusing ions of ≈5000 Da. However, the pulse voltage change does not affect the determination of the molecular weight distribution. The number average (M_n) and weight average (M_w) molecular weight for three repeat experiments at each pulse voltage vary by only 0.1%.

Figure 2 is the MALDI spectrum of PEG 3350 bis(Acetaminophen). The mass accuracy is 53±35 ppm across the entire distribution using external calibration with PEG 3350. Good mass accuracy is necessary for this compound to distinguish unlabeled, singly labeled and doubly labeled polymer which vary by 1 amu (see Figure 2). The peaks on the low mass end of the distribution demonstrate that during synthesis the polymer may undergo hydrolysis as all peaks correspond to doubly labeled product but some oligomers are of lower mass than starting material oligomers. The dispersity of the polymer is changed during modification. As a result, the shift in M_n and M_w does not accurately reflect the chemical modification.

Accurate molecular mass assignment is necessary to confirm the expected structure from chemical modification. Relying on the shift in M_n and M_w to demonstrate the success of a modification may not be reliable.

MW DETERMINATION OF SYNTHETIC POLYMERS FROM ESI & MALDI MASS SPECTRA

Charles McEwen, Christian Jackson, and Barbara Larsen
DuPont Central Research Department, P.O. Box 80228, Wilmington, DE 19880-0228

Electrospray ionization (ESI) and matrix assisted laser desorption ionization (MALDI) are capable of ionizing a variety of polymers. ESI mass spectra of oligomer distributions are complicated by the propensity of each oligomer to carry multiple charges. But ESI has the advantage of better mass resolution and mass accuracy than MALDI TOF. With MALDI on the other hand, a wider variety of solvents can be used than with ESI and thus applicable to a wider variety of polymers. In addition, multiple charging is limited resulting in higher mass ranges obtained and less complicated spectra.

In this report, we are attempting to determine the value of these ionization techniques in providing unique or more accurate polymer characterization than is available through GPC, light scattering, nmr, osmometry, etc.. Individual oligomers of t-butyl end-capped polymethylmethacrylate (isotactic and syndiotactic 25 and 50 mers) were collected by SFC and weighed to provide equimolar solutions.[1] By ESI, peak areas and peak heights of the multiply charged ions underestimated the molar concentration of the 50 mers relative to the 25 mers. However, after accounting for peak area compression of multiple charging (i.e. a double charge peak will have only 1/2 the area of a singly charge peak, a triply charged peak only 1/3 the area, etc.) the areas of the 25 mers and 50 mers were the same for equimolar concentrations within experimental error. MALDI produced only singly charged ions for these oligomers and the peak areas were equal for equimolar solutions. Fragmentation of the molecular ions were not observed with either technique.

The above data suggests that for narrow distributions, ESI and MALDI should produce accurate values for the weight and number average molecular weights (Mw, Mn) as well as polydispersity (Mw/Mn), D, and Mp (most probable mass as measured by GPC) for low molecular weight PMMA polymers. Comparing MALDI values with the GPC data for narrow distribution PMMA standards showed reasonably good agreement, but MALDI values were consistently low, particularly the Mp values. Low Mp values for MALDI data of PMMA standards has recently been reported.[2]

A narrow polymer distribution can be simulated by a Poisson distribution of oligomers using the following equations for a weight average and number average distribution where x is the degree of polymerization and v is the number of monomers reacted per initiator.

$$W_x = \frac{x\, e^{-v}\, v^{x-1}}{(v+1)\,(x-1)} \qquad N_x = \frac{e^{-v}\, v^{x-1}}{(x-1)!}$$

The weight fraction distribution, W_x, is measured by GPC while mass spectrometry measures number fraction, N_x. Plotting these distributions on a linear scale shows that for a Poisson distribution Mp will be one monomer mass lower for a number average distribution than for a weight average distribution over any mass range. When the weight fraction distribution is plotted on a logrithmic scale as in GPC, the Mp value is two monomer masses higher than the Mp number fraction plotted on a linear scale. Clearly showing that the Mp values as determined by M.S. will be at least two monomer masses below the Mp values determined by GPC.

Mp values determined by mass spectrometry are measured over just a few oligomer species and thus over a narrow mass range. The results from the PMMA 25 and 50 mers show reasonable (± 5%) molar ion abundance's can be measured over a 2X mass

difference. Therefore, the much smaller mass difference needed to determine Mp would suggest that Mp values measured by mass spectrometry are accurate.

Wide distribution PMMA standards have been reported not to give reliable data by mass spectrometry based partly on Mp values.[2] MALDI of a standard with a reported Mp of 33,000 gave an Mp of only 2200 by MALDI. Our experiments show a similar discrepancy, (see Figure) but not as large for a PMMA Mp=17,000 (American Standards Laboratory) resulted in a Mp by MALDI of 7500. Because MALDI of narrow distribution PMMA standards gave results close to those reported by the manufacturer (Polymer Laboratories, Ltd.), we mixed equimolar amounts (based on Mn values) of PMMA 2400, 6950, and 21,600. Peak areas were measured for the 2400, and 6950 distributions and summed (the area under the 21600 distribution was estimated). Surprisingly, the total distribution areas were in the approximate ratio of 1.0:2.0:3.0 for PMMA 2400, 6950, and 21600, respectively (107 picomoles of each distribution loaded on the target). Reducing the concentration to 7 picomoles/distribution gave a ratio closer to expected (1.0:1.07:1.15). These surprising results suggested that at least for the Finnigan Vision 2000 MALDI instrument, MW distribution values should be skewed higher mass rather than lower mass.

The 17 K wide-distribution polymer standard was run by GPC with refractive index and light scattering detectors and the results plotted on a linear mass scale as both weight fraction and number fraction distributions. The GPC was calibrated using narrow distribution PMMA standards. Mp and Mw determined by GPC and by light scattering were found to be ca. 12600. However, when plotted on a linear scale, Mp was ca. 6500 as a weight fraction distribution and ca. 3000 as a number fraction distribution. These results indicate that comparing weight fraction Mp values obtained by GPC with number fraction values obtained by mass spectrometry is not appropriate. The Mp number average depends on polymerization and termination mechanisms whereas Mp from GPC is almost independant of these mechanisms and close to Mw for linear polymers.

Mn obtained by mass spectrometry (Mn = 7900) for the 17 K PMMA was in good agreement with the GPC (Mn = 7200) and LS (Mn = 8000) values. Mw by MALDI was only 10300 and compared to 12600 by GPC and LS. The difficulty is in the high mass tail above 25K where the signal obtained by mass spectrometry is not discernable above the noise but the contribution to the weight fraction in the GPC results is significant. Recalculating the GPC results by eliminating the signal above 25000 Da, results in a Mw value of 10400 in agreement with MALDI without significantly changing Mn. These results suggests that mass spectrometry can obtain reasonable molecular weight distribution values from polymers with a wide polydispersity only if the signal-to-noise ratio can be enhanced so that high mass tails of polymer distributions can be observed.

Mass Spectrometry of Otherwise Fragile Polymers by Resonant Multiphoton Ionization of End Group Chromophores.

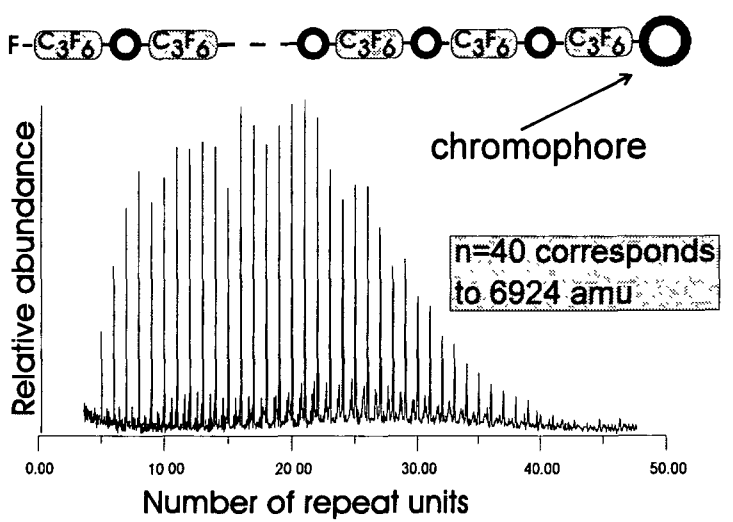
Deon S. Anex, Heinrich E. Hunziker, and Mattanjah S. de Vries
IBM Almaden Research Center, 650 Harry Road, San Jose CA 95120-6099

Perfluorinated polyethers are polymers of practical importance, yet are difficult to characterize mass spectrometrically because they fragment when analyzed by conventional techniques. To overcome this problem we demonstrate the use of laser desorption with separate photoionization of end group chromophores. In this way we have (a) obtained complete parent molecular weight distributions in a mass range of up to 8000 amu, (b) characterized compositions of copolymers in detail, (c) studied polymer degradation products, and (d) performed wavelength dependent spectroscopy on mass selected polymers.

We studied polymers with repeat units $\mathbf{R_i}$ of the form $-O-(CF_2)_i-$ with i = 1, 2, or 3, and with one or both end groups containing a phenyl chromophore. The chromophore can either be part of the original polymer or it can be chemically attached. Laser desorbed neutral molecules were entrained in a pulsed, supersonic expansion, which leads to vibrational and rotational cooling. Downstream the molecules were resonantly two-photon ionized and subsequently detected in a reflectron time of flight mass spectrometer. We obtained complete parent molecular weight distributions, showing no fragmentation and in good agreement with averages obtained from NMR. When using this technique to characterize copolymers of the type $-(\mathbf{R_1})_n-(\mathbf{R_2})_m-$, the parent mass spectrum makes it possible to map the relative abundance of all possible combinations of n and m, providing a characterization with unprecedented detail. This information is crucial for

elucidating degradation products and selective adsorption characteristics of such polymers. We obtained further information by scanning the ionization laser wavelength over the electronic origin of the S_{0-0} transition while observing specific mass to charge ratios of the resulting ions. From the spectra we deduce the formation of van der Waals dimers between chromophore end groups. While polymers with a single chromophore form inter-molecular dimers, our results also show the formation of internal dimers in bifunctional polymers.

Finally these results must be discussed relative to the general problem of photoionization of large molecules. This issue is important both theoretically and because of the question how generally the technique of separate laser desorption and laser ionization with minimal fragmentation can be applied to high mass molecules.



IN-SOURCE DIRECT PYROLYSIS MASS SPECTROMETRY AND LIBRARY MATCHING TECHNIQUES FOR DIRECT ANALYSIS OF POLYMERS IN INDUSTRIAL PRODUCTS

[a]Kuangnan Qian*, [a]William E. Killinger and [b]Gordon Nicol
[a]W.R. Grace & Co.--Conn., Washington Research Center, Columbia, MD 21044; [b] Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

INTRODUCTION

Direct pyrolysis mass spectrometry (DP/MS) has been found particularly valuable in industrial product analysis where matrix interference and detection limit may present challenges to the application of other techniques. Polymers can be pyrolyzed within an ion source of a mass spectrometer using a resistively-heated insertion filament. Compared to conventional DP/MS, in-source DP/MS avoids the condensation of pyrolysis products during transportation, and therefore is able to provide unbiased polymer mass spectra suitable for library matching purposes. In addition, since the temperature of the filament is scanned at a controlled rate, non-polymeric material can be removed prior to the pyrolysis of polymer components. Thus, it is possible to directly analyze polymers in industrial products with minimum sample preparation.

EXPERIMENTAL

The DP/MS experiments were carried out on a Finnigan MAT TSQ 700 mass spectrometer using a direct exposure probe (DEP) for polymer pyrolysis. The filament current of the DEP was increased from 250 to 700 mA at a constant rate of 75 mA/minute. The polymer library was created using a library editor provided by the Finnigan software. The electron energy was fixed at 70 eV to maximize the reproducibility of the polymer spectra. The mass analyzer was scanned from m/z 33 to 600 at a scan rate of 1 sec/scan. The integrated mass spectrum across the TIC peak top (90% of the peak height) of the pyrogram was used to create the library entry.

RESULTS AND DISCUSSION

Most polymers studied in this work were found to fall into three categories based on their pyrolysis patterns. In the first category, the polymers degrade via backbone scission and produce mostly monomers and low molecular weight oligomers. The mass spectra of these polymers are similar to that of their monomers and are normally easy to interpret. The second type of polymer, although also showing a single peak in the pyrogram, degrades via the random chain cleavage mechanism. The polymer spectra of this type therefore are very different from their monomer spectra. The third type of polymer contains thermally labile sidechains and pyrolyzes via two steps. The mass spectra of this type of polymer are normally very complicated and less characteristic of their monomer structures.

The impact of various experimental parameters on polymer mass spectra was studied. Within a wide range, polymer mass spectra were found to be unaffected by the heating rate, sample loading and polymer molecular weight.

The temperature resolved in-source DP/MS offers a possibility to differentiate polymers by their pyrolysis temperatures. This has been found particularly successful in the analyses of polymer blends and co-polymers with a large degree of blockness in monomer distribution. Figure 1 illustrates the total ion current (TIC) pyrogram of an industrial copolymer of styrene/isoprene. There are two clearly separated peaks corresponding to the pyrolysis of polystyrene and polyisoprene, suggesting that there is a certain degree of blockness in the monomer distribution. High quality library matches can be obtained by background subtraction as shown in Figure 2. In most cases, however, different polymer components may not be differentiable by their pyrolysis

temperatures. Spectrum-subtraction of top library hits has been found very useful in these cases to deconvolute the polymer spectra.

The library currently contains more than seventy polymer entries and is still in rapid expansion as this paper goes into print. Our next step is to test the compatibility of the polymer spectra on different instrumentation at different labs.

Glow discharge (GD) sources have been widely applied for the direct solids elemental analysis of metals, alloys, and semiconductors. The inherent ability of the radio frequency (rf) powered glow discharges to sputter/atomize nonconductors allows for the analysis of polymer and composite materials. From a recent study, different types of adhesives were employed to mount glass particles for elemental rf-GDMS analysis, and upon spectral evaluation the mounting materials produced predictable spectral features of polymer films. This suggested that the rf sputtering process was sufficient to bring substantial amounts of the polymer fragments into the gas phase for subsequent ionization in the glow discharge plasma. In this presentation, the preliminary observations of polymeric material analysis by rf-GDMS are described in terms of discharge parameters, signal intensity, stability, sample thickness, and topology. Comparison to static SIMS spectra is also described.

For this presentation a copolymer of polytetrafluorethylene (PTFE) and perfluoroalkoxy (PFA), in addition to three Teflon sheets of thickness 1 mm, 1.5 mm, and 3.0 mm were studied and reported by the use of this rf-GD source, and the characteristic ion fragments monitored in a peak jumping mode of the quadrupole mass filter. Figure 1 is a typical rf-GD mass spectrum of Teflon. Figure 2 shows the temporal response curves of selected fragments during the analysis of Teflon, which exemplifies the stability of the rf-GD source. The primary scope of this research is to assess the feasibility of this technique for the analysis of various polymeric materials. A preliminary evaluation of the role of discharge parameters and sample thickness on the fragment intensities was also preformed. Scanning electron micrographs of the sputtered region of 1.5 mm thickness Teflon provided some insight on the effects of sputtering on polymeric materials. A similar experiment was conducted on a terpolymer consisting of tetrafluorethylene, hexafluoropropylene, and vinylidene fluoride, and the resulting rf-GD mass spectrum was in good agreement with the static SIMS spectra of the individual polymer components. All of the results obtained herin suggest that the implementation of this rf-GDMS system is a viable technique for the analysis of polymeric material.

FD-MS Studies of Samarium-Based Oligomerization of Ethylene.

John Greaves, Donna M. DeCoster and William J. Evans.

Department of Chemistry, University of California, Irvine CA 92717-2025

Bis(pentamethylcyclopentadienyl) samarium complexes such as $(C_5Me_5)_2Sm$, $[(C_5Me_5)_2Sm(\mu\text{-}H)]_2$ and $(C_5Me_5)_2Sm(THF)_2$ can be used to catalyze polymerization of ethylene without a co-catalyst such as trialkylaluminum compounds or methylalumoxanes as required in the Ziegler-Natta systems. The polyethylene produced is insoluble and therefore of high molecular weight (>150,000 daltons). It is difficult to understand the basic steps in the polymerization processes and the influence that reaction conditions have on the process and the products because of the rapid polymerization rate of the reaction. In addition, while analysis of the molecular characteristics would assist in this understanding, the high molecular weight and insolubility of the product renders it particularly difficult to analyze. However, in the presence of hydrogen the molecular weight of the polyethylene produced is limited by hydrogenolysis. The resulting ethylene oligomers have molecular weights in approximately the 300-1000 dalton range and thus are amenable to characterization by FD-MS.

Analyses were conducted on a Fisons Autospec with a high field (4,500 dalton) magnet. The acceleration and extraction voltages were 8 kV and 4 kV respectively. A 4400 - 100 dalton scan was used with a scan rate of 7 sec/decade. Spectra were collected in continuum mode and all scans collected were averaged to obtain the profile of the oligomers being investigated. The emitter (Linden ChroMasSpec) current was programmed from 0-50 mA at 1 mA/min.

The efficiency of FD-MS was assessed using narrow molecular weight range polyethylene and polystyrene standards. Analyses of 800, 1100 and 2000 molecular weight polyethylene standards showed that all three molecular weight ranges could be could be analyzed by FD-MS and gave primarily the molecular ions although some loss of H_2 was observed which became dominant at higher masses. There was a significant loss of sensitivity for the 2000 dalton standard (factor of 50) as compared to the 800 dalton standard which could not be accounted for by the difference in molarity or the increased number of oligomer chains in the 2000 standard. This is in contrast to the analysis of 800 and 1800 dalton polystyrene standards which showed much less of a reduction in sensitivity for the higher molecular weight standard most of which could be accounted for in the molarity and number of oligomer chains. The reason for the difference between the two types of standards is not known but may relate to items such as volatility, or ability to stabilize a charge. It should be noted that when a highly branched poly(1-octene) was characterized by FD-MS, under the same conditions, ions up to the limit of the scan (4400 daltons) were observed. The ability to analyze samples in the low mass region was also assessed using a mixture of single hydrocarbons; $C_{20}H_{42}$, $C_{30}H_{62}$ and $C_{34}H_{70}$. The results showed that little of the $[C_{20}H_{42}]^+$ ion was observed although it comprised more than 50% of the mixture. In addition, it was only observed in the first few scans, before there was a significant emitter current, indicating that the C_{20} was being lost to vacuum during its introduction into the instrument. The overall result of the standard analyses was that FD-MS is an effective approach for analyzing polyethylene providing highly diagnostic molecular ions but that there are limitations to the technique for assessing the average molecular weight distribution of the polymer samples because of the rapid loss of low molecular weight components (<300 daltons) and loss of sensitivity at higher masses (e.g., 2000 daltons).

The lanthanide compounds used in the polymerization reactions are air- and moisture sensitive. They require handling under nitrogen or argon with the rigorous exclusion of air and water using high-vacuum, Schlenk and glove-box techniques. Typical reaction conditions used 0.04 mmol of the organolanthanide in 40 mL toluene. Measured ratios of ethylene and hydrogen were

introduced to the solution at atmospheric pressure. The reaction started immediately and was allowed to proceed until gas uptake had ceased. The reaction was terminated by addition of water and the polymer precipitated with 150 mL methanol. The precipitate was recovered by filtration and dried overnight prior to analysis.

The averaged FD-MS spectra of the polyethylene produced by this technique showed a distribution of polymer chains. The molecular ions, $[M]^+$, were separated by 28 mass units as expected. There were some ions at $[M\text{-}2]^+$ but by NMR the presence of olefins could not be detected. This data supports the report of Heine and Geddes (Org. Mass Spectrom. 29, 277-282, *1994*) that the formation of the $[M\text{-}2]^+$ was because of the loss of an H_2 fragment. The mechanism of formation of the ethylene oligomers was investigated using deuterated gases and D_8-toluene. When the synthesis was carried out utilizing CD_2CD_2:H_2 mixtures the resulting polymer gave $[H(CD_2CD_2)_nH]^+$ molecular ions separated by 32 mass units. Whereas, synthesis with CH_2CH_2 under D_2 gave $[D(CH_2CH_2)D]^+$ ions separated by 28 mass units. When CH_2CH_2 under H_2 was reacted in D_8-toluene there was no evidence of the introduction of deuterium into the polymer chain. The conclusion from this data is that the polymerization process is through the elongation of the chain by clean insertion of ethylene and termination by hydrogenolysis. There was no evidence of radical processes which would be expected to result in branching and the abstraction of D from the D_8-toluene into the oligomer. The choice of samarium II compounds, e.g. $(C_5Me_5)_2Sm$ and $(C_5Me_5)_2Sm(THF)_2$, did not appear to alter the composition or distribution of the polyethylene generated. The catalytic cycle may involve a samarium III hydride is the active species and reactions with isolated $[(C_5Me_5)_2Sm(\mu\text{-}H)]_2$ also gave the same results.

In order to test for the possibility of altering the composition of the polymer produced various olefins were introduced into the reaction mixture at differing concentrations. A typical example was 1-pentene which was used at 8.8, 36 and 210 equivalents per samarium. The FD-MS of the products showed the presence of an odd number carbon envelope at 15%, 50% and 85% of the mixture for the three concentrations. The results were indicative of the inclusion of only one pentene per oligomer chain but this was not certain because the inclusion of two pentene molecules would have resulted in an even carbon chain. When the reaction was carried out with CD_2CD_2 and D_2 there was no evidence of the inclusion of two pentenes, which would have had a unique molecular weight. However, when styrene was added to the reaction, the FD-MS data comprised three envelopes with different molecular compositions. The major envelope consisted of oligomers into which one styrene had been incorporated giving $[H(CH_2CH_2)_n(C_8H_8)H]^+$ ions. The second envelope was the homo-polymer, $[H(CH_2CH_2)_nH]^+$, while the smallest envelope consisted of oligomers into which two styrenes had been incorporated thus giving $[H(CH_2CH_2)_n(C_8H_8)_2H]^+$ ions. It was also noted that for the chains into which styrene had been incorporated ions could be observed at higher molecular weights (m/z > 2,500).

The overall conclusion is that even though FD-MS appears to be limited in mass range for polyethylene discriminating against higher masses, i.e., outside the 300-1000 mass range, the ability of FD-MS to provide molecular ion data means that the technique is particularly suited to investigating the polymerization of ethylene, enabling labeling experiments and other synthetic manipulation experiments to be carried out which would not be possible with other analytical techniques such as NMR or GPC. Manipulations that result in alterations in the structure (e.g., co-polymers or branching) extend the mass range over which FD-MS can be used.

Protein & Peptide Analysis by A Low-Flow, High Sensitivity NanoES Source

Matthias Wilm, and Matthias Mann

European Molecular Biology Laboratory, Meyerhofstr. 1, 69 012 Heidelberg, Germany

Following a theoretical investigation[1] into the electrospray mechanism we built an electrospray ion source with a very low flow rate of 20 - 30 nL/min and implemented the source on a triple quadrupole instrument (API III, Sciex, Ontario, Canada). The low flow rate leads to an initial droplet diameter of 180 nm. The small diameter of the initial droplets exposes 100% of the analyte molecules in the sprayed solution to the mass spectrometer in a form accessible to desolvation. Nothing of the sample is lost in the form of large droplets. This feature of our "NanoElectrospray" source (NanoES) allows us to center the ion source with respect to the axis of the quadrupole at a distance of 1 - 2 mm in front of the orifice. The small droplet size and the geometry of the set-up insures a high transmission. The NanoES source consists of a finely drawn metal coated glass capillary (fig.1). The sample is sprayed out of an 1 - 2 µm orifice. The flow rate is established by the electrostatic force. In the case of samples with high viscosity a small air pressure of less than 0.8 bar supports the flow. No pumps are used and no nebulizing gas is needed nor an electron scavenger to prevent discharge.

The NanoES source is a stable electrospray ion source which allows to do extensive MS/MS investigations on 1 µl sample. The low flow rate does not compromise the concentration sensitivity and peptide measurements on 10 fmol/µl are possible. The small droplet size facilitates the desolvation for glycosilated proteins. 11 different glycosilation states on ovalbumin could be resolved. The stability of the source makes it possible to add more than 800 scans to compensate for electronical fluctuations in the ion signal. The C-terminal sequence of a 40 kDa protein digested with a carboxypeptidase could be confirmed by this technique (fig.2). The NanoES is also very tolerant towards buffers, thus the buffer can be optimized to the needs of the sample. This facilitates the analysis of non-covalent interactions. Complementary DNA strands are observed as a double stranded DNA when sprayed in negative mode in an aqueous buffer after annealing. The main advantage of this stable, low flow ion source is the routine availability of the MS/MS mode on virtually every sample which can be analyzed by ES. Combined with efficient cleaning and desalting techniques proteins can be identified via MS/MS sequencing of their tryptic peptides[2] (fig.3).

Biochemical Characterization of EGF receptor-SRC SH2 Interactions

Christian R. Lombardo, Thomas G. Consler, Michael Luther, and Daniel B. Kassel, Glaxo Research Institute, Research Triangle Park, NC 27706

Introduction

The epidermal growth factor receptor (EGFR) is a prototypic member of a family of receptor tyrosine kinases. Upon binding EGF, receptor autophosphorylation on tyrosine residues creates high affinity interaction sites for several SH2 containing proteins including c-src, PLC-g, grb2, the p85 regulatory subunit of PI3-kinase , shc and GAP. These proteins act in concert to effect a cascade signal transduction ultimately responsible for the control and regulation of mitogenesis. The role of *c-src* binding to autophosphorylated EGFR in EGF mediated signal transduction is not well understood. Cell lines overexpressing src have increased EGF induced mitogenesis which requires myristylation, and active SH2 and kinase domains. In addition, v-src expressing cell lines have elevated levels of receptor phosphorylation. These findings implicate c-src in the upregulation of EGFR signalling. Current efforts are focused detailed bioanalytical and biophysical studies of the interaction of the EGF receptor with the SH2 domain of c-src.

Results and Discussion

ESI/MS in conjunction with microaffinity chromatography is being utilized to study *in vitro* protein-protein interactions involved in signal transduction. LC/MS of the purified EGF receptor autophosphorylation domain (aa residues 976-1186) demonstrates that it is a substrate for both the EGFR and c-SRC tyrosine kinase activities. Tryptic phosphopeptide mapping and the technique of negative ion orifice potential stepping of the phosphorylated domain has enabled the sites of tyrosine phosphorylation by c-src to be rapidly identified. Several of the sites were phosphorylated by both kinases. c-SRC also was capable of phosphorylating additional sites distinct from EGFR tyrosine kinase activity. This analysis directly identified Y1086, Y1148 and Y1173 of the EGFR C-terminal domain as c-src phosphorylation sites. Tryptic peptides containing two putative phosphorylation sites were subjected to analysis via Edman sequencing or secondary digestion with Asp-N and LC/MS to identify the phosphorylated residue. Y992, Y1068 and Y1101 were identified as c-src phosphorylation sites by these methods. Kinetic analysis of site specific phosphorylation demonstrated that Y992, Y1086 and Y1173 are the most rapidly and extensively phosphorylated residues. LC/MS/MS was also performed to confirm the assignment of these phosphorylation sites. These data are summarized in Table I.

These phosphorylation sites have been demonstrated to interact with the c-src SH2 domain. Synthetic phosphopeptides derived from the 8 potential phosphorylation sites of the C-terminal domain of EGFR were evaluated for their ability to bind to the SH2 domain of c-src. Microaffinity chromatography of these EGFR phosphopeptides on SH2 columns coupled with LC/ESI/MS has enabled the amino acid sequences contributing to EGFR-SH2 interactions to be determined. Phosphopeptides derived from Y992, Y1086, Y1101, and Y1148 bound directly to the c-src SH2 domain (Fig. 1). Finally, extensive c-src phosphorylation of EGFR is

demonstrated to promote its conversion to a form that exhibits high affinity (K_D= 380 nM) and co-operative binding to the SH2 domain of c-src as measured by BIAcore™ . These model studies offer that the approach of microaffinity chromatography and ESI/MS will be generally applicable for the affinity selection and identification of novel protein-ligand and protein-protein interactions. The identification of c-src phosphorylation sequences on EGFR C-terminal domain as c-src SH2 binding sites supports the notion that this interaction plays a key role in the biology of mitogenic signal transduction.

IDENTIFICATION OF SPECIFIC RECEPTOR PEPTOID LIGANDS IN COMBINATORIAL MIXTURES BY AFFINITY SELECTION AND MASS SPECTROMETRY.

S. Kaur, V. Huebner, D. Tang, L. McGuire, R. Drummond, J. Csetjey, J. Strattton-Thomas, S. Rosenberg, G. Figliozzi, S. Banville, R. Zuckermann and G. Dollinger.

Chiron Corporation, 4560 Horton Street, Emeryville, CA 94608-2916.

For many years, new drugs have been discovered by the systematic screening of diverse chemical compounds isolated from plants, marine organisms and synthetic reactions. This approach suggests that the screening of chemical compounds prepared by combinatorial synthetic methods similarly could provide lead compounds for drugs. In combinatorial chemistry, peptides are ideal candidates for generating molecular diversity because of their modular structure; parallel and mixing synthetic strategies can be used to generate rapidly libraries of tens of thousand of compounds. Furthermore, once active structures have been identified, they can be prepared easily in a pure form for detailed pharmacological studies. To date, peptide libraries have been used to find ligands for cellular receptors, to determine substrate specificities of enzymes and map epitopes for antibody binding (1-4). While peptide libraries offer great potential in drug discovery, the poor pharmacokinetic properties of peptides make them less than ideal drug candidates. The poor pharmacokinetic properties of peptides can be circumvented if metabolically stable "unnatural" monomers are used to synthesize peptide-like oligomers. Such "unnatural" peptides, known as peptoids, e.g., oligo(N-substituted)glycines, have been prepared by automated solid-phase synthesis (5, 6). In a drug design strategy, diverse mixtures of peptoids can be used to screen for components with favorable binding characteristics to enzymes or receptors. Once target compounds have been identified, chemically similar mixtures can be generated to optimize binding characteristics.

We have developed an affinity selection and mass spectrometry-based strategy (7) to identify resin-free peptoids with favorable binding characteristics in combinatorial mixtures containing multiple compounds (Fig. 1). This strategy uses the receptor to "fish out" the peptoids of interest from the mixture and directly identify the structures by mass spectrometry. The procedure involves incubation of the peptoid mixture with the receptor of interest, at various levels of molar excess. The incubation mixture is rapidly fractionated by size exclusion chromatography; the receptor with bound ligand is excluded from the column and the excess unbound ligands are eluted in the included volume. An aliquot of the bound peptoids is introduced to an electrospray triple quadrupole mass spectrometer using an on-line reversed phase trap cartridge. Under the conditions used for elution off the reversed phase cartridge, the receptor-peptoid complexes dissociate readily. The molecular weight range of the peptoid mixture is scanned to determine the molecular weight of the peptoid ligands. As a control, the binding experiment is repeated in the presence of a natural receptor ligand with high binding affinity. The peptoids that bind specifically are hence identified readily, since they are observed only in the absence of the natural ligand. The remaining peptoid sample is used to confirm the structure of the peptoids that bind using collision-induced-dissociation (CID) MS/MS. The sensitivity of the mass spectrometry experiments (low pmol peptoid) allows ligands of a variety of affinities to be identified in the combinatorial mixtures.

Fig. 2a-c shows the electrospray mass spectra from an affinity selection experiment using soluble human urokinase plasminogen activator receptor (uPAR) and a combinatorial mixture containing 576 peptoid trimers. The complexity of the starting peptoid mixture is shown in Fig. 2a, where numerous singly charged molecular ions are observed in the range m/z 350-800. Fig. 2b shows the mass spectrum of the peptoids binding to uPAR in the absence of the receptor binding domain (residues 1-48) of human uPA(1-48) and identifies protonated molecular ions m/z 708 and 676. Fig. 2c shows the mass spectrum for the control experiment and indicates that compounds m/z 708 and 676 do not bind in the presence of uPA(1-48); only multiply-charged ions from uPA(1-48) are observed. Since compounds m/z 708 and 676 compete with uPA(1-48), these peptoids presumably bind specifically at the receptor binding site. The structures of compounds m/z 708 and 676 were confirmed by low energy CID MS/MS and comparison with the structures predicted in the mixture. Using structural features from the ligands identified in initial experiments, further combinatorial mixtures were generated to attempt to optimize binding characteristics. Using this strategy, a number of ligands were readily identified.

The Identification of Proteins Associated with Hypertrophy of Cardiomyocytes by 2D Gel Electrophoresis Combined with Microcapillary LCMS and Tandem MS

David Arnott, Kathy King, Mark Bier*, Adrian Land*, and John T. Stults
Genentech, Inc., 460 Point San Bruno Blvd., South San Francisco, CA 94080, and *Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

Congestive heart failure is a serious health threat which caused the deaths of 39,000 Americans in 1991. One manifestation of heart disease is enlargement (hypertrophy) of the heart, resulting in a loss of pumping capacity. Cardiac hypertrophy is an adaptive response to hypertension and damage from myocardial infarction, but eventually becomes pathological. The search for heart disease treatments would benefit from a better understanding of cardiac hypertrophy at the molecular level. Several model systems have been developed; hypertrophy in cultured myocytes (muscle cells), for example, can be induced by phenylepherine. Two dimensional polyacrylamide gel electrophoresis (2D-PAGE) and electrospray ionization mass spectrometry were used to identify proteins associated with cardiac hypertrophy.

Methods

2D Page: The cell pellet from a single 60 mm plate of cultured cardiac myocytes was dissolved in 10-25 µL O'Farrel's lysis buffer,[1] and centrifuged at 4°C. The supernatant was diluted with sample buffer[1] and 2D PAGE was carried out on a Pharmacia Multiphor II system. The isoelectric focusing step used 18 cm immobilized pH 3-10 gradient strips. The second dimension used SDS-PAGE gels (245x180x0.5 mm, 12-14% polyacrylamide gradient, pre-cast on a plastic support). Proteins were silver stained[2] or electroblotted onto PVDF membranes which were stained with Coomassie Blue.[3]

***In Situ* Digestion:** Protein spots were cut out of the blot, wet with MeOH and destained by vortexing in 70% MeCN. Disulfide bonds were reduced by addition of 100 µL of 10 mM DTT, 5 mM EDTA, 500 mM Tris HCl with incubation for one hour at 45°C. Cys residues were carboxymethylated by addition of 10 µL 200 mM iodoacetic acid in 0.5 M NaOH, with incubation in the dark for 20 min. The membranes were washed 3x with 10% MeCN, shaken 20 min. in 0.5% w/v PVP-360, 0.1% HOAc. The membranes were washed 2x with 10% MeCN, 1x with 20% MeCN, and 1x with digestion buffer (50 mM NH_4HCO_3, 10% MeCN). Proteins were digested 16 hr @ 37 °C with 0.05 µg endo Lys-C in 15 µL digestion buffer. The membrane was removed and washed with digestion buffer. The pooled samples were acidified with HOAc, reduced to <5 µL by vacuum centrifugation, diluted to 10 µL with 0.1 M HOAc, and frozen.

Mass Spectrometry: Samples were introduced to the ESI source of the mass spectrometers by capillary HPLC. Reverse phase microcolumns with 15 cm of POROS R2 10 µm beads packed in 75 µm i.d. x 190 µm o.d. x 30 cm fused silica were constructed.[4] Samples were loaded hydrostatically and peptides were eluted by a 15 minute gradient of 0-80% MeCN in 0.1 M HOAc from an ABI model 140A dual syringe pump. A pre-column split of the mobile phase was used to obtain column flow rates of 0.2 - 0.5 µL/min.

Mass spectra were recorded on a Finnigan TSQ-7000 triple quadrupole MS with an API-ESI ion source. A liquid sheath of 70% MeOH/0.1 % HOAc @ 1.5 µL/min. was used. The spray was assisted by N_2 gas flow from sheath and auxiliary gas ports. Spectra were acquired every 1.5 sec. from 300-1600 Da. CAD experiments were carried out at 2.5 mTorr Ar in the collision cell; collision energies of 13-20 eV, 20-30 eV were used for CAD of triply, and doubly charged peptides. Q3 was scanned at 500 amu/sec in MS/MS mode. Sensitivity was enhanced by operating at less than unit resolution (FWHM =1.5 amu).

Spectra were also acquired using a prototype Finnigan LCQ ion trap mass spectrometer. The ESI source and its operating conditions were the same as for the triple quadrupole. One virtue of this instrument is the ability to rapidly change scan modes in a data-dependent manner. Samples were introduced by LCMS as before, and spectra acquired under computer control. A full mass range scan was taken, followed by a high resolution narrow range scan of the base peak. A charge state was calculated from the isotope spacing, and CAD was carried out. This cycle repeated throughout the HPLC run.

Database Searching. Proteins were identified from the mass spectral data by searching a compilation of protein and DNA databases using the program FRAGFIT, developed at Genentech.[4] For each protein spot, the masses of the peptides were input along with partial sequences from MS/MS. Additional parameters include enzyme specificity, mass tolerance, approximate protein MW, Cys alkylation regent, allowance for Trp and Met oxidation, allowance for incomplete digestion, and the number of matching masses required.

Results and Discussion

Proteins were extracted from neonatal rat cardiac myocytes with or without phenylepherine induced hypertrophy (~ 150 µg protein from ~ $2x10^5$ surviving cells), and resolved by 2D PAGE. Analytical gels were silver stained, and scanned with a flat bed scanner. Spots were located and matched among gels with BioImage 2D analysis software. For mass spectrometry, 3 samples were pooled, and blotted onto PVDF membranes after 2D PAGE. Spots were identified by *in situ* digestion and analysis by LC-ESI-MS.

Figure 1 illustrates the experimental method for one protein spot from normal cardiomyocytes. Ten percent of the digested sample was injected on a capillary HPLC column and eluted into the mass spectrometer (1A). Molecular weights were measured for each peptide (1B), and MS/MS performed on major peptides (1C). The TSQ7000 required two or more injections to accomplish both MS and MS/MS; the ion trap required only one HPLC run when the data dependent experiment was performed. Both instruments were capable of CAD on tens of fmol of peptide. The use of partial sequence information along with MW data resulted in highly discriminating database searches; frequently a single mass with 3-4 residues of sequence was sufficient to uniquely identify a protein.

Initial experiments to validate the method focused on the more abundant proteins found in cardiac myocytes; 12 such proteins were identified and are listed in Table 1. Each is a protein which would be expected in heart cells, although two had not previously been sequenced in rats. Preliminary results indicate that myosin light chain 1 (atrial isoform) was found in 100% greater abundance in hypertrophic cells than in normal cells. A number of similarly upregulated proteins are under investigation.

Identification of Amino Acid Transformations during Oxidation of Peptides and Proteins: Modifications of Methionine and Tyrosine

S.K. Chowdhury, J. Eshraghi, H. Wolfe, D. Forde, A.G. Hlavac, and D. Johnston, Sanofi Winthrop, Inc., 9 Great Valley Parkway, Malvern, PA 19355

Liquid chromatography/electrospray ionization mass spectrometry (LC/ESI-MS), tandem mass spectrometry with on line liquid chromatography (LC/ESI-MS-MS) and high resolution mass spectrometry with liquid secondary ionization (LSIMS) were utilized to identify the modified amino acids in peptides and proteins formed during oxidation with performic acid. The procedure of protein oxidation was chosen to assist in protein unfolding by oxidizing the cystines to cysteic acids to allow for more complete proteolytic digestion and to create additional cleavage sites for endoproteinase Asp-N. Investigation of the Asp-N peptide map of oxidized superoxide dismutase (SOD) by LC/ESI-MS revealed that an expected proteolytic fragment of the protein was missing. In its place, two peptides with molecular weights (MWs) 66 and 100 higher than that calculated for the missing peptide were observed. To identify the modified amino acids in the unexpected peptides, a model peptide with some amino acid similarities (tyrosine, arginine, methionine, and lysine) to the missing peptide was chosen and was subjected to the similar oxidation and enzymatic digestion steps, conditions and reactions. After oxidation and digestion, the model peptide (TAP, sequence: Ac-MDKVLNRY) showed 3 major peaks in LC/MS (Figure 1). The peptides in the three peaks were identified to be the unmodified peptide (peak a) and two peptides whose MWs were 66 (peak c) and 100 (peak d) higher than that of TAP. The LC/ESI-MS-MS of these reaction products demonstrated that in the two modified peptides the N-terminal methionine has been transformed into methionine sulfone (MW increase of 32), whereas m/z values of all the fragment ions containing C-terminal arginine and tyrosine were 34 (peak c) and 68 (peak d) higher than those in the unmodified peptide (figure 2 and Chart 1). To establish whether the arginine or tyrosine or both were modified, another peptide Neuromedin N (sequence: KIPYIL) was chosen that contains tyrosine but no arginine or methionine. The LC/MS analysis of the oxidized peptide again showed three peaks (Figure 3). The early eluting peak corresponds to residual unmodified peptide (peak a) and the MW of the two later eluting peptides are respectively 34 (peak b) and 68 (peak c) higher than that of Neuromedin N. The LC/ESI-MS-MS of the peptides confirmed that the tyrosine underwent transformations with an increase of MW by 34 or 68 (Chart 2). Accurate m/z of the monoprotonated molecules of the two peptides were determined to 780.44294 (calculated m/z 780.44267 for $C_{38}H_{63}N_7O_8Cl$) and 814.40391 (calculated m/z 814.40369 for $C_{38}H_{62}N_7O_8Cl_2$). The measured values agree with those calculated to 0.35 and 0.27 ppm, respectively). We believe that sodium chloride used as buffer in peptides and SOD solutions produced electrophiles in the oxidizing medium that caused electrophilic aromatic substitution in tyrosine (scheme I). This observation was further supported by the identification of mono and dibromo peptides when chloride salts were replaced with bromides.

IDENTIFYING PROTEINS BY NANOELECTROSPRAY TANDEM MASS SPECTROMETRY AND PEPTIDE SEQUENCE TAGS

M. Mann, M. Wilm, A. Shevchenko and G. Neubauer
European Molecular Biology Laboratory (EMBL)
Postfach 10.2209, D-69012 Heidelberg, Germany

Identification of proteins is an important analytical challenge in molecular biology. Peptide Sequence Tags have recently been introduced as a highly specific probe for the identification of proteins in sequence databases[1]. A fragmentation spectrum usually contains a short, easily identifiable series of sequence ions, yielding a partial sequence. This partial sequence, together with its starting and end mass is a signature of the peptide which we term a "peptide sequence tag". Peptides can be identified even in the presence of unknown post translational modifications or amino acid substitutions between an expected sequence and the measured peptide. Just two to three amino acid residues derived by fragmentation are usually enough to identify the peptide. Using Apple Scripts, the process of finding a protein in the database has been reduced to selecting three fragment peaks in the tandem mass spectrum.

Peptide Sequence Tags can be obtained in various ways including ES MS/MS, ES orifice fragmentation or MALDI post source decay (PSD). Examples from NanoES[2] of unseparated mixtures of peptides, such as the one shown in fig 1 demonstrate the power of the technique. Even the minimal information present in the partial spectrum is enough to uniquely locate the protein. As a "second pass" the found sequence is loaded and compared to the rest of the MS/MS spectrum giving an additional unambiguous selection step. When several other peptide sequence tags are added identification is positive (fig 2). The sequence of the protein (see caption to fig. 2) only contains very few peptides which would have been in the preferred mass range between 1000 and 2500 Da for identification by mass fingerprinting.

When compared to identification by "mass fingerprinting", peptide sequence tags are vastly more specific even when using very few peptides. Indeed, in almost all cases, a single peptide is enough to obtain a unique hit in the database. In practice, we have found several proteins which could not be identified by mass fingerprinting but were readily identified by peptide sequence tags. Sequence tags can furthermore readily resolve proteins mixtures. The concept applies also to an extended form of peptide mapping in which partial tandem mass spectra are taken of each of the components in a peptide mixture of a protein of (putatively) known sequence. This approach is orders of magnitude more specific than peptide mapping by masses alone, yet does not entail the difficult complete interpretation of tandem mass spectra.

MALD AND ES MASS SPECTROMETRY OF COVALENT PEPTIDE-OLIGONUCLEOTIDE HYBRIDS

Ole N. Jensen[1], Sandhya Kulkarni[2], Jane V. Aldrich[4], Samuel E. Bennett[1], Dale W. Mosbaugh[3], and Douglas F. Barofsky[3]. [1]Department of Biochemistry and Biophysics, [2]College of Pharmacy, and [3]Department of Agricultural Chemistry, Oregon State University, Corvallis, OR 97331. [4]Department of Pharmaceutical Sciences, University of Maryland at Baltimore, 20 North Pine St., Baltimore, MD 21201.

INTRODUCTION. We are in the process of developing and implementing a novel protocol for characterization of protein-nucleic acid interactions. The protocol employs photochemical cross-linking techniques followed by mass spectrometric analyses of protein primary structure [1]. We have previously demonstrated that intact, UV-crosslinked protein-nucleic acid complexes can be analyzed by MALD mass spectrometry [2, 3]. In the study presented here, we have investigated how peptide-oligonucleotide hybrids behave during MALD and ES mass spectrometric analyses.

EXPERIMENTAL. Photochemically crosslinked peptide-dT_{20} hybrids were obtained by tryptic digestion of Escherichia coli uracil-DNA glycosylase (Ung) photochemically crosslinked to dT_{20} followed by anion-exchange chromatography [3]. Synthetic hybrids were prepared by reacting an eleven residue synthetic peptide containing an internal carboxyl-group (Asp side chain) with an amino-linker-5'pdT_6 or an amino-linker-5'pdT_{10} oligonucleotide [4]. The synthetic hybrids were purified by RP-HPLC. MALD mass spectrometry was performed on a custom-built linear time-of-flight instrument equipped with a frequency tripled (355 nm) Nd:YAG laser. Peptide-oligonucleotide hybrids were prepared for MALD by mixing them with a matrix consisting of 2,4,6-trihydroxyacetophenone in 50 mM diammoniumcitrate/50% acetonitrile. ES mass spectrometry and ES tandem mass spectrometry were performed on a Sciex API III Plus mass spectrometer system. Samples (5 uL) were flow injected in 5 mM ammonium acetate/50% acetonitrile at a flow rate of 3 uL/min.

RESULTS AND CONCLUSIONS. We have demonstrated that MALD MS is a facile means for ascertaing the identities of photochemically crossslinked and synthetic peptide-oligonucleotide hybrids. We have further demonstrated that sufficiently pure synthetic peptide-oligonucleotide hybrids can be easily analyzed by ES MS.

Scrutiny of MALD mass spectra of tryptic peptide mixtures of Ung indicates that the presence of free peptides completely suppress ionization of the peptide-oligonucleotide hybrids. However, separation of the hybrids as a group from the free peptides by anion-exchange chromatography is sufficient to allow MALD mass spectra of the peptide-dT_{20} hybrid mixtures to be obtained with only 5-10 pmol of sample. We have been able to deduce the DNA binding domain of Ung from such mass spectra and complementary sequence information obtained by Edman degradation [3].

The sensitivities of MALD MS and ES MS for peptide-oligonucleotide hybrids are similar to their respective sensitivities for pure oligonucleotides. The presence of free peptides or oligonucleotides in a sample suppresses ionization of the hybrids - this is especially marked in the case of ES MS. In general, MALD MS is less affected by sample impurities and more sensitive than ES MS for these compounds, while ES MS has greater

mass accuracy and resolution than MALD linear TOF MS, e.g. salt adducts can be resolved by ES MS on a triple quadrupole instrument. The behavior of peptide-oligonucleotide hybrids in solvent systems (matrix in MALD, spray solvent in ES) seems to be governed mainly by the oligonucleotide, whereas their ionization seems to be predominated by the peptide, i.e. the peptide seems to promote positive ion formation in both MALD MS and ES MS.

Positive ion ES tandem mass spectrometry yielded the complete oligonucleotide sequence and more than 50% of the peptide sequence of a peptide-dT_6 hybrid (Figure 1). Thus, ES MS/MS has the potential for localizing sites of crosslinking or branching, i.e. for identifying the modified amino acids, in peptide-oligonucleotide hybrids. Mass spectrometric structural characterization of covalent peptide-oligonucleotide hybrids should find widespread application in photochemistry/photobiology, in molecular biology, and in antisense research.

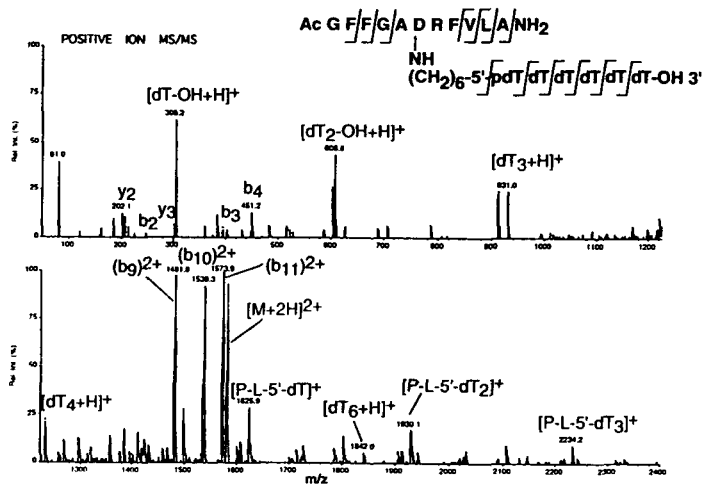

Figure 1. Positive ES-CID spectrum of the doubly charged ion of the peptide-dT_6 hybrid.

Studying Noncovalent Protein-Peptide Interactions by Electrospray Ionization Mass Spectrometry

Joseph A. Loo, Peifeng Hu, and Venkataraman Thanabal
Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, 2800 Plymouth Road, Ann Arbor, MI 48105

Electrospray ionization mass spectrometry (ESI-MS) has been applied for detection of noncovalently-bound biochemical complexes, including peptide-peptide, protein-cofactor, and protein subunits. The detection of these complexes is the first step of an MS-based methodology. The next steps are to relate the observations back to the more relevant solution phase studies and to determine how the molecules are interacting on a structural level. To assess the usefulness of ESI-MS for studying noncovalent interactions, we have examined the binding of various peptide inhibitors to v-src SH2 (Src homology 2) domain protein (12.9 kDa). SH2 motifs in proteins are critical in the signal transduction pathways of the tyrosine kinase growth factor receptors. SH2 domains bind to the phosphotyrosine-containing growth factor receptors. Electrospray ionization mass spectrometry with a magnetic sector instrument and array detection has been used to detect the protein-peptide complex with subpicomolar sensitivity.

The relative abundances of the src protein complex with several nonphosphorylated and phosphorylated peptides were compared and were found to correlate well to the known binding constants derived from solution-based methods, indicating that the mass spectrometry-based method can be used to assess the specificity of such interactions. Covalent modification by a nonpeptide inhibitor of the putative binding site of the protein inhibits detection of the protein-peptide complex. Peptide inhibitors studied include those based on the -pTyrGluGluIle- motif that has been demonstrated to bind to src SH2 domain with high specificity (K_d ~ 0.6 μM). Peptides without a *phospho*tyrosine residue exhibits very little binding in ESI mass spectra (except at very high peptide concentrations) (Figures 1 and 2). Other phosphopeptides examined include sequence stereoisomers with a wide range of binding affinities. For example, peptides based on the sequence Ac-Gln-pTyr-Glu-homoPhe-NH_2 have a wide range of IC_{50} values (concentration required to inhibit specific binding by 50%).

There are several ESI-MS methods to differentiate peptide binding affinities that differ in IC_{50} values by as little as a factor of 2. Titration experiments and measuring the amount of relative binding shows differential binding to src SH2. However, a more straightforward method is to perform competitive binding experiments with another inhibitor of known affinity. For example, ESI-MS of tertiary mixtures of src SH2 protein, a phosphopeptide with an IC_{50} ~ 4 μM (*I*), and either the D- or L-homoPhe[4] peptide (see above) at a molar ratio of 1:3:3 respectively show that the D-homoPhe[4] peptide (IC_{50} ~ 6 μM) has nearly equal affinity to peptide *I*, whereas the L-homoPhe4 peptide (IC_{50} ~ 15 μM) has a lower affinity to src SH2 than *I* (i.e., does not competitively bind to src SH2 against peptide *I*).

Solution-phase equilibrium constants may be determined by measuring the amount of bound and unbound species as a function of peptide inhibitor concentration for construction of a Scatchard graph. Preliminary analysis of peptide Ac-Gln-pTyr-Glu-Glu-Ile-Pro-NH_2 shows a binding constant of ~ 0.5 μM measured by ESI-MS, in good agreement with the literature value of 0.55 μM (K_d) for the larger peptide Ac-Lys-Gly-Gly-*Gln-pTyr-Glu-Glu-Ile-Pro*-Ile-Pro-NH_2 (Ladbury et al., *Proc. Natl. Acad. Sci. USA* **1995**, *92*, 3199).

Electrospray ionization MS may have potential for analyzing complex mixtures for finding potent inhibitors. Possible candidates derived from mixtures from combinatorial chemistry (e.g., peptide libraries) may be initially screened by the method. ESI-MS of src SH2 protein with a mixture of phosphopeptides (where [total peptide] > [src SH2]) showed the expected complex(es) as the dominant species in the mass spectrum.

Many examples have been reported to suggest that some aspects of solution phase interactions are retained in the gas phase. Careful control of all experimental parameters is necessary for studying noncovalently-bound complexes by ESI mass spectrometry. Particular attention to the variables affecting droplet/ion desolvation needs to be taken. Source temperature, countercurrent gas flow rate, collision energy in the ESI interface, ESI spray angle, and many other variables can affect the relative amount of noncovalent binding to proteins indicated in a mass spectrum. However, by establishing experimental conditions to provide consistent desolvation behavior, relative binding affinities can be determined.

Acknowledgments. The authors wish to thank T. K. Sawyer, E. Lunney, M. Plummer, and K. Para (Parke-Davis) for providing the peptide inhibitors and helpful discussions.

Mass Spectrometry in the Development of Recombinant Protein Drugs

Alan Kubis, Tom Chen, Krishendu Ghosh, David Natale, Lynette Settles, Somesh Nigam and
*James E. Labdon, Regeneron Pharmaceuticals, 777 Old Saw Mill River Road, Tarrytown, NY 10561

During the course of development of pharmaceuticals from recombinant DNA technology, it is necessary to fully characterize the structure of the candidate proteins and determine the nature of any modified forms. Mass spectrometry is an indispensable tool for the development of therapeutic proteins in the biotechnology industry. ESIMS and MALDI-TOF methods are used to investigate the primary structure (sequence), tertiary structure (folding), stability and modified forms of therapeutic proteins prior to toxicology studies or clinical trials. This is illustrated by the analysis of recombinant brain-derived neurotrophic factor (rHuBDNF)[1], a homodimeric, neuronal growth and survival factor with therapeutic potential in certain neurological disorders.

BDNF elutes as three peaks by reversed-phase HPLC, depending upon prior treatment with denaturants or reducing agents. The second peak represents an partially unfolded form of the first peak which retains the disulfide bonds. The fully reduced molecule elutes with greatest retention time. E. coli-derived human BDNF (mass 13,505) is extremely heat stable (Td=87°C) and is resistant to trypsin without prior heat denaturation. The disulfide arrangement was determined by LCMS and a sequential digestion technique using trypsin and thermolysin at pH 8.0. Capillary LC-ESIMS peptide mapping revealed all expected tryptic peptides from the protein, including disulfide-linked peptide ions indicating a 1-4, disulfide arrangement (Figs. 1,1a). In addition, a disulfide tripeptide was observed (Figs. 1,1b), which was consistent with a 2-5, 3-6 or 3-5, 2-6 arrangement ("x "in Fig .1a). In order to determine the arrangement of cystine pairing within the tripeptide, a thermolysin fragment of the tripeptide was generated which cleaved the peptide bond between Cys-109 and Val-110. The detection of an ion at m/z 783 (Fig. 2) demonstrated that the BDNF disulfide arrangement was consistent with the crystal structure of NGF, another homologous member of the neurotrophin family.[2] These peptides were not observed in BDNF in which the cystine residues were reductively alkylated.

Several heterodimer variants comprising 1-2% of total protein were observed in in the manufacture of rHuBDNF High-temperature (60°C) HPLC with online ESIMS analysis allowed the separation and mass determinations of variant forms of the protein (Fig. 3). The approximate mass differences from unmodified BDNF were deduced from accumulated scans in Fig. 3 as follows: a=+16 amu, b=BDNF, c= - 340 and +43 amu, d= -664, e,f= -18 and g= - 36 amu.

LCMS tryptic mapping and Edman sequencing revealed the nature and location of several covalent modifications of the protein and supported the interpretation of the variants from Fig. 3. as follows: Oxidized methionine (a), N-terminal deletions of 3 (c) and 6 (d) amino acids from the N-terminus, and carbamylation of lysine side chains (c). In addition, a -18 amu form of tryptic peptide 5 from the digest of variant (e) was found to shift to a later retention time in LCMS. Edman sequence analysis and fluorometric amino acid analysis of the peptide confirmed the substitution of norleucine for methionine at position 31 (M31Nle, DM -18 amu predicted) arising from the mistranslation of one (e,f) and possibly two (g) modifications of methionine residues.

Stability studies of BDNF in phosphate buffered saline, pH 7.0 showed extensive degradation after several weeks at 45°C, but little change at 4°C. HPLC of the degraded product showed increased levels of variant peaks 1 and 2, consistent with oxidation of the protein, along with a shoulder peak on the trailing edge of the main BDNF peak. LC/ESIMS of the degraded products showed three cleaved forms (Fig. 4) corresponding to removal of 1 3 and 4 amino acids from the N-terminus of BDNF. Edman sequence analysis also detected a sequence beginning with residue 60, indicating a cleavage between residue 59 and 60. This modification would not be expected to appear as discrete peptides in LCMS analysis without prior reduction of the disulfide bonds linking these fragments together. Figure 5 summarizes the modification sites.

Application of Micro-ES/MS/MS for Monitoring the Effects of Drugs of Abuse. Mark R. Emmett* and Richard M. Caprioli, Dept. of Biochemistry and Molecular Biology and the Analytical Chemistry Center, The University of Texas-Houston Medical School, P.O. Box 20708, Houston, Tx 77225.

In vivo microdialysis (Md) is a sampling technique that has been used to monitor a variety of endogenous neurotransmitters (1). Md has not been widely used in the study of endogenous neuropeptides due to low extracellular concentrations coupled with poor recoveries of these larger molecules and their contamination with high concentrations of salts. Because of the dilute nature of the microdialysate (attomole/μl), previous experiments have been performed with antibody radioimmunoassays of wide specificity which interact with all proteins/peptides containing homologous sequences (2).

The opiate neuropeptide, [Met]^5-enkephalin (ME) belongs to a family group that share homologous amino acid sequences. ME has been proposed to be involved in the natural reward pathway which is thought to contribute to the addictiveness of many drugs of abuse (3). To test this idea, we have developed a highly sensitive and specific mass spectrometric assay that is used to analyze and quantitate ME from *in vivo* brain dialysates. **In this presentation, we show the effects of various drugs of abuse on endogenous ME release in the globus pallidus/ventral pallidum region of rat brain.**

MATERIALS AND METHODS

ES/MS/MS: ES spectra were generated using a modified Vestec Electrospray Ion Source (PerSeptive Biosystems-Vestec Corporation) mounted on a Finnigan TSQ 70 mass spectrometer (Finnigan Corporation) with a 20 kV dynode. MS/MS data were gathered with Q_1 focused on the parent ion of 574.4 m/z with a resolution of approximately 2.5 AMU. The collision gas was Xenon at a pressure of 1.4 mT. Q_3 was scanned over the mass range of 390-405 AMU every 0.4 sec.

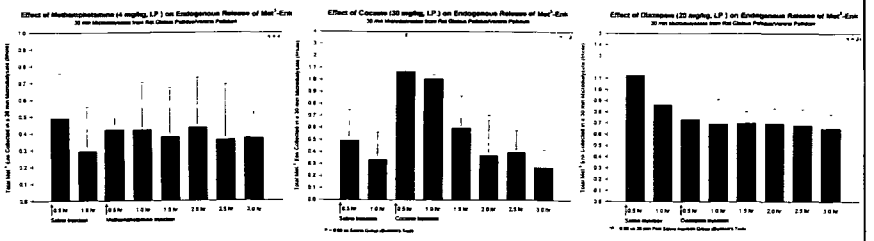
Microelectrospray: The micro-ES interface (4,5) was specifically developed for the detection of the endogenous release of neuropeptides via microdialysis. Packed micro-ES needles (50 μ i.d., packed with a 40 nL bed volume of 10 μ C18 particles [YMC Corp.]) were used to desalt and concentrate samples.

Microdialysis: CMA/10 microdialysis probes (CMA/*Microdialysis*, Acton, MA) were used in the *in vivo* experiments. Cannulae were stereotaxically implanted into the brain of male Sprague/Dawley rats under pentobarbital anesthesia; such that, when the microdialysis probe was inserted it extended into the Globus Pallidus/Ventral Pallidum region of the brain. The animals were allowed to recover for at least four days after the surgery. The experiments were all performed on freely moving animals using an Instech (Plymouth Meeting, PA) freely moving animal apparatus. Freely-moving animals were necessary for these experiments due to the inhibition of neurotransmitter release by anesthetics (6). After insertion of the probe, the animal was allowed a 3 hr equilibration time before beginning the experiment. During this time and all during the experiment artificial CSF (5 mM KCl, 120 mM NaCl, 1.2 mM $MgCl_2$, 1.8 mM $CaCl_2$, 0.15% phosphate buffered saline, pH 7.4) was perfused through the probe at a rate of 436 nL/min. A control injection of drug vehicle was administered I.P. and two, 30 min dialysates were collected. The drug of abuse (Morphine, Methamphetamine, Cocaine or Diazepam) was administered I.P. and 30 min samples were collected over the next 3 hrs. Perfusate samples were analyzed by micro-ES/MS/MS.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

RESULTS

Previous data showing the release of endogenous ME by local depolarization and systemically administered morphine has been reported (7,8).



DISCUSSION

1) Micro-ES/MS/MS permits the identification and quantitation of endogenous [met]^5-enkephalin collected from rat brain by *in vivo* microdialysis.
2) Morphine (10 mg/kg, I.P.) and Cocaine (30 mg/kg, I.P.) activate an enkephalinergic pathway that releases [met]^5-enkephalin in the Globus Pallidus/Ventral Pallidum region of rat brain, supporting the hypothesis that endogenous opiates may be involved in the reward pathway.
3) Diazepam (20 mg/kg, I.P.) does not activate an enkephalinergic pathway to the Globus Pallidus/Ventral Pallidum region of rat brain.
4) Methamphetamine (4 mg/kg) unexpectedly does not activate an enkephalinergic pathway to the Globus Pallidus/Ventral Pallidum region of rat brain. This data infers that the mechanism of addiction for methamphetamine differs from that of morphine or cocaine.

Nucleotide (n = 10^1-10^2) Sequencing and Screening Using ESI/FTMS

Daniel P. Little, David J. Aaserud, Gary A. Valaskovic, Peter B. O'Connor, Fred W. McLafferty

Chemistry Department, Baker Laboratory, Cornell University, Ithaca, NY 14850-1301

The presence of a single DNA base mutation or deletion within a gene is often sufficient to incapacitate an organism. Clinical diagnostics will demand sensitive analytical methods to verify the integrity of loci known to contain disease sites, as well as to identify new ones The advantages of Fourier transform mass spectrometry (FTMS), including ppm mass measuring accuracy, fmol sensitivity, speed, and ultrahigh resolution make it ideal for this, especially when coupled with electrospray ionization (ESI). Synthetic DNA strands as large as 100-mers have been measured with 1 Da accuracy, with minor (<5%) N - 1 and N + 1 failure sequences easily characterized.[1]

For small (n≤14) oligonucleotides, dissociation products of the multiply charged ions from ESI give consecutive backbone cleavages providing full sequence in <1 minute[2] With nozzle-skimmer (NS) and infrared multiphoton (IRMPD) dissociation, fragmentation patterns consistent with those of McLuckey were observed,[3] with w (3') and a - BH (5') ions predominating For longer strands (50- to 108-mers), however, we now find that NS yields exclusively 5' sequence (b, d, and a - B ions), while IRMPD (MS/MS, MS^3) provides w, a - BH, and internal region fragments determining most of the remaining sequence The advantage of predictable fragmentation types made of only four building blocks (A, T, C, G) make it possible to determine a fragment's type and composition with only accurate MW determination A computer program has been developed to exploit this; a separate program searches for fragments differing by the mass of a single nucleotide unit, generating overlapping partial sequences

Thus we outline a strategy for sequencing oligonucleotides using tandem FTMS: 1) Accurate MW determination, 2) IRMPD for 3' and internal stretches and 5'-3' pairs, 3) MS^n to establish each of these as w or a - BH, 4) NS for 5' stretches, 5) overlap of 5', 3', and internal regions from steps 2-4, and 6) verification of determined sequence considering all fragments, including those not identified by mass alone Using this methodology, the full sequence of a 50-mer DNA was determined, except for order ambiguity in one region of three bases and in four regions of two bases (Figure 1). An unknown mutated 50-mer gave a 9.04 Da lower MW, consistent with A→T, IRMPD pinpointed the mutation at base 27 (Figure 2) With conventional ESI, each experiment requires 1-3 pmol, interfacing through a microelectrospray source decreases this by more than an order of magnitude.[4,5]

SEARCHING CHEMICAL DIVERSITY FOR MOLECULAR RECOGNITION BY ESI-MS

Richard D. Smith, James E. Bruce, Xueheng Cheng, Gordon A. Anderson, Ruidan Chen, David C. Gale, Steven A. Hofstadler and Brenda L. Schwartz

Chemical Sciences Department, Pacific Northwest Laboratory, Richland, WA 99352

The traditional approach to drug lead development has generally involved the synthesis or high purity isolation of individual compounds followed by their screening and evaluation through a series of chemical and biological assays. A key step in the screening process may involve identification of candidate compounds that display high binding affinity *in vitro* to a targeted biopolymer, e.g., a specific protein or DNA segment. More recently, the *in vitro* selection of pharmacologically active molecules from mixtures of compounds has been shown effective, leading to the development of potential new drugs. Identifying the biologically most active compounds, often those displaying the highest affinity of noncovalent binding, from such "libraries" has become a major enterprise. In particular, the generation and searching of large "combinatorial" libraries has become popular for certain classes of compounds. In the "combinatorial" approach, many compounds are synthesized to deliberately produce a complex mixture, and then subsequently examined for their affinity to the targeted biopolymer, often by partitioning subsets of the library so as to facilitate the identification of the most active components. This is commonly performed by binding either the target or library molecules to a solid support, often in some fashion designed to facilitate identification of the active components. The combinatorial approach has proven attractive since it allows much larger numbers of compounds to be screened more rapidly than other serial approaches involving the individual synthesis and assay of each prospective affinant.

An essential aspect of screening large libraries of compounds is the ability to identify the active components, often on the basis of their strong binding to the selected target. The ability to screen very large libraries is obviously attractive, and essential if a broad range of molecular diversity is to be explored. For example, in the case of tripeptides, a library containing all variations for three amino acid residues will consist of 8,000 peptides (twenty possible for each of three residues, i.e., 20^3). The number of possible hexapeptides is 6.4×10^7 (i.e., 20^6). The conventional screening of combinatorial libraries is most effective when the synthesis is well behaved (i.e., components are generated in nearly equimolar quantities, unsuspected components are not present, etc.), the general composition is well established, and suitable analytical methods are available. From this viewpoint, libraries consisting of polypeptides or oligonucleotides are attractive, since the well-developed tools of biochemistry and molecular biology may be invoked for their synthesis and analysis. On the other hand, such libraries offer only a limited range of structural diversity and can have limited utility as drugs due to their generally rapid degradation by enzymatic processes. Thus, there is considerable interest in chemically more diverse libraries, where the synthetic and analytical advantages that apply for linear biopolymers do not currently exist. Furthermore, as much as the combinatorial approach can speed drug screening, it may still require weeks or months (even for libraries based upon linear biopolymers) to generate a library, develop a combinatorial selection scheme, and then identify potential candidates for more extensive evaluation.

The new approach we demonstrate, "bioaffinity characterization mass spectrometry" (BACMS), may potentially aid studies involving conventional libraries by providing much more rapid and direct analysis, as well as applicability to chemically more diverse libraries. Current methods that involve the use of solid supports, such as affinity chromatography, can suffer from contributions due to modified or nonspecific binding, as well as the need for time-consuming retrieval and purification of the selected

species prior to analysis, and the accompanying loss in sensitivity introduced by the additional sample handling required. The BACMS approach would exploit the ability of electrospray ionization (ESI) for the transfer of noncovalent complexes from solution[1-4] as a key step for the rapid screening of combinatorial libraries, and could greatly speed the initial screening process.

The BACMS approach exploits several newly developed Fourier transform ion cyclotron resonance (FTICR) methods, as well as the high sensitivity and gentle nature of the electrospray process. These technologies, when coupled to electrospray ionization (ESI), allow the investigation of specific noncovalent complexes formed in solution. BACMS utilizes the well-known attributes of FTICR, such as the high resolution mass analysis and $(MS)^n$ ($n \geq 2$) capabilities, as well as the recently developed techniques involving quadrupolar excitation (e.g., selected-ion accumulation[5,6]). Also crucial is the extraordinary sensitivity achievable ($<10^{-9}$ M) without the use of separations. Recent studies by Cheng et al at our laboratory, conducted in collaboration with Professor George Whitesides and co-workers (Harvard University), have shown the capability for measuring binding for two inhibitor mixtures with bovine carbonic anhydrase (BCA)-inhibitor dissociation constants (K_D's) spanning 2-3 orders of magnitude (approximately 10^{-6} M^{-1} to 10^{-9} M^{-1})[7]. The ESI-MS measurements showed the complexes contained one Zn(II) cation (which is known to bind to three histidine residues in the active site of BCA, and is involved in the catalytic process). The results showed that neither ESI nor the FTICR detection methods caused any significant dissociation of the complexes, and that structural information for the noncovalently bound inhibitors could be obtained in one FTICR experiment. The most important aspect of this work was that the individual inhibitors could be isolated from the dissociated complexes, and their relative abundances were shown to correlate well with the known binding constants. Beyond this, the isolated inhibitors could be dissociated and the products measured with high resolution to aid in their identification. Thus, these methods appear to offer the potential to rapidly evaluate the binding of sets of compounds to a specific target molecule in one experiment that consumes only very limited amounts of both the target compound and the ligand "library."

These results and others have indicated that even relatively weak associations are amenable to study (K_D's of $> 10^{-6}$ to 10^{-7}) with the proper selection of ESI and solution conditions. These results also support the potential for obtaining semi-quantitative or quantitative information about relative binding constants when no dissociation of the complexes is observed during the ESI process. It is reasonable that gas phase abundances of the complexes under such conditions will most directly reflect relative abundances in solution, and provide conditions under which relative binding affinities can be derived from appropriately designed studies.

Direct Connection of an Inductively Coupled Plasma and an Ion Trap Mass Spectrometer

C.J. Barinaga, G.C. Eiden, D.W. Koppenaal
Pacific Northwest Laboratory*,
PO Box 999, Richland WA 99352

The good sensitivity and tandem mass spectrometric capability of the quadrupole ion trap mass spectrometer (ITMS) has made it a useful instrumental technique for organic analysis. These same qualities might be useful for elemental analysis, including techniques like inductively coupled plasma mass spectrometry (ICP-MS). Two existing ITMS capabilities, prolonged ion injection and MS/MS could be immediately helpful. Long ion trapping times could be advantageous for determination of trace level elements and isotopes. MS/MS could be used to resonantly excite and collisionally dissociate polyatomic ions that arise from the plasma gas (argon) and sample matrix (water, various acids, and high concentration sample components) and that are nominally isobaric with analyte ions below 81 m/z. In addition slow scanning techniques suggested that greater mass resolution was possible. The most direct approach would be to couple the ICP and ITMS directly with minimal intervening vacuum interface and ion optic hardware. However the limited ion capacity of the ion trap before onset of significant space charge effects and the intense Ar ion current from the plasma raised concerns that the direct connection would quickly fill the trap with Ar ions, rendering the trap useless for detection of trace ions. Therefore, in our first instrument system (denoted as ICP-Q_L-Q_T), a linear quadrupole was employed between the vacuum interface and the ion trap to act as as an RF-only high pass filter, an RF/DC selective mass filter, or as a notch filter to.reduce or eliminate the Ar and matrix ion currents to the ion trap.

This instrument approach (ICP-Q_L-Q_T) was successful (1,2). Surprisingly a significant reduction in the intensity of the Ar ion signal was noted as was the nearly complete absence of matrix related polyatomic ions. Auger neutralization processes have been invoked to explain the reduction in Ar ion beam intensity during injection. Further loss of Ar ions occurs by charge exchange with background water in the trap. The loss of matrix related polyatomics is due to collision induced dissociation of these ions by the helium bath gas. Detection limits for the heavier elements is in the ten's of ppt range with a pronounced decrease in sensitivity for lighter mass ions. Also noted was the time and water vapor pressure dependent formation of metal oxides and hydroxides especially for the strong oxide-bond forming metals, e.g. lanthunum, thorium, uranium, etc. Greater than 90% of the metal ion signal could be recovered by the selective removal of water from the trap atmosphere.

The strong attenuation of the Ar ion beam suggested that the direct connection of an ICP and ion trap was feasible. This work reports the first direct connection ICP/ITMS instrument (denoted ICP-Q_T), assembled as illustrated in Fig.1. The result is a much smaller and less complex instrument. Preliminary data indicate performance very comparable to the ICP-Q_L-Q_T instrument. The Ar ion beam is still strongly attenuated in the ICP-Q_T system so that it does not immediately fill the trap. Plasma and sample matrix related polyatomic ions are also eliminated during trapping, Fig. 2. (2% HCl). Certain metal oxides and hydroxides are seen but the better pumping arrangement of the trap chamber results in lower levels than the original ICP-Q_L-Q_T system. Sensitivity remains in the low ppt region for the new ICP-Q_T system. A significant reduction in instrument size and complexity has also resulted from this new approach.

Glow Discharge Ion Trap Mass Spectrometry Employing Filtered Noise Fields

Douglas C. Duckworth, David H. Smith, Douglas E. Goeringer, Scott A. McLuckey
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6375

Introduction

In previous work we have shown quadrupole ion traps to be promising mass analyzers for glow-discharge-generated ions. Among the benefits are the spontaneous dissociation of weakly bound polyatomics and the ability to dissociate more strongly bound polyatomic ions through the application of a resonance excitation frequency. To date, this has been accomplished using single frequency excitation. In this work, we use digitally synthesized broadband noise fields for simultaneous resonance excitation of several m/z species. Because they are digitally synthesized, these filtered noise fields (FNF's) can be single or multiple notch filters which can be employed for selective ion accumulation and mass isolation.

Experimental

An argon direct-current glow-discharge ion source was interfaced to a Teledyne HST-2000 quadrupole ion trap mass analyzer. Ions extracted from the cell passed through an ion exit orifice and were focussed through the entrance endcap with a three-element lens system. The second element was a pair of half-plates, which were used to gate ions into the trap.

Results

Figure 1 shows mass spectra from NIST SRM 1103 Free Cutting Brass. In the absence of a FNF notch filter (Figure 1a), space charge effects are evident from the lack of mass resolution. When the FNF notch filter is used during ion injection, only the Sn ions undergo stable trajectories in the trap, resulting in selective ion accumulation, improved sensitivity, and improved mass resolution.

Two filtered noise fields are shown in Figure 2. Figure 2a shows the frequencies applied to the endcaps to isolate the polyatomic species assigned as CuO^+ and $CuOH^+$. These ions were generated from Cu in a brass matrix. The resulting spectrum is shown in spectrum 3a. Upon the application of a broadband resonance excitation field (109 - 120 kHz) shown in 2b, the polyatomic ions dissociate. The product ions, ^{63}Cu and ^{64}Cu, are recovered with ~80% efficiency (Figure 3b).

Conclusion

Filtered noise fields have proven to be an effective means of selective ion accumulation, which will be necessary for routine detection at low concentration levels. The ability easily tailor waveforms with high selectivity will be essential as matrices change. The ability to dissociate polyatomic ions may allow purely atomic spectra to be observed.

TIME-OF-FLIGHT MASS SPECTROMETRY WITH A PULSED GLOW DISCHARGE SOURCE

Robert E. Steiner, Cris L. Lewis, and Fred L. King
Department of Chemistry, West Virginia University, Morgantown, WV 26506

A pulsed glow discharge plasma makes a nearly ideal ionization source for time-of-flight mass spectrometry. This combination exhibits distinct advantages for the direct determination of trace elements in solid state samples. Improvements in sensitivity and selectivity result from the pulsed operation of the glow discharge. These improvements arise from the selective enhancement of the Penning ionization processes occurring during the time period immediately following the termination of the discharge power[1].

$$Ar^m + M \rightarrow Ar + M^+ + e^-$$

Time-of-flight mass spectrometry uniquely affords the ability to monitor a narrow temporal window for a time varying process such as ion formation in the pulsed glow discharge plasma. Because electron ionization processes terminate with applied power termination, the ion extraction into the ToF-MS after power termination yields a mass spectrum that is free from contributions arising from electron ionized species.

Variation of the temporal location of the repeller pulse within the 20 ms discharge pulse cycle permits investigation into the temporal evolution of the ion formation within the plasma. Moving this pulse to a time window after the termination of the discharge power results in improved analytical performance because the analyte ion signals are at a maximum while the discharge gas ion signals are at a minimum. Such sampling eliminates the saturation of the detector arising from the strong argon ion signal. Spectra representative of this temporal selectivity are shown below. ToF mass spectra for the plateau and afterpeak time regimes are shown in Figure 1 for a copper-iron-silver pressed disk. The plateau region spectra exhibits signals from both analyte and discharge gas species. The spectra aquired during afterpeak region shows no contribution from discharge gas species and is dominated by the Fe, Cu, and Ag signals.

Pulsed radio-frequency glow discharge ionization sources may also be interfaced to the time-of-flight mass spectrometer. The pulsed operation mode of the RF power source again makes temporal selectivity possible. Another distinct advantage of the pulsed RF source is its ability to sputter nonconducting materials. This capability allows analytes such as glasses or ceramics to be analyzed via ToF mass spectrometry.

The pulsed GD-TOFMS system implemented in our laboratory suffered from poor resolution. One method known to improve resolution is the implementation of a narrow slit place behind the skimmer cone and oriented in an orthogonal geometry with respect to the flight tube[2]. In theory this slit will narrow the ion beam entering

the accelerator region and therefore like analyte ions pulsed into the flight tube will have a narrower range of flight distances. However, a problem arises when the width of this slit becomes too narrow or too great as shown in Figure 2. At narrow widths, species at low concentrations may not provide sufficient signals to trigger the detector, resulting in lower observed signal intensities. This is evident for the $^{63}Cu/^{65}Cu$ ratio. At narrow slit widths this isotope ratio may increase as much as two fold over the actual value. When no slit is utilized, the isotope ratio actually falls below the known value. This observation can be attributed to saturation of the detector. Spectra collected with no slit also have characteristic low energy tails for analyte signals with high intensities that degrade resolution.

Inductively coupled plasma-mass spectrometry (ICP-MS) is a sensitive technique for elemental analysis which provides submicrogram-per-liter (sub-ppb) detection limits (DLs) for most elements. The drive towards lower DLs in response to regulatory mandates and the need to eliminate problems imposed in quantitative analyses by sample matrices are research areas of active pursuit in ICP-MS. A generic means to effectively lower concentration detection limits and eliminate matrix effects is an on-line preconcentration/matrix elimination device In our hands, anodic stripping voltammetry (ASV) coupled on-line with ICP-MS has proven to be an effective and relatively simple method for on-line preconcentration and matrix elimination [1,2].

ASV utilizes an electrochemical deposition step to preconcentrate metal species from solution into the small volume of a mercury electrode. After deposition, the metal is electrochemically oxidized, thereby stripping it from the electrode back into solution. In previous work [1,2], we have shown that concentration detection limits for our VG Plasma Quad, equipped with a conventional nebulizer and spray chamber, could be lowered by at least an order-of-magnitude for some elements (e.g., Tl) with on-line ASV-ICP-MS using a thin-layer, low-dead volume (i.e., 1.0 µL) flow-by electrochemical cell. This flow cell consists of a 6-mm dia glassy carbon working electrode, a s.s. auxiliary electrode, and a Ag/AgCl reference electrode. We also showed that quantification was feasible at metal concentration levels below the normal detection limits of our ICP-MS and that matrix interferences could be effectively eliminated with problem samples such as urine. The linear calibration curves for Tl shown in Figure 1 demonstrate the large dynamic range of the combination and the low detection limits (3σ/sensitivity).

Even though the quality of the data obtained with our prior experimental setup was good, there were two major limitations imposed by the high flow rates (near 1.0 mL/min) necessary for operation of the conventional spray chamber and nebulizer. First, the electrolytic efficiency of the thin-layer cell was low thus requiring longer plating times (and sample volumes of a few milliliters) to achieve the desired level of preconcentration. Second, the mercury thin-film electrode used for preconcentration was not physically stable for longer than a few experimental runs (e g., about 30 min). Therefore, frequent stripping and replating of the film was necessary which decreased sample throughput. These problems have recently been circumvented by incorporation of a direct injection nebulizer (CETAC Technologies, Inc.) into our system which operates at much lower flow rates. ASV-ICP-MS experiments are now carried out at 50-60 µL/min and film lifetimes are greater than 8 hrs. The increased electrolytic efficiency of the cell (ca. 80 %) has reduced sample consumption to a few hundred microliters or less for elements present at or above the low ppt level. Another area being explored with this new system is multi-element analysis. As illustrated by the data in Figure 2, we can now analyze for at least six elements simultaneously by first plating all six (180 s, -1 25 V) then simultaneously stripping them (0.25 V) from the film. Each of the six elements shown was present in the sample at the low ppb level.

LASER ABLATION ICPMS ANALYSIS OF REAL WORLD SAMPLES.

Michael S. Kahr, Christopher Brink, Deborah Figg

Los Alamos National Laboratory
Los Alamos NM 87545

INTRODUCTION

There is a need to develop a rugged, rapid, accurate in-situ technique to provide elemental data for solid radioactive (hot) samples. Laser ablation inductively coupled plasma mass spectrometry (LA/ICPMS) is an attractive method for application to this problem. LA/ICPMS provides rapid analyses without the need for sample preparation or digestion. LA/ICPMS is also capable of providing in-situ analysis with spatial information for elemental composition. Laser ablated material can be introduced remotely via tubing into an inductively coupled plasma mass spectrometer (ICP/MS) system. This allows the mass spectrometer and operator to sit away from the actual sample, which is ideal for hot sample analysis. Mass spectrometric detection allows positive identification for elements with less spectral interferences than for atomic emission spectroscopy (AES).

EXPERIMENTAL

The fundamental, frequency doubled, and frequency quadrupled output of a Nd:YAG laser at 1064 nm, 532 nm, and 266 nm, respectively, was employed for ablation. Power can be varied by changing the voltage of the laser flashlamp or by employing a laser power attenuator. Particle size distributions were measured using a commercially available laser Raman scattering particle size instrument which has a useful analysis range of 0.1 μm to 2.0 μm. Laser powers were measured after the last mirror in the optics set-up prior to focusing the laser beam for ablation. The glass sample employed for these experiments was West Valley 205, a waste glass simulant. The sample cell was mounted to an x,y,z computer controlled positioning stage. Ablated material was carried into the ICP mass spectrometer by argon flowing through the sample cell.

RESULTS AND DISCUSSION

The relative change in elemental fractionation was monitored by taking the ratio of the raw counts for each isotope to the raw counts for Zr 90. This was calculated at each z position and then normalized to the ratio determined at the focus point. This fractional change of the ratios is shown in Figures 1 and 2 for 1064 nm and 266 nm, respectively. Lower ablation powers at 266 nm produced ratios that were relatively constant throughout the range of z motion (+/- 20% throughout a delta z of 15-20 mm).

Elemental fractionation as a function of z position was observed for both the 532 and 1064 nm wavelengths. In addition to the elemental fractionation, an elemental bias becomes obvious at higher ablation powers. It appears that for the elements studied there are two groups of behavior. The first group includes Ba, Ce, Nd, La, and Al. These elements behave similar to Zr with ratios to Zr that are laser focus independent. The second group includes Si, Ru, Ni, Na, and Fe. The relative elemental responses for the second group, unlike the first group, are laser focus dependent. As this sample is a glass, it is expected that most of the constituent elements are in their oxide form. The oxides of the first group of elements (similar to Zr) have high melting points, while those of the second group have low melting points, decompose or sublimate. The second group is thus more sensitive to the local heating of the surface by infrared and visible light which presumably ablates via a thermal mechanism.

ANALYSIS OF NOMINALLY FLAT SAMPLES BY RADIO-FREQUENCY POWERED GDMS

Charles R. Shick, Jr. and R. Kenneth Marcus

Clemson University, Department of Chemistry, Howard L. Hunter Laboratory, Clemson, SC 29634-1905.

INTRODUCTION.

Glow discharge mass spectrometry (GDMS) has persevered through the years to become a widely accepted method for performing sensitive direct solids analysis of metals, alloys, and semiconductors. Non-conducting samples are required to be made conducting by either mixing with a conducting binder like copper powder or utilizing a secondary, sacrificial metal cathode to initiate a GD at the surface of the non-conducting sample. In this laboratory, radio-frequency (rf) powered GD sources have been developed for the analysis of non-conducting samples. These sources can atomize both conducting and non-conducting samples and produce stable ion beams leading to reliable mass spectrometric analysis. The objectives of this work were to optimize rf-GD parameters, provide figures of merit, and investigate rf power losses through non-conducting samples for a flat-type sample rf-GDMS source.

EXPERIMENTAL.

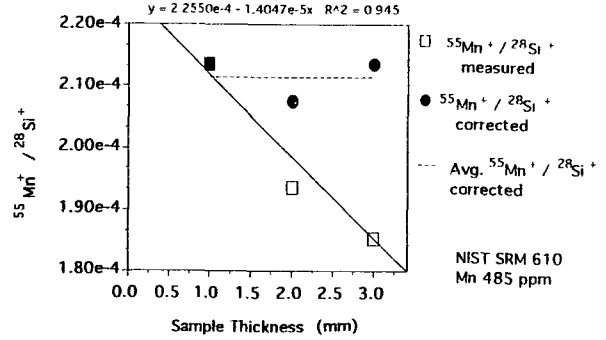
With only slight modifications, a VG GloQuad (Fisons Instruments, Elemental) has been developed into an rf-GDMS system. This system is a quadrupole-based instrument with two detectors installed: a Faraday cup for ion currents typical of matrix species and an electron multiplier for minor and trace measurements. A novel flat sample holder was designed to mount onto the end of a direct insertion probe (DIP).

RESULTS AND DISCUSSION.

Optimization study. A series of parametric studies for both conducting and non-conducting samples were performed towards identifying an optimum source geometry and set of discharge conditions. Three discharge cells, which varied in length from 6 to 10 mm (cell length is the distance from the edge of the discharge cell to the ion exit orifice) were evaluated according to the response of analyte signal to changes in the rf power, Ar flow rate (cell pressure), and limiting anode orifice plate. The optimum conditions for conducting samples were a 10 mm discharge cell length, 10 mm anode orifice plate, 2.50 - 3.00 sccm Ar flow rates, and 30 - 35 W rf powers. For the non-conducting samples, the optimum conditions were also with the 10 mm discharge cell length and 10 mm anode orifice plate; however, the better analytical ion beams were found between 1.50 - 2.00 sccm Ar flow rates and 35 - 40 W rf power range.

Non-conducting sample considerations. Temporal stability and external repeatability of non-conducting samples are hindered because most of these samples are either porous or contain significant amounts of trapped gases. These residual gases have the undesired effects of producing isobaric interferences, irreproducibility (stemming from the variability in the "wetness" from glass sample to glass sample), and discharge instability. In order to achieve some consistent level of sample preparation and to reduce residual gas/contaminant contributions, non-conducting samples must be pre-sputtered for approximately an hour. The dielectric nature of the non-conducting samples causes rf power losses as a function of sample thickness and in turn affects the ion beam intensity. Figure 1 demonstrates the linear relationship between $^{55}Mn^+/^{28}Si^+$ as a function of sample thickness. A correction could be obtained for this effect where $R_{corrected} = R_{measured}$ + (slope*change in thickness).

Figure 1.



SUMMARY.

A complete optimization and evaluation study of this rf-GDMS system has determined the optimum conditions for both conducting and non-conducting samples. Plasma stabilization times are < 5 minutes for conductors and < 60 minutes for non-conductors. The overall internal (< 5 %RSD) and external (< 12 %RSD) repeatabilities were reported. RSF variations for non-conductors was shown to be due to rf power losses through different sample thicknesses. Preliminary observations for rf-GDMS depth profile analysis were also presented.

High Precision Continuous Flow D/H Measurement from Hydrogen Gas and Water

H. J. Tobias; K. J. Goodman; C. E. Blacken; J. T. Brenna
Division of Nutritional Sciences, Cornell University, Ithaca NY 14853

High precision gas isotope ratio mass spectrometry (GIRMS) has been the technique of choice for determination of isotopes of the light elements, H, C, N, O, and S for several decades. Fast, continuous flow techniques have been developed for all the classic IRMS elements except for H. A system capable of determining D/H ratios via continuous flow is presented here.[1]

A Varian 3400 gas chromatograph (GC) with a split/splitless injector set at 250°C equipped with 10 meters of fused silica capillary, is interfaced with an IRMS. Hydrogen gas samples are swept by Ar or He carrier through the capillary and directed to a Pd foil held at 330°C (Fig 1). The Pd foil is mounted on a tube that leads into the mass spectrometer ion source. At elevated temperatures, the Pd absorbs and transfers only hydrogen isotopes into the vacuum, and so serves as a hydrogen filter. Purified H_2 and HD then flow to the ion source and *m/z* 2 and 3 are continuously monitored. Precision for repeated injections of H_2 gas is S.D. (δD) < 6 ‰ over a range of δD = -200 to 340 ‰. Linearity over this range for gas injections corresponds to an r^2 > 0.99996 and accuracy is < 2 ‰, when referenced to dual inlet analysis.

Liquid water samples (100 nL) are injected into a He carrier, are passed through the capillary and directed into a reduction furnace loaded with Ni metal and held at about 850°C (Fig 1). A combustion furnace filled with CuO and Pt metal can be positioned before the reduction furnace for potential extension to hydrocarbon analysis. A Nafion™ (DuPont) water trap removes trace quantities of unreduced water from the stream and flow is directed to a Pd foil. Source nonlinearities were characterized for hydrogen analysis in which no carrier gas enters the ion source. These nonlinearities can be corrected; water sample analyses with precisions of S.D. (δD) < 10 ‰ over a range of δD = 400 ‰ and accuracy of < 4 ‰ are obtained. A significant problem with water analysis is that of sample memory.[2] Memory effects were assessed for repeated water injections over a larger range of δD from about -50 to 4700 ‰. Consecutive injections show no signs of memory effects, even for injection of tap water (sample a) after five consecutive injections of δD ~ 4700 ‰ water (sample j) as shown in Fig 2.

A FIELD MASS SPECTROMETRIC SYSTEM FOR ISOTOPIC ANALYSIS OF ACTINIDES.

Michael S. Kahr, José A. Olivares, Kent D. Abney and Scott Kinkead
Chemical Science and Technology Division
Los Alamos National Laboratory
Los Alamos NM 87545

INTRODUCTION

An important need exists for field instrumentation capable of providing isotopic analysis of uranium and plutonium samples. Currently, the time required for actinide isotopic analysis of field samples is weeks to months. Clearly this delay is too long to make appropriate decisions by inspectors. This data could be obtained rapidly on site by employing the transportable field mass spectrometer system which has been developed and tested by our group.

EXPERIMENTAL

A compact transportable mass spectrometric system based upon a commercially available quadrupole residual gas analyzer has been developed and evaluated. The system has been minimized for size and weight and currently fits into a large suitcase.

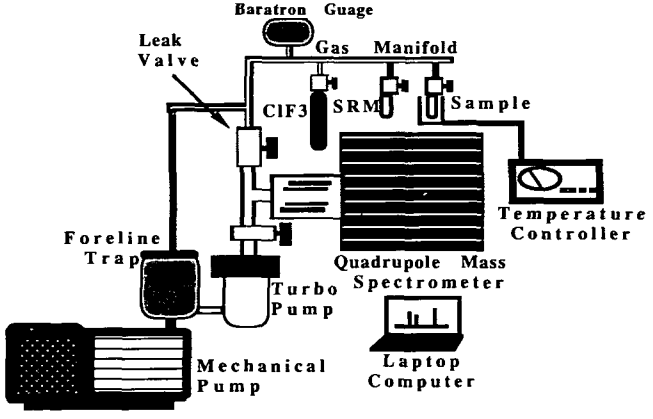

FIGURE 1: Block diagram of the transportable mass spectrometer system for actinide analysis.

For these studies, uranium samples are converted into volatile hexafluorides by reaction with chlorine triflouride. Chlorine trifluoride rapidly converts all uranium compounds studied to UF_6, including high fired uranium pellets. The uranium hexafluoride is then introduced into the mass spectrometer for isotopic analysis. Isotopic ratios are measured from the doubly charged uranium ion signal using peak heights.

RESULTS

Standard (NIST) reference uranium samples and a highly enriched sample from Los Alamos National Laboratory were analyzed for their isotope ratios. The quantitative results are reported in Table 1. Without calibration or mass bias correction the differences between the measured and reported values for the standards was better than 10% in all cases.

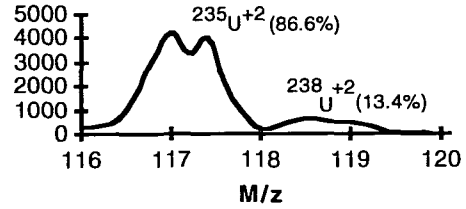

Figure 2: Mass spectrum of a highly enriched sample (The Alpa Wing sample, see Table 1 below) This sample was measured to be 86.6% 235U.

Table 1: Quantitative Results

Sample	%U235 (NBS)	%U235 (Best Value)	Average Error (%)	RSD
U950a	0.7	0.8	12.3	N.A.
Depleted Uranium	<0.7	0.4	N.A.	N.A,
U030	3.0	3.1	6.1	7.3
U500	50.0	48.1	6.6	4.6
Alpha Wing	N.A.	86.6	N.A.	N.A.

CONCLUSION

A small transportable mass spectrometer system has been constructed and employed to analyze a range of uranium samples with various isotopic compositions including a highly enriched sample which was measured to be 86.6% ^{235}U. Accuracy is currently better than 10% without calibration or mass bias correction employing a simple peak height algorithm. Accuracy is expected to improve by employing calibration, mass bias correction and peak areas with background subtraction.

Nuclear Isotope Measurement in the Hanford Environment

J.F. Wacker, J.J. Stoffel(s), J.M. Kelley, L.A. Bond, R.A. Kiddy, and F.P. Brauer
Pacific Northwest Laboratory, Richland, WA 99352

The Pacific Northwest Laboratory (PNL) is located at the federal government's Hanford Site in southeastern Washington State, which was built during World War II as part of the secret Manhattan Project to develop the atomic bomb. Hanford produced the plutonium for the Trinity test and for the bomb exploded on Nagasaki on August 9, 1945. The war ended six days later.

Monitoring of the Site itself and surrounding environs for Hanford-related radionuclides has been a routine part of the operations since 1944. One of the most sensitive analytical methods used is thermal ionization mass spectrometry (TIMS) with triple-sector mass spectrometers. Our normal geometry instruments have an abundance sensitivity of 10^{-9} for uranium while our newest Triple-Sector Isotope Mass Spectrometer (TRISM), utilizing a new ion-optical design developed at PNL, has an abundance sensitivity of 10^{-11} [1]. In favorable cases, sensitivity is such that complete isotopic analyses are obtained on total samples in the femtogram range; and minor isotopes in the attogram range are measured.

Plutonium Measurement

Plutonium is a highly toxic element that has been distributed over the earth's surface by atmospheric testing of nuclear weapons. To distinguish plutonium from a second source, such as Hanford production facilities, it is necessary to resolve the contribution of that source from the global burden of fallout plutonium in soil Soil and sediment samples of typically 1 gram are dissolved by microwave digestion. The plutonium is chemically separated, purified, and loaded into an ion-exchange resin bead for analysis by positive thermal ionization.

Table 1 shows the concentration and isotopic composition of plutonium in soil as a function of distance from the Hanford source in the center of the Site. Distant from the Site, the plutonium isotopic composition, as characterized by the $^{240}Pu/^{239}Pu$ ratio, is the global mean value for fallout. At a distance of two miles from the plant, the plutonium concentration is elevated and has an isotopic composition that is a mixture of Hanford product and fallout. Only one mile from the plant, the plutonium concentration is higher and has an isotopic composition characteristic of weapons-grade material. Beyond the Site boundary, Hanford plutonium is not detectable in soil.

Table 1. Plutonium concentration and isotopic composition in soil, fallout and Hanford product

Distance from plant (miles)	Replicate samples	Pu concentration (fg/g ± 1σ)	Isotopic composition ($^{240}Pu/^{239}Pu$ ± 1σ)
200	3	91 ± 7	0.1785 ± 0.0095
2	4	212 ± 16	0.0957 ± 0.0013
1	2	263 ± 31	0.0522 ± 0.0005

Radioiodine Measurement

Another important application of TIMS at Hanford is measurement of the long-lived (half-life=16 million years) fission product, ^{129}I Groundwater beneath the Hanford Site is contaminated with ^{129}I as a result of past waste disposal practices. The contaminated groundwater seeps into the Columbia River along the Site boundary. The Columbia River is monitored quarterly with samples from locations above the Hanford Site and at the pumphouse for the City of Richland's water system downstream of the Site.

Iodine samples are spiked with ^{125}I to obtain the concentrations of both ^{129}I and natural ^{127}I by isotope dilution, and are analyzed by negative thermal ionization. Two ion detectors are required for measurement of the large isotope ratios, a Faraday cup to measure the intense beam of natural ^{127}I (typically 10^{-9} A) and a pulse-counting electron multiplier for the minor isotopes. The minor isotope measurement limit, due to contaminant interference in the mass spectrum, is 10^7 atoms (2 fg) of ^{129}I.

Table 2 gives data for 1993. The concentration of natural ^{127}I in the river was the same above and below Hanford, ~1 μg/L. Although the concentration of ^{129}I below Hanford, 678 fg/L, was 26 times greater than above Hanford, the amount is still negligible The ^{129}I concentration downstream from Hanford corresponds to an activity of 1.2×10^{-4} pCi/L. This is 8,000 times lower than the EPA Drinking Water Standard of 1 pCi/L for ^{129}I.

Table 2. Annual average iodine concentrations in Columbia River water during 1993

Location	^{127}I (μg/L ± 1σ)	^{129}I (fg/L ± 1σ)
Above Hanford	1.04 ± 0.30	26 ± 7
Below Hanford	1.06 ± 0.40	678 ± 147

TEAMS

The objective of the TEAMS project is to combine the efficiency of a thermal emission (TE) ion source with the isobaric selectivity of an accelerator mass spectrometer (AMS) for measurement of ^{129}I and other nuclides in small (less than microgram) samples. We have completed construction of a thermal emission ion source module that is being installed on the AMS at Lawrence Livermore National Laboratory. The module is equipped with the same commercial thermal ion source that is used on our new TRISM mass spectrometer. We have also built and installed a low-current Faraday cup for small sample measurements.

In our collaboration with LLNL, we have been developing a small sample capability with their existing Cs^+ sputter ion source. We have already reduced the sample size that can be run by a factor of 100--from 3 mg down to 30 μg--with reproducible results. The AMS measurement limit for ^{129}I is 10^6 atoms. We expect the TEAMS system to push that limit down to 10^5 atoms.

Thermal Ionization Cavity Source for Mass Spectrometry

José A. Olivares, Edwin P. Chamberlin, and Yixiang Duan, Los Alamos National Laboratory, Chemical Science and Technology Division, Los Alamos, NM 87545

Thermal ionization mass spectrometry (TIMS) is widely used for isotopic determination, and elemental concentration measurements by isotope dilution. TIMS is applicable to over 70 elements in the periodic table, often, with very high sensitivity, low detection limits, high precision, and high accuracy.[1] Probably due to its success and simplicity, the traditional resistively heated filament type ion source, used in TIMS, has remained relatively unchanged in the past 50 years Only minor changes in the number of filaments used for vaporization and ionization, and the shape of the filament have been employed. Much of the science of thermal ionization has focused on sample preparation, and chemical ionization enhancers.

Beyer et al.[2], in the USSR, and Johnson et al.[3], later in the US, introduced a new high temperature cavity-type thermal ionization source for isotope separation on-line (ISOL) projects. Delmore et al.[4] introduced a similar cavity-type source for the study of thermal emission of primary ions for secondary ionization mass spectrometry (SIMS)

A new thermal ionization cavity-type source for mass spectrometry has been developed in our laboratories. The source is based on the sources developed for isotope separation but, has been miniaturized for use on small quadrupole and sector mass spectrometers, see Fig. 1. The redesign of the source has kept, as the main objective, the high sample utilization efficiency for which the original sources are well known. The new source has been characterized on an isotope separator and on a quadrupole mass spectrometer The source gives ionization efficiencies of 2% for thorium, 8% for uranium, and rare-earths and other elements can exhibit around 50% ionization efficiency. This is 10-100 times better sample utilization efficiency than achieved by conventional filament type thermal ionization sources.

Vaporization and ionization of the sample is governed by the temperature required to give a substantial vapor pressure (~10^{-4} Torr) of the element of interest in the source cavity. This is exemplified in Figure 2, showing a spectrum of Eu, Sm, and Lu taken from the oxide powders loaded into the source. Note the absence of MO^+ ions in these spectra. For the actinides the MO^+ ions are more prominent and must be controlled, typically with the use of graphite. The enhanced ionization is caused by the multitude of atom to surface interactions as the atoms evaporate and leave the source cavity

Internal isotopic precision measurements have been made on various rare-earths The precision varies with the element, and source conditions. Typical precisions for short measurement periods (~10 min) are around 1% Yet, some measurements with precisions in the 10's of ppm have been observed, see Table I.

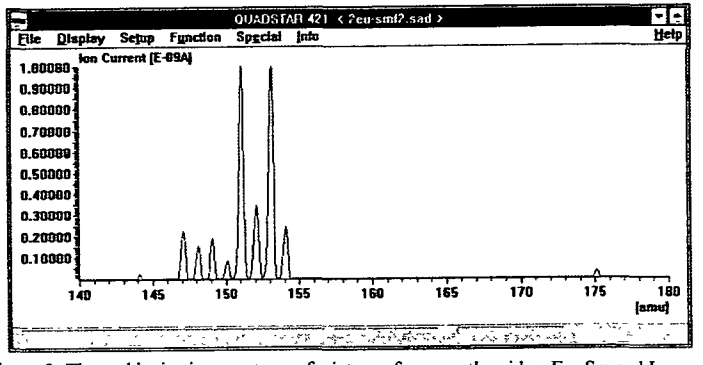

Figure 2. Thermal ionization spectrum of mixture of rare-earth oxides, Eu, Sm and Lu.

Carbenes represent an important class of reactive intermediates in organic chemistry.[1] Their reactivity is determined, in part, by their spin multiplicity. Methylene, the simplest of all carbenes, is a ground state triplet and reacts via radical-type multi-step reactions which produce biradical-type intermediates. Substitution of one or more hydrogens by π-donating, σ-withdrawing groups can stabilize the singlet state relative to the triplet state. Singlet carbenes react via single-step concerted pathways with retention of stereochemistry.

Recently, our laboratory determined the heats of formation of CF_2 and CCl_2, both ground state singlets, by measuring the threshold energy for collision-induced halide loss from CF_3^-, and CCl_3^-.[2] We complete the chlorine and fluorine containing carbene series by measuring thermochemical properties for CHF, CHCl, and CFCl, molecules that are of interest due to their possible role as intermediates in the stratospheric degradation of chlorofluorocarbons (CFC's).

CH_2Cl_2, CH_2ClF and $CHCl_2F$ were allowed to react with OH^- in the room temperature flow tube. The ions $CHCl_2^-$, $CHClF^-$, and CCl_2F^- were then mass selected by Q1. Collision-induced dissociation occurs in Q2 with argon serving as the collision target. An appearance curve is generated by monitoring the intensity of the Cl^- product as a function of collision energy in the center of mass frame.

The appearance curve is fit with an assumed model function which explicitly accounts for ion internal energy and the possibility of a kinetic shift due to slow dissociations.[3] From this model, average energy thresholds for collision-induced chloride loss of 1.57 ± 0.11, 0.96 ± 0.09 and 1.07 ± 0.06 eV were determined for $CHCl_2^-$, $CHClF^-$ and $CFCl_2^-$ dissociations.

Gas phase acidities of the parent neutral halocarbons CH_2ClF and $CHFCl_2$ were determined by bracketing techniques. Gas phase acidities of $\Delta H_{acid}(CH_2ClF)$ = 386.1 ± 2.0 and $\Delta H_{acid}(CHFCl_2)$ = 360.9 ± 2.0 kcal/mol were measured. A value for the gas phase acidity of methylene chloride of 369.0 kcal/mol was derived from gas phase equilibrium studies with t-butyl alcohol. The gas phase acidities of the halocarbon precursors were estimated using *ab initio* molecular orbital theory. Acidities calculated from the G2[4] and G2MP2[5] procedures produce are in excellent agreement with our experimental acidities.

The gas phase acidities were then combined with the threshold energies and supplemental thermochemistry to derive the final heats of formation of $\Delta H_{f,298}(CHCl)$ = 80.1 ± 2.8, $\Delta H_{f,298}(CHF)$ = 34.9 ± 3.4 and $\Delta H_{f,298}(CFCl)$ = 7.6 ± 2.6 kcal/mol.

Theoretical estimates for the heats of formation of the halocarbene were calculated using G2 and G2MP2 methods. Heats of formation were determined from the G2 heats of atomization, and from the energies of the isodesmic dihydrogen transfer reaction shown in reaction 1. The values for the heats of formation of the

$$CXY + CH_4 \longrightarrow CXYH_2 + {}^1A_1\ CH_2 \qquad (1)$$

halocarbenes predicted from these methods are in excellent agreement with the heats of formation derived from the threshold energy experiments.

Analogous procedures were used to determine the absolute heats of formation of $SiCl_2$ and SiClF. Average threshold energies for collision-induced chloride loss from $SiCl_3^-$ and $SiCl_2F^-$ were determined to be 2.38 ± 0.05 and 1.99 ± 0.08 eV.

G2MP2 theory was used to predict the gas phase acidities of $SiHCl_3$ and $SiHCl_2F$. Values of $\Delta H_{acid}(SiHCl_3)$ = 338.2 and $\Delta H_{acid}(SiHCl_2F)$ = 344.3 kcal/mol were determined. Combining these energy thresholds with the acidities give values for the heats of formation of $\Delta H_{f,298}(SiCl_2)$ = -37.2 ± 2.5 and $\Delta H_{f,298}(SiClF)$ = -93.8 ± 2.5 kcal/mol. G2 and G2MP2 predictions for the heats of formation of the halosilyleneswere were also carried out and are in good agreement with the experimental values.

Calculated and Measured Double-ionization Energies of Carbon Tetrachloride

[1] Russell P. Grant,[1] Frank M. Harris,[2] Stuart R. Andrews,[2] David E. Parry,
[1] Mass Spectrometry Research Unit,[2] Chemistry Department, University of Wales
Swansea, Swansea, SA2 8PP, Wales, U.K.

Introduction

Previous investigations of the carbon tetrachloride molecule using Auger-electron (AE) spectroscopy [1] and double-charge-transfer (DCT) spectroscopy [1-3] have yielded considerable information regarding singlet and triplet state energies of CCl_4^{2+}. The theoretical study reported here using the multiple scattering X alpha (MSXalpha) computational method in a semi-empirical form [4], however, predicted that considerably more states exist than had previously been revealed by experimentation. To confirm these predictions, DCT spectroscopy studies of the double-ionization energies (DIEs) to the singlet and triplet electronic states of CCl_4^{2+} were undertaken in the present investigation.

Experimental

3 keV H^+ and OH^+ projectile ions interacted with CCl_4 molecules contained in the collision-gas cell situated in the second field-free region of a Finnigan MAT 8230 mass spectrometer. Double-electron-capture (DEC) reactions generated CCl_4^{2+} and H^-/OH^- ions, the translational energies of which depended on the electronic states of the dication being populated. The H^-/OH^- translational-energy scale was calibrated using xenon, the DIEs to states of Xe^{2+} being known. Because of spin conservation in DEC reactions, the use of H^+ and OH^+ projectile ions populated singlet and triplet electronic states, respectively, of CCl_4^{2+}.

Results

A typical DCT spectrum for H^+/CCl_4 is shown in figure 1. A considerable number of peaks are evident and the DIEs determined from their positions are shown in table 1. Also shown in this table are the DIEs to singlet states of CCl_4^{2+} predicted using the MSXalpha computational method. It can be seen that the predicted and measured DIEs are in good agreement. The increased resolution of the mass spectrometer yields information where previous studies had yielded little, particularly in the 29.1-30.9 eV region, where only one state had been previously reported but four had been predicted.

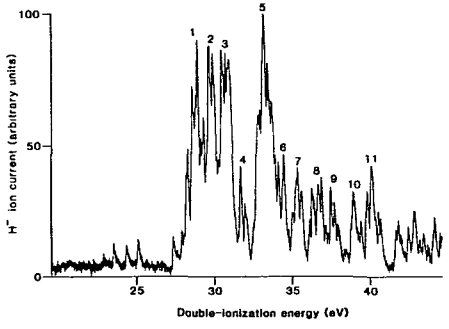

Figure 1

Typical H^+/CCl_4 spectrum.

The data for the OH^+/CCl_4 DCT spectroscopy study is shown in table 2. The predicted data correlates well with the measured data although the density of states from 30.5-32.2 eV is too high for the predicted peaks to be revealed experimentally.

Table 1 Measured and calculated DIEs to singlet states of CCl_4^{2+}.

Peak	Measured[a] (eV)	Calculated[b] (eV)	State configuration	State designation
1	29.1 ± 0.1	29.1	$1t_1^{-2}$	$^1A_1, ^1E, ^1T_2$

E	35.6 ± 0.3	35.7	$3t_2^{-1}2t_2^{-1}$	$^3A_1, ^3E, ^3T_1, ^3T_2$
F	36.7 ± 0.2	36.5	$1e^{-1}2t_2^{-1}$	$^3T_1, ^3T_2$
G	37.9 ± 0.3	38.0	$1t_1^{-1}2a_1^{-1}$	$^3T_1$
H	39.0 ± 0.3	38.9	$3t_2^{-1}2a_1^{-1}$	$^3T_2$
-	-	39.7 }	$1e^{-1}2a_1^{-1}$	^3E
-	-	40.0 }	$2t_2^{-2}$	$^3T_1$
-	-	43.2	$2t_2^{-1}2a_1^{-1}$	$^3T_2$

Conclusions

The present study has greatly enhanced the information regarding the electronic-state energies of CCl_4^{2+}. The accuracy of the predictions is confirmed by the consistently good agreement obtained between the measured and calculated double-ionization energies.

Determination of Se-H Bond Energy of Benzeneselenol

Diane T. Leeck, Ruomei Li, Leonard J. Chyall, and Hilkka I. Kenttamaa*

Department of Chemistry, Purdue University
West Lafayette, IN 47907-1393

Benzeneselenol is a useful trapping agent for distonic ions because it transfers a hydrogen atom to distonic ions faster than any other reagent studied. The rate of the trapping reaction depends on the reaction enthalpy. Unfortunately, the Se-H bond dissociation energy of benzeneselenol is unknown. Hence, it is not possible to accurately predict and interpret the outcome of reactions involving benzeneselenol. The objective of this study was to determine the homolytic Se-H bond energy of benzeneselenol.

The experiments were carried out in a dual-cell Fourier-transform ion cyclotron resonance mass spectrometer (FT/ICR). The instrument consists of a differentially pumped dual cell that is aligned collinearly with a magnetic field produced by a 3 T superconducting magnet. Reactant ions were generated in one side of the dual cell, transferred into the other side, and collisionally cooled with argon. The ion of interest was isolated and allowed to react with the desired neutral reagent for a variable period of time.

The homolytic Se-H bond energy of benzeneselenol was determined experimentally by using two independent routes. The hydrogen-selenium bond strength was directly bracketed to be $\leq 82 \pm 2$ kcal mol^{-1} by measuring the efficiency of hydrogen atom abstraction by several radical cations (Figure 1). Another estimate for the Se-H bond energy was obtained from the thermochemical cycle shown in Scheme 1. The ionization energy of benzeneselenol was determined to be 8.3 ± 0.1 eV by measuring the efficiencies of various electron transfer reactions (in the forward and reverse directions; Figure 2). Similarly, the proton affinity of $C_6H_5Se\bullet$ was bracketed to be $201 \pm$ kcal mol^{-1} (Figure 3). Using the thermochemical cycle, the homolytic Se-H bond energy was calculated to be 79 ± 3 kcal mol^{-1}.

The second method is considered to give the better value for the homolytic Se-H bond energy than the first method since the barrier height is not known for hydrogen atom abstraction from benzeneselenol by radical cations. Hence, the value recommended for the Se-H bond energy is 79 ± 3 kcal mol^{-1}. Based on this value, hydrogen atom abstraction from benzeneselenol by most distonic ions is concluded to be highly exothermic.

$$D(\text{Se-H; kcal mol}^{-1}) = IE(C_6H_5SeH) + PA(C_6H_5Se\bullet) - IE(H\bullet) \quad (1)$$

SINGLE COLLISION CID STUDIES OF ALKALI-METAL, 12-CROWN-4 COMPLEXES BY FTICR

Marshall Pope and David V. Dearden
Brigham Young University, Dept. of Chemistry and Biochemistry, Provo, Utah 84602

Introduction

Gas phase studies of the chemistry of multidentate ligation offer opportunities to observe metal-ligand systems in the absence of the interfering effects of solvent. Several studies have determined the *relative* bond strengths of various ligands for a given metal, using equilibrium techniques. *Absolute* bond strengths, which are of fundamental importance, have proven more difficult to determine. One study has appeared which used threshold CID in a Fourier transform ion cyclotron resonance instrument to determine a few alkali metal ion / 18-crown-6 bond strengths,[1] but agreement between this work and recent high-level theory[2] is poor. Experimental studies are hampered by the very large number of internal degrees of freedom in these systems, leading to large kinetic shifts. Rapid radiative stabilization leads to a so-called *intrinsic shift* which also complicates the measurement of bond strengths. We begin our work on this problem by investigating the smallest readily-available member of the crown ether series, 12-crown-4, to minimize kinetic shifts. Likewise, to maximize observation time and decrease the kinetic shift problem, our experiments have been performed in the low-pressure (1-3 x 10^{-8} mbar) environment of a Fourier transform ion cyclotron resonance mass spectrometer.

Experimental

All experiments were performed in a Fourier transform ion cyclotron resonance mass spectrometer (model APEX 47e, Bruker Instruments) equipped with an ion source external to the high-field region of a 4.7-Tesla superconducting magnet. Electrospray ionization from 49:49:2 methanol:water: acetic acid, spiked with alkali metal acetates or nitrates, was used to generate the ions. Electrostatic focusing and injection techniques were used to transfer ions from the source to the field-corrected ("Infinity") trapping cell of the instrument. Isolation of the parent ion was by conventional FTICR techniques (chirp and shot ejection of unwanted ions). The CID target was Ar, and neutral pressures were measured using a magnetically-shielded ionization gauge (Balzers). Fragment spectra at a given excitation duration were collected in narrowband mode. Sixteen identical scans were accumulated in memory for each activation duration. The same experiment was then repeated to permit narrowband acquisition of the remaining parent ion abundance. The excitation duration was incremented, and the cycle was repeated. The data are reported as fragment/parent intensity ratios as a function of center-of-mass kinetic energy (calculated following McMahon.[3])

Results and Discussion

Figure 1 illustrates a set of trials for 12-crown-4 / K^+. Data are plotted as the ratio of fragment ion intensity to parent abundance. The ordinate scale is proportional to center-of-mass energy,

$$E_{com} = \frac{m_t}{m_t + m_p} \frac{E_{rf}^2 t_{rf}^2 e}{8 m_t}$$

where m_t is the mass of neutral argon background, m_p is the mass of the parent crown, E_{rf} is measured in volts per meter and t_{rf} is the duration of the acceleration pulse prior to a 20 msec delay to allow collisional activation. Recent ab-initio calculations on the Na^+/ 12-crown-4 complex suggest a bond strength of 60 kcal mol^{-1};[4] we would expect this to be an upper limit for K^+ bond strengths. Our current results for 12-crown-4 / K^+ set an appearance threshhold for fragmentation at ~64 ± 17 kcal mol^{-1} if the onset region is extrapolated. However, the high energy region of our data, which appears to have better precision, extrapolates to 109 ± 8 kcal mol^{-1}. These fragment appearence threshholds do not represent bond strengths. We expect, but did not observe, competative fragmentations at these energies (but fragmentation may be unobservable if it occurs in the neutral product).

When the alkali metal is varied, the relative order of fragment appearence energies is in good agreement with the expeeted order of alkali metal-crown bond strengths. There exists, however, a stark contrast between the absolute magnitudes and our expectations based on simple chemical intuition. Because

experimental scatter seems to increase for the lighter fragments, we suspected a mass-dependent instrumental response. To check for this we performed CID on 12-crown-4/K^+ at three electric field intensities. The data show good correlation in the onsets and similar scatter.

Other features of the data suggest that even our longest CID delay, 100 msec, was insufficient to overcome the sizable kinetic and intrinsic shifts in these systems. The energy onsets for K^+ cation fragmentation from 12-crown-4/K^+ were compared at several different CID delays. It is interesting that the three different delays give different slopes but that, within experimental error (± 8 kcal/mole), they yield the same intercept. The slope does not vary if the pressure•CID delay product is fixed. Both kinetic shift and multiple collisions would shift the intercept. Kinetic shifts however, have a more pronounced effect on the slope. Though kinetic shifts for these large systems are beyond our control, we believe that a more accurate calibration of the energy scale (against a reference system) may redeem the onsets as a fair estimate of the relative bond strengths of two metals for a given crown.

CATION AFFINITIES OF PYRIDINE BASES: STERIC EFFECTS

John J. Isbell* and Jennifer S. Brodbelt, Deparment of Chemistry, University of Texas at Austin
Austin, TX 78712-A5300

INTRODUCTION

The nature of hydrogen-bonding has been studied extensively in solution and in the gas phase due to the importance of these forces in both intra- and intermolecular interactions.[1] In solution hydrogen-bonding interactions comprise the dominant intermolecular interaction responsible for drug-receptor recognition. In the solvent-free environment of the mass spectrometer it is possible to examine the intrinsic reactivities of the proton without the interference of solvent effects. We have begun several systematic studies of hydrogen-bonding interactions in a variety of ion-molecule complexes, and in this report we describe the evaluation of gas-phase basicities and boronium ion affinities of a series of substituted pyridines. The pyridines are strong bases in which the nitrogen can be effectively blocked by neighboring substituents. The borinium ion serves as a model of a 'steric proton', thus allowing a second means of probing steric effects on cation affinities and hydrogen-bonding interactions.

EXPERIMENTAL

All experiments were performed in a Finnigan MAT ITMS. The manifold temperature was maintained at 393K (uncorrected) The pyridines mixture was admitted to the chamber through heated leak valves at pressures ranging from $3x10^{-7}$ torr to $3x10^{-6}$ torr Trimethyl borate was introduced at a static pressure of $5x10^{-7}$ to $5x10^{-6}$ torr (uncorrected) and helium buffer gas was added to increase the total pressure to one millitorr There was no fluctuation in K_{eq} over these pressure ranges.

RESULTS and DISCUSSION

Rationale

Several workers have shown the influence of entropy on the relative proton affinities of similar molecules.[2] However, to the best of our knowlege, little gas-phase work has quantitatively addressed the effects of sterics on electron-deficient addition reactions.[3] Such a study could provide the foundation for obtaining a better understanding and a method for quantifying ion bulk with reactivity. Protons are not very large, and simply adding a ligand to a proton to increase its bulk is not sufficient to ensure that the liganded proton is the one transfered in subsequent reactions. In addition, the use of a 'derivatized proton', such as $P1H^+$, would require the formation of a heterodimer complex as a precursor to transfer of the bulky proton, and such a complex may not readily form if the proton affinity of P2 is much larger than that of P1. It was for these reasons that an alternative model of a steric proton was chosen.

Monomethyl- and dimethylpyridines proved to be ideal bases for the examination of the influence of sterics on ion affinity due to the availability of all the isomers

Determination of Relative Borinium Ion Affinities

The quadrupole ion trap, due to its ability to trap and store ions for seconds, is nearly ideal for equilibrium determinations. However, the main problem with the ion trap for these types of measurements is the temperature uncertainty [4] To compensate for this shortcoming, the relative gas-phase basicities were determined for each pair of pyridines studied in order to normalize them with respect to the known gas-phase basicities of the neutrals.[5] The gas-phase basicities at 393K were extrapolated from those at 300 or 320 K and the corresponding proton affinities. Thus the relative free energy of dimethoxy borinium binding was calculated using the equation: $\Delta G_{(Borinium)} = (\Delta G_{(Borinum)expt}) * (\Delta GB_{lit}/\Delta GB_{expt})$

Examination of the relative borinium ion affinities in Table 1 shows that $(3,5\text{-lutidine/B(OMe)}_2)^+$ is favored over $(3\text{-Picoline/B(OMe)}_2)^+$ by 4.4 kcal/mole, while the basicity of the latter is 3.1 kcal/mole greater. The 3,4-lutidine/3-picoline pair yielded similar results. Since the methyl groups are removed from the site of ion attachment for these pyridines, it was anticipated that there would be no steric influence on binding, and, therefore, this system should provide relative binding energies for the dimethoxyborinium ion that are most similar to the relative proton affinities. An examination of Table 1 shows that for similarly-hindered systems, the borinium ion affinity parallels the gas-phase basicity.

Steric inhibition of binding was pronounced for the 2,6-lutidine/pyridine and 2,3-lutidine/3-picoline systems. These reactions were essentially thermoneutral even though the lutidines have greater basicities, demonstrating the repulsive interactions between the methyl groups and the dimethoxy borinium ion.

TABLE 1

System	$\Delta G\ (B(OMe)_2)^+$ (kcal/mole)[a]	$\Delta G\ B^b$ 393K
3,5-Lutidine/3-Picoline	4.4 ± 0.2	3 1
3,4-Lutidine/3-Picoline	3.2 ± 0.6	3.8
2,3-Lutidine/3-Picoline	-0.2 ± 0.5	3.8
2,4-Lutidine/2-Picoline	1.8 ± 0.4	1 8
2,6-Lutidine/Pyridine	0.2 ± 0.5	7.1

a. ΔG for transfer from lutidine to picoline or Pyridine. b. GB = gas-phase basicity (in kcal/mole)

CONCLUSIONS

The data presented herein supports the idea of using trialkylborates as models of 'steric protons' and such models may prove to be a better probe of reactivity for explaining why certain reactions do not occur For instance, this comparison can be done by simply chosing the appropriate alkoxy borinium ion as a probe so that it is comparable in size to the ion used in the ion-molecule reaction Since the borinium ions bind strongly to heteroatoms, the lack of an addition product would provide strong evidence for steric inhibition of the reaction. In addition, the use of a series of increasing dialkylborinium ions would permit bracketing of the range of 'sizes' of the ion permitted for an addition reaction to occur.

Charge Repulsion in Peptides and Basicities of Different Charge States.

Igor A. Kaltashov, Catherine Fenselau*
Department of Chemistry and Biochemistry
University of Maryland Baltimore County
5401 Wilkens Ave., Baltimore MD 21228

Values of gas phase basicities of different charge states of the same peptide or protein are influenced by both electrostatic repulsion and conformational changes. Careful experimental determination of thermochemical parameters may provide insight on the three dimensional structure of peptides and proteins in the gas phase and its relation to conformations in solution.

A modified kinetic method[#1] has been used to measure gas phase basicities of protonated peptides. Unimolecular decomposition of a doubly charged dimer, formed by M (a peptide) and B (a reference base):

$$^{+}HM\cdots H^{+}\cdots B \begin{cases} \xrightarrow{k_1} MH_2^{2+} + B & (1) \\ \xrightarrow{k_2} MH^{+} + BH^{+} & (2) \end{cases}$$

in a third field-free region of a four sector mass spectrometer (JEOL HX110/HX/110, Tokyo, Japan) provides information on both "apparent" second gas phase basicity $GB_{app}(MH^+)$ (see Fig. 1) and electrostatic repulsion between the two protons δ (as kinetic energy release in (2), see Fig. 2). A true value of the second gas phase basicity can be calculated as $GB(MH^+) = GB_{app}(MH^+) - \delta$.

In the present work a second gas phase basicity of bradykinin fragment [1-8] (RPPGFSPF) was determined to be $GB(MH^+)$=191.7±1.2 kcal/mol. The value of Coulombic repulsion δ=22.4±1.2 kcal/mol (Fig. 2, insert) was independently confirmed by KER experiments with metastable MH_2^{2+} ions. The first gas phase basicity of the peptide was determined by the classical kinetic method[#2] to be GB(M)= 254.8± 0.4 kcal/mol (see Fig. 1).

Two models were considered for localization of protons in the doubly charged peptide RPPGFSPF: the Arg[1] side chain and the N-terminal amino group (maximum "local" proton affinity) or, alternatively, the Arg[1] side chain and the C-terminal carboxylic group (maximum charge separation). The two models ($R^{\oplus\oplus}$PPGFSPF and $R^{\oplus}$PPGFSPF$^{\oplus}$) were subjected to molecular dynamics calculations using the CHARMm22 semi-empirical force field. The calculations revealed that the most probable intercharge distance in $R^{\oplus\oplus}$PPGFSPF is 7.00 Å (Coulombic repulsion of 47.1 kcal/mol, which is twice as high as the experimentally measured value). In contrast, the most probable intercharge distance for $R^{\oplus}$PPGFSPF$^{\oplus}$ is 14.55 Å (Coulombic energy of 22.8 kcal/mol, which is strikingly close to the experimentally measured value of δ). Also, the lowest energy conformation of $R^{\oplus}$PPGFSPF$^{\oplus}$ is 16.9 kcal/mol lower than that of $R^{\oplus\oplus}$PPGFSPF. This suggests that in doubly protonated RPPGFSPF the "extra" protons are located so as to maximize the distance between them, not to occupy the sites with highest "local" proton affinities.

Bradykinin fragment [2-9] (peptide PPGFSPFR) has the same aminoacid composition as bradykinin fragment [1-8], but differs by the position of the Arg residue along the chain. The second gas phase basicity of this peptide has been determined to be $GB(MH^+)$=197.6±1.4 kcal/mol ($GB_{app}(MH^+)$=220.2±1.0 kcal/mol and δ=22.6±1.0 kcal/mol). This is significantly higher (by 5.9 kcal/mol) than the second gas phase basicity of bradykinin fragment [1-8], because the two most basic sites of PPGFSPFR (Arg[8] side chain and N-terminus) are separated much further, and the second proton is not forced to a more distant site with a lower local proton affinity.

Polyatomic Cations Affinities of Pyridines Determined by the Kinetic Method

Yang, S. S.; Chen, G.; Wong, P.; Ma, S.; Cooks, R. G.
Department of Chemistry, Purdue University, IN 47907

Gozzo, F. C.; Eberlin, M. N.
State University of Campinas, Institute of Chemistry, CP 6154 Campinas, SP 13081-970, Brazil

The affinities of polyatomic cations, like those of protons, can be measured by the kinetic method [1] This is done by using ion/molecule reactions in a pentaquadrupole mass spectrometer[2] to generate dimeric clusters in which neutral pyridine molecules are bound to such cations as $OCNCO^+$, $SiCl_3^+$, and $SiCl^+$ ions The dimeric adducts, viz. $Py_1[X]^+Py_2$ where Py_1 and Py_2 represent substituted pyridines, where X represents $OCNCO^+$, $SiCl_3^+$ or $SiCl^+$, are dissociated to yield the corresponding monomeric adducts All polyatomic cation complexes of meta- and/or para-substituted pyridines display excellent linear correlations between the fragmentation abundance ratio, $\ln[Py_1[X]^+/Py_2[X]^+]$, and the proton affinity difference of the pyridines (Figures 1, 2) The relationships between the affinities of $[OCNCO]^+$, $SiCl_3^+$, and $SiCl^+$ and the proton affinities of the pyridine are relative $[OCNCO]^+$ affinity (kcal/mol) = 0 96ΔPA, relative $[SiCl_3^+]$ affinity (kcal/mol) = 0.86ΔPA, and relative $[SiCl^+]$ affinity (kcal/mol) = 0.55ΔPA, with the assumption of an effective temperature as 555 K (i.e. the same as those of the corresponding Cl^+-bound dimers) [3] The smaller constant in the relationship between the relative $SiCl^+$ affinity and the relative proton affinity is ascribed to the influence of the non-bonding electrons on Si atom in producing a weaker inductive interaction with the pyridine

The MS/MS/MS[4] experiments and the linear relationships observed for all three polyatomic cations show the complexes are loosely-bound with the pyridines symmetrically attached to the central polyatomic cations Ab initio calculations show that the $[OCNCO]^+$-bound pyridine dimer has a structure where nitrogen atoms on pyridines are bound to the carbon atoms on $[OCNCO]^+$ Structures for $[SiCl_3^+]$- and $[SiCl^+]$- bound pyridine dimers are proposed to have nitrogen/silicon bonding.

Steric interactions between ortho-substituted pyridines and the central $OCNCO^+$ and $SiCl_3^+$ ions reduce the bond strengths for these cations The magnitude of the steric acceleration of fragmentation allows gas phase steric parameters (S^k) to be determined (Table 1) Dimers consisting of ortho-substituted pyridines in the $OCNCO^+$ and $SiCl_3^+$ systems, display steric effects which are similar to those observed previously for the chlorine cation.[3] The $OCNCO^+$ bound dimers have the largest steric parameters due to the bulky central $OCNCO^+$ (Table 1)

Anomalous behavior is observed in the $SiCl^+$ clusters with ortho-substituted pyridines All of the ortho-substituted pyridines, except 2-methylpyridine and 2,4-dimethylpyridine, show abundance ratios which lie above the linear correlation line (Figure 2) This enhanced stabilization in the case of $SiCl^+$ is believed to be due to the sterically favorable orientation of the ortho-substituted methyl group, which promotes intramolecular auxiliary bonding between the methyl group and the central silicon atom It is worthy of note that the deviation from the linearity in the cases of the ortho-substituted pyridines is the combined result of the electronic and steric effects and that both effects apparently cancel in the 2-methylpyridine and 2,4-dimethylpyridine cases

Acidities of Long Chain Alcohols: Kinetic versus Equilibrium Methods

Priscilla R Higgins,* John E Bartmess, Dept of Chemistry, University of Tennessee, Knoxville TN 37996-1600

Cooks' method of dissociation of dimers[1], when used by Boand and co-workers to determine the acidities of long chain n-alkanols,[2] showed a monotonic strengthening in acidity of these from the C-4 to the C-9 case. The increase per methylene group was 0 9 kcal/mol at C-4 decreasing to 0 5 kcal/mol at C-9.

Haas and Harrison[3] found that the acidities obtained by this method for small and highly-branched alcohols were insensitive to conditions of preparation and internal energy, but that long chain alcohols were appreciably weaker in acidity under low energy CID conditions, relative to the other alcohols.

To resolve this difference, we have carried out equilibrium measurements of the gas phase acidities of many of these alcohols using the ICR mass spectrometer.

Equilibrium studies were carried out in a homebuilt Ion Cyclotron Resonance (ICR) mass spectrometer. The instrument was operated both at 25°C and 75°C, in which the temperature was measured outside the analyzer manifold. Methoxide was generated from methyl nitrite.

The acidity ladder below reveals that there is a non-monotonic trend in the n-alkanol acidities· C4<C7<C8<C5<C6. The C7 alcohol is appreciably <u>weaker</u> as an acid than C6 We are unsure of the C9 value at present due to volatility problems. At 75°C, all these alcohols were more acidic by ca 0.8 kcal/mol, relative to the nitriles This implies that ΔS_{acid} for the long chain alcohols is >25 eu; they are <u>less</u> ordered on ionization than small alcohols.

The actual temperature of the cell with the instrument operated hot was not well regulated. This is currently being corrected, to obtain accurate equilibria at higher temperatures.

The fit of the acidities of the branched alcohols to the CID data indicates that the kinetic method is working for such structures. It is only for the longer alcohols, where the distal end can interact with the reactive site, that we see deviations.

A similar case for diol acidities has been noted,[4] where the diols are appreciable <u>stronger</u> in equilibrium acidity than indicated by the kinetic method. That effect was assigned to an enthalpic interaction not present in the precursor dimer in the kinetic method transition state.

The effect observed here may be due to the "straight chain anomaly" of Brown, seen in all aqueous pKas (Table 1) and in gaseous dimerizations.[5] At a certain chain length, entropic factors become important when one form in an equilibrium has interactions between the ends of the chain, not present in the other form. For shorter chains, these interactions are not present in either form; for longer chains, in both forms. A non-monotonic increase in reactivity is not surprising, therefore.

Catalan[6] has attributed the non-regular increase in long chain alcohol acidities, seen in the low energy CID work, to intramolecular hydrogen bonding, rather than a general coiling/polarizability interaction.

Some preference for hydrogen bond donation by the terminal methyl, relative to methylene groups, is expected based on the stronger gas phase acidity of primary versus secondary alkanes

Although we still must obtain accurate temperature dependent data to sort out these entropic effects, there is a real non-monotonic change in acidities observed here. The kinetic method must be used with caution when there are possible interactions between two functional groups, or the reactive site with the end of a long chain, in the structures under investigation.

Reactivity and Thermochemistry of Quadricyclane Anion

Hack Sung Lee and Veronica M. Bierbaum

Department of Chemistry and Biochemistry
University of Colorado, Boulder, CO 80309-0215

A flowing afterglow - selected ion flow tube instrument has been used to measure the rates of reaction of amide ion with quadricyclane(QC) and deprotonated quadricyclane anion($C_7H_7^-$) with ammonia. Use of the established gas phase acidity of ammonia and the equilibrium rate constant yields a value, $\Delta_{acid}G_{300}(QC) = 395\ 0 \pm 0.5$ kcal/mol. Combined with *ab initio* calculations, the enthalpy change, $\Delta_{acid}H_{300}(QC) = 403.3 \pm 0\ 8$ kcal/mol, has been derived. Electron transfer reactions of $C_7H_7^-$ ion with several neutrals set a limit on the electron affinity of C_7H_7 radical, which agrees with the results of photoelectron spectroscopy (PES) study (0.96 ± 0.01 eV)[1] Using these thermochemical values one can derive C-H bond dissociation energy (111.9 ± 1.0 kcal/mol). Gas-phase acidity of QC measured against monomethylamine and benzene also agrees within experimental uncertainties (see Table)

To generate the $C_7H_7^-$ ion in the source flow tube, QC was added downstream of amide ion. If hydroxide ion is used instead, the mass 91 ion shows very different reactivity. This ion turns out to be benzyl anion, confirmed by PES study. It is not clear whether the benzyl anion is produced in the collision complex of hydroxide and QC, or from toluene impurity in QC.

Reaction of the $C_7H_7^-$ ion with ND_3 shows 3 fast and 2 slow H/D exchanges, implying that two structures of anion may be present (less than 3 kcal/mol energy difference according to *ab initio* calculations). This result collaborates with the reaction of amide ion with dideuterated QC (63 %/ 37 % loss of H^+/D^+). It is interesting to note that, in the case of norbornadiene, only 3 H/D exchanges were observed[2]. However, when $C_6D_5^-$ ion reacts with QC, no H/D exchange occurred. This suggests a barrier for H/D scrambling within the collision complex. Reactions with CS_2 and COS gives $C_7H_7S^-$, N_2O gives HC_2O^-, CO_2 gives $C_5H_5^-$ and numerous other products including adducts. S_N2 reaction with methyl chloride is fast, whereas E2 reaction with diethyl ether is slow, although it is exothermic.

Several isomers of $C_7H_7^-$ ion show distinct collision induced dissociation (CID) mass spectra . C_2H^-(74 %), $C_5H_5^-$(18 %), $C_3H_3^-$(8 %) for QC, C_2H^-(98 %), $C_5H_5^-$(2 %) for norbornadiene, and no CID for benzyl anion.

When O^- ion reacts with QC, $C_7H_6^-$ ion is formed. Dideuterated QC (two D's on the bridge of 5 - and 4 - membered rings) reacts with the oxygen anion to give 32 %/ 54 %/ 14 % loss of H_2^+/ HD^+/ D_2^+. This seems to suggest that almost all hydrogens are involved in this reaction. Further study is needed to elucidate the structure of the $C_7H_6^-$ ion.

Table. The gas-phase acidity of quadricyclane determined from ammonia, monomethylamine and benzene.

$$B^- + QC \underset{k_r}{\overset{k_f}{\rightleftharpoons}} (QC - H)^- + BH$$

Base	$\Delta_{acid}G(BH)$ (kcal/mol)	k_f / k_r (cm^3/sec)	$\Delta_{acid}G(QC)$ (kcal/mol)
NH_3	396.4 ± 0.4	8.1 ± 0.2 (-10) 8.0 ± 1.0 (-11)	395.0 ± 0.5
CH_3NH_2	395.8 ± 0.5	7.2 ± 0.8 (-10) 9.7 ± 0.6 (-11)	394.6 ± 0.6
C_6H_6	392.9 ± 0.4	2.2 ± 0.8 (-12) 3.2 ± 0.4 (-11)	394.5 ± 0.6

Temperature Dependence of Radiative Association rates

Victor Ryzhov and Robert C. Dunbar*
Department of Chemistry, Case Western Reserve University, Cleveland, OH 44106

Introduction

Radiative association is an important part of the chemistry of interstellar molecule-building as well as a common process in ion trapping experiments. The bimolecular rate constant for radiative association at zero pressure limit is given by

$$k_2 = k_{ra} = k_f k_r/(k_b + k_r), \qquad (1)$$

where k_f is the bimolecular rate constant for the collisional complex formation, k_b is the unimolecular redissociation rate constant, k_r is the unimolecular rate constant for IR photon emission from the energized complex. k_{ra} is expected to depend strongly on the temperature. Despite the fact that some theoretical modelling has attempted to rationalize the observed trends[1], a universal theory to explain the temperature dependence of radiative association rate constants is yet to be developed.

In the present work the temperature dependence of NO^+ associating with 3-pentanone was studied. This system has been shown[2] to have a fairly fast association at room temperature that makes it convenient for a thermal behavior study. The experimental results were compared with phase space theory and simple RRKM modelling.

Methods

Rates of radiative association were measured in the temperature regime from 300K to 400K. The pressure of 3-pentanone varied from 1×10^{-8} to 3×10^{-7} torr while the pressure of NO was 3×10^{-8} torr. The ion gauge pressure readings were calibrated to match the known proton transfer rate constant between methane molecular ion and neutral methane[3].

Experiments were performed on a FT-ICR spectrometer with a 2.54 cm cubical cell. After the electron beam pulse (electron energy 15 eV), the parent ion of pentanone and any other ion species except NO^+ were ejected. Then a thermalization time was provided to give 5-6 ion-neutral collisions. After one more ejection sequences NO^+ ions were allowed to react for a time which ranged from 400ms to 8s and the extent of association and charge transfer was measured as a function of the reaction time. The temperature in the cell was measured by a copper-constantan thermocouple located inside the chamber on the trapping plate. To avoid extra heating by the filament, it was turned off before the thermalization period, and an idle time up to 5 s was provided in each working cycle.

Results

The reaction consists of two channels, radiative association (ra) and charge transfer (ct):

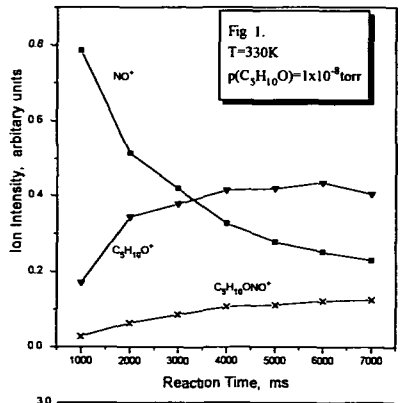
$$C_5H_{10}O + NO^+ \xrightarrow{k_{ra}} C_5H_{10}ONO^+ \qquad (2)$$

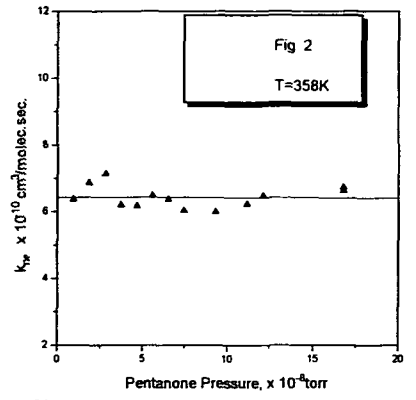
$$C_5H_{10}O + NO^+ \xrightarrow{k_{ct}} C_5H_{10}O^+ + NO \qquad (3)$$

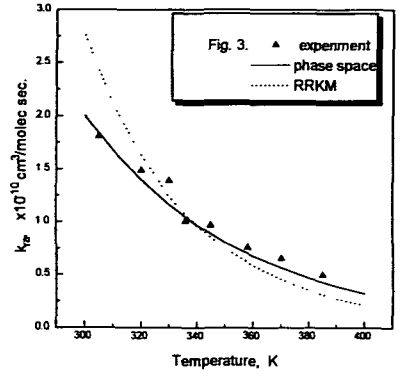
An illustrative time plot is shown in Fig.1. The overall rate constant for the NO^+ disappearance, $k_{rx} = k_{ra} + k_{ct}$, was obtained for each individual pressure and averaged for each temperature. After that the individual bimolecular rate constants for both channels were easily obtained. The lack of pressure dependence in each case (Fig. 2) indicates clearly that our association is purely radiative. As expected, the radiative association is fairly fast at room temperature (collisional efficiency of radiative stabilization about 8%). As temperature goes up the association rate drops very fast and at 400K almost vanishes (Fig. 3 and 4). The charge transfer is very efficient (about 25% of the Langevin rate) in this temperature range.

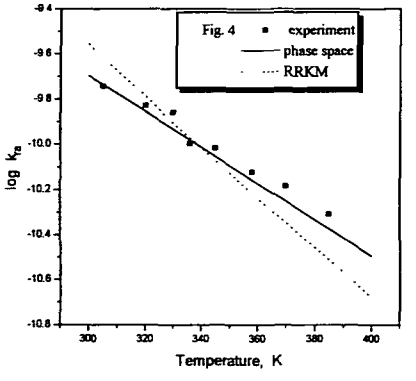
Comparison with theory

A high level phase space approach to radiative association reactions developed by prof. S.J.Klippenstein was used to describe the temperature dependence of the reaction of interest. The geometry of the association adduct $C_5H_{10}ONO^+$ was calculated *ab initio* along with its vibrational frequencies and IR intensities. This led to a calculation of the photon emission rate k_r which is otherwise not known. Subsequent canonical phase space treatment of Eq. 1 at different temperatures gave excellent agreement with the experimental values (see Fig. 3 and 4). The simple "standard hydrocarbon" model[4] that was found useful in describing the size dependence of radiative association[2] predicts a faster decrease of the association rates as the temperature goes up compared to the experimental data (Fig.5 and 6). This crude model, however, still gives a good qualitative picture of the temperature dependence.









Conclusions

- The NO^+ + 3-pentanone system represents a suitable object for the thermal behavior study of radiative association over a wide range of temperatures.
- The phase space calculations applied here show excellent agreement with the observed experimental temperature dependence.
- The simple RRKM modelling predictions are somewhat less exact but give a very easy and acceptably accurate estimate of the temperature dependence.

A REACTION WINDOW IN CROSS-SECTIONS FOR DOUBLE ELECTRON CAPTURE REACTIONS

W. J. Griffiths, M. L. Langford and F M. Harris.
Mass Spectrometry Research Unit, University College of Swansea, Singleton Park, Swansea SA2 8PP, Wales.

Double charge transfer (DCT) reactions of the type

$$A^+ + B \longrightarrow A^- + B^{2+} \qquad (1)$$

where A^+ is a fast moving projectile ion and B a collision gas molecule, can be discussed in terms of a reaction window model The conversion of reactants to products can be considered in terms of two quasimolecules (i) A^+,M and (ii) A^-,M^{2+}. The long-range potential energy functions may be described as a function of the internuclear separation, r, of A and M For the reactants

$$V_{A^+,M}(r) = -\frac{Z^2e^2\alpha(M)}{2r^4} \qquad (2)$$

where $\alpha(M)$ represents the dipole polarizability of the collision gas molecule. For the products the potential energy function is dominated by the strong coulombic attraction between A^- and M^{2+}, but also has a weaker attractive component owing to the polarizability of A^- and M^{2+}

$$V_{A^-,M^{2+}}(r) = -\frac{2Ze^2}{r} - \frac{Z^2e^2[\alpha(A^-) + \alpha(M^{2+})]}{2r^4} \qquad (3)$$

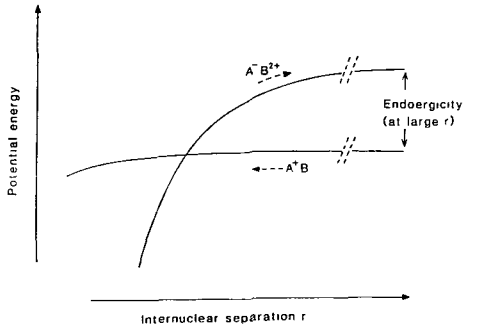
A schematic representation of these potential energy functions is shown in fig. 1. Although the double electron capture (DEC) reaction (1) is strongly endoergic (as the energy to doubly ionize M is greater than that released in the charge inversion of A^+), avoided crossing of the potential-energy function can occur with the resulting double electron transfer from M to A^+. It has been shown that the cross-section for a DEC reaction is strongly dependent on a quantity β This is a complex function but is strongly dependent on the endoergicity of the reaction It is predicted that the cross-section passes through a maximum at a particular value of β. This means that a reaction window exists in which the endoergicity must fall in order that a reaction can take place. The endorergicity (ΔE) of the DEC reaction (1) is described by equation (4)

$$\Delta E = IE_2(M) - E(A^+ \rightarrow A^-) \qquad (4)$$

where $IE_2(M)$ is the energy required to convert M into M^{2+}, and $A \rightarrow A^-$ is the energy released in converting A^+ to A^- .

We have attempted to determine the endoergicity at which the maximum cross-section occurs for the DEC reactions between both 6-keV OH^+ and F^+ projectile ions and a series of halogenated benzene collision gas molecules. The experiments were carried out using a ZAB-2F reverse-geometry double focusing mass spectrometer (VG Analytical Ltd., Manchester, England).

A reaction window has been found, the lower limit of which has a ΔE value of approximately 8eV and the upper limit a value of approximately 20eV. The centre of the window where the cross-section for DEC is at a maximum is in the range 10 - 14eV.



Reactions and laser photofragmentation processes of SiF_2^{2+} and SiF_3^{2+}

Yin-Yu Lee, Stephen D Price,* and Stephen R. Leone
Joint Institute for Laboratory Astrophysics, National Institute of Standards and Technology and University of Colorado, and Department of Chemistry and Biochemistry, University of Colorado, Boulder, CO 80309-0440
and
*Chemistry Department, University College London, 20 Gordon Street, London WC1H 0AJ, UK

Multiple product channels are observed for the reactions of SiF_2^{2+} and SiF_3^{2+} with the rare gases at 49 eV laboratory collision energy. The dication beam is generated in an electron impact ion source and mass selected using a quadrupole mass spectrometer. The ion beam is focused into a collision region and a time-of-flight mass spectrometer is used to monitor the reaction products. Reactions of SiF_2^{2+} produce SiF_2^+, SiF^{2+}, SiF^+, Si^{2+}, Si^+, and F^+ ions and reactions of SiF_3^{2+} produce SiF_3^+, SiF_2^{2+}, SiF_2^+, SiF^{2+}, SiF^+, Si^+, and F^+ ions (Fig. 1).

The corresponding rare gas ions are formed when charge transfer occurs. The relative yields of these products are quantified. For reactions of both dications, there is a substantial increase in the total reaction cross section as the collision partner is varied from He to Xe. The collision induced neutral loss reactions are observed to be a major product channel for reactions of SiF_3^{2+} or SiF_2^{2+} with the lighter rare gases, He and Ne. However, collision induced dissociation and charge transfer processes dominate when the ions react with the heavier collision partners, Kr and Xe. The doubly charged product yield is largest for systems in which charge transfer does not compete effectively with the collision induced process The atomic dication Si^{2+} produced in those collision reactions implies that the chemical structure of SiF_2^{2+} has most of the electron deficiency on the silicon atom.

Experiments to measure the product channels by laser photodissociation of SiF_2^{2+} and SiF_3^{2+} show that both dications readily absorb near infrared radiation and are promoted to excited states which dissociate by neutral-loss or charge-separation (Fig. 2). Detailed studies show that the dissociation occurs by single-photon absorption, which promotes the molecule to unbound excited states. Energetic thresholds for the photoinduced neutral-loss and charge separation reactions of SiF_3^{2+} are obtained from the data. A simple electron transfer mechanism was used successfully to explain the competition of neutral-loss and charge-separation reactions from the same electronic state of SiF_3^{2+} following excitation.

Partially Chlorinated Hydrocarbons: Gas-Phase Anion-Molecule Reactions

Joseph J. Grabowski and Jennifer A. Braun
Department of Chemistry
University of Pittsburgh, Pittsburgh, PA 15260

The hazardous effects of chlorinated organic compounds on the ozone layer limit the use of these species in our society. We previously studied the anion-molecule reactions of chlorofluorocarbons, and in these reactions carbanions are formed by chloride transfer. These results led us to investigate similar pathways for chlorinated hydrocarbons.

We have examined the reactions of hydroxide and allyl anion with several chlorinated ethanes and toluenes at 300 K in a 0.30 Torr He buffer gas using the flowing afterglow. Other anions were only examined peripherally. We chose hydroxide and allyl anion as our nucleophiles because they have similar proton affinities but differ in their localization. The chlorinated toluenes studied include 1,1,1-trichlorotoluene, 1,1-dichlorotoluene, and 1-chlorotoluene and the chlorinated ethanes studied include 1,1,1-trichloroethane, 1,1-dichloroethane, and chloroethane.

The distribution of products for the reactions of chlorinated toluenes with hydroxide and allyl anion is shown in Figure 1. The proton transfer product $(M\text{-}H)^-$ is always the major product when HO^- is used as the base. Of the three neutrals, only 1,1,1-trichlorotoluene undergoes S_N2 as well as PT to produce Cl^- as a minor product. A significant difference in product distribution occurs when allyl anion is used as the nucleophile instead of hydroxide; the major pathway when $PhCCl_3$ is used as the neutral is chloride transfer. As is also evident in Figure 1, the competition between PT and S_N2 increases (as compared to hydroxide reaction) when allyl anion is the base

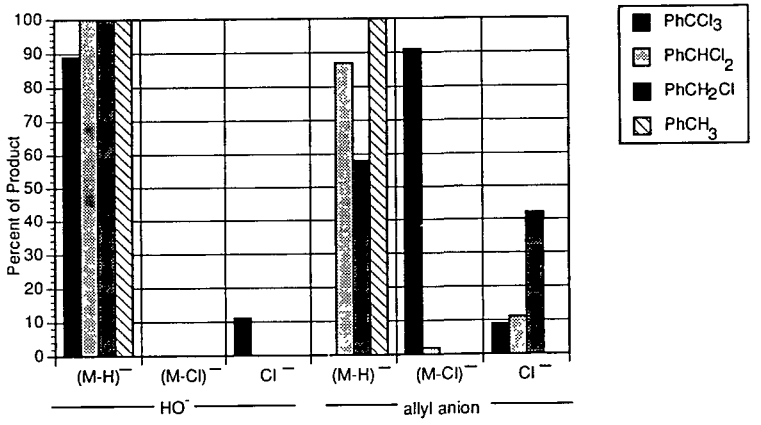

Figure 1. Product distribution for the reaction of Nu^- + $PhCH_nCl_{3-n}$.

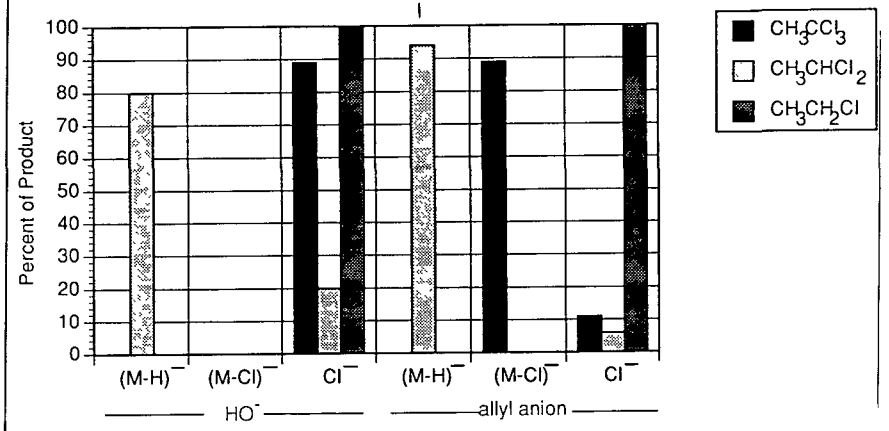
Figure 2 gives the product distribution for the reactions of hydroxide and allyl anion with the chlorinated ethanes. For the hydroxide reactions, PT dominates when it is thermodynamically feasible, otherwise Cl^- is produced presumably through elimination. With allyl anion, once again the trichlorinated hydrocarbon gives the chloride transfer product as the major product. As can be noted in Figure 2, chloroethane and 1,1-dichloroethane give similar results with both hydroxide and allyl anion.



*HO^- + CH_3CCl_3 also gives 11% $Cl^-(H_2O)$.

Figure 2. Product distribution for the reaction of Nu^- + $CH_3CH_nCl_{3-n}$.

Several conclusions can be drawn about the competition between various pathways for the reaction of an anion with a chlorinated hydrocarbon. First, chloride transfer is the major pathway for $RCCl_3$ ($R \neq H$) compounds with allyl anion. For all hydroxide reactions, chloride transfer is endothermic; therefore it is not observed. The exclusive reaction for CH_3CCl_3 with hydroxide is E2 (we assign E2 as the mechanism based on 11% $Cl^-(H_2O)$ formed), which is also a minor channel with CH_3CHCl_2. Proton transfer dominates whenever it is thermochemically allowed. With the exception of ethyl chloride, S_N2 is essentially unobserved in HO^- reactions. S_N2 is a major channel for allyl anion with benzyl chloride (and possibly ethyl chloride), but with the other four substrates S_N2 is a minor pathway. The reaction of allyl anion with CH_3CCl_3 is an excellent source of the carbanion, $CH_3CCl_2^-$ for future CID studies to determine the heat of formation of the corresponding carbene. The reaction of Me_3Si^- + CH_3CCl_3 may be a better source of $CH_3CCl_2^-$, however more quantitative studies are needed in order to determine the best source of the carbanion

REGIOSELECTIVITY OF OXYGEN ADDITON INDUCED DECHLORINATION ON PCBs AND DDT ANALOGS IN ECNCI

F. Lépine[1], O. A. Mamer[2] and S. Milot[1]
[1] Institut Armand-Frappier, 531 des Prairies Blvd., Laval, Can. H7N 4Z3
[2] Biomedical Mass Spectrometry Unit, Mc Gill University, 1130 Pine ave., Montreal, Can.,H3A 1A3

INTRODUCTION

The Electron Capture Negative Chemical Ionization (ECNCI) spectrum of many chlorinated compounds presents ions at 19 Da lower than the molecular ion. These ions are due to reactions between the organochlorine and trace amounts of oxygen present in the source. They correspond to the addition of one oxygen with the simultaneous loss of one chlorine atom.

Because we observed previously that the dechlorination reactions of PCBs and various DDT metabolites in a mass spectrometer were very regioselective, especially under ECNCI, we were interested to see if such regioselectivity could be observed for the oxygen addition induced dechlorination of these organochlorines in ECNCI.

MATERIAL AND METHODS

The synthesis of the various labelled PCBs and DDT analogs was described previously (Lépine et al, *Org. Mass Spectrom.*, **27**, 1311, 1992 and Lépine et al., *J. Mass Spectrom.*, in press). The labelled compounds were obtained as mixtures and were analyzed by GC/MS with a Hewlett-Packard 5988A using a 30 m. DB-5 column. The PCBs analyses were performed in triplicate. The moderator gas was a 1/5 mixture of oxygen in methane. The source pressure was 0.3 Torr and the source temperature was 150 °C. The DDT analogs were analyzed under the same conditions.

RESULTS

In order to evaluate the regioselectivity of the dechlorination, various penta- and hexachloro- PCBs labelled at various positions with one or two ^{35}Cl were used. With oxygen present in the moderator gas, the mass spectra of all the PCBs consist almost exclusively of M-19 ions.

The regioselectivity of the dechlorination reactions is reflected by the residual amounts of label in the M-19 ion cluster. This value is calculated by measuring the isotopic distribution of the cluster (Lépine et al., *Org. Mass Spectrom.*, **27**, 1311, 1992). The structure of the labelled PCBs and the percentage of the label retained in the M-19 ion are presented. The M-19 ions of all the pentachloro- PCBs retained between 77 and 78 percent of the label. For the hexachloro-PCBs this value varies between 81 and 84 percent.

The DDT analogs were labelled with one ^{37}Cl on each aromatic ring. Because of the extensive fragmentation and the corresponding low intensities of the ions of interest, accurate quantification of the residual label cannot be achieved. However qualitative information could be deducted from these spectra.

Ions corresponding to M-19 were observed for p,p'- DDMU and p,p'-DDE. The mass spectrum of p,p'-DDD show many similarities with the one of p,p'-DDMU. An intense 254 ion can be observed for every compound, except for o,p'-DDD.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

DISCUSSION

In a previous publication (Lépine et al., *Org. Mass Spectrom.*, **29**, 133, 1994) using pure methane as moderator gas, the labelled PCBs all presented molecular and M-35 ions in ECNCI. This dechlorination reaction was found to be highly regioselective. With oxygen in the source, the results presented indicate that the dechlorination is completely non regiospecific. The percentage retention of the label are very close to 80 and 83 percent for the penta- and hexachloro congeners, respectively. These two values correspond to random loss of one chlorine atom out of the five or six initially present. This lack of regioselectivity could be due to the relatively high concentration of oxygen in the source. Under these conditions, oxygen probably picks up electrons preferentially over the PCBs and the $^{-}O_2$ radical then reacts non regioselectively with the neutral PCBs. The fact that the molecular ions of PCBs were generally not observed would tend to confirm this hypothesis.

The spectrum of DDMU (MW=286) presents ions at M-4 (282 Da) and M-19 (267 Da). The former fragment probably represents addition of O_2 with the loss of HCl. An intense ion appears at 254 which probably corresponds to 4,4'-dichloroacetophenone. The 282 Da ion could be a precursor of 254 trough loss of CO. The isotopic distribution of all these ions indicate that the aromatic chlorines are retained.

The spectrum of p,p'-DDE (MW=316) presents ions at M-19, M-35, M-47 and the 254 ion. The M-47 ions are probably generated through loss of CO from the M-19 ions. The chlorine atoms retained in these ions were the aromatic ones.

The spectrum of o,p'-DDD shows ions at M-40, M-55 and M-70. These fragments corresponds to M-2HCl+O_2, M-HCl+O-Cl and M-2Cl, respectively. The isotopic distribution of the clusters indicates that the aromatic chlorine are retained in every ions.

The spectrum of p,p'-DDD presents ions at M-282, M-267 and the 254 ions. This spectrum is almost identical to the one of p,p'-DDMU. It is likely that in a first step, p,p'-DDD undergoes loss of HCl to produce p,p-DDMU. Because the spectra of these two compounds are completely different when pure methane was used as moderator gas, the initial loss of HCl observed here must be due to hydrogen abstraction of the alpha hydrogen, possibly by a $^{-}O_2$ radical anion or related species, followed by loss of chlorine anion. The degradation pathways of the o,p'- and p,p'-DDD are then quite different although dechlorination proceeds only at the aliphatic chlorines in both cases.

Formation of 4,4'-dichlorobenzophenone in the decomposition pathways of many DDT analogs is also interesting, as this compound is also observed upon gamma irradiation of these compounds in aliphatic solvents in presence of oxygen (Lépine et al., *J. Agric. Food Chem.*, **42**, 2012, 1994). Formation of this compound in both cases is probably due to an attack at the alpha position by the $^{-}O_2$ radical.

CONCLUSION

The regioselectivity of the dechlorination reaction of various organochlorines in ECNCI in the presence of oxygen is very dependent of the structure of the organochlorine. Contrary to what was observed previously with pure methane as moderator gas, PCBs, under the conditions used, were not regioselectively dechlorinated. DDT analogs however, where regioselectively dechlorinated at the aliphatic chlorines.

Dissociative Attachment in Sulfonate and Carboxylate Compounds

Kim Andrews,* John E. Bartmess, Daniel N Sorensen, Cathy A. Crowder,
Department of Chemistry, U. of Tennessee, Knoxville TN 37996-1600

The generation of cations by electron ionization is straightforward: above the ionization energy, all compounds form some cations, with only ca. two orders of magnitude variation in the ionization cross-section. Formation of anions, however, is much more variable The cross-section for the dissociative attachment process:

$$A\text{-}B + e^- \longrightarrow [AB^-]^* \longrightarrow A^- + B^\cdot$$

varies over more than seven orders of magnitude, and in a non-monotonic fashion with electron energy. Few compounds fall in the high-cross-section end of the range.

There are numerous small molecules such as H_2O, NH_3, NF_3, CCl_4, MeONO, etc. that yield anions of interest by dissociative attachment. The cross sections for anion production from these, however, vary widely. For use in ICR spectrometry, we need compounds in the high-cross-section range for production of anions, due to the limited pressure range of the ICR spectrometer.

Approaches to this problem include, in descending order of cost:
- external ion sources
- pulsed valve admittance of the precursor gas (see poster WPE111)
- design of appropriate chemical precursors

We focus on the last choice here.

A Rational Design Strategy:
Based on the known cases, we predict that dissociative attachment will be favored by:
- a bound or low-lying LUMO in AB, for capture of the electron, to form an intermediate with enough excess energy to fragment, but not too much, to minimize electron detachment
- a weak A-B bond, that thermochemically favors fragmentation of the intermediate, as opposed to electron loss.
- a stable A^- anion (large electron affinity)

Compounds of the type $PhN{=}NC(Me)_2G$, where G is a good electron acceptor group like nitro, cyano, etc. were targeted as possible dissociative attachment sources of $Me_2C{=}G^-$ carbanions These possess the desired pi system (PhN=N-) to capture the electrons, easily broken bonds (N_2 is the best leaving group in chemistry), and can be tailored to form a variety of carbanions. The methyl groups are desired to prevent the carbanion from deprotonating the more acidic precursor. This approach was successful for G = $-NO_2$ and $-CF_3$, but for G = -COMe, a pNO_2- group on the phenyl ring was necessary to increase the cross section; the parent compound gave negligible amounts of anions. The cross section σ is ~1 $Å^2$, similar to NF_3. PhN=NNHPh gave $PhNH^-$ comparably.

Not all azo compounds are good dissociative attachment candidates: AIBN, $NC\text{-}C(Me)_2\text{-}C(Me)_2\text{-}CN$, with no aromatic pi system to capture the electron, gives no anions.

Methyl methanethiosulfonate, MeSO2SMe, yields principally $MeSO_2^-$, plus some $MeSO_2S^-$ and MeS^- due to ion-molecule reactions of $MeSO_2^-$ with the neutral. The σ at 0 eV is ca. 1 $Å^2$. This makes use of the fact that $RSO_2\text{-}X$ BDEs are among the weakest known

The acidity of $MeSO_2H$ is bracketed as between CF_2HCO_2H and CF_3CO_2H, or ΔG_{acid} = 319.2 kcal/mol We are unsure if the conjugate acid formed has the hydrogen bound to sulfur or oxygen, no reliable MO calculations appear to have been carried out PM3 predicts the -OH isomer to be 18 kcal/mol more stable than the -SH form.

Similarly, dimethyl sulfate, $MeO\text{-}SO_2\text{-}OMe$, yields primarily $MeOSO_3^-$, with small amounts of $MeOSO_2^-$, and SO_3^{--}.

A wide variety of MeCOX and PhCOX compounds yield X^- anions in large σ of ~1 $Å^2$, including X = OAc, Cl, Br, and CN. The first case, typically acetic anhydride, is our preferred method of generating carboxylate anions. These are thus available over a 30 kcal/mol range of basicity. Interesting, formic acetic anhydride yields only formate on dissociative attachment, the thermochemically favored product by 5 kcal/mol

No anions were observed from PhCONHPh, MeO_2Me, or MeCOF The last is intriguing, in that the thermochemistry is favorable.

Although semi-empirical calculations will not be exceptionally accurate in describing these structures, as general guides to the thermochemistry (±10-15 kcal/mol) they are useful in designing structures, and evaluating performance

The Gas-Phase SO_2N^- Ion: Experiment and Theory

Nelson H. Morgon, Harrald V. Linnert, and José M. Riveros

Instituto de Química, Universidade de São Paulo, Caixa Postal 26077, São Paulo, Brazil, CEP 05599-970

Experiments carried out in a homemade FT-ICR spectrometer reveal that the reaction of NH_2^- with SO_2F_2 proceeds rapidly through the two channels as shown below with their respective branching ratios. The overall rate constant could not be measured accurately because of the competing reaction of NH_2^- with the background water present in the instrument. Yet, this rate constant is comparable to that of OH^- with SO_2F_2, determined to be close to the ADO collision limit.

$$NH_2^- + SO_2F_2 \rightarrow HF + HNSO_2F^- \quad 0.15$$

$$NH_2^- + SO_2F_2 \rightarrow 2\,HF + NSO_2^- \quad 0.85$$

Ion isolation experiments for either product ion, $HNSO_2F^-$ and NSO_2^-, reveal that both ions are unreactive towards the parent SO_2F_2.

The above reaction represents an easy way to generate the sulfonyl imide ion, NSO_2^-, isoelectronic with SO_3 and hereto an elusive anionic species. In fact, the successful isolation of NSO_2^- had not been reported until the synthesis of $Cs^+NSO_2^-$ was claimed in 1982.[1] Yet, the evidence for the actual existence of $Cs^+NSO_2^-$ was disputed by Chivers *et al*[2] based on the analysis of infrared, Raman and NMR spectra which were shown to be consistent with an NSO^- anion.

The proton affinity of the NSO_2^- species cannot be directly measured from the usual gas-phase acid-base equilibrium experiments since the conjugate acid, $HNSO_2$, is not known as a stable species. Thus, an estimate of the proton afinity of NSO_2^-, or the gas-phase acidity of $HNSO_2$, was obtained by bracketing techniques. For these experiments, NSO_2^- ions were first isolated in the cell after all the NH_2^- ions had reacted (typically 200 to 250 ms), and were then allowed to react with volatile compounds of known gas-phase acidities to establish the occurrence and ease of proton abstraction. Reactions were followed up to 5 s at substrate of pressures ranging from 5×10^{-8} to 2×10^{-7} Torr. No proton abstraction was observed for HCOOH, $CH_2(COMe)_2$, or MeCHClCOOH whereas rapid and complete proton transfer was observed with CF_3COOH. No attempt was made to study proton abstraction from due to the fact that the NH_3, used to generate the reactant NH_2^- ions, is flowed together with the reagent gas. Our measurements therefore allow us to estimate,

$$\Delta H^\circ_{acid}(HNSO_2) = 330 \pm 5 \text{ kcal/mol}$$

Preliminary experiments revealed the ability to photodetach the electron with the fourth harmonic of the Nd:YAG laser at 266 nm but not with the third harmonic at 355 nm. Thus,

$$EA(NSO_2) > 3.49 \text{ eV}$$

Ab initio calculations were carried out with the GAUSSIAN/92 program in the cluster of work stations available at the Computer Center of the Unversity of Campinas (CENAPAD-SP). Starting with a DZVPD basis set, the Generator Coordinate Method[3] (GCM) was used to improve the description of the diffuse character of the electron cloud of negative ions. Diffuse functions were added to the H, O, N and S by analysis of the weight functions following the procedure outlined in Ref. 3.

The theoretical calculations performed at the MP4SDTQ level with the geometries optimized at the MP2 level predict the N atom to be the preferred protonation site in NSO_2^- and yield the following thermochemical parameters.

$$\Delta H^\circ_{acid}(298\text{ K}) \text{ for } O_2SN\text{-}H = 331 \text{ kcal/mol}$$

$$\Delta H^\circ_{acid}(298\text{ K}) \text{ for } NS(O)O\text{-}H = 306 \text{ kcal/mol}$$

$$EA(NSO_2) = 3.76 \text{ eV}$$

$$D_0(O_2SN\text{-}H) = 104.6 \text{ kcal/mol}$$

The uncertainty in the distinction between NSO_2^- and NSO^- in condensed phases lead us to carry out a similar calculation on NSO^-. The experimental ΔH°_{acid} (298 K) for HNSO was determined earlier[4] to be 344 ± 5 kcal/mol. Our calculated values for this species yield

$$\Delta H^\circ_{acid}(298\text{ K}) \text{ for } OSN\text{-}H = 347 \text{ kcal/mol}$$

$$\Delta H^\circ_{acid}(298\text{ K}) \text{ for } NSO\text{-}H = 327 \text{ kcal/mol}$$

$$EA(NSO^\cdot) = 3.53 \text{ eV}$$

$$D_0(OSN\text{-}H) = 115 \text{ kcal/mol}$$

A Negative Ion Study of The Isomers of Dinitrobenzene Using an ASGDI Source

W. Mo, M.L. Langford, A.M. Franklin and J.F.J. Todd
The Chemical Laboratory, University of Kent at Canterbury
Canterbury Kent, CT2 7NH, UK

The differentiation of isomers on Mass Spectrometers has always been a difficult task: the spectra of the isomers from the standard data bases are always nearly identical. In this investigation of all three isomers of dinitrobenzene (DNB) has been carried out using an Air Sampling Glow Discharge Ionization (ASGDI) source coupled to an Finnigan MAT ITMS quadrupole ion trap mass spectrometer.

In the ASGDI source the sample is drawn into the glow discharge by an ambient air stream and thus the sample constitutes a low percentage of the total gas sample. To produce a DC glow discharge a voltage of 350-400 volts was applied across plates 1 and 2, at a pressure of ca. 8×10^{-1} Torr. Samples were introduced into the source by placing them on a glass spoon in the sampling chamber and any vapour from the sample was drawn into with the stream of air. The ASGDI source is rich in ion/molecular reagent anions formed from the background, which helps the identification of isomers through the dissociation of product ions.

The anions of interest are isolated and then subjected to collisional dissociation (MS/MS) in order to observe the fragmentation pathways. The same values of the tickling period (10 milliseconds) and tickling voltage (350 millivolts) are applied in each of the MS/MS experiments.

Differences in pathways of the dissociation of the molecule ions have been observed (the CID pathways deduced for the molecular ions of the isomers are shown in Fig. 1). For all three isomers, an NO neutral molecule is first detached from the molecular ion 168^- forming 138^- (the loss of NO and CO are known to occur in similar systems under negative ionization[1]) ; when the CID of 138^- ions is performed 108^- ions are observed as the result of losing a second NO group. Differences in the spectra have been observed in

the CID of the 138^- ions which are formed from each of the isomers: in the dissociation of 138^- ions formed from 1,3- DNB, 80^- ions have been observed (as a result losing an NO and a CO group), as well as the 46^- and 108^- ions; in the spectra from the same experiment on 1,2- and 1,4- DNB, no ion 80^- has been observed. When 108^- ions formed from each isomer are subjected to CID, differences in pathways have been observed: the 108^- ions formed from 1,2- DNB and 1,3- DNB are further dissociated losing a CO molecule and producing 80^- ; the 108^- ions formed from 1,4- DNB cannot be dissociated any further, indicating a relatively stable structure.

INVESTIGATION OF VAN DER WAALS CLUSTERS BY A NOVEL TECHNIQUE FOR ICR

K. GARBADE, K.P. WANCZEK
University of Bremen, POBox 33 04 40, D-28334 Bremen, Germany

Introduction

Research on clusters is of growing interest in present mass spectrometry. However different things are understand by the term cluster: Metal clusters and atom clusters like S_8 or C_{60} are more or less stable and classified as molecules. By contrast clusters of the van der Waals type, for example $(CO_2)_n$ or Ar_n, are fragile aggregates and only available by special techniques like ion-molecule association reactions, an adiabatically gas expansion or evaporation of liquids or solids. This poster deals only with van der Waals clusters.

The investigation of weakly bound clusters is important for understanding molecular interactions, chemical reactions, condensation and solvation processes.

In our work group in Bremen van der Waals clusters of carbon dioxide have been subject of research for a long time. G. ROMANOWSKI examined clusters generated in a supersonic beam instrument by means of a quadrupole mass spectrometer observing cluster sizes up to ten molecules, vaporization and fragmentation reactions. Reaction kinetics and lifetimes could be studied [1].

M. BAMBERG coupled the supersonic cluster source to an ICR spectrometer with an external ion source. With this system the first ICR spectra of small cluster ions of carbon dioxide are obtained [2].

The next idea presented at this poster is a simplification of the experiment. We tried to place the supersonic gas expansion directly in front of the ICR cell. To realize this a special inlet system with a pneumatic valve working inside the magnet has been constructed.

Methods

The ICR spectrometer is modified CMS-47 FT-ICR spectrometer (Spectrospin AG Fällanden, Switzerland) with cylindrical cell. A grid as a trapping plate ensures minimal irritation of the supersonic jet. The ICR experiments are controlled by an Aspect 3000 microcomputer. Internal ionization by electron impact or chemical ionization can be used. The magnetic field of the superconducting magnet (Oxford Instruments) is 7.02 Tesla. The vacuum system is home build and pumped by an oil diffusion pump (Edwards Kniese & Co, Marburg) with a liquid nitrogen cooled baffle. The capacity of the pump is 150 l/s. The pressure is measured by an IMR 132 hot cathode ion gauge (Balzers) in combination with the Balzers IMG 050 vacuummeter

The gas inlet system (Fig. 1) has been built by EMG, Bremen. A tube of 2 cm diameter made of a non-magnetic alloy is placed inside the ICR vacuum chamber. Its mean part is a pneumatic valve at its end facing the ICR cell. The cluster beam is passing directly through the cell. The distance to the front of the cell can be varied. The sample gas reaches the valve passing through a capillary circuit guaranteeing good flushing of the system. An electron microscopic lens serves as a nozzle for the gas expansion. The diameter of the orifice is 100 µm. Lenses with different orifice diameters can be used. The valve is controlled by pulses from the ICR console used in automation programs. The stagnation pressure of the gas is 2 bar.

1. ICR cell
2. electron microscopy lens
3. pneumatic valve
4. sample gas circuit
5. compressed air pipe
6 correction of the distance valve – ICR cell
7. valves controlling the sample gas flow
8. valve controlling the compressed air
9. leak valve
10. pressure gauge
11. diffusion pump

Investigations planned

Generation of ICR spectra with sample inlet right in front of the cell is possible. Unfortunately spectra with cluster peaks have not yet been obtained. The following experiments are in progress:

- Change of the design of nozzle, cell and holding device or use of an open endcap cell avoids negative influence on the supersonic jet and allows shorter distance between valve and cell
- Use of higher stagnation pressure adjusts pressure reduction inside the capillary system
- Cooling of the cell reduces the influence of thermal radiation of the ICR cell
- Investigations on different van der Waals clusters and ion molecule reactions of clusters

First results will soon be published.

Consecutive reactions of conjugated dienes

Rappmund A., Wanczek K. P., Institute of Inorganic and Physical Chemistry, University D-28334 Bremen, Germany

The present study examined the consecutive reactions of 2-methyl 1.3-butadiene and 1 3-butadiene with the Fourier-tansform mass spectrometer (FTMS) after electron impact ionisation. Both related systems reacted with its neutral precursor in several stages. The reaction channels of these reactions were proved by double resonance experiments.

2-methyl 1.3-butadiene

At a pressure pressure of $1*10^{-7}$ peaks of C_6H_9 (m/z 81), C_7H_9 (m/z 93), C_7H_{11} (m/z 94), C_8H_{11} (m/z 107), C_8H_{13} (m/z 108)and C_9H_{13} (m/z 121) are visible This is the significant pattern in the first stage reaction between 2-methyl 1.3-butadiene with the neutral precursor. But no ion/molecule dimer complex was detected. This observation is consistent with the results of earlier authors.
Ejection of this ion/molecule complex during the reaction time results in decreasing of the relative abundances of the pattern for this system. At the pressure of $2*10^{-6}$ mbar peaks of $C_{11}H_{17}$ (m/z 149), $C_{12}H_{17}$ (m/z 161), $C_{12}H_{19}$ (m/z 163), $C_{14}H_{17}$ (m/z 185), $C_{15}H_{19}$ (m/z 199) and $C_{16}H_{20}$ (m/z 212) were detected. The formation of these masses can be explained by series of double resonance experiments The pattern of the ion/molecule dimer complex reacted with the neutral isoprene to form these masses (see scheme1). No reaction pathway was found to form the fragment ion $C_{11}H_{12}$ (m/z 144).
We assume this ion was formed by decomposition of a meta stable ion. Finally this ion reacted with the neutral to $C_{16}H_{20}$ (m/z 212) Ejection of C_8H_9 (m/z 105) results in decreasing of $C_{10}H_{11}$ (m/z 131).This observation can interpreted by the reaction of:

$$C_8H_9 \text{ (m/z 105)} + \text{Isoprene} \rightarrow C_{13}H_{17} \text{ (m/z 173)} \rightarrow C_{10}H_{11} \text{ (m/z 131)} + C_3H_6$$

At a pressure of $1*10^{-5}$, the main fragment ion of $C_{11}H_{17}$ (m/z 149) can undergo further reaction with isoprene to form the product ion $C_{16}H_{24}$ (m/z 217).

1.3 butadiene

The spectrum of 1 3 butadiene at a pressure of $2*10^{-6}$ is similar to that of isoprene. Also these ion reacted in several stages with the neutral butadiene, but the explanation of these consecutive reaction is difficult and succeded only in a few cases by double resonance experiments. The main fragment ion of C_5H_7 (m/z 67), C_6H_7 (m/z 79), C_6H_8 (m/z 80), C_6H_9 (m/z 81), C_7H_7 (m/z 91) and C_7H_9 (m/z 93) are decomposition products of the ion/molecule dimer complex. Permanent excitation of the dimer complex during the reaction time results not in decreasing of the relative abundance of these pattern. The life time of this metastable ion is not long enough to remove the ion before it decomposes. These primary ions also reacted with the neutral. The ion of $C_{11}H_{13}$ (m/z 145) was formed by the reaction of:

$$C_7H_7 \text{ m/z 91} + \text{butadiene} \rightarrow C_{11}H_{13} \text{ m/z 145}$$

Ejection of $C_{11}H_9$ (m/z 141) decreased the abundance of $C_{14}H_{27}$ (m/z 195), ejection of $C_{10}H_{11}$ (m/z 131) that of m/z 141 and m/z 195, so we propose the reaction pathway of

$$C_{10}H_{11} \text{ m/z 131} \rightarrow (C_{14}H_{17} \text{ m/z 185})^{\#} \rightarrow C_{11}H_9 \text{ m/z 141} \rightarrow C_{14}H_{27} \text{ m/z 195}$$

The rection pathway to form the product ion C_8H_9 (m/z 105) and C_9H_9 (m/z 117) were not found But also these ions reacted in consecutive reactions:

$$C_8H_9 \text{ m/z 105} + \text{butadiene} \rightarrow C_{12}H_{11} \text{ m/z 159}$$

$$C_9H_9 \text{ m/z 117} + \text{butadiene} \rightarrow C_{13}H_{15} \text{ m/z 171}$$

Polymerisation and Ion Chemistry of 2-Butenal, studied with ICR

Harder A., Spiess I. Institute of Inorganic and Physical Chemistry
University of Bremen, Germany

Introduction:

The double bonds of α,β-unsaturated aldehydes shows a characteristic chemistry in polymerization processes. We investigated the oligomerization and oxidation of 2-butenal with FT-ICR spectroscopy. In purpose to understand the aging processes in polymeres, the chemistry of aged bulk 2-butenal in the gas phase is examined.

Experimental:

The pure 2-butenal is investigated with a gas inlet system and ionized with electron impact with an electron energy of 70 eV.

A new improved electric pulse induced desorption EPID method is used to characterize the ion chemistry of bulk 2-butenal. The emitter is a thin aluminium filament deposited on a plate which also contains the two electrical connections. Ionization is induced by a discharge of a capacitor with a short current pulse of 2 ns duration . Because of the high heat capacity of the emitter we excluded the possibility of thermal ionization. The emitter is fixed on a push rod of 900 mm length. The push rod is used to place the sample more directly in front of the ICR cell. A cylindrical sreened ICR cell of 50 mm diameter is employd to improve yield of ion collection. The investigation is performed with a Bruker Spectrospin FT-ICR spectrometer equipped with a superconducting magnet of 7.02 T.

Results and discussion:

Pure 2-Butenal, Ion Chemistry in the gas phase

Figure 1 shows an ICR spectrum of pure 2-butenal introduced by gas inlet and ionized by electron impact with an electron energy of 70 eV The most abundant peaks are the molecule $[M+H]^+$ m/e= 71 and the molecule $[M-H]^+$ m/e=69. We observed no fragment ions or ion-molecule reaction products with a reaction delay of D3=0 s.

Figure 2 shows an ICR spectrum of 2-butenal with a reaction delay of D3=10 s We observed the dimer $[M_2+H]^+$ m/e=141. After a reaction delay of D3=15 s the trimer $[M_3+H]^+$ m/e=211 occured.

Bulk 2-Butenal, condensed phase

We investigated bulk 2-butenal with the EPID ionization method [1]. From the bulk material, several types of polymerization and oxidation products could be characterized: m/e= 87, $C_4H_7O_2^+$ protonated 2-butene acid, m/e=139, $C_8H_{11}O_2^+$ $[M_2-H]^+$of 2-butenal, m/e=155, $C_8H_{11}O_3^+$ oxidated dimer of 2-butenal. Under our experimental conditions with a reaction delay of D3=0 s we observed mainly these molecule-molecule reaction products which are produced during the aging process in the condensed phase (see Fig. 3) We increased the reaction delay for observation ion-molecule-reaction products. After a reaction delay D3=2 s we detected the oligomers m/e=211 $[M_3+H]^+$and m/e=279 $[M_4-H]^+$. Using a reaction time of 15 s we observed m/e= 419, $[M_6-H]^+$. It is a surprise that we could not detect the oligomer M_5.

Conclusions:

In the ion-molecule chemistry experiments with pure 2-butenal in the *gas phase*, we could examine the beginning processes of the polymerization. The stepwise increase of dimer and trimer was observable as result of extending the reaction time.

The aged bulk 2-butenal is a mixture of mainly monomer, dimer and their oxidation products such as acids and ketones This mixture shows a more complicated chemistry in the *condensed phase* The products can be detected with EPID method and a reaction delay D3=0 s. The extension of the reaction time causes the formation of many new compounds, because many reaction pathways exist. Their molecular masses grow with the increase of the reaction time. We could observe the formation of the oligomeres M_2, M_3, $M_4$and M_6 Unexpectedly the oligomere M_5 could not be found. The peak m/e=391, probably a fragment of M_6, had a noticeable high abundance In comparision with the results of the experiments in the gas phase, we could observe advanced steps of the polymerization in the condensed phase

Many long-lived (> 300 ms), low energy organic molecular ions isomerize to energetically more stable species in the gas phase. Ion-molecule reaction experiments in the Fourier-transform mass spectrometer are a well-known method for studying the structures of radical cations. Surprisingly, this technique has not been applied to the structural characterization of simple long-lived, nondecomposing aldehyde and ketone radical cations. Therefore, the ion-molecule reactions of acetaldehyde, acetone, acrolein, vinyl methyl ketone, benzaldehyde, acetophenone, propanal, and 2-pentanone radical cations were examined in the Fourier-transform mass spectrometer. This investigation focused on the comparison of the reactivity of aldehyde and ketone radical cations with cyclopentanone and the application of this information to the structural characterization of larger aldehyde and ketone radical cations.

Typical reaction experiments in the Fourier-transform mass spectrometer have been described elsewhere [1]. The change in abundances of the reactant and product ions are measured as a function of time. In the presence of excess neutral reagent, pseudo first-order kinetic laws can be applied to ion-molecule reaction kinetics. This assumption simplifies the process of determining the experimental rate constant (k_{exp}) from the measured data. Information about the structure of radical cations is learned by examining the type of products formed, the reaction rates, and the energy dependencies of reactions.

The heats of reaction for the charge exchange and proton transfer and reactivity of the aldehyde and ketone radical cations are summarized in Tables 1 and 2. The keto and/or enol forms of acetaldehyde, acetone, acrolein, vinyl methyl ketone, benzaldehyde, and acetophenone radical cations were of known structure and used as references in this investigation. Based on the exothermicity of charge exchange and proton transfer processes, the keto form of aldehyde and ketone radical cations investigated could react with cyclopentanone by both charge exchange and proton transfer. The keto forms of the aldehyde radical cations indeed react by both processes; however, the ketone radical cations only react by charge exchange in spite of the exothermicity for proton transfer(See Table 1).

Charge exchange is endothermic for the reaction between the enol form of the aldehyde and ketone radical cations and cyclopentanone; therefore, no charge exchange reaction was expected to occur. In agreement with the thermochemical prediction, no charge exchange products were observed. The heats of reaction for the enol form of acetaldehyde and acetone radical cations are exothermic for proton transfer. As expected, only proton transfer was observed. The results from the reactions with cyclopentanone indicate that keto and enol forms of aldehyde and ketone radical cations can be distinguished based on their reactivity with cyclopentanone. This information was applied to the structural characterization of the long-lived, nondecomposing propanal and 2-pentanone radical cations, which structures are not known.

Propanal radical cations react with cyclopentanone mainly by proton transfer. The enol from of propanal radical cation, generated from the molecular ion of 2-methylbutanal, reacts with cyclopentanone exclusively by proton transfer and displays linear kinetics. A small portion of the propanal reactant ions reacts by charge exchange, and an even smaller portion remains unreactive towards cyclopentanone resulting in non-linear kinetics. These findings suggests that some of the propanal radical cations isomerize to the enol form and another structure.

Although charge exchange and proton transfer are thermochemically favorable for the reaction of 2-pentanone radical cations, slow charge exchange and production of m/z 143 were the only processes that were observed. This finding suggests that a portion of the population 2-pentanone radical cations retains its keto form. At least 90% of the 2-pentanone radical cations appear to remain unreactive. Deviations from linear kinetics indicates that the long-lived molecular ions of 2-pentanone exists as a mixture of keto form and isomeric structure other than the enol form.

Generation and Reactivity of Charged Phenyl Radicals

Rebecca L. Smith, Hilkka I. Kenttämaa
Department of Chemistry, Purdue University, West Lafayette, IN 47907.

Distonic ions (species with spatially separated charge and radical sites) may be a useful tool for the examination of free radical reactivity in the gas phase, provided that the charge site of the ion is unreactive. A method was developed that allows the synthesis of a series of charged phenyl radicals with different unreactive charge sites.

The charged phenyl radicals were formed by nucleophilic *ipso*-substitution of a halogen atom in an ionized dihalobenzene[1] followed by CAD to remove the second halogen atom (Figure 1). The charged phenyl radicals (Figure 2) were structurally characterized by CAD, ion-molecule reactions and comparisons with isomeric ions. For example, the ions were identified to be distonic ions on the basis of the observation of $^{\bullet}SCH_3$ abstraction from dimethyl disulfide and $^{\bullet}SeCH_3$ abstraction from dimethyl diselenide. Conventional radical cations do not undergo these reactions. The *ortho*, *meta*, and *para* isomers of the ion **d** were differentiated on the basis of their reactivity toward allyl iodide.

The charged phenyl radicals react with neutral reagents in a manner analogous to that of the neutral phenyl radical and other neutral radicals. For example, ion **a** reacts with allyl bromide predominately by allyl radical abstraction as is observed for the phenyl radical.[2] Ion **b** reacts with trimethyl phosphite similarly as the phenyl radical, by elimination of $^{\bullet}OCH_3$ from an adduct.[3] Like neutral free radicals, the ions **a**, **b**, and **d** react with cyclohexene by addition to the carbon-carbon double bond and by hydrogen atom abstraction. Further, ion **a** reacts with benzeneselenol by adduct formation and hydrogen atom abstraction and this occurs approximately ten times faster than with thiophenol, in agreement with the reactivity of neutral alkyl radicals toward these two reagents.[4]

The reactivity of the charged phenyl radicals toward electron rich reagents was found to be enhanced by additional electron-withdrawing substituents. Substituting one of the hydrogen atoms adjacent to the radical site with an electron withdrawing group (a fluorine atom) (ion **h**) enhances the reactivity of the ion toward dimethyl disulfide by a factor of 23. Four fluorine atoms on the phenyl ring (ion **i**) cause even a larger rate enhancement: ion **i** reacts with dimethyl disulfide 69 times faster than ion **c**. A similar rate enhancement has been observed in solution for neutral phenyl radicals substituted with electron withdrawing substituents. For example, *p*-nitro phenyl radical reacts with dimethyl disulfide 11 times faster than neutral phenyl radical.[5]

INTRODUCTION

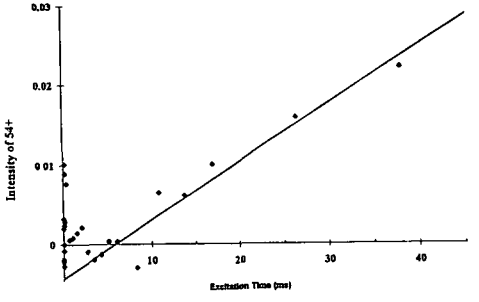
The propargyl $C_3H_3^+$ cation (m/z 39) has been extensively studied as a precursor ion to the formation of soot in the pyrolysis of fuels and other hydrocarbons (1,2,3). Studies involving soot nucleation in flames point to an ionic mechanism, versus a neutral free radical mechanism, driving the formation of aromatic hydrocarbons. These aromatic hydrocarbons are believed to continue the transformation process from a molecular level to particulate systems to soot aggregates (1) These studies show that the propargyl $C_3H_3^+$ cation is critical to this transformation.

Studies by Eyler et al. have involved modeling the soot particle initiation process through reactions of $C_3H_3^+$ with acetylene and diacetylene using FT-ICR (2,3). Using Fourier transform ion cyclotron resonance (FT-ICR), the gas phase reactions arising during the pyrolysis of hydrocarbons can be modeled. In these types of experiments, two forms of $C_3H_3^+$ are observed: i) The reactive linear propargyl cation (l-$C_3H_3^+$), and ii) the unreactive cyclopropenyl cation (c-$C_3H_3^+$). Theoretical calculations reported by Wong and Radom (4) shows a significant activation energy of 97.6 kcal/mole required for rearrangement of the propargyl form to the cyclic form. It is estimated that under flame conditions that the concentration of the propargyl cation is less than 1% of the total $C_3H_3^+$ concentration. Therefore, the reactions of the cyclic form is critical to the proposed mechanism.

The scope of the following research centers around developing an understanding of the mechanisms driving the formation of products during the pyrolysis (thermal decomposition in the absence of oxygen) of hydrocarbons, i e styrene butadiene rubber (SBR). Among those systems studied using FT-ICR was and 1,3-butadiene which produces $C_3H_3^+$ upon electron impact of the neutral target gas. Although this work examines the endothermic charge transfer reactions of cyclopropenyl with small conjugated dienes, the scope of this research centers around developing an understanding of the gas phase reactions of $C_3H_3^+$ during the pyrolysis process and the implications of these reactions performed on a large scale.

EXPERIMENTAL

An IonSpec Omega 50 Fourier transform mass spectrometer (FTMS) based on the concept of ion cyclotron resonance was employed for the experiments described in this report.he Omega 50 FTMS instrument uses a Walker Scientific resistive electromagnet which was set with a magnetic field strength of 1 03 T. Samples were introduced through a Varian Series 951 leak valve into a single vacuum chamber Background pressure was maintained at 8 x 10^{-10} torr using a Balzers 330 liter/second turbomolecular pump backed by an Alcatel direct drive roughing pump. Pressures were monitored using a Bayard Alpert ionization gauge, with average experimental pressures set between 2 0-3.0 x 10^{-7} torr. The temperature was monitored using a calibrated thermocouple attached to the vacuum chamber and the neutral gases were allowed to equilibrate prior to kinetic measurements. Ionization followed a 20 ms electron beam with ion current set between 1.2-1 5 μA and electron energy of 60 eV. Values for the excitation time required for the mass and energy selective partitioning of the molecular ion of butadiene was obtained and compared to the dimensions of the skimmer orifice in the rear trap plate.(5). This data was used to calibrate the amplitude of the rf ejection fields used



Results and Disscussion

To study the charge exchange reactions between the cyclopropenyl isomer A stable population of the cyclic isomer of C3H3 cation was trapped and thermallized int the FT-ICR mass spectrometer by allowing the more reactive linear propoargyl isomer to react away prior to the isolation of ions of m/z 39 The cyclopropenyl isomer was then allowed to collisionally relax to thermal internal energies by collisions with background neutrals of 1,3 butadiene These ions were then given increasing amounts of translational energy using resonant rf bursts,and the products were observed. As seen in figure 1, there is no initial intensity of m/z 54 which corresponds to a charge exchange product between the cyclopropenyl cation and the neutral 1,3-butadiene. However, following the resonant acceleration of the ions of m/z 39, the formation of ions of m/z 54 is observed indicating the occurance of an electron transfer. The emperical threshold was determined to be ca. 6 9 eV. This emperical data was then compared to differences in ionization potential which were calculated at the MP2/6-31G level using Gaussian 92. The results of these calculations are seen in Figure 2. The good corelation between the calculated ionization potentials and the emperical data suggests that in the collision both the neutral 1,3-butadiene and the cyclopropenyl cation are destabilized, resulting in the endothermic charge transfer reaction.

SELECTIVE ION-MOLECULE REACTIONS OF BENZOYL IONS IN A QUADRUPOLE ION TRAP: APPLICATION TO SAMPLES OF PHARMACEUTICAL INTEREST.

Colin S. Creaser and Brian L. Williamson, Deparment of Chemistry and Physics, Nottingham Trent University, Clifton Lane, Nottingham, NG11 8NS, UK.
Brian M. Stockton, Department of Analytical Sciences, SmithKline Beecham Pharmaceuticals, Old Powder Mills, Nr Leigh, Tonbridge, Kent, TN11 9AN, UK.

The benzoyl ion, $[C_6H_5CO]^+$, has been shown to undergo ion-molecule reactions with hydroxy related compounds in a quadrupole ion trap.[1] This ion shows limited reactivity towards other oxygenated compounds and therefore has potential as a selective reagent for chemical ionisation. An ion trap mass spectrometric study has been undertaken on the selectivity of the ion-molecule reactions of the benzoyl ions of the type $[C_6X_nH_{5-n}CO]^+$, (X= H, F, 4-CH_3), with analytes of pharmaceutical interest containing hydroxy, double bond and amine functional groups.

Experiments were performed using a quadrupole ion trap mass spectrometer (Finnigan MAT ITMS), operated at 120 °C. In a typical experiment, the benzoyl ion was generated as an electron ionisation fragment of acetophenone, isolated and allowed to react with neutral sample vapour for 100 ms. Reagent pressure was 2×10^{-6} torr and typical sample pressures were 5×10^{-6} torr. Helium bath gas was maintained at 1×10^{-4} torr measured using the vacuum chamber ion gauge.

The reactions of the benzoyl ion with hydroxy containing compounds produce the characteristic product ions; $[M+105]^+$ (adduct), $[M-OH]^+$, and $[M-H]^+$. Product distributions are determined by the structure of the hydroxy compound, making it a potentially useful probe for establishing the presence and chemical environment of hydroxy groups.

(i) *Keto-enol tautomers of methylacetoacetate*
Methylacetoacetate is an analogue of a β-diketo ester used in the synthesis of the drug candidate SK&F96067 (SmithKline Beecham). The EI GC/MS chromatogram of methylacetoacetate is shown in Figure 1a. It shows two well resolved peaks assigned to the keto-enol tautomers of methylacetoacetate, but the EI spectra do not allow these tautomers to be distinguished. The corresponding benzoyl ion selective CI GC/MS chromatogram of methylacetoacetate is shown in Figure 1b. Reaction with the double bond of the enol tautomer is observed, giving the spectrum shown in Figure 2, but there is no reaction with the keto tautomer.

(ii) *The product related intermediates of 2-(8-phenyloctyl)benzaldehyde*
2-(8-Phenyloctyl)benzaldehyde (POB)[2] is the precursor of SK&F104353,[3] a high affinity peptidoleukotriene antagonist (SmithKline Beecham). The $[C_6H_5CO]^+$ ion reacts with the hydroxy and double bond containing intermediates of POB, forming electrophilic addition product ions. Both benzyl alcohol and phenylheptyl alcohol undergo hydroxy abstraction to produce $[M-OH]^+$ ions, where as phenylheptene reacts to form a $[M+105]^+$ adduct ion. Bibenzyl undergoes a side reaction, which leads to the formation of $M^{+\cdot}$ by charge exchange. The pentafluorobenzoyl ion, $[C_6F_5CO]^+$, a much stronger electrophile than $[C_6H_5CO]^+$, reacts with chloride, hydroxy, carbonyl and double bond containing intermediates of POB, to produce $[M+105]^+$, $[M-H]^+$, $[M-Cl]^+$ and $[M-OH]^+$ ions. The 4-methylbenzoyl ion, a much weaker electrophile than $[C_6H_5CO]^+$, only reacts with benzyl alcohol, to produce $[M-OH]^+$ hydroxy abstraction ions.The electrophilic nature of the benzoyl ion can therefore be controlled easily,

allowing its selectivity to be varied. It therefore has potential for trace analysis as a selective chemical ionisation technique and product ion distributions may allow functional group assignment.

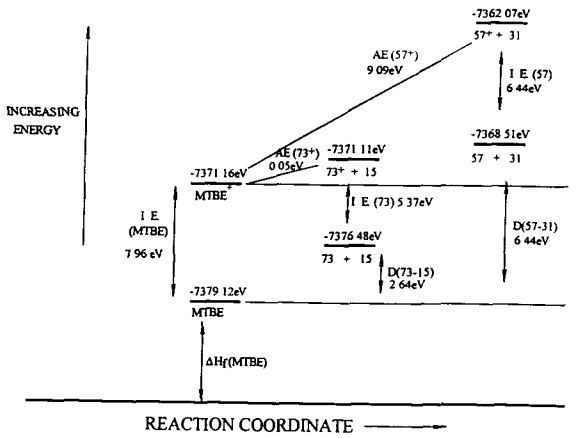
Gas-Phase Ion-Molecule Reactions of Methyl tertButyl Ether (MTBE)

Scott Peterman, Michaela Rich, and Curtiss Hanson
University of Northern Iowa, Cedar Falls, Iowa 50613

The evaluation of Methyl-tert Butyl Ether has been intensively studied since its initial use in the late 1970's. In general, there has been fewer studies concerning the fragement ions formed under combustion conditions. MTBE has been the fastest growing chemical in production during the past decade[1]. Its major use is an octance inhancer. Since MTBE is a labile molecule, the energy of combustion does produce chemical reactions that must be recognized. With the health complaints associated with blended gas, the need for an understanding of the chemical reactions occurring from combustion must be understood.

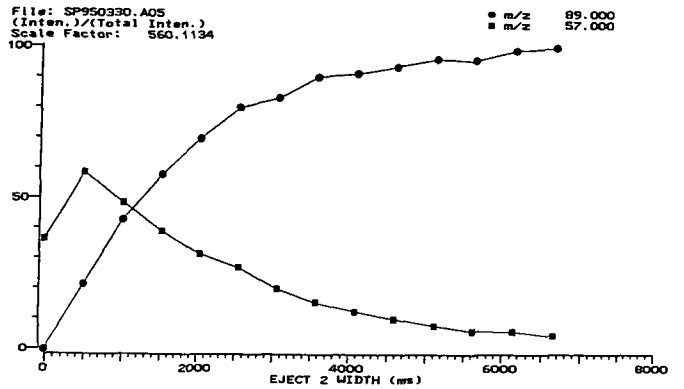
The use of a Fourier transform ion cyclotron resonance mass spectrometer was used for all experimental work. The FT-ICR was chosen due to the ability to model combustion conditions at an ideal rate for observation. All theoretical calculations were done on the Spartan RISC 6000 system calculated at the MP2 6-31g* theory level Using both methods, a complete picture was provided of the fragmentation patterns and bi- and unimolecular reactions of MTBE

The intial spectrum of MTBE displayed fragmentation at minimal energy into two primary ion, m/z 73 and m/z 57, with no cold molecular ions Spartan was used to calculate the thermochemical energy relationship for the unimolecular ion decomposition of MTBE



Becuase of the lability and the time frame of combustion, the chemical reactions of these fragment ions were studied. Time delays were implemented to distinguish bimolecular reactions occurring. Through this study, a gas-phase acid was determined to be the t-butyl ion, m/z 57. Studies done

by Gray and Westbrook focused on MTBE in a shock tube experiment, determining that the primary product was the t-butyl radical[2]. The heat of formation for this radical was 6.92 eV, the ion was calculated to be 7.13 eV[3]. Spartan calculations for the ionization energy of the t-butyl ion was determined to be 6.44 eV.



From the delay scan, a rate of proton transfer was calcautaed to be 3.24 x 10^{-10} cc/(molecules x sec) This rate was compared to similar systems and evaulated to be a strong gas-phase acid

The t-butyl ion also functioned as base. The strenght of the ion coupled with the lability of the neutral allowed the ion to abduct an electron from the neutral, causing fragmentation. From this, the formation of the m/z 73 ion was observed. Through labelled experiments, the isomer of this ion was identified.

Collisional activation of the protonated MTBE ion shows the formation of two ions, m/z 57 and m/z 74. The amount of energy imparted on m/z 89 was calculated to be 1 75 eV for the m/z 57 ion, and 2 72 eV for the m/z 74 ion Spartan calculations gave theoretical values of 1.69 eV and 3.03 eV for the m/z 74.

Ion/Molecule Reactions with Polyethylene Glycols

Adebayo Onigbinde, D. P. Ridge, Tianlan Zhang, and Burnaby Munson
Department of Chemistry and Biochemistry
University of Delaware
Newark, DE 19716-2522

Polyethylene glycols have many industrial applications. The compounds also show strong evidence for intramolecular interactions in ion chemistry. The electron ionization (EI) mass spectra of homologous compounds are very similar and contain no molecular weight information for identification of the compounds. The CH_4 CI mass spectra contain structurally useful fragment ions and MH^+ ions. The abundance of MH^+ ions, however, depends on the PEG concentration, which increases across the chromatographic peaks and result from sample ion/sample molecule reactions, probably from $C_2H_5O^+$, the dominant ion in the CH_4 CI mass spectra of PEG.

FT/ICR/MS was used to study the ion/molecule reactions of $C_2H_5O^+$ from three sources with PEG to determine the reaction products and the rate constants for the ion/molecule reactions. $C_2H_5O^+$ ions were produced by electron ionization of PEG; by ion/molecule reactions in ethylene oxide, C_2H_4O; and by electron ionization of dimethyl ether.

The glycols were introduced with the probe. The ethylene oxide and dimethyl ether were introduced through the pulsed valve and the $C_2H_5O^+$ ions were transferred from the analyzer to the source to react with PEG. The source temperature was approximately 27 °C. Pressures were of the order of 10^{-7} -10^{-8} torr (gauge). Rate constants were calculated using the indirect method of pressure determination of Pan and Ridge (J. Am. Chem. Soc. 1992, **114**, 2773).

The products and their abundances from ion/molecule reactions with PEG of $C_2H_5O^+$ made by electron ionization of PEG were very similar to the products and abundances obtained in CH_4 CI of PEG. The dominant $C_2H_5O^+$ ion decreased in relative abundance with increasing sample concentration in the CH_4 CI studies and with increasing time in the FT/ICR/MS studies. Essentially no MH^+ ions were present at low concentrations or zero time and the abundance of MH^+ increased with increasing concentration in CH_4 CI studies and with increasing time in the FT/ICR/MS experiments. Therefore, $C_2H_5O^+$ is the primary source of MH^+ ions in the CH_4CI spectra of PEG.

Studies were made on the time dependences of product ions from reactions of $C_2H_5O^+$ made from three different sources with PEG in order to differentiate between the structures of the ions. $C_2H_5O^+$ ions made from ethylene oxide and by electron ionization of PEG were expected to be the same and different from $C_2H_5O^+$ ions made from dimethyl ether. Plots of the relative abundances of product ions from the reactions of $C_2H_5O^+$ ions from PEG and from ion/molecule reactions in ethylene oxide were very similar. Some of the major product ions from the reactions of $C_2H_5O^+$ from dimethyl ether with PEG were different from those observed from reactions of $C_2H_5O^+$ from the other two sources. Consequently, we believe that the $C_2H_5O^+$ ions from electron ionization of PEG have the protonated ethylene oxide structure, not $CH_3OCH_2^+$.

The rate constants for reactions of $C_2H_5O^+$ from PEG and of $C_2H_5O^+$ from ethylene oxide were very similar for ethylene glycol, diethylene glycol, triethylene glycol, and tetraethylene glycol and relatively close to the calculated ADO values. The rate constants for the reaction of $CH_3OCH_2^+$ with ethylene glycol and diethylene glycol were significantly lower than rate constants for reaction of $C_2H_5O^+$ from PEG or ethylene oxide. The rate constants for reaction of $CH_3OCH_2^+$ with tri- and tetraethylene glycols were approximately the same as the calculated ADO values.

The observation of protonated dimers, $(PEG)_2H^+$, in the CH_4 CI spectra of ethylene glycol and diethylene glycol at high concentrations, but not in the spectra of tri- and tetraethylene glycol suggests that the proton is internally solvated in MH^+ ions of the higher glycols.

CS_2 AND BENZENE CI OF METHYL ESTERS AND PARAFFINS

Jason J. Evans, Burnaby Munson, Gordon Nicol
Chemistry and Biochemistry
University of Delaware
Delaware, 19716 DE

Charge exchange chemical ionization (CI) can sometimes provide mass spectra containing primarily molecular ions. Advantages that can be realized include enhanced sensitivity and ease of quantitation. Benzene CI, for example, has been used for the analysis of gasoline samples with a moderate degree of success.

Saturated esters and paraffins have ionization potentials around 10.0 eV, slightly below IP(CS_2). The CS_2 CI spectra of saturated esters and paraffins contain essentially no fragment ions. Benzene has an ionization potential of 9.25 eV. Therefore, a charge exchange reaction does not take place. The proton affinity of benzene is 7.8 eV. The $C_6H_7^+$ will not transfer a proton to a paraffin, but proton transfer is observed with saturated esters.

The EI spectra of unsaturated esters contain low abundance molecular ion peaks. The CS_2 CI spectra of unsaturated esters show some fragmentat ions but the molecular ions are the most abundant peaks in the spectra. The C_6H_6 CI spectra of unsaturated esters contain only the molecular ions.

The EI spectra of acetals do not contain molecular ions. Benzene CI gives $(M-H)^+$ ions at about ten percent of the base peak, which can aid in identification.

Studies of the CS_2 CI GC/MS system were performed on a VG 7070E mass spectrometer modified for high pressure work. CS_2 CI spectra can be obtained at source pressures between 0.25 and 0.40 torr of a 70:30 He/CS_2 mixture. He and CS_2 were introduced through separate inlet lines. The GC column was brought into the source through a Vespel plug. A manometer was connected to the source through Tygon tubing and a Vespel plug. There is a broad maximum in sensitivity between 0.25 and 0.40 torr. However, with pure CS_2 the TIC decreases signficantly quickly with time during continuous operation. Such declines in sensitivity are not observed with He/CS_2 mixtures. The sensitivities are also higher using He/CS_2 mixtures as the CI reagent gas than using pure CS_2 at the same pressure.

Benzene and CS_2 CI spectra obtained with a VG Autospec mass spectrometer under normal CI operating conditions contain much more fragmentation than is observed with the 7070E mass spectrometer at 0.3 torr. It appears that the source pressure is low and some direct electron ionization is occurring in addition to the charge exchange CI reactions. The CS_2 and benzene CI spectra obtained with the Autospec are still useful for identification purposes and show enhance abundances of $M^{+\cdot}$ compared with EI spectra.

Benzene and CS_2 CI GC/MS can be useful in the analysis of fatty acids as the methyl esters. Assignment of molecular weights is much easier from CI spectra of unsaturated esters with both reagent gases than from the EI spectra.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Benzene CI is perhaps the best technique for identifying acetals. Quantitation of the saturated esters using CS_2 appears promising since the spectra contain only molecular ions. Also, the rate constants for charge exchange of CS_2^+ with C14 through C20 methyl esters should very similar, scaling only slightly with molecular weight; therefore, the compounds should have similar molar sensitivities.

Benzene CI is not a sensitive technique for the analysis of methyl esters of saturated fatty acids. However, quantitation of the methy esters of unsaturated fatty acid using benzene CI is promising. It can be informative to use both reagent gases in GC/CIMS analyses of complex mixtures of methyl esters of fatty acid sample. The CS_2 chromatogram will show all methyl esters with approximately equal ionization efficiencies. In benzene CI, however, the unsaturated esters peaks are enhanced relative to the peaks for the saturated esters peaks. One can, therefore, identify some unsaturated esters which are present only in trace amounts. In the EI and CS_2 chromatograms these peaks may be masked by intense peaks of saturated esters.

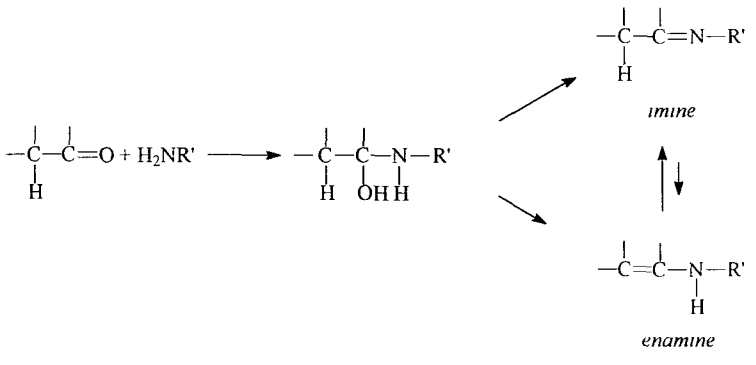
CS_2 CI appears to be a powerful tool for the analysis of paraffins. The molecular ions of paraffins are often barely detectable in EI mass spectra. Determining the molecular weights from the fragment ions is impossible. Quantitation of paraffin mixtures using CS_2 is also promising.

GAS PHASE ION-MOLECULE REACTIONS OF AMINES WITH CARBONYL COMPOUNDS

Mika Pykäläinen and Pirjo Vainiotalo

Department of Chemistry, University of Joensuu, P.O. Box 111, FIN-80101 Joensuu, Finland

Both imines and enamines are important intermediates in many synthetically significant reactions. In solution, the nucleophilic addition of ammonia, amine, hydroxylamine or hydrazine to a carbonyl-containing substrate followed by the elimination of water gives rise to the formation of an imine or enamine (Scheme 1). However, the reaction of primary amines to carbonyl compounds produces imines rather than enamines.



Scheme 1

In this work, ion-molecule reactions of several mono- and diamines with acetone and 3-pentanone were investigated under chemical ionization (CI) using the carbonyl compound as reagent gas. The main aim was to establish whether the nucleophilic addition-elimination reaction takes place under these conditions and what is the structure of possible product ions.

In addition to protonation, the most important ionization reactions were the formation of the $[M+43]^+$, $[M+59]^+$ and $[M+57]^+$, $[M+87]^+$ adduct ions under acetone and 3-pentanone CI, respectively. All the primary amines gave rise to the $[M+59-18]^+$ and $[M+87-18]^+$ ions which at least formally correspond to the products of the nucleophilic addition-elimination reaction either with imine or enamine structure. Comparison of the collision induced dissociation (CID) mass spectra of the $[M+59-18]^+$ ions with those of authentic imines showed that imine formation really takes place in the gas phase. However, under 3-pentanone CI the nucleophilic addition-elimination products, the $[M+87-18]^+$ ions, in most cases formed a mixture where portion of the enamine structure was considerable in addition to the imine structure (Fig. 1) Further experiments showed that the amount of enamine formed was strikingly dependent on the structure of ketone.

The principal reactions of diamines were the same observed for monoamines The formation of the product ions of the nucleophilic addition-elimination reaction was, however strikingly more favourable with diamines than with monoamines both under acetone and 3-pentanone CI In some cases these ions even gave rise to the base peak in the spectrum. Comparison of the CID mass spectra of the $[M+59-18]^+$ and $[M+87-18]^+$ ions generated from diamines with the corresponding spectra of primary monoamines showed that fragmentations in both cases are quite similar.

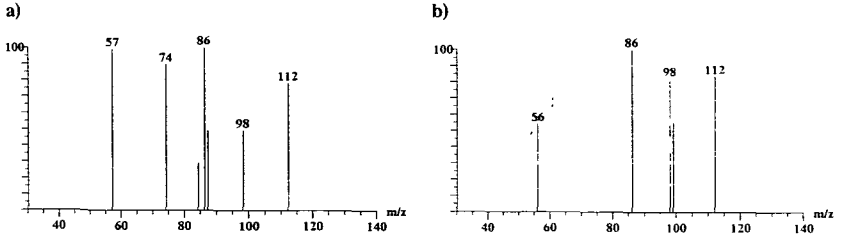


Figure 1. a) The CID mass spectrum of the product ion m/z 142 under 3-pentanone CI

b) The CID mass spectrum of the authentic protonated imine m/z 142 under isobutane CI.

In Situ Investigation of Soot Formation

Helge Egsgaard

Department of Combustion Research, Risø National Laboratory,
DK-4000 Roskilde, Denmark

Soot as collected from flames is likely to be more well-defined that commonly realized as consisting of chainlike aggregates of spherical units with a diameter of 10-50 nm. The spherical units are characterized by having a hexagonal substructure and a very high carbon to hydrogen ratio.

The soot formation involves a series of distinct steps namely nucleation, growth to spherical particles, and the final agglomeration. The most widely accepted mechanism for soot formation is based on free radical reactions and the other on an ionic mechanism, i.e. the Calcote mechanism [1]. The ionic mechanism is initiated by the $C_3H_3^+$ chemi-ion, which rapidly grows by the addition of, e.g. acetylene. It should be noted that a flame may regarded as a weak plasma being the result of highly energetic *chemical* reactions, e.g. between the parent methylidyne, CH, and atomic oxygen.

Very recently we have demonstrated the application of tandem mass spectrometry to chemi-ions based on supersonic molecular beam sampling [2]. This methodology gives unique possibilities for studying the reactivity of isolated chemi-ions [3]. Thus, our studies on soot formation are experiments involving the species actually present in the flame and conceivable reactants under highly controlled conditions.

Our studies of the first step of the Calcote mechanism may serve as an illustrative example. The mass spectra following the reaction of the $C_3H_3^+$ chemi-ion with C_2H_2 and C_2D_2 are shown in Figure 1. The primary adduct $[C_5H_5^+]^*$, m/z 65, is directly observed (Fig. 1a). A very high deuterium content is observed in this complex (m/z 65 - m/z 70) as well as in the C_3-species (m/z 39 - m/z 42) in the C_2D_2 experiments (Fig 1b). An unique feature of the reaction is that if the C_5-complex breaksup the $C_3H_3^+$ ion is re-formed in an mixture of linear and cyclic C_3-species [4]. Thus, the reaction causes a distribution of the isotopic label originating from acetylene in the products, i.e. the ionic C_3-species and acetylene. This leads ultimately to the very high deuterium content of the C_5-complex.

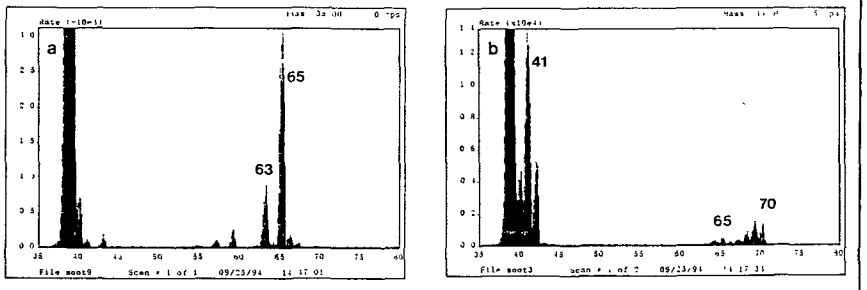

Figure 1. Ion distribution following reaction of the $C_3H_3^+$ chemi-ion with a) acetylene and b) D_2-acetylene. The $C_3H_3^+$ chemi-ion was selected by the first quadrupole, and following reactive collisions in the second quadrupole, the ionic products were analyzed by the final quadrupole.

The translatory energy is in general kept low, i.e. ≤ 0.5 eV. Raising the energy has a pronounced influence as the complex is not traced. The isotopic pattern of the C_3-ions indicates, on the other hand, that the complex does form as evidenced by deuterium inco-operation. Thus, the complex breaks up before collisional deactivation takes place as a result of a possible weak, but sufficient transformation of translatory energy to ro-vibrational energy, causing a much more rapid fragmentation of the encounter complex than observed near thermal kinetic energies. Finally, it should be noted that the product distribution is very dependent on pressure. Thus, the intensity ratio of the $C_5H_5^+$ and $C_5H_3^+$ ions increases with increasing pressure. The comprehensive studies on the ion-molecule reactions related to the ionic soot mechanism will be published elsewhere.

An Ion Trap Tandem Mass Spectrometric Study of $[C_{14}H_{10}]^{+\cdot}$, $[C_{10}H_{10}]^{+\cdot}$ and $[C_{10}H_8]^{+\cdot}$ Ions formed in Ion/Molecule Reactions

Xiaomin Wang, Raymond E. March[1], Alan C. Hopkinson and Diethard K. Bohme, Department of Chemistry and Centre for Research in Earth and Space Science, York University, North York, ON, CANADA M3J 1P3,

[1]Department of Chemistry, Trent University, Peterborough, ON, CANADA K9J 7B8

The experimental results presented here are complementary with those obtained with a Selected-Ion Flow Tube (SIFT) wherein it was observed that diacetylene condenses rapidly with benzene cations;[1] the structure proposed for $C_{10}H_8^{+\cdot}$ product ions was that of the naphthalene cation. In experiments performed in a modified ion trap detector, it was observed that diacetylene and vinylacetylene condense with benzene cations and that vinylacetylene condenses with vinylacetylene cations in the gas phase as shown in reactions (1-3), respectively.

$$C_6H_6^{+\cdot}+C_4H_2 \rightarrow C_{10}H_8^{+\cdot}, C_{10}H_6^{+\cdot}+H_2 \quad (1)$$

$$C_6H_6^{+\cdot}+C_4H_4 \rightarrow C_{10}H_{10}^{+\cdot}, C_{10}H_9^{+}+H^{\cdot}, C_{10}H_8^{+\cdot}+H_2, C_9H_7^{+}+CH_3^{\cdot} \quad (2)$$

$$C_4H_4^{+\cdot}+C_4H_4 \rightarrow C_6H_6^{+\cdot}+C_2H_2,\ C_8H_7^{+}+H^{\cdot} \quad (3)$$

$$C_6H_6^{+\cdot}+C_4H_4 \rightarrow C_{10}H_9^{+}+H^{\cdot}, C_{10}H_8^{+\cdot}+H_2$$

$$C_{10}H_8^{+\cdot}+C_4H_4 \rightarrow C_{14}H_{10}^{+\cdot}+H_2$$

The rate constants for the reactions of benzene cations with both diacetylene and vinylacetylene, and of vinylacetylene cation with vinylacetylene were determined to be 3.69×10^{-10}, 2.70×10^{-10} and 7.59×10^{-10} $cm^3 molecule^{-1} s^{-1}$, respectively. The principal product ions detected from these reactions were $C_{10}H_8^{+\cdot}$, $C_{10}H_{10}^{+\cdot}$ and $C_{14}H_{10}^{+\cdot}$. These experiments were carried out in argon at 10^{-4} Torr and at 475 K; both benzene and vinylacetylene cations were produced by electron impact(~70 eV). Three possible modes of formation of $C_{10}H_8^{+\cdot}$ by ion/molecule reactions are illustrated in Scheme 1. A comparison of collision-induced dissociation mass spectra of $C_{10}H_8^{+\cdot}$ produced in reactions (1-3) is shown in the Table 1. This comparison of the CID mass spectra of $C_{10}H_8^{+\cdot}$, together with an evaluation of thermochemical data and observation of chemical reactivity permit the relatively unambiguous determination of the $C_{10}H_8^{+\cdot}$ ion structures. $C_{10}H_8^{+\cdot}$ produced from the reactions of benzene cation with diacetylene(1) and vinylacetylene cation with vinylacetylene(3), have been proposed as ionized naphthalene; while $C_{10}H_8^{+\cdot}$ produced from reaction of benzene cation with vinylacetylene(2) has been proposed as ionized 1-methylene-1-H-indene. Using the same method as described above, ions of $C_{10}H_{10}^{+\cdot}$ (from reaction (2)) and $C_{14}H_{10}^{+\cdot}$ (from reaction (3)), have been proposed as ionized 3-methylindene and 9H-9methylene-fluorene, respectively.

Scheme 1. Formation and Collision-Induced Dissociation of $C_{10}H_8^{+\cdot}$

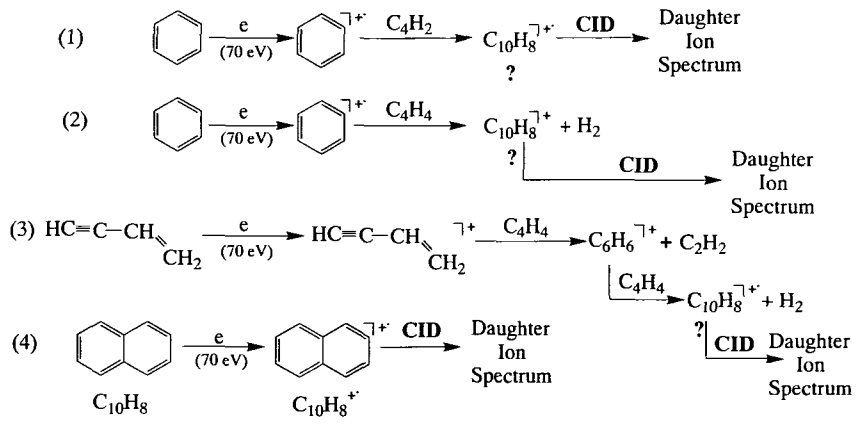

Table 1. Relative abundances of fragment ions of the product ions formed from (1) $C_6H_6^{+\cdot}+C_4H_2$, (2) $C_6H_6^{+\cdot}+C_4H_4$ and (3) $C_4H_4^{+\cdot}+C_4H_2$ and the collision-induced dissociation efficiency, E_f[a]

Parent Ion	Fragment Ion	Relative Abundance %	E_f %
(1) $C_{10}H_8^{+\cdot}$	$\rightarrow C_{10}H_7^{+}+H^{\cdot}$	9	60
	$\rightarrow C_{10}H_6^{+\cdot}+H_2$	45	
	$\rightarrow C_8H_6^{+\cdot}+C_2H_2$	32	
	$\rightarrow C_6H_6^{+\cdot}+C_4H_2$	14	
(2) $C_{10}H_8^{+\cdot}$	$\rightarrow C_9H_7^{+}+CH^{\cdot}$	78	40
	$\rightarrow C_6H_6^{+\cdot}+C_4H_2$	22	
(3) $C_{10}H_8^{+\cdot}$	$\rightarrow C_{10}H_7^{+}+H^{\cdot}$	15	35
	$\rightarrow C_{10}H_6^{+\cdot}+H_2$	5	
	$\rightarrow C_8H_6^{+\cdot}+C_2H_2$	50	
	$\rightarrow C_6H_6^{+\cdot}+C_4H_2$	30	

[a] E_f is a fragmentation efficiency, which is the sum of the daughter ions collected following CID divided by the sum of all ions detected following CID.

ISOMERIC FORMS OF THE PRODUCTS OF ION-MOLECULE ASSOCIATION REACTIONS

Kelly K. MATTHEWS and Nigel G. ADAMS, Department of Chemistry, University of Georgia, Athens, GA 30602

Product ions of many association reactions could have different isomeric forms. The identity of the product ion is important for understanding the chemistry occurring in interstellar clouds as well as gaining insight into mechanisms of the reactions by which the more complex species observed there are formed. For example, $(CH_3)_2O$ and C_2H_5OH have been detected.

It has been suggested[1] that radiative association reactions of the type:

$$CH_3^+ + CH_3OH \rightarrow (CH_3)_2OH^+ + h\nu \quad (1a)$$

$$\rightarrow C_2H_5OH_2^+ + h\nu \quad (1b)$$

followed by dissociative electron-ion recombination could produce these species. The collisional association analog of the reaction

$$H_3O^+ + C_2H_4 \rightarrow (CH_3)_2OH^+ + h\nu \quad (2a)$$

$$\rightarrow C_2H_5OH_2^+ + h\nu \quad (2b)$$

has been suggested as an alternative production route by Jarrold et al[2], which they believe proceeds by channel (2b)

We have used a selected ion flow tube (SIFT) to study the isomeric forms of the ionic products of the collisionally stabilized analogs of reactions (1) and (2). To distinguish between the isomeric forms, differences in reactivities of the isomers have been used as a diagnostic. Though reactants were initially chosen on the basis of proton affinities, other reaction channels are possible. Reactions of $C_2H_5OH_2^+$ and $(CH_3)_2OH^+$ with the chosen species are also being studied to help identify the form of the association product ions. The ions CH_3^+, H_3O^+, and $C_2H_5OH_2^+$ were separately produced in low and high pressure ion sources and injected into flowing He at 0.5 Torr. The $C_2H_7O^+$ association ions were produced by adding CH_3OH and C_2H_4 into the flowing ion swarm. Reactant gases and vapors were added further downstream. All measurements were made at 300K. Rate coefficients obtained for the collisional analogs of reactions (1) and (2) compare favorably with previous values (2.6×10^{-9} cm^3s^{-1} for reaction (1) and 7.8×10^{-11} cm^3s^{-1} for reaction (2)).[1,3,4]

Our results indicate that the $C_2H_7O^+$ produced from $CH_3^+ + CH_3OH$ is different from the $C_2H_7O^+$ from $H_3O^+ + C_2H_4$. For example, the rate coefficients measured in reaction with toluene differ by more than 50%. Though the study is not yet complete, results from the protonated ethanol reactions suggest that the $C_2H_7O^+$ (CH_3^+/CH_3OH) is not $C_2H_5OH_2^+$ Allene reacts slowly with $C_2H_7O^+$ (CH_3^+/CH_3OH) ($k = 6.8 \times 10^{-12}$ cm^3s^{-1}) while the reaction with $C_2H_5OH_2^+$ is closer to gas-kinetic ($k = 4.8 \times 10^{-10}$ cm^3s^{-1}). Additional evidence is based on the reactions of these ions with cyclopropane. In the reaction with $C_2H_5OH_2^+$, two products corresponding to different association-type products were observed. However, only one product ($C_4H_9^+$, possibly a weakly bonded association ion of CH_3^+ and cyclopropane) was observed for the reaction with $C_2H_7O^+$ (CH_3^+/CH_3OH). The observed product suggests that the $C_2H_7O^+$ (CH_3^+/CH_3OH) is the association ion $CH_3^+{\cdot}CH_3OH$ rather than $(CH_3)_2OH^+$ as suggested previously.[1,3] Support for our conclusion comes from an ICR study[5] in which 14% of the products from the isotopically labeled $^{13}CH_3^+ + CH_3OH$ reaction were produced via the intermediate complex $^{13}CH_3^+{\cdot}CH_3OH$. Stabilization of these complexes will be likely to occur in the higher pressure SIFT Comparisons with results from $(CH_3)_2OH^+$ reactions in progress will better ascertain the identity of the ion.

Jarrold, et al,[2] concluded from collisional induced dissociation that the $C_2H_7O^+$ (H_3O^+/C_2H_4) was $C_2H_5OH_2^+$, though energies involved could have been high enough to overcome the barrier (10 kcal mol^{-1}) from a stable minimum, corresponding to a proton-bound dimer structure (H_2O---H^+---C_2H_4), as calculated by Radom[6]. Protonated ethanol was found to be the most thermodynamically stable structure in that investigation Comparison of results between $C_2H_7O^+$ (H_3O^+/C_2H_4) and $C_2H_5OH_2^+$ is less definitive, and no final conclusions have been reached about the form of the $C_2H_7O^+$ (H_3O^+/C_2H_4).

During the studies of $C_2H_7O^+$, interesting products have been observed from reactions of $C_2H_5OH_2^+$ never before investigated. Reactions with cyclopropane and acetic acid produce cluster ions as primary products in addition to simple proton transfer products. Only a cluster product ion is observed in reaction with allene

COMPETITIVE SNi/SN2 FROM EPIMERIC 1-2 HYDROXYETHER AND DIETHERS 1-2 INDANES IN AMMONIA CHEMICAL IONISATION .

Gervat V.[1], Perlat M.-C.[1], Bourhis C.[1], Fournier F.[1], Mandelbaum A.[2], Tabet J.-C.[1*]

[1]Laboratoire de Chimie Structurale Organique et Biologique, EP 103, U.P.M.C., FRANCE,
[2]Department of Chemistry, Technion, Institut of Technology, ISRAEL.

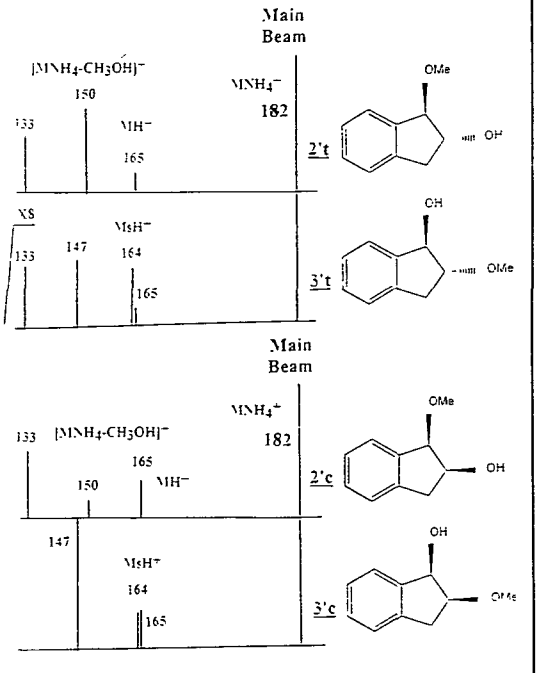
In a recent study[1], the comparative reactivity of the epimeric diether derivatives of the 1-2 indanediols towards the NH_3/NH_4^+ system has been investigated under CI-NH_3 conditions First, competitive MH^+ and $[M+NH_4-ROH]^+$ (noted as MsH^+) ions are generated as well as fragment ions The abundance of these ions depends upon the stereochemistry The occurrence of these reactions reflectes the similarity of PA values of ammonia and substrat In addition, submitted low collision energy , MNH_4^+ fragments into MH^+ and MsH^+ as well as by consecutive processes yielding the $[MH-ROH]^+$ ions and/or $[MsH-NH_3]^+$ ions. Note that formation of the substituted MsH^+ ions is stereospecific of the trans epimers since it is not produced from the cis epimers Alternatively, this reaction occurs regioselectively at the benzylic position independantly of the size of the ether group located at this reactive position (from heterogeneous diethers, e g ethyl-methyl or methyl-ethyl diethers) This behavior is unexpected since proton affinity of benzylic ethers has been shown higher than that of ammonia and this PA effect should hinder formation of the substituted ion formation The relative high PA values for diethers is confirmed by the absence of NH_4^+ ions from CID of the selected adduct ions which prefer to lead to formation of the MH^+ ions in contrast with that observed from the epimeric indanediols which fragment mainly into ammonium ion However, very likely, the particular polarisability of the benzylic ether group must allow the nucleophilic substitution process which occurs from the trans epimers in CID conditions by SNi mechanism associated with configuration retention From the cis isomers, function exchange being observed in ion source and not in the collision cell, the mechanism of the MsH^+ formation must follow a like-SN2 pathway with configuration inversion From the former isomers, the enhanced fragmentations leading to the benzylic leaving group loss under collisions is due to an anchimeric assistance induced by the homobenzylic group[2] The CI mass spectra of the 1-methylether 2-hydroxy indanes (2'c and 2't) as well 1-methylether 2-hydroxy indanes (3'c and 3't) display the adduct ions as base peak These ions react according to different pathways as shown in the following Table 1

Table 1. *Major ions diplayed in ammonia CI mass spectra of the epimeric cis trans hydroxy ethers.*

cis epimer	MH^+	$Ms''H^+$	MsH^+	$[MH-H_2O]^+$ $[M''sH-NH_3]^+$	$[MH-CH_3OH]^+$ $[MsH-NH_3]^+$
2'c (MNH_4^+, m/z 182)	165 (4)	—	150 (17)	—	133 (2)
3'c (MNH_4^+, m/z 182)	—	164 (67)	—	147 (12)	—
trans epimer					
2't (MNH_4^+, m/z 182)	165 (5)	—	150 (31)	—	133 (15)
3't (MNH_4^+, m/z 182)	—	164 (62)	—	147 (35)	—

The adduct ions are produced as base peak in CI mass spectra of four isomers However, observation of MH^+ is only observed from the cis and trans 1-2 indane methylether alcohols (2'c and 2't) This suggests that protonation is due to the increase of the benzylic group PA On the orther way, from these 2'c and 2't epimers, competition between the protonation and the SN processes is reinforced the latter one in the trans 2't epimer (PA(trans) < PA(cis)) Absence of MH^+ ion from the hydroxy ethers (3'c and 3't) is comparable to that observed from indanediols Then, it can be considered that NH_4^+ solvation in source takes place mainly by the benzylic position This assumption is confirmed by CID of the MNH_4^+ ions since only the benzilic site is lost independantly to the PA value of the leaving group However, from the latter pairs of isomers, the importance of the stereochemical effects is some what lowering which contrasts with that observed in low energy collision conditions, since enhancement of stereochemical effects is observed from fragmentations of the selected MNH_4^+ ions (*Figure 1*)

Figure 1. *CID spectra (E_{lab}=10eV, single collision) of MNH_4^+ ions (m/z 182) from the pair of the 2'c/2't and 3'c/3't epimers.*



Spectacular stereochemistry influence on relative ion abundances is observed for MH^+ and MsH^+ The observed protonation is explained by considering the relative frequency factors allowing competition between simple cleavage and group substitution (via rearrangement) in contrast with that occurs in source from the lower internal energy $[M+NH_4]^+$ ions SNi occurs from cis and trans isomers as for the corresponding diols This results to the lowering of PA of hydroxy-ethers relative to the diethers Likely, the hydrogen bond is not sufficiently strengh to hinder formation of the four center nucleophilic transition state of SNi which occurs regioselectively at the benzylic position. All these results are consistent with calculation approachs and estimated PA values.

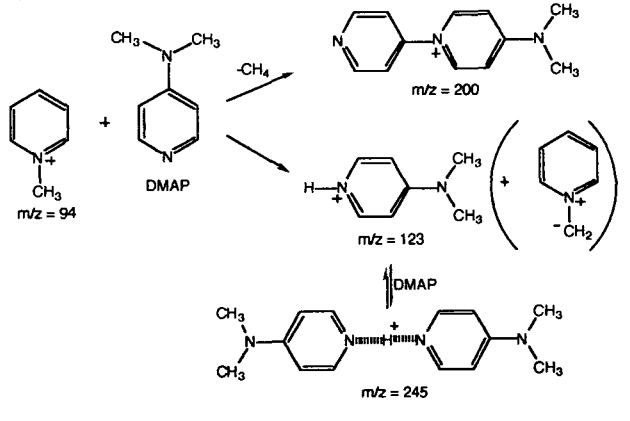
Ion-Molecule Reactions with Alkyl and Acyl Cation Transfer by Electrospray FT-ICR-MS

R D.Burton, P Shipkova, A.R. Katritzky, C.H. Watson, and J.R. Eyler
Department of Chemistry, University of Florida, Gainesville, FL 32611-7200

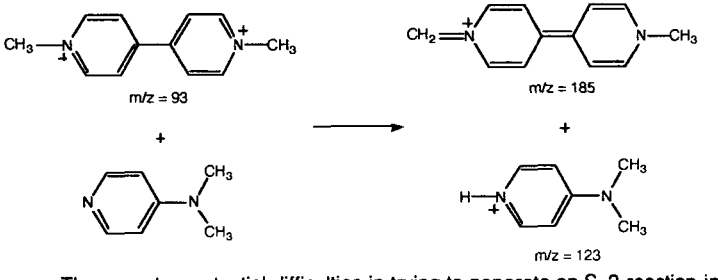
In the past, we have been interested in examining the gas phase chemistry of several alkylpyridinium cations.[1,2] Collisionally-Activated Dissociation (CAD) of these molecules was performed using FT-ICR mass spectrometry in order to determine bond dissociation energies. In addition, the bimolecular chemistry of several 1-benzylpyridiniums was studied in the presence of various neutral nucleophiles Nucleophilic substitution products were formed via S_N1 reaction pathways, however, no evidence was seen for products formed from an S_N2 pathway In order to generate an S_N2 reaction, it seemed logical to replace the benzyl group with an alkyl group of poorer leaving ability. Certainly a 1-methyl pyridinium is not a good candidate for S_N1 chemistry (due to the instability of a methyl cation) and should provide a better substrate for an S_N2 reaction.

It was therefore our intention to generate a gas phase S_N2 reaction between a 1-methylpyridinium and a neutral nucleophile thus effecting a transfer of the methyl cation. Using electrospray ionization, these organic salts were transferred from a 50/50 H_2O-MeOH solution into the gas phase where the pyridinium cations were trapped in the ICR analyzer cell Next, all other ions were ejected from the cell leaving only the substrate cation and the neutral nucleophile, which was leaked in to a constant background pressure of ca. 1 x 10^{-7} Torr. Although no S_N2 reactions were seen, several other reaction pathways were detected upon RF heating.



In one of these reactions, 1-methylpyridinium cation reacted with dimethylaminopyridine (DMAP) to form aromatic nucleophilic substitution product(s), protonated DMAP, and a proton-bridged structure containing two DMAPS (see figure above). The reaction mechanism was determined by doing a series of individual ion ejection experiments. From these experiments it is clear that the product at m/z 200 is most likely formed from the parent ion and a neutral DMAP with loss of methane. Our assignment of para rather than ortho aromatic substitution comes from a second reaction which we examined where methylviologen dication was used as the substrate

Despite the fact that the methylviologen dication should have been even more reactive than the 1-methylpyridinium, only protonation of the DMAP was seen. In this case, the para position is blocked to nucleophilic attack indicating the likelihood that the aforementioned aromatic nucleophilic substitution on 1-methylpyridinium occurs at the para position



There are two potential difficulties in trying to generate an S_N2 reaction in the gas phase The first is the existence of large transition state barriers in the absence of solvent which, according to Brauman et. al, are likely.[3] The other is an entropy effect Since this work was done at extremely low pressures (< 5 x 10^{-7} torr), few collisions will occur where the reactants' molecular orbitals are in the correct orientation to generate the reaction. Despite the fact that no S_N2 reactions were seen for any of the systems studied, we will continue to search for this type of gas phase chemistry.

Association and Bimolecular Ion-Molecule Reactions of Small Sulfur Ring Systems

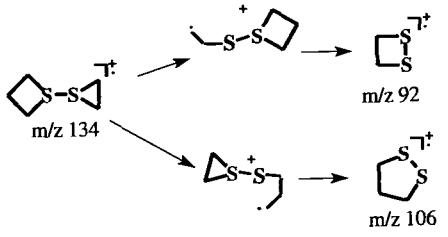
Mary A. James, Jennifer Gidden, Michael Peschke and Andreas Illies*
Auburn University
Department of Chemistry
Auburn University, AL 36849-5312

The association and bimolecular reactions of thiirane with trimethylene sulfide radical cation are presented here. In the neat thiirane system, m/z 92, m/z 124 and m/z 156 were experimentally observed and computationally studied.[1] m/z 92 is a four membered ring with two endocyclic sulfur atoms. Subsequent sulfur atom addition occurs until a six membered ring is formed. In neat trimethylene sulfide, m/z 106, a five membered ring with two endocyclic sulfur atoms, was observed. This ion however, did not undergo further sulfur addition to form a six membered ring (m/z 138) containing three sulfur atoms.[2] These results indicated the bimolecular reactions lead to ring expansion via incorporation of sulfur atoms into the ring.

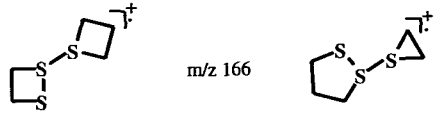
In the present study on the mixed system of thiirane (cSC_2H_4) reacting with trimethylene sulfide radical cation ($cSC_3H_6^+$), unique product ions were observed at m/z 134, m/z 166, m/z 138 and m/z 198. Interestingly, the six membered ring (m/z 138) was observed in the mass spectrum of the mixed system, suggesting that the driving force behind the ring expansion mechanism may be in the thiirane moiety.

The ion-molecule experiments were done with a highly modified Dupont mass spectrometer with a hybrid drift tube / ion source. The metastable and collision induced dissociation experiments were done with a modified ZAB-1F. These modifications included a variable temperature source and a collision zone in the second field free region.

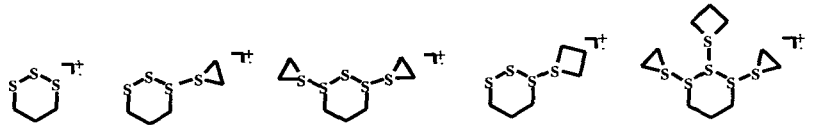
The metastable and CID studies of m/z 134 indicate that this species fragments into m/z 92 (a four membered ring with two sulfur atoms) and m/z 106 (a five membered ring with two sulfur atoms). This suggests the following pathways occur.



m/z 166 is the intermediate leading to m/z 138 (the six membered ring). m/z 92 and m/z 106 are observed in the metastable and CID experiments on m/z 166, suggesting that the two structures shown below contribute to the ion intensity.



m/z 138 (the cyclic ion) undergoes association reactions with thiirane and/or trimethylene sulfide to produce interesting cluster ions. Possible structures for some of the observed clusters are shown below. Determination of the structure of these clusters are still under investigation.



m/z 138 m/z 198 m/z 258 m/z 212 m/z 332

Ion/Molecule Reactions of Allyl Chloride in The Ion Trap Mass Spectrometer

W. Mo, A.M. Franklin and J.F.J. Todd
The Chemical Laboratory, University of Kent at Canterbury
Canterbury Kent, CT2 7NH, UK

This presentation covers the ion/molecule reactions of the ions formed from allyl chloride with neutral allyl chloride and with air present in the ion trap mass spectrometer (ITMS). The ITMS is an ideal instrument for the investigation of ion/molecule reactions due to the long residence time of the reactant and product ions before the detection and the range of techniques available to aid structure and pathway elucidation.

All experiments were carried out on a modified Finnigan MAT ITD (San Jose, CA, USA) system, which is given the capability of an ITMS. Dynamically Programmed Scanning [1] was utilised in the data acquisition after the DC isolation of a certain species of ions: the parameters of reaction time, or tickle time, or tickle voltage were dynamically scanned in the investigation of the ion/molecule reactions and the relevant pathways.

The ion/molecule reactions between the fragments of allyl chloride and allyl chloride neutral are widely observed during the trapping period. Typically, reactions between 41^+ ($C_3H_5^+$) and allyl chloride neutral are observed when the reaction time is dynamically scanned after the DC isolation, resulted in producing 55^+, 79^+, 81^+ and 91^+.

In the experiments when tickle voltages or tickle frequencies (corresponding to tickle mass) are dynamically scanned, it is observed that when different amounts of energy are deposited in the ions, the reaction can be switched to different pathways.

As a result of the isolation of specific ions and dynamically scanning one of the above parameters, the reaction pathways have been fully investigated. Ion Trap Mass Spectrometry, combined with Dynamically Programmed Scanning is a powerful method with which to investigate the ion/molecule reactions in a complex chemical system.

Mechanism of H/D Exchange in the Reaction of BH_2^+ + Deuterium

Joseph A. Hankin, Gustavo E. Davico, Charles H. DePuy, and Robert Damrauer
Department of Chemistry and Biochemistry
University of Colorado
Boulder, CO 80309-0215

Ionization of diborane by electron impact in the source of a Flowing Afterglow-Selected Ion Flow Tube (FA-SIFT) gives rise to an enormous number of borohydride anions and cations. Many of these ions have been identified by earlier studies in an ICR[1], or analyzed using *ab initio* computations[2-6].

Because boron consists of appreciable amounts of two isotopes, ^{10}B and ^{11}B, several different ionic species may appear at the same mass. The ion at *m/z=13 is purely the* $^{11}BH_2^+$ *isotopomer. The FA-SIFT enables selection of this* ion out of the source mixture using a source quadrupole.[7] This "SIFTed" ion can then be injected into a second flow tube for reaction studies.

The chemistry of BH_2^+ has been initially probed by studying the mechanism and energetics of H/D exchange in the reaction of $BH_2^+ + D_2$. BH_2^+ is the boron analog of methyl cation, and it is hoped that comparisons of the chemistry of these two ions will elucidate mechanistic aspects of the reactions of methyl cation. *Ab initio* computations have been carried out to help define the reaction pathway.

The reaction of $CH_3^+ + D_2$ is a fast, efficient reaction that results in random mixing of H/D.[8] The analogous reaction of BH_2^+ is slower, less efficient, and involves less exchange **(Figure 1)**.

$$CH_3^+ + D_2 \longrightarrow CH_2D^+ + HD \quad 65\%$$
$$CHD_2^+ + H_2 \quad 35\%$$

$k_r = 6.8 \times 10^{-10}$ cc/molecule-sec; efficiency = 58%

$$BH_2^+ + D_2 \longrightarrow BHD^+ + HD \quad 91\%$$
$$BD_2^+ + H_2 \quad 9\%$$

$k_r = 4.1 \times 10^{-11}$ *cc/molecule-sec;* efficiency = 3.4%

Figure 1: Reaction data for $CH_3^+ + D_2$,[8] and $BH_2^+ + D_2$.

The reaction, $BD_2^+ + H_2$ was also studied, and was found to have a slower rate ($k_r = 3.9 \times 10^{-11}$ cc/molecule.sec) than $BH_2^+ + D_2$. This was expected as this reaction proceeds in the endothermic direction ($\Delta H_r = +0.4$ kcal/mol) of the forward and reverse reactions. $^{11}BD_2^+$ was made in the FA-SIFT by adding D_2 into the flowing afterglow source along with B_2H_6. No other ions or isotopically substituted ions were present at this mass (m/z=15).

The potential energy surface for the reaction of $BH_2^+ + D_2$ has been determined computationally using Gaussian 92 (MP4//6-311G**//MP2(full)/6-311G**).[9] The energetics of the reaction of $CH_3^+ + H_2$ were determined experimentally by Kebarle[10] and various CH_5^+ intermediate and transition state structures have been calculated by Schleyer et. al.[11] A comparison of the two systems reveals that both form 3-centered 2 electron bonded complexes as low energy adduct structures. However, the entrance channel for $CH_3^+ + H_2$ is much larger than for $BH_2^+ + D_2$ (-40 vs. -14.8 kcal/mol), and the transition state for exchange of H/D is much smaller (relatively) for CH_3^+ than for BH_2^+ ($\Delta G^{\dagger\dagger}$= -+2 kcal/mol ($CH_3^+$) vs. +16.3 kcal/mol ($BH_2^+$). These differences in reaction energetics account for the experimental differences in rates, efficiencies, and amounts of H/D exchange observed.

Isotope Effects in the Dissociation of Aniline and Protonated Aniline

Yasmin A. Ranasinghe and Gary L. Glish
Department of Chemistry, University of North Carolina, Chapel Hill, NC 27599

The essence of mass spectrometric analysis is structure characterization and the determination of fragmentation pathways. Exchange of 'active' hydrogens with deuterium in an ion is a widely recognized technique for structure elucidation. The number of acidic/exchangeable hydrogens can be determined by using many different types of mass spectrometers.

However, discrepancies are often observed between different mass spectrometers depending on the internal energy deposited into the ion during formation in the ion source. In addition, different time frames for reactions lead to difference in spectra between instruments. At low internal energies, isotope effects can contribute significantly to the observed results. In this work we are investigating isotope effects in a quadrupole ion trap compared to a sector mass spectrometer.

ND_3 was leaked into the ion trap using a Varian leak valve and chlorobenzene was pulsed in using a pulsed solenoid valve. Helium was used as a buffer gas and was maintained at a pressure of 1.4×10^{-3} torr. CID was performed by kinetically exciting the parent ions by applying a resonance excitation voltage to the endcaps. The experiments in the sector was performed by introducing chlorobenzene using the injection port or the solids probe. The reagent gas ND_3 was leaked in through the CI gas inlet and the pressure is estimated to be ~ 0.5 torr. The ions formed from the reaction of $C_6H_5^+$ with ND_3 were observed by performing a magnetic scan. Metastable ion spectra dissociations occurring in the first field free region were obtained by performing a linked scan at constant B/E to detect the product ions.

$C_6H_5^+$ reacts with ND_3 to give three product ions. The ion trap showed an increased propensity for H vs. D loss compared to the sector. The H:D loss ratios were found to be 6:1 for the trap vs. 2:1 for the sector. Greater isotopic discrimination observed could be due to the different time frames of the experiment which could lead to sampling of the ions of different internal energies.

			Relative Abundance		
			m/z	Trap %	Sector %
$C_6H_5^+ + ND_3$	$\rightarrow C_6H_{5-n}D_nNH_{3-m}D_m^+$		97	73	85
	$\rightarrow C_6H_{5-n}D_nNH_{2-m}D_m^+$	+ H	96	23	10
	$\rightarrow C_6H_{5-n}D_nNH_{3-m}D_{m-1}^+$	+ D	95	4	5

$n+m = 3$

A substantial amount of H/D scrambling between the ring and substituent hydrogens is observed. This results in different isomeric structures. Evidence for the interchange of aromatic and ring hydrogens have also been observed by Dookeran et al. in the reactions of protonated aniline with ND_3.[1] Because of the time frame of the experiment, a nearly statistical distribution of H/D exchange is observed in the ion trap, whereas that is not the case with the sector.

The MS/MS results show that the isotope effect observed for the ion trap is 2.7 as opposed to a value of 3.0 for the sector. The smaller difference in the secor vs. the ion trap is attributed to the lower internal energies of the metastable ions in the sector as opposed to the increased internal energies of the resonantly excited ions in the trap, vs. the ion source generated ions. For the ions formed by H loss from the adduct (m/z 96) DNC loss is 1.5 times more favorable than HNC loss. This isotope effect is a secondary effect related to transfer of H or D from the nitrogen to the ring.

Hydrogen/Deuterium Exchange of Multiply-Protonated Cytochrome *c* Ions

Troy D. Wood, Ziqiang Guan, Peter B. O'Connor, Russell A. Chorush, and Fred W. McLafferty, Department of Chemistry, Baker Laboratory, Cornell University, Ithaca, NY 14850-1301.

Low resolution measurements show gaseous multiply-protonated cytochrome *c* ions undergo hydrogen/deuterium (H/D) exchange with pseudo first-order kinetics [1] at three distinct exchange levels, suggesting the co-existence of gaseous protein conformations. Although exchange levels first increase with increasing charge values, they decrease at the highest charge values, consistent with solution-phase behavior of cytochrome *c*, where the native structure unfolds with decreasing pH until folding into a compact A-state at lowest pH. High resolution measurements indicate the presence of at least six H/D exchange levels [2]. Infrared (IR) laser heating and fast collisions via quadrupolar excitation (QE) increase H/D exchange levels (unfolding) while charge-stripping ions to lower charge values can increase or decrease H/D exchange levels (unfolding or folding). Wolynes has suggested studying proteins *in vacuo* could play an important role in delineating the contributions various forces play in the protein folding process, provided appropriate comparisons can be made between gas-phase and solution-phase structures [3].

Tandem mass spectrometry of multiply-protonated cytochrome *c* ions produces up to 35 sequence informative fragment ions. Sustained off-resonance irradiation/ collisionally-activated dissociation of gas-phase deuteriated species representing the previously identified states I (16+, 112 exchange level), II (16+, 129, and 9+, 138), and V' (15+, 121) reveal subtle structural differences between the different species. The low (I) and high (II) exchanging conformers of 16+ have almost identical exchange levels in the N-terminal 25 residues, but differ by 9 D's in the C-terminal 35 residues. State II 16+ and 9+ show identical H/D exchange everywhere except between residues 26-50. Clearly, tandem mass spectrometry can provide considerable insight into subtle structural differences between these species and may be used to identify additional conformations. Exchange in individual amino acid residues can be tracked in regions where fragmentation occurs at adjacent amide bonds (Figure 1). H/D exchange levels for cytochrome *c* under prolonged high velocity collisions (by QE) approach the denatured level (190 out of 198), giving further evidence of gas-phase unfolding (Figure 2). Possible mechanisms of H/D exchange have recently been proposed for oligopeptides [4]. For cytochrome *c*, the role of protonated sites was probed by removing charges from gas-phase deuteriated 16+ (to 9+); the 16+ exchanged ~77 D's after 5 minutes, while charge-stripped 16+ --> 9+ exchanged ~75 D's. Thus, H^+'s (and not D^+'s) were primarily removed, suggesting H/D mechanisms requiring H^+'s do not predominate for multiply-protonated cytochrome *c* ions. This work was supported by the National Institutes of Health (GM16609).

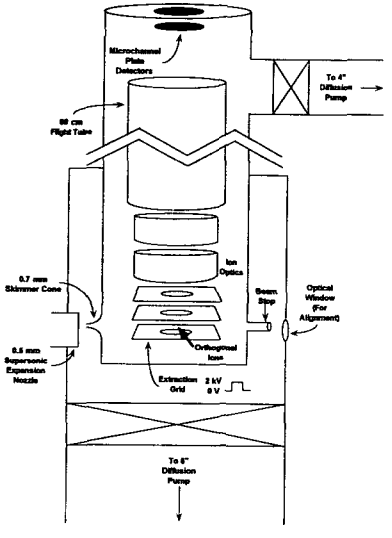
Ion Resolvation in a Time of Flight Mass Spectrometer

*M. A. Lasater and D. A. Laude

Department of Chemistry, The University of Texas at Austin, Austin, TX 78712



Schematic of Time-of-Flight Region

Figure 1

Supersonic expansions of molecular beams have been used to create clusters of molecules Clusters are of an intermediate size between individual gas phase molecules and the bulk solution. As such, the properties of the clusters span this potentially fruitful area.

In this work, a study of alcohol clusters were intersected with alkali metal cations and then accelerated by use of a very fast high voltage pulser into a TOF mass spectrometer. Also, an electrospray source of ions has been added to explore the nature of the electrospray ionization process itself

A general schematic of the system is shown in Figure 1. A pulsed expansion valve (Newport Corporation) was used to create a supersonic expansion of an alcohol from vapor saturated nitrogen. The saturated vapor was formed by bubbling the gas through dried solvent and taking the resultant vapor into the supersonic expansion chamber. The resulting collection of internally cooled clusters was skimmed and then allowed to react with thermally desorbed sodium ions. The heat of solvation from the reaction was dissipated by evaporation of the alcoholic clusters. The resulting internally warm clusters were orthogonally accelerated by using a 2 kV extraction pulse from a fast (25 ns rise time) high voltage pulser (Directed Energy, Inc.). The ions were then focused with electrostatic lenses and detected using a

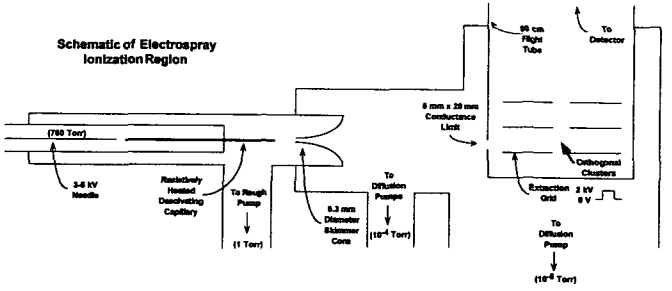


Figure 2

25 mm microchannel detector (R.M. Jordon Corporation). The extraction pulse was varied between 100 ns and 1 μs to maximize the resolution and signal. A delay generator (Interstate Electronics Corporation) was used to vary the time between the pulsed expansion valve opening and the high voltage extraction pulse to accommodate the travel time between the valve and the middle of the ion extraction region. An electrospray probe mount has also been recently added in addition to the thermal ion source This design is shown in Figure 2. The data were collected on a 150 MHz Digital oscilloscope (LeCroy Instrumentation). With methanol clusters, there was a distinct preference for both $Na(MeOH)_3^+$ and $Na(MeOH)_4^+$, as well as a preference for the $Na(MeOH)_6^+$. The $Na(MeOH)_5^+$ cluster was also seen. $Na(MeOH)^+$ and $Na(MeOH)_2^+$ were uncommon. The higher order clusters were rarely seen. An example of the methanol data is seen in Figure 3a. Moving up to ethanol, the 3 and 4 cluster is still preferred but the 2 cluster was also frequently observed. Again the 1 cluster was uncommon, and the higher order clusters were not observed. When isopropanol is used, the incidence of successful clustering is sharply reduced. However, the lower clusters (1-4 IPA's) were all observed with approximately equal frequency. Again, higher order clusters were not observed. An example of this data is in Figure 3b. The resolution of the individual peaks is good for a time-of-flight, with a resolution of 974 for Na^+. In increasing size from methanol to alcohols of larger size, the maximum common cluster size shifts from 6 to 4. This is somewhat counterintuitive as the heat of vaporization trends upward with larger alcohols (This would mean that fewer molecules of solvent would have to evaporate to dissipate as much energy.) However, bulkier side chains may prevent as many molecules from binding into the inner solvent sphere. There is also a trend towards smaller S/N as the solvent size increases. This is probably due to the decreasing efficiency of the ion focusing at higher masses. Future work includes improving the cluster source, optimizing electrospray ionization for this system, and improving the constancy of the thermal ion source The adaptation of this technique to a Fourier transform mass spectrometer will be attempted to study structural information. The electrospray ion source will allow the exploration of fundamental questions involving this ionization process

The Influence of Ion Structure on Coulomb Energy in Multiply Charged Ions

Deborah S. Gross, Sandra E. Rodriguez-Cruz, and Evan R. Williams
Department of Chemistry, University of California, Berkeley, CA 94720

Multiply protonated ions formed by electrospray ionization (ESI) provide a unique opportunity to study the effects of charge on the conformation and reactivity of highly charged gas-phase ions in the absence of solvent. Highly charged ions are more reactive toward proton transfer and dissociation. We have developed a method to quantitatively measure the Coulomb repulsion between charges in gas-phase ions through measurements of their proton transfer reactivity. Because of the 1/r distance dependence of the Coulomb energy, these measurements provides information about the gas-phase conformation of these multiply charged ions. From the kinetics of proton transfer reactions with neutral reference bases, the apparent (or kinetic) proton affinity (PA^{app}) of a site of protonation can be assigned. The difference between the PA^{app} and the intrinsic PA of the site of protonation in the neutral molecule ($PA_{Intrinsic}$) can be fit to a point-charge model (1). In situations where the entropic terms cancel, the Coulomb energy can be obtained by measurement of gas-phase basicities:

$$\text{Coulomb Energy} = GB_{Intrinsic} - GB^{app} \qquad (1)$$

This method has been demonstrated for 1,*n*-diaminoalkanes (n = 7 - 10, 12) in which the distance between charges varies (this distance is obtained from molecular modeling) (2). Because the singly protonated ion cyclizes to solvate the proton in the gas-phase, monoaminoalkanes of equivalent chain length are used as a reference of the intrinsic reactivity (3). For these ions, the measured GB^{app} values fit eq. 1 with a dielectric polarizability $\varepsilon_r = 1.01 \pm 0.07$, indicating that these reactions follow a point-charge Coulomb potential, and that -(CH_2)- groups provide negligible shielding in the gas-phase. In order to determine the effects of functional groups between the charges, we are investigating a series of analogous diamine molecules in which there are branched hydrocarbon chains and ether groups between the charges. The proton transfer rates and the Coulomb energy are given in Table 1 for $CH_3CH(NH_2)CH_2[OCH_2CH(CH_3)]_nNH_2$, n = 2, 3. $CH_3OCH_2CH_2NH_2$ (GB = 215.0 kcal/mol (4), on an adjusted GB scale (5)) is used as a reference for the $GB_{Intrinsic}$ value. For the n = 2 and n= 3 species, we measure CE = 19.0 and < 17.0 kcal/mol, respectively, and, when combined with the distance between charges, we obtain dielectric polarizabilities of $\varepsilon_r = 1.4$ and $\varepsilon_r > 1.2$, respectively. This indicates that branched alkanes and ether functionalities more efficiently shield the charges in the gas-phase than the straight-chain alkanes.

In order to test the point-charge Coulomb model presented here, we have extended our measurements on the cyclic peptide gramicidin s (6) to a series of $(M + H + X)^{2+}$ ions of the gramicidin s, where X = Li^+, Na^+, and K^+. The proton transfer rates are slower than those of the doubly protonated ion. Kinetic curves obtained for the reactions of the X = Li^+ ions are shown in Figure 1. The proton-transfer rate constants for all of these ions are given in Table 2. The GB^{app} of the singly charged gramicidin s $(M + X)^+$ ions are found to be 223.3 kcal/mol for all X, compared to 219.1 kcal/mol obtained for the $(M + H)^+$ ion (using the revised GB scale (5)). The GB of the neutral peptide is > 243.3 kcal/mol. Using the previously determined dielectric polarizability of $\varepsilon_r < 1.4$ (GB scale from reference 5) for gramicidin s, we calculate the distance between the charge sites to be 11.9 Å in these

43rd ASMS Conference on Mass Spectrometry and Allied Topics

metal ion systems. This value is greater than the 9.5 Å obtained for the doubly protonated ion indicating that the alkali metal cation is attached to the exterior surface of the peptide and is most likely not as efficiently solvated as the protons in the doubly protonated ion.

Acid/Base effect on FAB ionization process

Francisco L. Amado, Pedro N. Domingues,
M. Graça O. Santana Marques and A. J. Ferrer Correia

Department of Chemistry
Mass Spec. Lab., University of Aveiro, Portugal

In this work, we have tried to understand the effect of the addition of acids or bases, in both FAB positive and negative ionisation processes. In face of our results, different interpretations had to be used for a comprehensive approach of the acid/base effect.

Figure 1 shows the variation of the $[M+H]^+$ (FAB+) and $[M+H]^-$ (FAB-) ion signals in the presence of the different acids and bases. Generally it can be seen that there is an increase of the $[M+H]^+$ ion yield production with acid addition and an increase of the $[M-H]^-$ ion yield production with NH_3. From the results we can suggest the following mechanistic interpretations.

Its not possible to speak about a direct effect due to AcOH. The signals of AcOH ions disappear from the spectra within approximately two minutes. Volatile compounds will disappear quickly, as it occurs with the cosolvents normally used like water or methanol, and an enrichment of the ionised forms is obsserved. As we are in the presence of a weak acid it is possible that it passes to the gas phase in the neutral form acting as a coanalyte. This explanation its also possible for tris-(hydroxymetyl)-aminomethane (Tris). Signal divergence could also be caused by variation of physical properties of the matrix, namely viscosity.

In the negative ion mode, when NH_3 is added there is a signal increase of the analyte, whatever analyte is used. However, in the gas phase NH_3 behaves simultaneously as an acid and as a base. This feature explains the quasi molecular ion improvement both in positive and negative FAB.

In the positive ion mode whatever the analyte used there is a signal increase when. trichloroacetic acid (TCA), hydrochloric acid (HCl) or trifluoroacetic acid (TFA) is added. In the negative mode, in the presence of TFA there is always a decrease on the $[M-H]^-$ ion yield production. Cluster formation between the acid and the analyte is observed. In the TPP/TFA spectrum do not see these clusters. Glutathione/TFA or TCA (Figure 2) spectra only show one cluster each. Arginine clusters with one and two acid ions. This feature could be interpreted as a experimental evidence of a possible general mechanism of the acid effect. At the pH values of the different solutions all the amino acids glutathione and TPP molecules are on their ionised form. Acids act as counter-ions and the passage to the gas-phase occurs via ion pair formation. Therefore, in the gas phase one of the three situations can occur: the ion pair doesn't dissociate; the ion pair loses one proton and appears in the negative FAB spectra; the ion pair dissociates producing analyte positive ions and acid negative ions.

Signal improvement can be explained because as there are more molecular ions in the gas phase, more protons are available for $[M+H]^+$ ion production.

With extensive ion-ion recombination in the gas phase, it is likely that ion pairs pass through intermediate neutralisation and reionisation steps. With this mechanistic picture it is understandable that the number of basic groups within each analyte molecule determines the different negative cluster ions formed when the carboxylic group of the basic compound loses a proton. Molecular structure, ionic bond strength, volatility and matrix viscosity diminution are also factors that should determine the final ion mass spectra.

ION/MOLECULE REACTIONS FOR IMPROVED EFFECTIVE MASS RESOLUTION IN ES/MS

Scott A. McLuckey and Douglas E. Goeringer
Chemical and Analytical Sciences Division
Oak Ridge, TN 37831-6365

Tandem mass spectrometry can improve the effective mass resolution in electrospray mass spectrometry of multiply-charged ions. The technique involves selecting a population of ions within a narrow range of mass-to-charge values and allowing the ions to undergo proton transfer reactions. The shifts in mass-to-charge associated with product ions formed by proton transfer allow for mass and charge assignment. The success of the technique relies on the relative enrichment of ions of a particular charge state that occurs in the mass-to-charge selection step. This approach can be used to extend the polymer mass range amenable to measurement, analyze mixtures that might otherwise be too complex for reliable mass measurements, and improve mass measurement precision when a mixture of cations is present within a given charge state. The technique is illustrated with a quadrupole ion trap.

The use of proton transfer reactions in conjunction with tandem mass spectrometry to improve effective mass resolution in electrospray MS is illustrated conceptually in **Figure 1**. **Figure 1a** shows a simulated electrospray mass spectrum of a hypothetical biopolymer of M_r = 15 kDa in which ions of charge states 14+-10+ are present. For the purpose of illustration, the isotopic distribution associated with each charge state is shown as an envelope the width of which was arbitrarily defined to be sufficiently broad to result in significant overlap between charge states. **Figure 1b** shows a peak profile for a mass-to-charge-selected portion from the most intense part of the spectrum shown in **Figure 1a**. It is critical to the success of this approach that the selected region be narrow enough to ensure that it is significantly enriched in one component of the mixture of ions present in the mass spectrum. **Figure 1b** also shows the peak profiles associated with each component present in the selected region along with the total peak profile. Note that the 12+ charge state is by far the most important contributor to the total peak intensity. **Figure 1c** simulates the spectrum observed after a 400 ms reaction period in which a strong base, present at a number density of 3×10^9 cm^{-3}, undergoes proton transfer reactions with the rate constants on the order of 1×10^{-9} cm^3-$molecule^{-1}$-s^{-1}. **Figure 1d** shows the mass spectrum obtained when no mass selection step precedes the ion/molecule reaction period. Comparison of the spectra of **Figures 1c** and **1d** illustrates the utility of ion/molecule reactions as part of an MS/MS experiment. The mass selection step serves to simplify the mixture of ions that undergo proton transfer reactions. The proton transfer reaction provides part of the m/z information necessary for a mass assignment. The resolution of the analyzer itself is unaffected.

Figure 2 shows the results from a negative ion application in which trifluoroacetic acid was used to transfer protons to anions of E coli tuna, strain W. **Figure a** shows the electrospray mass spectrum derived in the absence of trifluoroacetic acid. The spectrum of **Figure a** reflects a complex mixture of species, arising from sample heterogeneity and a mixture of cations, which precludes a mass measurement. **Figure b** shows the results obtained when a relatively narrow portion of the ion population was mass-to-charge-selected and allowed to react with trifluoroacetic acid for 200 ms. Two charge states at higher mass-to-charge clearly emerge allowing for both charge and mass assignment. Although it was

not possible to determine the most probable charge of the ion population initially selected for reaction, the shifts in mass-to-charge associated with the product ions indicated that the mass-to-charge selection process yielded an enriched relative concentration of the 17-charge state. The total signal is greatly reduced due to the fact that the majority of the analyte ions was ejected. However, such a sacrifice is clearly warranted given the fact that no mass information could be obtained from **Figure a**.

* Department of Chemistry, Florida State University

Stored Waveform Ion Modulation (SWIM) two-dimensional FT-ICR MS/MS[1] offers an automated method for identifying connectivities between primary and secondary ions for all ion-neutral reactions in a single experiment. The Stored Waveform Inverse Fourier Transform (SWIFT) excitation waveforms of the SWIM experiment modulate primary ion speed and hence the number of secondary ions derived from those primary ions by means of ion-molecule collisions and/or reactions. Peaks along the diagonal line of the 2-D spectrum represent the conventional one-dimensional FT-ICR mass spectrum. Each off-diagonal peak corresponds to a unique ion-molecule reaction whose reactant ion and product ion can be identified by horizontal and vertical projections to the diagonal.

Previously we have shown that the SWIM technique may be used with laser desorption ionization.[2] Here we show that the SWIM technique can help to elucidate the structures of biological molecules in multi-component samples in an automated fashion. Preliminary results obtained for MALDI generated quasi-molecular ions of bradykinin and angiotensin II, a two-component system with similar fragmentation patterns, are reported and discussed. A key component in two-dimensional analyses is reproducibility in total signal intensities. For mass spectrometry by use of MALDI, 2D requires minimal shot to shot ion production variations. Results reported herein indicate promise for 2D analysis of biochemical complex mixtures.

This work was supported by NIH (GM-31683) and the National High Magnetic Field Laboratory at Florida State University. We thank Michael Dunk of Waters Extrel-FTMS for valuable discussions concerning implementation of the SWIM waveforms.

Ion Cyclotron Resonance Evidence for the Formation of α-Chloroethenethiolates and Thioketenes during Biotransformation of Chloroalkene-Derived, Cytotoxic 4-Thiaalkanoates

Tian-lan Zhang,[†] Liping Wang,[†] Mazzaz Hashmi,[‡] M.W. Anders,[‡] Colin Thorpe,[†] and Douglas P. Ridge.[†,*]

[†]*Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716*
[‡]*Department of Pharmacology, University of Rochester, Rochester, NY 14642*

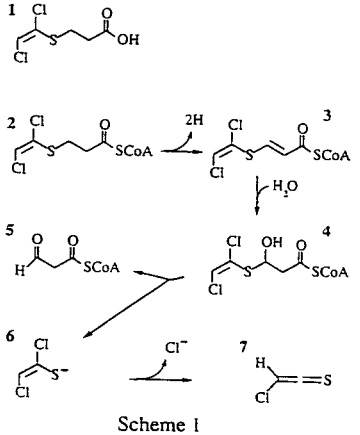
Characterization of the reactive intermediates formed during the bioactivation of xenobiotics is an important step in understanding their cytotoxicity. Nephrotoxic chloroalkenes generate cysteine S-conjugates that are proposed to undergo ß-lyase-dependent bioactivation affording α-chloroenethiolates and thioketenes as reactive intermediates. Formation of thioketenes has also been proposed during the metabolism of 5,6-dichloro-4-thia-5-hexenoic acid **1** (Scheme 1) and related analogues. This report describes the use of ion cyclotron resonance to provide the first direct evidence for the formation of thiolate and thioketene species from a cytotoxic 4-thia-carboxylic acid.

Bioactivation of **1** involves conversion to the corresponding CoA thioester **2** and oxidation by the medium chain acyl-CoA dehydrogenase to **3** is followed by hydration to the thiohemiacetal **4**. Elimination of 1,2-dichloroethenethiolate **6** would give malonylsemialdehyde-CoA **5**. Thiolate **6** and related α-chloroalkenethiolates have not been observed directly in aqueous solution. However, their formation as precursors to thioketenes (*e.g.* **7**) has been inferred from indirect evidence

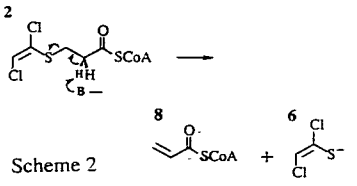
Our recent studies with the acyl-CoA dehydrogenase suggest that removal of a C-2 proton from **2** can also lead to the direct elimination of **6** (Scheme 2). The present report shows the utility of Fourier Transform ion cyclotron resonance (FT-ICR) in modelling this enzymatic reaction. FT-ICR provides unequivocal evidence for the formation 1,2-dichloroethenethiolate **6** and for the subsequent elimination of chloride to yield the putative chlorothioketene **7**.

The propyl thioester analogue of **2**, **9** (Scheme 3) was introduced on an unheated probe inserted into the reaction chamber of a dual cell FTMS 2000 FT-ICR mass spectrometer. The volatility of **9** and the pumping rate maintained a sample pressure of ca. 10^{-7} torr. The instrument has two differentially pumped ion analyzer-traps. OH^- was formed by electron impact on water vapor admitted into one of the analyzer-traps through a valve opened for 15 msec. OH^- formed by electron impact on the water vapor was transferred to the adjacent analyzer-trap where it was exposed to neutral reactant **9** in the adjacent analyzer. The results of the gas-phase encounter of **9** with OH^- were interrogated at various delay times by FT-ICR analysis of the resulting ions.

Figure 1 illustrates typical results. As the reaction time increases the OH^- ion concentration decreases exponentially with a corresponding increase in two product ions. The neutral reactant, **9**, is present in large excess so these pseudo first-order kinetics unambiguously demonstrate that the bimolecular reaction between OH^- and **9** produces an anion of the stoichiometry of **6**, $C_2HCl_2S^-$, and the chloride anion (Scheme 3). Thus, while **6** has been deduced as a cytotoxic intermediate from indirect evidence in condensed phase studies, it is directly observed here in the gas phase as a product of the action of base on **9**.



Scheme 1



Scheme 2

The postulate that **6** loses chloride to give thioketene **7** was tested using collision induced decomposition (CID) FT-ICR. The results showed that elimination of Cl^- from **6** is facile and suggest that the neutral product of the elimination is the expected thioketene **7**. These studies support earlier proposals for the cytotoxicity of **6** and suggest that FT-ICR may be generally useful in modelling enzymatic elimination reactions.

ION-MOLECULE CHIRAL RECOGNITION BY AMINE EXCHANGE EQUILIBRIA

Chadin Dejsupa, Yongjiang Liang, and David V. Dearden
Brigham Young University, Department of Chemistry, Provo, Utah 84602

Introduction

Like other analytical techniques for chiral species, successful mass spectrometric methods rely on differences in the reactivity of enantiomers with a chiral reagent. Recently, fast atom bombardment (FAB) mass spectrometry has been used to examine the relative intensities of adduct peaks arising from interactions of chiral species.[1-4] Fourier transform ion cyclotron resonance mass spectrometry was used several years ago to measure equilibrium populations of clusters of chiral molecules such as L- and D-dimethyl tartrate.[5,6] The equilibrium approach has the advantage that equilibrium constants are easily related to free energy changes, so the degree of chiral recognition can be quantified.

Our own prior gas phase studies of chiral recognition in gas-phase ion-molecule reactions[7] use similar equilibrium techniques. The host molecule, dimethyldiketopyridino-18-crown-6 (hereafter designated "**1**"), has two stereocenters. The guest, α(1-naphthyl)ethylammonium, is designated $NapEtNH_3^+$. The chiral host, *S,S*-**1**, and an achiral host, 18-crown-6, were both admitted into the trapping region of a Fourier transform ion cyclotron resonance mass spectrometer. Either *R*- or *S*-$NapEtNH_2$ was also admitted into the trapping region, and $NapEtNH_3^+$ was formed by self-CI. Reaction of $NapEtNH_3^+$ with the neutral ligands afforded the host-guest complexes. The exchange of the guest between the chiral and achiral hosts, reaction (1), was allowed to proceed to equilibrium. The attainment of equilibrium was verified by monitoring ion intensities as a function of reaction time until the ratio of the 18-crown-6•$NapEtNH_3^+$ and *S,S*-**1**•$NapEtNH_3^+$ ion intensities became constant. Perturbation of the system away from equilibrium by ejection of either of the complexes always resulted in re-establishment of the same equilibrium ratios after an appropriate delay, attesting to the fact that true equilibrium was reached.

$$S,S\text{-}\mathbf{1}\bullet(R\ or\ S)\text{-}NapEtNH_3^+ + 18C6 \rightleftharpoons S,S\text{-}\mathbf{1} + 18C6\bullet(R\ or\ S)\text{-}NapEtNH_3^+ \quad (1)$$

These were difficult experiments. First, *S,S*-**1** is fairly involatile, so that usable vapor pressures were barely attainable when the ligand was inserted into the high vacuum region of the instrument on a direct-exposure solids probe. Second, achiral 18-crown-6 binds $NapEtNH_3^+$ much more strongly than the chiral ligand, making equilibrium difficult to observe unless there is a large excess pressure of the less volatile, chiral *S,S*-**1**. Finally, measurement of the partial pressures of the ligands, which is crucial to the results, is difficult and introduces a great deal of uncertainty into the results.

Amine Exchange Equilibria

Our new experiments were performed using a model APEX 47e (Bruker Instruments) external source Fourier transform ion cyclotron resonance mass spectrometer. Rather than observing equilibria for exchanging an *ammonium guest* among *neutral hosts*, we observe the exchange of *neutral amines* by a *protonated host* ion, reaction (2). One enantiomer of the chiral amine, as well as an achiral reference amine, are introduced into the trapping cell as neutrals. One of the host enantiomers is electrosprayed in the external source, and the resulting protonated host ions are guided into the trapping cell and captured. Reaction of the protonated host with the neutral amines results in formation of complexes. Exchange of the chiral and achiral amines on the protonated chiral host is allowed to proceed to equilibrium, which is verified as before. The experiments are then repeated with the other enantiomer of the host or the guest.

$$(S,S)\text{-}\mathbf{1}H^+\bullet R\text{-}NapEtNH_2 + \text{cyclohexylamine} \rightleftharpoons (S,S)\text{-}\mathbf{1}H^+\bullet\text{cyclohexylamine} + R\text{-}NapEtNH_2 \quad (2)$$

It is interesting to note that not all protonated host molecules form complexes with neutral amines. Of the ligands we studied, only 18-crown-6 and *S,S*-**1** were observed to form amine adducts, while neither protonated dicyclohexano-18-crown-6 nor protonated dibenzo-18-crown-6 formed amine complexes. These differences have not yet been explained.

When both host enantiomers are available (as is the case for host **1**), switching between the two enantiomers can be done rapidly enough (by simply flushing the solution of one enantiomer out of the electrospray needle, and replacing it with a solution of the other enantiomer) that pressure conditions in the trapping region do not change appreciably between the two measurements. Since the results for the degree of chiral recognition depend on a ratio of the two equilibrium constants for the two enantiomers, if the partial pressures of the amines do not change the pressures cancel in the ratio and pressure is no longer a variable in the measurement. This is a very significant advantage, since the pressure measurements are the largest potential sources of error in the experiments.

The approach of the system to equilibrium was observed from both "forward" and "reverse" directions. In these experiments, the achiral reference amine was cyclohexylamine, the chiral amine was *R*-$NapEtNH_2$, and the chiral ligand was *R,R*-$\mathbf{1}H^+$. Ejection of either the complex of *R,R*-$\mathbf{1}H^+$ with the chiral amine (at m/z 525) or with the achiral amine (at m/z 453) was followed by re-establishment of the equilibrium ratio of about 1 for these two peaks. At equilibrium, the *R*-$NapEtNH_2$•*S,S*-$\mathbf{1}H^+$ complex peak is much more intense relative to the reference than the *R*-$NapEtNH_2$•*R,R*-$\mathbf{1}H^+$ complex peak. This corroborates our earlier results, obtained with the more difficult experimental method, that indicated stronger complexation between *R*-$NapEtNH_3^+$ and *S,S*-**1**.

Quantitatively, the difference in equilibrium constants corresponds to the free energy of binding in the *R*-$NapEtNH_2$•*S,S*-**1** complex being 3.1 ± 0.4 kJ mol^{-1} (at 300 K) greater than in *S*-$NapEtNH_2$•*S,S*-**1**. The results obtained using amine exchange equilibrium are in good agreement with those obtained earlier using ligand exchange (4.2 ± 0.4 kJ mol^{-1} at 350 K), especially when it is noted that the two experiments were done at different temperatures.

The simplicity of the new experiments, along with the ease of electrospraying large, enantiomeric crowns, has now enabled us to examine a number of other chiral guests for recognition by **1**. The results, shown in Table 1, reveal some of the structural requirements for recognition in this system. Both enantiomers of *sec*-butylamine and cyclohexylethylamine reacted identically with respect to the achiral reference; the chirality of both these guests was not recognized. Recognition was observed for phenylethylamine, but the difference in free energy of binding for the two enantiomers was only about 0.7 kJ mol^{-1}. This suggests that the π-π stacking interaction is essential for recognition in this system. No recognition is seen in guests lacking the π system, and recognition is much weaker for phenylethylamine than for naphthylethylamine, because the former is too small to simultaneously allow optimal hydrogen bonding and π system overlap

Table 1. Difference in Free Energy of Binding Chiral *R*-amines by *S,S*-1 vs. *R,R*-1 at 300 K.

amine	ΔΔG°, kJ mol^{-1}
sec-butyl	0
cyclohexylethyl	0
phenylethyl	0.7 ± 0.4
naphthylethyl	3.1 ± 0.4

Chiral Recognition in Molecular Host-Guest Complexations using FABMS

Masami Sawada, Yoshio Takai, Hitoshi Yamada, Shigeki Hirayama
The Institute of Scientific and Industrial Research,
Osaka University, Ibaraki, Osaka 567, Japan
Kimiko Kamada, Keiji Hirose, Yoshito Tobe, and Koichiro Naemura
Department of Chemistry, Faculty of Engineering Science,
Osaka University, Toyonaka, Osaka 560, Japan

Chiral recognition in molecular host-guest complexations is one of the highlights in modern organic chemistry. Various chiral crown ethers have been synthesized and various degrees of chiral recognition have been achieved. Several methods were used for determining chiral recognition of chiral crown ether hosts. Examples are extraction/NMR, extraction/polarimetry, titration NMR, variable temperature NMR methods and so on. Mass spectrometry is highly sensitive, but primarily uninformative for this purpose because of the absence of these mass differences.

We report here the successful detection of chiral recognition by a simple and direct method using FAB mass spectrometry. The method particularly uses a 1:1 mixture of a labeled and an unlabeled guest enantiomer, which is called as FABMS/EL (Enantiomer Labeled) method. Diastereomeric host-guest complex ions, $[(H + G_R)^+$ and $(H + G_{S\text{-}d3})^+]$, produced by a chiral crown ether host (H) and an enantiomeric pair of guests (G_R and $G_{S\text{-}d3}$: deuterium-labeled) have different masses and then, simultaneously appear as a pair of host-guest complex ion peaks. Since the complex ions are identified by the aid of the isotope tag, both the degree and the direction of the chiral recognition properties of a given crown host toward a given amino acid ester ammonium ion guest can be directly determined using the relative peak intensities of the corresponding host-guest complex ions in one spectrum as $I[(H + G_R)^+]/I[(H + G_{S\text{-}d3})^+]$, which is abbreviated as $I_R/I_{S\text{-}d3}$. A typical FABMS spectrum is shown in Fig. 1 (NBA matrix).

Application and applicability of this methodology are presented. Among several crown ether hosts and the related natural compounds, it is found that host **2** possesses a high degree of chiral recognition ability and shows remarkably large guest's structure-dependency upon the chiral recognition properties: the $I_R/I_{S\text{-}d3}$ values vary from 0.7 to 5.4. Typical results of the $I_R/I_{S\text{-}d3}$ values are illustrated in Fig. 2.

Very importantly, the $I_R/I_{S\text{-}d3}$ values determined by the FABMS/EL method are compatible with the relative thermodynamic stabilities (K_R/K_S) in solution.

For example,

host **2** + (*R*)-Met-OMe in $CD_3OD/CDCl_3$(10/1) at 25°C, $K_R = 78.6\ M^{-1}$
host **2** + (*S*)-Met-OMe $K_S = 15.9\ M^{-1}$

Then, $K_R/K_S = 4.9$ by the titration NMR method.
$I_R/I_{S\text{-}d3} = 5.4$ by the FABMS/EL method.

As a summary, the FABMS/EL method is a novel and practically useful technique for determining chiral recognition properties in the highly structured host-guest complexations.

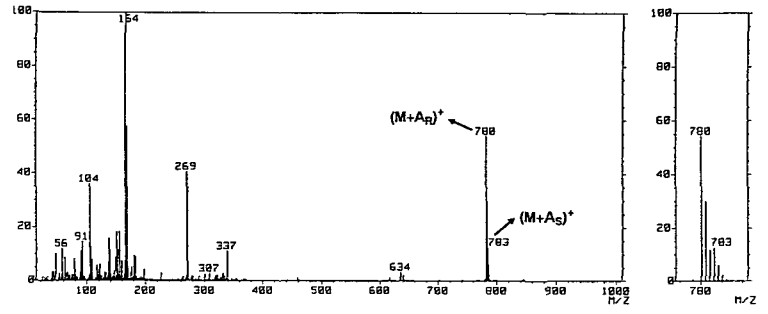

Fig. 1. A FAB mass spectrum (NBA) of a mixture of host **2** with guest Met-OMe(Cl⁻).

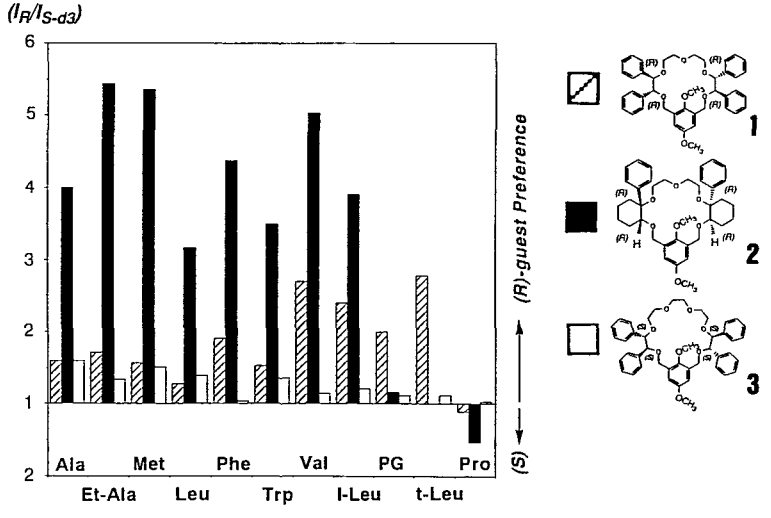

Fig. 2. Chiral recognition properties of hosts **1** - **3** toward various amino acid methyl ester ammonium ion guests determined by the FABMS/EL method.

SFC/MS using a glow discharge ionization source

D. Carazzato, P. Bélanger, A. Carrier and M.J. Bertrand
Department of chemistry, University of Montreal, Montreal, Canada, H3C 3J7

Many organic pollutants and drugs are thermo-labile compounds or have a low volatility and, therefore, are analysed by liquid chromatography. These compounds can also be handled by supercritical fluid chromatography. From an instrumental point of view, interfacing SFC to mass spectrometry seems to be simple as compared to HPLC, because carbon dioxide is easily vaporized at low temperature. The use of a thermospray-type interface (TS) seems quite simple and more appropriate than the moving belt, which appears to be more adapted to packed columns, as well as particle beam interfaces which suffers from a lack of sensitivity. A TS interface requires simple instrumentation and is relatively easy to operate, provided that an efficient back pressure restrictor is used. For the present work, several types of thermospray restrictors have been utilized and very few are capable to widthstand the tendency to clog. The most effective, involved the use of a pinched stainless steel needle attached to a capillary column.

Amongst the ionization techniques that have been routinely used for SFC detection, CI has shown greater sensitivity than EI. Attempts at obtaining pure EI spectra have mostly resulted in combined EI and CI processes. Most of the problems associated with the use of these sources concern the contamination of their inner components and the reduced lifetime of the filament. In previous work[1] we have developed and evaluated the analytical potential of a glow discharge source. Recently we have investigated the usefulness of the same prototype as an ion source for capillary SFC introduction. Until now, the work that was been done mainly involved isothermal and isoconfertic operation with pure carbon dioxide. It has already been shown that the charge and proton transfer are important processes leading to the ionization of organic molecules in glow discharges operating at moderate pressures. The contribution of electron ionization is found to be relatively low and, there is no high energy metastable states capable of ionizing organic molecules. The ion distribution in the background plasma appears to be strongly anisotropic and apart from the carbon dioxide ion, only a few others are observed. Because of the intensity of CO_2^+ it is expected that charge exchange involving carbon dioxide ions will play a major role at a short distance from the cathode while it's importance will be significantly lower at longer distances, where protonated water (not shown on the spectrum) and water clusters (m/z 37) are present.

An interesting feature of the glow discharge technique is its ability to also sample negative ions. The high densities of low energy electrons favour electron attachment to molecules having positive electron affinities and ion lifetimes of a few microseconds. The "background" spectrum of the CO_2 discharge in the negative ion mode exhibits a large CO_3^- ion as well as some oxygen based, chlorine and C_xO_y ions. Since the use of glow discharge devices for organic analysis is uncommon, various substances have been injected through the SFC system in order to obtain an idea of the spectral features in both positive and negative ion mode. Different chemical classes were analyzed and mass spectra of 2 compounds are presented in Figure 1 and 2. In the positive ion mode they exhibit spectral features compatible with charge exchange with carbon dioxide and fragments characteristic of the chemical structures are observed. It is believed that the spectral features could change drastically from EI to CI characteristics upon the addition of a

modifier in the CO_2 phase. Although this will result in the loss of structural information by reducing fragmentation, the CI ionization process usually provides better sensitivities. In the negative ion mode, molecules with high electron affinities such as 5-nitroacenaphtene (Fig 1) show a dominant $M^{-\cdot}$. Ions resulting from ion-molecule reactions such as $(M+15)^-$ are the result of the $M+O_2\text{-}OH\cdot$ process that is usually found in oxygen containing discharges. Since more than one oxygen atom can be added to the molecule, such common reactions often complicate the interpretation of the mass spectra. Calibration curves for estrone (positive ion mode) and 5-nitroacenaphtene (negative ion mode) are presented in Figure 3. Detection limits close to 10^{-12} g have been found with linearity extending over 4 orders of magnitude. In conclusion, results obtained indicate that charge transfer is the main process leading to the ionization of organic molecules. The measured sensitivity and linearity with the prototype indicate that it can be used for organic analysis. Spectral features shows molecular peaks as well as some fragmentations carateristic of the structure of the compound.

A novel low-power rf glow discharge ion source

*ML Langford, WT Povey and JFJ Todd

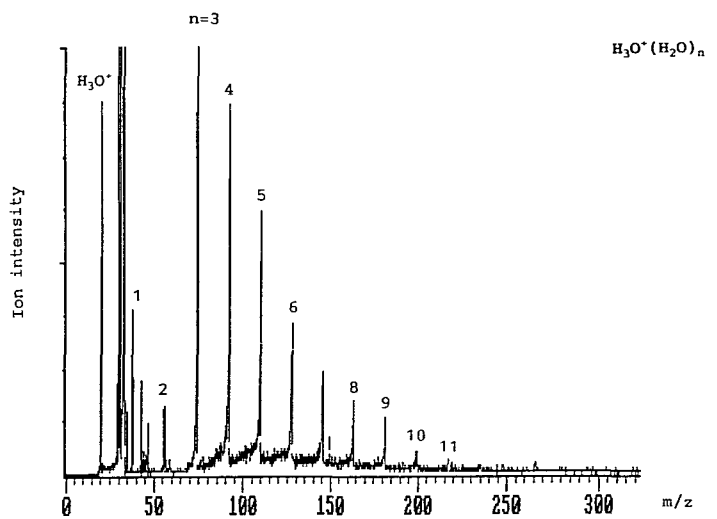
Chemical Laboratory, University of Kent, Canterbury, Kent CT2 7NH, UK
**Building S18, DERA Fort Halstead, Sevenoaks, Kent TN14 7BP, UK*

A novel radio frequency ion source has been constructed. Positive and negative ions are produced in a rf plasma and extracted using a pressure differential into a lensing system which directs a positive or negative ion beam into a mass spectrometer.

The structure and configuration of the discharge electrodes was designed to favour low power operation. This was successfully achieved and spectra were obtained using powers less than 0.5 Watts. This enabled the source to be driven by a wide-band transistorised rf power amplifier with associated signal generator and miniaturised matching circuit.

One of the outstanding features of this low power ion source is its versatility. The source is able to operate in a variety of gaseous environments including air and under a wide range of pressure conditions including atmospheric pressure. The plasma conditions can be altered to achieve different purposes. It can be run at different rf frequencies, different rf peak-to-peak amplitudes, different source pressures, in different source environments and it can produce both positive- and negative-ion spectra.

Figure 1 shows a spectrum which was collected by allowing the airstream to pass over a glass spoon containing water before it passed through an aperture into the ion source. The intensities of water cluster peaks in air were recorded as a function of rf amplitude, rf frequency and source pressure. Cluster formation was facilitated at higher source pressures, fragmentation reactions were increased at higher rf amplitudes and lower rf frequencies. Both positive and negative-ion spectra were obtained.



Background mass spectrum plus $H_3O^+(H_2O)_n$ cluster spectrum. each cluster is identified by its value of n.

MICRO - ELECTROSPRAY ON A MAGNETIC SECTOR MASS SPECTROMETER

R.S. Bordoli, A. R. Woolfitt and R. H. Bateman,
VG ORGANIC, Floats Road, Wythenshawe, Manchester M23 9LZ, U.K.

The micro - electrospray (μ-ESI) interface developed by Mann's group [1] which utilises drawn and gold coated glass capillaries has been shown to have significant advantages over higher flow rate interfaces.

In this presentation we describe the use of fine stainless steel capillaries operating at a flow of 50 nl/minute, which are considerably more robust than drawn glass [1] or ground fused silica [2] capillaries. They are produced by grinding a 25 μm ID x 178 μm OD stainless steel needle to a fine point, with a tip diameter of around 50 - 70 μm.

To take full advantage of magnetic sector instrumentation we have developed a dual spray system for making high precision μ-ESI accurate mass measurements, Figure 1. The sample sprayer, operated at 50 nl/minute, is mounted directly on a syringe, so as to minimise dead volumes. The second sprayer, containing the mass reference, in this case PEG 400 or PEG 600, is operated at 500 nl/minute. The second sprayer is advanced or withdrawn in order to produce mass spectra of the reference or sample material, respectively. Figure 2 shows one measurement on the M^+ ion of rhodamine B, at a resolution of 8000 (10% valley definition), obtained by summing the sample and reference spectra A total of 8 similar measurements were made over a 15 minute period (0 75 μl consumed), yielding an overall RMS error of 1 62 ppm.

A new first field free region gas cell has been designed for use with electrospray, to facilitate more efficient fragmentation of the relatively cold ions It incorporates a much longer collision region to give increased collision frequency, while at the same time giving negligible formation of product ions outside of the cell. This design also has the advantage that there is increased sensitivity towards the low mass part of the spectrum, and better product ion resolution

In order to try to assess the likely performance of the μ-ESI system with precious samples, we have attempted to complete both accurate mass analyses and B/E linked scans during a period of 20 minutes, corresponding to the total consumption of 1 μl of sample at 50 nl/minute The results from the analysis of 1 μl of leucine enkephalin are shown in Figure 3 The RMS error is within 3 ppm, and the linked scan spectrum is characteristic of that obtained using a high energy collision regime The two spectra were obtained using a combined total of 6 pmol in 200 nl, leaving up to 80% of the sample available for optimising the tuning or for other measurements

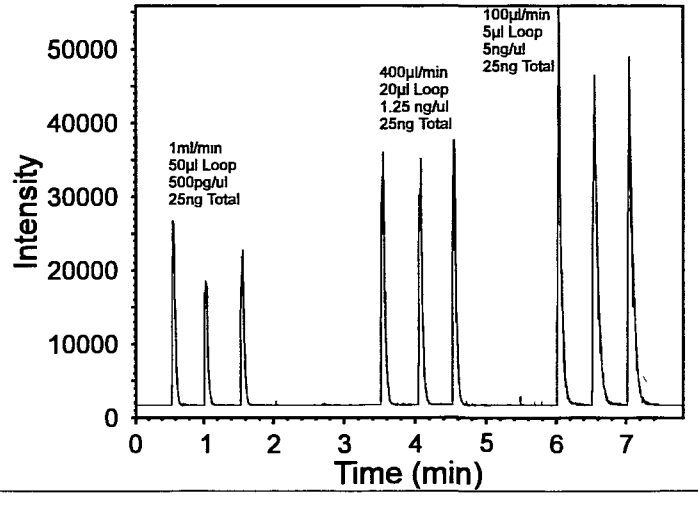
ATMOSPHERIC PRESSURE CHEMICAL IONIZATION BY CORONA DISCHARGE.

B. A. Andrien, T. Dresch, P. J. Haren, C. M. Whitehouse, and S. Shen.
Analytica of Branford Inc., 29 Business Park Dr., Branford, CT 06405.

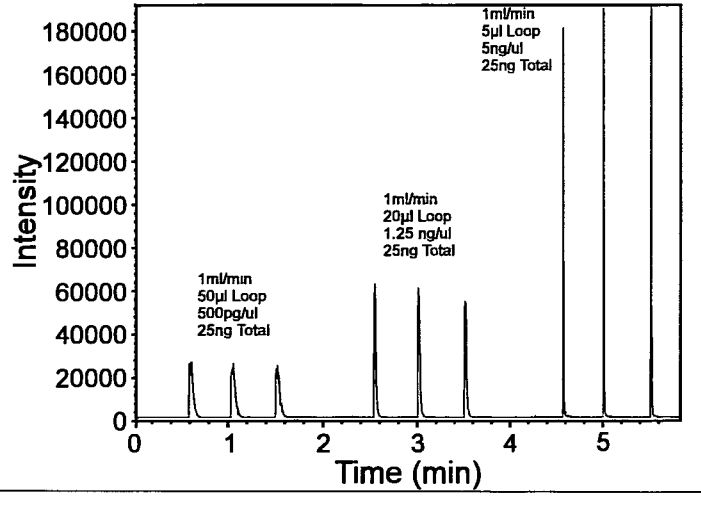
An atmospheric pressure chemical ionization (APCI) source using corona discharge for promoting chemical ionization has been combined with Quadrupoles, Sectors, and time-of-flight (TOF) mass spectrometers (MS). This APCI source uses a pneumatic nebulizer to form droplets of the liquid sample and solvent which are entrained and collimated by the focusing carrier gas. This sample and solvent mixture is then evaporated and vaporized in the APCI heater and is subsequently ionized in the corona discharge region. A portion of the sample and solvent related ions formed in the corona discharge region are focused into the dielectric capillary entrance by high voltages and subsequently swept into vacuum. Some of these ions are accelerated and focused through a series of skimmers, electrostatic lenses and vacuum pumping stages before entering the MS platform. Singly charged compounds from less than 100 daltons to singly charged compounds well over 2000 daltons can be analyzed by APCI. Two examples are, Alanine (90 daltons) and Polyethylene Glycol 2000 (2400 daltons).

SIM and Scan data taken on a Quadrupole (HP5988), Sector (VG ZAB), and TOF (Analytica) mass spectrometer have been analyzed and all found to be linear in peak height and peak area as a function of total mass injected with linear correlation coefficients (r>0.990). The total mass sensitivity limits differ for these platforms by a factor of twenty whereas, the concentration sensitivity limits only vary by a factor of five. This being caused by the scan speed of the MS platform, which requires a larger injection loop size for slower scan speeds. Thus, both the total mass injected along with the concentration need to be compared when evaluating performance of a system.



Signal of Reserpine versus flowrate was obtained by flow injection analysis on all the platforms from 100µl/min to 2ml/min. Each of these sets of data where similar and showed an increased in peak signal with flowrate but a decrease in peak area with flowrate. This flowrate data is ambiguous, however, the ratio of loop size/flowrate was not constant since the same size injection loop was used. To shed some light on this two experiments where performed. Figure 1, shows data at different flowrates but with the same ratio of loop size/flowrate with the same total mass injected. This makes the injection slug pass the corona needle in the same time frame for each flowrate. Thus, it is expected that there is the same gas phase concentration at the corona needle. Both peak height and peak area increase with lower flowrates and higher concentration. This shows for a fix scan speed that better sensitivity can be achieved with smaller loop sizes and higher concentrations.

Figure 2, show data at 1ml/min but with different loop sizes with the same total mass injected. This makes the injection slug pass the corona needle in a different time frame for each loop. Both peak height and peak area increase with lower loop sizes and higher concentration. This also shows for a fixed scan speed that better sensitivity can be achieved with smaller loop sizes and higher concentrations. It was also found that loop size is almost linear with peak area and that concentration is linear with peak height. If the system was a mass detector we would expect that the peak area would be constant for each of these injections. Thus, we reconfirm that APCI-MS is a concentration detector. These results suggest that for a given total mass and mass spectrometer scan speed that the best sensitivity that can be obtained is when the highest concentration and smallest loop size is used with the highest flowrate which does not compromise the sampling of the injection peak.



A New Atmospheric Pressure Microwave Induced Plasma Ionization Source for Mass Spectrometry

Mehdi Moini, Ming Xia, Bernhard Hofmann, Anthony Holbert, Kimberly Mathews

Department of Chemistry and Biochemistry, University of Texas at Austin
Austin, TX 78712

Historically, microwave induced plasmas (MIP) have been used in conjunction with spectral or mass analyzers for elemental analysis. More recently, attempts have been made to use the MIP as a soft ionization source for mass spectrometry. The initial examples of the MIP as a soft ionization source for mass spectrometry were accomplished by introducing the sample into the expansion stage of a low pressure plasma. This technique, however, was applicable only to compounds which were gaseous at the plasma pressure, and thus it was not possible to interface these sources with separation techniques such as HPLC. More recently, Shen and Satzger[1] have developed an atmospheric pressure MIP ionization source for mass spectrometry using a new torch design. With this design they were able to observe quasi-molecular and molecular fragment ions of a number of organic vapors as well as an ion pair in aqueous solution. In addition they were able to control the degree of fragmentation by adjusting the microwave power.

Because Shen and Satzger's source was able to desolvate and ionize tetrabutylammonium hydroxide in aqueous solution, it shows promise for the use of MIP as an interface between liquid chromatographic techniques and mass spectrometry. They obtained quasi-molecular peaks with a signal stability of approximately 40% relative standard deviation. Since the primary use of HPLC is the separation of thermally labile and/or non-volatile compounds, in order for MIP to be used as an interface it must be able to desolvate and ionize such compounds intact. This paper presents an improved torch design for atmospheric pressure MIP and demonstrates its use for the quantitative analysis of a number of non-volatile and thermally labile compounds.

The microwave induced plasma (MIP) ionization source consists of three sections, the MIP torch, the MIP cavity, and the vacuum interface. The design of the torch is outlined in Figure 1 The liquid sample passes through the torch in the inner glass capillary and a carrier gas flow (typically at 40 psi) passes through the outer glass capillary. The plasma gas passes through the outer quartz tube. The ceramic tube is positioned so that the sample is introduced into the afterglow region of the plasma.

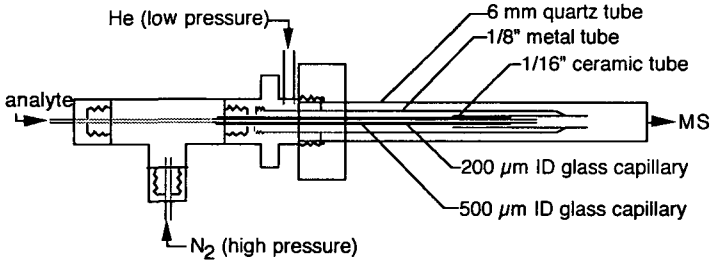


Figure 1. Schematic diagram of the MIP torch.

[1] Shen, W.-L.; Satzger, R. D. *Anal. Chem.*, **1991**, *63*, 1960.

Good sensitivity was obtained for the protonated molecular peaks of all 20 amino acids as well as several other thermally labile and/or non-volatile compounds. The flow rates, solvent composition, and sample types were consistent with those used in HPLC. The stability and reproducibility of this ionization source is sufficient for quantitative study, as is demonstrated by the injection of four consecutive 20 μl aliquots of a 0.1 M lysine solution shown in Figure 2. The spectrum obtained for lysine is shown in Figure 3.

MULTI-VACUUM STAGE MULTIPOLE ION GUIDE FOR ESI/MS INTERFACE

Erol E. Gulcicek, and C. M. Whitehouse
Analytica of Branford, Inc., Branford, CT 06405

A small size hexapole ion guide operated in a Radio Frequency-only (RF-only) mode has been incorporated into an electrospray ion source to interface with variety type of mass spectrometers. The ion guide was especially designed to go through two or three differentially pumped vacuum stages without any interruptions inside the longitudinal dimensions of the rods (ie. without any apertures or cuts in between the stages). In an ESI MS interface, typically, a capillary is used to transfer electrospray generated ions from atmospheric pressures into a viscous flow and/or intermediate flow pressure regions pumped by mechanical pumps. Then, through a series of ion optics in the following high vacuum stages, the ions are accelerated and focused into a final vacuum stage that contains the mass analyzer and the detector. In the present work, we show that an ion guide is used in place of a number of ion optics and skimmers to effectively capture substantial part of the ions emanating from a capillary in a viscous flow/intermediate flow pressure regions and efficiently transfer them inside of a mass analyzer contained in a high vacuum area.

As it will be presented, when an ion guide is used in the present configuration, the focusing, density, intensity, and the kinetic energy distribution of the ions are improved substantially compared to widely used static lens configurations. The main reason for these improvements come from the fact that the ions are entrained inside the ion guide at relatively higher pressures of the gas expansion before they reach free molecular flow pressure region. Since the ions are accelerated directly into a mass analyzer from the ion guide, The kinetic energy of the ions can be controlled to any practical level and can be decreased almost to the thermal kinetic energy levels. This feature is highly desirable for many type of mass analyzers, for it improves the mass resolution of the overall instrument without loosing much of the ion intensity.

Due to its high ion transmission, and tight ion focusing features, typical sensitivity gains for small molecular weight ions, ie.less than 300, have been observed to vary from 10 to 20 over the previous conventional ion optic lens assemblies. The observed sensitivity gains for higher singly and multiply charged molecular weight compounds were between a factor of 2 to 10. Figure 1 shows a three compound mixture mass spectra obtained with static lens and hexapole ion guide configurations under the same experimental conditions on a HP 5989 quadrupole mass spectrometer. The increase in signal sensitivity can be seen in all of the 3 compounds, although it is more pronounced for the 177 amu ion. Similar gains in sensitivity are also seen with other type of mass analyzers. Figure 2 shows not only signal sensitivity improvement for the doubly charged gramicidin S peaks (a factor of 2 to 3 between 3kV spectra), but also improvement of the natural resolution on a JEOL 102 SX magnetic sector instrument with the ion guide configuration. The gramicidin S concentration was 17 pmole/µl in 1:1 MeOH:water. Similarly, FTMS (Bruker Analytical Systems) results also show signal sensitivity improvements with the utilization of the ion guide over the static lens configurations as evidenced from Figure 3.

ION TRANSMISSION THROUGH GLASS AND METAL TUBES.

Jian-Ru Cao, Joan Rosell and John B. Fenn
Virginia Commonwealth University, Richmond, VA 23284-2006

Many electrospray mass spectrometers depend upon tubes of glass [1] or metal [2] for the transfer of ion-bearing gas from the source at atmospheric pressure to the first stage of the vacuum system where pressures range from a few torr to a few millitorr. Lin and Sunner recently presented data on the efficiency of such transfer from corona and electrospray sources with both metal and glass tubes of various dimensions over a wide range of flow conditions [3] We present results from a similar and supplementary study. Early in our work we found that total transmitted current measured with a collecting electrode and a picoammeter as used by Lin and Sunner, did not relate consistently to the ion flux, total or mass selected, measured by the multiplier detector in a triple quadrupole mass spectrometer (Delsi Nermag R3010). Therefore, all results reported here relate to "realistic" conditions in which the tubes performed in their intended roles as conduits for ions from an ES source into a mass analyzer. The MS detector output was taken as the measure of the flux of free ions, whether total or mass selected, entering the mass analyzer from the source via the tube

Three different tubes were used, each mounted in an ES source from Analytica of Branford· (1) A standard glass capillary 18 cm in length with a bore of 0.57 mm, an OD of 6.5 mm and metalized on the outside at each end; (2) A solid metal tube whose dimensions, bore and external shape were identical with those of the glass tube; (3) A typical Chait-type source capillary of stainless steel hypodermic tubing with length and bore the same as for tubes (1) and (2) but with an OD of only 0 8mm Data were collected with all three tubes unheated except by the small flow of hot gas "inhaled" from the bath gas (room air or carbon dioxide) flowing annularly around the tube inlet, counter-current to the flux of charged droplets and ions from the ES injection needle. Data were also obtained with the Chait tube heated but without a counter-current flow of bath gas. Analytes included tetrabutyl ammoniumbromide (TBAB), bovine insulin (INS), and cytochrome C (CYT) at micromolarities respectively of 190, 22 and 2.9 in 50.50 methanol-water which for the protein solutions contained 0 5 % acetic acid All were infused at a flow rate of about 2 uL/min.

The figures shows some examples of the spectra obtained with the cyctochrome C solution. Panels a and b relate to the unheated glass and Chait tubes respectively with desolvation by counter-current gas Panel c is for the Chait tube with desolvation by heating the tube to 493 K. Interesting but not shown were the differences in the mass spectra as the tube temperature rose from 323 K to 493K The abundance of small ions attributable to protonated clusters of solvent molecules decreased markedly as the temperature rose. Not immediately obvious are how those ions were formed and whether this temperature dependence was due to incomplete desolvation in the tube, resolvation during the free jet expansion, or some combination of the two. Somewhat provocative is the absence of any cytochrome C ions except at the high tube temperatures, eventhough some TBA+ ions (due to residual traces of TBAB from runs with that solute) appear at the lowest temperatures Essential results are summarized in the Table The take-home message is that overall the signal strength is about the same for all three tubes when desolvation is effected by a counter-current flow of heated gas The Chait tube provides somewhat less signal when desolvation is by heating alone, without counter-current bath gas.

TABLE OF RESULTS

Tube (Desolv. by)	TBAB Total	TBAB Selected	Insulin Total	Insulin Selected	Cytochrome C Total	Cytochrome C Selected
	Analyte Signal in Megacounts					
Metal (cc CO_2)	10.5	1.38	10.0	1.43	36.0	4.98
Glass (cc CO_2)	7.0	1.20	10.0	1.58	38.0	5.71

Design of a Composite Liquid-Junction/Electrospray Interface for CE/MS

Timothy Wachs, Robin L. Sheppard, and J.D. Henion, Analytical Toxicology, Diagnostic Laboratory, Cornell University, 927 Warren Drive, Ithaca, NY 14850

Coupling a capillary electrophoresis system to an atmospheric pressure ionization mass spectrometer entails challenges that are more demanding than those for coupling an LC system to a mass spectrometer. Of the two "coupling" systems, Olivares' et al. (1) "sheath-flow" interface is generally easier to implement than Lee's et al. (2) "liquid junction" interface. The latter system generally requires a high degree of precision in aligning and spacing the CE capillary and the sprayer capillary. In contrast, the sheath-flow approach can suffer from incomplete mixing of the sheath and analyte leading to ion current instability.

We have developed a simple composite liquid-junction/electrospray interface system for the precise alignment of the capillaries combined with a positive make-up flow. The capillary from the CE instrument and the sprayer capillary are held in a single piece of PEEK tubing, the internal diameter of which matches the outside diameter of the entrance and exit capillaries. Prior to assembly, a notch or "window" is cut half-way into the PEEK tubing. The CE and sprayer capillary are butted together with the junction centered in the window. The PEEK tubing is held in a drilled-out PEEK Tee (Figure 1) with the window aligned with the side-arm of the Tee. When the ferrules are tightened, the capillaries are held tightly and in proper alignment. A continual flow of solvent is added to the side-arm of the Tee, providing a continuous sweep of the junction with the majority of flow exiting the sprayer capillary. This also prevents contamination of the junction solvent while flushing the capillary. With a controlled continuous positive flow, band broadening is minimized and the solvent flow and/or composition can even be varied during a CE run by using a programmable micro LC pump. Because the analyte from the CE capillary is picked up by the flowing make-up, there is less problem with mixing than in the sheath flow interface. The device is used in the electrospray mode thus providing a small and simple interface. Electrical connection is either via the side-arm of the Tee (when fused silica is used for the sprayer) or directly to a metal sprayer capillary.

This interface has been used on both a Sciex API-III mass spectrometer system and on a PE-Sciex API-300 LC/MS/MS system. Figure 2 is a comparison

of the sheath flow and composite interfaces for the chiral separation of terbutaline. Although the sensitivity by infusion of the composite interface is higher than that of the sheath flow interface, the opposite is true in this example. This is probably due to the slightly lower (~5%) resolution in the composite liquid-junction interface. However, the signal-to-noise ratio for the composite liquid-junction interface is better by a factor of 3 to 4 for both the infusion and CE experiments. We attribute this to better mixing which results in better spray stability.

Longer migration times are sometimes reported when using a liquid-junction interface vs. a sheath flow interface. The positive pressure used to deliver the make-up solvent can "push" the analyte backwards in the capillary. Using a Hewlett-Packard model ^{3D}CE system, a pressure of a few millibars was applied to the inlet of the capillary to counteract this flow. The interface has been used to obtain SRM-CE/MS data on low (20-130) femtomole quantities (injected) of beta-agonists extracted from spiked human urine.

The authors acknowledge the generous loan of equipment from Hewlett-Packard Co. and PE-Sciex, Inc. Financial support of PE-Sciex, Inc. and the National Institutes of Health (GM47931) is appreciated. RLS thanks Xerox Corp. for providing this educational opportunity.

A Versatile, Stable CE-ESI Source

Dan Kirby, The Barnett Institute, Northeastern University, Boston, MA

With the increased availability of ESI-MS, the stimulus to interface it with liquid-based separations systems has likewise increased One of most exciting areas of ESI-MS interfacing is that with capillary electrophoresis (CE) and its offer of fast, efficient separations using extremely small sample quantities. Since the first report of CE-ESI-MS interfacing in 1987, many laboratories have contributed to its growth. Numerous reports have discussed interface improvements to overcome difficulties obtaining and maintaining a stable electrospray, especially at low flow rates, to correct poor reproducibility, and to improve sensitivity Use of pointed/tapered capillaries and the need to match liquid sheath tube and capillary geometries have been noted Occasionally in print, but more frequently in conversation, is discussed the fact that sensitivity and stability benefit from, and in many cases demand, correct placement of the capillary within the liquid sheath tube Our experience has been that correct positioning can be determined by (time consuming) trial and error, and once found is satisfactory as long as other experimental parameters are not changed too much.

We have modified two commercial ESI sources to incorporate the above ideas and, most importantly, to permit dynamic adjustment of the capillary with respect to the liquid (and gas) sheath tube(s) during CE-ESI-MS operation In practice this procedure enables one to establish a stable electrospray quickly and reliably over a wide range of flow rates, liquid compositions and component geometries Liquid sheath flows of less than 1uL/min are readily accommodated. Use of this system permits one to choose experimental parameters, such as capillary and liquid sheath flow rates, liquid sheath composition, and others, and then adjust the capillary position to achieve stability As a result, one is able to choose experimental parameters independently of stability requirements (we had often been forced to use liquid sheath flow rate to achieve stability) and, for example, optimize peak efficiency or sensitivity through optimal choice of liquid sheath flow rate

Figure 1 shows examples of electrospray instabilities often encountered in CE-MS· periodic "dropouts", where ESI and MS ion current are momentarily lost, and high noise in the MS ion current Both of these instabilities are reduced or eliminated by adjustment of the capillary position while observing, for example, the total ion current In practice one can chose experimental parameters, such as liquid sheath flow rate, then use capillary adjustment to stabilize the system Figure 2 shows the effect of liquid sheath flow rate on separation sensitivity and efficiency In general we have found that increased liquid sheath flow results in improved peak efficiency but increased S/N because of the dilution effect of the sheath liquid

CE-MS Instabilty Problems

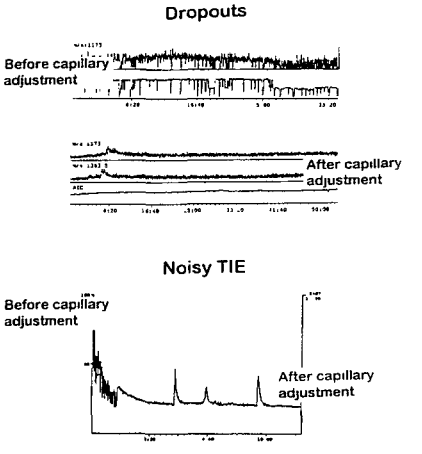

Figure 1. Examples of instabilities often encountered in CE-MS. Both have been corrected with very minor adjustment of the CE capillary with respect to the liquid sheath tube Efffective adjustments are often as small as 10-20μM.

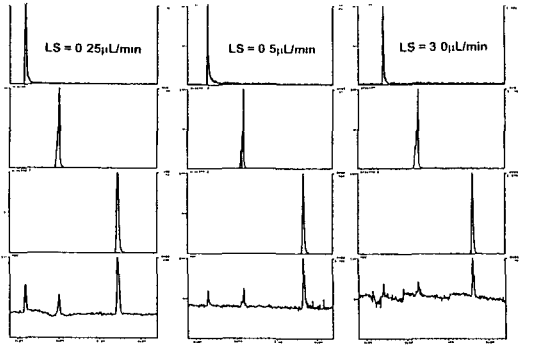

Figure 2. CE-MS analysis of a mixture of peptides with varying liquid sheath flow rates **Capillary:** 34cm x 285μM O D x 50μM I.D with a neutral coating, **Liquid sheath tube:** 24 gauge needle; **Buffer:** 20mM e-amino caproic acid, pH 4.5; **Liquid sheath:** 25-75-0.1:H_2O-MeOH-HAc, **Sample:** KRTLRR, Substance P [1-4] and Substance P [1-9], 100pM/μL each

REAL TIME UV DETECTION WITH ON-LINE CE-ESI-MS

F. Foret*, O. Mueller, W. Goetzinger, J. Thorne, B.L. Karger, P. Vouros and D.P. Kirby.
Barnett Institute, Northeastern University, Boston, MA 02115.

Coupling of capillary electrophoresis (CE) to electrospray mass spectrometry (ESI-MS) is one of the most powerful separation techniques for analysis of biologically important mixtures. In developing a CE-ESI-MS separation, one typically optimizes off-line the CE operational parameters (buffer composition, field strength, sample injection, etc.) without tying up the mass spectrometer. Most CE-ESI-MS systems do not include an optical detector since this addition usually requires increased capillary length resulting in long analysis times. Furthermore, when the detector is located relatively far from the ESI interface only limited information about separated species exiting the capillary can be obtained. Hence, there can be an uncertainty involved in transferring an off-line separation to on-line CE-ESI-MS. Also, since many important ions contain a chromophore or fluorophore, optical detection may be more sensitive than ESI-MS detection in the scanning mode. Hence, simultaneous use of optical detection close to the ESI interface can facilitate on-line CE-ESI-MS analysis. First, the presence of a real time optical signal permits rapid troubleshooting of applications that have been developed off-line. The presence (or absence) of an optical signal just prior to migration into the MS quickly differentiates CE or MS related problems. Next, precise knowledge of the exit times of low concentrated species, visible to optical detection but not in the total ion current, allows one the ability to locate the relevant MS information. Finally, simultaneous optical detection can provide additional, useful information about migration of the sample matrix ions as well as the presence of disturbances due to electroosmosis, hydrodynamic flows and/or migration of ionic boundaries.

In this work we have constructed and evaluated a miniaturized integrated CE-UV-ESI interface. Mass spectrometry was done with a TSQ 700 (Finnigan MAT, San Jose, CA). The original electrospray interface was removed and substituted with a laboratory built interface for capillary electrophoresis. The interface operated in the liquid sheath flow mode [1], with an optional gas sheath [2]. The scheme of the interface is in Fig. 1. The CE as well as the ESI high voltage power supplies were connected through the sheath liquid tube. The position of the CE capillary was adjustable with respect to both the electrospray tip and the fiber optic detection cell. The position of the detection point close to the capillary exit was achieved using a fiber optic-based UV detector. The performance of the interface was evaluated in separations of proteins, peptides and nucleotides in both zone electrophoresis and isoelectric focusing mode.

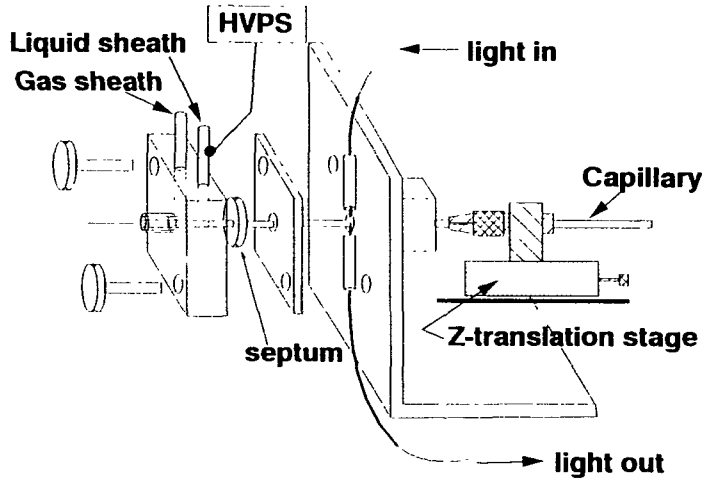

Figure 1.
The scheme of the CE-ESI interface.

Advanced Liquid Ionization Mass Spectrometry for Analysis of a Mixture

Masayuki Inoue, Takeo Kaneko, Li Yaming, Masahiko Tsuchiya, *Niwa Yoshio
Yokohama National University, Tokiwadai, Hodogaya, Yokohama, 240, Japan
*National Institute of Material and Chemical Research, Tsukuba, 305, Japan

Although polar compounds are easy to measure by soft ionization techniques, it is not to measure a mixture containing less polar compounds and rather hard job for ordinary chemists to select a solvent and an adequate chromatographic column for analysis of an unknown sample.

Liquid Ionization (LI) mass spectrometry 1,2], a kind of atmospheric pressure ionization, is applicable to analysis of a mixture containing either polar or non polar compounds. Therefore, LI ion source is complementary for ESI and APCI. Several improvements were performed to improve the reproducibility and sensitivity of the LI method. Those are;

1) use of Teflon coated sample holder for ionizing a sample effectively, 2)use of computer-controlled temperature programming for better separation of analytes, 3) use of matrix (referred to as vapor-matrix) continuously supplied through a vapor phase, 4) devices for introducing a liquid for measuring clusters.

Use of a needle (sample holder) coated by thin Teflon film, except its very sharp end, gives much better reproducibility and sensitivity to the to the LI method.Since a sample is concentrated on the needle tip, the sample loaded can be ionized with much higher efficiency than before.

It was confirmed that the temperature at which the desorption of MH^+ ions begins is characteristic of each compound and almost constant, regardless of heating rate. The computer controlled power supply is useful for adequate temperature programming for the analytes. The desorption profiles (selected ion profile) of characteristic ions give useful information about separation and thermal property of analytes.

Vapor-matrix introduction technique is very useful to analyze a mixture and observe MH^+ of analytes with high desorption temperature, because matrix molecules are continuously supplied to disperse analyte molecules up to the end of the experiment.

Chemical reactions occurred in solution are observed by LI method. Figure 1 shows LI mass spectra of an aqueous solution of paraformaldehydes mixed with methanol (1:1 by volume). The spectra were measured 5 min after mixing. Top of Fig.1 shows total ion profile, in which abscissa indicate scan numbers, corresponding to temperature. The temperature of the sample was ambient up to scan No.15 and increased almost linearly. Protonated polyoxymethylene glycol, $HO(CH_2O)_nH(H_2O)_mH^+$ (refer to as $A_nW_mH^+$) desorb at about 40-80 C (scan No.17-26) as shown in Fig.1 (bottom right). LI mass spectrum (bottom left) observed at ambient temperature (scan No. 1-10) indicate that protonated monomethyl ether oligomers, $CH_3O(CH_2O)_nH(H_2O)_mH^+$ were produced soon after mixing. About 15 min after mixing, almost no polyoxymethylene glycol oligomers remained in the solution.

Collision induced fragmentation is useful. In the case of ZDTP, fragment peaks corresponding to the successive loss of alkyl groups appeared as shown in Fig.2. These peaks were unable to observe by FAB and ESI.

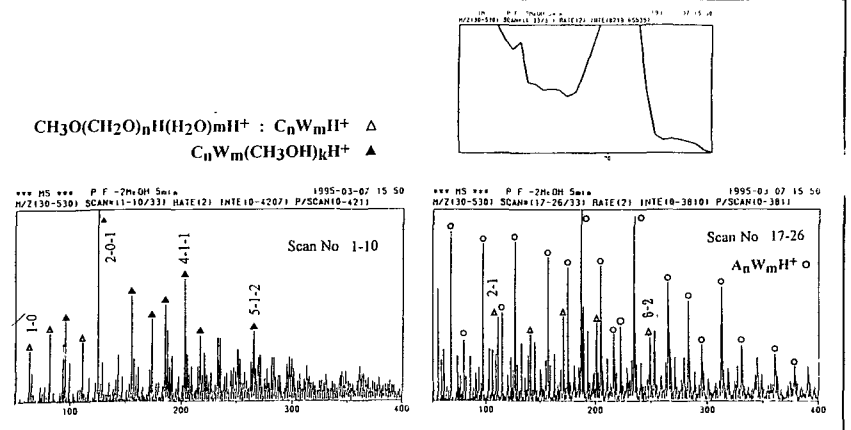

Fig.1 LI mass spectra of an aqueous solution of paraformaldehydes mixed with methanol (1:1 by volume), measured 5 min after mixing.

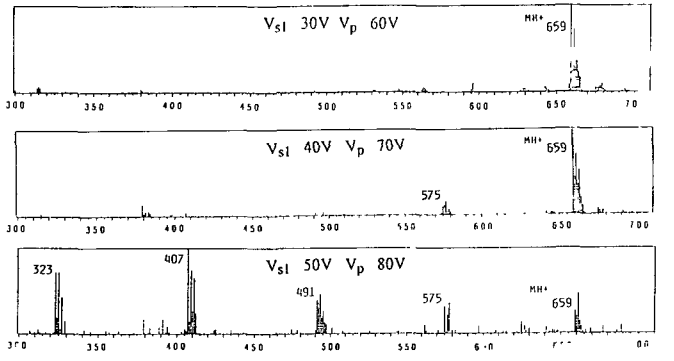

Fig.2 CID (Collision-Induced Dissociation) occurs between Skimmer-1 and Skimmer-2. Fragment peaks correspond to the successive loss of alkyl groups (C6H12 = 84). These disociation is novel in comparison with other ionization method.

ELECTRIC EVAPORATION OF IONS FROM LIQUID IN CHANNELS OF POLYMER FILM

A.A.Balakin, A.F.Dodonov, L.I.Novikova, V.L.Talrose, B.S.Yakovlev†
(†Deceased May 19, 1993)
Institute of Energy Problems of Chemical Physics, Russian Academy of Sciences, Moscow, Russia

In spite of the attractive feature, the method of electric evaporation of ions from molecular liquids (EHDI) [1] has not been developed as well as thermospray or electrospray methods. Recently a new method of ion extraction from liquids was proposed by B S.Yakovlev, V.L Talrose et al.[2,3] The method uses polymer films densily perforated with channels as an interface between a solution at atmospheric pressure and a vacuum chamber of MS A goal of the present report is elucidation of the main physical processes driving work of the membrane ion source

For a liquid with adequate conductance the stability of the surface in an external electric field is determined by the Rayleigh criterion [4] The estimation for glycerol shows that the radius of capillary needle used in EHDI is too large to prevent destruction of the surface of a liquid by electric field strange $>10^6$ V/cm. To provide stability for a liquid surface at p=1 atm, and $E \approx 10^6$ V/cm one would need for glycerol a capillary with radius < 0,1 μm Many difficulties creating by this requirement overcame by using a system of thin channels in a polymer film The channels have much lower radii than those used in EHDI, nevertheless their number provides a huge ion current from the liquid [5]

The membrane investigated in present work· a) prevents air flow into the MS vacuum chamber, b) provides ion transport to liquid/vacuum boundary, c) makes conditions for ion extraction

Major questions are 1) what physical processes do control the operation of membrane ion source? 2) what of primary charge particles are extracted from the liquid?

Methods. A liquid sample is placed on the atmospheric side of nonconductive polymer film. The 10 μm thick film contains multiple narrow channels To create the electric field two electrodes are used. The one is sunk in the liquid and the other is placed in vacuum in form of a grid. The distance between vacuum side of membrane and the extracting grid was 0,3÷3 mm The channels density was about 10^7 cm^{-2} They were made by irradiation poly (ethylene terephthalate) film by high energy Xe ions with a special chemically treatment of tracks [6]

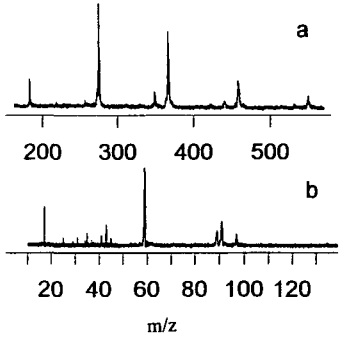

Fig 1

The Dodonov's orthogonal ion optics [7] was used to MS measurements The TOF MS device was supplied with the membrane ion source, which is similar in physical arrangement to the one described in [3,5]

RESULTS. The degree of fragmentation in spectra obtained depends on variation of potential difference between liquid and the accumulator. Fig 1a shows the mass spectra obtained from glycerol when MS indicates particles which have the maximal energy There are cluster ions in this case only. The energy dependence for intensity of mass picks observed for "pure" glycerol is shown in fig 2 Fig 1b shows mass spectra of ions with the energy less than that corresponding to potential difference between liquid and accumulator of MS. In this case, declustered ions can be observed as well as clusters and their fragments.

DISCUSSION

What conditions do provide of ion extraction? The channel filling of conducting liquid is like to a very sharp

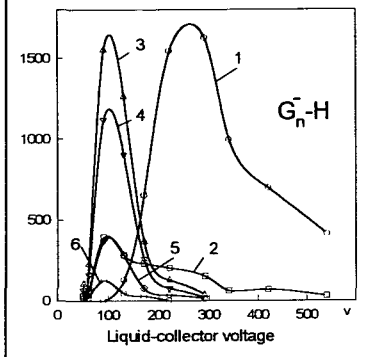

Fig 2

needle in insulating polymer, if the surface density of channels is low enough. So the localelectric field strange at liquid surface of membrane used is significantly higher than U/d, were U is extracting voltage, d is the liquid-extracting grid distance

The choice of channel radius affords the implementation of the Rayleigh criterion

The transport of ions The voltage drop across the channels of the membrane is equal to $\Delta U_{channel} = U_{liquid} - U_0$ where U_{liquid} is potential supplied to the liquid sample, U_0 is collector potential corresponding to appearance of current in the accumulator of MS It was shown that the electric field strange in channel is about $10^4 \div 10^5$ V/cm at film thickness about 10 μm The electric field helps ions to enter from sample the channels and clears the channels from ions of other sign

The nature of charge particles extracted. The ions extracted are formed due to dissociation of molecules of solvent and solute, considered as a subject of chemical analysis. The energy of ions extracted from liquid is equal to $\varepsilon = e\,(U_{liquid} - U_{collector} - \Delta U_{channel})$ were $U_{collector}$ is the potential of collector

The gas pressure in vacuum chamber of MS was too low to promote dissociation of ions by gas phase collision Therefor one can anticipate that the particles extracted from liquid have the energy distribution $\sim k_B T$ As one can see, the energy distributions all of ions observed are appreciably broader then the energy resolution of MS (~5 eV) The ions with n equal to zero or one are observed only if the energy of particles entering the accumulator is more than that for ions detected by MS Those ions are detected probably after collisions of primary ions with electrodes of the accumulator [5]

CONCLUSIONS. The electric evaporation of ions from liquid in channels of polymer film is controled by many physical processes, the main from which are . a) the emission from liquid, b) the ions transport through channels, c) the way of a strong electric field formation

The possibilities of investigation of particles extracted from liquid were demonstrated by analysis of energy distribution of ions detected

It was shown that the cluster ions only are extracted from solutions expected.

Acknowlegment. The research was suppored by the grant N95-03-09083 of Russian Basic Reseaches Foudation.

MOLECULAR WEIGHT ENHANCEMENT IN GC-MS WITH SUPERSONIC MOLECULAR BEAMS

Shai Dagan and Aviv Amirav
School of Chemistry, Tel Aviv University, Tel Aviv 69978, Israel, Fax: 972-3-6409293

Supersonic molecular beams are characterized by the supercooling of the molecular vibrational temperature, a controlled unidirectional kinetic energy in the hyperthermal range (0.1-30 eV) and a high flow atmospheric pressure sample inlet with optimal jet separation capability. The vibrational supercooling induces a considerable enhancement in the relative abundance of the molecular weight peak under 70 eV electron impact (EI) ionization, combined with tail free GC-MS traces, regardless of the sample volatility.

The elimination of the intramolecular thermal energy makes the electron energy the only parameter that governs the degree of ion dissociation. Therefore, at reduced electron energies such as 18 eV, the molecular weight peak in n-alkanes and in many other compounds, is the dominant mass spectral peak, being higher by more than a factor of 10 than any other peak. Due to the diminished fragmentation, the sensitivity reduction at reduced electron energies is minimal. Improved library search is achieved with 70 eV EI-MS in SMB by limiting the search using the molecular weight peak information, while ignoring its intensity. EI-SMB provides EI and chemical ionization (CI) information simultaneously, as well as accurate isotopic and elemental information, taken from the peak height ratios of the M, (M+1), (M+2) ions.

In the rare cases where the M^+ peak is missing, a unique Cluster CI can be employed. It is based on the co-expansion of methanol (or water) vapor and the sample molecule, forming clusters of the sample molecule with few methanol molecules. The EI ionization of the cluster is followed by energy removal through cluster desolvation and intra cluster proton transfer to form a protonated molecular ion. This method is demonstrated with aldicarb sulfone as shown in figure 1. The addition of deuterated methanol (or heavy water) to the supersonic expansion induces an effective deuterium exchange of all the labile OH and NH hydrogens. In this routine mode of EI-SMB, in contrast to conventional CI, the EI fragmentation pattern contains labile hydrogen information as shown in figure 2 for 17-β-estradiol. Note also the dominant M^+ peak in this 70 eV EI mass spectrum of 17-β-estradiol.

An additional ionization method used with SMB is Hyperthermal Surface Ionization (HSI). The hyperthermal sample molecules are ionized through scattering from a suitable surface such as rhenium oxide. HSI is an ultra sensitive ionization method, providing sub-femtogram detection limits. It is also a tunable selective method for molecules with low ionization potential,

such as the polycyclic aromatic hydrocarbons (PAH's) (exhibiting mass spectra with a molecular peak only in HSI), or nitrogen containing molecules. HSI is selective against aliphatic hydrocarbons, a fact that helps in the GC-MS analysis of complex mixtures such as screening of drugs in urine. This selectivity is achieved by reducing the molecular kinetic energy using helium as a carrier gas. At this low kinetic energy, HSI becomes a soft ionization method.

SOFT IONIZATION VIA ELECTRON IMPACT ON FREE-JET CLUSTERS

Dingneng Wang and Robert J. Evans
National Renewable Energy Laboratory, 1617 Cole Boulevard, Golden, CO 80401

The combination of a molecular beam sampling source with mass spectrometric detection provides a versatile tool for studies of high temperature processes to produce renewable energy resources, such as pyrolysis, gasification and the combustion of biomass.[1] Among the many advantages of molecular beam mass spectrometry (MBMS) is its ability to detect a wide range of products simultaneously, rapidly and in real time. Even fragile species can be detected because of the extensive cooling as a result of the supersonic free-jet expansion during the molecular beam formation. However, the popular configuration of using an electron-impact ionization source makes it difficult to obtain molecular ion information for pyrolysis products of carbohydrates, which are an important component of biomass. For example, only a weak molecular ion ($M^{+\cdot}$) peak is observed for levoglucosan with low energy EI ionization using the MBMS instrument, while no $M^{+\cdot}$ signal is found in its 70 eV library spectrum.

We have developed a novel technique to achieve soft ionization in a molecular beam mass spectrometer (MBMS), ensuing a conceptual discussion at a recent MBMS meeting.[2] It employs the cluster formation ability of a molecular beam source, and the local high density (or pressure) within clusters provides an ideal environment for intramolecular chemical ionization as well as the release of excess energy on ionization. We report some preliminary results in this paper and compare this technique with other common soft ionization techniques

Experimentally, this soft ionization technique involves the following procedure The gaseous sample or a stream of product vapors is mixed with a helium carrier gas and a clustering agent such as water or methanol in a heat-traced zone at atmospheric pressure. The gaseous mixture is then extracted through an orifice into three consecutive vacuum stages. During the supersonic, free-jet expansion, a molecular beam is formed that contains a series of clusters of the analyte molecule (M) with the agent molecules (A), MA_n, n=1,2,3,.. The molecular beam enters the electron impact (EI) ionization region of a triple quadruple mass analyzer, where the clusters, MA_n, are ionized to produce positive ions. The mass spectrum of the analyte contains not only an enhanced molecular ion ($M^{+\cdot}$) peak, but also intense signals for MH^+, $MA_{n-i}^{+\cdot}$, and $MA_{n-j}H^+$ (i,j=0,1,2,.. ,n-1).

$$M + nA \xrightarrow[\text{clustering}]{\text{free-jet}} MA_n \xrightarrow[e^-]{\text{EI}} MA_i^{+\cdot} \;\&\; MA_jH^+$$

Shown in Figure 1 are mass spectra obtained for levoglucosan with MeOH, H_2O and D_2O as clustering agents There is more than an order of magnitude enhancement in the formation of the molecular ion and cluster ions that contain the intact molecule. The ionization of free-jet clusters leads to the enhanced formation of molecular ion products but at the low operating pressure of the EI source, which is about five orders of magnitude lower than that required for chemical ionization in a quadrupole mass spectrometer. Fragment ions are still observed but the extent of fragmentation is reduced because of the free-jet cooling and the removal of energy from the ionized cluster by boiling off molecules of the clustering agent. In addition, facile H/D exchanges occur prior to detection with D_2O as the agent, thus revealing the number of hydroxyl groups present in the molecule (a shift of four amu for levoglucosan, which has three HO groups) Where the H/D exchange takes place is unclear H/D exchanges both before and after ionization are likely to occur

The mass spectra of ionized free-jet clusters are further simplified, but at the expense of reduced sensitivity, by carrying out collision-induced dissociation (CID) experiments in the neutral-loss (NL) mode.

Only product ions that lose a molecule of the clustering agent are detected, thus filtering out almost all the fragment ions of any remaining unclustered analyte molecules Figure 2 shows such mass spectra of levoglucosan, glycerol, and a mixture of aromatic compounds, demonstrating the selectivity for detecting molecular ions of polar species. We are examining the effects of experimental parameters, including clustering agent type, partial pressure, temperature, orifice shape and size, ionization energy, and collision energy to achieve optimum sensitivity. Applications of both techniques to the analysis of products derived from pyrolysis of lignocellulosic materials are also under investigation

Concentration Enrichment in High Pressure Ion Sources, Part II.

D. H. Williamson, W. B. Knighton and E. P. Grimsrud,
Department of Chemistry, Montana State University, Bozeman, MT, 59717

INTRODUCTION

The pulsed high pressure mass spectrometry technique has proven to be the most successful method available for the measurement of ion-molecule equilibria in the gas phase and has also been extensively used for the determination of rate constants for ion-molecule reactions (1). The accuracy of the measurements obtained with this or other techniques which use mass spectrometry to sample a high pressure gas depends on the validity of two assumptions:

1. The relative ion abundances measured by the mass spectrometer must accurately reflect the actual ion abundances present within the ion source. Accurate ion sampling typically demands the use of very small ion sampling orifices which provide near molecular flow conditions (1).

2. The concentrations of the neutral reagents within the ion source must also be known.

The use of molecular flow conditions, however, can lead to a concentration enrichment of the heavier reagent neutrals within the ion source due to mass dependent ventilation rates of the ion source contents through the ion source orifices (2). Thus, a contradiction between the two criteria for accurate measurements appears to exist, since conditions that satisfy one of the criteria seem to violate the other. In a previous study (2) we characterized the effect that near molecular flow conditions had on the observed rate constant measurements of the S_N2 nucleophilic displacement reaction,

$$F^- + CH_3I \rightarrow I^- + CH_3F \qquad (1)$$

In the present study, we examine the use of viscous or near viscous flow conditions on the same kinetic system. It will be shown that certain combinations of source pressure and aperture size provide accurate rate constant determinations of Reaction 1 The effect of employing viscous or near viscous flow conditions on association equilibria measurements will also be discussed.

INSTRUMENTATION

All the measurements reported here were obtained using a pulsed e-beam high pressure mass spectrometer (PHPMS) which was constructed in our lab. This instrument consists of two major component systems a gas handling plant and a mass spectrometer Gas samples were prepared in CH_4. The total pressure of the gas mixture was typically 800 torr The contents of the GHP were leaked into the ion source at a rate sufficient to maintain source pressures from 0.5 to 8 Torr. The mass spectrometer consists of a commercial quadrupole instrument equipped with a specialized high pressure ion source. A unique feature of this ion source is that its contents exit solely through the ion exit and electron entrance apertures. In this study, two sets of apertures having diameters of 150 μm and 200 μm were used. Negative ions formed within the ion source were monitored by a quadrupole mass filter and an ion counting detector. The time-dependence of each ion signal was recorded with a multichannel scaler.

ION SOURCE FLOW DYNAMICS

The nature of the flow of a gas through an aperture can be estimated by calculating the ratio of the mean free path of the gas (L_a) to the critical dimension (a) of the aperture as follows (3): $L_a/a > 1.0$ molecular flow; $0.01 > L_a/a < 1.0$ transition region; $L_a/a < 01$ viscous flow. Figure 1 shows a plot of L_a/a versus ion source pressure where the term, a, corresponds to the aperture radius and L_a is the mean free path of either the CH_4 buffer gas or the CH_3I minor component. The L_a/a values for CH_3I are included in Figure 1 because previously (2), this quantity was found to be a better indicator of the nature

of the flow out of the ion source. Regardless of which series of L_a/a values are considered, the flow conditions within the ion source are clearly in the transition region over the pressure range of 1 to 10 torr.

RATE CONSTANT MEASUREMENTS

Figure 2 shows a plot of the apparent rate constants for the reaction of F^- with CH_3I at 150°C over the pressure range of 0.5 - 8.0 torr. At low pressures, 2 torr and below, the apparent rate constants increase significantly with decreasing pressure. This effect is attributed to the concentration enrichment phenomena which occurs as molecular flow conditions are approached. Also shown in Figure 5 is the limiting value of the rate constant expected under pure molecular flow conditions where $k_{obs} = k(M_{CH3I}/M_{CH4})^{1/2}$. However, at higher ion source pressures the rate constants determined here become less pressure dependent and essentially equal to the known value of the rate constant.

CONCLUSIONS

Accurate kinetic measurements can be obtained with the use of large ion sampling apertures when near viscous flow conditions exist within the ion source. This success is attributed to the elimination of the concentration enrichment phenomena by providing convective flow of the contents out of the ion source. No problems associated with convective flow of gas through the relatively large apertures (Point 1 - Introduction) were observed. We do not, however, recommend performing cluster equilibria measurements under viscous flow conditions. This is because of the potential for increased cluster growth which can result from the cooling of the gas as it expands through the ion exit aperture. This effect can be quite significant and has been previously documented in a PHPMS ion source (1).

Using a Portable Mass Spectrometer to Measure Surface Contamination

Hugh Gregg, Michael Meltzer, Jean Lindsey, and Heather Edberg
Lawrence Livermore National Laboratory, PO Box 808, L-310, Livermore, CA 94550

One of the major sources of hazardous waste and VOC air emissions throughout the manufacturing industry is parts and equipment cleaning operations. Modification of the cleaning process to use non-hazardous cleaning agents may be the best way to eliminate these sources, but some operations still require the use hazardous solvents. Monitoring the contamination levels during cleaning operations can provide useful feedback for reducing waste generation and air emissions due to over- or under-cleaning. Near real-time evaluation of cleaning operations can help reduce pollution in a wide variety of industries, including aerospace, electronics, and metal finishing industries.

Two common techniques for the verification of cleanliness include the water break test (very crude and subjective), and non-volatile residue (NVR) analysis. NVR analysis utilizes solvents (freon, 1,1,1-trichloro-ethane) to further "clean" the surface; the solvent is flash evaporated and the residue weighed. NVR analysis is quantitative, but is dependent on the sampling solvent being able to remove the expected contaminant. In addition to NVR, a number of instrumental methods are commonly used to measure surface contamination, including ellipsometry and FTIR. These techniques are sensitive to the surface conditions (smooth or rough?) and composition (aluminum, quartz, other?), and can be difficult to calibrate.

We have developed a mass spectrometry based analyzer that has similar or better sensitivity than ellipsometry or FTIR and is more tolerant of surface conditions and composition. In addition, the instrument is relatively portable and can be used to help identify unknown surface contamination. Our method uses vacuum and thermal desorption to remove volatile and semi-volatile contaminants from the surface. A quadrupole mass spectrometer is used to identify and measure the contamination. A bench-scale model of our "contamination analysis unit" employs a residual gas analyzer (RGA) mated to a small, internally heated inlet that samples a surface.

The current version of the instrument has the following features:

- ~7 cm^2 sampling surface with a Viton O-ring seal (maximum temperature of 240°C)
- resistance heater (constant temperature ramp, maximum rate 1.4°C/sec)
- spring loaded thermocouple in contact with surface
- residual gas analyzer (quadrupole mass spectrometer) with an open ion source, 1 to 200 dalton mass range and both a Faraday cup and an electron multiplier
- LabView control of the RGA, heater, and thermocouple

Trimsol, a machine tool coolant, was the contaminant used in these tests. Test coupons (aluminum) were cleaned with methylene chloride and baked in a vacuum oven at 150°C for two hours. Trimsol was brushed onto the surface and wiped off. The cleaning solutions were prepared according to the manufacturer's specifications. The coupons were cleaned in an ultrasonic bath for five minutes, then were washed twice with deionized water. Air drying completed the test coupon preparation. Coupons used for calibration were cleaned, and spotted with a known amount of Trimsol diluted in methylene chloride, and allowed to air dry.

The intensity at three m/z values (95, 97, 109), characteristic of Trimsol, were recorded as the temperature was ramped from ambient to 230°C. The area under an intensity vs. temperature curve was integrated from 65°C to 225°C, and this integrated value provided the basis for quantitation.

Several aqueous based cleaners were obtained from our waste minimization group, and they all produced excellent results. Freon TE is a common degreaser used in industry, and is presented here as a baseline cleaning product. The CO_2 cleaned samples were "CO_2 blasted" (similar to sandblasting) using CO_2 pellets (~2 to 4 mm) and snow (~0.5 to 1 mm).

Cleaning solvent /method	µg Trimsol	µg/cm² Trimsol
Brulin 1793	< 4.	< 0.6
Brulin 1990GD	< 4.	< 0.6
CitriSafe	< 4.	< 0.6
Hurisafe	< 4.	< 0.6
JALSAC	< 4.	< 0.6
Brulin 815GD	4.3 ± 1.6	0.6 ± 0.2
Freon TE	5.1 ± 1.9	0.7 ± 0.3
CO_2 pellet	14. ± 1	2. ± 0.1
CO_2 snow	120. ± 2	17. ± 0.3
4.5 µg check sample	4.0 ± 0.6	0.6 ± 0.1

One of our goals is to travel to an assembly line (e.g. for aircraft components) and measure parts before and after cleaning operations. While the work to date proves that this method works, there are three aspects of this technique that we hope to improve.

1) Increase the sensitivity of the instrument
   a) Change the open ion source to a closed ion source, creating a higher pressure region in the new source
   b) Make a smaller sample interface which is directly coupled to the closed source

2) Make the instrument more portable
   a) Smaller pumping system
   b) More compact control system

3) Incorporate better data analysis methods
   a) Acquire full scan mass spectra (vs. selected ions)
   b) Create a library of common contaminants
   c) Identify and deconvolute multiple contaminants

Conclusions

The system, as currently configured, has comparable performance to an FTIR. It is not a universal tool for measuring surface contamination (some surfaces cannot be heated up to 200°C; non-volatile contaminants cannot be desorbed), but it can be used in a wide variety of applications not suitable to ellipsometry or FTIR analysis. With the modifications outlined above, the instrument should be more sensitive, allowing for the determination of smaller amounts of surface contaminants.

Heather Edberg is now attending the University of Washington.

Work performed under the auspices of the U. S. Department of Energy by the Lawrence Livermore National Laboratory under contract W-7405-ENG-48.

Conversion of HP 5985 GCMS to Automated, High-Volume ESMS

Jennifer Kiesel, Alan Jackson, Kevin Depperman, Fred Hileman, Kevin Duffin
Monsanto Corporate Research, Monsanto Company
700 Chesterfield Parkway North, St Louis, Missouri 63198

INTRODUCTION

A retired Hewlett-Packard 5985 gas chromatograph/mass spectrometer (GC/MS) was modified to operate as an electrospray mass spectrometer (ESMS) The gas chromatograph was removed and a new ionization source was fabricated to replace the existing electron ionization (EI) source The mass spectrometer has a mass range of 1,000 amu and can be operated in the positive or negative ion mode For the past two years this system has been used for routine structural confirmation of synthetic, pharmaceutical samples

A PC-based Teknivent data system was incorporated to 1) enhance instrument control and consequently performance, 2) control satellite liquid chromatography (LC) and flow injection autosamplers (AS) resulting in increased sample throughput, and 3) automate data acquisition and processing to reduce operator-instrument interaction

To enhance instrument sensitivity, conversion from a high-energy dynode multiplier to a pulse-counting multiplier was done

INSTRUMENT CONFIGURATION

Mass Spectrometer HP 5985 Quadrupole Mass Spectrometer, Electrospray Ionization (ESI), Pulse-counting multiplier

Data System Teknivent - Vector Two Version 2.02.02

Computer 486 IBM Compatible, 32 MB RAM, 200 MB Hard Drive
IEEE-488 Instrument Interface

Operating System IBM OS-2 Version 2.1, Multitasking, Windows User Interface, Local area network (OS-2 LAN Server) with additional instruments to permit remote data processing.

Instrument Interface The data system and interface provide digital control of all instrument functions This permits real time computer driven manipulation of selected ion focus elements even during a scan.

CONCLUSIONS

Good sensitivity
Detection limits of approximately 500 pg/ul for reserpine in the positive ion mode with the pulse-counting multiplier Detection limits of approximately 5 ng/ul for adenosine triphosphate in the negative ion mode with the pulse-counting multiplier. Noticeable sensitivity improvement, particularly in the negative ion mode, with the pulse-counting multiplier vs. the HED multiplier

Degree of fragmentation can be controlled
The potential between the capillary and the skimmer is variable. Higher values induce the formation of fragment ions which becomes useful in structure elucidation. Lower values enhance formation of intact molecular ions for molecular weight determination of compounds in solution. This is particularly good for mixtures, because it provides semi-quantitative data based on relative ion count intensities

Easy to use
Data system can be tailored to run multiple vendor instrumentation which lends itself to networking and remote data retrieval and reporting. Operator training is minimized due to universally applied software.

Autosampler increases sample throughput and reduces redundant, manual operator tasks ESI useful for a wide variety of compounds in pharmaceutical research. The upgrades are cost effective.

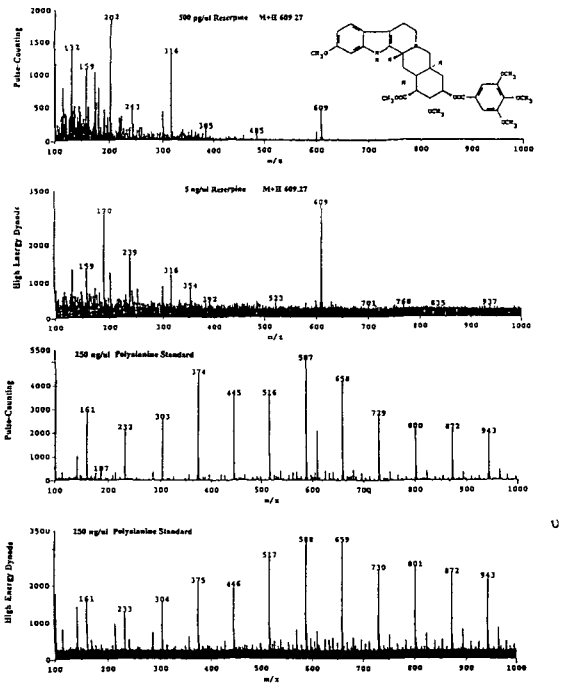
Positive Ion Mode Detection Limits for Pulse-Counting and High-Energy Dynode Multipliers



Improving Sensitivity in the H.P. MSD Mass Spectrometers

John J. Manura
Scientific Instrument Services, Inc., 1027 Old York Road, Ringoes, NJ 08551

The H.P. MSD instruments (Models 5970, 5971 and 5972) have proven to be very efficient, low cost, highly sensitive and versatile mass spectrometers. Sensitivity in the MSD's can be improved by decreasing the background or noise level, increasing the sensitivity of the mass spec or detector or by improving the resolution of the GC peak for the analyte of interest. The 5971 MSD sensitivity has increased at least 10 fold by incorporating the improvements in the GC and the MSD as described below.

GC/MS Transfer Line

In the standard GC/MS transfer line on the HP 5971, the GC capillary column bottoms out inside the transfer line tip inside the MSD source. The GC column flow elutes at 90° to the normal GC flow. This design does not provide for an efficient straight through flow of the GC effluent into the MSD source and the analytes eluting off the GC capillary column are exposed to hot metal surface. A straight through transfer line tip eliminates the exposure of the GC analytes to this metal surface and provide for a straight through flow of the capillary column effluent into the MSD source. Therefore the analytes are eluted off the GC column directly into the MSD source without exposure to any metal surface.

Mass Spectrometer Source

Over the last 20 years we have continued to improve on our source cleaning methodology. These cleaning methods have been perfected to provide the cleanest source possible and therefore the optimum sensitivity of the mass spectrometer. Highly polished metal (mirror like) surfaces help to maintain cleaner sources since they do not contain the small scratches and uneven surfaces that are prone to contamination.

Electron Multiplier

Electron Multipliers have improved significantly over the last few years. The newest multipliers from Galileo have with 2 to 10 times increase in sensitivity. Galileo has improved the electron multiplier sensitivity, reduced extraneous noise, increased the dynamic range and increased electron multiplier life. The new Galileo Model 5778 for the HP 5971, 5972 and GCD and the corresponding Model 5772 for the HP 5970 series of MSD's have recently been introduced as the latest enhancements to sensitivity and performance. These newest multipliers improved sensitivity at least 5 fold as compared to the original multipliers supplied with these instruments.

Vacuum System

HP installed either an Alcatel UM2002 or a small Edwards E2M1 or E2M2 in the MSD's. Both of these vacuum pumps are small, run at high RPM's, run very hot and have a history of limited life. They have a pumping speed of about 30 to 50 liters per minute. In our lab, we wanted to move the rough vacuum pumps on the other side of the wall from the MSD in order to reduce the noise level in the mass spec lab, therefore we chose to use the Alcatel UM2015. This pump has a pumping speed of 300 liters per minute. These larger rough pumps result in a much faster pumping speed which is especially noticeable during initial pump down after the system has been vented. In addition the system runs at a lower vacuum level due to this increased pumping efficiency.

Proper care of the rough pumps is very important. The rough pump oil should be changed every 3 to 6 months. Dirty or contaminated oils, increase the wear on the metal shafts of the pump and the pump runs much hotter. This higher temperature escalates pump wear. If the rough pump oils are routinely changed, the rough pump should have a life of about 5 years before an overhaul is required.

In the last two years, a new rough oil has been introduced called Inland 45. It is a highly refined and distilled oil with a low vapor pressure that will provide for increased performance in the rough pumps used on mass spectrometers. This oil will provide a much lower vacuum level, reduced hydrocarbon background and increased performance from the vacuum pump and mass spectrometer.

Santovac 5 has a history of being the best vacuum pump oil for use in diffusion pumps. This oil is a highly refined polyphenyl ether fluid that can achieve vacuum levels of 1×10^{-10} torr in research grade mass spectrometers. Santovac 5 is routinely used in the diffusion pumps on most mass spectrometers manufactured over the last 25 years. Other lower grade diffusion pump fluids are available such as the Dow Corning diffusion pump fluids, but will not provide the vacuum levels achievable by Santovac 5.

GC Septum

The most common source of GC background is the GC septum. Most GC septum are constructed of silicone. The common mass spec background peaks appearing at mass values of 207, 281, 267 and 355 can all originate from the siloxanes in the GC septa. We performed a series of studies to determine the degrees of background contamination that can originate from the GC septum from different manufacturers. The Supelco Thermogreen LB-2 septa were determined to be the best GC septa on the market. They produced the lowest septa bleed.

Cleaning the GC Injection Port

The GC injection port should be cleaned on a regular basis or when it becomes contaminated. The recommended procedures involves the physical cleaning of the injection port with small wire brushes and solvents followed by the baking out of the GC injection port at high temperature with preheated carrier gas and no column installed. This high temperature flow conditioning of the GC injection port purges all parts of the injection port with gas at the highest temperature possible. The hot gas flushes the injection port area including the septum area and also flushes the septum purge and split vent lines. Areas of the injection port that are not normally cleaned are thoroughly cleaned and purged during this high temperature flow conditioning.

GC Capillary Columns

The manufacturers of GC capillary columns are continuing to produce columns with lower column bleed. Since the introduction of bonded phase capillary columns, column bleed has been steadily reduced by the manufacturers. At Pitt Con this year J&W introduced an even lower bleed DB5 column for mass spec use called the DB-XLB column. This new non-polar capillary column provides for the lowest column bleed and is the recommended non-polar column for GC/MS analysis.

Conclusion

A number of changes in the mass spec and GC that have been made to the HP 5971A MSD in order to improve performance. These changes will increase the sensitivity by a factor of between 5 to 10 fold over the original instruments performance.

Modification of a Hewlett Packard 5972 MSD to Accept a Direct Insertion Membrane Probe

Scott Bauer, Jan Bauer, MIMS Technology Inc.
1900 S. Harbor City Blvd. Suite 115
Melbourne, FL 32901

Much of the previous work in the field of membrane introduction mass spectrometry (MIMS) has been performed on expensive research grade mass spectrometers equipped with direct insertion probe interfaces, or with modified ion traps. There are thousands of Hewlett Packard 5971 and 5972 mass spectrometers in use in laboratories throughout the world. Most of these are relegated to gas chromatographic use by design. Often chromatography is a sideline and the mass spectrometer sits idle in the laboratory where it may be put to better use in other investigations. Although these spectrometers are inexpensive, the quality of results is quite good. Modifications incorporated into the 5972 model make it very attractive for membrane inlet or solids probe use.

Modification of the 5972 to accept direct insertion probes is troublesome due to the lack of an internal source heating mechanism. The 5972 source is heated by the GC transfer line and temperature controls are incorporated into the GC operating system. The experiments described here demonstrate a relatively simple modification to heat the source in the absence of a GC transfer line.

An auxiliary heater block was attached to the 5972 source frame. Wires to the heater cartridge are routed down through the calibration gas port to a modified vacuum feed-through fitting. An external power circuit with a high / low switch setting controls power to the heater cartridge. At the low setting, the source will operate at approximately 90°C. The high setting provides a 180°C source temperature more suitable for solids probe work. A vacuum interlock assembly from MIMS Technology Inc. was fitted to the side KF flange of the 5972. This completed the direct probe modification. Although source temperature is controlled externally, the actual source temperature can still be monitored through the MSD operating system. The modified 5972 was configured for membrane introduction mass spectrometry (MIMS) use. A 1900-C1 capillary membrane probe and FIA-TC1 flow injection module obtained from MIMS Technology Inc. was installed to complete the system as shown in the diagram.

The mass spectrometer was tuned with the membrane probe inserted and water running through the system. Volatile organic standards were prepared in laboratory de-ionized water at 0.5, 1, 5, and 10 parts-per-billion by weight. The four standards for each compound were injected into the 5972 MIMS system to assess linearity of response and detection limits. All of the compounds studied demonstrated good linearity over the concentration range that was used. Detection limits were good with many of them at or below one part-per-billion. A table of compounds studied and their detection limits was displayed.

This relatively simple modifications will allow the use of direct insertion probes in the Hewlett Packard 5971/5972 MSD. The present study demonstrated that the 5972 can perform very well in MIMS mode and future experiments are planned to investigate solids probe use.

TWO VINTAGE QUADRUPOLE MASS SPECTROMETERS MODIFIED FOR COORDINATED PYROLYSIS-MS

Jon G. Wilkes[1], Kent J. Voorhees[2], James P. Freeman[1], Dietrich A. Volmer[1], and Jackson O. Lay, Jr.[1]

[1]FDA, National Center for Toxicological Research, NCTR Drive, Jefferson, AR 72079
[2]Colorado School of Mines, Golden, CO 80401

ABSTRACT

Two vintage quadrupole mass spectrometers were modified and upgraded to create an integrated system for identification of bacteria using pyrolysis mass spectrometry (Py-MS) with computerized pattern recognition. If, using one of the instruments, pyrolysis spectra of bacteria were produced that were essentially identical to those collected on the other instrument, the feasibility of Py-MS data bases for unknown identification would be demonstrated.

Modifications to both instruments included fitting them with flexible, mutually compatible data acquisition systems (Galaxy2000 by LGC, San Jose, CA), cold traps to reduce background, and 5 kV conversion dynodes for increased high mass sensitivity. A pyrolysate introduction system, including a probe vacuum lock and high temperature transfer line (350 °C), was developed which could be used on either instrument.

Comparison of calibration gas and Py-MS bacterial spectra both demonstrated the successful achievement of the goal.

INTRODUCTION

Pyrolysis mass spectrometry (Py-MS) with computerized pattern recognition (PRec) has been used successfully 1) for rapid identification of microbial agents responsible for infectious outbreaks in hospitals and also 2) for "fingerprinting" well-defined chemical mixtures to detect product adulteration. Particularly in the first case, production of sufficiently reproducible pyrolysate patterns has only been possible within batches: standard and unknown bacteria inoculated together on media from the same lot, cultured in the same incubator, and analyzed on the same day on the same pyrolysis mass spectrometer. These constraints significantly restrict potential large-scale implementation of the technique in a regulatory setting - screening for food-borne pathogens, for example, an application of particular interest to the FDA.

The cost/benefit relationship dictates both economy of design and high productivity to justify a high-tech solution involving mass spectrometry for such an analytical problem.

EXPERIMENTAL

Two older quadrupole mass spectrometers having significantly different secondary design features were available: a Finnigan-MAT (San Jose, CA) model 5100 GC/MS (1985) and a Vestec (Houston, TX) model 201 LC/MS (1985; quadrupole rods 1977). The differences between these two instruments presented substantial challenges to the goal of producing near-identical spectra. Once modifications were complete, the integrated use of the instruments was tested by comparing PFTBA calibration gas spectra (Table 1) and by performing Py-MS with PRec on bacteria. Species tested [and 1 digit symbols used in FIGURE 2] included *Shigella flexneri*(1), *Staphylococcus aureus*, *Pseudomonas*

fluorescens(3), *Bacillus cereus*(4), *Escherichia coli* 078:H11(6), *Salmonella typhimurium*(7), *Serratia marcescens*(X), *Bacillus circulans*, and *Mycobacterium pyr-1*(Z).

PYROLYSIS VACUUM INLET DESIGN/PERFORMANCE

Specifications for the heated transfer line included indefinite, stable operation at temperatures up to 340 °C with no cold spots, containment within a probe of no greater than 0.25" o.d., and sufficient length to be inserted into the vacuum manifolds of the 5100 or the 201 or (eventually) a Hewlett-Packard 5970 MSD.

The design adopted is shown schematically in Figure 1. Ceramic tubes served as electrical insulation between the probe shaft and transfer line. A thermocouple with fiberglass insulated leads was spot welded to the transfer line and read by a thermocouple thermometer. Also, the pyrolyzer sample probe was redesigned to traverse an upstream vacuum lock. *Results*: Temperature of the pyrolysate transfer line adjustable to 300 ± 1 ° C. The probe vacuum lock performed easily. Time/pyrolysis: < 4 min. [Compare 35 - 40 min. @ for a MIDI (GC-based) system.] Equipment acquisition and modification costs for the two mass spectrometers and the PRec system totaled only $98.2K

Figure 1.Pyrolysis-MS Vacuum Inlet System

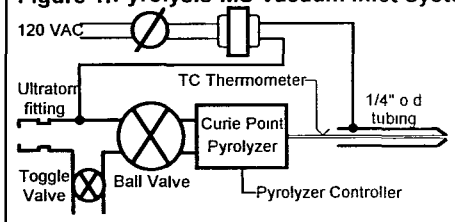

Figure 2.

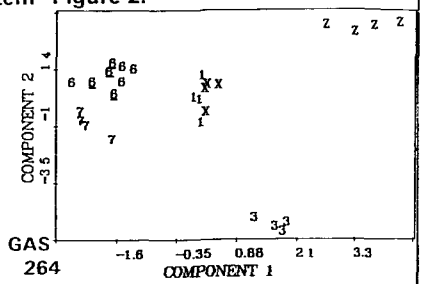

TABLE 1: PEAK RATIOS (%) FOR PFTBA CAL. GAS

MASS SPEC *m/z*→ ↓	69	131	219	264
5100	*100*	*41.60*	*63.76*	*16.15*
201 (autotune)	100	38.54	53.55	13.72
201 (manual tune)	*100*	*41.44*	*63.82*	*16.70*

PY-MS APPLICATION RESULTS

Bacteria were pyrolyzed on the 5100 and 201 with data subject to both Principal Component and Canonical Variate Analyses. Figure 2 is a discriminant component factor plot in which four replicates of each bacteria from the 5100 were used except for *E. coli* (symbol 6), with eight replicates. The four underlined symbols (6) came from 201 runs. The other four were from the 5100. *Results*: well-defined clusters for replicates in which the *E. coli* spectra from the different instruments were classified into the same factor space.

CONCLUSIONS

Py-MS with PRec is possible with coordination between different mass spectrometers and with operation on different days if there is sufficient instrumental and sampling control.

EXAMINATION OF A VARIETY OF SHEET MATERIALS FOR USE AS MEMBRANES IN MEMBRANE INTRODUCTION MASS SPECTROMETRY

Amy J. Maden‡ and Mark J. Hayward*
American Cyanamid - Agricultural Research Division
P.O. Box 400 - Princeton, NJ 08543-0400

Abstract: Several polymers including silicone, latex, PVC, Teflon®, polyurethane, polyimide, polyethylene, and nitrile have been utilized as membranes for membrane introduction mass spectrometry (MI/MS) in order to explore the relative performance of each material for MI/MS analyses. Each of the membrane materials were tested by exposing them to separate aqueous solutions containing the analytes benzene and ethanol in order to represent the results that may be achieved for environmental analyses and fermentation monitoring (respectively). These solutions were used to measure the relative analyte quantification limits, response times, and permeation of water as a function of temperature for each membrane material. It was observed that natural latex and polyurethane yield similar MI/MS performance characteristics (in aqueous matrix) to the commonly used silicone membranes for both benzene and ethanol solutions. Polyethylene was observed to work well with benzene as an analyte and simultaneously provides very high selectivity over water. While the other materials allowed aqueous matrix MI/MS to be performed, poor quantification limits or slow response times made these materials undesirable for this purpose. Two membrane materials which showed especially low organic permeability and higher water permeability, polyimide and Teflon, were briefly tested with polar analytes and non-polar solvent. For the polyimide material, the analytes acetone, acetic acid, chloroform, ethanol, ethylacetate, and water were readily observed in hexane solvent.

MI/MS Membrane Materials Which Yield Best Performance For Aqueous Matrix Samples

Performance Characteristic	[a]Fermentation Monitoring	[b]Environmental Analyses	Selectivity Over Water (30 °C)	Selectivity Over Water (60 °C)
[c]Membrane Materials Giving Best Performance	Polyurethane (ether) Latex Silicone	Silicone Latex Polyethylene Polyurethane (ether)	Latex Silicone	Polyethylene Silicone

[a]Based on quantification limits and response times for ethanol.
[b]Based on quantification limits and response times for benzene
[c]Listed in order of performance level with the best listed first.

OPTIMAL DESIGN OF A MALDI TIME-OF FLIGHT INSTRUMENT FOR MS-MS OF PEPTIDES

J.B. Hoyes, J. M. Brown, R.H. Bateman, S.G. Curbishley
VG ORGANIC, Floats Road, Wythenshawe, Manchester, M23 9LZ, UK

Introduction A high performance MALDI-TOF instrument for MS and MS-MS of proteins and peptides has been designed and built. The TofSpec SE consists of a three stage source, gas cell for CID work, a Bradbury-Nielson ion gate for precursor ion selection and a single stage reflectron.

The source consists of a target sitting at the acceleration voltage of the instrument (up to 30 KV in linear mode and 26KV in reflectron mode), a field extraction electrode and a focusing lens for high ion transmission through the analyser. A high extraction field leads to high PSD yield with monoisotopic resolution possible on product ions, whereas lowering the extraction field reduces the PSD ion yield. A gas cell installed close to the ion source yields high energy CID.

A Bradbury-Nielson ion gate gives precursor ion selection for MS-MS operation with parent ion selection resolution in excess of 100 being achievable. The co-axial geometry coupled with a single stage reflectron gives high transmission and simple linear calibration law for product ions. Full product ion spectra can be taken with fewer voltage steps on the reflectron than with two stage "V" geometry designs.

Experimental To characterise the performance of the instrument a number of well characterised peptides were run. An example of the high resolution attainable on the daughter ions is show in figure 1 for a synthetic peptide MW 1498.7 (M+H = monoisotopic). Here two species differing by only two mass units the B10 and Y9 fragments are clearly resolved.The resolution is enhanced by using the ion gate to narrow the energy width of the parent (and associated fragments).

The PSD process generates fragment ion spectra that resemble those taken on triple-quadrupole instruments. The process is a function of both matrix and extraction field strength. Carr et al [TPG259 ASMS 95] have shown that the degree of CID with respect to PSD depends on the matrix choice.

A practical approach to observe CID is to allow the PSD process to occur and then to admit gas into the gas cell. Figure 2a shows a spectrum of the Glu-Fibrinopeptide-B under normal PSD conditions with the majority of ions being backbone cleavages more reminiscent of low energy collisions . Figure 2b shows a mass spectrum under the same voltage conditions as 2b but with the addition of air as a collision gas into the cell. It can be seen that new species are present in this spectrum, specifically side chain cleavages that are traditionally associated with the high energy collisions produced on magnetic sector instruments.

Conclusions A high performance MALDI-TOF machine has been developed with enough resolution to see single isotopes upto 3000 daltons. This means 1 Da differences such as would occur in a de-amidation reaction can be distinguished. PSD spectra +-0.1Da mass accuracy can be produced with parent ion selectivity sufficient to eliminate the sodium adduct at masses 2500Da (for example) permitting MS/MS on individual components in complex mixtures.A collision cell introduces high energy CID products that are superimposed on the low energy like PSD spectra. Switching between pure PSD and mixed PSD/CID modes is accomplished simply by turning the gas on and there is no need to recalibrate the instrument. For peptides the high energy CID process produces side chain cleavages that permit important differentiation between isobaric residues such as leucine and isoleucine.

Modulated Sample Membrane Inlet MS: Theory and Practice

Fei Liu, Michael Davenport, and Christie G. Enke
Department of Chemistry, The University of New Mexico, Albuquerque, New Mexico 87131

Most membrane inlet work to date has employed steady-state diffusion through the membrane[1,2,3]. In order to utilize the diffusion coefficient (diffusivity) D as a distinguishable property of organic compounds, we have investigated modulated sample introduction.

We have developed a computer program to simulate the diffusion process through a membrane with a modulated sample stream. In our simulation, the motion of the alternating valve is modeled as, or close to, a periodic step function. The resulting diffusion flux profile for each component converges to a periodical function for which the time lag, shape, and magnitude are related to the diffusivity and concentration of that component[4]. The deviation between the flux profile obtained from our simulation and the results calculated from analytical solutions[5] for steady-state cases is within 2%. The shape of the flux profile, but not the magnitude is independent of membrane geometry. For the same membrane thickness and surface concentration, the diffusion through a flat sheet membrane gives a higher flux than that through a hollow fiber membrane where the diffusion in from the inside out The proportionality constant is 0.707 for 2:1 ratio of inner and outer diameters.

An experimental system to implement modulated sample introduction has been assembled. The membrane inlet is switched periodically between the sample and background streams. The sample components are detected by a Finnigan MAT Ion Trap Detector. A time-dependent response pattern, called a chronogram such as seen in the figure, is produced for each m/z value in the mixture spectrum. The profile of each chronogram depends on the concentrations and diffusivities of the components contributing to the response at that m/z value. The theoretical flux profiles and the experimental chronograms have been compared separately for the rising and falling edges using slightly different diffusivities for single m/z values and agreements have been reached. The difference in apparent diffusivities between sample turn-on and turn-off is due to a corresponding pressure change in our present apparatus. For multiple component sample, the significant difference has been observed among the channels to which only signal component contributes and those to which multiple components contribute.

Sample modulation and chronogram analysis provides a useful second dimension for mixture analysis. Although modulated sample introduction with the membrane provides less temporal separation than normal speed GC, the modulated membrane is simpler than

a GC and achieves faster update rates. Due to its simplicity and rapid update rate, the sample modulation at membrane inlet mass spectrometry should find useful applications for relatively simple mixture such as in process control.

Ion storage study for a segmented-ring ion trap source for time-of -flight mass spectrometry

Qinchung Ji[1,3], M R Davenport[3], J F. Holland[2], and C G Enke[1,3]
Department of Chemistry[1], Department of Biochemistry[2], Michigan State University, East Lansing, MI 48824
Department of Chemistry[3], University of New Mexico, Albuquerque, NM 87131

For time-of-flight mass spectrometry (TOF-MS) analysis of continuously introduced samples, continuous ion generation and storage of ions between ion extractions is an effective method to achieve good sample utilization efficiency [1,2] We are developing a segmented-ring ion trap source for time-of-flight mass spectrometry to achieve ion storage without losing the resolution and spectrum generation rate of conventional TOF-MS[3] During the ion extraction period, a linear, uniform extraction field is generated in this source by applying a set of dc voltages proportional to the positions of the ring and extraction electrodes Between ion extractions, ions will be accumulated and stored in this ion source by applying radio frequency (rf) field between the rings and caps

A time-of-flight mass spectrometer with this segmented-ring ion trap source has been constructed. This instrument is composed of a segmented ring ion storage source, a broad energy range reflectron and a microchannel plate detector Electron impact ionization is used to generate sample ions inside ion source Ion storage is evaluated by measuring the ion peak area for various values of the delay time between sample ionization and ion extraction When operated without an rf field applied to the ring electrodes of the segmented ring ion storage source, 85% of $[CH_3C{=}O]^+$ ions generated in the ion source remain there for 1 4 μs based on their thermal velocity and the physical dimensions of the ion source As shown in Figure 1, only 10% of the ions will remain 4 6 μs after ionization has ceased For continuously introduced samples, and a 200 μs extraction cycle time, 99% of the sample ions will lost between extractions. Enhanced ion storage is obtained when the rf field is applied to this segmented-ring ion trap storage source between ion extractions The peak area profile in Figure 2 shows that $CHCl_2^+$ ions are stored efficiently for at least 12 μs when an rf field is applied Lower mass ions are removed for delay times of 500 ns and 12 μs due to the dc offset, frequency, and amplitude of the rf applied as shown in Figure 3 This demonstrates the possibility of selective ion storage. Extensive collisional cooling is not required to achieve either ion storage or good mass resolution as the $CHCl_2^+$ ion peaks in the spectra is unchanged from 500 ns to 12 μs storage The ability to extract ions without delay allows frequent ion extraction (2500 Hz) and thus greatly improves ion statistics

Rf operation of the segmented-ring ion source acts as a kind of cylindrical ion trap between ion extractions This ion trap source is providing efficient, long term storage of ions generated in the source as well as good resolution with frequent extraction The development of this approach to TOF-MS source design should greatly improve sample utilization efficiency for analysis of gaseous samples by time-of-flight mass spectrometry.

A new design of Ion Storage Accelerator for Time–of–Flight MS

A. Kraft, H. Wollnik
II.Physikalisches Institut, Justus–Liebig–Universität, 35392 Giessen,Germany
V. Laiko, A.F. Dodonov
Institute of Energy Problems of Chemical Physics, Russian Academy of Sciences, 142432 Chernogolovka, Russia

A new Time–of–Flight MS (fig.1) for orthogonal extraction has been constructed. It consists of a API–source, the orthogonal extraction optic and a single stage reflectron as well as a detector with two MCP's in Chevron–arrangement. The extraction optic has a new design in respect to the prevention of disturbing fields. Such fields take influence on the primary beam during accumulation mode and causes noise as well as broadening of mass peaks. This fields arises from the penetration of field through the grid between the two stages of the extraction optic. In our construction these penetration is compensated by the introduction of an additional electrode which is hold at the average virtual potential of the separation grid (fig.2).
By adjusting all electrical parameters of the mass spectrometer (extraction-pulser, backplane of reflector, focussing optics) the peakwidth had been otimized. It has been shown that the peakwidth strongly depends on the potential of the compensation electrode (fig.3). The optimal value corresponds in good agreement with the calculated value (1.7V instead of 1.56V).
In the case of Gramicidin S (m=1140) a resolving power of 2000 is achieved (fig.4).

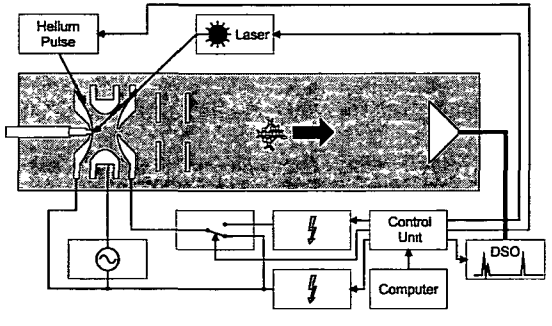
A New MALDI Tandem QUISTOR, Time-of-Flight Mass Spectrometer

Markus Stoeckli, Peter Kofel, Joern Krause, Urs P. Schlunegger,
Institute of Organic Chemistry, University of Berne, Freiestr. 3, CH-3012 Berne, Switzerland

Matrix-assisted laser desorption/ionization (MALDI) is a powerful technique to get molecular ions of large molecules. Because of the pulsed nature of the ionization process, mass analysis is best done with an analyzer capable to accept a broad range of m/z values simultaneously. Especially suited to this need are time-of-flight, ion trap and ICR instruments. For the standard MALDI/time-of-flight system mass resolution is low and few structural information is obtained [1,2]. To gain more insight into and possibly overcome these limitations we have constructed a new MALDI/QUISTOR/time-of-flight instrument.

The instrument is built around a QUISTOR (QUadrupole Ion STORage trap) with 1 cm ring electrode radius (same design as [3]). The trap is placed inside an ultra-high vacuum system with a 100 cm flight tube. The design of axial ion production allows to operate the instrument also in direct linear time-of-flight mode, which is useful for control and tuning purposes.

Samples were prepared by mixing on a stainless steel probe tip 0.5 µl of a 0.5 mM aqueous solution of the proteins with 0.5-1.0 µl of a 1 M solution of the matrix in a 1:1 acetonitrile /ethanol mixture, followed by rapid drying in vacuum. Using this procedure a total amount of 250 pmol of sample was deposited on the probe tip, which lasted for up to 1000 laser shots. The probe was inserted into the instrument, the probe tip parked at the QUISTOR end cap and the probe removed. Then the trap was floated to 1.5 kV, and the rf voltage (20 to 200 V, 50 kHz) was applied to the ring electrode of the trap.

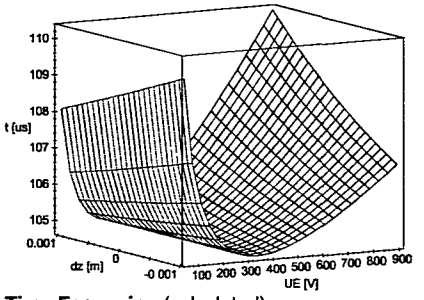


The experiment is characterized by a pulse sequence from a purpose built control unit. Helium was pulsed in for 1 ms to a peak pressure of $>10^{-2}$ Pa. 1 ms later the nitrogen laser was fired. After 1 s for collisional cooling the *extraction end cap was pulsed to* 1.3 kV for time of flight analysis of the stored ions. 20 kV post-acceleration and averaging on a digital storage oscilloscope (1000 sweeps) were used for ion detection.

Sensitivity and resolution were found to be strongly dependent on the phase angle of the laser shot and the extraction pulse, buffer gas pressure, storage time and extraction amplitude. Good sensitivity and resolution were always obtained when both the laser shot and the extraction were done at 270 deg, i.e. when the maximum negative amplitude was at the ring. The longer the ions are stored, the better the resolution gets. The initial axial spread of the ions in the QUISTOR can be time focussed by tuning the extraction amplitude. Further examination of this effect may allow to improve the limited resolution obtained so far.

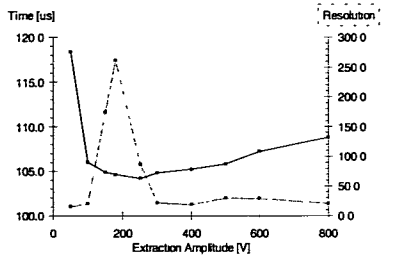
[1] Chambers et al., Anal. Chem. 65, 14 (1993).
[2] Michael et al., Anal. Chem. 65, 2614 (1993).
[3] Kofel et al., Org. Mass Spectrom. 26, 463 (1991).

In contrast to earlier predictions the results prove that large mass ions may be trapped with very small trapping fields (as low as 20 V amplitude on the ring electrode and trapping well depths down to 1 eV), as long as the frequency is suitably adjusted. At least a significant part of the molecular ions produced by MALDI are trapped intact in the QUISTOR. Comparison with measurements in the direct linear mode suggests that the observed molecular ions are identical. At q_z values around 0.5 the ions can be stored in the trap for several minutes. During storage clustering reactions of Melittin ions with background DHB matrix molecules have been observed. This may open the possibility for selective determination of specific functional groups by ion/molecule reactions.



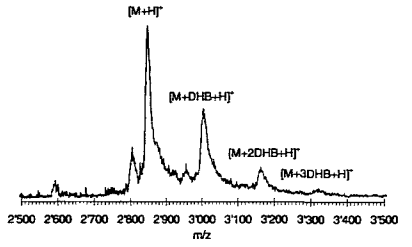
Time Focussing (calculated)

Calculated time of flight t for an ion with m/z 2'846 in dependence of the extraction voltage UE and the distance dz from the trap center. For UE ≈ 200 V all the ions have nearly the same time of flight independent of their initial *dz-location in the trap.*

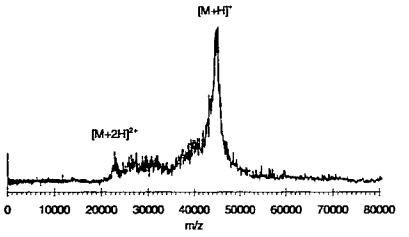


Time Focussing (measured)

Measured time of flight (solid line) and time resolution (dotted line) for m/z 2'846 as a function of the extraction amplitude. By combining these data with the calculation results (see at left), the axial spatial distribution of the ions at the start of extraction was calculated to be dz = +/- 3 mm.



Melittin from honey bee venom (MW 2'846.5)
Matrix: DHB; trapping voltage: 40 V.



Albumin from chicken egg (MW ~45'000)
Matrix: Sinapic acid; trapping voltage: 180 V.

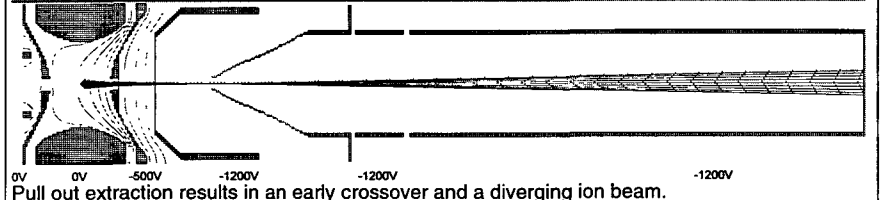
A NEW LC ELECTROSPRAY ION TRAP TIME-OF-FLIGHT MASS SPECTROMETER

Alex Mordehai, Joe Karnicky, Béla Limbek, and S. E. Buttrill, Jr.
Varian Associates - Ginzton Research Center
3075 Hansen Way, Palo Alto, CA 94304-1025

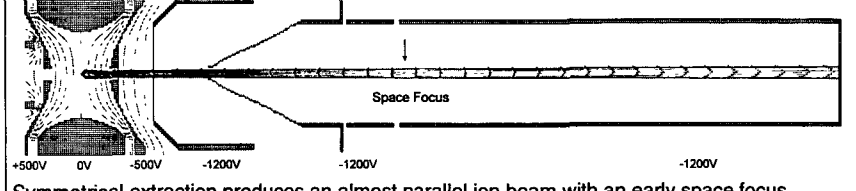
The recent work by David Lubman and his students [1] has highlighted the advantages of the ion trap time-of-flight (IT TOF) mass spectrometer. This arrangement has high sensitivity because of its large duty factor. When ion currents are weak, ions may be accumulated in the trap for 100 milliseconds or longer. The ions are then pulsed out into the TOF for mass analysis, which typically requires less than 200 microseconds. The duty factor for mass analysis and detection of all ions from a continuous ion source can therefore in principle be greater than 99%. In practice, the time for ion cooling in the trap and the reset time for the electronics limits the duty factor to about 95%. The purpose of this project is to explore the potential of IT TOF MS, and especially its suitability for electrospray LC/MS.

Our system uses pneumatically assisted electrospray (ion spray) together with a two stage differentially pumped API interface with a heated stainless steel capillary. The ion trap reflectron time-of-flight mass spectrometer was purchased from R. M. Jordan Co., Grass Valley, CA and uses a 20 mm two stage microchannel plate detector. The 500 megasample per second transient digitizer is a Model 9846-500 from Precision Instruments.

We have found that the performance of the IT TOF can be improved by using a symmetrical or nearly symmetrical pair of extraction voltage pulses applied to the ion trap end caps. The two plots below from a SIMION analysis of the ion trajectories shows that the beam quality with symmetrical extraction is much better than with the use of a single pullout pulse. Use of a push out pulse results in a diverging ion beam (not shown).

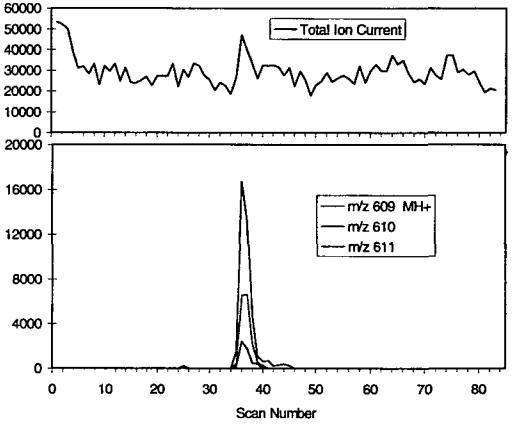


Pull out extraction results in an early crossover and a diverging ion beam.
Contours shown at -10, -100, -200, -300, -400, -600, -800, and -1000 volts.

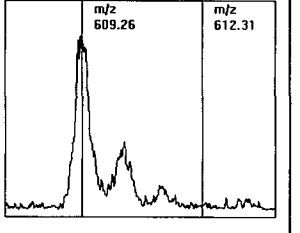


Symmetrical extraction produces an almost parallel ion beam with an early space focus.
Contours shown at 400, 300, 200, 100, 0, -100, -200, -300, -400, -600, -800, and -1000 volts.

The performance of the LC/MS system is shown below. A 15 pg sample of reserpine was injected using a 5 microliter injection loop. The mass chromatograms and the Total Ion Current plot were obtained from the mass spectral peak areas. The raw data for the scan at the top of the reserpine LC peak are shown on the right. The 15 pg injection contains about 10 pg of pure C12 reserpine, about 4 pg of reserpine C13 and less than one pg of reserpine with two atoms of C13 at m/z 611.



LC column: 2.1 mm i.d. C8
Flow rate: 0.20 ml/minute
75% acetonitrile: 25% water
0.1% acetic acid
20 mM ammonium acetate



Raw data from scan 36

Mass resolution of over 2200 FWHH is shown below for the bradykinin MH+ ion at m/z 1060 and the sodium ion adduct peak at m/z 1082.

MALDI-TOF/TOF of peptides: Past, Present and Future.

Cordero M.M.; Cornish, T.J.; Cotter, R.J.
The Johns Hopkins University School of Medicine, Baltimore, MD 21205

The ability to perform *high* energy collisional-induced dissociation (CID) in a low-cost, compact instrument is very appealing. Recently this laboratory has produced several versions of an instrument that combines MALDI with CID: a tandem time-of-flight mass spectrometer.[1] An overview of its performance is presented here.

The initial instrument design contained two linear reflectrons: one for mass selection and the other for product ion dispersion. A pulsed valve introduced He required for the CID process. A nitrogen laser was used for ionization. CID results for dermorphin and Met-enkephalinamide, among others, indicated that *only* those ions close in mass to the precursor ion achieve maximum resolution at the position of the detector. A new version of the instrument was built incorporating a curved field reflectron (CFR) which energy focuses all ions to within a small region near the detector. (Fig. 1) A striking improvement in the resolution was noted when using the CFR to disperse CID products.

CID mass spectra obtained for RYLGYLE and FERFEIFPKE (Fig. 2) presented many sequencing ions. These peptides, however, were difficult to detect at low concentration due to loss of sensitivity by metastable decay of the precursor.

As expected, post-source decay (PSD) MS obtained with a coaxial curved field reflectron TOF-MS also developed in this laboratory [2] gave both higher sensitivity and resolution for the same peptides. (Fig.3)

The next generation of MALDI-TOF/TOF will probably have:
i) A shorter first reflectron and drift region, to minimize metastable decomposition of the precursor ion.
ii) A coaxial curved field reflectron to energy-focus the product ions and maximize ion transmission.

Laser desorption of proteins and peptides using liquid matrices is an alternative strategy to conventional MALDI experiments Previously we have reported use of binary liquid matrices for which a light absorbing molecule is mixed with a vacuum compatible liquid matrix [1] Light absorber molecules like Rhodamine 6G, sinapinic acid and alpha-cyano-4-hydroxy cinnamic acid have been used successfully These experiments were performed in a static fashion, where the analyte - liquid matrix droplet was placed on a stainless steel probe surface and introduced in a TOF. Recently we began investigating dynamic liquid MALDI, where both the analyte and the matrix are continuously introduced in the TOF Our goal was to develop an interface which will couple the technique of capillary electrophoresis to TOF-MS So far, well-known developments in CE-MS interfacing have been based either on electrospray ionization or CF-FAB The main advantages of using a TOF as a CE detector is that (theoretically) there is no upper mass limit for analytes, and that much higher scan rates can be used

The interface we have constructed, Fig 1, consists of a metal cylinder housing two fused silica capillaries, 15 µm i d , one for the introduction of a liquid matrix and the other for the introduction of the analyte The capillaries are attached with epoxy onto the back of a stainless steel probe and terminate flush with the probe surface, where the sample and matrix mix The interface fits the standard vacuum interlock of a Bruker Reflex TOF, and the probe tip makes electrical contact with the acceleration plate We have examined a number of experimental parameters, including matrix viscosity, capillary diameter, flow rates of the matrix and the analyte, and composition of the binary matrix mixture Alpha-cyano-4-hydroxy cinnamic acid was found to perform better for these experiments than sinapinic acid. With it, we obtained better resolution, increased sensitivity and reduction of capillary clogging. To maintain low pressures in the TOF, we originally used glycerol as the liquid matrix Memory effects were observed, thus we eliminated glycerol, the present working matrix consists of water / acetonitrile / TFA saturated with alpha-cyano-4-hydroxy cinnamic acid

Shown in Fig 2 are spectra of bradykinin and insulin, $1x10^{-10}$ mol/µl, in reflectron mode Flow rates into the TOF are 1 5 µl/min for matrix and 100 nl/min for analyte The bradykinin resolution in linear mode is 130, in reflectron 368 Adduct formation observed in such techniques as aerosol MALDI [2] are not present here Limit of detection was $1x10^{-11}$ mol/µl for bradykinin At this concentration the insulin peak did not appear due to supression effects Currently, we are investigating the use of the analyte delivery capillary as a capillary electrophoresis column for performing CE - MALDI mass spectrometry

Based on the principle of "inverted perfectron"[1], we have designed and constructed [2] an electrospray ionization (ESI) orthogonal time-of-flight mass spectrometer. Ions are injected into the mass spectrometer orthogonal to the ion flight-path. A novel "beam dump" for the molecular beam permits large loading of ion beams while maintaining high vacuum in the flight tube. Using a molecular beam to introduce a well collimated ion beam minimizes the degradation of the theoretically perfect focusing of the "inverted perfectron" geometry. An extremely large detector (20 cm x 8 cm multichannel plates) permits the efficient acceptance of the ion packet and drift compensation. A novel detection system consisting of opto-electric coupling of the floating detectors (10 kV) and a custom data system designed in conjunction with Sensar (Salt Lake City, Utah) permit high sensitivity, high resolution and fast data acquisition of either positive or negative ion signals.

Preliminary results indicate an instrumental resolution of ~ 930 at m/z~2045 (Fig. 1a) for lyzozyme (egg white) 7+ charge state and a signal-to-noise ratio of ~ 50 for single-shot spectrum of Angiotensin I at 200 pmole/μL concentration (Fig. 1b). For the latter, the sample consumption is about 300 attomoles and the acquisition time is about 300 μs. Furthermore, capillary electrophoresis has been coupled with the inverted perfectron TOF instrument. A model mixture system of neurotensin, angiotensin I and mellitin (Fig. 2) was analyzed successfully demonstrating the potential of TOF-MS for on-line fast separation analysis.

The formation of a beam of electrosprayed ions is a very important process in any gas-dynamic interface. While undergoing expansion into a vacuum with subsequent acceleration by the declustering potential, the ions acquire large velocities and spatial dispersion, i.e. they occupy a large volume in phase-space. However, it is possible to improve the ion beam quality by subsequently passing the ion beam through an RF quadrupole or sextupole operating at relatively high pressure [1,2]. Collisions with molecules of the buffer gas damp the velocities of ions, while the RF field constrains them close to the axis of the quadrupole.

We have redesigned the previous ES gas-dynamic interface for orthogonal ion injection into our TOF III mass spectrometer [3] and installed a new section containing a small RF quadrupole. The schematic diagram of the ion source interface is shown in Figure 1. The new section is evacuated by a 30 l/s Leybold mechanical pump. The small diameters of the skimmer orifices (0.35 mm for s1 and 0.75 mm for s2) are sufficient to keep the pressure at ~ 0.1Torr in the quadrupole and at $2x10^{-7}$ Torr in the main chamber of the TOF III. The quadrupole rods are driven by a small sine-wave signal generator coupled through an ENI broadband RF power supply providing operating frequencies from 100 kHz to 2 MHz and output voltages from 0 to 750 volts peak-to-peak.

The RF quadrupole has significantly increased the sensitivity of the TOF III mass spectrometer. Figure 2 shows a spectrum of soybean agglutinin (SBA, M.W. ~ 116,000u) recorded in 10 seconds, using a conventional electrospray technique; 120 femtomoles of the sample was consumed. Much higher sensitivity for the same sample (in the attomole range [4]) was obtained using the nanospray technique [5].

The new interface allows us complete control over the energy of the orthogonally injected ions by applying the appropriate potential to the second skimmer, whereas previously this energy depended strongly on *m*, *m/z* and the declustering potential. A numerical simulation performed by our group to study the operating principles of the quadrupole verify the phase-space reduction. This provides a number of advantages in instrument performance. Figure 3 shows the deconvoluted mass spectrum of bovine insulin (average M.W. 5733.58u), demonstrating that a resolution of ~ 10,000 can be achieved when no deflection potential is required to steer the orthogonally injected ions to the detector. Figure 4 shows the spectrum of a mixture of four compounds, Substance P (M.W. =1346.74u, molar concentration 1 μM), Cytochrome C (12,360u, 1 μM), SBA (~116,000u, 3 μM) and Catalase HP II (~ 339,100u, 5 μM), which was prepared in a water/0.08% acetic acid solution. The spectrum reveals no mass discrimination over a wide range of m/z.

THE LASER IONIZATION GC-TOF/MS ANALYSIS OF ORGANOMETALLICS

Steven M. Colby, Kent H. Hanser, William A. Harris, and James P. Reilly
Dept. of Chemistry, Indiana University, Bloomington, IN 47405

In previous work we illustrated the sensitivity of laser ionization GC-TOF/MS by demonstrating a detection limit of 1.5 fg for tetraethyltin[1]. In this method ultra-violet laser light is used to atomize organometallic compounds eluting from a gas chromatograph and ionize the atomic fragments. The ions are then detected using a time-of-flight mass spectrometer. The method was primarily limited by the relatively small duty cycle of the laser. As a consequence of the short (8 ns) laser pulse only a fraction (~ 1 in 10^5) of the GC effluent was exposed to light. Two approaches to increasing sensitivity have recently been examined. The first involves a TOF/MS source in which the GC effluent was partially confined and therefore had more than one chance to pass through the laser beam[2]. While this method increased the signal obtained from concentrated samples (e.g. 10 pg in 1 µl), sensitivity to more dilute samples was not enhanced because the GC carrier gas was also confined. The He or Ar gas increased the pressure in the source region and became the source of a large number of ions produced by photoemission electron impact ionization[3].

A second approach to increasing sensitivity has been more successful. As illustrated in Figure 1 it employs a cryogenically cooled 12 cm diameter drum to trap the analyte as it exits the GC column. The drum rotates so that the sample is transported into the source region of the TOF/MS where it is laser desorbed and ionized. The advantage to this approach is that most of the analyte is trapped on the drum and then exposed to the laser while the nitrogen carrier gas is not trapped on the liquid nitrogen cooled surface. We are thus able to increase the interaction of the ArF laser with the analyte while reducing the concentration of carrier gas within the ionization region.

An important aspect of this new system is that background signals reappear in the chromatogram with each rotation of the drum. (140 sec. period) Figure 2 displays a chromatogram with a number of peaks separated in time the one drum rotation period. These signals are due to the injection of a concentrated sample (1 µg) of tetraethyltin that was used to align the laser light with the trapped analyte. We have found that samples over ~400 ng remain on the drum for many days even after it has been warmed to room temperature. The same sample spot can therefore be used for daily alignment over an extended period. Unlike the higher concentration depositions, smaller samples are removed from the drum by each pass of the laser. A sample on the order of 10 ng will be detected for 5 or 6 rotations while those below 10 pg will only be seen once. Using this new system we have recorded chromatograms by injecting samples as small as 100 attograms of tetraethyltin in 1 µl. An example is shown in Figure 3. The width of the peak is due to a poorly heated valve between the chromatographic column and the GC-MS interface. One advantage of the repetitive nature of the background is that they it easily be subtracted from the chromatogram. Figure 4, for example, displays the same data as in Figure 3 except that the latter part of the chromatogram has been subtracted from the first part. This is valid because the latter part of the data contains only signals that are correlated with the drum and therefore reappear every 140 seconds. These signals can therefore be used as a legitimate background for the first part

The 100 ag sample peak is seen only once in the first part of the data and therefore is the only strong peak remaining after background subtraction.

The method is currently being applied to organolead compounds.

Russia

A Time-of- Flight Mass Spectrometer (TOF-MS) coupled to a Gas-Chromatograph (GC) yields just the retention time of the eluation components but also the accompanying mass spectras. Monitoring the intensities of ions of several masses as function of time on find the GC-spectrum as the sum of all ion signal In contrast to scanning mass spectrometers a GC-TOF-MS system permits also to calculate a GC-chromatogram under consideration of a single mass or selected characteristic masses, which are recorded under exactly the same conditions. Further the available datas of the mass spectras give the possibilities to process these mathematically and separate unresolved GC peaks effectively.
The time spread in a TOF-system with an electron impact ion source is caused mainly by the energy distribution owing to the different start positions in the ionisation region and the turn-around-time depending on the initial ion energy and the extraction field strength.
The TOF-system operates with ion energies of 2keV and extraction field strength of 250V/mm, so that a mass resolving power (FWHM) of about 2000 has been achieved routinely. The overall flight distance of the system lies in the range of 1500mm and facilitates to record a full mass spectrum in less than 100µs
A chromatogram was taken by injecting 0 2µl of a 5-component mixture of hydrocarbons diluted in hexane at concentrations of 15ng/µl per component. For a split range of 1:1700 the amount on column of the substances was in a range of 2pg. The signal-to-noise ratio calculated by the quotient of peak-intensity to the standard deviation of the noise level shows a ten times better result for the Selected-Ion-Chromatogram (SIC) compared to the Total-Ion-Chromatogram (TIC) in our experiment (see table and Fig 1 and Fig. 2)

No	compound	amount A [pg]	TIC noise ΔA [fg]	SIC noise ΔA [fg]
1	Toluene	2 11	± 148	± 12
2	Chloro Benzene	2 18	± 121	± 12
3	Nonane	1.97	± 121	± 23
4	Chloro Heptane	2.27	± 352	± 84
5	Tert. Butyl-Benzene	2.39	± 127	± 16

To specify an explicit component of the injected substance we use a filter algorithm [2], which folded the accompanying mass spectra and the chromatogram in a mathematical way and allows to identify exactly the interesting component during the rest will be suppressed (see Fig 3). This filter will be also helpfull to differ clearly overlapping peaks of a sample with nearly equal retention times, but different mass spectras.

Design Criteria for a GC-TOF/MS Analyzer for Human Breath

Paul H. Miyares and Christie G. Enke
Department of Chemistry, University of New Mexico
Albuquerque, NM 87131

The human breath contains a vast amount of information about metabolic processes occurring in the body. The analysis of human breath, though, is a difficult and challenging task. As many as 400 volatile organic compounds have been observed[1]. Breath analysis is complicated by the presence of a high concentration of water, up to 40 mg/L at 37°C, and the large concentration range over which the components may be present. For medical diagnostic purposes, both qualitative and quantitative analysis of trace components is required. Furthermore, the speed of analysis must be such that results can be obtained within the span of a normal office visit.

The system required to perform breath analysis consists of six major components; sample collection, water removal, sample preconcentration, analyte separation, detection, and data analysis. Design criteria have been developed for each of the individual components of the breath analyzer.

The sample collection system serves to both collect the breath sample as well as introduce the sample into the analyzer. The system is equipped with a mouth piece through which a sample can be collected directly from the subject. A glass chamber serves as the collection vessel. A unidirectional valve allows the subject to exhale breath into the chamber and inhale clean air from a supply tank. Large diameter tubing is used to allow the subjects breathing to be uninhibited. The glass chamber is fitted with a draw tube where the sample is withdrawn via vacuum into the instrument. A purge gas supply and purge vent are used to clean the chamber between sample collections. A syringe port is added to allow for the addition of internal standards after sample collection. The chamber and tubing are heated in order to prevent condensation and subsequent loss of analyte along the surfaces.

The water removal device is used to reduce the physical and chemical interferences present due to the high concentration of water in the breath sample. It uses a silicone hollow fiber membrane[2] has a higher rate of permeation for organic compounds than for water. A pump is used to draw the sample into the hollow fiber. A constant vacuum applied to the chamber around the hollow fiber maintains the concentration gradient across the membrane.

The preconcentration system is used to enhance to detection capability of the system for trace component analysis. It utilizes a thick film, wide bore capillary trap. The trap is maintained at liquid nitrogen temperature in order to trap even highly volatile components. Flash heating is used to desorb the trapped compounds. The wide bore tubing is used to allow rapid flow

rates and to help prevent blockage from formation of any ice crystals that may form. The thick film stationary phase is used to increase the capacity of the trap resulting in greater preconcentration, thus better detection capability.

A gas chromatographic system is used to the first level of selectivity in the sample analysis and serves as the introduction system to the mass spectrometer. The chromatograph is equipped with a dual column configuration; a standard 100% methylsilicone (DB-1) column (5m x 0.53mm ID) and an aluminum oxide porous layer open tubular (PLOT) column (5m x 0.53mm). The PLOT column will separate low molecular weight compounds that are normally unretained on a DB-1 column. The columns are connected through a valve system that splits the low molecular weight fraction toward the PLOT column while routing the remainder of the sample directly to the mass spectrometer. The short, wide bore capillary columns allow for rapid flow rates thus decreasing the analysis time and better utilizing the capabilities of the detector. Cryogenic focusing[3] is used the ensure a narrow injection band required for rapid gas chromatography.

Detection by time-of-flight mass spectrometry (TOF/MS) with time array detection (TAD) is used due to the inherent "full-scan monitoring" mode and rapid spectral generation rate. This allows for rapid detection, excellent sensitivity and effective deconvolution of overlapping chromatographic peaks. The TOF/MS is a home-built reflectron time-of-flight instrument equipped with an electron impact (EI) source, a two stage gridded reflectron[4] and an active film electron multiplier detector (Model AF820 ETP-PTY Limited, Ermington, Australia). The reflectron design coupled with a flight tube length of 1.5 m and a small reflectron turnaround angle of three degrees enhances the resolution of the mass analyzer. The active film electron multiplier is used to provide high signal response with little noise.

A data system is used to provide control over the instrument including the sample collection and processing systems, the valve system of the chromatograph and the electronics of the mass spectrometer. It also serves to collect, process and store the data. Deconvolution algorithms will be developed to extract the desired quatitative and qualitative information from the spectral data.

The integration of these six systems results in an analyzer designed for the rapid analysis of human breath. Quantitative and qualitative information should be obtainable over a dynamic range of 10^4 to 10^5 with ppb detection limits.

TIME-OF-FLIGHT MIRRORS WITH IDEAL TIME-FOCUSING IN TANDEM MASS SPECTROMETRY

Alexander A. Makarov*, Emmanuel N Raptakis, Peter J Derrick
Institute of Mass Spectrometry and Department of Chemistry, University of Warwick, Gibbet Hill Road, CV4 7AL, Coventry, UK

Widespread usage of matrix-assisted laser desorption (MALDI) as a tool for producing impulse packs of protein ions has resulted in a real renaissance of time-of-flight (TOF) mass-spectrometry. To expand the analytical capabilities of MALDI TOF for structural analysis, tandem instruments are employed. The second or both stages may employ TOF and molecular structure elucidation of high-mass molecules is most favourably carried out using high-energy collision-induced dissociation

As velocities of fragment ions are close to the parent ion velocity while the differences in masses may be up to orders of magnitude, fragment ions have energies from <1 to 100% from parent ion energy, i e from hundreds to ten(s) kiloelectronvolts for high-energy collisions

The challenge of providing at least unit mass resolution for all these ions simultaneously can not be successfully met by traditional reflectrons Instead, quadratic-field mirrors providing independence of TOF from initial energy and angular spreads over wide ranges (i e *ideal time-focusing*) are required.

The most practically feasible quadratic fields possess some type of symmetry, e.g planar [1]

$$U(x, y, z) = k_{/2}\,(z-a)^2 - k_{/2}\cdot(x-b)^2 + d\,y + C \qquad (1)$$

where x, y and z form a Cartesian coordinate system, or rotational symmetry [2-4].

$$U(r, z) = k_{/2}\cdot(z-a)^2 - k_{/4}\,r^2 + e\cdot\ln(r_{/f}) + C \qquad (2)$$

where r is radius, z is the initial ion direction and k, a, b, C, d, e, f>0 are constants (in [2-3] e=0)

The objective of the present theoretical work has been to reveal in general how close to the ideal the characteristics of quadratic-field mirrors may approach for fragment mass analysis, i e what are the general limitations inherent to mirrors of this class

The following classifications of limitations have been revealed

A. Limitations on sensitivity.

In simple quadratic-field mirrors (i e with field (1) or (2) with e=0), such limitations arise from defocusing in the transverse direction (x or r) In quantitative terms, it means that the detector size should be made about four times larger along x for field (1) and about two times larger along r for field (2) than would be necessary for a linear drift tube with the same TOF dispersion.

B. Limitations on mass resolution.

Though at first glance mass resolutions of quadratic-field mirrors seems to be unlimited, more careful investigation reveals a number of general limitations on TOF resolution. These are of two main types.

1) fundamental, i.e unavoidable even when the electrostatic field is perfectly defined, such as:

- Small drift region, unavoidable in practice due to the need to separate spatially elements of construction (e.g. detector from collision cell), results in poor resolution at lower masses. This may be corrected by "shifting" the fragment ion energies to higher values (by less than 5-20% of the maximum energy) through introducing a slight acceleration after the collision cell This factor becomes practically negligible provided that the acceleration gap is <5-10% of the drift region which is, in its turn, <10-20% of the mirror length
- The uncertainty in the co-ordinate of ion fragmentation inside the collision cell limits resolution. On the basis of the impulsive collision transfer theory [5], we have developed a model of high-energy ion

scattering and dissociation in the collision cell Fig 1a, b shows the dependence of mass resolution on the mass of the fragment ions for two different collision gases and compares the results with these for an idealised orthogonal scheme (100% transmission in both cases, 3 kDa singly-charged precursor ions, 10 keV collision energy, 0 1 eV energy release, 2 m effective flight path, 20 mm collision cell length and, in orthogonal scheme, 10 mm wide push-out gap with a 1 kV pulse followed by a 4 kV static acceleration). This figure demonstrates that the latter is superior to quadratic-field mirrors only for fragment ion masses <10-20% of the precursor ion mass and does not compare favourably at higher masses

- The metastable decay of ions inside the mirror limits resolution. In this case, "ghost" peaks will does appear Due to the inherent smoothness of quadratic fields, these peaks will be smoother and much lower in intensity than analogous peaks in any traditional reflectron

2) practical, i e. arising due to imperfections in the field approximation when using the multi-electrode systems:

- The long-range field sag due to field non-linearity limits resolution. This sag may be minimised by shifting electrodes potentials in such a way that the weight-averaged integral of the difference between ideal and real potentials vanishes Then introducing, for example, a flat detector on the flange of the mirror (i.e. distorting field near the plane z=0) does not result in any significant loss of mass resolution provided all ions penetrate into the mirror to a distance deeper than 3-5 times size of the detector
- Short-range field perturbations due to "granularity" of boundaries limit resolution Their influence becomes negligible as soon as the ion trajectories lie at distances from the boundaries of more than 3-5 times the centre-to-centre separation of adjacent electrodes

It has been concluded that quadratic-field mirrors are capable of providing better than unit mass-resolution over the wide mass range up to 3-5 kilodaltons

HIGH VOLTAGE DEFLECTORS FOR MASS SELECTION ON A WIRE GUIDE MALDI/TOF

B.J. Bolanos, D.A. Laude, Department of Chemistry and Biochemistry,
The University of Texas, Austin, TX, 78712

Wire ion guides are employed to improve ion transport in matrix assisted laser desorption and ionization(MALDI)/time-of-flight(TOF) mass spectrometry as a means to enhance instrument sensitivity. Unfortunately, the wire guide is not mass selective and a large abundance of low-mass ions generated by MALDI can saturate standard microchannel plates(MCP) and mask the detection of the later arriving biomolecules. A number of research groups have employed techniques to combat detector saturation. However, for the most part success is limited by reduced ion deflection efficiency and poor mass selectivity(1,2). In the work to be presented, a high voltage deflection ring positioned at the end of the flight tube is demonstrated to provide the selective ion deflection needed to prevent MCP saturation. This approach is shown to have superior mass selectivity and sensitivity compared to the alternative bipolar pulsed wire method(2).

Experiments were performed on a 1.43 m linear TOF mass spectrometer with a dual microchannel plate detector.. MALDI ions formed by a 4.5 ns, 2 x 10^7 W/cm^2 354 nm pulse from a Nd:YAG laser are accelerated to between 5 and 30 kV before entering the flight tube. The wire guide consists of an electrically isolated 0.53 mm diameter stainless steel wire aligned along a 7.62 diameter stainless steel tube support. A deflection ring, 8 cm long and 4 cm in diameter, was mounted at the end of the wire guide tube support 10 mm away from the detector. In order to drive the deflection ring, a GRX 3.0K-H switching circuit from DEI was used in combination with a 5 kV power supply to allow for 3 kV pulses with no greater than 35 ns rise and fall times. Samples were prepared as a 2000:1 mixture of sinapinic acid to protein deposited on a sample probe tip and allowed to crystallize. Acceleration potential remained constant at 20 kV and wire guide potentials ranged from 0 V to -500 V. Spectra were generated from the coadding of ten laser firings on the same sample spot.

A typical MALDI spectrum which exhibits high-mass signal suppression due to detector saturation is shown in Figure 1. The baseline noise is pronounced even up to 25 µs due to enormous matrix and K^+ signals, and obscured desired sample signals up to several kDa. The use of bipolar pulsing techniques to correct for saturation can be successful in deflecting low-mass ions away from the detector, and increasing the signal/noise of the protein. For example, shown in Figure 2 is the spectrum for a a 5 µs, +100 V deflection pulse on the wire guide followed by a static -200 V potential prevents detector saturation and improves the bovine insulin signal/noise five-fold.

There are important limitations in mass selection when applying the bipolar technique. This is because the bipolar method requires that all ions, including analyte ions, experience the deflection voltage on the wire. A strong correlation between the magnitude of the deflection pulse used to eliminate the matrix ions and the decreased intensity of the protein signal was observed. Another problem with the bipolar technique is the difficulty in defining the conditions for optimal low-mass deflection without pronounced loss of bovine insulin signal.

The effectiveness of the deflection ring is demonstrated in Figure 3 for increased bovine insulin signal. As shown, a 2.5 kV 50 µs pulse on the deflection ring is acceptable to permit low-mass deflection without influencing the bovine insulin ions, which have a flight time of approximately 58 µs. The deflection ring allows protein ions to experience wire guide focusing

for their entire flight times for better signal/noise enhancement. Employing this technique provides a fifteen-fold increase in signal/noise, three times that of the bipolar spectrum in Figure 2, as well as a more efficient deflection of low-mass ions. Additionally, the deflection ring technique allows for more flexibility in optimizing focusing conditions since ions of interest don't experience competitive deflection and focusing voltages.

A deflection ring positioned at the end of the flight path allows for increased mass selective deflection of ions well-separated by time-of-flight. The mass selectivity of the deflector technique is demonstrated in Figure 4 in profiles of bovine insulin and gramicidin S signal with varied length of deflection pulse. Both profiles demonstrate a wide range of deflection conditions for optimal protein signal, in addition to well defined deflection windows for increased mass-selectivity. In the case of bovine insulin a deflection pulse of 30 µs is sufficient to deflect abundant low-mass ions for a dramatic increase in signal intensity, which remained constant through a 55µs pulse. Complete loss of protein signal occurred at a 60 µs pulse length due deflection of the protein ions prior to arrival at the detector at 58 µs.

Improved Space-Focusing Using Non-linear Ion Acceleration Fields in Time-of-flight Mass Spectrometry

Ben D. Gardner[1] and John F. Holland[2]

Departments of Chemistry[1] and Biochemistry[2], Michigan State University, East Lansing, MI 48824

Viatcheslav B. Artaev

Meridian Analytical Systems, Inc., 2310 Science Parkway, Okemos, MI 48864

In time-of-flight mass spectrometry (TOFMS), the resolution parameter is, by definition, the temporal coincidence of iso-mass ion arrivals at the detector surface Deviations from coincidence are, in essence, manifestations of variations in energy along the transmission axis The primary factors responsible for these deviations are the initial spatial and energetic (including turn-around effect) distributions of ions in the source at the moment of extraction. For ionization methods where the axial spatial distribution is quite narrow, the ion energy distribution will be the dominant factor However, for three-dimensional ionization techniques acting on gas phase molecules, the initial ion location in the source determines the axial energy induced by the extraction field which, in turn, is the dominant cause of ion energy variation

Compensation for the spatial distribution is achieved by placing the detector at the position along the flight path where the temporal distribution of iso-mass ions is minimized, a position known as the space-focus plane [1] Space focusing is currently achieved using linear extraction fields. Unfortunately, the use of linear fields does not provide the optimal focus condition Theoretically, ideal space-focusing may be achieved through the use of non-linear ion acceleration in the extraction region of the ion source We have previously described a computational model based on numerical analysis for determining the potential profile required to provide complete space focusing in a given instrument geometry [2] This model includes calculations of short linear electric field segments along the flight axis within the ion source, beginning at the ion source exit, following the equation

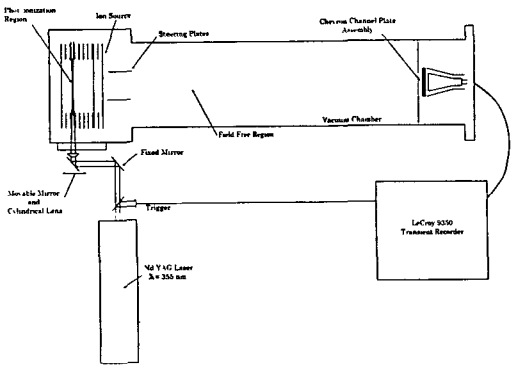
$$t=\sqrt{\frac{2m}{q}}\left[\sum_{n=1}^{i}\frac{\sqrt{U_0+q\sum_{j=n}^{i}x_jE_j}-\sqrt{U_0+q\sum_{j=n+1}^{i}x_kE_k}}{E_n}\right]+D\frac{\sqrt{2m}}{2\sqrt{q\sum_{i=1}^{i}x_iE_i}}$$

where t is the time required for an ion, beginning at some axial location within the source, to arrive at the space-focus plane, and is a function of mass m, charge q, initial energy U_0, electric field E, and field-free distance D Subsequent to the entry of a predefined t, the computation outputs an iteratively solved solution for a series of electric fields E_j having x_j width. When the applied width of these fields is short relative to the ion source dimension, a non-linear field distribution is approximated

We have fabricated a TOF instrument, illustrated in Figure 1, to test the validity of the computational model and experimentally evaluate the performance of various non-linear source geometries.

The ion source of this instrument consists of several parallel, grid-free, ring electrodes spanning the ionization region, and two gridded electrodes defining the acceleration region Photoionization of gas-phase molecules is accomplished using a Nd YAG laser operating at λ=355 nm. The laser beam is guided to the ionization region using a mirror assembly and is focused into the center of the ionization volume using a cylindrical lens By laterally adjusting the mirror assembly, the ionization volume is shifted along the ion source transmission axis

Figure 1



Using this instrument, the arrival-time dependence of iso-mass ions on initial ion position can be tomographically mapped throughout the source Initial results have substantiated the temporal limitations of ion sources utilizing linear electric fields, with the experimental results closely matching theoretically predicted behavior Our current efforts center on optimization of the non-linear ion source configuration A major challenge has been the application of appropriate voltages to the source electrodes in order to achieve the optimal electric field along the cylindrical axis Non-linear electric fields are not strictly orthogonal to the cylindrical axis, yielding an offset between the applied electrode voltage and the axial potential. Both the offset and field curvature must be accounted for in the ion source design.

Ultimately, tomographic mapping of the computationally designed non-linear ion source will reveal the extent to which the mathematical model is applicable We expect that the use of extended ionization regions may require the use of non-linear extraction fields

DESIGN OPTIMIZATION FOR A COAXIAL, CURVED FIELD REFLECTRON TIME-OF-FLIGHT MASS SPECTROMETER

Timothy J. Cornish and Robert J. Cotter, The Johns Hopkins University, Baltimore, Maryland, 21205

A coaxial time-of-flight mass spectrometer utilizing a curved field reflector has been developed in order to facilitate both high speed and high sensitivity analysis of bio-polymers These performance enhancements over conventional reflectron TOF designs can be realized because the complete sequence information of MALDI generated ions is obtained without the requirement of voltage stepping or scanning of the reflector

Shown in Figure 1 is a diagram of the instrument In contrast to a single stage constant field reflector, which focuses only stable ions and requires that L= 4D, the curved field reflector will focus all ions, both stable and metastable, if L ≅ D.

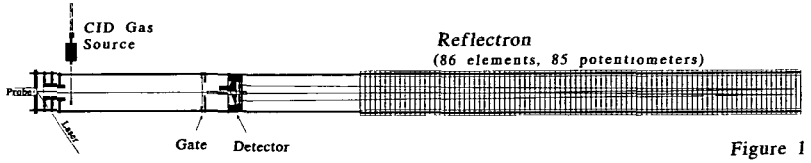

Figure 1

The MALDI generated ions are produced by the pulse of a nitrogen laser and extracted using a low voltage (4 kV) drawout potential Gating elements and a center-hole detector are located midway down the drift tube in order to allow sufficient time dispersion of the precursor ions in the first linear TOF region. A pulsed valve (Iota One General Valve Corp), capable of producing pulses of 250 μs duration, has been installed so that the collision gas intersects the ion beam near the beginning of the first drift region

Performance of the gate assembly is shown in Figure 2. Using PEG as a test compound, it was found that the minimum effective gate width is ± 50 Da at mass 1000 Da (±5% of the target mass) While not as selective as the gate of a true tandem MS, this configuration allows, in many cases, the isolation of single components from within a mixture.

Figure 3 shows the CID product ion spectrum of caffeic acid. The 163 Da peak was gate selected and fragmented using helium as the collision gas Instantaneous calibration of the product ion spectrum is accomplished using the time-of-flight data processing program TOFWARE© (ILys Software, Pittsburgh, PA) Based on the curve depicted in Figure 4, the entire procedure requires only the mass assignment of the parent ion. This calibration curve, which closely resembles the arc of a circular function, represents a plot of the normalized product ion data. The deadtime is mass dependent and represents the total time the parent ion spends in the field free regions

A single post source decay (PSD) spectrum of a polyproline derivative (P_{14}-R 20 data points total) was used to produce the calibration curve presently in use In Figure 5, these sequence ions are shown comparing the TOFWARE generated masses with those expected from theoretical calculations Further refinement by incorporation of data from many known product ion spectra is currently in progress

An Interleaved-Comb Ion Deflection Gate

D. J. BEUSSMAN[1,2], P. R. VLASAK[2], T. A. ERICKSON[1], M. R. DAVENPORT[1], and C. G ENKE[1,2]
[1]Department of Chemistry, University of New Mexico, Albuquerque, NM 87131
[2]Department of Chemistry, Michigan State University, East Lansing, MI 48824

We have designed and constructed an ion deflection gate and implemented it in a time-of-flight (TOF) mass spectrometer This gate is based on the ion gate, adapted from the electron filter design of Loeb[1], and first implemented in a TOF mass spectrometer by Schlag[2] This gate can be used to select a single *m/z* ion packet for further fragmentation in a tandem mass spectrometer, as well as to eliminate a range of ions such as those due to the matrix in MALDI or the carrier gas in GC-MS. Since time-of-flight mass spectrometers are batch array detectors, with all ions that are extracted from the source reaching the detector, a gate device is crucial for tandem time-of-flight instruments using post-dissociation acceleration. The gate allows a single *m/z* ion packet from the normal spectrum to be transmitted while deflecting all others This ensures that the product spectra are not convoluted with ions from the normal mass spectrum

Our interleaved-comb ion deflection gate is constructed from two stainless steel wires that are strung back and forth through alternate holes in an insulating material, thus creating a plane of wire segments approximately 1 mm apart. The two wires are attached to separate high-voltage pulsers such that equal but opposite voltages can be applied with pulse widths as narrow as 135 ns

The gate is 'open' when the wires are at the field-free voltage, allowing ions to pass through the gate unimpeded. The gate is 'closed' when one of the wires is pulsed to 250 V above the field-free voltage, while the other is pulsed to 250 V below the field-free value This creates a strong field between alternate wires, causing ion deflection from the normal ion trajectory Since the wire segments are interleaved and only 1 mm apart, the deflection field does not extend a significant distance into the field-free region from the gate device, as opposed to conventional deflection plates For example, in order to deflect *m/z* 167 ions by the same amount using either the interleaved-comb deflection gate or conventional 1 5 cm deflection plates, ±5 V field lines extend 1 3 mm into the field-free flight path from the center of the gate device, while they extend 28 mm from the center of the deflection plates This allows better gating resolution to be achieved in pulsed-field mode using the interleaved-comb ion deflection gate

A practical electronic pulsing system has been designed and implemented. Pulse amplitude and duration are adjustable from 0 to ±500 V and from 135 ns to dc respectively Circuitry for minor timing control and voltage offset of each of the pulsers has been designed to ensure that the two pulse shapes complement each other. The rise- and fall-times for the ±250 V pulses have been measured to be approximately 20ns (10%-90%)

The ability to transmit or eliminate a single *m/z* ion packet is demonstrated below using the molecular ion region of diphenylmethane (*m/z* 168) Figure A below shows the entire molecular

[1] Loeb, L. B *Basic Processes of Gaseous Electronics*, University of California Press Berkeley, CA, 1995.
[2] Weinkauf, R., Walter, K.; Weickhardt, C.; Boesl, U ; Schlag, E W *Z. Naturforsch*, **1989**, *44a*, 1219-1225.

ion region of diphenylmethane from *m/z* 163 to 169 This was obtained with the gate 'open' for 2.5 µs, allowing the entire region to be transmitted. Figure B shows the selected transmission of *m/z* 167 with the deflection of all other ions. This spectrum was obtained with the gate 'open' for 135 ns, and the delay timed to transmit the desired ion packet. Figure C indicates the ability to deflect a single *m/z* ion packet while transmitting all others by keeping the delay the same as in figure B but reversing the gate so that it is 'closed' for 135 ns.

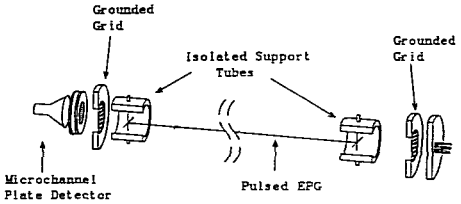
Ion Isolation in MALDI-TOF Mass Spectrometry Using a Bipolar Pulsed EPG

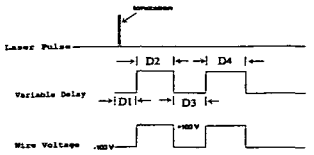
Curtiss D. Hanson and Nathan A. Adams
University of Northern Iowa Chemistry Department, Cedar Falls, IA 50614

Time of flight mass spectrometry (TOF-MS) has come to the forefront of high-mass analysis due to the high sensitivity and extended mass range offered by the instruments.[1-3] These techniques have shown superb sensitivity for sample sizes within the range of a few hundred attomoles,[3,4] and the mass range of TOF-MS is theoretically unlimited.[5] Although the high sensitivity and mass range of MALDI-TOF provide strong arguments for its use, the spectra are complicated by the high-intensity background peaks that result from the matrix which limit both the resolution and detector response, reducing the effectiveness of the technique for high molecular weight biomolecule analysis.

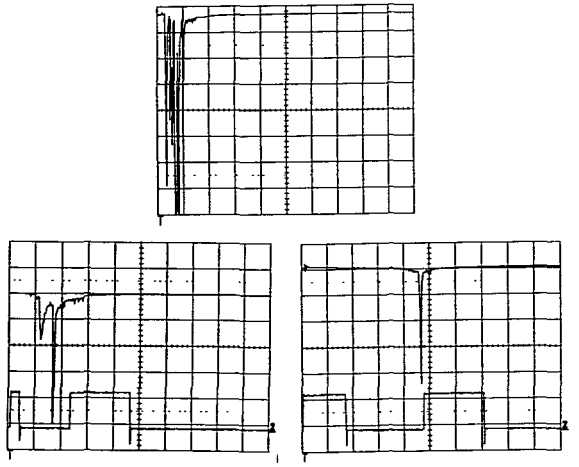
Microchannel Plate (MCP) detectors are ideally suited for high-sensitivity applications due to the rapid response coupled with a very high gain.[2,6] However, these same characteristics make the MCP detectors susceptible to saturation resulting from the low mass ion component in the MALDI spectrum. An individual channel of the microchannel plate array becomes saturated following generation of the electrode cascade, and a recovery of up to several milliseconds is required before the channel is restored to an active state. Because a large component of the ion flux in MALDI is composed of low-mass ions (m/z<300), and because the time scale of the experiment is in the microsecond range, early saturation of the detector occurs frequently, resulting in a reduced capacity to detect high-mass ions.[2]

One approach to selective elimination of low molecular weight matrix ions was demonstrated by use of a bipolar pulsed EPG.[7] The ability to apply pulsed positive and negative voltages on the EPG allows one to combine the deflection capability of an EPG that traverses the full length of the flight region. The bipolar pulsed EPG not only deflects undesired ions away from the detector but recaptures divergent high molecular weight ions into an elliptical, spiraling orbit about the EPG back toward the detector. This mode of operation permits the selective elimination of low-mass ions by operating the bipolar pulsed EPG as a high-pass filter.





The mechanism and selectivity of the ion elimination can be described on the basis of ion motion about the EPG derived by Oakey and Macfarlane.[8] A particle injected into the potential field of a centrally located EPG will have a velocity with vector components parallel and perpendicular to the ion axis. The perpendicular component of the ion's velocity, vp, results in an eccentric spiral motion around the EPG. Ions trapped by the radial electric field are transported to the detector by the velocity component parallel to the ion axis. It is important to note that the parallel component of the velocity is unchanged by the radial electric fields and therefore does not alter the time of flight of the ion. When the polarity of the EPG is made positive to create a repulsive electric field, the ions are accelerated toward the flight tube walls. Ions are therefore eliminated by collision with the walls of the flight tube. If the polarity of the applied voltage is changed to create an attractive electric field (i.e., negative) prior to collision with the flight tube, the ion will by recaptured into a stable orbit. This ability to recapture and detect deflected ions results in a highly selective ion elimination technique. This technique was shown to be an effective method of selected reduction of unwanted background peaks and provides an increase in both dynamic range and sensitivity.[9]



The work presented here demonstrates the effects of the addition of a second pulse to the pulsing sequence to allow for ion isolation. This allows the EPG to be used as a band-pass filter for the ions Ion isolation using an EPG permits a method of selecting specific ions for structural analysis. Because the EPG has no field vectors along the flight axis, ion selection does not effect the TOF of the selected ions. However, presently the resolution of the second pulse is fairly low because the initial pulse gives the ions a radial velocity distribution. If coherency could be induced in the ions prior to the second pulse, the resolution of this technique would increase dramatically.

Comparison of Ion Detectors for Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry

Richard C. King and Kevin G. Owens, Department of Chemistry, Drexel University, Philadelphia, PA 19104
Scott D. Hanton, Air Products & Chemicals, Inc., Allentown, PA 18195

Time-of-Flight mass spectrometry (TOFMS) is a pulsed technique requiring ion detectors with special properties. These detectors must have fast response times to resolve closely-spaced ior packets, high gain to amplify weak ion signals, high current capability to prevent saturation, and a sensitive conversion surface. Two different types of detectors are commonly used in TOFMS: continuous dynode microchannel plate (MCP) detectors[1-3] and discrete dynode electron multipliers (EM). The MCP detector is valued for its fast response time, but is prone to saturation even for relatively low ion current. EM detectors have become popular recently due to improvements in their rise times.

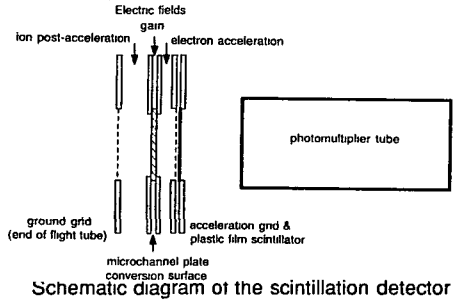
In most MCP and EM detector configurations the secondary electron gain is directly coupled to the ion post-acceleration potential. Post-acceleration is often used to increase the sensitivity of detection[4] while maintaining the mass resolving power gained through low voltage ion extraction. Additionaly, low voltage extraction reduces the risk of ion fragmentation through collisions with neutral material in the expanding plume and decreases the probability of detection for any neutrals formed from these fragmentation processes. Post-acceleration increases the ion kinetic energy, improving the detection of high mass ions by improving the ion/electron conversion efficiency. Unfortunately, this can lead to saturation by lower mass materials (both ions and neutrals) incident on the detector. Decoupling the detector post-acceleration and gain poses some experimental difficulties: providing separate electric fields to decouple the ion conversion from the electron gain in the detector, the addition of coupling capacitors to recover the signal from high post-acceleration potentials and protecting the signal amplifiers from high voltage spikes.

To address the problems of using MCP or EM detectors, a scintillation detector (SD) is constructed that employs a fast scintillator to convert electrons to photons that are then detected with a fast photomultiplier tube (PMT)[5]. The performance of the SD (schematic shown below) is compared to the tandem MCP detector and a commercially available EM detector (model AF820 ETP Scientific, Inc. Auburn MA). Factors investigated include the mass response, rise time, detector saturation, and ion (and neutral) kinetic energy effects. The SD has advantages, particularly for the analysis of polymers by matrix-assisted laser desorption mass spectrometry compared to the MCP and EM detectors. The performance of the detectors will be compared and the advantages and disadvantages of each detector will be presented.

Results

The tandem microchannel plate detector, although it possesses extremely high temporal resolution, was found to suffer from severe saturation effects. Low mass blanking was always necessary in order to observe higher mass analyte ion signals during the MALDI analyses.

The ETP EM was found to yield excellent results when used for synthetic polymer analyses. The significantly flatter ion/electron conversion characteristics allowed for the faithful reproduction of low mass (<2000 MW) polymer oligomer distributions. The lack of saturation obviated the need for using low mass beam blanking, which was found to significantly shift the flight times of ions experiencing the falling edge of the blanking pulse. Elimination of the need for beam blanking also significantly simplifies the experimental setup.



Schematic diagram of the scintillation detector

Excellent results were obtained with the scintillation detector, even when used with a less than optimum PMT. The sensitivity of the detector was high, enabling much lower desorption laser intensities to be employed for the MALDI experiments. The time response, although slower than that of the ETP multiplier or tandem MCP, is acceptable for ion signals observed in the MALDI experiment. The detector does seem to suffer from the same low mass signal enhancement (high mass discrimination) as the tandem MCP detector. This is likely due to the use of the MCP ion/electron conversion surface Future work on the scintillation detector will involve combination of the active surface used in the ETP Scientific AF820 discrete dynode multiplier with the scintillator/PMT combination.

Experimentally, there are significant advantages to the SD. Under normal operating conditions for both positive and negative ion detection the front of the MCP is held at ground potential and the rear is biased at up to -1000V The Ni mesh grid in front of the PFS is held at -3000V, defining the electron acceleration region. The photocathode of the PMT is biased at up to -1100V while the anode is held at ground potential (the standard operating conditions). Each of the potentials can be changed independently, optimizing the ion/electron conversion and initial electron amplification, the electron/photon conversion, and subsequent photon collection and signla amplification. In order to post-accelerate either positive or negative ions, the MCP and grid/PFS combination can be floated at any potential. As the signal is coupled out of this portion of the detector via photons, the overall detector signal is always recovered at ground potential. This eliminates the need for signal coupling capacitors under any conditions, simplifying the electronic setup, decreasing the noise pickup in the circuit, and adding a measure of protection for the signal conditioning and recording devices.

TANDEM MS UTILIZING AN ORTHOGONAL ACCELERATION TIME OF FLIGHT MS AS MS-II

R. L. Cerny, K. W. Wulser and D. L. Smith Deparment of Chemistry, University of Nebraska Lincoln, NE 68588
R. H. Bateman Fisons Instruments Manchester, U.K.

The use of tandem mass spectrometry in the structure determination of biomolecules is well established. There continues to be, however, need for improvements in both detection limit and mass accuracy to allow routine characterization of molecules derived from *iv-vivo* studies. We have recently installed a new VG Autospec hybrid magnetic sector-orthogonal acceleration time of flight (oa-TOF) mass spectrometer in our laboratory. This instrument is being used in conjunction with continuous flow FAB or electrospray ionization (ESI) for the structure determination of peptides resulting from the enzymatic digestion of proteins.

EXPERIMENTAL CONDITIONS All data were obtained using continuous flow FAB as the ionization method. The solvent system used was a 1:1 mixture of water:acetonitrile to which was added 1.5% glycerol, 1.5% thioglycerol and 0.1% TFA (by volume). The flow rate was 5 µl/ minute. An 8125 Rheodyne injector with a 5 µl loop was used to introduce the samples. The source temperature was 50 C. A Cs^+ ion gun operated at 25 keV was used to provide the primary beam. The instrument was operated at an accelerating voltage of 8000 v. Xenon was used as the collision gas and was admitted to the collision cell at a level to attenuate the precursor ion by 50 to 75%. Spectra were obtained at 30 to 90 kHz depending on the mass of the precursor ion. Spectra were bunched and stored as a single spectrum every 3 seconds.

HEMOGLOBIN A 10 nmole sample of human hemoglobin was digested with an equal amount of pepsin for 5 min at 0 C and a pH of 2.4. The resulting peptides were fractionated using reversed phase HPLC with an analytical C-18 column. A gradient of 0 to 40% acetonitrile over 40 min followed by 40 to 60% over 10 min was used for the separations. Fractions were collected and then dried using a Speed Vac system. Samples were reconstituted with 50 µl of water containing 0.1% TFA. The MS/MS spectra were obtained on 5 µl of these solutions. The incomplete digest results in pmole amounts of peptides. A representative MS/MS spectrum is shown in Figure 1.

EYE LENS CRYSTALLINS Three normal human lenses were homogenized with .05 M NaCl, centrifuged, and the precipitate redissolved in urea. The protein monomers were isolated using size exclusion chromatography. The crystallins were further purified by ion exchange and reversed phase chromatography. Two nmoles of α B protein isolated from the monomer fraction were digested using AspN for 4 h at 37 C and pH of 7.8. The resulting peptides were fractionated using reversed phase HPLC with a microbore C-8 column. HPLC fractions were collected based on UV absorbance at 215 nm. The collected fraction volumes ranged from 40 to 60 µl. The MS/MS spectra were obtained on 5 µl of these solutions. It is estimated that 40 to 80 pmoles of peptide were used in the analysis. A representative MS/MS spectrum is shown in Figure 2.

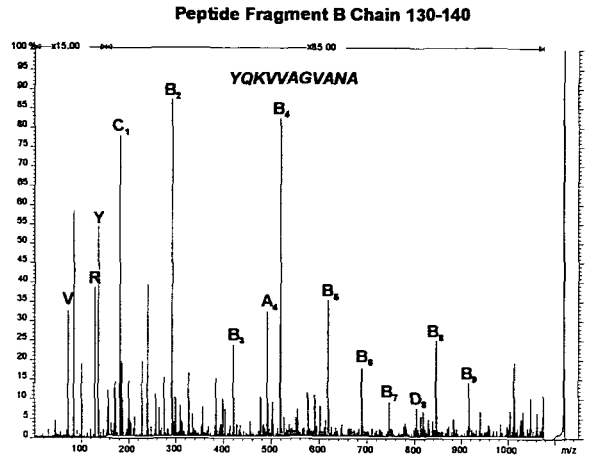

Figure 1 Tandem MS spectrum of peptide fraction isolated from pepsin digest of human hemoglobin.

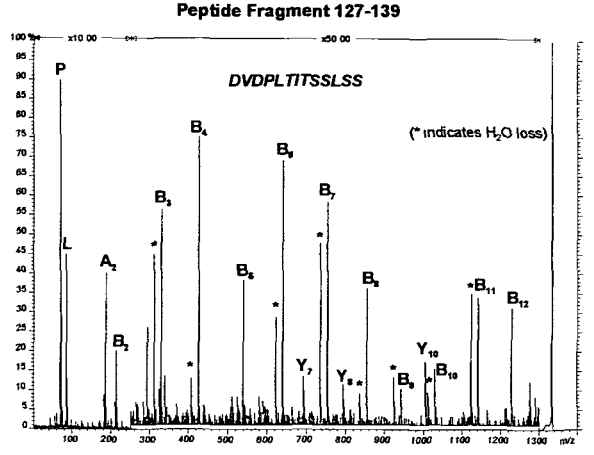

Figure 2 Tandem MS spectrum of peptide fraction isolated from AspN digest of α-B lens crystallin.

MS and high energy CID MS/MS of ESI and MALDI ions on a Magnetic Sector - TOF instrument

R H Bateman, M R Green, G Scott, VG Organic, Manchester, M23 9LE, UK.

Low and high energy CID MS/MS of singly charged ions from LSIMS and continuous flow LSIMS ion sources have been shown to yield different and complementary mass spectra which can be used to aid structural determinations of biomolecules. To date most MS/MS spectra using Electrospray ionisation (ESI) and MALDI ion sources have been acquired using low energy collisions on a triple quadrupoles in the case of ESI and by the techique of post source decay (PSD) on MALDI time-of-flight instruments. In this work high energy CID spectra for ESI and MALDI ions are investigated. The instrumentation used is a combined magnetic sector - TOF tandem MS/MS instrument, employing orthogonal acceleration time-of-flight In addition a "magnet by-pass" has been fitted to the magnetic sector which allows the whole of the ion beam to be transported, without mass analysis, from the ion source directly to the TOF analyser. This allows the high sensitivity spectrum acquisition characteristics of the TOF analyser to be used for MS as well as MS/MS Fast switchover between MS and MS/MS is achieved simply by switching the "magnet by-pass" on and off.

Figure 1 shows a plan view of the combined magnetic sector -TOF instrument MS-1 is a VG AutoSpec magnetic sector mass spectrometer fitted with two additional electrostatic deflection systems, situated before and after the magnet, and an interconnecting straight flight tube. Switching these deflectors on, and the magnet off, transmits the total ion beam without mass selection through this *magnet by-pass* to the oa-TOF for fast high sensitivity acquisition of full mass spectra.

Figure 2 shows the electrospray mass spectrum from 16 fmol of Lysozyme acquired on the oa-TOF via the magnet by-pass at a solvent flow rate of 10 ul/min. The spectrum over the mass range from 1 to 3500 dalton was acquired in 1 second.

The AutoSpec may be fitted with a MALDI ion source which operates at 8kV. A Nitrogen 337 nm UV laser is used in the MALDI source and operated at 10 Hz pulse rate. The precursor ions selected by MS-1 arrive at the gas collision cell some microseconds after the laser is fired. These ions are decelerated to 800 eV energy before entering the gas collision cell, which is operated at a pressure such as to give an average of one or two precursor ion collisions. These and the resulting product ions travel with essentially the same velocity, and therefore arrive at the orthogonal acceleration chamber at the same time. The oa-TOF extraction field is applied just at this moment so that the sampling efficiency is 100 %. This required delay time is calculated and controlled by the data system. The ion signal from the MCP detector is acquired using a 1 GHz time to digital convertor. The TOF detector is long enough to detect the whole product ion spectrum for each laser pulse.

Figure 3 shows the product ion spectrum from the $(M+H)^+$ ion from a 10 pmol loading of [Glu]-Fibrinopeptide B (m/z 1570.7) for 800 eV Xenon CID. Unlike PSD data, the spectrum exhibits the side chain cleavage ions expected for high energy CID MS/MS.

A HYBRID TANDEM MASS SPECTROMETER II.

A. Duhr, J. Stadlmann, P. Stracke and H. Wollnik

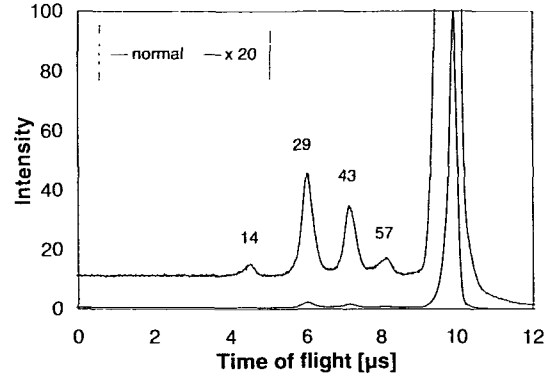
2. Physikalisches Institut der Justus–Liebig–Universität, Heinrich-Buff-Ring 16, 35392 Gießen, Germany.

A hybrid tandem mass spectrometer (Tandem–MS) was build for the study of molecular fragmentation reactions (see lower Fig. on opposite page). The first stage of the Tandem–MS is a high resolution sector field type. The second one is a Time–of–flight(TOF) instrument which allows a simultaneous detection of fragmented ions. The interface between the two different mass spectrometers was build with a microchannel plate as a collision target which yields a high fragmentation efficiency and a high ion transmission [1,2,3]. The resulting spectrum is recorded by counting single ions in the collision cell as well as at a stop detector located at the end of a drift tube or a reflectron, respectively, and measuring their time difference by a time to digital converter (TDC).

The electron released by the ion that hits the channel wall is guided by electric and magnetic fields to a MCP chevron assembly. There it is amplified and finally detected as start pulse for time counting. The collision cell is operated in high vacuum and can be heated up to 250 °Centigrades, resulting in less dark noise in the electron detector and far less surface impurities on the fragmentation channel plate. As a result of these changes SIMS products that are frequently mentioned by other authors in the fragmented ions spectrum are now reduced to invisibility.

By floating the collision cell in potential the collision energy is varied and the probable energy transfer variates. The collision cell works simultaneously as a detector for the first stage mass spectrometer. No moveable parts, therefore, are contained in the setup. In particular, this allows scanning of the first stage MS and switching to tandem mode at the same moment. The use of thos collision cell does not influence the properties of the first stage MS. The time for data aquisition in the second stage depends on the required statistic accuracy and may be as small as 10 seconds or less for an intense primary ion.

The mass resolution of the second stage depends on the time-of-flight MS used. In linear mode with 5 keV post accelleration it is limited to approx. 10 (see top Fig. on opposite page).



The spectrum of Hexane aquired in pulsed mode of the linear TOF is shown in the upper picture. The whole tandem mass spectrometer in an overview (bottom).

A new 2-D / 3-D-TOF MS

H. Bernhard Linden and Michael Bamberg;
Linden ChroMasSpec GmbH, Auf dem Berge 25,
D-28844 Leeste, Germany

In recent years time-of-flight mass spectrometry (TOF MS) has become very popular. TOF-instruments have the basic merits of simplicity, high sensitivity, and unlimited mass range. Improvement is desired with respect to mass resolution and fragment ion analysis [1-4].

In order to improve these draw-backs, we have developed a new type of TOF MS equipped with dispersion electrodes the potentials of which vary with time [5]. Ions penetrating said electrodes after each other, experience different fields and are respectively dispersed:

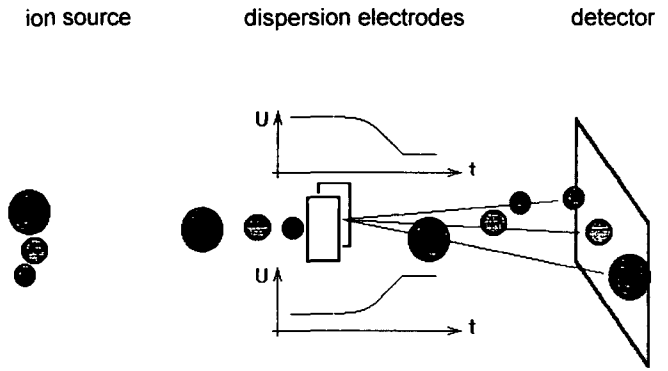

Fig. 1 Basic 2-D / 3-D TOF mass separation with $U \sim t^2 + t_d$

Dispersion potentials varying with the square of the flight time generate linear mass scales on the detector plate. To compensate for different energy, an electrical sector is added:

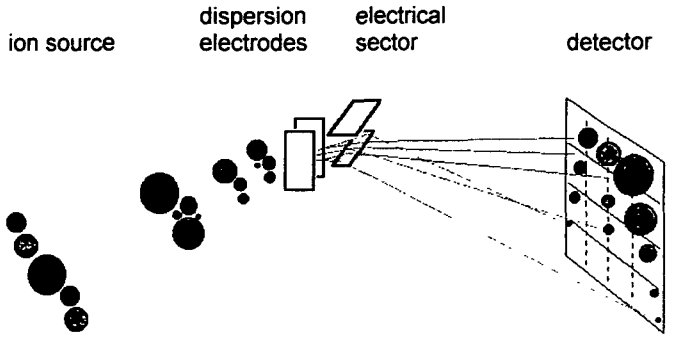

Fig. 2 Advanced 2-D / 3-D TOF mass and energy separation: every shot exhibits the entire information on precursors and related fragments

The experimental setup has an effective TOF flight path of 17 cm, kinetic ion energy of 150 V, chevron type detector with postacceleration and phosphor screen, and a high resolution CCD-camera with video image processing software.

Spectra are presented confirming the theory that at constant mass unit distances the resolution increases with the mass. Simplicity of handling is preserved: Mass range and resolution are individually selectable by setting 1 specific parameter only.

The new 2-D / 3-D-TOF MS is able to disclose information on several precursor ions and their fragment families simultaneously in every shot.

The Evaluation of a Comprehensive MS Reference Library

V Zaikin*(1-1), P Ausloos, C. Clifton, S. Lias, A Mikaya, D. Sparkman, S.Stein*(1-2)
1-1 Topchiev Institute of Petrochemical Synthesis, Moscow, Russia
1-2 NIST, Gaithersburg, MD, USA

The confidence in correctly identifying a compound by matching its spectrum with a reference library spectrum depends directly on the quality of the library. Since it has become clear that automated quality control algorithms are unreliable, a spectrum-by-spectrum evaluation of the source archive of the NIST/EPA/NIH Mass Spectral Library has been undertaken over the past four years. This archive, containing over 110,000 spectra, has been exhaustively examined by individuals well trained in mass spectrometry. Once 20,000 recently obtained spectra are also subjected to this evaluation, NIST will release a fully evaluated collection of spectra. Because of unavoidable uncertainties in judging the quality of a spectrum, an important requirement has been the agreement on both the analysis and the remedy (correction or deletion) for each spectrum by at least two individuals. An exact record of any modifications to the spectra has been maintained. Where possible, suspect spectra have been remeasured.

Below are the criteria for inclusion in the distributed database and the factors used to evaluate spectra, along with examples of difficult evaluations

Criteria For Spectrum Inclusion

- Spectra consistent with structure and containing all the most characteristic peaks
- Incomplete spectra with 10 or more of the most characteristic peaks
- Monoisotopic spectra of compounds which cannot be remeasured
- Modified spectra (correction of nonspectral data, peak coordinates, deleting peaks, adding isotope peaks, etc.)

In some cases, the spectrum will be excluded from use in the distributed database because it is obviously incorrect. However, in other cases, it may be desirous to take corrective action. Whenever possible, compounds with suspect spectra are remeasured There are some spectra where this is not possible. Listed below are the corrective actions that can be taken Peaks are never added except in the case of monoisotopic spectra of compounds containing chlorine and/or bromine or multiple atoms of silicon and/or sulfur Then, only characteristic isotope peaks are added at high mass to help in the visual identification of the spectrum.

When mass assignment or transcription errors are detected in a spectrum, peaks are never shifted more than one m/z unit

A critical requirement is that the evaluation and any corrections must be agreed on by at least two experienced, independent evaluators.

Evaluation Factors

- Consistency of name, structure, formula, molecular weight and CAS registry number
- Identification and analysis of molecular ion and important fragment peaks
- Consistency of formula with presence of significant isotope peaks (for Cl, Br, Si & S)
- Interpretation of spectrum based on mass spectral rules.
  - Nitrogen
  - Even-Electron
  - Stevenson-Audier
  - Bond Cleavage Adjacent to Unsaturation
  - Primary Fragmentation Rules
    - Simple cleavages
    - Rearrangement processes, including skeletal rearrangement
- Identification of background, impurity and other phantom peaks
- Visual and computerized comparison to other spectra
  - Replicate spectra of the same compound
  - Stereoisomers
  - Homologous Series
  - Derivatives
  - Spectra of the same compound in other collections
- Comparison of observed isotope peak intensity to calculated (performed with software specially developed by NIST)
- Comparison of calculated neutral losses to observed values (performed with software specially developed by NIST)

If a spectrum is labeled as a certain compound and the evaluation does not agree with the label, the identity of the compound is never changed The spectrum is excluded from use in the distributed database. If the source of the data is available, such as spectra taken from the literature, the changes will result in a spectrum with a new NIST number, which will then be reevaluated.

If two independent examiners agree the spectrum meets all evaluation criteria or that corrections can be made within the restrictions enumerated above, the spectrum will be included in the distributed version of the NIST/EPA/NIH Mass Spectral Library. Where there is more than one spectrum available for a given compound, the best spectrum (covering the widest mass range, requiring the least corrections and having the largest number of plausible peaks) will be selected for the Main Library Depending on the overall quality of the remaining spectrum or spectra for a given compound, inclusion in the Selected Replicates Library will be considered.

This fully evaluated mass spectral database will contain approximately 100,000 spectra for over 80,000 compounds. This version of the NIST/EPA/NIH Mass Spectral Main and Selected Replicates Libraries will have 7,000 to 8,000 spectra measured by NIST by GC/MS. This process of measuring spectra of commercially available compounds will continue and allow further growth of the database. As in the past, NIST solicits the donation of other collections of mass spectra for either recognized or anonymous inclusion in the database after evaluation

Odor Analysis by GC/MS/FTIR using Substucture Based Spectral Libraries.

A Nikiforov[1], Barbara Remberg[1], G Buchbauer[2], L.Jirovetz[2] and S.Kórnig[3]

[1] Inst. Org Chem , Univ.Vienna, Wahringerstr 38, 1090 Vienna, Austria, Fax· 011-43-1-31367-2280
[2] Inst of Pharmaceutical Chemistry, Univ.Vienna, Althanstr. 14, 1090 Vienna, Austria,
[3] Chemical Concepts GmbH, Boschstr 10, Weinheim, Germany

The odor attributes of complex odor systems, which exhibit distinct effects in medical and aroma applications (aromatherapy, perfumery), could not be predicted until today. Thus it was the aim of this work to investigate, whether there is a correlation between the concentration displacement of the volatiles and the odor attributes of such complex systems.

In the first part of this work, the selection of appropriate odor systems, the preparation of olfactorically representative samples and the instrumental analysis were performed. The dynamic headspace method was used for the preparation of 25 samples of the following odor systems flowers. apple, grape, Exacum affine, different plant parts of Aesculus hippocastanum, leaves of Plectranthus coleoides, different mushrooms, sunflower stems, peels of Juglans nigra, Chenopodium botrys plant, SCF-extract of shellac, needles and twigs of Douglas Fir, as well as old books and fragrance candles with different notes Sensoric evaluation was performed by professional perfumers who classified the samples in terms of "flowery", "fruity", "fresh", "green" and "mushroomlike" odor notes Investigation by means of GC-FID, GC-FTIR-MS and GC-Sniffing technique allowed the identification of more than 350 different components in total, mostly terpenes, ketones, lactones and esters

In the second part, the structures of 61 796 components of NIST/EPA/NIH mass spectra library and of approx 130 000 entries of Wiley (R) Spectral Library were transferred (authorized work), together with the corresponding ID numbers, as MOL-files in the commercially availably structure and substructure based "ISIS/BASE (R)" of MDL Information Systems. Using this data files, substructure

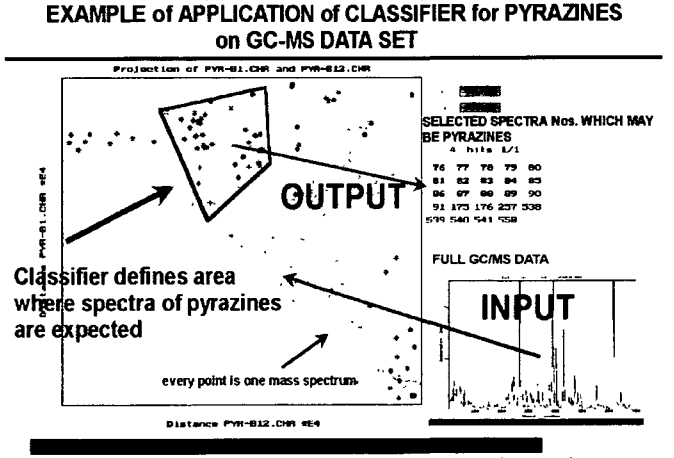

Fig.1: Example of a planar classifier based on MS-data for pyrazines

search (queries) subsequently enabled, via the ID library numbers, the selection of mass spectra (as contained in the spectral libraries of NIST/EPA/NIH resp Wiley) for training data sets These training MS data sets, in turn, were used for the development of classifiers for semiautomatic preselection, via multivariate analysis, of groups of target compounds in instrumental data of the odor systems investigated. The classifier's performance is mostly essentially improved if classifying criterions based on IR data are also included An example of planar classifier for pyrazines, based on MS data exclusively is given in Fig. 1

The structure files in MOL formate have additionally proved to be useful as a structure pool for input in a variety of programs which use MOL formates (see MDL Information Systems "Affinity" Group), e g MOLGEN (R) structure generator of Chemical Concepts GmbH, Weinheim, Germany, etc.

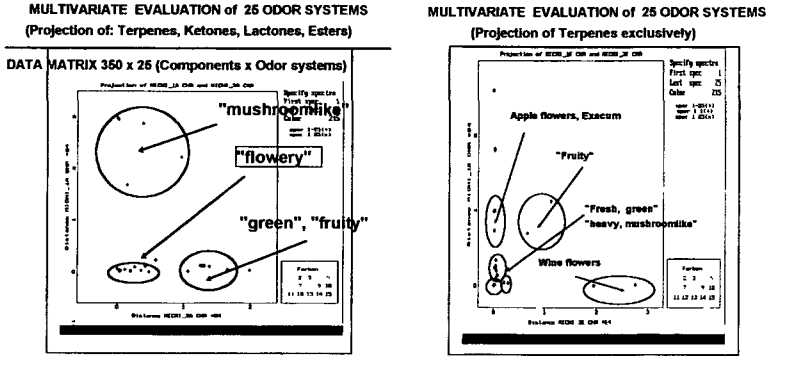

Fig.2: Correlation of MS-data of combined substance classes (terpenes, ketones, lactones and esters) and of terpenes alone with the odor notes of 25 aroma systems

In the third part of this work, multivariate evaluations, via PCA (projection in plane of the 1st and 2nd eigenvector), of 350 selected components, which were identified in investigated odor samples, based on a 350 x 25 (volatiles identified x odor systems) data matrix, were performed in order to find out if the displacement of the components concentrations of the samples correlates with their odor notes, as defined by professional perfumers. As a result of this, it became clear that the odor notes "flowery", "fruity", "fresh", "green" and "mushroomlike" may be correlated with a certain distribution of terpenes, alcohols, aldehydes and ketones, but not with the group of terpenes alone (Fig 2) Nevertheless, the prediction of odor notes based on instrumental data via multivariate analysis of the volatiles of complex mixtures is principally possible.

Experimental: The GC/FTIR/MS data were registered in a serial arrangement of IR and MS (HP-5965B IRD with 5970C MSD). The recorded data was converted into own data arrays for subsequent data processing All calculations were made as desktop applications using a Highscreen 60 MHz Pentium PC For multivariate analysis own programs MSIR (written in TurboPascal) were used.

Acknowledgement: The support of the „**Hochschuljubiläumstiftung der Stadt Wien**" (**Project H-78/94**) is gratefully acknowledged.

A FULLY AUTOMATED SYSTEM FOR CONFIRMATIONAL MASS SPECTROMETRIC ANALYSIS

Saul W. Fink, William L. Thompson, and John R. B. Slayback
Bristol-Myers Squibb Pharmaceutical Research Institute
One Squibb Drive, P. O. Box 191, New Brunswick, NJ 08903

Mass spectrometry (MS) is a vital tool in the development of novel pharmaceutical compounds. There are benefits of automating an MS system for routine analysis in the laboratory. First, rapid turnaround of analytical data is necessary as the results may be used to determine the next step of the synthesis. An automated MS system can support a turnaround time of one day or less of data without creating a "sweatshop" atmosphere in the laboratory. Second, routine MS analysis without automation requires many personnel hours. The time consuming elements of these routine samples can be substantially lightened using an automated MS system which provides more time for the operator to work on other challenging MS experiments.

Although GC/MS systems have been automated successfully for many years, instrument manufacturers have been slow in their progress towards automating other hyphenated chromatography (e.g. liquid, supercritical fluid) and MS techniques. A few laboratories have invested a significant amount of time to develop automated systems for MS analysis.[1,2,3,4] Described herein is an automated system for preparing and analyzing samples, and processing MS molecular weight data with a minimal amount of "hands-on" time.

EXPERIMENTAL

A Zymark Benchmate™ II Workstation equipped with an injection port, is used to prepare the sample solutions. There are two 2-tube methods running in series to prepare the samples. One method prepares solid samples (powders and crystals) and another prepares liquid samples (oils and solutions). There is a capacity of 100 samples/run.

A schematic diagram of the instrumental setup for the automated system is shown in Figure 1. A Waters 600 MS HPLC pump is connected to a Zymark Benchmate™ II which prepares and injects sample solutions into the Sciex API III triple quadrupole mass. The mass spectrometer is operated in the flow injection mode at 50 µL/min using the ionspray LC/MS interface and a mobile phase of 50/50 (acetonitrile/2 mM ammonium acetate, pH 6.0 using acetic acid). The mass spectrometer is equipped with the AutoGate option which allows the cryo-pumped vacuum system to be recycled (shutdown) in the absence of an operator.

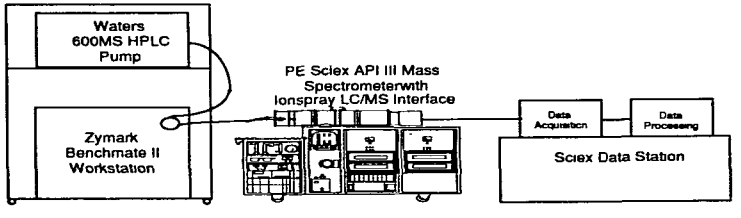

Figure 1. Schematic diagram of the instrumentation for the fully automated MS system.

The analyst inputs the sample information into a file in the automated acquisition program (RAD) and determines whether to analyze the samples using the positive or negative ion mode. A script code has

been written to automate the MS data processing. The macro, developed with the assistance of Dr. Ron Bonner of PE Sciex, processes a batch of files, sums the data from a specified range of MS scans, and background subtracts scans prior to the scans of interest. The MS spectra are then printed to a local printer for distribution to the submitting chemist.

RESULTS and DISCUSSION

Repetitive injections of standards were made to show the reproducibility and ruggedness of the automated system. Figure 2 displays the ISP-MS total ion chromatogram (m/z 300-1100) and selected mass chromatograms for injections of 200 ng of paclitaxel and reserpine using the solid method for sample preparation. The MS data show little, if any, carry over of sample between injections demonstrating the ruggedeness of the system. The standard deviations for the repetitive injections of reserpine and paclitaxel standards are 5.38% and 5.79%, respectively. Although the automated system is used for qualitative purposes exclusively, the results demonstrate the reproduciblity of the system.

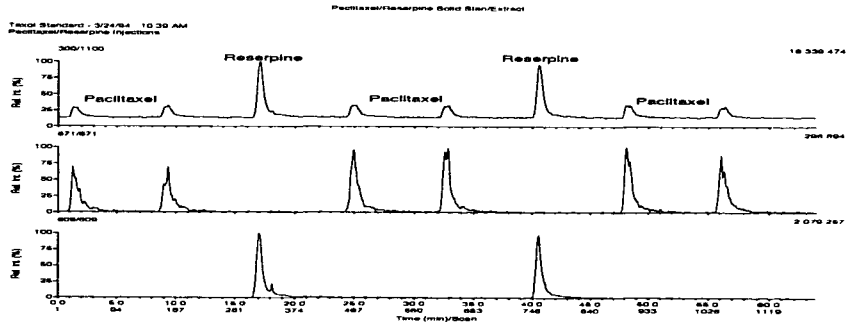

Figure 2. ISP-MS total ion chromatogram (m/z 300-1100) and mass chromatograms (m/z 871 and 609) for injections of 200 ng of paclitaxel and reserpine, respectively.

SUMMARY

An automated system has been developed which allows us to prepare, analyze and process molecular weight data for routine confirmational MS samples. A minimal amount of analyst time is necessary giving the operator time to work on other experiments while the routine samples are analyzed. The system is capable of analyzing the samples overnight, generating more instrument time during the day to conduct more challenging MS experiments or to increase MS sample throughput. The automated system yields reproducible results and there is little, if any, noticeable carry-over. To date, 94% of all samples analyzed using this system have produced good quality MS spectra with minimal operator intervention. In a one year period, we estimate that the enhancement in productivity has saved at least 600 direct labor hours.

SPECTRAL RESOLUTION OF ISOMERIC ALKANES: A PROCESS MASS SPECTROMETRY APPLICATION

Martin L. Haddix and Kelsey D. Cook, Department of Chemistry, University of Tennessee-Knoxville, TN 37996-1600

Isomer resolution by mass spectrometry (MS) is not widely practiced, in large part due to the strong similarity among isomer mass spectra. However, the need for such an application has arisen, in attempting to exploit the speed of MS for monitoring a process isoprene stream (a complex mixture of C_4-C_6 alkanes, alkenes, and alkynes) being examined in collaboration with a member of the University of Tennessee Measurement and Control Engineering Center. As a first step in assessing feasibility and reliability, mixtures comprised of two components from the isoprene stream (pentane and isopentane) have been examined by EI MS using an Extrel quadrupole-based process analyzer. Reference spectra of these two components (Figure 1) show expected overlap (*i.e.*, all ions in one spectrum are also in the other), but there are distinct differences in relative abundances, suggesting that resolution should be feasible. The problem of optimizing the accuracy, precision, and speed of determination of the relative concentrations of the two compounds in a mixture then becomes a problem of *parameterization*, selecting which part of the spectrum to use for deconvolution. Since much of the spectrum contains only noise (*i.e.*, at those m/z ratios where there is no significant signal), it is clear that deconvoluting the *entire* spectrum will not provide optimum efficiency. At the other extreme, two concentrations can, in principle, be determined by monitoring as few as two ion signals, provided that the intensity ratios for those ions differ in the spectra of the pure components. If consideration is limited to ions of relative abundance greater than 10% in the pure component spectra (thus the eight most intense peaks in a spectrum from a 50/50 v/v mixture of pentane and isopentane), there are 28 such pairs possible. Similarly, there are 56 possible combinations of three ion signals selected from among the eight peaks, 70 combinations of four, *etc.*, comprising a total of 247 possible combinations of two to eight peaks The utility of any of these parameter choices for providing the needed deconvolution depends on the signal-to-noise ratio of the signals monitored and the differentiation among the intensity ratios in the pure component spectra. Even ions of high abundance may not be useful for deconvolution if their intensities do not differ in the reference spectra.

There is little guidance in the statistics literature to facilitate optimum parameterization in cases like this For a relatively simple case (such as this prototype binary system), it is feasible to employ a "brute force" approach, wherein all possible combinations are tested for accuracy and precision. As spectra become more complex, the number of combinations increases rapidly, making this exhaustive approach impractical. Therefore, it is instructive to examine the impact of various parameterization alternatives in an exhaustive treatment, to try to discern guidelines that may provide short-cuts to optimum parameterization as we move from the two-component prototype to the more complex process mixtures of real interest. This is the main goal of the current study.

In the exhaustive treatment of the 8-peak mixture spectrum, data for each m/z ratio can be used to obtain 124 different estimates of the vapor composition. Figure 2 presents the accuracy and precision (standard deviation of 5 replicate determinations) of each of these estimates for each m/z, using data obtained from a binary mixture estimated to provide vapor comprised of 45.1% pentane. (The preponderance of positive errors suggests that there may have been a systematic error in preparing the sample or estimating its vapor composition.) Figure 3 shows the average and range of values obtained using 2-, 3-, . ., up to 8-parameter fits. The largest error (1400%) occurred for a 2-parameter estimate (m/z 29 and 41), although these two parameters gave reasonable results in other 2-parameter combinations . Some 2-parameter estimates were quite accurate (*e.g.* 2% error using m/z 15 and 43). Use of all eight peaks did not afford the most accurate (6% error) or precise (std. dev. = 0.009) results. In general, however, the accuracy of the

determination did increase with the number of peaks used for prediction. In contrast, the precision varied widely and erratically (0.004 < standard deviation < 1.8) (Figure 2b).

From the spread of values in Figure 2, it is evident that the ion at m/z = 57 gave accuracy and precision generally better than that obtained with most other ions. This can be rationalized based on fragmentation pathways, as shown in Figure 4. The methyl-loss products at m/z 57 and 15 are the only major fragments which can be formed by more equivalent pathways starting with isopentane (three), than starting with n-pentane (two). Clearly, if such rules can be placed on a more quantitative basis, they can greatly facilitate parameterization. A "scoring system" aimed at quantitating the distinguishing ability of ions in a spectrum is under development. Failing that, more empirical approaches (*e.g.*, neural networks, partial least squares, or principal components analysis) will be invoked as we move from prototype to more complex process systems.

Figure 1

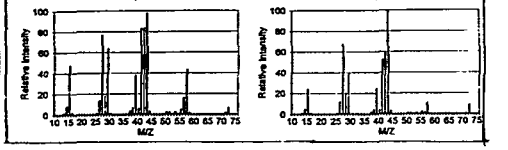

Figure 3a **Accuracy summary**

Figure 4

Ion with m/z 57 tends to give "superior" results.

Tentative explanation: Fragmentation schemes for Pentane & Isopentane

2 pathways to m/z 57 — 3 pathways to m/z 57

Only m/z 57 (and 15) have more equivalent pathways for Isopentane than pentane.

DISTINGUISHING BETWEEN ISOMERIC C3H5 MOIETIES USING DAUGHTER ION SPECTRA

John Glass Green

Louisiana Division Analytical Sciences Laboratory
Research and Development, B-2503
Plaquemine, Louisiana 70765-0400

During the analysis of a complex mixture resulting from the reaction of various chloropropanols with propylene oxide, a compound was detected that apparently had molecular weight 134 u. Isobutane chemical ionization confirmed the molecular weight. Based on the m/z 134,136 cluster, the compound contained one chlorine atom. The EI spectrum let to the conclusion that the compound was a propenyl 1-chloro-2-propyl ether. The question then arose as to which propenyl isomer was present. The m/z 58 base peak held the key to the structure of this portion of the molecule. Proton transfer from the chloropropyl moiety to the ether oxygen gave the m/z 58 ion.

The daughter in spectrum of the m/z 58 ion was obtained. (Figure 1) This spectrum was compared to the spectra for three model compounds, acetone, propanal, and allyl alcohol. (Figures 2-4) McLafferty has shown that the tautomers of acetone give similar CAD spectra.[1] This is also true for propanal. Regardless of which tautomer is involved, the CAD spectra of acetone and propanal are quite easily distinguished.

The CAD spectrum for acetone shows a significant m/z 43 daughter. The base daughter peak in the CAD spectra for both allyl alcohol and propanal is m/z 57 with essentially no m/z 43 present. McLafferty reported that the spectra for allyl alcohol and propanal are identical.[1]

The m/z 58 ion from the unknown was thus determined to be of the 2-propenyl structure.

Experimental

These experiments were conducted with a Finnigan MAT 95 high performance mass spectrometer using the linked scan capability. Collisional activation was done using helium in the collision cell in the first field-free region with 5kV accelerating voltage. Helium pressure was adjusted to give a 50% reduction in the parent ion intensity.

Structure Elucidation Using a Multi-Disciplinary Analytical Approach

D. J. Russell, S. W. Fink, L. M. Mallis, and J. R. B. Slayback

Bristol-Myers Squibb Pharmaceutical Research Institute
1 Squibb Dr., Building 90
New Brunswick, NJ 08903

The traditional role of an analytical spectroscopy group is to provide technical expertise in areas related to specific disciplines. Structure characterization problems are then carried out as independent problems within the different disciplines. This fragmentation of effort leads to the inefficient use of both the instrumentation and expertise available in the analytical environment. In our department, the focus has been moved away from analytical techniques and centered on problem solving. Our approach to structure elucidation is use of all available techniques in a concerted, cohesive fashion to solve the problem.

To show how this approach is applied, we present the structure elucidation of a chlorinated intermediate of the thromboxane antagonist, BMS-180291. Ionspray mass spectrometry (ISP-MS) and ISP-MS/MS techniques were used to determine the molecular weight of the compound and to verify the presence of a chlorine atom. Interpretation of the MS/MS data provided some substructure information about the molecule, but the position of the chlorine atom was ambiguous. Interpretation of ^{1}H and ^{13}C NMR data showed that during the chlorination reaction a quaternary carbon was formed from a methine carbon in the preceding reaction intermediate. Classical 2D NMR analysis provided unambiguous information regarding the site of substitution. Thus, it was the combination of disciplines, using one and two-dimensional NMR, ISP-MS, and MS/MS techniques, which allowed the unambiguous assignment of structure.

Our approach improves the efficiency of small molecule structure elucidation by driving the project exclusively within the analytical domain while maintaining a high level of confidence in the result through the use of teamwork between the various disciplines.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Practical Applications using Automated Mass Spectrometry in Drug Discovery

L.M. Schaffter*, R.C. Spreen, G.H. Cureton and F X. Morris
Zeneca Pharmaceuticals, A Business Unit of Zeneca, Inc.
Wilmington, Delaware 19850-5437

Our laboratory is currently using a VG Platform mass spectrometer (Fisons Instruments) with ApCI (atmospheric pressure chemical ionization) for molecular weight analysis of small molecules in drug discovery. The instrument has been automated and utilizes "Open Access" software as discussed previously by Taylor *et al* The system allows chemists to directly submit a prepared sample to a large tray autoinjector for flow analysis. Name and sample ID are input into a log-in computer and choice of positive or negative ionization is selected Sample ions are formed, the mass analyzer measures the spectrum, the MS computer processes the acquired data and prints the spectrum in both graphical and tabular form

The objective of the study discussed in this presentation was to optimize instrumental variables to facilitate automated production of abundant molecular ion signal (relative to fragment or adduct ion formation) for a wide range of chemical compounds.

Table 1. Qualitative Comparison of Positive and Negative ApCI

Compound Name	isotopic MW	Molecular Ions	
		Positive	Negative
[illegible]	651 3 amu	Yes	Yes
Creatinine	113.1 amu	Yes	Yes
2-acetyl-5-bromothio-phene	203 9 amu	Yes	No
aurintricarboxylic acid	422.1 amu	No	Yes
[illegible]	744 4 amu	No	Yes
5-acetyl-2,3-isopropylidene-adenosine	349 1 amu	Yes	Yes
9-acetyl anthracene	220 1 amu	No	Yes
2-amino-7-methyl-5-oxo-5H-[1] benzopyrano [2,3-b] pyridine-3-carbonitrile	251 3 amu	Yes	Yes
2,5-dichloropurine	188 0 amu	No	Yes
2-(trifluoromethyl)- phenothiazine	267 0 amu	Yes	Yes
(S,R)- Noscapine	413 1 amu	Yes	Yes
(S)-(+)-Camptothecin	348 1 amu	Yes	Yes

[1]L.C.E Taylor, R.L. Johnson, L. St. John-Williams, T. Johnson and S.V Chang, *42nd ASMS Conf. on Mass Spectrom. Allied Topics,* **1994**, p. 322.

Table 1 is a list of the twelve standard, non-proprietary compounds that were used in the study. A qualitative comparison was made of positive versus negative molecular ion formation using these compounds, to determine if providing the option of automated negative ion analysis in addition to positive ion analysis would be of benefit. The data shown above illustrates that if only positive ion analysis had been performed for four of the twelve standard compounds, no molecular ion would have been identified.

Several carrier solvent systems were examined but it was found that pure methanol gives the most consistent results in the flow injection system A variety of solvents may be used to dissolve the analyte prior to auto-injection into the carrier solvent flow, without a deleterious effect on the molecular ion signal (*e.g.* methanol, methylene chloride, acetone, DMSO, THF, DMF)

From this study it is clear that appropriate choice of both probe temperature and cone voltage is important. Too high of a setting for either of these two variables causes most analytes to fragment to a high degree. However, too low of a setting (< 350 degrees, Celsius for probe temperature and $\leq$ 15 volts for cone voltage) can also be a problem. Some analytes will not form molecular ions at these low settings, and when the probe temperature is this low it causes carry over between samples. Compromise values for both of these variables were selected for the final automated experiment. A value of 400 degrees, Celsius allows formation of molecular ions that are not particularly thermally labile and prevents significant carry over. A value of 20 V for cone voltage is high enough to produce molecular ions of most analytes, without causing too much fragmentation of compounds with more labile bonds.

Because of the short analysis time (approx. 4 minutes for each analysis) the instrument's high success rate at producing molecular ions and the system's overall versatility, many of the chemists in Zeneca's Medicinal Chemistry Department have more than doubled their use of mass spectrometry as an analytical tool In addition to analysis of isolated products and intermediates, the chemists commonly use the system for reaction monitoring, screening of fractions and analysis of TLC spots

Diversity Profiling: Rapid Pharmaceutical Development Based on ESI/MS

Mike S. Lee[1], Edward H. Kerns[2], Gerald C. DiDonato[1], Richard Gedamke[1], Mark E. Hail[1], Steven E. Klohr[2], Robyn Rourick[2], Anne M. Starrett[1], Susan C. Taylor[1], William L. Thompson[3], Kevin J. Volk[2], Bethanne M. Warrack[1] and Jeffrey L. Whitney[2]
Bristol-Myers Squibb Pharmaceutical Research Institute, [1]Princeton, NJ 08543-4000, [2]Wallingford, CT 06492, [3]New Brunswick, NJ 08903-0191

Electrospray ionization/mass spectrometry (ESI/MS) is ideally suited for the structural analysis of mixtures. Recent trends which highlight the utility of this tool for the analysis of pharmaceuticals have focused on biomolecule structure analysis and the identification of metabolites, impurities and degradants contained in complex matrices. These tasks are representative within the dynamic scope of drug discovery and pharmaceutical development and are often repetitive in that identical or similar assays are performed throughout the lifetime of the program.

Currently, our approach for rapid structure analysis utilizes liquid chromatography/mass spectrometry (LC/MS) based profiling protocols. Our strategy emphasizes early "lock-in" of analytical methods, a template motif for the generation of structure based libraries and proactive methods for the predictive structure analysis of mixtures. Here we describe our ESI/MS approach for supporting the rapid development of drugs and provide insight into further extensions of this valuable analytical tool for pharmaceutical applications, in particular, applications involving the micro-scale generation of diverse mixtures of compounds.

Early Method Lock-In

Perhaps the cornerstone of any analysis is the analytical method. The early development of analytical methods which are "universal" to all samples within the particular study (and beyond!) provide distinct advantages for drug development and product support. Standardized methods allow for quick response to diverse needs and changing priorities. Universal methods also allow for the easy transfer of methods from laboratory to laboratory.

A key to the successful launch and implementation of these methods is the realization that not all studies will be amenable to these methods. We streamline this approach by using an "80/20 rule" which provides realistic constraints. This rule provides a benchmark of method success to 80 percent of the samples and helps to avoid unnecessary and time-consuming method refinement. Thus, some detail such as resolution and specificity is sacrificed for increased speed of analysis.

Traditional molecular weight determinations using ESI/MS methods successfully incorporate this strategy. Utilized exclusively as a "front-line" ionization method, structural prescreen ESI/MS approaches have also been developed which provides useful relationships between structural features (i.e., compound class, functional groups, basicity) and ionization. Generally, small molecule analysis involves the use of conventional LC columns with volatile buffers and modifiers (optimized for sample concentration, solvents, eluent modifiers, pH and flow rates) while biomolecule analysis utilize polymeric microbore LC columns in combination with "trap cartridges" for rapid desalting or preconcentration. The rapid molecular weight profiling of flavones in fermenation broths represents an example of this early method lock-in approach.[1]

Generation of Structure Based Libraries

A template motif is utilized to generate structure based libraries using our universal LC/MS methods in conjunction with tandem mass spectrometry (MS/MS). This strategy makes use of substructural templates which are generated for each standard compound (impurity or metabolite) using on-line LC/MS/MS techniques. Structures are proposed based on differences between diagnostic ions in the MS/MS product ion spectra. Structural libraries are created which provide quick reference to proposed structure, relative retention time, molecular weight and diagnostic functional groups.

Structure libraries are generated for impurities, degradants and metabolites as well as for combinatorial libraries. Combined libraries can be used to facilitate selection of a drug candidate for development and correlate structure with activity, bioavailability, lipophilicity or solubility. These libraries can also be used to indicate potential problems associated with long-term storage (stability) and scale-up (impurities). The structure based library generated for taxanes is an accurate illustration of the utility of this approach.[2]

Application of Predictive Models

Predictive models allow for a proactive approach to establish a structural data base. These methods involve the use of chemical modification and solid phase synthesis to simulate realistic conditions and provide a diverse ensemble of potential metabolite, impurity or degradant structures. Structures are obtained from these models using micro-scale LC/MS methods consistent with our current profiling methods allowing for the ultimate incorporation with the structure libraries generated from actual samples.

Chemical modification methods employ a general scheme of conditions representing oxidation, reduction and hydrolysis as well as acylation, alkylation and halogenation. The standard compound, typically the final product, is subjected to these conditions and the products are monitored. Related compounds or a standard corresponding to a strategic structural analog (i.e., key intermediates, known impurities) are also subjected to these chemical modification conditions. Reagents such as HOAc, NaOH, K_2CO_3 and $KMnO_4$ provide abundant information with preliminary investigations dealing with modified captopril analogs.

Solid phase synthesis of analogs represents a potentially powerful approach for obtaining a head-start with metabolite, impurity and degradant structure analyses. Our protocols have been refined using captopril on a N-Fmoc-L-proline resin ester solid support. Analogs were generated from the coupling of the deprotected Fmoc-proline Rink acid resin with a variety of carboxylic acids followed by the release from the resin. This approach has promise for other compounds containing a carboxylic acid or amine functional groups.

Conclusions

The early identification of potential metabolites, impurities and degradants as well as the early lock-in of analytical methods provides a streamline continuum within the drug discovery-pharmaceutical development interface and provides benchmarkable measures of consistency. Current ESI/MS based methods provide an excellent tool for profiling a diverse array of structures. Combined with early method lock-in strategies, structure based libraries and proactive models utilizing chemical modification or solid phase synthesis, ESI/MS approaches can be developed to facilitate the discovery and development process. In combination with combinatorial chemistry methodologies, this type of analytical approach may be applicable to the rapid screening and characterization of small organic molecules with specific enzymes.

Changes in Volatile Organic Composition in Milk over Time

Santford V. Overton and John J. Manura
Scientific Instrument Services, Inc.
1027 Old York Road, Ringoes, NJ 08551

Volatile and semi-volatile organic compounds present both in the matrix and the headspace aroma are largely responsible for the flavor qualities of the foods we eat. Flavor is always considered the most important factor of any of the quality categories when comparing various dairy products. Because milk possesses a bland and soft flavor, the appearance of an objectionable off-flavor or off-odor is readily noticeable. There is a delicate balance between many flavor compounds that produce a desirable milk flavor and if this balance is disturbed, off-flavors may occur. In assessing its overall flavor quality, it would be extremely advantageous to have a reliable and efficient method for the detection, identification and quantification of the volatile organic compounds responsible for the degree of freshness in milk. Analytical techniques are needed to profile a wider range of volatile and semi-volatile organics in milk and to identify the flavors, off-flavors, off-odors and potential contaminants that may be present. The purpose of this investigation is to develop an analytical technique that could detect and identify a wide range of volatile and semi-volatile compounds in milk over time and relate the differences in volatile organic composition to the quality of milk. For this study, volatile organic compounds were purged from samples of milk followed by trapping onto Tenax TA adsorbent resin using a dynamic purge and trap technique (P&T). The adsorbent traps were subsequently analyzed by thermal desorption-gas chromatography-mass spectrometry (TD-GC-MS)

Several brands of milk that were freshly opened and allowed to sit at room temperature for two days were analyzed by a Purge and Trap technique to relate the off-flavor/off-odor to changes in the volatile organic composition of milk. In addition, several milk cartons were analyzed by "Direct Thermal Extraction" to determine if any volatile organics from the cartons contributed to the flavor profiles of milk. Sample sizes of 0 5 ml of the various milks were pipetted into a 10 ml test tube and heated to 60°C for 90 minutes. The surface of the samples was purged with high purity helium at 20 ml/min with an additional 25 ml/min dry purge using the S.I.S. Purge and Trap System. Volatile analytes were purged from the liquid matrix and carried to a preconditioned 4.0 mm i.d glass-lined stainless steel desorption tube packed with 200 mg of Tenax™TA. Approximately 25 mg of each of the milk carton samples with different colored inks were inserted into a 4.0 mm i d glass-lined stainless steel desorption tube and purged for 2 minutes at 80 ml/min to remove any moisture from the sample The desorption tube with sample was then attached to the Short Path Thermal Desorption System and a syringe needle attached. The desorption tube was injected into the GC injection port at desorption block temperatures of 250°C for 10 minutes and a flow rate of 1 ml/min for samples collected via purge and trap For samples to be analyzed by "Direct Thermal Extraction", the desorption block temperatures were set at 220°C.

Three different manufacturers of milk (Grade A, Half & half and a glass bottled milk) as well as samples from milk cartons with different colored inks were analyzed by Purge and Trap techniques and "Direct Thermal Extraction" to identify and compare the volatile organics present, and from the data, relate off-flavor/off-odor to the differences in composition of the volatile organic compounds Over 100 volatile organics were identified in the fresh and two day old milk. Most of the milk studied

produced 50 or more volatile organics which were identified in addition to many more that were either too weak to identify or in which a good NBS library match was not achievable. The milk samples were found to contain numerous straight and branched chain hydrocarbons, aldehydes, alcohols, ketones, fatty acids, esters, phenolic compounds, lactones and other miscellaneous compounds. Significant differences in the volatiles present occurred in the fresh milk samples versus the 2 day old samples. Although many of the same volatiles are present in all of the milk samples, there is a distinct variation in the quantities as well as the variety of volatile organics present. This variation could be due to the cow's diet, environment, heat treatment, bacterial spoilage, storage and the oxidation of lipids. In addition, the milk packaged in carton containers contained several volatile organic compounds that appear to be derived from the ink used in the manufacturing of the milk cartons

Among the hydrocarbons identified, tetradecane, pentadecane, hexadecane and heptadecane were the most abundant. They are derived either from the autooxidation of free fatty acids or from plants used in cow feed. Limonene was the predominant terpene hydrocarbon identified in the milk samples. Because only plants and some microorganisms synthesize terpenes, they must be transferred to the milk through the rumen The aliphatic compounds octanal, nonanal and decanal which are typical products of lipid oxidation were identified in each of the milk samples When these compounds pass a certain threshold, they are considered significant contributors to the development of rancid flavor Among the ketones, 4-methyl-3-penten-2-one, 4-hydroxy-4-methyl-2-pentanone, 3-methyl-2-cyclohexen-1-one, 3,5,5-trimethyl-2-cyclohexen-1-one and 2-nonanone were identified However, 1-phenyl-ethanone was only detected in the 2 day old milk samples packaged in carton containers In addition, 1-butanol, isoamyl alcohol and acetic acid, propanoic acid and butanoic acid were identified in the 2 day old milk samples. The differences in composition of the alcohols between the fresh and 2 day old samples may contribute to the difference of odor characteristics between the samples Most of the esters were found in the 2 day old milk samples. 2,6-Di-*tert*-butyl-*p*-cresol (BHT) was the predominant phenolic compound detected in each of the milk samples and may have been added as an antioxidant. The compounds 2-(2-methoxyethoxy)-ethanol and 2-(2-butoxyethoxy)-ethanol were only found in the milk samples packaged in the carton containers and not in the glass bottled sample. These compounds are believed to be derived from the ink used in the manufacturing process of the cartons Both of these compounds were also detected in carton samples containing different colored inks using the "Direct Thermal Extraction" technique. In addition, the milk cartons contained numerous straight and branched chain hydrocarbons, aldehydes, alcohols and terpene compounds.

The dynamic P&T technique together with TD-GC-MS has been utilized for the detection and identification of volatile organics, aromas and flavor components in milk over time and how these differences in volatile organic composition relate to the quality of milk. This analytical technique can be utilized for the quality control during the production of milk as well as a technique for the detection of potential contaminants in milk. The dynamic P&T technique offers several unique advantages over static headspace including greater sensitivity and the detection of a wider range of volatile organics including higher molecular weight compounds and is more sensitive by a factor of at least 100 as compared to the static headspace technique. This technique can easily be incorporated into troubleshooting techniques to detect problems in a wide variety of commercial food products, to compare various competing manufacturers' products as well as the implementation of a quality control program for the food industry.

MONITORING A CHEMICAL SYNTHESIS USING MASS SPECTROMETRY

Robin Sheppard, Mark Hayward* and Jack Henion, Analytical Toxicology,
Diagnostic Laboratory, Cornell University
927 Warren Drive, Ithaca, NY 14850
* American Cyanamid Company, Agricultural Research Center
P.O. Box 400, Princeton, NJ 08543-0400

The chemical synthesis of *o*-anilinocyclopropylketone was investigated using flow injection ion spray mass spectrometry and direct probe mass spectrometry. The reaction outline is shown in Figure 1. The goal is to monitor the by-products of the reaction and to identify reaction intermediates leading to the by-products in order to eventually understand and optimize the reaction parameters to improve the yield of the desired product.

This is a challenging application for ion spray mass spectrometry since the reaction is mediated with boron trichloride thereby requiring that it be carried out in non-aqueous conditions in a chlorinated solvent. The mass spectrometer used is a Sciex TAGA 6000E triple quadrupole upgraded to an API III with a home-made ion spray interface. We have monitored the reaction mixture as the reactants were added and at hourly intervals to characterize the reaction dynamics and to attempt to observe the reaction intermediates for this reaction. Full-scan spectra were collected for each sample and MS/MS was used to obtain product ion scans of abundant ions although essentially no fragmentation was obtained for the boron containing compounds. Figure 2 shows representative spectra obtained in these experiments. The major ions are identified to be protonated aniline (m/z 94), the protonated borazole by-product (m/z 187), the methyl ester of 187 caused by reaction with the methanol sheath (m/z 201), and the $[2M+H-H_2O]^+$ of the borazole (m/z 355).

In separate experiments, samples of the reaction mixture were analyzed by both EI and CI direct probe mass spectrometry using isobutane for ionization on a Finnigan MAT 95. MS/MS data was also obtained for many of the species monitored. Several ions of interest were identified to be: the amidine (m/z 161) which is formed after aniline addition, the acylation product (m/z 205) formed after $AlCl_3$ addition, a new intermediate (m/z 241), and the same m/z 355 ion seen in the ion spray data. The amidine formation does not depend on $AlCl_3$ or reflux. The mechanism for the borazole formation is shown in Figure 3. The MS/MS spectrum of m/z 241 is shown in Figure 4. This intermediate (m/z 241) helps explains the preferred charging order which favors the borazole intermediate: (1) cyclopropylnitrile, (2) BCl_3, (3) aniline, (4) $AlCl_3$. Formation of this intermediate (m/z 241) leaves the nitrile CI positioned for $AlCl_3$ catalyzed Freidel-Crafts acylation to an ortho position on the phenyl ring. The data suggests that formation of the m/z 241 is the rate limiting step as it is only observed prior to $AlCl_3$ addition and not during the several hours of reflux afterward.

This work shows the feasibility of using off-line mass spectral monitoring of this chemical synthesis for the optimization of reaction yield and shows promise that on-line monitoring could also be used to study such reactions. While ion spray mass spectrometry was not as useful for qualitative analysis of the actual reaction species because of reaction quenching in the sheath solution, it successfully allowed monitoring of reaction by-products. Direct probe mass spectrometry successfully identified important reaction species; however it is not

amenable to possible on-line analysis. Particle beam mass spectrometry may be a good choice for on-line analysis where both qualitative and quantitative information is desired. Preliminary experiments using particle beam with flow injection sampling show that the same qualitative results obtained with direct probe are easily achieved.

Cyanamid Agricultural of Puerto Rico
P.O. Box 243 - Manati, PR 00674

Membrane introduction mass spectrometry (MI/MS) has been used to identify, quantify, and locate the source of a low level volatile unknown that was observed by routine gas chromatography analyses of the vent stacks for all tanks containing toluene at a company manufacturing plant. Samples including the reaction streams, fresh toluene, recycled toluene, and the starting material for the process were all examined in order to understand the nature of the unknown. Sample preparation required only diluting each sample 1000 fold in water. Electron impact mass spectra permitted identification of the unknown as benzene and quantification of the benzene in each of the samples. Confirmation of the identification of benzene was carried out using tandem mass spectrometry. All analyses were readily carried out in one day by using totally automated flow injection sample introduction techniques as shown in the accompanying figure. The results obtained provided two key pieces of information: (i) the source of the benzene was the starting material, and (ii) that simple distillation of the toluene during the recycle part of the process raises the benzene concentration in the retentate because it is carried through with the toluene. When presented with these results, the supplier of the starting material acknowledged the presence of benzene and agreed, in the future, to provide starting material without significant levels of benzene. The primary benefit of using MI/MS (as opposed to other analytical techniques) to solve this problem was the unprecedented high speed at which the results were obtained. The high speed can be attributed to the following two qualities of MI/MS: (i) the ease of automation using flow injection sample delivery and, (ii) the ability to analyze complex mixtures without complicated sample preparation or method development. Based on these results, we view MI/MS as an important tool that should be included among the arsenal of interfaces utilized by mass spectrometrists to rapidly solve chemical problems.

On-line Monitoring of the Photolysis of Benzyl Acetate by Membrane Introduction Mass Spectrometry (MIMS)

N. Srinivasan, P. Wong, N. Kasthurikrishnan and R.G. Cooks*
Aston Laboratory, Department of Chemistry, Purdue University, West Lafayette, IN 47907.

P. Wedge, J. A. Pincock, and J.S. Grossert
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada, B3H4J3.

Exploration of the photochemistry of many organic compounds in water is difficult because the low solubility makes product characterization and determination of their yields difficult. We have applied MIMS [1] to such reactions because its high sensitivity overcomes the problem of low solubility and its capability for on-line monitoring potentially adds detailed insights into the course and kinetics of the process.

All the on-line photolysis monitoring experiments used a triple quadrupole mass spectrometer (Finnigan TSQ 4500) equipped with a sheet direct-insertion membrane probe.[2] The membrane employed was a dimethyl vinyl silicone sheet membrane with a thickness of 0.0125 cm. A solution of 400 mg/L benzyl acetate in 1:1 methanol-water in an 8 mL quartz tube was irradiated in a Rayonet photoreactor at a wavelength of 254 nm. The solution was recirculated by a peristaltic pump at a rate of 1 mL/min *via* Teflon transfer lines The probe, inserted directly into the source of the mass spectrometer, was heated to 80 °C. Analytes permeating the membrane were chemically ionized by either ammonia or isobutane. External calibration was accomplished by aspirating 500 μL of either sample or standard solutions into the membrane probe.

Scheme 1 shows the general mechanism for the photolysis of benzyl acetate in methanol-water [3]. Under isobutane CI conditions, several characteristic ions (m/z 107, 123, 183) are formed. The ion at m/z 123 is identified as protonated benzylmethyl ether by collision induced dissociation experiments (argon 17 eV) The ion at m/z 183 (bibenzyl, $[M+H]^+$) has a very low abundance indicating that this is a very minor product The ion at m/z 107 cannot be uniquely assigned due to the fact that both ethylbenzene and benzyl alcohol yield this ion.

Under ammonia CI conditions, ethylbenzene and benzyl alcohol yield characteristic ions of different mass-to-charge ratio. All the products yield the respective ammonium adduct ions $[M+NH_4]^+$ except ethylbenzene which yields M^+ at m/z 106. Benzyl alcohol was not observed under these conditions. Figure 1 shows that the ion abundance at m/z 168 (benzyl acetate, $[M+NH_4]^+$) decreases with time while the abundance of m/z 140 (benzylmethyl ether, $[M+NH_4]^+$) shows a corresponding rise with time. Figure 2 exhibits the ammonia CI mass spectrum of benzyl acetate after photolyzing for 20 minutes.

The concentration of benzyl acetate, benzylmethyl ether, bibenzyl and ethylbenzene were found to be 32, 44, 7.6, 32 mg/L respectively, after about 20 minutes of photolysis. These measurements were made by calibration using external standard solutions as shown in Figure 3. This corresponds to 92% conversion of benzyl acetate and the corresponding yields of benzylmethyl ether, ethylbenzene and bibenzyl are 14%, 11% and 3.1% respectively. Previous experiments in methanol solvent showed yields of 26%, 19% and 23% respectively [3]. The differences may be ascribed to the change in solvent. The initial rates of formation of benzylmethyl ether, ethylbenzene and bibenzyl were found to be 4.0×10^{-7}, 3.7×10^{-7} and 5.8×10^{-8} Ms^{-1} respectively. Hence, the relative rate constant ($k_{ethylbenzene} / k_{benzylmethylether}$) is about 0.93.

In conclusion, MIMS can be applied for on-line monitoring of an organic photochemical reaction due to its high sensitivity and selectivity and appears to be a very promising technique in studying reaction kinetics. The results show that the yields are dependent on the solvent and the products formed are consistent with earlier demonstrations by Pincock *et al.* [3] that the photolysis proceeds through both ion and radical pair intermediates.

Direct Analysis of Organic Compounds in Organic Matrices by Reverse Phase Membrane Introduction Mass Spectrometry (MIMS)

Scott Bauer, Jan Bauer, MIMS Technology Inc.

1900 S. Harbor City Blvd. Suite 115

Melbourne, FL 32901

Membrane introduction mass spectrometry (MIMS) has been applied to the direct analysis of volatile organic compounds in water with great success for many years. The high speed, low maintenance, inexpensive nature of MIMS makes it a natural choice for industrial monitoring applications. Unfortunately, most industrial processes take place in organic phases. In 1992 a method for the direct analysis of polar organic compounds in organic phases was demonstrated at Purdue University This method employed microporous membranes in a direct insertion membrane probe installed in a Finnigan TSQ 4500 spectrometer. This spectrometer has a differentially pumped source and can handle the high sample matrix flow across the microporous membrane. Unfortunately, the high cost of these spectrometers precludes their use in process monitoring applications. Bench-top mass spectrometer vacuum systems can not cope with the high flow of sample entering through a microporous membrane.

This presentation describes a method for the direct analysis of polar volatile organic analytes dissolved in non-polar organic solvents. Pervaporation membranes have long been used for direct analyses of organic compounds in water. They work well in benchtop mass spectrometers because the flux across the membrane can be managed by the instrument vacuum system. Polyvinyl alcohol (PVA) membranes are selective toward very polar compounds like water and reject less polar organic compounds. A PVA membrane was installed in a 1900-S1 sheet membrane probe from MIMS Technology Inc. The probe was installed in a Finnigan Magnum ion trap mass spectrometer. Sample introduction was performed using flow injection analysis techniques with an FIA-TC1 flow injection module from MIMS Technology Inc. Samples of volatile organic compounds such as acetone, methylethyl ketone, methanol, and THF were prepared at the low part per million level in hexane The flow injection module was filled with hexane and the flow rate through the system was set to 1 5 mL/minute. Although the PVA membrane discriminated against the non-polar hexane stream, enough of the matrix flowed through the pervaporation membrane to be used as a chemical ionization (CI) reagent gas.

Solutions of polar organic compounds were injected into the system to assess instrument response Parts-per-million level samples were easily detected and the mass spectra are clearly identifiable. All of the samples analyzed were protonated by the hexane CI reagent gas

Analytical Potential of the MAB source for routine analysis of organic compounds

D. Faubert, P Mireault and M J. Bertrand.
Department of Chemistry, University of Montreal, Canada, H3C 3J7.

Electron ionization (EI) and chemical ionization (CI) have long been used for the analysis of thermally stable and volatile organic compounds. The former is known to induce fragmentation and often provides molecular weight information. However, many compounds do not provide intense molecular ions in EI and it is common for those to resort to CI that yields protonated parent species but relatively weak fragment ions Penning ionization (PI), which has been rather neglected as a common ionization technique for organic analysis, can offer many of the combined advantages of EI and CI while eliminating some of the limitations of those techniques Using different rare-gases, a range of internal energies can be transferred to the analyte providing spectral information that can be very specific or extremely general. We have recently developed a series of ionization sources based on the principle of Penning ionization. These sources use Metastable Atom Bombardment (MAB) to ionize molecules in the gas phase. The commercial version of the MAB ion source was provided by Dephy Technology (Quebec, Canada) The MAB source acts as an energy tunable ionization source, since different rare-gases can be employed The accessible energies are in the range of 8 32-20 61 eV depending on the metastable atoms used (Xe, Kr, Ar, Ne and He) By selecting the appropriate rare gas, the MAB source can achieved both hard and soft EI-like ionization. Thus, MAB is an excellent energy tunable ion source.

Most mass spectrometry techniques such as accurate mass measurement, MS/MS, LC/MS and GC/MS are used in chemical analysis of complex mixtures. Reproducibility of quantification is important in most applications Electron ionization is the preferred ionization technique but it is often used in the so-called "low-eV" mode In this mode the electron energy is reduced to minimize fragmentation and generate mostly molecular ions. This results in a lost of sensitivity and in low reproducibility. In order to solve some analytical problems more analysts are resorting to MS/MS techniques. It is desirable in this technique to generate only one ion per component in the mixture so as to reduce the number of species and have most of the ion current in the molecular ion to increase sensitivity In view of the ionization features required, it appears that MAB can offer advantages in terms of ionization and fragmentation selectivity To illustrate this, a mixture of 15 compounds (Figure 1) has been analyzed with the MAB source using Krypton and the mass spectrum shows 15 major peaks each corresponding to a compound in the mixture Thus, the MAB source affords softer ionization then EI giving an exclusive or a predominant molecular ion signal. This characteristic makes the MAB source ideally suited for MS/MS experiments In another experiments, a mixture containing typical compounds present in petroleum samples and compounds having amino groups has been analyzed with the MAB source using Xenon Results (Figure 2a) show that only molecules containing an amino group are ionized by the Xenon metastable atoms. For comparison, the mass spectrum of the same mixture obtained with electron ionization is shown at Figure 2b. The molecular peaks characteristic of compounds containing amino group are lost among all the fragments spawned by aliphatic chains The MAB source using Xenon can selectively ionize certain classes of compounds with low ionization energies such as amines, thioethers, polycyclic aromatic hydrocarbons (PAH), some polysubstituted aromatic compound, etc By using Krypton or Xenon gas, the MAB source can generate intense molecular ion even for extremely labile compounds

as methoxychlor, while electron ionization does not provide intense molecular ion. Figure 3 shows the case of a molecule synthesize in laboratory The MAB source using Krypton generates a mass spectrum with the molecular ion as major peak (Figure 3a), while the molecular ion is weak in electron ionization (Figure 3b). Thus, MAB is an excellent ionization source for routine analysis Furthermore, the MAB source has the advantage of requiring no maintenance for many months.

UV Laser-Induced Selective Dissociation of Nitro Groups in Nitrocellulose

Mo Yang*, J. Michael Ramsey*, and Byung J. Kim**
* Oak Ridge National Laboratory, Oak Ridge, TN 37831-6142
** U.S. Army Construction Engineering Research Laboratory, Champaign, IL 61826-9005

Photon-induced dissociation of organic molecules is becoming an useful method for destruction of toxic or hazardous materials in the environment, since the absorption of a photon often results in selective dissociation of radicals that make the materials toxic or hazardous. In this case, mass spectrometric measurement of the dissociation products can also be a detection method that verifies the presence of those materials. In this paper, UV laser-induced dissociation of nitro groups in nitrocellulose (high explosive material known as smokeless gun powder) and its dependence on the laser parameters have been investigated using an ion trap mass spectrometer.

Figure 1 shows the experimental setup. The nitrocellulose sample with a nitrogen content of 13.56 % was spread on a glass plate in a vacuum chamber and irradiated by laser beams through a quartz window. The gaseous products released from the sample were ionized by an electron gun and the ion masses were analyzed by the ion trap mass spectrometer. The distance from the sample to the ion trap was 12 cm, so that the ions produced primarily by the laser irradiation were excluded in the ion mass analysis.

Figure 2 shows a typical mass spectrum of the gaseous products from nitrocellulose by irradiation with a pulsed UV laser. Only two significant mass peaks were observed, dominantly at m/z = 30 (nitric oxide) and a small one at m/z = 48. MS/MS analysis through ion mass selection and collision induced dissociation in the ion trap confirmed that ions of m/z = 48 were composed of nitric oxide attached by water vapor ($NO{\cdot}H_2O$). In conclusion, irradiation of nitrocellulose with pulsed UV laser produces primarily nitric oxide and a small amount of water vapor, implying that the nitro groups in nitrocellulose are selectively dissociated.

The quantity of gaseous NO produced by 266 nm irradiation was four times greater than the amount produced at 355 nm, as shown in Figure 3. Irradiation of nitrocellulose with 532 nm laser light did not produce any measurable level of gaseous products. The wavelength dependence of denitration measured with a tunable dye laser in the vicinity of 320 nm shows a linear decrease in NO yield with increasing laser wavelength. The weight loss rate of the sample (nitrogen content 13.6 %) due to denitration induced by 266 nm laser light was measured to be 3.9 ± 0.4 μg/J. This indicates hat the photon to nitro group conversion efficiency may be up to 6 %. Increased laser intensity and repetition rate resulted in thermal decomposition of nitrocellulose rather than selective denitration. The laser intensity threshold for sample detonation was found to be 7 mJ/cm² at 266 nm and 10 Hz repetition rate.

Direct dissociation of nitrocellulose into NO without producing NO_2 or other gaseous products suggests that nitrocellulose may have a peroxide structure (R-O-O-NO) rather than an ester structure (R-O-NO_2). UV induced selective denitration demonstrated with nitrocellulose in this paper can be applied for the safe destruction of explosives and the treatment of waste water containing explosive materials without using any chemical or biological reagents.

MS of Prepolymers 1,10-Undecadiyne & 1,2,10,11-^{13}C-1,10-Undecadiyne

Robbins, Ronny C.; Berg, Fred J.
U.S. Army
ERDEC, SCBRD-RTE
E3549, Berger Laboratory
Aberdeen Proving Ground, Maryland 21010-5423

Alpha-omega diynes are very useful compounds in the production of poly-acetylene type polymers. The mass spectra of both short chain and long chain terminal mono-alkynes contain an intense ion at mass m/Z 95. The mass spectra of short chained alpha-omega diynes contain an intense ion at m/Z 91 and a minor peak at m/Z 45.5 indicating an aromatic type of structure for the m/Z 91 ion. Carbon-13 labeling experiments for 1,7-octadiyne, 1,8-nonadiyne and 1,9-decadiyne also indicate the formation of some type of ring system before fragmentation. Ring formation may be of some utility in the study of long chain prepolymers that are alpha-omega diynes.

	Mass to Charge								
m/Z	89	90	91	92	93	94	95	96	97
1,7-Octadiyne	1%	0%	100%	8%	0%	0%	0%	0%	0%
1,2,7,8-^{13}C-1,7-Octadiyne	0%	0%	0%	0%	4%	84%	68%	2%	0%
1,10-Undecadiyne	0%	0%	77%	20%	21%	3%	3%	0%	0%
1,2,10,11-^{13}C-1,10-Undecadiyne	0%	0%	0%	17%	39%	30%	44%	11%	0%
1,23-Tetraeicosa-diyne	0%	0%	12%	11%	31%	28%	49%	20%	11%

Table 1: EI Mass Spectra on Perkin-Elmer Q-Mass 910 Mass spectrometer connected to a Perkin-Elmer Autosystem Gas Chromatograph Model 1020, Mass To Charge versus Relative Intensity in the range of m/Z 89 to 97

The mass spectra of alkynes with only one terminal triple bond have a large peak at m/Z 95 and very minor peak at m/Z 91. The mass spectrum of 1,10-undecadiyne contains an intense m/Z 91 ion. Carbon-13 labeling experiments indicate that this ion is produced from cyclic precursors. The difference in intensity of the 91 m/Z ion in the 1,10-undecadiyne to that of the m/Z 95 ion in the 1,2,10,11-^{13}C-1,10-undecadiyne indicates that the four carbon atoms in the two triple bonds are retained.

The data in table one indicates that prepolymers the length of 11 carbons in the case of 1,10-undecadiyne and 24 carbons in the case of 1,23-tetra eicosadiyne undergo ring formation. In the case of 1,23- tetraeicosadiyne, the prepolymer is acting more like two terminal mono-alkyne molecules bonded together giving a large m/Z 95 ion. As the chain length of the alpha-omega diyne increases, the m/Z 91 ion should greatly decrease in intensity.

Experimental

All mass spectra were collected on a Perkin-Elmer Q-Mass 910 Mass spectrometer connected to a Perkin-Elmer Autosystem Gas Chromatograph Model 1020.

Future work

The 1,2,23,24-^{13}C-1,23-tetraeicosadiyne will be synthesized and the mass spectrum taken to determine the degree of ring formation.

THE TMS-ESTERS OF DECENOIC FATTY ACID ISOMERS. CHARACHTERIZATION OF DOUBLE BOND POSITION AND GEOMETRY IN ROUTINE GC/MS.

J.E. Jalonen, M.J. Mäkelä*, H.O. Hassila, P.H. Joensuu and E. Haapaniemi
Chemistry Department, University of Oulu, POB. 333, FIN-90571 Oulu, Finland
*** Oulu Regional Institute of Occupational Health, FIN-90220 Oulu, Finland.**

Many different approaches have been utilized in the mass spectral characterization of fatty acids.(1) A major problem in the analysis of unsaturated fatty acids has been reliable determination of the position and geometry of a double bond in electron impact (EI) mass spectrometry because of the easy isomerization of the double bond. Available methods often require multistep synthesis or special MS instrumentation and therefore simple and reliable method for routine GC/MS applications is still needed.
In order to study these problems systematically, we prepared *cis*- and *trans*- 2-, 3-, 4- and 5-**decenoic acids (DA)**.(2) We then tested the behavior of corresponding TMS (trimethylsilyl-) esters, used widely in GC-work to improve the volatility of polar organic compounds.
In **TMS-2-DA** the differentiation between *cis* and *trans* isomers was easily done by comparing RI (relative intensity) of peaks in molecular ion (m/z 242) region. In the spectrum of TMS-*cis*-2-DA, RI of m/z 242 is 25% of the m/z 227, i.e. $(M\text{-}Me)^+$ ion. This peak itself is about 60% of the base peak (m/z 73) as seen in Fig. 1 A. In *trans*-isomer m/z 227 is the base peak while molecular peak itself is hardly detectable. We subsequently used this observation to study enzymes catalyzing dehydration of D-3-hydroxydecanoyl-CoA to *trans*-2-decenoyl-CoA. (3)
The spectra of **TMS-3-DAs** differ very much from the corresponding spectra of 2-DAs. The base peak is m/z 73 with only two peaks of some importance; m/z 117 and m/z 227 both about 5% RI. See Fig. 1B (TMS ester of *cis*-3-DA). Determination of a double bond geometry was not possible.
In the spectra of **TMS-4-DAs** the base peak is also m/z 73. Fragment ion m/z 117 is now about 65% RI and $(M\text{-}Me)^+$ is 20%.(Fig. 1C) Molecular ion is also clearly detectable. No unambiguous identification of *cis* and *trans* isomers was possible.
In the case of **TMS-5-DAs** the base peak is m/z 117. The ion at m/z 75 is about 65% RI and both molecular peak and $(M\text{-}Me)^+$ intensities are significant. (Fig. 1D) Once again the differences between geometrical isomers were minimal.
Since TMS esters of cis and trans-2-DAs were easily differentiated from each other, we examined how general is this feature. TMS esters of following cis- and trans-2-enoic fatty acids were selected: 2-dodecenoic, 2-hexenoic, 2-pentenoic and 2-butenoic acids. In *trans*-TMS-2-enoates intensity ratios of $(M\text{-}Me)^+$ ion to molecular ion varied from 40 to 200. In *cis* isomers the corresponding ratios were from 4 to 15. In addition, in all *trans* TMS-2-enoates examined m/z 227 was the base peak.
Other important structure specific ions in *cis* TMS-2-enoates were m/z 155 and m/z 171. They were 4- 20 times greater in intensity than corresponding fragments in *trans* isomers. Exact mass measurement gave composition of $C_4H_9O_2Si$ for m/z 117 and $C_7H_{11}O_2Si$ for m/z 155. The ion at m/z 117 is probably CO_2SiMe_3.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

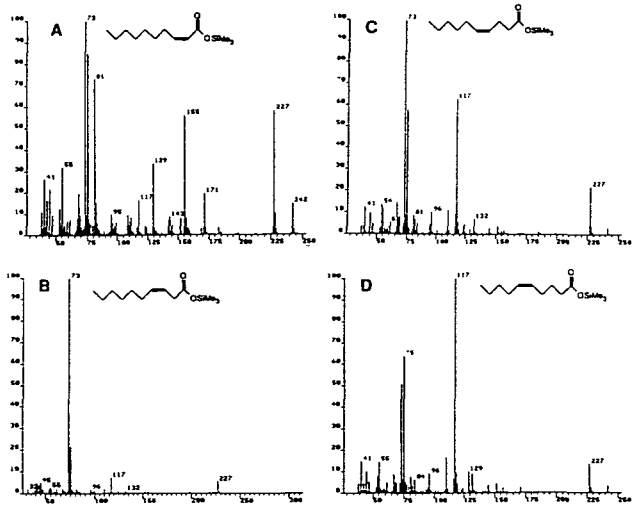

Figure 1. 70 eV EI-spectra of TMS *cis*-decenoates. See text.

AM1 MO calculations gave further insight to the structures of these specific ions. It is suggested that cyclic ions are often most stable and the charge at Si site will effectively direct the formation of these stable ions. However, the very recent results of another silyl derivative, TBS (t-butyldimethylsilyl) esters of *cis* and *trans*-2-decenoic acid showed that the mass spectra of these compounds are identical. The base peak is again at m/z 227 corresponding elimination of t-butyl group, not methyl group.
MS/MS study of $M^{+\cdot}$ showed m/z 226 i.e methane elimination as for $(M\text{-}Me)^+$ ions mainly m/z 129 fragment and some other nonselective fragmentations were observed depending on the CA conditions (res./nonres.). Structure specific ions m/z 155 and 171 were not noticed.
As a conclusion these simple TMS derivatives, used generally in GC work, can be utilized easily for the determination of double bond position of decenoic fatty acids. In the case 2-enoates the geometry of the double bond can be solved as well. This novel method is based on the ordinary EI spectra produced by routine GC/MS, e.g. bench-top instrument.

Experimental: All spectra were recorded with a Kratos MS80RF mass spectrometer: The esters were introduced through a Carlo Erba 4160 capillary chromatograph. MS/MS measurements were done using a Varian Saturn 4D GC/MS/MS instrument. AM1 calculations were carried out using Spartan 3.1 program on a Silicon Graphics workstation.

DEVELOPMENT OF GC-MS DETERMINATION OF NICOTINIC ACID AND NICOTINAMIDE

Amy J. Dame, Karin Wiberg, Myron K. Jacobson, and Jan St. Pyrek,
MS-Facility, College of Parmacy, University of Kentucky,
Lexington, KY 40536-0082

Nicotinic acid (niacin) and nicotinamide serve as precursors for the synthesis of NAD. At high therapeutic doses, nicotinic acid is well known as hyperlipidemic agent while nicotinamide may prevent diabetes (e.g. German Nicotinamide Intervention Study (DENIS)). The involvement of NAD as a substrate for poly(ADP-ribose) polymerase, an enzyme involved in DNA repair, may also indicate a preventive role of these two vitamins in cancer. In this context, the relation of a dietary intake of nicotinic acid and nicotinamide, their metabolism, blood levels, and the content of tissue NAD is of importance but is poorly understood. Current analytical methods (primarily HPLC with UV detection) used for quantitation of blood levels of nicotinic acid and nicotinamide are sufficiently sensitive to monitor their levels following large therapeutic doses (e.g. 0.5 to 3.0 g of nicotinic acid per day used for the treatment of cholesterolemia). Their sensitivity, however, is not sufficient to monitor a small dietary intake, fasting levels, and levels resulting from the sustained release dosage formulations.

Following the only example of the GC-MS analysis of nicotinic acid [1] we examined this method for the determination of both nicotinic acid and nicotinamide in human and canine plasma employing respective deuterated compounds as internal standards. The standard of d_4-nicotinic acid was obtained from ISOTEC and was transformed to nicotinamide in our laboratory via standard reactions. Although the GC-MS analysis of trimethylsilyl derivatives (TMS) was straightforward, its application to relatively low levels in plasma required two consecutive purification stages (ion exchange "SO_3H cartridge" and reverse phase C_{18} HPLC separation) prior to the derivatization (BSTFA-Pyridine) and gas chromatography (splitless injection on 15M, 0.3μ, DB-5MS capillary; temperature program 60° for 1 min to 280°, 10° per min). For the definitive identification both "full scan" and SIM of M-15 ions 180/184 and 179/183 for TMS of nicotinic acid and nicotinamide respectively. Importantly, the TMS derivative of nicotinamide (probably acting as a silylating agent) was found to be very sensitive even to a minor column deterioration producing serious peak broadening and even peak splitting.

This analytical approach was verified with radiolabeled compounds (per cent recovery measured for six samples: nicotinic acid 93 ±5, nicotinamide 94 ±1). This method provided full agreement with the HPLC determination of nicotinic acid in canine plasma following a therapeutic dose. Most importantly, it allowed to measure fasting levels of nicotinic acid (about 40 ng/nl) and nicotinamide (about 15 ng/ml) in the human plasma [Figure 1].

FIGURE: Example of the SIM determination of nicotinic acid (TOP GRAPH) and nicotinamide (BOTTOM GRAPH) in a fasting plasma. Deuterated internal standards were added in the amount of 20 ng each per 0.5 ml plasma sample. After a two-stage purification, about 4% of the silylated sample was injected (splitless mode). Note D_4 compounds preceding D_0 compounds by about 7 scans.

Identifying Polyol Borate Ester Complexes by Negative Ion ESI MS

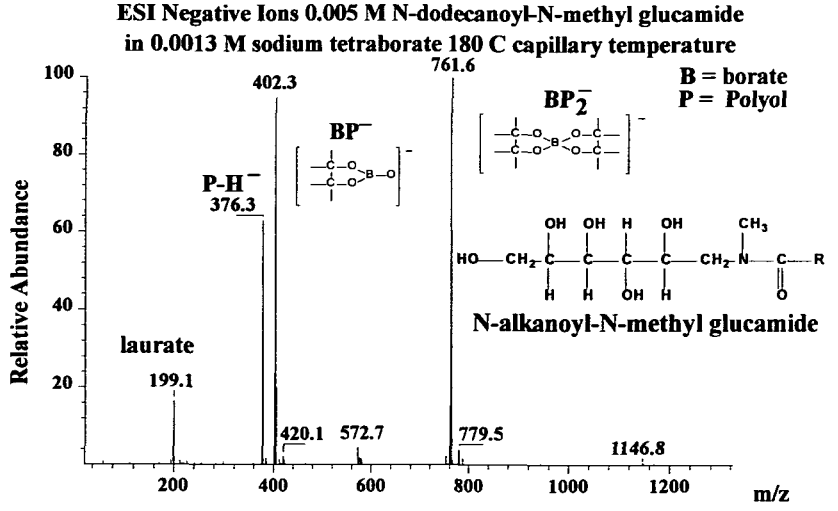
Brian J. Shay, Nancy Falk, and Henry T. Kalinoski
Unilever Research US, Edgewater, New Jersey, 07020, USA

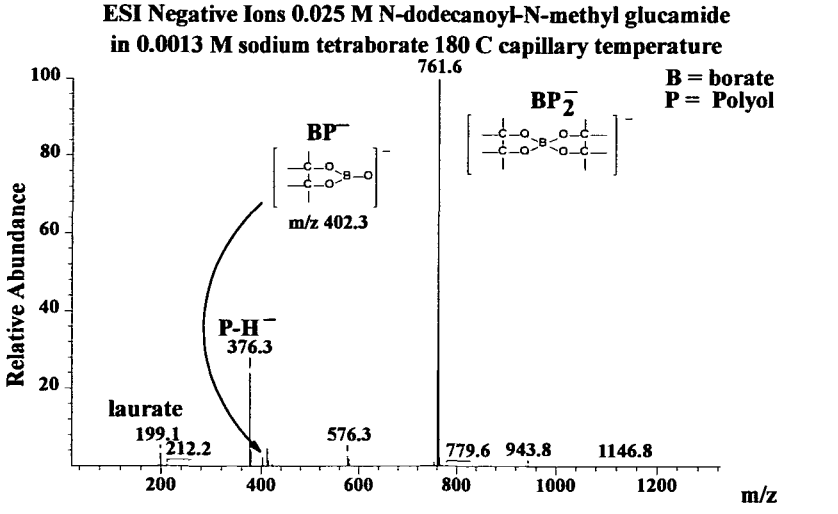
In water solution borate (BO_3) is known to complex covalently with polyhydroxy molecules such as glycerol and various sugars to form borate esters. Formation of these complexes is a reversible process for which pH titration data has been employed to obtain equilibrium constants. Modelling of the pH titration data to obtain equilibrium constants requires knowing the identities of the borate esters formed. This led us to apply electrospray mass spectrometry to confirm the presence of the complexes assumed in the model and to identify any other species. Several carbohydrate-based surfactants were evaluated with data for one compound shown here. Trends in the polyol concentration dependance on complex formation and pH will be discussed.

Sample solutions of .005 to .025 M N-dodecanoyl-N-methylglucamide ("polyol") were prepared by dissolving the polyol at .025 M in .0013 M sodium tetraborate aqueous borate with brief heating to 40 °C then diluting with .0013 M tetraborate to the desired concentration. These polyol and borate concentrations are much higher than one normally requires for electrospray analysis but were chosen to study systems with high polyol/borate complexation and to simulate practical levels in liquid detergents. N-dodecanoyl-N-methylglucamide was synthesized in-house, sodium tetraborate decahydrate was purchased from Fisher Scientific, and ethoxylated alkylsulfate from ChemService Standards.

Electrospray data were collected using a Finnigan TSQ Mass Spectrometer with a Finnigan electrospray interface, employing a heated capillary design. The analyte sample volumes of polyol/tetraborate were kept small (1 μL) and were injected into a 20 μL/min deionized water stream to keep the system relatively clean. The spray voltage was adjusted to -3 kV by flow injecting 1 μL samples of .005 M polyol in .0013 M tetraborate to give a reasonable discharge current of *ca.* 1-2 μA as opposed to the 8 μA observed at -3.4 kV. Other parameters were 35 psi N_2 sheath gas, 150 and 180 °C capillary temperatures, and 0 V octapole voltage. No organic modifiers, such as methanol, were added to the samples themselves and no sheath liquids or auxiliary gases, such as SF_6 or O_2 (to prevent discharges) were used.

Electrospray mass spectrometry was chosen for this analysis as it has been used previously as a fairly accurate probe of solution phase species. Carbohydrate based surfactants $(P\text{-}H)^-$ and their borate esters BP^- and BP_2^- (and for certain analytes $B_2P_2^-$ and $B_2P_3^-$) are easily and selectively detected by negative ion electrospray-MS. Expected and novel borate containing species are identified by boron's distinctive ^{10}B and ^{11}B isotope pattern of the anions containing these isotopes. The negative ion mode preferentially detects the borate-containing species since they readily form anions in solution. Positive ion spectra also yield information on free polyol and borate esters, but contained intense sodium bound dimers of the polyol and of the borate esters. Hence, the positive ion mode was not the method of choice.





ELECTROSPRAY / ION TRAP MS^n FOR STRUCTURE ELUCIDATION OF SURFACTANTS

Robert J. Strife, The Procter & Gamble Co, Miami Valley Laboratories,
P.O. Box 538707, Cincinnati, OH 45253-8707
&

San Jose CA 95134

Electrospray ionization (ESI) produces predominantly pseudo molecular ions of organic compounds. While compounds that provide pre-formed ions in solution (e.g., "quats") exhibit the highest relative molar response factors, even neutral components may be ionized if the matrix contains appropriate ions (e.g., cationization of ethoxylates). In the case of ESI of a complex mixture, like a crude extract of a shampoo for consumer use, a qualitative array of ions representing many of the individual components is produced (Fig. 1).

The combination of the ion trap with ESI provides several distinct advantages over linear arrays of quadrupoles including: 1) ion integration capabilities, ideal for a "dim" ion source like ESI; 2) sequential product ion experiments in the time domain (MS^n) so that ions may be refragmented and probed for their organic structure; 3) efficient mass selective storage, via "notched" wave forms, for isolating a component from a mixture and 4) very efficient observed CID efficiencies.

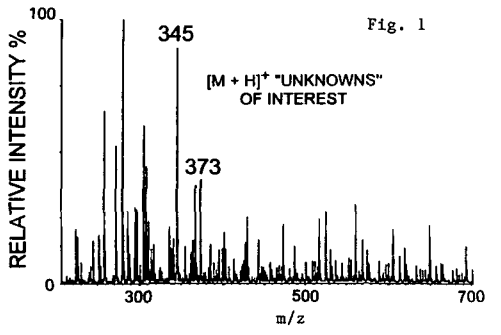
EXPERIMENTAL -- Pure standards were diluted to 1-2 ng/µL for analysis using a prototype of the Finnigan-MAT LCQ. Shampoo extracts which had previously been analyzed using an ESI / triple quadrupole instrument were diluted 100x for analysis on the LCQ prototype. Samples were infused through the electrospray device at 220°C at 5 µL/min. Ion injection periods from 1 ms to 500 ms were used, with longer times being applied at higher stages of MS^n. Mass selective storage was accomplished by adjusting the q_z value of ions of the desired m/z value to 0.83. A notched wave form of variable amplitude was applied to eject ions of unwanted m/z values. CID was carried out at q_z of the parent ion of 0.2 - 0.3.

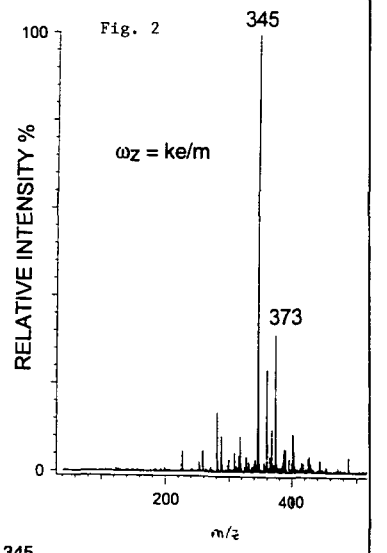
RESULTS & DISCUSSION -- The ESI / Ion Trap analysis of a shampoo extract is shown in Fig. 2. The injection parameters were intentionally tuned to emphasize the region of interest, where m/z 345 and 373 represent a surfactant of "unknown" structure. MS/MS on both instruments produced one main daughter ion of m/z 226 or 254, respectively. To probe the structure of these ions further, the ESI / ion trap offered the possibility of refragmentation. MS^3 of m/z 226 revealed a series of ions separated by methylene units (m/z 67, 81, 95, 109, 123) and refragmentation (MS^4) of some of these ions showed preferred losses of 42 and / or 28 u. The s/n at the MS^4 stage is greater than 20 (Fig. 3).

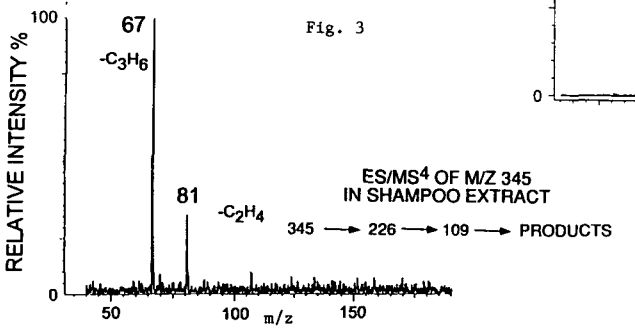
Since CID of pseudo molecular ions generated by electrospray should be dominated mainly by even-electron fragmentation processes, the ion of m/z 226 should contain at least one nitrogen center. Likewise, since the MW's are 344 and 372 (even), the total number of nitrogens present must be at least two. Furthermore, the product ions of m/z 226 have odd m/z's and if they are even-electron species, likely represent combinations of C, H, O. Further studies in our lab (data not shown here) have led us to propose that the 67, 81, 95, 109, 123 series represent carbonium ions of the empirical formula C_nH_{2n-3}. The ions are derived from species containing a fatty acyl function and may be derived by rearrangement and dehydration of the even-

electron acylonium ion. The MS^4 fragmentations are losses of ethylene and propene. Given the nature of the sample (shampoo-derived), it was quite likely that the alkyl chain was C_{12}/C_{14} fatty acyl amide and that the partial structure of m/z 226 was $C_{11}H_{23}CONCH_2CH_2$-X. MS^2 studies using (-) ES yielded a key fragment ion of m/z 161, containig the remaining portion of the molecule. Higher orders of MS^n gave evidence that X = N (CH_2COOH)(CH_2CH_2OH), 118 u (344 = 226 + 118) and 161^- is HNCH2CH2X. When a standard of the proposed material was obtained, its spectral properties were found to match those of the "unknown."

In conclusion, refragmentation played an essential role in the elucidation of these structures, which was not achieved by MS/MS alone. While electrospray MS^n experiments have been reported previously, the major advantages here are: 1) the ease with which such experiments are now programmed, being easily executed in a one-hour time frame, and 2) mass selective storage of desired parent ions via "notched" wave forms with unit resolution and no loss in sensitivity. Finally, other strucutural hypotheses were possible during the elucidation process. Our experience with CID of surfactants was an important factor in suggestions we made.







CHARACTERIZATION OF MONOAZO DYES BY CHEMICAL IONIZATION MS/MS.

Jia-shen Wang
Clairol Inc., Stamford, CT 06922

INTRODUCTION

Many azo dyes have been successfully characterized by traditional electron impact (EI) MS, since very often the spectral patterns of this type of dyes correlate well with the azo unit (Ar-N=N-Ar'). A typical example is shown in Figure 1. For dyes with complex aromatic rings, however, the spectral patterns tend to show the partial structures and provide very little information about azo unit. An example is shown in Figure 2. In this spectrum, the base peak (269) clearly indicates the presence of an alkylamino group ($-NCH_2CH_2OH$), but not much information on other structural features. This program, therefore, was developed to determine the structures of azo dyes using the analytical capabilities of (CI)MS/MS.

Figure 1.

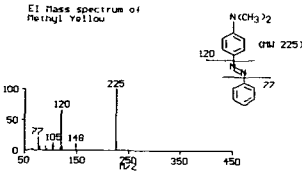


Figure 2.

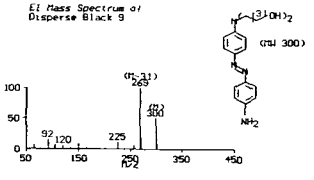


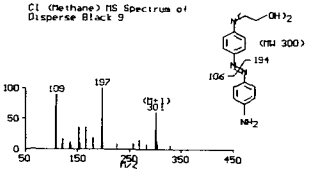
EXPERIMENTAL

In this study, all analyses were carried out using a Finnigan TSQ-7000 triple quadrupole mass spectrometer. Samples were introduced by a solid probe. All of the samples are commercial available.

RESULTS & DISCUSSION

Unlike most CI spectra of other compounds which show mainly the protonated molecular ions, we have observed two features in the CI spectra of azo dyes which are quite interesting. An example is shown in Figure 3a. The intensity of molecular ion $[m]^+$ (by charge exchange reactions, presumably) is relatively high, and the presence of two ion clusters (197 and 109) is rather unusual. The $[m]^+$ with high intensity enables us to perform MS/MS analyses.

Figure 3a.



The daughter spectrum of $[m]^+$ (m/z 300) is shown in Figure 3b. The similarity of this spectrum and that of the EI spectrum (Figure 2), suggests that the fragmentation pathways to produce both spectra are similar (by odd-electron ion fragmentation mechanisms, presumably). This characteristic allows us to utilize the library search capability of the data

system. The daughter spectrum of the protonated molecular ion is shown in Figure 3c. As expected, the spectral patterns of 3b and 3c are quite different since $[m+1]^+$ is an even-electron ion. Here the important part is that neither 3b nor 3c shows evidence for the 300 and 301 ions to be the precursors of 109 and 197 clusters.

Figure 3b.

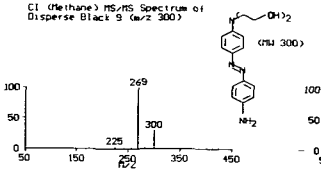


Figure 3c.

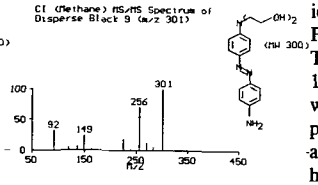

The daughter spectra of the 196 and 108 ions are shown in Figures 3d and 3e. The structures of the 108 and 196 ions were elucidated to be phenylenediamine and N,N-bis(2-hydroxyethyl)-phenylenediamine. The authentic EI spectra of the respective compounds are shown in Figures 3f and 3g. Indeed, we have found that all MS/MS spectra of these cluster ions are consistent with those of reference compounds. We, therefore, concluded that under CI ionization conditions, reactions may occur for azo dyes at the azo unit sites to form the respective amino compounds.

Figure 3d.

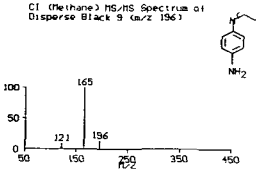

Figure 3e.

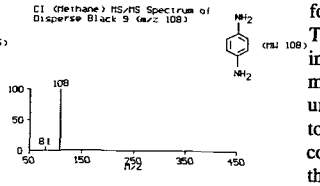

We have observed similar phenomena for other azo dyes. The relative ion intensities of the CI mass spectra are unavoidably sensitive to the experimental conditions, especially the source pressure. It, however, does not cause problems in this application.

Figure 3f.

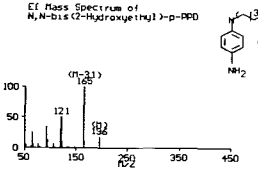

Figure 3g.

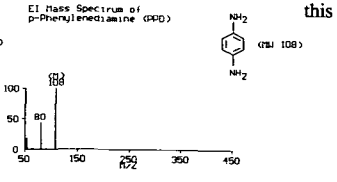

CONCLUSION

The characterization of azo dyes by CI/MS/MS is demonstrated. A CI mass spectrum provides the sub-structural information related to the azo unit of a compound. An $[m]^+$ MS/MS spectrum allows one to perform structural elucidation with the readily available mass spectral data bases and searching capabilities of the system.

Analysis of Dibenzofuran and Dibenzo-p-dioxin in Diphenyl Oxide

Paul L. Sherman, Fred D. Hileman, and Jay M. Wendling
Monsanto Corporate Research, 800 N. Lindbergh Blvd., St. Louis, MO 63167

Diphenyl oxide (DPO) is a common agent used as a substrate for the production of brominated flame retardants Dibenzofuran (DBF) is a contaminant in DPO and is structurally very similar to DPO. Pressure to reduce trace levels of halogenated dibenzofuran and halogenated dibenzo-p-dioxin (DBD) in halogenated products such as DPO has resulted in demands for lower levels of nonhalogenated DBF and DBD in DPO As an example, the Environmental Protection Agency and various European agencies have begun to set standards for the levels of brominated DBFs and DBDs in brominated DPOs at the low part per billion (ppb, ng/g) level. Facilities producing DPO can typically measure DBF in DPO to a detection limit of 1 part per million (ppm, ug/g) using capillary column gas chromatography with flame ionization detection. However, it is desirable to measure for both DBF and DBD to low ppb levels to be in compliance with the new standards. An analytical procedure has been developed which uses a column chromatography sample isolation procedure followed by gas chromatography chemical ionization mass spectrometry to achieve these desired levels of detection.

The procedure (Figure 1) involves the dissolving of one gram of DPO in 10 mL of hexane and this solution is then spiked with both D_8-DBF and $^{13}C_{12}$-DBD The hexane solution is passed through a Woelm basic alumina column, which is then eluted with 8 mL of 10% CH_2Cl_2/hexane which strips the DPO from the column while allowing the DBF and DBD to remain. The DBF and DBD are eluted from the column using 10 mL of CH_2Cl_2 to which is added 20 uL of undecane to serve as a keeper and the eluate is concentrated under a steam of dry nitrogen This concentrate is then analyzed by gas chromatography (see Figure 2) on a 60 m SP-2330 capillary column with detection by chemical ionization (CH_4) mass spectrometry with selected ion monitoring for the protonated molecular ions for DBF (m/z 169), D_8-DBF (m/z 177), DBD (m/z 185), and $^{13}C_{12}$ DBD (m/z 197) It is necessary to use chemical ionization rather than electron impact ionization (EI) since EI results in the fragmentation of DPO (loss of H_2) to form an ion with the same mass as DBF which contributes to the background noise and thus raises the detection limits for DBF. The highly polar SP-2330 was also essential in providing a high degree of separation of DBF and DBD from DPO and from each other The key to the success of this method is the use of stable labelled DBF and DBD as internal standards. The alumina column chromatography separation is effective but inexact in its ability to separate DBF and DBD from DPO. These labelled materials allow compensation for any losses during the sample preparation and analysis The detection limits for DBF and DBD are somewhat variable due to the variability in recovery from the alumina column. Typical detection limits for DBF and DBD in DPO using this method are 1-5 ppb and 5-10 ppb respectively

7-[(Chlorocarbonyl)methoxy]-4-methylcoumarin (CMMC) is a fluorescent reagent for precolumn derivatization of hydroxy compounds in liquid chromatography [1]. The synthesis of the acyl chloride involves the use of thionyl chloride, which has been subsequently shown to unexceptably introduce highly fluorescent impurities due to over-chlorination. An improved derivatization reagent utilizes a reactive acyl imidazole, instead of the acyl chloride, offering a purer product while maintaining desirable reagent characteristics such as ease of handling, mild derivatization conditions, etc. Reaction of 7-[(imidazolemethanoyl)methoxy]-4-methylcoumarin (IMMC) with various hydroxy compounds produces esters which are readily separable under reversed-phase HPLC conditions compatible with detection by thermospray mass spectrometry.

Synthesis of 7-[(Imidazolemethanoyl)methoxy]-4-methylcoumarin (IMMC). To a stirred solution of 102.3 mg (0.44 mmol) of 7-(carboxymethoxy)-4-methylcoumarin in 7 ml of tetrahydrofuran was added 1,1'-carbonyldiimidazole (70.9 mg, 0.44 mmol) in one portion. The stirred reaction mixture was heated to reflux for 30 min, whereupon heating was discontinued but stirring continued an additional 5 hours; as the reaction mixture cooled, a white precipitate formed. The white solid was isolated by filtration and then freed of solvent *in vacuo*, yielding 84.1 mg of crystals (0.30 mmol, 68%) mp 161-162°C (melts with decomposition). MS (EI, 70 eV) *m/z* (% relative abundance): 284 (M^+,94), 189(32), 159(30), 103(24), 81(100). HRMS: *m/z* 284.0793 (calcd for $C_{15}H_{12}N_2O_4$: 284.0797).

Sample Derivatization and Analysis. IMMC was reacted with several 1° and 2° alcohols, as well as *tert*-butyl alcohol. A typical procedure is as follows: to a solution of IMMC (0.60 mg (2.1 μmoles)) in 2.5 ml of toluene and 0.75 ml of acetonitrile was added benzyl alcohol (20 μl, 20.9 mg, 194 μmoles) and 0.15 ml of acetonitrile containing 4-dimethylaminopyridine (0.014 mg (0.11 μmole). The resulting solution was vigorously mixed, heated to 60°C for 1.5 hr, cooled, concentrated to dryness under a stream of nitrogen gas at room temperature. The sample was then reconstituted in 0.3 ml of acetonitrile-0.1*M* ammonium acetate buffer, pH 5.5-methanol (50:48.5:1.5, v/v/v). A 5-μl aliquot of this solution was injected onto the chromatographic system. Separations were conducted at ambient temperature under isocratic reversed-phase conditions on a 3.9 mm I.D. x 15 cm stainless steel column packed with 4 μm Nova-Pak C_{18}. A mobile phase composed of acetonitrile-0.1*M* ammonium acetate buffer, pH 5.5-methanol (50:48.5:1.5, v/v/v) was employed at a flow rate of 0.7 ml/min. The effluent was introduced directly into a Hewlett-Packard 5989A mass spectrometer equipped with a thermospray LC-MS interface. The thermospray interface was operated in the filament-assisted ionization mode with either positive- or negative-ion detection. The operating temperatures for the interface were as follows: ion source, 280°C; probe stem, 112°C; and probe tip, 235-245°C.

Results. Although initially intended as a fluorescent label for hydroxy compounds, IMMC smoothly reacts with primary and secondary hydroxyl compounds to produce esters which have been found to be

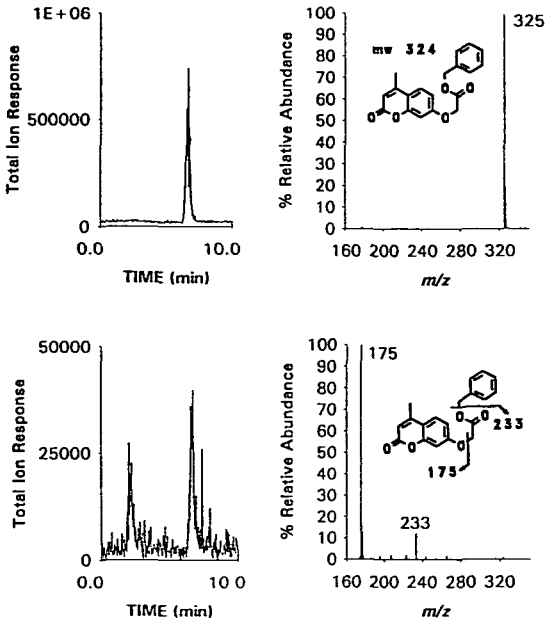

Figure 1. Total ion response chromatograms and averaged TSP mass spectra acquired during the elution of 1.2 μg of the ester product of IMMC with benzyl alcohol by continuous scanning over a mass range of 160-350 u with positive (top) and negative-ion (bottom) detection.

quite responsive to thermospray ionization. When observed by positive ion thermospray mass spectrometry, these compounds give [M+H]+ ions as the base peak of their mass spectra with no discernible fragmentation. In the negative ion thermospray mass spectra of these compounds, the proton-abstracted anion of 7-hydroxy-4-methylcoumarin (appearing at *m/z* 175) is, without exception, the base peak. A quantity of 7-[((methoxy)-carbonyl)methoxy]-4-methyl-coumarin (the ester resulting from reaction of IMMC with methanol) was synthesized and its response to thermospray ionization was evaluated by LC/MS using filament-assisted, positive ion thermospray ionization. Using selected ion monitoring, we found that this compound gave a response curve which was linear over a range of < 10 ng to over 100 ng injected on-column. Easily detectable to 0.8 ng (S/N = 3), a 10-15 ng sample produced an integratable peak in the ion chromatogram that possessed a signal-to-noise ratio of about 10.

The response to thermospray ionization thus makes these compounds extremely useful in derivatization and post-column detection of hydroxy compounds. Following initial precolumn derivatization, a sample may first be examined by LC/MS using negative ion thermospray detection to identify all compounds possessing the coumarin-based fluorescent tag. From the subsequent LC/MS analysis using positive ion thermospray, molecular weight information can be easily deduced for derivatizable hydroxy compounds present in the original sample. Once the molecular species has been determined, the analyst is then presented with the option of performing low-level quantitation using selected ion monitoring thermospray mass spectrometry.

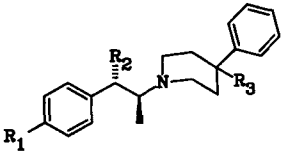
Specific Structural Features which Promote Cluster Formation in FAB Mass Spectra

Thomas R. Sharp
Analytical R&D, Central Research, Pfizer Inc., Groton, CT 06340 U.S.A.

FAB mass spectrometry of a series of compounds, represented by the genral structure shown below, indicates that certain of the hydroxyl groups on the molecule play a determinant role in their tendency to form abundant proton-bound dimers and counterion-containing dimers of the formula $[2M+counterion+2H]^+$. The parent molecule for which this study was initiated is compound 1, a drug substance under development as an antiischemic compound [1], in which all three R groups are hydroxyls.

Observations were made on a VG 70-S magnetic sector instrument using a 7 kV fast xenon beam generated by a saddle field gun. The matrix used was the dithiothreitol-dithioerythritol mixture of Witten *et al.*[2] Samples of compounds were dissolved in methanol. Aliquots of this solution were added to the matrix on the FAB probe target. Five compounds, the structures of which are indicated in Table 1, were examined in addition to the free base and two salt forms of 1.



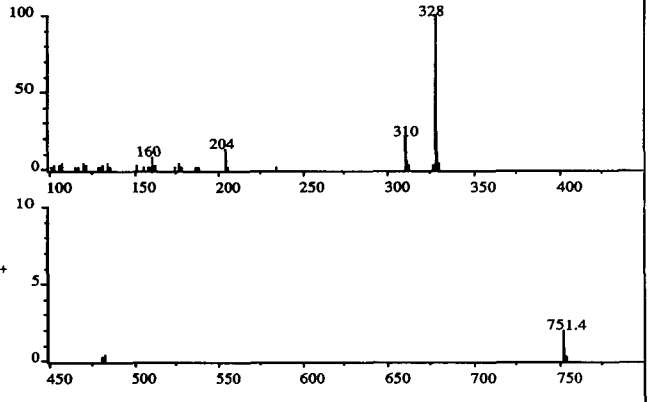


Figure 1: FAB mass spectrum of compound 1 methanesulfonate salt. $[M+H]^+$ at m/z 328. The m/z 751.4 species corresponds to a methanesulfonic acid-containing proton-bound dimer of the empirical formula $(C_{20}H_{25}NO_3)_2(CH_3SO_3H)H^+$ Note that the lower panel y-axis is 10% relative abundance.

The FAB mass spectrum of compound 1 methanesulfonate salt is shown in Figure 1. All three R groups on compound 1 are free hydroxyls. In addition to the abundant $[M+H]^+$ at m/z 328, the two structurally significant ions are m/z 310 and m/z 204. The m/z 310 species results from neutral loss of H_2O from $[M+H]^+$. Examination of structural analogs 2 and 3 (Table 1) indicates that either the benzylic hydroxyl or the piperidinyl hydroxyl can be lost, although the data suggest that loss of the benzylic hydroxyl is the more fascile reaction. The m/z 204 fragment corresponds to loss of *p*-hydroxybenzyl alcohol from

$[M+H]^+$. This point is also corroborated by observations on the analogs. FAB accurate mass measurements on ions of compounds 1, 2 and 3 support these assignments.

The approximately 2% relative abundance peak in Figure 1 at m/z 751.4 corresponds to a van der Waals dimer containing two molecules of compound 1, a proton which carries the electrostatic charge, and a molecule of methanesulfonic acid. The empirical formula for this ion would be $(C_{20}H_{25}NO_3)_2(CH_3SO_3H)_1H^+$. Investigation of the behavior of the hydrochloride salt form of compound 1, and of the free base, indicates that these forms of compound 1 also produce the van der Waals dimer, although to a lesser extent.

Structural analogs were obtained in which the various hydroxyl groups were removed, blocked or replaced with a different oxygen oxidation state. Compounds 2 through 5 (Table 1) are structural analogs which retain various combinations of two of the three hydroxyl groups. Data suggest that two specific hydroxyls of the three are necessary for formation of these clusters. The only analog which retains the ability to form an observable dimer is compound 5, in which both R_2 and R_3 are present as hydroxyl groups. Further, the presence of an attached oxygen in these positions is insufficient. The group cannot be a carbonyl group, but must be a hydroxyl group, as demonstrated by compound 4.

The compounds form proton-bound dimers when observed as the free bases of the compounds. The tendency to form counterion-containing clusters appears to be independent of the identity of the counterion. Both hydrochloride salts and methanesulfonate salts form counterion-containing clusters.

Table 1:
Correlation of Dimer Formation with Presence of Free Hydroxyl Groups

Compound & Salt Form	R_1	R_2	R_3	Dimer Formation	Dimer Abundance % of $[M+H]^+$
1 free base	OH	OH	OH	+	0.5%
1 hydrochloride salt	OH	OH	OH	+	1.0%
1 mesylate salt	OH	OH	OH	+	2.0%
2 free base	OH	OH	H	-	0
3 free base	OH	H	OH	-	0
4 free base	$OCH_2C_6H_5$	=O	OH	-	0
5 free base	OCH_2C_6H5	OH	OH	+	0.2%

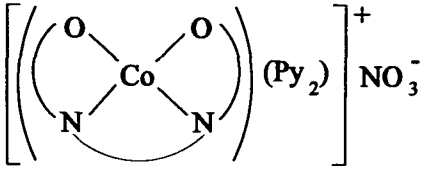
STUDY OF COBALT COMPLEXES WITH TETRADENTATE SHIFF BASES BY IS- AND FAB-MS

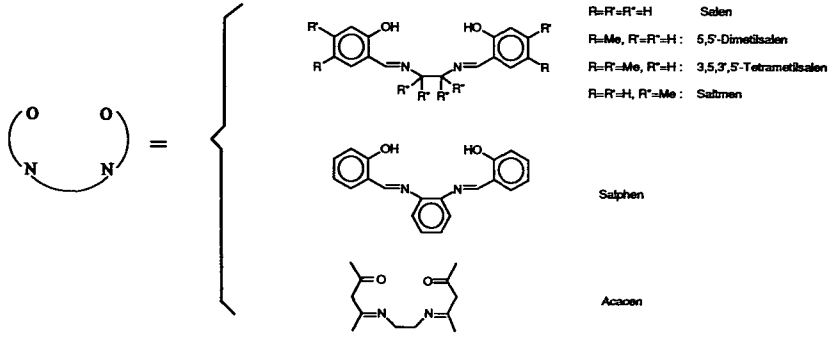
by Andrea RAFFAELLI, Sergio PUCCI, Sonia DI SACCO, Mauro ISOLA

Centro di Studio del CNR per le Macromolecole Stereordinate ed Otticamente Attive, Dipartimento di Chimica e Chimica Industriale, Università di Pisa, Via Risorgimento 35, 56126 PISA, Italy.

Nitrosyl derivatives of transition metals, M(NO), have recently drawn the attention of several researchers, as they are involved in some biological processes and in some catalytic cycles. Oxidation by molecular oxygen of nitrosyl complexes of cobalt containing tetradentate Shiff bases, in the presence of pyridine, affords cationic Co complexes of the type $[Co(L\frown L\frown L\frown L)(Py)_2]^+NO_3^-$. We report here the results obtained in the MS study of a series of such complexes, with different tetradentate Shiff bases. Ionspray (IS) and Fast Atom Bombardment (FAB) ionization techniques were used in order to get complementary information and to compare the two techniques for the study of these compounds.



General structure of the Co complexes examined



FAB-MS measurements have been performed on a VG 70-70E double focussing mass spectrometer, while IS-MS and IS-MS-MS measurements have been carried out on a Perkin Elmer Sciex API III plus triple quadrupole mass spectrometer. The main MS data for the complexes examined are summarized in the table. The structure of the complexes has been completely confirmed, both by IS and FAB ionization. The comparison between the two techniques showed some interesting differences. Under FAB conditions, it was possible to observe the formation of clusters, whereas using IS ionization these clusters could not be detected. It is worthy to note that the molecular cation peak was usually very weak with

FAB, and practically not present for the less stable complexes of the series, the base peak being the $[M\text{-}2Py]^+$ ion. Under IS conditions, the fragmentation afforded the $[M\text{-}Py]^+$ and $[M\text{-}2Py]^+$ species together with the molecular cation M^+, even working with a low orifice potential (35 V), but the M^+ peak was present in all cases, even if it was very weak for the less stable complexes.

Table. Main MS Data of the Cobalt Complexes Examined

Ionization	Ligand	M^+ (*m/z*-%)	$[M\text{-}Py]^+$ (*m/z*-%)	$[M\text{-}2Py]^+$ (*m/z*-%)	"Dimer" (*m/z*-%)
F.A.B. MS	Di-Me-SALEN	511 - 2	432 - 9	353 - 100	706 - 7

	SALOPHEN	531 - 25	452 - 100	373 - 95	==

IS-MS-MS spectra, at different values of collision energy, allowed to figure out the relative stability of the complexes examined. The stability scale obtained was perfectly in keeping with the electronic and steric stabilization effects of the substituents present on the tetradentate ligand.

The general fragmentation pattern involved the initial loss of the two molecules of pyridine consecutively. This loss takes place already with low values of collision energy (10-15 eV) and also in the source. Further fragmentation of the $[M\text{-}2Py]^+$ species were more difficult, and it could be observed only with relatively high values of collision energy (40-50 eV).

Quantitative Analysis of Fluorinated Ethylchloroformate Derivatives of Non-protein Amino Acids and Hydrolysis Products of a Tripeptide Using Positive and Negative Chemical Ionization Gas Chromatography / Mass Spectrometry

Ping Cao and Mehdi Moini*
Department of Chemistry and Biochemistry,
University of Texas at Austin, Austin , Texas 78712

Recently, Husek introduced a derivatization procedure for gas chromatographic (GC) analysis of protein amino acids using ethylchloroformate(ECF) [1]. The main advantages of this technique include: 1) *simultaneous N(O,S)-derivatization of amino acids in one step*, 2) *derivatization of amino* acids in aqueous solution, 3) reaction time of only a few seconds, 4) derivatization with inexpensive reagents, and 5) GC or GC/MS identification of products.

To date, most of the reported data shows the application of ECF derivatization to protein amino acids. Here we report the application of the ECF derivatization to non-protein amino acids using trifluoroethanol as the esterifying agent. GC/MS was used to analyze the products using positive and/or negative chemical ionization (CI) mode.

The procedure for the derivatization of non-protein amino acids is the same as before [1] except trifluoroethanol is used as the esterfying agent. An equimolar solution of twenty-three non-protein amino acids (2.5 μmol/ml) was diluted by two to six orders of magnitude using 0.1 N HCl solution for the qualitative analysis. Other experimental conditions are reported elsewhere [2,3].

The reconstructed total ion chromatogram (RIC) of the twenty-one ECF + trifluoroethanol + pyridine derivatives of non-protein amino acids under positive chemical ionization mode is shown in Figures 1. Mass spectra of these non-protein amino acid derivatives showed characteristic $[M-19]^+$, $[M+1]^+$, $[M+29]^+$, and $[M+41]^+$ peaks in the positive CI mode, and $[M-1]^-$, and $[M+35]^-$peaks in the negative CI mode. Three non-protein amino acids containing an aromatic ring, anthranilic acid, *m*-aminobenzoic acid , and *p*-aminabenzoic acid, gave relatively strong peaks in negative CI mode compared to positive CI mode.

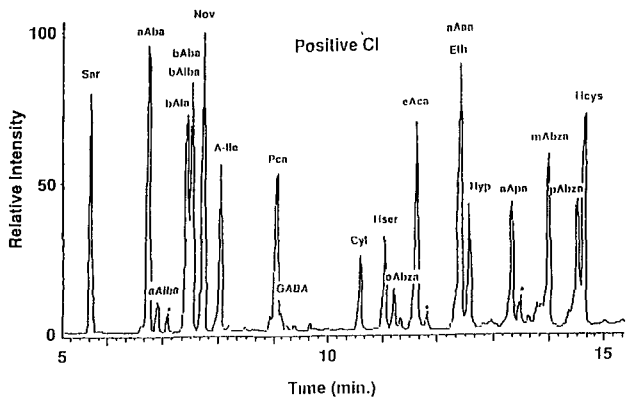

Figure 1. Reconstructed TIC of positive chemical ionization GC/MS of the trifluoroethanol ECF derivatized non-protein amino acids. Peaks marked with an asterisk were mostly ethyl derivatives.

The detection limits and linear dynamic range of the ethylchloroformate derivatives of non-protein amino acids were studied using chemical ionization in the positive ion mode. The results are given in Table 1. As is shown, the detection limits are mostly in the femtomole range.

Furthermore, to investigate the application of the ethylchloroformate + trifluoroethanol derivatization of amino acids to the hydrolysis products of peptides, a tripeptide diprotin B (VAL-PRO-LEU) was used. A solution of the three amino acids in diprotin B was identically treated for comparison. The relative ratios of derivatization and ionization efficiencies of three amino acids from the peptide and amino acid mixture after hydrolysis from 72 hr at 110°C were 100:73:92 and 100:67:83, respectively.

Table 1. Detection limits and linear dynamic ranges of trifluoroethyl ester ECF derivative non-protein amino acids.

Non-protein amino acid	Detection limit (ng)	Linear dynamic range (orders of magnitude)	Correlation coefficient
α-aminobutyric acid (aAba)	5.00E-03	3.7	0.988

A Direct Method for the Quantification of Free Saturated Fatty Acids in Tobacco

Jiu Ai

US Tobacco Manufacturing Company, Inc., 800 Harrison Street, Nashville, TN 37203

GC methods for quantitative determination of free fatty acids require tedious sample preparation steps such as derivatization and clean-ups before injection. Without sample preparations, a GC chromatogram of underivatized fatty acids shows poorly resolved peaks that can be interfered by enormous chemical background when a complex mixture is injected. It is very difficult to quantify such peaks. In this study, a new direct method is developed to quantify free fatty acids in complex mixtures without sample cleaning and derivatization by selecting an appropriate GC column to improve peak shapes and by choosing a highly selective detection method to eliminate the chemical background.

The peaks of underivatized saturated fatty acids eluted from a bonded phase polyethylene glycol GC column (DB-WAX of J&W) are better resolved than those eluted from a non-polar column (DB-5 from J&W). Mass spectrometers with multiple analyzing devices, such as triple quadruples, etc., provide great selectivity when used at tandem scanning mode. It is possible to selectively detect a specific compound or a specific group of compounds from a complex mixture using the selected reaction monitoring (SRM) scanning mode. Thus, the chemical background in the complex mixture can be completely eliminated.

A Finnigan TSQ700 mass spectrometer was used in this study and the SRM scanning was set for the m/z 129^+ to m/z 87^+ fragmentation pathway during the collision. With this SRM scanning, all the saturated straight chain fatty acids having more than eight carbons were selectively detected. Figure 1 shows two MS chromatograms of a CH_2Cl_2 tobacco extract. The total ion scan chromatogram was very complex and the SRM chromatogram of the same extract was much simpler and clearer. Only those underivatized saturated fatty acids showed up in the SRM chromatogram and their peaks were completely resolved for quantitative integration.

Since the volatility of underivatized fatty acids is low, there is always concern that they might be detained in the GC column. A study was performed to compare ratios of the peak intensities of saturated fatty acids eluted from the DB-WAX GC column with those measured from a direct probe insertion. Intensity ratios of C16, C17 and C18 acids to C14 acid from the GC/MS/MS measurement were very close to those of the Probe/MS/MS measurement, respectively. This indicates that the introduction of underivatized fatty acids into the mass spectrometer ion source through a DB-WAX GC column is comparable to the direct probe insertion.

Table 1 Fatty acid concentrations of acid spiked and un-spike tobacco

Fatty Acids	Spiked Samples		Un-spiked samples		Concen. Difference
	Concen. (μg/ml)	*RSD*	*Concen. (μg/ml)*	*RSD*	*(μg/ml)*
decanoic acid	11.6	2.5%	0.7	7.4%	10.9
dodecanoic acid	11.4	2.4%	0.8	10%	10.6
tridecanoic acid	11.5	3.7%	0.6	12%	10.9
tetradecanoic acid	13.8	4.1%	2.6	6.0%	11.2
pentadecanoic acid	14.1	5.4%	2.9	6.5%	11.2
hexadecanoic acid	51.7	5.2%	41.5	6.1%	10.2
heptadecanoic acid	14.2	8.2%	3.6	6.6%	10.6
octadecanoic acid	24.1	10%	13.4	6.9%	10.7

Six calibration solutions were prepared containing C10 to C18 straight chain saturated fatty acids with C11 acid as the internal standard. The amount of acids injected ranged from 4.0 ng to 120 ng and the correlation coefficients for all the eight fatty acids were 0.999 or higher. Two tobacco samples were spiked with a mixture of standard fatty acids before CH_2Cl_2 extraction. The spiked concentration was 10 μg/ml for each one of the acids. Table 1 lists saturated fatty acid concentrations in CH_2Cl_2 extracts of the spiked and un-spiked tobacco samples. The concentration differences between the spiked and un-spiked samples quantified by the GC/MS/MS method were very close to 10 μg/ml for all the eight fatty acids studied. The data were the averages of six measurements from two different pairs of spiked and un-spiked samples prepared in the same way.

Concentrations of the eight saturated fatty acids were determined in two types of tobacco and two types of Chinese green tea (Longchin and Gun powder). The results are shown in Table 2. In both tobaccos and green teas, hexadecanoic acid (palmitic acid) was the major saturated fatty acid, followed by the octadecanoic acid (stearic acid). Other prominent fatty acids were tetradecanoic acid, pentadecanoic acid and heptadecanoic acid. There were trace amounts of decanoic acid, dodecanoic acid and tridecanoic acid. Several other fatty acids found in tobaccos with the SRM scanning, but not yet quantified, were nonanoic acid, 13-Me-tetradecanoic acid, 12-Me-tetradecanoic acid, 14-Me-pentadecanoic acid, 14-Me-hexadecanoic acid, 16-Me-heptadecanoic acid, oleic acid, nonadecanoic acid and eicosanoic acid.

Table 2 Fatty acids in tobacco and green tea samples

Fatty Acid	Tobacco no. 1	Tobacco no. 2	Longchin green tea	Gun powder
	(ppm)	*(ppm)*	*(ppm)*	*(ppm)*
decanoic acid	0.5	1.8	0.3	-
dodecanoic acid	0.7	2.9	1.0	1.2
tridecanoic acid	0.2	2.0	0.6	-
tetradecanoic acid	17.4	19.2	7.2	5.6
pentadecanoic acid	22.0	23.0	5.1	5.2
hexadecanoic acid	242.6	371.8	78.6	171.1
heptadecanoic acid	18.8	26.7	-	9.4
octadecanoic acid	77.5	110.4	18.5	25.8

A NEGATIVE ION STUDY OF INDOLE AND QUINOLINE USING AN ASGDI SOURCE

S. N. CAIRNS, M. L. LANGFORD, A. M. FRANKLIN AND J.F.J.T. TODD
The Chemical Laboratory, The University of Kent, Canterbury, Kent, CT2 7NH, UK

Introduction

Indole and quinoline both have a significant part to play in petroleum chemistry and are found in alkaloids frequently observed in nature. In this study quinoline and indole have been investigated using an Air Sampling Glow Discharge Ionization (ASGDI) source coupled to an ion trap mass spectrometer. The ability of the ion trap to carry out high efficiency tandem mass spectrometry was utilized to illuminate some of the fragmentation pathways present.

The processes involved in an ASGDI source can produce a complex array of chemical reactions which often lead to the spectra being difficult to interpret. In order to complement the interpretation of the complex spectra semi-empirical AM1 calculations were carried out to give qualitative thermodynamic stabilities of the possible adducts and fragments.

Experimental

All the experiments were carried out using a Finnigan MAT Ion Trap Mass Spectrometer (ITMS) coupled to an Atmospheric Sampling Glow Discharge. To produce a DC glow discharge a potential of 350-400 V was applied at a pressure of ca 800 mTorr. Samples were introduced into the source by placing them on a glass spoon in the sampling chamber and any vapour from the sample was drawn into source with the stream of air.

In a DC glow discharge the energies of the electrons present range from thermal (immediately following ejection on electron impact) to energies defined by the source voltage, source pressure and the ionization of energy of the discharge gas. Collisionally induced dissociation reactions between energetic electrons and sample molecules give rise to the production of neutral fragments. These fragments and the sample molecules may form negative ions by the capture of low energy electrons. The anions formed in the source are extracted and are injected into the ion trap via a lensing system.

In addition, because of the high proportion of background air which is taken in to the source, a large number of small, highly reactive anions of air molecules are produced which react with the sample to form anionic adducts which are characteristic of this technique.

Computational Chemistry All the computational chemistry was carried out using the molecular modeling package HyperChem™. Semi-empirical AM1 SCF calculations were used. The Restricted Hartree Fock (RHF) approximation was employed for the neutrals and Unrestricted Hartree Fock (UHF) for the anions. The molecules were first geometry-optimised and then a single point calculation was carried out on the ion or neutral to evaluate the heat of formation. The adiabatic electron affinity of a particular species was calculated by subtracting the heat of formation for the optimised neutral species from the heat of formation of the corresponding geometry-optimised anion.

Results and Discussion

Ion Formation The anions appear to react in three main ways with the indole and quinoline:

1. Removal of a proton to form $(M\text{-}H)^-$ (hydrogen atom abstraction): this can occur by reaction with a BrØnsted base e.g. O^-, O_2^-, NO^- e.g. $O^- + M \longrightarrow (M\text{-}H)^- + OH^-$
2. Formation of an adduct ion e.g. $(M+O\text{-}H)^-$ (H-atom displacement): this can be occur by reaction with O^- e.g. $O^- + M \longrightarrow (M+O\text{-}H)^- + H^-$
3. The anions or molecules present can undergo a loose association with the sample to form a cluster ion. The formation of a cluster can occur with neutral and a charged particle, e.g. $(M\text{-}H)^-{:}O_2$ or $(M\text{-}H){:}O_2^-$

Electron Affinities In the negative ion spectra it is not just the ions that are the most abundantly formed but also the ions that are most stable that will be more dominant in the spectrum. In the glow discharge the ions that will accumulate and hence be dominant in the mass spectrum are the ions with the largest electron affinities. The electron affinity plays a very large role in the abundance of peaks seen in the spectra obtained. The ratios of the $(M\text{-}H)^-$ and the $(M+O\text{-}H)^-$ peaks for three methyl quinolines are shown to be correlated to the electron affinities of the ions theoretically obtained.

Position of Adducts The semi-empirical calculation results can also give an indication of the position of adducts. . For the negative ions the strongest force will be the electron affinity of the final adduct. The knowledge of where the adduct has attached to the sample or where the greatest proportion of adduct attached is useful in interpreting and predicting the chemistry of the ions.

Clusters There is evidence in the results obtained of both cluster formation and of reaction of the indole and quinoline with the oxygen molecule.. The molecule is therefore likely to initially form a cluster or tight ion pair that allows the oxygen molecule to migrate around the deprotonated quinoline. The oxygen then over a period of time reacts with the quinoline to give the covalent interactions which lead to the reaction pathways observed. This set of conditions governing the production of ions makes there interpretation complex.

Conclusion

The way in which the ions are formed in a glow discharge, where many reactive ions and neutrals present at different energies and excited states, makes it an almost impossible task to try to predict a mass spectrum. However, Semi-empirical calculations can be used successfully as an aid to the interpretation of the complex spectra produced from ASGDI sources The most useful information for use in interpretation being gained in the area of electron affinities.

FAB-MS OF PROTECTED STEROIDS AND BILE ACIDS USING ALKALI METAL ADDITION

Suresht K. Aggarwal, Robert Y. Pogue, and Jan St. Pyrek, MS-Facility, College of Pharmacy, University of Kentucky, Lexington, KY 40536-0082

Metal attachment ions are frequently observed in FAB-MS and LD-MS spectra [1]. Their formation may be induced by the dissolution of suitable salts in a FAB matrix. Very early, the combination of sulfolane with group I iodides, silver (I) and thallium (I) have been used to characterize compounds such as antibiotics and peptides [2,3]. Metal attachment ions, especially MLi^+, are frequently used in the FAB-MS-MS analysis. This is exemplified by macrolide antibiotics [4], flavonoid and steroidal glucosides [5], free and acetylated triterpenoid acids [6], and carbohydrates [7]. Similarly, salt addition may be used in LD-MS as also exemplified for the underivatized steroid glucosides [8].

In relation to our interest in the area of bile acid, the evaluation of FAB-MS in a nitrobenzyl alcohol (NBA) matrix saturated with alkali metal iodides was undertaken for 84 fully acetylated steroidal (C_{27}, C_{24}, C_{21}, and C_{19}) glucosides and methyl glucuronides. Most (69 compounds) originated from the collection of Dr. Harry E. Hadd, others were either previously obtained in our laboratory or especially prepared for this study. In addition, a series of fully acetylated major C_{24} bile acid methyl esters and tetrahydropyranyl ethers (THP) of selected steroids and bile acid methyl esters have also been tested.

Such highly non-polar derivatives are frequently used both in the chemical synthesis and characterization of natural compounds. As a rule, such multiply blocked compounds produce great difficulties in the MS analysis by EI, CI and FAB due to extremely facile eliminations of acetic acid or dihydropyrane moieties.

EXPERIMENTAL: Spectra were measured using CONCEPT IH (Kratos). In most cases, the mass spectrometer was scanned from 100 to 2,500 u (at 4 kV), 3 sec/decade, with a 3 kHz filter and the "raw" data were acquired at resolution of about 2,000-2,500. Solutions of CsI and CsI-RbI were applied for mass calibration using a "home made" SS double sided FAB probe (one side for sample another for the standard). Matrices were prepared by saturation of NBA with LiI, NaI, KI, RbI, and CsI to give stable solutions. About 1 μl of a selected matrix was mixed on the probe tip with ethyl acetate solution of a sample (1 to 10 μg).

RESULTS AND DISCUSSION: For mono-, di- and tri-THP ether of several available steroids and C_{24} bile acids variable intensity of $\mathbf{MLi^+}$ and $\mathbf{MCs^+}$ ions was observed. Only a few compounds produced fully diagnostic and lucid spectra. On the other hand, MeAc of C_{24} bile acid, MeAc derivatives of all tested steroidal glucosides and glucuronides produced prevalent metal attachment ions and a highly suppressed fragmentation. In addition to the prevalent $\mathbf{MLi^+}$, the following

ions were also present (usually below 2%) with a decreasing intensity $\mathbf{MLiILi^+}$, $\mathbf{M_2Li^+}$, $\mathbf{M_2(LiI)Li^+}$, and $\mathbf{M_2(LiI)_2Li^+}$. In some cases, however, the ion $\mathbf{M_2(LiI)Li^+}$ was more abundant than $\mathbf{M_2Li^+}$. Moreover, for the NBA-CsI matrix such cluster ions were usually less pronounced. Relatively simple daughter ions scans were observed and included a prominent elimination of one AcOH and lithiated sugar fragments.

The lasting signal of $\mathbf{MMetal^+}$ ion allowed long spectral registration. The spectra were especially clear at toward the end of acquisition when most of transient signals disappeared. This was especially valuable for the accurate mass peak-matching. For this NBA-PEG-CsI was used as a matrix and $PEGCs^+$ ions as mass reference ions.

This extensive survey demonstrated general applicability of a FAB measurement with group I iodides dissolved in a NBA matrix to non-polar derivatives of glycosylated sterols, steroids and bile acids. All compounds investigated produced dominant $\mathbf{MMetal^+}$ **ions** with sensitivity allowing a facile characterization of a μg and below, sufficiently sensitive for many applications such as synthesis and isolation. Many functional groups incorporated in the structure did not interfere. This included free hydroxyl groups, ketones and acetonides with no influence on the MS response. Semicarbazones, especially when two were present, lowered the response considerably. For 17Ā-hydroxy compounds with 20-ketone, the additional weak ion was always observed at M+13 [$\mathbf{(M-H)LiLi^+}$].

Preliminary data obtained by MALDI FT-MS (4.7 Tesla magnet, external LD ion source with a N_2 laser) showed also abundant formation of MNa+, MK^+ ions (no salt addition). These ions were completely suppressed by MCs^+ with the addition of CsI to the DHB matrix. Ions MNa-AcOH and M-2xAcOH were observed but these eliminations were completely absent for MK^+ and MCs^+ ions. We thank to Dr. Richard L. Hunter, IonSpec Corporation, for the help in these measurements.

M[ALKALI METAL]$^+$ IONS IN FAB SPECTRA OF PROTECTED BILE ACID GLUCOSIDES

Suresht K. Aggarwal, Robert Y. Pogue, and Jan St. Pyrek, MS-Facility, College of Pharmacy, University of Kentucky, Lexington, KY 40536-0082

Increased plasma level and urinary excretion of bile acid (BA) are augmented in certain diseases and involve conjugation with sulfuric and glucuronic acids and recently revealed glucosamine and glucose conjugation [1,2]. Toxic lithocholic acid represents an important example. It is 6α-hydroxylated to hyodeoxycholic acid (3α,6α-dihydroxy-5ß-cholan-24-oic, HDCA), 6-glucuronidated [3], and (probably) 3- and 6-glucosidated by distinct enzymes. Following detection of BA glucosides, the site of a sugar substitution was addressed by chemical and enzymatic synthesis and MS [4-6]. We isolated the product of UDP-Glc-specific glucosyltransferase (from human liver microsomes) formed with HDCA. It was characterized as its MeAc derivative by proton NMR indicating that sugar is attached at C-6 [7]. Now, we synthesized all three possible glucosides of HDCA. Analysis by (+)FAB in the NBA matrix saturated with alkali metal iodides provided an excellent method for characterization of this and others blocked BA derivatives.

EXPERIMENTAL: Synthesis of BA glucosides was performed as described for BA glucuronides [8]. All FAB spectra were measured using CONCEPT IH (Kratos), scanned from 100 to 2,500 u, 3 sec/decade, "raw" data were acquired with the mass resolution of about 2,000. Matrices were prepared by saturation of NBA with LiI, NaI, KI, RbI, and CsI to give stable solutions. About 1 μl of a selected matrix solution was mixed on the probe tip with ethyl acetate solution of a protected BA. A long lasting response was obtained using about 1 μg samples.

RESULTS AND DISCUSSION: We favor handling and spectral characterization of MeAc derivatives of BA glucosides and glucuronides. This is because: (a) MeAc derivatives are easily formed by Koenigs-Knorr reaction; (b) MeAc derivatives are stable and can be separated and purified by different chromatographic methods; can be analyzed by high temperature GC and by low eV EI-MS [9]; NMR of MeAc derivatives indicates the point of a sugar attachment in the most unambiguous way; (c) isomeric glucosides and glucuronides have the same MW (e.g. the same $(M-H)^-$ ion in (-)FAB spectra) but for MeAc derivatives of hydroxyl and carboxyl attached isomers the number of Me and Ac groups differs leading to a different MW; (d) blocked ester-glucosides/glucuronides are deprotected with breakage of the glycosidic bond. Because of all these reasons, it is easier to derivatize metabolic products and to perform their comparison with the direct synthetic product. Consequently, we searched for a suitable MS method allowing unambiguous measurements of their MW.

We measured FAB spectra of the MeAc derivatives of BA glucosides listed in the **TABLE** below. In NBA alone, only a barely detectable MH^+ ion was accompanied by an extensive fragmentation consistent with a presumption that these non-polar compounds are not compatible with the FAB analysis. However, encouraged by many reports of the use of metal ion attachments for FAB and LD-MS, we found that all these MeAc derivatives produce intense alkali metal attachment ions and highly

suppressed fragmentation when analyzed in the NBA matrix saturated with LiI, NaI, KI, RbI, and CsI.

BILE ACID	3	6	7	12	glucose position	MLi^+
lithocholic	α				3	727
lithocholic	α				COOH	755
chenodeoxycholic	α		α		3	785
ursodeoxycholic	α		ß		3	785
deoxycholic	α			α	3	785
hyodeoxycholic	α	α			3	785
hyodeoxycholic	α	α			6	785
hyodeoxycholic	α	α			COOH	813
cholic	α		α	α	3	843
cholic	α		α	α-OH	3	801

Peracetylated cholesterol ß-D-glucoside is another good example. In NBA-LiI, it shows the predominant MLi^+ ion (m/z 723), followed by $MLiILi^+$ (857) and weak ions corresponding to M_2Li^+ (1439), M_2LiILi^+ (1574), and $M_2(LiI)_2Li^+$ (1708), elimination of AcOH (663), steroid derived fragments (369, 368, 367) and lithiated and non-lithiated "sugar ions" (355, 331, 295, and 169). Linked scan (daughter ions) indicated the formation of ions 663, 355, and 295 from the MLi^+ ion. Ions 369, 368, 367, and 331, however, were more abundant when MH^+ (of a negligible intensity) was selected as a precursor. These ions were also detected in NBA matrix and their presence suggests that the lithiation may not be complete.

Fragmentation of 3,7-dialkyl-1,5-diphenyl-3,7-diazabicyclo[3,3,1]-nonan-9-ones under electron impact

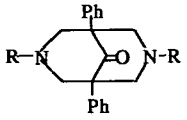
Natalia Yu. Tretyakova, J. Ronald Hass

Department of Environmental Science and Engineering, University of North Carolina, Chapel Hill, NC 27599, USA

Sergey Z. Vatsadze, Albert T. Lebedev, Nikolay V. Zyk, Nikolay S. Zefirov

Department of Chemistry, Lomonosov University of Moscow, Moscow, 119899, Russia

3,7-Diazabicyclo[3,3,1]-nonan-9-ones (bispidones) are of interest to organic chemists due to their conformational behavior. A wide range of bispidones has been recently examined as new biologically active agents. 1,5-Diphenylbispidones were shown to have the properties of local anesthetics. In the present paper, various 3,7-dialkyl-1,5-diphenyl-3,7-diazabicyclo[3,3,1]-nonan-9-ones have been prepared, and the details of their mass fragmentation under electron impact have been elucidated.



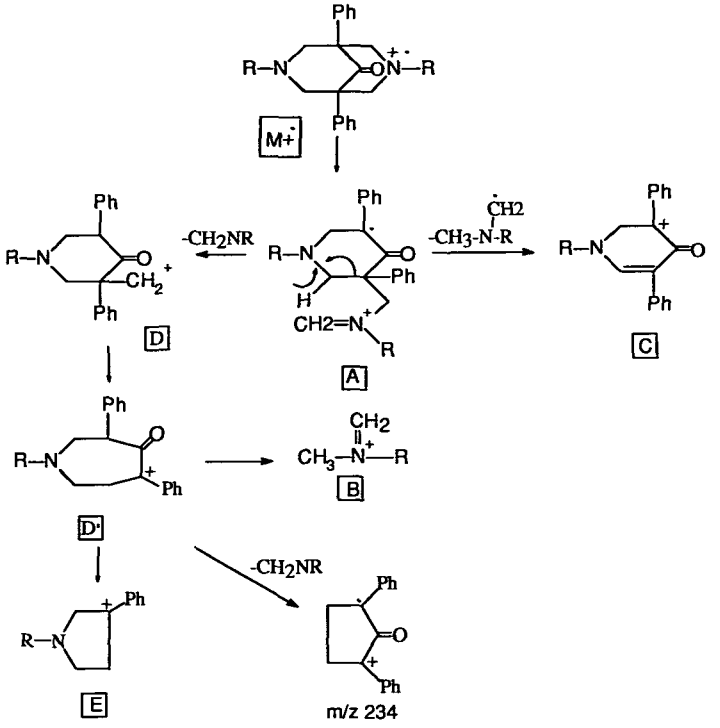
1, R = Me
2, R = Et
3, R = i-Pr
4, R = $-CH_2-CH=CH_2$
5, R = $CH_2-CH_2-O-CH_3$

The molecular ions of each compound under consideration were observed in their EI spectra. Full-scan spectra exhibited a number of fragment ions which were clearly assigned using substituent shifts, collision-induced dissociation spectra of selected ions B/E and B^2/E scans) and accurate mass measurements (for compound 1). From these results, the fragmentation process in the scheme below is suggested.

C1-C2 bond cleavage results in the formation of intermediate A. Hydrogen migration through a six-membered-ring intermediate similar to the odd-electron McLafferty rearrangement leads to abundant ions B. This can be accompanied by charge migration yielding cyclic species (ion C). According to the Stevenson Rule (1951), the favored ion product should form from the fragment of lower ionization energy. Since both

ions are observed at comparable intensity, B should have close ionization energies. Alternatively, A can eliminate an imine molecule giving ion D. The latter probably rearranges to a more stable ion D' which gives rise to abundant ions at m/z 234 present in the EI spectra of all the compounds.

The results of the present work can be useful in selecting the fragment ions suitable for identification and quantitation of 1,5-diphenylbispidones in biological matrices.



Trace Analysis of Degraded Antibiotics by ESI-LC/MS

Jong Shin Yoo[1], Jin Young Kim[1], Sung Ho Kim[2]
1. Korea Basic Science Institute, Taejon, Korea
2 Department of Chemistry, Soonchunhyang Univ., Asan, Korea

Amoxicillin is one of the important classes of β-Lactam antibiotics. During its preparation, the presence of trace amount of degradation products or by-products, however, is thought to be responsible for its adverse effects in clinical use. Because these compounds exist in less than 1% of total weight and are very unstable in solution with various solvent composition, and pH conditions, it was hard to collect and detect them individually for analytical characterization. In this study amoxicillin and its unknown residues were separated and identified by HPLC/MS system using electrospray ionization(ESI) technique.

All samples were dissolved in 40% aqueous methanol solution with 0.05% formic acid to make 1mg/mL solution. They were kept less than an hour to prevent any compositional change in the solvent before analysis. The optimum separation condition for the analysis of amoxicillin products in HPLC system was determined by using a 2.1×200mm×5μm, C_{18} column. The end of the column was connected through an electrospray LC/MS interface into a mass spectrometer. Due to the low flow-rate limitation for successful electrospray ionization, a post-column split ratio of 20:1 for the eluent from a column was chosen to provide the required flow-rate(approximately 20μL/min). ESI-MS and ESI-MS/MS spectra of the compounds were obtained on a VG Quattro Triple Quadrupole Mass Spectrometer under the operation conditions as follows; capillary tip voltage, 3.5kV; cone voltage, 20V; N_2 curtain gas flow rate, 250L/h; source temp., 70℃; Ar as collision gas. The mass spectrometer was scanned from mass-to-charge ratio(m/z) 300 to 800 for 3 seconds.

For the amoxicillin sample aged 4 years since preparation, the trace compounds in it were considered to be the degraded products of amoxicillin In LC/MS analysis shown in Figure 1, they were monitored at the retention time of 9 and 25 min, and represented with the $[M+H]^+$ peaks at m/z 340 and 705 respectively. The peak at m/z 366 indicates amoxicillin which has a molecular weight of 365. The structural identification through fragmentation pattern of the degraded products was further obtained by the use of collision induced dissociation technique in the second collisional chamber of the triple quadrupole mass spectrometer(Figure 2). In all of the spectra we could see the loss of 17 mass unit from pseudomolecular ion $[M+H]^+$, which is the typical pattern for the amoxicillin. They also showed various fragmentation, mostly within the β-Lactam ring and the amide group. Usually, the fragmentation followed the pattern of amoxicillin and most of penicillin type of antibiotics, showing a characteristic cleavage product of the β-Lactam ring, $[C_6H_9HSO_2+H]^+$ at m/z 160, and a further loss of COOH at m/z 114. The fragmentation pattern of the compounds with molecular weight of 339 and 704 showed the possible spectrum for amoxicillin derivatives. In addition, from the same UV maxima at 195 nm and 230 nm in diode array spectra of each compound, they could be expected to have the same structure as amoxicillin.

From these results the compounds with molecular weight of 339 and 704 were assigned to be the penilloic acid of amoxicillin and its additional product. And the compounds which have exactly the same peak at m/z 340 but different LC retention time were thought to be two possible empimers of the penilloic acid of amoxicillin. In conclusion the LC/MS approach with electrospray ionization showed good sensitivity and selectivity for the detection of trace amounts of degradation products by selected ion monitoring of pseudomolecular ion peaks of amoxicillin derivatives. It was proven to be one of the most suitable methods for the analysis of trace mixture of labile compounds such as β-Lactam antibiotics.

Semi-Quantitative Analysis of Pharmaceutical Product Impurities by API/LCMS

Michael R. Wakefield, Mark Sanders, Jonathan L. Josephs and Iain Mylchreest
Finnigan MAT, 355 River Oaks Parkway, San Jose CA 95134

FDA regulations require pharmaceutical companies to identify impurities present at >0.1% in their products. Recent technological advantages in atmospheric pressure ionization (API) now permit LC/MS analysis of low level impurities in pharmaceutical products on conventional 4.6mm id columns. In addition the LC/MS/MS process may be automated, thereby streamlining the identification of the product impurities. Two examples of automated Smart MS/MS of product impurities are presented.

For a conventional MS/MS experiment first a Q1MS LC/MS chromatogram is obtained, the peaks are analyzed and molecular ions in each peak are determined. A second chromatogram is then run in which the instrument is programmed to change the parent mass with retention time in order to obtain MS/MS product ion spectra. The experiment requires that retention times do not shift and that the list of allowable parent set masses is greater than the number of impurity peaks. Additional experiments may then be performed, *e.g.* a neutral loss/parent scan LC/MS/MS run will reveal compounds which have a common structural motif. This may well uncover minor impurities not obvious from the Q1MS data. To obtain product ion MS/MS data on these peaks would then require yet another chromatographic run, once more programming the mass spectrometer to change the parent set mass with retention time.

The concept behind Smart MS/MS is a simple one[1]. The mass spectrometer does in real time what the chemist would do post acquisition. The instrument detects an HPLC peak when an ion signal exceeds a preset threshold. Depending on the incoming data a parent ion is selected, the appropriate mass ranges are set and an MS/MS product ion spectrum is recorded. The Smart MS/MS experiment takes one of three basic forms. 1) Q1MS mode - all peaks above threshold have product ion spectra recorded. 2) Parent mode - only compounds with a common product ion have their product ion spectra recorded. 3) Neutral loss mode - only compounds exhibiting a certain neutral loss would have their product ion spectra recorded.

One example is the analysis of fumonisin B_1, a member of a family of mycotoxins isolated from *Fusarium moniliforme* which is found on corn. The other is the analysis of the analgesic, anti-convulsant carbamazepine which was spiked with known levels of impurities. Both analyses were performed on a Finnigan MAT TSQ 7000 using electrospray ionization (ESI). In order to accommodate the high column loading required to see impurities at the 0.1% level normal bore HPLC columns (4.6mm) were employed at a flow rate of 1ml/min with no presource splitting. For the analysis of fumonisin B_1 Q1MS spectra of low level impurities are illustrated along with the semi-quantitative results. The parent mode Smart MS/MS experiment was performed. Screening for parents of m/z 352 reveals impurities with an unmodified backbone, specifically fumonisin B_1 at m/z 722 and four compounds showing monomethyl side chain modifications at m/z 736. The associated product ion spectra are also shown. The carbamazepine analysis showed impurities at the 0.02% level. A neutral loss to product ion MS/MS experiment screened for compounds with the carbamate moiety, and produced the associated product ion spectra for these impurities.

In conclusion automating semi-quantitative assays of chemical impurities in pharmaceutical compounds has become a routine task. Using the Smart MS/MS technology of the Finnigan MAT TSQ 7000, sample throughput and information acquired per analysis are increased. In addition impurities not revealed by conventional HPLC detectors can be detected.

Predictive Impurity Profiling in Pharmaceutical Research Utilizing Rapid LC/MS and Chemical Degradation

William L. Thompson[1], John S. Venesky[1], Kevin Volk[2], Steven E. Klohr[2], Edward H. Kerns[2] and Mike S. Lee[3]

Bristol-Myers Squibb Pharmaceutical Research Institute, [1]New Brunswick, NJ 08903-0191, [2]Wallingford, CT 06492, [3]Princeton, NJ 08543-4000

The profile analysis of degradants and other impurities present in pharmaceuticals plays a key role in pharmaceutical research. Unfortunately, this role is frequently a "just in time" activity and can negatively impact critical development timelines. In addition, this responsibility may be performed by multiple groups throughout the company and lead to redundancy due to lack of effective technology transfer strategies.

Here we describe our efforts to develop mass spectrometry-based methods and analytical approaches for the predictive profiling of potential impurities in pharmaceuticals. This approach utilizes intentional chemical degradation of a drug with a variety of reagents followed by LC/MS analysis to determine the structures of the impurities formed. This experiment will be conducted at the stage when a potential drug candidate passes from drug discovery to pharmaceutical development and the results will be cataloged in a structure based impurity library. This predictive library will then be made available to all investigators who work on the drug as it passes through development. This streamlined analytical approach is demonstrated with a model compound captopril.

The protocol is as follows:

1. React the final drug substance or the penultimate intermediate in its synthesis with various reagents.

2. Analyze the reaction mixture by HPLC/UV to find new impurities and to collect photo-diode array spectra.

3. Use LC/MS to characterize the impurities and propose structures.

4. Catalog the relative retention times (RRT), UV spectra, molecular weight, and proposed structure for each new impurity. This library will then be used later in the development process as an aid in identifying these impurities when they arise.

The following results were obtained for captopril:

Relative RT	Blank	HCl	HOAc	NaOH	NH4OH	K2CO3	NaHCO3	KMnO4	Air	Heat (75 °C)	CH3OH
0.33				7.26							
0.34			3.03	40.63							
0.37				1.6							
0.911						10.31					
0.970						27.46					
1.000	99.47	100	94.82	5.32	98.93	9.99	99.78	4.13	99.33	99.44	99.76
1.109				1.35							
1.210						2.1					
1.230						21.01					
1.237	0.53		2.15		1.07	14.98	0.22	0.09	0.67	0.56	0.24
1.300				34.42		14.15		55.08			
1.370				9.43							

The table above shows the relative retention times (RRT) and area percents of the impurities formed under the various chemical conditions (LC/UV). LC/MS studies gave ions ($M+H^+$) at m/e of 236, 449, 465, and 433 for peaks at RRT 0.45, 0.34, 1.10, and 1.18, respectively. The peak with mass 432 corresponds to captopril disulfide, a known compound. The peaks at 448 and 464 would correspond to the disulfide plus 1 and 2 oxygens, respectively. The peak at m/e 236 is unassigned.

The LC/MS phase is still in progress, and is expected to yield more information. In addition, LC/UV studies have been performed on the penultimate intermediate in the synthesis of captopril, the thioacetate. This work, when complete, should yield much additional information, since many "real life" impurities derive from the penultimate during the last step of the synthesis.

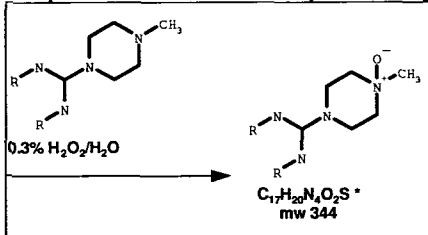
This procedure can also be applied to other areas of pharmaceutical development, including preliminary stability studies.

THE ROLE OF MASS SPECTROMETRY IN THE STRESS TESTING OF PHARMACEUTICALS

Craig Kemp, Gary Cooke, and The Chemical Characterization Team
Pharmaceutical and Analytical DevelopmentEli Lilly and Company,
Lilly Research Laboratories, Indianapolis, IN 46285

Part of the process of pharmaceutical development is a thorough characterization of the degradation products of the active drug substance. Accelerated degradation conditions are set up in accordance with predetermined protocols to satisfy specified regulatory requirements. The characterization scheme in our laboratory uses a MS technique to establish the molecular weight and the molecular formula of isolated degradation products. Since the impurities are true unknowns at this stage of the structure elucidation process, careful consideration must be given to information generated by the mass spectrometer. It is accepted that no one technique will always produce an unambiguous molecular ion and frequently the results from several techniques must be collected and compared to establish a true molecular ion. Three examples from recent projects have been selected to demonstrate the often critical contribution MS techniques make in solving difficult structure elucidation problems.

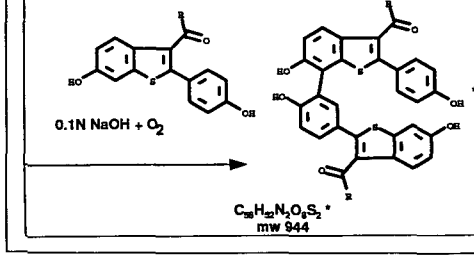
Compound A is an N-oxide formed by oxidative degradation of the parent drug molecule.



FAB	Intense M-O
FD	Intense M-O, weak M+
EI+	M-O
EI Accurate Mass	No Molecular Ion, M-O lost in baseline noise
ES+	M-O

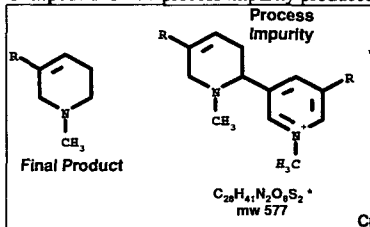
* Determined by Accurate Mass FAB measurements after sample was acidified

Compound B is a dimer produced by basic degradation of the parent compound.



FAB	Very weak [M+H]+
*Accurate Mass FAB	Calculated: 945.3243 Measured: 945.3249
ES+	$[M+2H]^{2+}$ and $[M+H]^+$

Compound C is a process impurity produced in the final step of the synthesis of the bulk drug.



*Accurate Mass FAB	Calculated: 557.2732 Measured: 557.2752
EI+	M^+
ES+	M^+

Cmpd C + D2O ⟶ No Exch Protons
Cmpd C + NaI ⟶ $[M^+ + M^+ + I^-]^+$

Since NMR data of this unknown showed no protons on the nitrogen in the aromatic ring the assumption was made that a **quaternary nitrogen** was present in the molecule. A recent paper[1] describes methods for recognizing quaternary ammonium compounds and this unknown presented an ideal opportunity to test these ideas.

A solution of the unknown was made up with sodium iodide and infused into the electrospray source. Figure 1 is the resulting ES spectrum showing the incorporation of iodide in the molecule and confirming the presence of a quaternary nitrogen in the structure of the unknown. The ion at *m/z* 557 is the *true* molecular ion for this unknown.

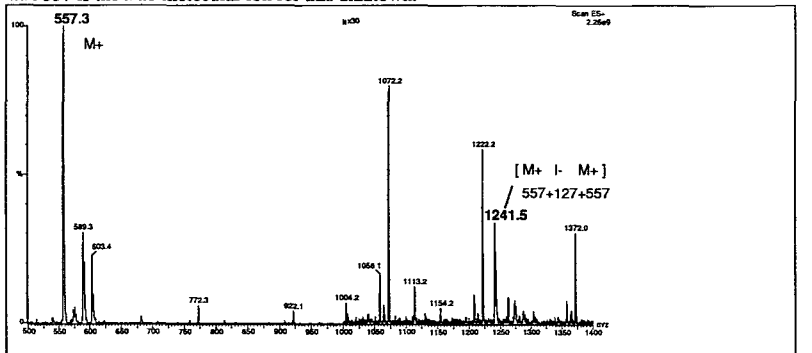


Figure 1: Positive Ion electrospray spectrum of compound C in 50/50 ACN/H2O 0.1mg/mL NaI

The vast majority of the compounds analyzed in our laboratory give an ion that can be established as the true molecular ion by a single ionization technique. The array of ionization techniques used for Compounds A, B, and C are the exception rather than the rule and are implemented only when the NMR spectrum cannot be reconciled with the molecular ion proposed by the mass spectroscopist from a single ionization technique. When these situations occur it is prudent to utilize all the ionization tools available for the MS experiment.

During the pharmaceutical drug discovery and drug development process, we employ a strategy using standard LC/MS profiling and LC/MS/MS substructural analysis methodologies to rapidly elucidate the structures of degradants and impurities. The analytical strategy includes a systematic approach for the identification of unknown impurities and degradants which retain key substructures of the parent drug. We utilize standard LC/UV conditions on-line for comparability to collaborating labs as well as standard LC/MS profiling conditions to determine molecular weight of unknowns in samples. Comparison of an unknown to known analogs provides additional information about relative polarity and difference in molecular weights. Structures of impurities and degradants are elucidated based on relative retention time, UV spectra, molecular weight, and MS/MS substructure analysis (Figures 1 and 2). In these studies, various sotalol preparations possessing distinct degradant and impurity profiles were examined using standard profiling conditions which facilitated the development of a structural database of sotalol impurities. We have examined long term storage stability samples of bulk drug, forced degraded bulk drug (oxygen and heat), and various formulated drug products using these methodologies and have proposed structures for 12 impurities and degradants.

Our standard profiling conditions utilize a Sciex API III tandem mass spectrometer equipped with an ionspray interface. For small molecule work we typically scan from m/z 100 to m/z 1200 using a step size 0.4 Dalton and a dwell time of 1.0 mSec. The choice of polarity modes is based on the structures of the parent drug as well as expected impurities and degradants. However, acquisition of data in both the positive and negative ion modes provides complementary information. A gradient HPLC with diode array UV detector (HP 1090) and a C-18 column (Zorbax, 2mm X 150 mm X 5 µm) with the gradient programmed from 90/10 (A/B) where solvent A is acetonitrile and solvent B is 2 mM ammonium acetate, pH 5.3 to 10/90 in 25 minutes at a flow rate of 200 µL/min. The LC/MS and LC/MS/MS strategies were developed to rapidly and accurately provide structural data which would have been time-consuming using traditional methods of structure elucidation. The use of standard LC/MS profiling conditions permits the development of a database consisting of molecular structures, chromatographic behavior, molecular weight, UV spectrum, and substructure specific (product ions) information. Structures and information are added to the database in support of one area of pharmaceutical development research and are often found to be critical in other areas of development. Ideally, an LC/MS structural database will have its origin in drug discovery research. It will be utilized and enhanced during the pharmaceutical development process, and provide support for future activities such as patent interference, product failures, and new generations of drug analogs.

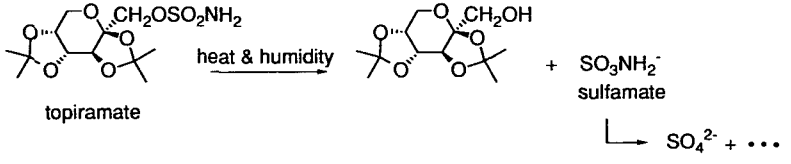
Online ion-exchange chromatography/electrospray mass spectrometry for the identification of organic and inorganic species in topiramate tablets

Xinzhen Xiang, Chan Y. Ko, H. Y. Guh

Analytical Research and Development
The R.W. Johnson Pharmaceutical Research Institute
Welsh and McKean Roads, Spring House, PA 19477-0776

Topiramate is a novel anticonvulsant drug under development [1,2]. Under normal storage conditions (ambient temperature and humidity), topiramate in the solid state is stable. However, it can degrade under stress conditions (elevated temperatures and humidities) and produce organic degradation products and inorganic sulfamate and sulfate as shown in Scheme 1. Since sulfamate and sulfate are: (a) produced stoichiometrically during topiramate degradation; (b) stable and nonvolatile; and (c) extractable quantitatively from the degraded drug tablets, a stability-indicating ion chromatographic method has been developed for monitoring topiramate degradation in topiramate tablets by quantifying sulfamate and sulfate [3]. When the topiramate tablet sample was analyzed on the anion-exchange column, many unknown peaks which are not obviously related to the excipients were detected. It is important to identify these peaks in order to control the chromatography effectively and to better understand the sample matrix. Since those unknown peaks could be either organic or inorganic species, a technique capable of providing elemental and molecular information for both organic and inorganic species is necessary.



Scheme 1

In the present work, an on-line ion-exchange chromatography/electrospray ionization mass spectrometer (IC-ESI-MS) was used successfully to identify organic and inorganic species present in topiramate tablets. An ion suppressor is placed between the column and detectors to replace sodium ions in the mobile phase with hydrogen ions supplied by the suppressor. The combination of the hydrogen ions with mobile phase hydroxide ions produces nonconducting water, thus first greatly reducing the baseline conductivity for the ion conductivity detector; and secondly, preventing nonvolatile sodium salts from clogging the heated capillary and contaminating the ion source of the mass spectrometer. The ability to detect analytes in solvents with a water content up to 100 % was demonstrated. The analytes, including lactate, glycolate, chloride, formate, sulfate, and oxalate were unambiguously identified by comparing their mass spectra and retention times with those of the authentic compounds as summarized in Table 1. IC-ESI-MS proved to be a convenient and powerful tool for the detection and characterization of a variety of organic as well as inorganic species of low to moderate molecular weight. Though the coupling of ion exchange chromatography to mass spectrometry has been reported previously with ion spray ionization [4], thermospray ionization [5], and particle beam ionization [6] respectively, this is the first experimental demonstration of IC-ESI-MS for the identification of unknown species in real samples, especially for the identification of both organic and inorganic species in the low mass range.

Table 1: Summary of retention times, m/z, and identities of the unknown peaks present in the placebo tablet, obtained from the analysis of IC-ESI/MS (in negative ion mode).

Peak	Retention time (minute)	Corresponding m/z	Species identified
A	4.4	89	lactate
B	4.9	75	glycolate
C	6.6	45, 89	formate
D	11.1	35, 37	chloride
E	15.7	97	sulfate
F	17.4	89	oxalate

ACKNOWLEDGMENT:
Valuable discussions with David J. Burinsky are gratefully acknowledged. We thank Arthur P. Micheel for his assistance in setting up the IC instrument.

Pharmaceutical Applications of IonSpray LC/MS for Cyclodextrin Analysis

Josie Visentini, Angelo Filosa, Caroline Rousseau and Conrad Winters,
Merck Frosst Centre for Therapeutic Research,
P.O. Box 1005,Pointe Claire-Dorval, P.Q. H9R 4P8 Canada

Cyclodextrins are cyclic oligosaccharides in which the number of glucose units increases from 6 to 7 to 8 for α–, β–, and γ-cyclodextrin respectively. Figure 1 shows the molecular structure of the parent β-cyclodextrin (BCD) and some BCD derivatives. The size of the cavity within the ring structure also increases from α (5.1Å) to β (6.3 Å) to γ-cyclodextrin (8.0 Å) and it is believed that the cavity size is a key factor in determining the degree to which cyclodextrins can form inclusion complexes with different molecules. This non-covalent complexation can potentially modify the physical and chemical nature of the included compound. These inclusion complexes are of particular interest to the pharmaceutical industry for improving the aqueous solubility of poorly water soluble drugs. The solubility of drugs can often be further increased by using substituted cyclodextrins such as hydroxypropyl-β-cyclodextrin (HPBCD) or methyl-β-cyclodextrin (Me-BCD) (Figure 1) which have a greater intrinsic solubility than the unsubstituted parent cyclodextrin. Since cyclodextrins do not contain chromophores, their HPLC analysis using conventional spectroscopic detectors is limited to methods involving the inclusion of chromophoric modifiers. These methods, however, often lack sensitivity and are vulnerable to interferences caused by the inclusion of impurities rather than the intended chromophore. The potential use of IonSpray LC/MS was explored for the detection of cyclodextrins and their drug-included complexes in both positive and negative ion modes. All inclusion complexes were prepared in a 1:1 molar ratio of drug to cyclodextrin except for spironolactone (SPL) which was prepared in a 1:2 ratio. The drug was dissolved in methanol and the cyclodextrin in water to give a 30:70 methanol:water cosolvent system. The mixtures were stirred for at least 8 hours, filtered using 0.22 μm filters and then diluted using water to 0.5 mg/mL cyclodextrin concentrations. Analyses were conducted by flow injection HPLC on a Hewlett Packard HP1090 coupled to a PE/Sciex API III+ mass spectrometer.

Preliminary work in the characterization of drug-included complexes was conducted using the parent BCD since the HPBCD and Me-BCD showed ranges of ion peaks for both the cyclodextrin and drug complexes while the spectra obtained for the parent BCD contained fewer peaks and were thus easier to interpret. Once the complexes had been characterized using the parent cyclodextrin, later work was conducted using the the more water-soluble and potentially more useful substituted cyclodextrins. Results from different drug-cyclodextrin systems showed the complex in both positive and negative ion modes corresponding to a 1:1 drug:cyclodextrin stoichiometric ratio. The relative amount of complex to cyclodextrin, however, was generally seen to be higher in negative ion mode than in positive mode. In some cases, such as that for the spironolactone+BCD complex, ions corresponding to the complex of drug fragments as well as the intact drug molecule were observed in both positive and negative ion modes. For example, as shown in the positive ion mass spectrum in Figure 2, complexes were observed for BCD+SPL and for BCD+fragments (m/z 43 and m/z 374) which are designated in the structure above the spectrum. Generally, mass spectra obtained for different drug-cyclodextrin combinations showed that only the types of ions observed for the drug alone are observed as complexes. It appears therefore that the ionization behaviour of the drug molecules alone is intimately related to that of the cyclodextrin complex. In the case of spironolactone, however, the methyl keto fragment (m/z 43) was only observed in the inclusion complex ion and not as a fragment of the drug. The absence of this fragment alone indicates that either this group is not ionized under the present conditions or that the BCD+intact drug

ion fragments to produce the BCD+fragment ion. This phenomenon is the subject of ongoing studies. Other studies were also conducted to study the relative affinities of ibuprofen (IBP) for unsubstituted α, β and γ cyclodextrins and the results are shown in Figure 3. The relative affinities of IBP for each cyclodextrin were approximated by calculating the relative ion intensities of complexed to uncomplexed cyclodextrin. The relative affinities of IBP for α and β cyclodextrins were 1.06 and 0.92 respectively while that for γ cyclodextrin was only 0.23 thereby indicating that the cavity size is indeed related to the degree of complexation.

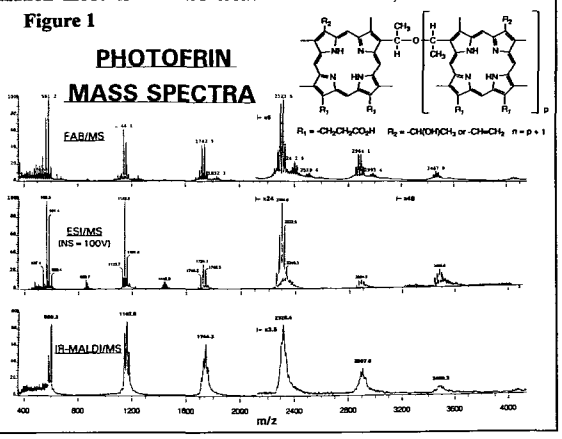
[4]Institute of Medical Physics, University of Münster, D-4400 Münster, FRG

INTRODUCTION PHOTOFRIN porfimer sodium is a porphyrin derivative used in the treatment of a variety of cancers by photodynamic therapy. In earlier work, FAB/MS was used to characterize PHOTOFRIN which was found to be a mixture of oligomers containing up to eight porphyrin units [1]. A FAB matrix was developed to suppress the effect of the salt present in PHOTOFRIN (~6% w/w NaCl) which consisted of glycerol:thioglycerol:TFA (1:1:1%). In recent work, Zhan *et. al* [2], using a 2LD/MS instrument, observed only PHOTOFRIN porphyrin monomers, so they suggested that PHOTOFRIN consists of micelles of monomeric porphyrin species. To resolve the structural issues related to PHOTOFRIN, the newer mass spectral ionization methods of ESI, UV- and IR-MALDI and LD/Jet-REMPI/MS [3], besides FAB, were used to analyze PHOTOFRIN, its permethyl ester and porphyrin monomers, dimers and trimers related to PHOTOFRIN.

RESULTS Desalted PHOTOFRIN was analyzed by FAB/MS (matrix: glycerol:thioglycerol:TFA [1:1:1%]), ESI/MS (solvent: for positive/negative ions: water:acetonitrile:acetic acid [1:1:30%]/ water:acetonitrile:ammonium hydroxide [2:1:15%])) and UV- and IR-MALDI/MS (matrix: 2,5-dihydroxybenzoic acid). In the FAB/MS, UV- and IR-MALDI/MS positive ionization modes, only singly charged porphyrin oligomers were observed with masses up to about 4,100 daltons (Figure 1). The distributions of the oligomers were nearly identical for all these mass spectra (Figure 2). The average oligomer length for PHOTOFRIN was about 2.7 porphyrin units.

In the ESI/MS positive and negative ionization modes, singly and multiply charged porphyrin oligomers were observed with corresponding masses up to 5,000 daltons. When the ESI/MS nozzle-skimmer voltage in the positive ionization mode is elevated from 20 to 200 volts, the abundances of multiply charged ions were significantly reduced and nearly all of the observed ions were singly charged (Figure 1), dehydration of the individual oligomers increased with increasing voltage and the oligomer distribution (≥100 volts) closely resembled that of the distributions observed in the FAB/MS and MALDI/MS spectra (Figure 2). The high voltage nozzle-skimmer experiments demonstrated that PHOTOFRIN is a mixture of covalently bound porphyrin oligomers since the observed components only partially dehydrated and did not break down into monomeric species which would be expected if PHOTOFRIN were a micelle mixture of porphyrin monomers.

Figure 1



ESI/MS positive ion spectra of PHOTOFRIN samples differing in concentration by over three orders of magnitude (~1.3 ng/μL - ~1.3 μg/μL) were obtained and showed no significant change in oligomer distribution as a function of concentration (Figure 3). These observations are consistent with the behavior of a mixture of covalently bound oligomers rather than micelles of non-covalently bound monomers.

The permethyl ester of PHOTOFRIN was analyzed by ESI, UV- and IR-MALDI, FAB [1] and LD/Jet-REMPI. Oligomers containing from 6 to 9 porphyrin units were observed in the mass spectra. Figure 4 illustrates the LD/Jet-REMPI mass spectrum, obtained at unit resolution and ionized at 193 nm (6.3 eV), demonstrating the presence of up to 6 porphyrin methyl ester units. The average oligomer length was calculated from the LD/Jet-REMPI distribution (Figure 2) as 2.9 porphyrin units.

All PHOTOFRIN spectra (Figure 1) exhibited ions originating from the monomeric species hematoporphyrin (MW 598), hydroxyethylvinyldeuteroporphyrin (MW 580) and protoporphyrin (MW 562). When mixtures of these pure monomers were analyzed by FAB/MS, UV- and IR-MALDI/MS and ESI/MS, no new higher mass oligomeric species related to PHOTOFRIN were generated. Likewise, the FAB, UV- and IR-MALDI, ESI and LD/Jet-REMPI mass spectra of synthetic methyl ester porphyrin dimers and trimers, components believed to be present in PHOTOFRIN as carboxylates, produced molecular ions and some fragment ions of lower mass oligomers. These results as well as the dilution and high voltage nozzle-skimmer ESI/MS experiments with PHOTOFRIN demonstrate that PHOTOFRIN is a mixture of porphyrin oligomers and is not micelles of the monomeric species as recently suggested by Zhan *et. al* based upon 2LD/MS experiments [2].

The University of Texas at San Antonio, San Antonio, Texas 78249-0663

INTRODUCTION

The contamination of air, water, and soils by a myriad of sources generates a large sample volume. Currently, sample volume for hazardous constituent analyses is approximately half a million samples per year [1] The total analytical costs associated with this are astronomical. The analysis of these samples is vital in terms of assessing the types of contamination present and to what degree a site has been contaminated. The results of these analyses are very important for making an informed, knowledgeable decision as to the need for remediation and what type of remediation processes should be initiated based on site suitability vs non-action for the various sample sites. With an ever growing environmental consciousness in todays society, the assessment and subsequent remediation of a site needs be accomplished promptly despite the time constraints traditional methods place on such actions.

In order to facilitate a rapid assessment, it is desirable to utilize instrumentation and equipment which afford the most information about a site allowing for optimization in environmental assessment while maintaining a realistic time schedule for the resulting remediation process Because there are various types of environmental samples that can be taken at a site, different combinations of instrumentation and methods are required for assessing the level and type of contamination present whether it is in air, water, or soils. This study is limited to analyzing soil-like media that would normally fall under EPA Method 8270 which is used to analyze solid waste matrices, soils, and groundwater for semi-volatile organic compounds.

One method currently under development at USEPA is a thermal vacuum desorption method. A vacuum distillation procedure which is currently in the approval process for becoming an EPA test method has been reported by Hiatt, Youngman, and Donnelly [2] Their study is on the use of vacuum distillation of water, soil, oil, and fish samples. The analyte recoveries were found to relate to the boiling points of the compounds unless solubilities of the compounds exceeded 5 mg/L. Also being investigated and developed as alternatives to standard extraction methods are supercritical fluid extraction (SFE) methods using carbon dioxide.[3,4] SFE is generally performed at low temperatures between 40 °C and 100 °C) but at high pressures (between 170 atm and 400 atm)

A fundamental obstacle in the analysis of soil samples is the time and labor intensive procedure necessary for the extraction of target compounds from the soil matrix It would be advantageous if samples, that did not contain target compounds above the minimum detection limits stipulated by the EPA, could be identified before they were subjected to the entire extraction and evaluation process. This project investigates the use of a solids insertion probe coupled with a quadrupole mass spectrometer. This investigation is designed to determine the feasibility of analyzing soil samples by loading a portion into a small tube, mounting the tube into a direct insertion probe, inserting the probe into the ionizer of the mass spectrometer, and analyzing the contents by running a temperature program on the solids probe If no compounds of interest are detected using this procedure then no further analysis would be necessary. Otherwise, the remainder of the sample could be analyzed routinely.

Initial runs were unbaked sea sand used as blanks. These experiments were conducted to establish a baseline for the blank soil matrix. The initial runs of the blank unbaked sea sand indicated the presence of contaminants when the solids probe was heated ballistically to 200 °C The sea sand was baked at 200 °C to remove the contaminants. The baked sea sand did not produce significant quantities of contaminants upon the heating of the solids probe. The relative ion counts for the baked sea sand were

less than one-sixth of the counts observed for the unbaked sea sand After establishing the baked sea sand as a blank soil matrix, the next step was to determine if organic chemicals contained within the sand could be detected using the solids probe The figure shows spectra taken immediately upon insertion (compounds are from the Ultra GBN-2 mix) The spectra clearly indicate the presence of these compounds.

Further investigations will involve using other target organic compounds as well as environmental reference standards. Determining reproducibility limits is also a high priority. Developing temperature profiles for various classes of compounds is also necessary Different soil-like media will also be studied as the relatively inert property of the sea sand has allowed for the simplest of analyses. For instance, a clay presence in the soil mixture may keep the semi-volatile compounds from coming off as readily as well as dropping the detection limits to well below that of the signal to noise ratio Another point to be addressed in future investigations will be the homogeneity of the soil sample This is a major concern since only a small fraction of the sample is being examined. Initial efforts will study methods of homogenizing the soil sample to ensure a representative sample for loading into the sample vial and to minimize contaminant loss.

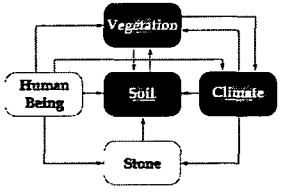
Analysis of Soils - Part I: Soil Dynamics and Climatic Change

M. Howald, S. Schuerch and U.P. Schlunegger, Department of Organic Chemistry, University of Berne,Freiestrasse 3, CH-3012 Bern

Introduction

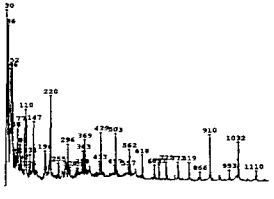
The reaction of soil characteristics to vegetative alterations as a simulation of the effects of a climatic change are investigated, because the organic matter of soils reflects the condition of nature. The search for suitable acreages is a basic condition, since the stage of being fallow, i. e. the time since the last agricultural use, is supposed to be the only variable. That is why a test area has to fulfil different criteria, as e. g. altitude, soil, slope, exposition, evapotranspiration, amount, intensity and duration of rainfall, amount of sunshine, humidity, temperature, definability and an only extensive use.



Six soils with different ages of fallow land fulfil all the postulated criteria and are dated with the aid of maps, aerial photographs and dendrochronolgy.

Analysis of the Soil Organic Matter

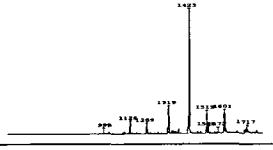
Organic Fragments (Py-GC-MS)



The vegetative change in the middle areas is shown by a slight decrease in the organic fragments, while in the two soils with the longest time of laying fallow especially the bigger fragments are heavily increasing.

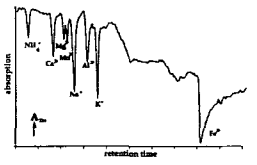
The fact that the fragments for each soil are very similar proves that the evaluation concerning the criteria mentioned above was successful.

Hydrocarbons (GC-MS)

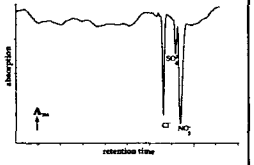


Here human intervention into nature is clearly visible, for after laying fallow for about twenty years the soil is seen in its original state in the pattern.

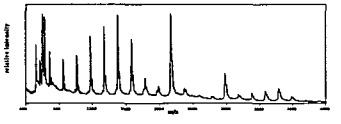
Inorganic Ions (Capillary Electrophoresis)



The distribution of eight inorganic cations seems to rely rather on incident for the sequence of laying fallow. In contrast, a strong overloading of the soil being used at present by nitrate shows with the three essential anions.



Oligosaccharides (MALDI-ToF-MS)



Once again, the amount of oligosaccharides shows the human influence on soil structures. For only with the end of agricultural use microorganisms and bacteria are able to produce larger cyclic sugar molecules.

Humic and Fulvic Acids

The amounts of humic and fulvic acids again point to human intervention, because in soil Collo, used at present, the production of humic acids is disturbed and therefore clearly too low. Also the amounts of humic acids of fractions of the six soils (sand, clay, schluff, 1mm, 500um, 250um, 125 m m and 53 mm) give evidence of the disturbtion in soil being used at present. The clay fraction plays a special role for the soil fertility as ion exchanger and water or nutrien reservoir. Under that aspect the small portion of humic acids in this fraction in the soil being used at present is alarming. The functional groups are analyzed by fourier transform infrared spectroscopy. It can be shown that with the rising age of fallow land the humic acids become bigger and therefore their acidity and the amounts of functional groups decrease. In contrast more aliphatic structures, e.g. saccharides, are built in.

Conclusions

The soil seems to have recovered after laying fallow for about 20 years, because from this time on the organic matter of the soil is in balance again. If we reflect this perception to a climatic change in company with a vegetative alteration, we can draw three conclusions concerning the effects: a climatic change will heavily disturb the state of the ground, this disturbtion will last relatively long, but after a convalescence of the climate nature has still the power for regeneration.

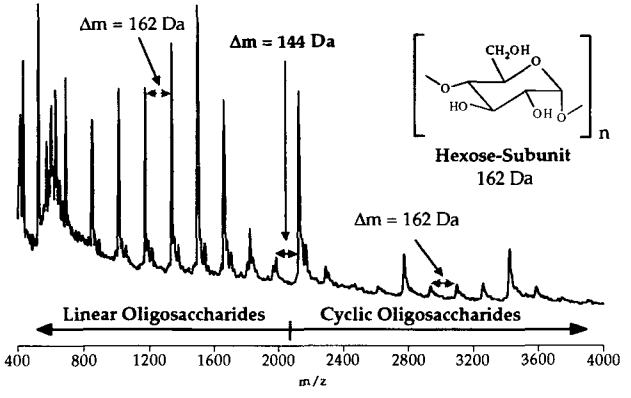
Analysis of Soils - Part II: Determination of Oligosaccharides in Soils by MALDI-Time-of-Flight Mass Spectrometry

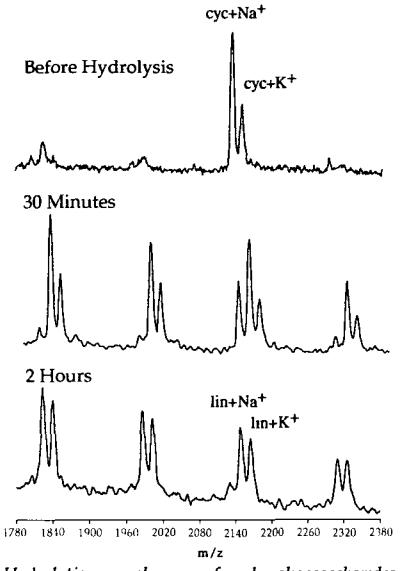
S. Schuerch, M. Howald and U.P. Schlunegger
University of Berne, Department of Organic Chemistry
Freiestrasse 3, CH-3012 Berne, Switzerland

Polysaccharides are the most abundant organic compounds in nature. Decomposition of plant and animal residues leads to a high polysaccharide content in soils. The decomposition of carbohydrates and subsequent mineralization of the products are part of the cylce of life on earth. In extracts of soils collected in the Valle Onsernone (Ticino, Switzerland), oligosaccharides of different size and structure have been identified by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (**MALDI-TOF-MS**). The selected soils show identical climatic parameters and pedological factors, whereat the age of fallow land is the only varying factor. Identification and structure elucidation of the oligosaccharides is performed by substrate-specific **enzymatic hydrolysis**. Moreover the appearance and the distribution of the oligosaccharides is correlated to soil genesis.



MALDI-TOF spectrum of a soil sample The spectrum shows two sequences of oligosaccharides: linear structures up to 2000 Dalton and cyclic oligosaccharides from 2000 to 4000 Dalton.

The MALDI-TOF spectra show periodically appearing peaks with a mass difference of 162 Dalton. They are attached to linear and cyclic hexose oligosaccharides consisting of up to 24 monomers. The MALDI-TOF spectra of the original soil samples do not give any information about the nature of linkage between the hexose-subunits and the degree of branching of the oligosaccharides. To get more structural information the oligosaccharides are exposed to degradation by substrate-specific enzymes.

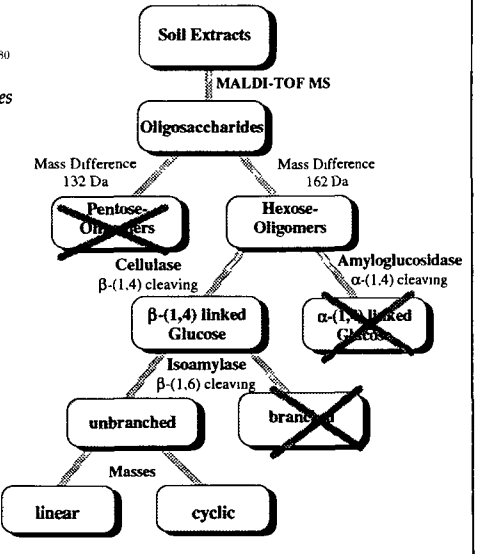


Hydrolytic ring cleavage of cyclic oligosaccharides by cellulase. The peaks are shifted to higher masses

The spectra show good reproducibility and allow to compare samples of fallow land of different age. A direct correlation of the age of fallow land to the oligosaccharide distribution is observed. The intensities of peaks corresponding to cyclic oligosaccharides increase with the age of fallow land. Therefore the MALDI-TOF spectra allow to estimate the age of fallow land in this series of samples. Cyclic oligosaccharides are formed by micro-organisms in the soil. Their activity is depth-dependent and reflected by the MALDI-TOF spectra as well.

The enzyme **cellulase** randomly hydrolyses the β-(1,4)-linkages between glucose monomers. The oligosaccharides found in soils are attacked by cellulase as well. Cyclic structures are opened by the enzyme after a short reaction time. The hydrolytic ring cleavage is accompanied with the addition of water. The reaction leads to a slightly increased molecular weight which is detected by the MALDI-TOF mass spectrometer.

The enzyme **glucoamylase** subsequently hydrolyses α-(1,4)-linked glucose units. **Isoamylase** cleaves β-(1,6)-glycosidic linkages appearing at branching positions in the molecules. In spite of very long reaction time no hydrolysis was observed in both cases. Therefore β-(1,4)-glycosidic linkages are present in the oligosaccharides only and the existence of β-(1,6)-linked side chains is excluded.



Structure elucidation of oligosaccharides by enzymatic hydrolysis.

RAPID ANALYSIS OF FAST GC EFFLUENTS BY TIME-OF-FLIGHT MS

Anthony J. Borgerding* and Charles W. Wilkerson, Jr.
Chemical Science and Technology Division
Los Alamos National Laboratory, Los Alamos, NM 87545

Recent studies in gas chromatography, utilizing short columns and increased flow rates, have reduced analysis times by a factor of 10 or more (1). Fast GC analysis of this type has great potential for improving environmental measurements. In addition to the improved sample throughput and resulting gains in productivity, rapid monitoring of various environmental systems is possible. There are, however, some difficulties interfacing Fast GC with mass spectrometry. Specifically, analyte peaks from Fast GC systems are usually less than a few hundred milliseconds, preventing the use of scanning instruments. In addition, the high volumetric flow rates from the GC can cause difficulties in maintaining a sufficient vacuum. In this paper, we study the potential of time-of-flight mass spectrometry along with the use of narrow bore GC columns to overcome these limitations. Early examples of the capabilities of this instrumentation for the analysis of volatile compounds in atmospheric samples are shown.

When doing rapid separations, the achievable chromatographic resolution often is limited by the initial temporal width of the injected analytes. Our instrument uses an injection system that cryogenically traps compounds from air onto a 25 cm length of 50 µm i.d. GC column. The tube is then isolated, heated to revaporize the analytes, and injected into the flow stream. This system serves both to concentrate dilute air samples, and also to allow rapid injection onto the column, resulting in narrow injection bands. A 4 meter DB-5 microbore column with an inner diameter of 100 µm was used. This column has two advantages relative to columns with diameters of 250 µm or more. Since chromatographic plate height is related to the square of the radius of the column, more theoretical plates per length of column are obtained. In addition, similar linear flow rates can be obtained with much lower volumetric flow rates, easing the pumping requirements of the mass spectrometer. For example, a 4 meter, 100 µm i.d. column has as many theoretical plates as a 25 meter column with a 250 µm i.d. and has volumetric flow rates over 6 times less at equivalent linear flow.

Fast GC peaks are usually less than a few hundred milliseconds and cannot be measured accurately using quadrupole or other scanning instruments. Several laboratories have used time-of-flight mass spectrometry, which can record 1000 or more mass spectra per second (2, 3). Our gas chromatographic system was interfaced to a reflectron time of flight mass spectrometer (2 meter flight path) by passing the column directly into a pulsed electron impact ion source via a heated transfer line. The source is pulsed at a rate of at least 100 Hz. Signal from a microchannel plate detector was digitized on a Sonix model 864 board (64 MHz). Waveform averaging was done to the extent possible. For example, compounds which are poorly retained and elute early

in a chromatogram usually have peak widths of less than 100 msec, making averaging difficult. Compounds which are retained better have peaks that are often as much as 5 times as wide, allowing several waveforms to be averaged without sacrificing chromatographic integrity.

The potential of this instrumentation for environmental studies was studied. Analyses that typically take a few minutes using conventional GC-MS were finished in less than 5 seconds using Fast GC-TOFMS. In addition, our injection system allows compounds to be samples while separation is taking place, allowing rapid reinjection immediately after the separation is complete. The example below shows repeat injections of a gaseous mixture of chlorodifluoromethane, dichloromethane, chloroform, and carbon tetrachloride. Eleven separations are accomplished in less than one minute, showing the ability of this instrument to monitor rapidly changing concentration levels in a system.

Real-Time Characterization of the Size and Chemical Composition of Individual Particles in Ambient Aerosol Systems in Riverside, California

Christopher A. Noble and Kimberly A. Prather*
Department of Chemistry, University of California, Riverside, California 92521

Atmospheric aerosols, although ubiquitous, are highly diverse and continually fluctuating systems A typical aerosol system may consist of particles with diameters between ~0.002 µm and ~200 µm Even in rural or pristine areas, atmospheric particle concentration is significant, with concentrations up to 10^8 particles/cm^3 not being uncommon. Chemical composition of atmospheric particles vary from simple water droplets or acidic ices to soot particles and cigarette smoke. Due to changes in atmospheric conditions, processes such as nucleation, coagulation or heterogeneous chemistry may effect both physical and chemical properties of individual particles over relatively short time intervals

Recently, aerosol measurement techniques are focusing on determining the size and/or chemical composition of individual aerosol particles Our research group has recently developed aerosol time-of-flight mass spectrometry (ATOFMS), a technique which allows for real-time determination of the size and chemical composition of individual aerosol particles. Single particle measurements are performed in one instrument using dual laser aerodynamic particle sizing and time-of-flight mass spectrometry

Aerosol-time-of-flight mass spectrometry is briefly described in several other abstracts in this publication [1-4]

Results and Discussion

A simple size distribution of all particles analyzed in one aerosol sample is shown as a histogram in Figure 1 This aerosol sample consists of 500 individual particles sampled from ambient conditions on 16May 1995, from 5 02 PM through 5.21 PM It can be seen in this sample that two distinct size modes occur, the smaller mode is centered at 1 1 µm, while the larger mode for this sample is at 1.4 µm

Particle distributions change over time as Figure 2 demonstrates. These ambient samples are from 11 May 1995, each histogram represents a sample of 500 particles Figure 1a shows that the earlier sample analyzed has a significant mode at 1.0 µm, with over 160 particles shared between two bins Only one hour later (as shown in Figure 2b), this mode is noticeably reduced, the particle count in the same two bins has dropped to less than half, with only 70 particles analyzed while the total sample size has remained unchanged Also in Figure 2b, there is a higher particle count of particles under 1 0 µm in diameter, with the highest number of particles in the 0.6 µm bin.

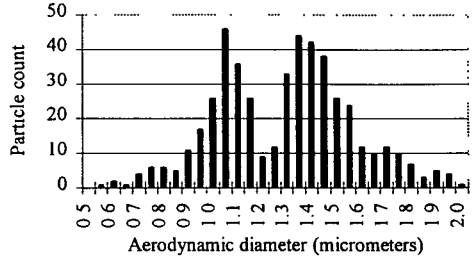

Figure 1: Particle size distribution of ambient aerosol.

A complete mass spectrum of each of these particles is also acquired, using a single pulse from a Nd:YAG laser to desorb/ionize individual particles in flight. Because the mass spectrum for each particle is acquired, particles may be divided into simple groups defined by chemical composition Ambient particles types which are observed in Riverside, CA are classified as organic, inorganic (non-marine), marine and soot.

Typically, smaller particles are more prevalent in the morning, larger size modes tend to grow in during the afternoon. The smaller mode, centered at ~0 6 µm, is mainly due to organic particle, which decrease in concentration in the afternoons. Larger size modes are representative of inorganic or soot particles

Figure 3 is the mass spectrum of an individual inorganic particle from ambient sampling It was analyzed on 11 May 1995 at 12.53 PM in Riverside, CA This spectrum is the result of a single laser desorption/ionization pulse impinged on the particle while it is in flight. Species commonly found in inorganic particles are labeled. The aerodynamic diameter of this particle is 1 4±0 2 µm

Mass spectra for other particles are also acquired along with corresponding particle size

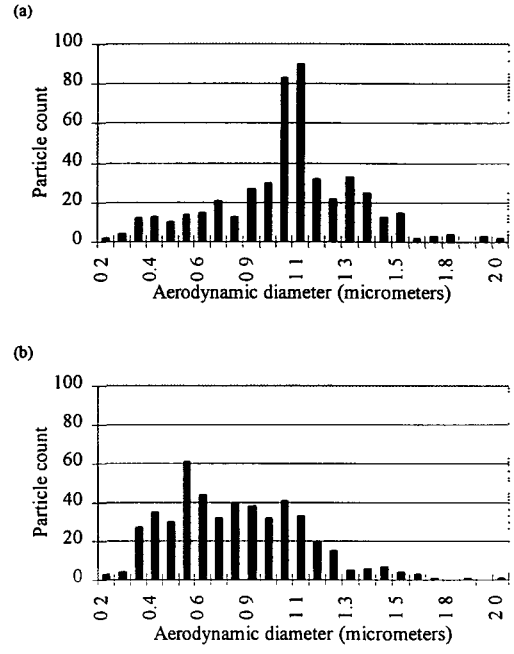

Figure 2: Total particle size distribution of ambient aerosol sample. (a) Sampling period: 9:19-9:33 AM. (b) Sampling period: 10:13-10:31 AM

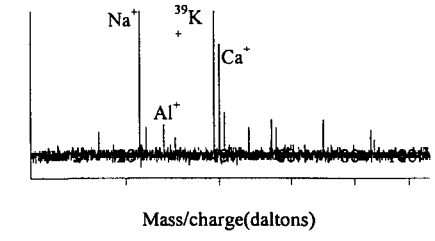

Figure 3: Mass spectrum of single inorganic particle.

Analysis of Single Inorganic Salt Particles Using TOF MS

Kimberly Salt and Kimberly A Prather*
Department of Chemistry, University of California, Riverside, CA 92521

Particles containing inorganic salts, such as sulfoxy and nitrogen oxide salts, play a vital role in atmospheric chemistry and air pollution and are of great environmental concern Sulfuric and nitric acid are the main acids responsible for the environmental effects of atmospheric acidity The deleterious effects of acid deposition on aquatic biota, vegetation and materials are well established while health effects from the inhalation of acidic aerosols is currently under investigation One goal of our research is to be able to determine the forms of sulfur and nitrogen present in atmospheric particles This determination may ultimately aid in developing an understanding of the mechanism of sulfate and nitrate transformation in the atmosphere

We have recently reported the technique of aerosol time-of-flight mass spectrometry (ATOFMS) which combines aerodynamic particle sizing with time-of-flight mass spectrometry for the determination of both size and chemical composition of individual aerosol particles [1-3] ATOFMS has proven to be a viable means to characterize particles containing sulfoxy salts and nitrogen oxide salts in real time

Particles of known size and composition were generated using a vibrating orifice aerosol generator (TSI Inc) The results obtained using ATOFMS to study sodium sulfoxy salts, namely Na_2SO_3 (Figure 1), Na_2SO_4, and $Na_2S_2O_3$, were compared to those obtained using laser microprobe mass analysis (LAMMA) (Figure 2) There is good agreement in the major mass peaks observed between the two techniques Relative peak heights give an indication of exactly which sulfur species is present and can be used even when the particles are composed of a mixture of the sulfoxy salt and another inorganic salt

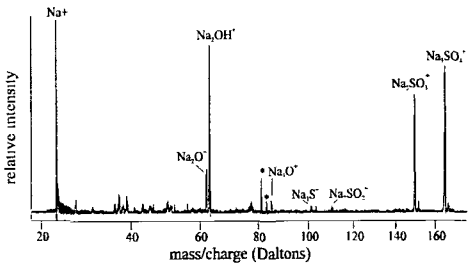

Figure 1: Typical positive ion mass spectrum for a single 2.12 μm Na_2SO_3 particle. The relative intensity of the peak at 149 to 165 is a major indication of which sulfoxy salt is present.

Particles of nitrogen oxide salts, $NaNO_3$ and $NaNO_2$, were also investigated The results for these samples are not in agreement with the LAMMA results as the mass spectra for the nitrate containing particles can only be observed when the nitrate salt is mixed with another inorganic salt species (Figure 3) Nitrite salts can be determined without another species being present and the results for the negative ion spectra are consistent with those reported by LAMMA

[1] Prather, K A., Nordmeyer, T , Salt, K *Anal Chem* , **1994**, *66*, 1403
[2] Noble, C A., Nordmeyer, T , Salt, K, Morrical, B , Prather, K A. *Trends Anal Chem*, **1994**, *13*, 218
[3] Nordmeyer, T , Prather, K A *Anal Chem* . **1994**, *66*, 3540

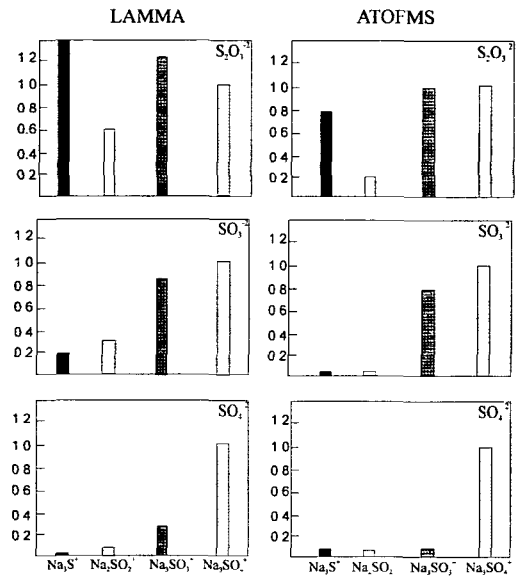

Figure 2: A comparison of the relative intensities of the major mass peaks seen the positive ion mass spectra of different sulfoxy containing particles observed using laser microprobe mass analysis (LAMMA) and aerosol time-of-flight mass spectrometry (ATOFMS). The particle size is 2 μm and the wavelength of the desorption/ionizaiton laser is 266 nm.

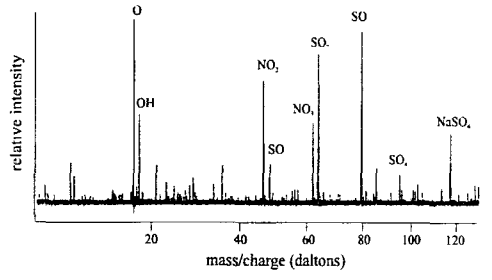
The effects of laser power, the wavelength of the desorption/ionization laser, and the particulate size on the mass peaks observed have also been investigated for both sulfur and nitrogen containing particles

From these studies, criteria for the determination of sulfur and nitrogen species have been established Future studies aim at examining ambient samples for these sulfur and nitrogen species and then quantifying the total amount of sulfur and nitrogen in the individual particles

Figure 3: Negative ion mass spectrum of a 2 μm particle containing $NaNO_3$ and Na_2SO_3 in a 2:1 molar ratio.



Aerodynamic Particle Sizing Versus Light Scattering Intensity Measurements as Methods for Real-Time Particle Sizing Coupled with Time-of-Flight Mass Spectrometry

Christopher A Noble, Kimberly Salt and Kimberly A. Prather*
Department of Chemistry, University of California, Riverside, California 92521

One emphasis in aerosol research includes the development of methods capable of single particle analysis in real time. Single particle measurements cover a broad range of both physical and chemical properties, such as size, shape, temperature and elemental or chemical composition. Various instruments have been developed which focus on the measurement of one or more of these properties. Particle size influences particle transportation and reactivity, while chemical composition determines which reactions may take place on the particle surface. Therefore, various researchers have placed an emphasis on determining the size and composition of individual aerosol particles. The two most common particle sizing methods coupled with mass spectrometry are light scattering intensity measurements and aerodynamic particle sizing

Our research group has recently developed aerosol time-of-flight mass spectrometry (ATOFMS), a technique which allows for real-time determination of the size and chemical composition of individual aerosol particles. Single particle measurements are performed in one instrument using dual laser aerodynamic particle sizing and time-of-flight mass spectrometry ATOFMS is a unique experimental platform capable of evaluating both of these sizing techniques This study is to aid in determining which particle sizing method will provide better results for a field portable ATOFMS system

Experimental Section

Figure 1 shows a schematic diagram of the light scattering region which determines the size of individual particles using either light scattering intensity measurements or aerodynamic particle sizing.

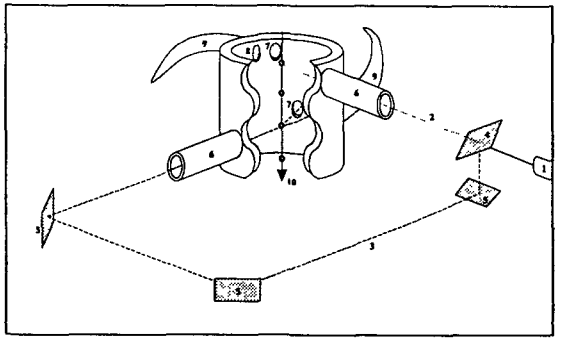


Figure 1: Cut away view of *light scattering region of* ATOFMS system. (1) Ar^+ laser. (2) 514 nm Ar^+ line. (3) 488 nm Ar^+ line. (4) Dichroic mirror. (5) Mirror. (6) Laser window and spatial filters. (7) Exit port for scattered light into light detection system. (8) Exit port for non-scattered light into light horn. (9) Light horn. (10) Particle beam trajectory.

Using a vibrating orifice aerosol generator, particles of known size (±1%) are produced to compare these two methods of particle size analysis. Particles of both NaCl and 2,4-dihydroxybenzoic acid (DHB) were used for this study. For determining particle size based on light scattering intensity

43rd ASMS Conference on Mass Spectrometry and Allied Topics

measurements, the peak height of each scattering pulse caused by a particle passing through the 514 nm laser line is recorded from a photomultiplier tube Aerodynamic sizing employs an electronic timing/logic circuit to measure the time between light scattering signals produced at both laser lines; the transit time of an individual particle is a function of its size.

Results and Discussion

The comparison of size measurements for DHB particles is shown in Figure 2 Because the number of data points taken for each measurement varied, all data sets are normalized to one hundred percent Typically, a minimum of 200 measurements are taken for the light scattering intensity method and 1000 measurements for aerodynamic sizing. Bin sizes used for all histograms were chosen to correspond to the range of the data measurements divided by ten Particles ranging from 1 to 3 μm were chosen for particle size measurement comparisons because particles in this size range will be the targets of future ambient monitoring studies

Figure 2a shows a frequency distribution of the light scattering signal intensity signals produced from particles passing through the 514 nm laser line for 1 0, 2.2, and 3.2 μm DHB particles. As shown in this plot, it is difficult to distinguish between these three different particle sizes based solely on the scattering signal intensity resulting from the single laser. This same trend may also be observed with NaCl particles

Frequency distributions for the transit times of individual particles are summarized in Figure 2b Clearly, the relative spread in transit times collected for aerodynamic sizing is narrower than the spread in the measured light scattering intensities. The narrow measured transit time distributions allow for accurate determination of particle size using this method.

Figure 3 shows the relationship between measured transit time and known diameter for NaCl particles within the range of 0.8 to 8.0 μm. As is evident, transit time is a linear function of particle diameter over the range shown, allowing for simple size determination of unknown samples.

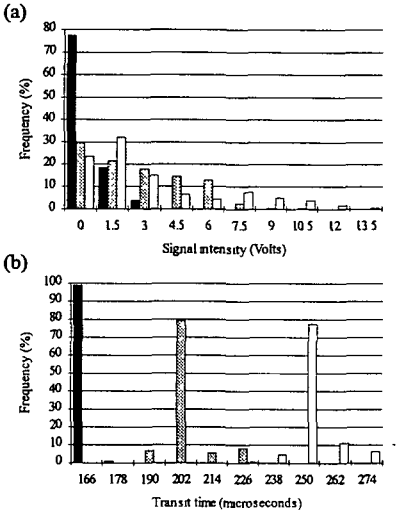

Figure 2: Frequency distribution for ■ 1.0, □ 2.2, and □ 3.2 μm DHB particles. (a) Light scattering intensity measurements. (b) Aerodynamic sizing.

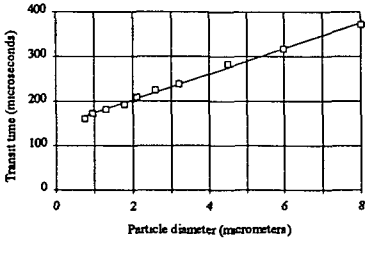

Figure 3: Transit time for NaCl particle as a function of time.

Size and Composition Determination of Sidestream Cigarette Smoke in Real-Time by Aerosol Time-of-Flight Mass Spectrometry (ATOFMS)

Bradley D. Morrical and Kimberly A. Prather*
University of California, Riverside
Riverside, CA 92521
*To whom correspondence should be addressed

Introduction

Exposure to cigarette smoke in both indoor and outdoor environments has become a major concern to the public over the past decade Sidestream and exhaled main stream cigarette smoke constitute a large portion of household, and public indoor air pollution It has also been determined that approximately 2 7% of anthropogenic air pollution in the Los Angeles basin is a result of cigarette smoking(1) I t has been difficult to clearly assess the extent to which pollution occurs from cigarette smoking primarily because of the complexity of the sample and the difficulty this presents when it comes to qualitative and quantitative analysis

Until now, particulate analysis of cigarette smoke has been performed using off-line techniques, such as GC/MS, that do not provide the real-time information of size and composition for individual particles As a result, off-line techniques cannot monitor environmental changes that occur in real-time Aerosol Time-of-Flight Mass Spectrometry (ATOFMS) is a real-time technique that has been used to obtain size and composition information from single particles and has been used to watch changes that occur in time

Experimental

The ATOFMS system (figure 1) consists of three main sections, an interface region, a light scattering region, and the mass analysis region. Particles are introduced into the interface region in which the undergo supersonic expansion into vacuum. The aerosol beam is collimated by the use of skimmer cones and then passed on into the light scattering region

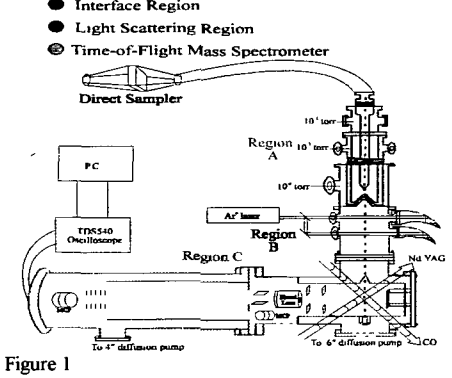

Figure 1

In this region an individual particles velocity is determined by the time it takes for the particle to pass through two scattering lasers 5cm apart The two Ar^+ lasers enter the region orthogonal to one another to insure that only particles traveling through the center of the system will be timed A timing circuit determines the particle velocity and also controls the firing of the Nd YAG desorption/ionization laser

1 Rogge,W F ,Hildemann,L.M.,Mazurek, M.A, Cass,G R, *Sources of fine Organic Aerosol 6 Cigarette Smoke in the Urban Atmosphere* Envirom Sci Technol 1994,28,1375-1388

43rd ASMS Conference on Mass Spectrometry and Allied Topics

When a particle reaches the center of the ion source in the TOFMS, the timing circuit causes the Nd.YAG to fire desorbing and ionizing the particle The ions are then detected by a reflectron time-of-flight mass spectrometer.

Results

Cigarettes were sampled directly into the ATOFMS system and a histogram was obtained (figure 2) for the size distribution of cigarette smoke particulates. The histogram consists of 1500 individual particles and shows the aerodynamic sizing capability of this instrument. A mass spectrum was obtained for each of the 1500 particles as well as the aerodynamic size of that particle. From figure 2 it can be seen that there are at least three major size modes with the composition of the particles within each mode differing. The histogram demonstrates the complexity of cigarette smoke as being heterogeneous in size, and the different size modes in general contain different chemical compositions. The chemical composition difference that is present in the different size modes is shown in figure 3. The top spectrum is from a particle with a aerodynamic diameter of approximately 0.4μm, putting it in the smallest size mode of this histogram. The particle was desorbed and ionized from a single pulse from an Nd:YAG operating at 266nm. This particle contains primarily organic carbon and has an interesting peak at m/z = 185 due to nicotine+Na^+. The bottom spectrum is from 1.17μm particle and contains primarily elemental carbon as evidenced by carbon envelopes extending to C_{13}.

ATOFMS has the capabilities for monitoring real-time size and composition changes for a complex system such as cigarette smoke The advantages this technique provides include the ability to obtain a complete mass spectrum per individual particle. This eliminates the need for depositing particles on a surface and averaging multiple shots together. Future work includes better qualitative characterization and quantitative determination of tracer components such as nicotine.

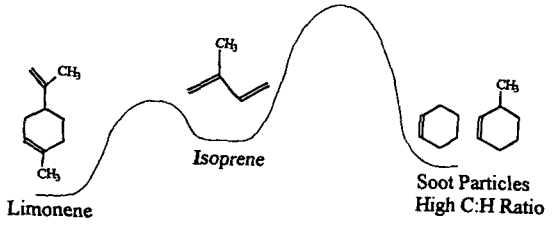
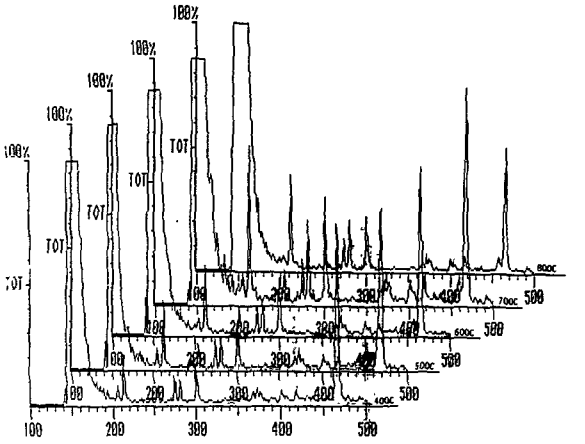
Modeling Scrap Tire Pyrolysis

Tim Burrell, James Haworth, Eugene Phillips,
and Curtiss D. Hanson
University of Northern Iowa, Department of Chemistry
Cedar Falls, IA 50614

Estimates of the generation of scrap tires in the United States are on the order of 2 million tons per year. Although these tires contain a high percentage of useful hydrocarbons of these 2 million tons only 30 percent are converted to other uses. The remaining 70 percent are simply disposed of in land fills, accumulated in large quantities at questionable concentration sites or they are illegally disposed of in such places as roadside ditches or river and stream beds. This 1.4 million tons of scrap tires better represent a resource for valuable and recyclable materials. The bead and belt steel has value and should be recycled. The rubber itself can be processed pyrolyticly and yield light hydrocarbon products such as limonene. The resulting solid char can be the starting material from which activated carbon is produced. Recently, pyrolytic recycling of scrap tires (thermal decomposition in the absence of oxygen) is receiving renewed interest because of its ability to produce valuable products which can dramatically offset the costs of the pyrolytic process. Our process is an improvement over current processes and procedures. Since pyrolysis is decomposition in the absence of a combustible atmosphere many processes evacuate their systems and use complex machinery to maintain this sealed system. We prefer to displace the combustible atmosphere with steam. At the same time we eliminate the need for evacuation we also eliminate the need for complex hard seals to seal and isolate the system. Since we operate at ambient air pressure we are able to use simple water traps to isolate our system from the atmosphere. This separation allows us to control emission releases in to the environment. This water trap sealing system also allows for material to easily and continuously be fed in to our system and for the solid products



43rd ASMS Conference on Mass Spectrometry and Allied Topics



to just as easily exit our system. Vapors generated are quickly and easily condensed along with the steam preventing a build up of pressure. The small amount of gases generated ar contained and easily removed from a collection tower also attached to the system. This process increases the affiance and control over present approaches and lowering the energy requirements while maximizing the collection and generation of valuable products. What we are presenting are some of the results of bench set ups which are also briefly described.

One of the more interesting results from our work is the proposed idea of that the residence time that the generated vapors spend in the heat of the reaction chamber influence the type of liquid products formed. As can be seen in the attached figure we propose that secondary reactions occur relative to the amount of energy the isoprene and products gain while in the reaction chamber. If the vapors do not escape the reaction chamber quickly they will obtain enough energy to form less desirable hydrocarbons having a high C:H ratio rather the more valuable saturated hydrocarbons, such as limonene. The chromatogram below shows the limonene peak at 468 is stable for the 4 temperatures prior to 800 degrees. But the limonene peak drops significantly at 800 degrees which corresponds to a change in the products formed due to increased gas phase reactions occuring in the pyrolysis reactor.

Analysis of Carbonyls: Intermediates of Chemical Oxidation Reactions

Thomas N. Feinberg and M. Judith Charles
Department of Environmental Sciences and Engineering
University of North Carolina at Chapel Hill
Chapel Hill, NC 27599-7400

Introduction

The identification of atmospheric photooxidation products of isoprene and toluene has been the subject of laboratory investigations over the last 20 years, but the products and mechanisms have yet to be completely explained[1]. The reasons for the uncertainty has been the lack of appropriate analytical methods to identify the highly polar intermediates. Previous work has shown that derivatization of carbonyls with Girard's Reagent P and analysis by Fast Atom Bombardment Mass Spectrometry is a sensitive method for molecular weight determination of carbonyls[2], but this method is limited to mixture analysis. We are developing an electrospray ionization mass spectrometry (ESI/MS) method for the identification of carbonyls in photochemical smog chamber impinger samples using Girard's Reagent P.

Experimental Methods

Aqueous standards of 15 carbonyl compounds were reacted with Girard's Reagent P in 50/50 acetonitrile/water with 0.5% acetic acid. Each standard carbonyl was mixed with the reagent to produce final concentrations of 5mM carbonyl and 1mM reagent. Tetraethylammonium bromide was used as an internal standard and spiked into each reaction mixture to a final concentration of 20μM. Solutions were allowed to react overnight. A syringe pump infused each solution at a rate of ~2μL/min into an Analytica of Branford electrospray ionization source retrofitted on a Finnigan 4000 mass spectrometer. The mass spectrometer was under computer control using the Teknivent Vector/Two data system. A calibration curve was constructed by determining the ratio of the ESI/MS signal for Girard's Reagent P (m/z 152) to that of the internal standard (m/z 130). Linearity of signal was observed over 3 orders of magnitude of reagent concentration (1μM-1mM). Derivatization yields for the carbonyls were determined by quantifying excess reagent by ESI/MS in reaction mixtures of known initial concentrations of reagent and carbonyl.

In order to alleviate ion suppression from using a high reagent concentration, an affinity column clean-up procedure was developed to remove excess reagent in samples by finding a suitable solid substrate with free aldehyde groups. A 1:10 w/v mixture of chopped Type 1 collagen and clean sand was packed into short disposable pipets to provide 6mL of column material. A 350μL aliquot of a 1mM solution of Girard's Reagent P was eluted from one column and a 350μL aliquot of a 500μM glyoxal and 1mM reagent solution was eluted from a second column. Fractions were collected from each column, pooled to 2mL volumes and the UV absorption at 260nm (reagent λ_{MAX}) was measured by a Hitachi U-2000 scanning spectrophotometer.

Results and Discussion

ESI/MS spectra of many carbonyl standards were dominated by molecular ion peaks 134u higher than the molecular weight of the carbonyl substrate. Dicarbonyls such as glyoxal (molecular weight of 58u) produced singly charged derivatives when the reagent was at low concentrations, while doubly charged ions were formed when reagent was in excess (Figure 1).

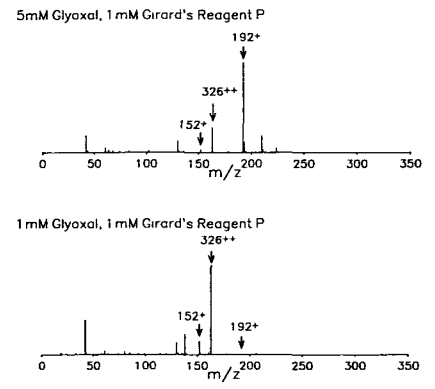


Figure 1

At carbonyl concentrations below 10μM, a high (>1mM) concentration of the reagent is necessary for greater than 90% derivatization yield of all tested analytes. This high reagent concentration is not necessary for aldehydes as derivatization equilibrium constants for aldehydes were generally greater than ketones by a factor of 10.

The affinity column technique was effective in removing over 90% of Girard's Reagent P from samples (Figure 2). The absorbance plateau of the glyoxal derivative suggests that derivatized carbonyls will freely exit the column (Figure 3).

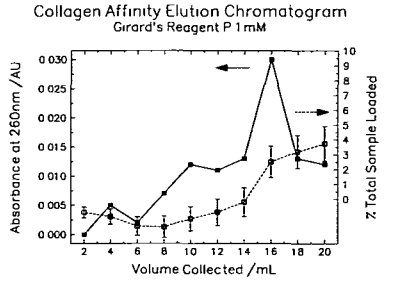

Figure 2

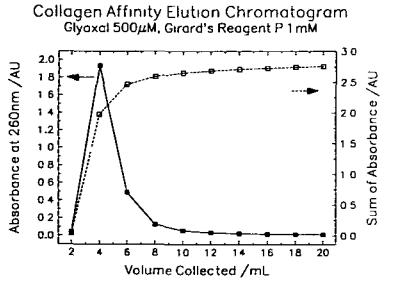

Figure 3

The high ionization efficiencies for electrospray ionization along with future implementation of a liquid chromatography interface such as capillary electrophoresis (CE) suggests an excellent potential for the determination of gas-phase carbonyl photooxidation products. This method is also applicable to identify carbonyl intermediates of oxidative processes in aqueous and biological systems.

A Study of the Oxidation of Heterocyclic Compounds using GC-MS Techniques

J Morris, M. R. Clench & D. W. Allen, Environmental Research Centre, Sheffield Hallam University, Pond Street, Sheffield, S1 1WB, UK.

The Wet Air Oxidation process has considerable attractions for the disposal of toxic organic wastes(1) A fundamental study is being made of the mechanism of oxidation under Wet Air and related conditions of a series of well defined substances known to occur as components of industrial wastes and which are known to present difficulties in the Wet Air Oxidation process. The progress of the oxidation reactions has been followed using GC-MS techniques, so as to establish the nature of the oxidation products formed. The oxidation of 2-, 3-, and 4-picoline was carried out under simulated Wet Air Oxidation plant conditions in a laboratory autoclave operating at 270°C and 750psi air pressure. The literature and some of the oxidation products observed so far suggest that the formation of the hydroxyl radical (•OH) under Wet Air conditions may be responsible for the initiation of the radical oxidation reactions(2). Therefore, the possibility of catalysis of the above systems by reagents known to generate •OH has been explored. Much literature suggests that Fenton's reagent (Fe^{II} + H_2O_2) provides a source of •OH(3), and so the oxidation of the picolines using Fenton's reagent under laboratory conditions and also as a catalyst in the autoclave process has been explored. Work has also involved comparisons of the effectiveness of other metal ion/hydrogen peroxide systems e.g. iron(III), copper (I) and (II), vanadium (IV), and titanium(III) as there is evidence from the literature of their involvement in oxidation chemistry(4). All of these systems were used as catalysts in the autoclave oxidation reactions of each of the picolines and in laboratory oxidation studies.

A wide range of oxidation products has been characterised from the oxidation of 2-picoline under both uncatalysed and catalysed autoclave conditions and from those catalysed oxidation experiments carried out in the laboratory. Similar observations were made in the oxidation of both 3- and 4-picoline, although the extent of oxidation varied in each case. Under the various conditions adopted there was evidence of destructive oxidation of the heteroaromatic ring. However, in addition to ring destruction products, a range of intermediate compounds were also observed, including a variety of dimeric structures. One that was identified from the Fenton Catalysed oxidation of 2-picoline was 1,2-bis(2-pyridyl)ethane at a retention time of 16.65 mins exhibiting an apparent molecular ion of 184.

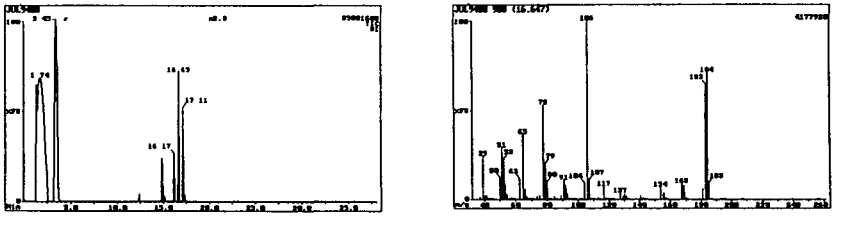

Figure 1 - GC trace from the Fenton Catalysed Oxidation of 2-Picoline and a Mass Spectrum of the Oxidation Product at a Retention Time of 16.65 mins

The study has also involved an investigation of the kinetics of the Fenton catalysed oxidation of 2-picoline. The data obtained illustrated that there is a first order dependence of the rate of the reaction on the concentration of 2-picoline.

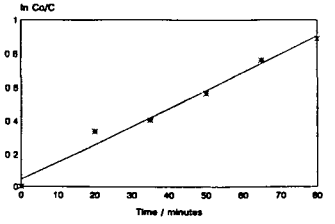

Figure 2 - First Order Kinetic Plot for the Fenton Catalysed Oxidation of 2-Picoline

GC/MS has been successfully used to identify products arising from the oxidation of picolines using a variety of oxidising conditions and investigate the kinetics of a typical Fenton catalysed oxidation reaction The radical responsible for the reactions occurring is thought to be the hydroxyl radical However, a recent suggestion in the literature(5) postulates that Fenton's reagent is not a principal source of hydroxyl radicals. The major oxidising species is thought to be a high oxidation state iron complex.

The aim of this work is now to establish if Fenton's Reagent and other metal ion/hydrogen peroxide oxidising systems are initiating radical chemistry, or not Studies are to continue involving the use of TEMPO, a radical trap, and EDTA, a complexing agent to compare the effect on the oxidation of each of the picolines. Essentially, the aim is to establish if incorporation of such catalytic systems into the WAO process will enhance the oxidation reaction occurring effectively.

A Simple Gas/Liquid Membrane Interface for a Mass Spectrometer (GLMIMS)

N.J.Clarke and J.F.J. Todd
The Chemical Laboratory, University of Kent, Canterbury, Kent, CT2 7NH, Uk

I. Introduction

The idea of using a selectively permeable membrane which would allow volatile organic molecules to pass through but actively hinder the passage of water and polar molecules was first suggested by Hock and Kok[1]. Such a membrane provides a simple and cheap means of transferring samples directly from their surrounding liquid medium into the gas phase and thence into the mass spectrometer More recently systems based on this idea have been used to examine a wide variety of samples, from fermentation vats to olive oil [2,3].

I.1 Description of standard MIMS system

The Membrane Inlet Mass Spectrometer (MIMS) interface described by Cooks et al [4] has become a standard design and uses silastic hollow fibre tubing inside a metal or glass casing. The membrane is normally around 15 cm long and is attached to deactivated silanised silica capillary tubing at each end through which helium gas is passed. Water containing the sample(s) is pumped through the gap between the outer casing of the interface and the membrane, in the opposite direction to the flow of helium. A silicone membrane is commonly used as this is a hydrophobic material which helps to prevent water passage through the membrane into the helium flow and ultimately the instrument. The volatile organic compounds in the sample are also hydrophobic and diffuse easily into the membrane which effectively concentrates them. Once a sufficient concentration of the compounds has been reached within the membrane they will naturally pass through into the hollow centre of the fibre by a process known as pervapouration and are swept into the mass spectrometer by the helium flow. The interface is placed inside a GC oven and heated to around 85°C, in order to facilitate the flow of organic compounds through the membrane.

I.2 Description of Gas/Liquid MIMS system

The system designed at Kent employs the same membrane as mentioned earlier, however instead of the system being encased inside a metal or glass tube, the membrane is wrapped in a helical manner around the outside of a glass sheath. (See Fig. 1) Because of this method of attachment the probe has a greatly increased surface area of membrane whilst still remaining very compact. Typically a membrane of 1 metre or greater is used and this increase in surface area leads to much faster response times and sensitivity.

The glass sheath is placed over a solids probe which has a built in heater and thermocouple, allowing the temperature to be easily monitored and controlled. Helium is then passed through the inside of the membrane into the mass spectrometer via silica capillary tubing as in the standard system but without passing through a jet separator.

Since the interface is now on a hand-held probe it can be easily manipulated and placed into confined spaces or containers, opening up the possibility of using the system for environmental monitoring either in the laboratory or as a portable, handheld unit for sensing in the field.

II. Experimental

All experiments were carried out on a modified Finnigan MAT ITD Quadrupole Ion Trap Mass Spectrometer and the results were acquired using dynamically programmed scanning software written at the University of Kent [5]. An investigation of the relationship between the concentration of ethanol in the headspace and liquid of a series of known concentrations in water was undertaken. An examination of compounds leaching from plastic cups in contact with hot or boiling liquid was also undertaken as an extension of work into detection of estrogenic materials, such as anti-oxidants, passing into foodstuffs from plastic containers. Finally an examination of car exhaust gases and volatile organics present in roadside soil was attempted.

III. Conclusions

1). The new probe can accommodate a much larger surface area of membrane compared to the existing interface.

2). The new probe design can sample both gaseous and liquid samples easily. Although it is possible to examine gaseous samples using the standard interface, the design is inappropriate to the requirements of such a task and the results are disappointing. Further the probe enables quantitative data to be gathered for samples in both the liquid and gaseous state.

3) The gas/liquid probe has been designed to be portable. The entire interface is only as large as the heated probe used. It is ideal for handheld use as well as a fixed atmosphere sensors within buildings etc. The standard MIMS system is extremely cumbersome, requiring a pumping system as well as a large oven.

4). The probe membrane is heated specifically meaning the environment experiences very little heat gain. By comparison the standard MIMS interface requires the entire interface plus sample to be heated which will affect any equilibria and as well as the system being sampled.

5). Less sample is needed to allow the experiment to be completed. Since a flow of sample is required using the standard interface a relatively large volume of liquid is needed. If one examines the headspace gas above a sample very little liquid need be used.

6). Gaseous examination of a system reduces the chance of contamination. This is especially useful when working with sterile environments such as fermenters.

A Rapid Srceening Procedure for the Analysis of Proliferation Compounds in Complex Matrices Using Solid Phase Microextraction (SPME) and SPME With *In-Situ* Derivatization

Armando Alcaraz*, Suzy S. Hulsey, and Brian D. Andresen
Lawrence Livermore National Laboratory, P.O. Box 808, Livermore, CA 94550

Introduction

A variety of methods have been established using advanced chromatographic techniques and new detection systems for the analysis of chemical signatures associated with nuclear and chemical weapon (CW) proliferation. Most of these analytical methods are used in the laboratory and seldom applied in the field. The Chemical Weapons Convention (an international treaty to ban chemical weapons) may require the rapid on-site analysis of environmental samples which contain CW agents, their precursors, and/or their degradation products. In addition to the fact that certain countries are involved in CW non-compliance, there is a current uncertainty regarding nuclear proliferation. This also creates new demands on sample work-up and analytical instrumentation use in the field. The isolation and identification of unique chemical signatures in complex samples such as soils, waste tanks, and decontamination solutions would determine non-compliance. However, a primary area of detection research continues to be sample preparation. Most of the established sample cleanup technologies involve liquid/liquid, Soxhlet, or most recently, solid phase extraction (SPE). Despite the success of these traditional sample preparation techniques, they are time consuming and require multi-step procedures (especially when preparing samples for gas chromatographic mass-spectrometric analysis). The goal of this work is to demonstrate the advantages of utilizing SPME and SPME in-situ derivatization techniques to eliminate time consuming steps necessary to prepare a sample for on-site GC-MS [1]. Our approach was to compare two SPME fibers and to develop methods to facilitate the isolation of polar and moderately polar proliferation compounds from complex environmental samples. This work will help to evaluate current SPME technologies for use during on-site environmental monitoring analysis.

Experimental

Two types of SPME fibers (Supelco, Inc.) were evaluated for each analyte: 100-um polydimethyl-siloxane and 85-um polyacrylate coatings. Samples were then analyzed directly by GC-MS (Varian Saturn III) or derivatized "on fiber" first, then analyzed by GC-MS. The "on-fiber" derivatization procedure is accomplished by gently coating the SPME fiber with N,O-bis(trimethylsilyl)-trifluoroacetamide (BSTFA) prior to GC-MS analysis. The sample matrices analyzed in this study included soil leachate (sandy loam, Livermore, CA), simulated sea water (Instant Ocean, Aquarium Systems Co., Mentor, OH), and canal water (rain runoff). The chemical signatures we selected for the proliferation of CW and nuclear weapons included dimethyl methylphosphonate (DMMP), diisoproplyl methylphosphonate DIMP), 1,4-dithiane, thiodiglycol (TDG), 2-(diisoproplylamino)ethanol (DIAE), and tributyl phosphate (TBP).

SPME Conditions for Analysis

SPME Fiber: Polyacrylate 85-µm coating

Sample: 10 mL of spiked solution*

Extraction: 10 min, fiber immersed in solution, rapid stirring, and heat to 55°C

Desorption: 3 min, 250°C

Desorption: 5 min, 250°C ("*on-fiber*" derivatization)

**Simulated Sea Water:* Added 10% NaCl, adjusted pH to 9.0 (NH_4OH)
Canal Water and Soil Leachate: Added 10% Na_2CO_3, resulting pH of 11

References

[1] K.D. Buchholz and J. Pawlisyn, *Anal. Chem.* 1994, *66* , 160-167.

GC-MS Conditions

Oven: 50°C (1 min) to 300°C at 8°C/min

Injector: Splitless/split closed initial 3 min, set at 200°C and at 10 psi
Column: DB-5MS, 30m x 0.25mm, 0.25um film (J&W Scientific), helium carrier gas

Scan: 50 to 400 Daltons, 1 scan/sec, 3 min EM delay, transfer line at 280°C

SPME (*On-fiber*) Derivatization GC-MS Conditions

Oven: 70°C (8 min) to 300°C at 8°C/min, Injector: Splitless/split closed initial 1 min, and set at 250°C. Scan: 50 to 400 Daltons, 1 scan/sec, 8 min EM delay

Results

The polyacrylate 85-um coated SPME fiber appears to extract DMMP, DIMP, TDG, 1,4-dithiane, DIEA, and TBP best. The polydimethyl-siloxane 100-um fiber does not extract DMMP, TDG, and DIAE as effectively. The use of SPME "on-fiber" derivatization increases the detection of DIAE, figure 1.

Thiodiglycol could be identified only by using "on-fiber" derivatization. Heating at 55°C, stirring, and adjusting the sea water pH to 9 (with NH_4OH) enhances the extraction of the polar analytes. These sample modifications do not significantly effect the extraction of moderately polar compounds (DMMP, DIMP, 1,4-dithiane, and TBP). Heating at 55°C, stirring, and adjusting the canal water and soil leachate pH to 11 (with Na_2CO_3) enhances the extraction of the polar analytes. These sample modifications do not significantly effect the extraction of moderately polar compounds. In the case of 1,4-dithiane pH adjustment by Na_2CO_3 appears to increase its extraction efficiency.

Lower Limits of Detection

Compound	Sea Water	Canal Water	Soil Leachate
Tributylphosphate (TBP)	10 ppb	0.5 ppb	50 ppb
Diisopropylmethylphosphonate (DIMP)	0 5 ppm	0 1 ppm	0.5 ppm
Dimethyl methylphosphonate (DMMP)	1 ppm	1 ppm	0.25 ppm
1,4-Dithiane (1,4-D)	5 ppb	5 ppb	12 ppb
2-(Diisopropylamino)ethanol (DIAE)	5 ppm	0.5 ppm	0.10ppm
Thiodiglycol (TDG)	Not detected	Not detected	Not detected
"On-Fiber"* Derivatization			
2-(Diisopropylamino)ethanol (DIAE)	50 ppb	50 ppb	50 ppb
Thiodiglycol (TDG)	30 ppm	30 ppm	50 ppm

* Derivatization with N,O-bis(trimethylsilyl)-trifluoroacetamide (BSTFA)

Conclusions

Solid-phase microextraction (SPME) can isolate target analytes in complex environmental samples rapidly for field analysis. Previously developed SPME methods (in the laboratory) will greatly optimize the analyte's partition between the sample matrix and fiber coating for field work. A set of systematic SPME procedures can be developed to extract sequentially a variety of analytes onto the solid-phase coating. This can be accomplished by varying pH, temperature, and using salting-out techniques. The use of SPME "on-fiber" derivatization greatly reduces the time required to analyze polar compounds. This technique offers a solution for the rapid field screening of polar compounds by GC-MS. New SPME fibers are needed for the extraction of small very polar compounds from polar solvents.

Thiodiglycol does not adsorb on the 100-µm polydimethyl siloxane or 85-µm polyacrylate fiber efficiently.

*Work performed under the auspices of the U.S. Department of Energy by Lawerence Livermore National Laboratory under contract W-7405-ENG-48.

The Detection of TNT and TNT Metabolites by Electrospray Mass Spectrometry

J. Carlson[1], P. Vouros[1], D. Kaplan[2]
[1]Department of Chemistry, Northeastern University, Boston, MA 02115
[2]U.S Army Natick, Research, Development and Engineering Center Natick, MA 01760

There exists great interest in determining the fate of TNT residues in soils at munitions plants and testing facilities throughout the United States. The storage, spillage, testing and usage of 2,4,6-trinitrotoluene (TNT) for well over a century has resulted in the introduction of TNT into the environment at numerous military installations and contractor facilities Aerobic and anaerobic methods of TNT degradation have been studied, but detailed information on reaction intermediates and mechanisms have not been thoroughly explored. Mechanisms for the transformation products and intermediates of TNT have been postulated, but these materials are often difficult to separate and identify in the complex matrices from which they originate. Several of the TNT intermediates are thermally unstable and cannot be analyzed by gas chromatography. Since electrospray mass specrtometry does not expose the intermediates to harsh conditions it is expected that these intermediates may be isolated and identified. In addition, once separated some of these materials are unstable and readily undergo degradation to more stable structures. In most cases TNT undergoes a long-term reduction in the environment to form the principal metabolites 2-amino-4,6-dinitrotoluene, 4-amino-2,6-dinitrotoluene, 2,4-diamino-6-nitrotoluene, 2,6-amino-4-nitrotoluene, 2,2',6,6'-tetranitro-4,4'-azoxytoluene, 2',4,6,6'-tetranitro-2,4'-azoxytoluene, and 4,4',6,6'-tetranitro-2,2'-azoxytoluene1.

TNT and the principal TNT metabolites were studied by direct injection electrospray ionization mass spectrometry (ESI-MS). In addition to the observed $[M+H]^+$ ion the collisionally induced dissociation (CID) of each of these analytes was conducted in order to determine the primary fragments. Under these conditions, fragments representing the loss of 46 amu are easily observed for each of the NO_2 group(s) present in the aromatic ring.

TNT and TNT metabolites with no functional groups on the aromatic ring other than NO_2 often require negative ion detection modes because of the strong electron withdrawing characterisitics of the NO_2 group(s). Collisionally Induced Dissociation (CID) of these compounds requires high pressures in the gas cell and low dissociation energies in order to fragment these molecules. This suggests that multiple reactions are required within the gas cell in order to produce stable fragments.

TNT metabolites with amine functionalities can be observed in the positive ion mode during electrospray, but the matrix must sometimes be acidified prior to analysis as is the case with the monoaminodinitrotoluenes.

The use of methylene chloride/water/methanol in a 2:3:5 ratio with direct flow injection produces a stable electrospray particularly in the negative ion modes. This solution matrix is desirable because of the limited solubities of the tetranitroazoxytoluenes in typical methanol/water solution matrices.

The comparison of negative and positive ion detection modes has shown the potential for improved selectivity in more complex matrices.

The collisionally induced dissociation (CID) mass spectra of 4,4',6,6'-tetranitro-2,2'-azoxytoluene and 2,2',6,6'-tetranitro-4,4'-azoxytoluene are shown in Figures 1 and 2 respectively. These isomers produce fragments only at high gas cell pressures (2.8 E-3 torr) and relatively low collisional energies (15V). The resulting mass spectra show entirely different fragmentation patterns due in part to the position of the methyl group relative to the azoxy

functionality. In addition, fragments representing the loss of NO (m/z 30) and NO_2 (m/z 46) are observed for the -4,4'-azoxytoluene which are not readily observed with the -2,2'-azoxytoluene.

Environmental Analysis by Flow-injection Tandem Mass Spectrometry

Michael Filigenzi and Michael Larson
Quanterra Environmental Services
880 Riverside Pkwy, West Sacramento, CA 95605

Flow-injection thermospray MS/MS (FIA-TSP/MS/MS) was used for the rapid screening of environmental samples to detect the presence of diethanolamine (DEA) and N-Nitrosodiethanolamine (NDEA).

Water samples were prepared by dilution with ammonium acetate to a level of 0.20M, and addition of d5-atrazine to a level of 50 ng/ml. Soil, wipe, and vegetation samples were prepared by shaking with 0.20M ammonium acetate. The ammonium acetate was withdrawn, filtered, and spiked to a level of 50 ng/ml. A method blank and a pair of spiked method blanks were extracted with each set of 20 samples of a given matrix. Matrix spike samples were also extracted with some sample sets.

All analyses were performed using Finnigan TSQ-70 mass spectrometers with TSQ-700 data systems, Finnigan TSP-2 thermospray interfaces, Waters 600 LC pumps, and Waters 717 autosamplers. Instrument conditions such as vaporizer temperature, source block temperature, and instrument tuning paramaters were optimized by continuous infusion of a 1 ug/ml DEA solution into the instrument. Argon was used as the collision gas with a collision pressure of 1.0 mtorr. The instrument was run in selective reaction monitoring mode, with m/z 106 as the precursor ion and m/z 70 as the product ion for DEA. For sample analysis, the LC pumps were set to deliver 1.2 ml/minute of 0.20M ammonium acetate solution. The spray was turned on several minutes prior to analysis in order to allow source conditions to equilibrate. Analytical runs were initiated by starting acquisition and starting the autosampler (in manual mode) simultaneously. The autosampler was set to inject each sample or standard in duplicate at a rate of approximately one injection every two minutes.

d5-Atrazine response in samples was monitored in order to detect any overall drop in response due to co-eluting compounds Its precursor ion was at m/z 221 and the product ion was at m/z 179.

Quantitation was performed using the external standard method. Three-point standard curves at levels of 1000, 100, and 10 ng/ml were run at the beginning of each day. These curves were required to show <30% relative standard deviation to be considered valid. The mid-level standard was re-injected after every 10 samples. It was quantified using the average response factor from the curve, and was required to give a value within 30% of the expected concentration. Exceeding these limits resulted in reinjection of the standard curve and reanalysis of any associated samples. DEA concentrations in samples were calculated using the average response factor from the associated standard curve.

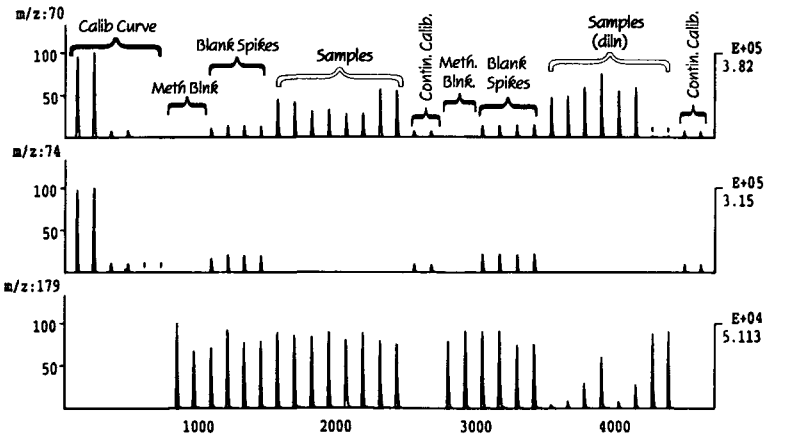
The associated chromatogram shows a complete analytical run for DEA (m/z 70), NDEA (m/z 74), and d5-Atrazine (m/z 179), including a 3-point calibration curve, quality control extracts, sample extracts (some diluted), and continuing calibration standards.

Response was good for DEA and NDEA at the 10 ng/ml level (>5:1 signal to noise). d5-Atrazine peak heights were stable in all samples. There was no evidence of suppression of response due to co-eluting compounds in any sample. Spike recoveries in

the spiked method blanks were routinely good. Matrix spike recoveries were somewhat lower, particularly in soil samples, reflecting differences in soil types and the gentle extraction technique which was utilized. Several background (uncontaminated) soil samples were also analyzed in order to evaluate the possibility that we could get false positive results from uncontaminated soils. These samples showed no evidence of DEA or NDEA.

Over 340 samples were analyzed using this method. Analyses were run quickly, with results for many samples provided within the 48-hour time frame. Quality control specifications were routinely met, although re-analyses were sometimes required due to drifting instrument response.

This data shows the viability of FIA-TSP/MS/MS for high throughput analysis of real-world environmental samples. The gentle extraction procedure combined with the sensitivity and specificity provided by TSP-MS/MS gives data which meets QC criteria consistent with those of common environmental mass spectrometry methods. The speed of the analysis provides the quick results necessary for some cleanup projects.



COMPARISON OF HPLC-MS INTERFACES IN THE DETERMINATION OF HETEROCYCLIC POLYCYCLIC AROMATIC COMPOUNDS*

Darren Thomas, P. Greig Sim, Institute for Marine Biosciences, National Research Council of Canada, Halifax, NS, Canada, B3H 3Z1 and**
Frank M. Benoit, Health Canada, Tunney's Pasture, Ottawa, ON, Canada, K1A 0L2

Polycyclic aromatic compounds (PACs) are generally regarded as one of the most widely disseminated groups of chemical carcinogens[1]. In our work we are interested in the determination of some of the heteroatom substituted PACs, particularly those containing nitrogen (PANHs) or sulfur (PASHs) in the aromatic ring structure. The reason for our interest in these compounds is the extreme carcinogenicity of many of them[2]. Further, the relative carcinogenicity can vary markedly between different members of a set of isomeric compounds. Any reliable assessment of the hazards associated with exposure to mixtures of PACs must, therefore, include analysis of the levels of these compounds in the mixture. The analytical technique used must also yield information about the relative amounts of different isomeric compounds.

The sample chosen for this study is an extract of PACs from the Sydney Tar Ponds, Sydney, Nova Scotia, Canada. The Tar Ponds represent the end result of approximately 80 years of the uncontrolled discharge of effluent from an industrial coking operation into a tidal lagoon. It is thus a rich source of complex PAC mixtures.

In general, PAC analysis is restricted to the determination of a preselected group of PAHs using well established GC-MS techniques. The determination of the PANH and PASH content of a sample is more complex and involves some form of preconcentration step to isolate the target group from the more abundant PAHs, followed by some form of chromatographic-mass spectrometric analysis. We have developed a technique using immobilized copper (II) on silica[3] (open column) or strong cation exchange resin[4] (preparative scale HPLC), and applied it to extracts from the Tar Ponds to separate the PAC fraction into three subfractions. The latter contain PAHs and PASHs (Fraction 1), carbazoles (Fraction 2) and other PANHs (Fraction 3).

In the present work, we have applied two HPLC-MS methods to the characterization of the PASH content of Fraction 1 and the PANH content of Fraction 3. The methods differed in the nature of the interface between the HPLC and the MS, and in the ionization process. The two techniques studied were the moving belt with EI ionization, and the heated nebulizer with APCI. We were interested in comparing the relative performance of these two techniques. The comparison was made on the basis of a number of criteria, including ease of use (and of automation), quality of mass spectra provided, preservation of chromatographic integrity, and sensitivity.

The heated nebulizer had considerable advantages in terms of ease of use, and of automation: we were able to leave it operating unattended for considerable periods of time, an advantage for the repetitive analysis of many similar samples. The heated nebulizer was also advantageous in the ionization of relatively involatile compounds. With the heated nebulizer, however, ionization is effected by at least two competing processes: charge exchange (to produce M^+ ions) and proton transfer (to produce MH^+ ions). The relative abundances of the ions produced by these two processes is dependent on a variety of factors. These include the molecular weight of the compound, in that lower mass compounds tend to yield ions formed from both processes whereas higher mass compounds yield predominantly protonated molecular

* NRCC # 38067
**Present address: Hazleton Europe, Otley Road, Harrogate, North Yorkshire, England, HG3 1PY

also be affected by other conditions in the laboratory environment, higher humidity favouring proton transfer ionization, for example. Both factors may come into play when the analyst is attempting to profile the isomeric content of a given sample, and may also affect the apparent sensitivity of the method.

The moving belt has a significant advantage in the nature of the mass spectra afforded. Under EI conditions almost all PACs yield simple spectra, dominated by an abundant molecular ion. Further, the relative sensitivity of ionization of different isomers is affected solely by properties of the compounds themselves, and not by external conditions. However, the moving belt has a well-known disadvantage in the analysis of less volatile compounds, since the ionization process cannot proceed without prior thermal desorption of the analyte from the material of the moving belt.

The analysis of dibenzo-, benzonaphtho- and phenanthro-thiophenes in Fraction 1, and of acridine, benzacridines and methyl benzacridines in Fraction 3 offers an opportunity to illustrate these features of the two techniques. Under normal laboratory conditions, the ionization of all PASH compounds using the heated nebulizer is dominated by the formation of molecular ions, in other words, they act as lower mass PAHs do in the same environment. However, when the moisture content of the laboratory air is extremely high, several of the higher mass compounds, particularly the phenanthrothiophenes, form relatively more abundant protonated molecular ions. Thus the analyst must constantly check the nature of the ionization process, if reliable results are to be obtained. The PANH compounds generally do not exhibit the same variability in behaviour. The higher mass PASHs also tend to give lower apparent sensitivity with the moving belt interface, which may be caused by difficulty in desorption from the surface. In general, the heated nebulizer does tend to give superior performance in the analysis of these compounds, but the analyst must be aware of factors affecting the ionization process.

USE OF TWO SPE-GC/MS METHODS FOR FIELD ISOLATION AND QUANTITATION OF POLYCYCLIC AROMATIC HYDROCARBONS

Edward T. Furlong, Janece C. Koleis, and Paul M. Gates,
U.S. Geological Survey, 5293 Ward Road, Arvada, Colorado 80002.

Increasing sensitivity and subsequently improving method-detection limits for a variety of organic contaminant compounds is an ongoing effort in environmental analytical chemistry [1]. Several field-deployable isolation techniques have been developed for concentrating hydrophobic organic contaminants from large (> 1 liter) volumes of aqueous samples [2-3]. The capacity of large-volume solid-phase extraction (LV-SPE) was used as part of a simple, efficient, field-operable technique for isolating microgram-per-liter to nanogram-per-liter quantities of polycyclic aromatic hydrocarbons (PAH) in 4- to 8-liter ground-water samples from a petroleum-contaminated aquifer near Bemidji, Minn. [4].

The analytical sensitivity (~100 picograms injected) and specificity of selected-ion monitoring gas chromatography/mass spectrometry (SIM-GC/MS) was coupled with two LV-SPE field isolation techniques compared in this study. The two approaches were as follows: (1) large (145 millimeter) diameter solid-phase extraction (SPE) membranes (M-SPE), and (2) 10-gram SPE cartridges (C-SPE). Both SPE types contain silica-bonded octadecylsilane as the solid-phase sorbent. These two SPE types were compared to determine which LV-SPE technology provided the most accurate and precise PAH concentration measurements. PAH recoveries from both M-SPE and C-SPE isolation methods were compared using (1) reagent water fortified with 18 individual PAH at 1.23 micrograms per kilogram, and (2) ground-water samples with trace (microgram per liter or less) quantities of ambient PAH in the presence of other hydrocarbons and hydrocarbon degradation products. In studies with M-SPE, samples were collected and the PAH isolated at the wellhead; with C-SPE, a separate, simultaneously collected sample was processed in a field laboratory. In the analytical laboratory, the SPE membrane or cartridge was extracted using dichloromethane and analyzed by SIM-GC/MS using electron-impact ionization. PAH were quantified by isotope dilution and internal injection standard methods.

In laboratory tests, PAH recoveries ranged from 78 to over 100 percent for lower molecular weight PAH (naphthalene to pyrene) using either C-SPE or M-SPE (Fig 1). M-SPE recoveries for higher molecular PAH (chrysene to benzo[*ghi*]perylene) ranged from 18 to 56 percent, greater than those measured for C-SPE (0 to 25 percent). The loss of higher molecular weight PAH, observed for both native PAH and perdeuterated PAH, may result from sorption onto surfaces in the sample processing equipment. Comparable amounts of lower molecular weight PAH, at concentrations as low as 20 nanograms per kilogram, were isolated by both M-SPE and C-SPE in oil-contaminated ground-water samples (Fig. 2.).

Although the data are variable, elevated ground-water PAH concentrations at Bemidji appear associated with elevated dissolved organic carbon (DOC) concentrations (Fig. 3), particularly downgradient of the emplaced oil. This suggests that DOC formed *in situ* from microbial degradation of oil in the aquifer [5] is sufficiently hydrophobic that it acts as a cosolvent dissolved in ground water and consequently facilitates aqueous transport of insoluble hydrophobic organic contaminants, including PAH [6].

VARIOUS MASS SPECTRAL TECHNIQUES FOR THE ANALYSIS OF NITRO-PAH

W. Miles and C.Chiu, Environment Canada, Environmental Technology Centre, Ottawa, Ontario, Canada K1A 0H3

Introduction

Nitro-polycyclic aromatic hydrocarbons are of environmental concern because of their mutagenic and carcinogenic properties(2). They are found in both combustion emission particulate matter and ambient air but at much lower levels than other organic compounds such as polycyclic aromatic hydrocarbons(2). Since the nitro-PAH are much more toxic than most other substances in these types of sample, there is a need for a sensitive and specific method for the accurate determination of this class of compounds.

Methods

All the data shown were obtained with a VG Autospec Q mass spectrometer equipped with a VAX 4000 model 60 data system using OPUS software. Negative chemical ionization was accomplished using methane as reagent gas at $3X10^{-5}$ torr indicated source pressure and resolution of 10000. MS/MS monitoring the loss of m/z 46 from the molecular ion utilized xenon as the collision gas at $4X10^{-6}$ torr indicated in the collision cell. The sector was set at 1000 resolution and the quad to unit mass resolution. The adduct experiments were conducted in EI positive mode with pyridine as collision gas at $3X10^{-6}$ torr indicated in the collision cell, sector resolution 1000,quad unit mass resolution. Tuning for adducts was done by introducing nitrobenzene to the septum inlet and monitoring the formation of the m/z 156 ion. Collision energy was the most critical parameter for good adduct yield and had to be optimized on a daily basis. GC separations were carried out on either a 30m DB5-MS (J&W) column or a 60m Quadrex 007-2 column using a Hewlett Packard 5890 series II GC.

Results and Discussion

Negative chemical ionization was examined as both a sensitive and selective analytical technique, avoiding a tedious and labour intensive sample clean-up procedure. Figure 1 shows the mass chromatograms of m/z=223 run by low resolution EI, low resolution NCI and high resolution selected ion recording NCI of an urban air sample. It can be seen that high resolution NCI eliminates many interferences and offers about three orders of magnitude better sensitivity than EI. Tandem mass spectrometry monitoring the loss of NO2 from the molecular ion was also examined as an alternative to high resolution. In some cases this was more selective than high resolution and in others the opposite was the case. Both methods demonstrated similar sensitivity and we find it convenient to use high resolution for routine analysis and MS/MS as a confirmation tool since this avoids the variables of collision gas pressure and quadrupole transmission. A calibration table prepared using seven native nitro-PAH's and three deuterated surrogates

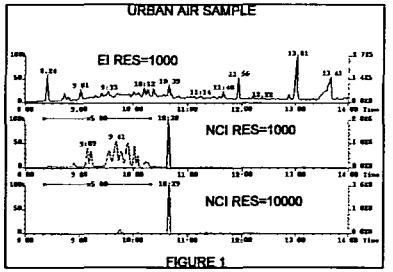

FIGURE 1

over a 100 fold concentration range gave a maximum relative standard deviation of 17% using the high resolution NCI method.

Pyridine Adducts of Nitro-PAH

In 1994 Freeman et al (1) published a paper describing a new instrumental technique to screen environmental samples for chemical contaminants having the propensity to covalently bond to biomacromolecules such as DNA. Since some nitro-PAH's are known mutagens, it was decided to investigate this technique for screening exhaust samples for potential mutagenic or carcinogenic compounds. Figure 2 shows the mass spectrum of neutral pyridine with 3-nitrofluoranthene which is representative of most of the nitro-PAH's studied in that the major and in this case only adduct ion, is due to the loss of the nitro group and the addition of pyridine. The reaction is given in figure 3 and was used for screening air samples. Figure 4 shows a chromatogram of a diesel exhaust sample analyzed by high resolution, loss of 46 from the molecular ion and adduct formation of m/z=247 with pyridine. It can be seen that only two of the peaks give adducts and that both adduct peaks are of similar size while the peak at 14:12 is about 30 times less than the one at 14:41 by both high resolution and loss of 46. Comparison with standards shows the first peak is 3-nitrofluoranthene and the second is 1-nitropyrene. Their mutagenicities for Salmonella typhimurium TA98 are 5,439 and 453 mutants per nmole respectively(2). This demonstrates that pyridine adducts can be used not only to indicate the presence of a mutagenic substance but also to provide a measure of its potency.

DETERMINATION OF NITRATED POLYCYCLIC AROMATIC HYDROCARBONS IN TREE BARK

DAVID. S DOUCE, MALCOLM. R. CLENCH, MICHAEL. COOKE.
Environmental research centre, Division of science, Sheffield Hallam University, Pond Street, Sheffield, S1 1WB.

INTRODUCTION

Nitrated polycyclic aromatic hydrocarbons (nitro-PAHs) are released into the enviroment from a variety of sources, including the combustion of diesel, gasoline and other organic fuels.

The most important source or nitro'PAHs, is believed to be the emissions from diesel fuelled vehicles. Monitoring of this class of compound is important due to their carcinogenicity (1), and mutagenicity (1).Sturaro et al (2)have shown that tree bark acts as a passive absorbant for polycyclic aromatic hydrocarbons (PAHs). They proposed that the use of a natural and passive sampler such as tree bark might lead to a less complex overall analytical strategy for environmental measurements.It was decided to modify the method proposed by Sturaro et al (1), in an attempt to monitor nitro-PAH levels absorbed into the tree bark from diesel emissions.

METHODOLOGY

Samples

1) Tree bark A. Adjacent to city bus station
2 Tree bark B. A park on the city outskirts

Tree samples were taken from between 1-2 metres above the base of the tree The fragments were stored in amber screw topped vials.

Extraction.

The bark was cut into small pieces and extracted with Dichloromethane in a soxhlet apparatus. The solvent was removed to produce a residual weight

Clean-up procedure.(3)

An hplc system, using an Alumina column - activated, basic, Brockman 1 (150 mesh) was used to separate the mixture into four distinct fractions:-

n-Hexane -Alkanes, Dichloromethane -PAHs,

Acetonitrile-Polar PAHs, Acetonitrile·Methanol (3·1) -Multi polar PAHs

Nitro-PAHs were detected in the acetonitrile fraction.

SEPARATION AND DETECTION

Gas chromatography, using either an electron capture detector or a mass spectrometer using negative ion chemical ionisation in selective ion monitoring mode (NICI-SIM) were used.

Figure 1 - Nitro-PAH standard.

Figure 2 - Acetonitrile fraction of tree bark A, from hplc procedure.

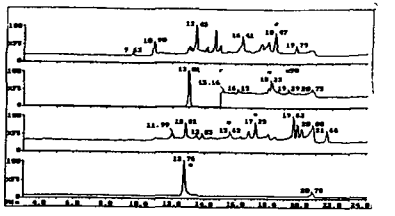

Figure 2.

QUANTITATIVE RESULTS

	1-Nitronaphthalene	4-Nitrodiphenyl	5-Nitroacenaphthene	2-Nitrofluorene	9-Nitroanthracene
GC/ECD TREE A	220 7 ng/g	Trace	Trace *	Trace	156 98 ng/g *
GC/ECD TREE B	103.0 ng/g	17 94 ng/g	10.12 ng/g	-	Trace *
NICI-SIM TREE A	154 8 ng/g	36 12 ng/g	50 62 ng/g	35 63 ng/g	177 09 ng/g

* Levels not seen in chromatograms provided

CONCLUSION

The NICI-SIM method of detection was highly specific, producing very clear quantitative results The result obtained from the electron capture detector are a little more difficult to interpret, due to the large quantity of interfering compounds still present in the cleaned up extract. Further steps need to be taken to improve the clean up fraction to concentrate and separate the nitro-PAH's from the other organics present in the tree bark sample.

However, we have shown that tree bark can be used as a passive monitor for the level of diesel pollution, both in the urban and rural environment.

Factors Effecting the Analysis of Organic Pollutants by Particle Beam-Liquid Chromatography-Mass Spectrometry

Mr.J.White and Dr.R.H.Brown
(Health and Safety Laboratory, HSE, Sheffield, S3 7HQ, U.K.)
Dr.M.R.Clench and Dr.D.A.Leathard
(Sheffield Hallam University, Ponds St. Sheffield, U.K.)

Liquid chromatography (LC) is probably the most versatile of chromatographic techniques as it can be used for compounds with a wide range of polarity and for compounds of low thermal stability or low volatility that are not amenable to gas chromatography. Additionally, many types of LC packing materials are available with varying surface chemistries to achieve the desired separation and a large amount of research has been carried out on the technique.

Mass spectrometry (MS) is probably the most versatile of detectors currently available. Using electron impact ionisation (EI-MS) generates characteristic fragmentation patterns ("fingerprints") which are of particular use for identification in forensic situations. Selected Ion Monitoring (SIM) can be used to simplify "noisy" or complicated chromatograms this is particularly of use for environmental samples.

An LC-MS system would therefore give the analyst an extremely powerful tool for the determination of unknown or trace compounds.

As part of a joint project between Sheffield Hallam University and HSL the use of particle beam-liquid chromatography-mass spectrometry (PB/LC/MS) for the analysis of environmental samples has been examined. The particle beam interface is perhaps the simplest PB/LC/MS interface available but has certain disadvantages. These are limited tolerance to some chromatographic buffers, non-linearity of response under certain conditions, poor sensitivity for some compounds (particularly those of low molecular mass) and operational difficulties due to interface blocking (particularly for "dirty" samples).

To investigate means of reducing these disadvantages a series of poly nuclear aromatic hydrocarbons (PAHs), the "EPA-16" **(1)** was chosen as trial compounds. Various methods of increasing sensitivity were examined, such as, instrumental factors (e.g. altering nebulizer position, increasing nebulizer gas pressure etc.), varying interface temperature and the addition of additives post column. These results were compared with those obtained from analysis by LC with diode array (UV) and programmed fluorescence detection and estimated detection limits compared. A variety of mobile phases, LC columns and gradient profiles was examined to give baseline resolution within an acceptable run time. Using the methods developed above PAH samples from environmental samples (refractory brick dust) were analysed. Various extraction and clean up procedures were examined for these samples.

Based on the above experiments a few comments may be made. Instrumental factors and interface temperature were shown to have an effect on sensitivity although this effect was not common throughout the sixteen compounds used as probes. Limits of detection obtained for PB/LC/MS were generally worse than those obtained by LC/DAD or LC/F . Detection for low molecular mass compounds (< 200) were generally very poor or undetectable. For higher molecular mass compounds detection limits improved until at RMM >270 similar limits to the other techniques were found. Further work shows this trend continues with coronene (RMM ~300). The post column addition of additives did improve sensitivity and linearity especially at low concentrations but again this effect was not uniform for all the PAHs and no single additive can be recommended. These findings are in accordance with the work of Apffel and Perry **(2)** who proposed a "low mass filter" model to account for this finding.

The use of solid phase extraction cartridges for the clean up of the brick dust extracts raised the following points. For both the silica gel (Si) and octadecyl silica (C18) cartridges used recoveries varied for each PAH. Again the lower RMM compounds were lost completely (up to mass 202). However preliminary work with gel permeation chromatography (GPC) also shows this effect which is probably due to sample work up after GPC or SPE e.g. drying down in the turbovap. Recovery work carried out on spiked SPE tubes (Si gel and C18) showed that C18 tubes gave slightly higher recoveries and better reproducibility than Si gel. In general it may be said that his type of sample proved to be difficult to analyse. LC/DAD traces in particular were very noisy and the PB interface was prone to being blocked by what were presumably brick dust particulates. GC/MS and LC/F gave acceptable chromatograms.

In conclusion it can be said that although PB/LC/MS shows great potential certain difficulties still remain especially low sensitivity for certain compounds. Further work in this study will look at GPC vs SPE clean up, different post column additives, and comparison of PB with electrospray, field and thermospray ionisation interfaces The use of PB-LC-MS for other classes of pollutants, such as pesticides and pharmaceuticals will also be investigated

Environmental Genotoxin Characterization by LC/MS Analysis of DNA-Adducts formed *In Vitro*.

Douglas W. Kuehl and Jose Serrano
U.S. Environmental Protection Agency
Duluth, MN 55804
(218) 720-5559

The a priori identification of those environmental chemical contaminants with the propensity to be genotoxic (covalently bond to DNA) from the total of those that may be present in a sample has been the subject of study for some time. Methods of assessment have ranged from multi-generation life cycle mammal dosing studies to the use of short term predictive methods, including quantum chemical calculations and analytical models. None of the short-term predictive methods provides a complete assessment of potential hazard; however, each can be complementary to another and provide an alert for further testing. We have proposed and evaluated another assessment technique, the use of liquid chromatography/mass spectrometric characterizations of chemical adducts of DNA formed *in vitro* to detect and identify those contaminants in the aquatic environment which have the propensity to be genotoxic The technique was evaluated using, first, a series of direct acting chemicals which have different electrophilic reactivities; and second, indirect acting chemicals, i.e., those that require metabolic activation to become reactive. LC/MS was done by C_{18} RP-HPLC and both thermospray and electrospray MS and MS/MS.

Allyl reagents (isothiocyanate, chloride, bromide and iodide) were used to demonstrate that LC/MS characterization of DNA-adducts formed with direct acting chemicals was linear with the concentration of toxicant (allylbromide) (r^2=0.995 for the formation of the N-7 adduct) and proportional to relative reactivity of each toxicant as measured by the nucleophilic reagent 4-(4-nitro-phenyl)pyridine (NBP) and to Ames mutagenicity test results (Table 1). It was also possible to determine from LC/MS the proportion of adduct formation of N-7 vs O^6 of deoxyguanosine. N vs O bonding is an important parameter in the assessment of the carcinogenic potential of many genotoxins. For low concentrations of allylbromide (25 nmol/µg DNA) the N:O product ratio was 69:1, indicating that the allyl reagent was a soft electrophile and most likely possess little carcinogenic potential.

Table 1

Allyl reagent	LC–TSP-MS, 7-A-Gua/dGuo	Alkylating activity, NBP (ΔE_{560})*	Mutagenic activity (revertants/µmol)

alkylating (NBP) and mutagenic activity obtained by Eder et al ·

B[a]P was selected as a model compound for indirect acting chemicals, such as PAHs. Standard microsomal incubation reactions were developed which provided sufficient B[a]P/DNA adduct formation for LC/MS characterizations when environmentally realistic concentrations of B[a]P were used. Standard reaction conditions were: 2 mg trout liver microsomes; 0.4 mg NADPH, 2 hr; 25° C; and 200 mg calf thymus DNA. LC/MS characterization of the formation of the anti- isomer adduct of B[a]P/DNA was linear (r^2=0.990) at doses of B[a]P < 50 pmol/µg DNA; but it was later shown that higher doses could exceed the range of linear response (Figure 1). This observation agrees with the hypothesis that B[a]P arylation of DNA is highly base site specific and that the dose of B[a]P can exceed available reaction sites. It was also shown that LC/MS analyses were sensitive to the ratio of anti- to syn-isomer formation when altered by the presence of co-contaminants in the microsomal incubation reaction mixture (Table 2).

Analysis of Serum PAH's and PAH Adducts by LC/MS

P Cheryl McClure, John R Barr, Vincent L. Maggio, Sarath Sirimanne, Li Ma, Donald G Patterson, Jr

Centers for Disease Control and Prevention, 4770 Buford Highway, Atlanta, GA 30341

Polycyclic aromatic hydrocarbons are an important class of chemical carcinogens There is potential for extensive chronic human exposure and EPA has listed many of these compounds as priority pollutants It is believed that PAH's can enter the body from a variety of environmental sources and then are metabolized by cytochrome P-450 to highly reactive electrophylic intermediates These intermediates can then react and form adducts with a variety of biopolymers such as DNA and proteins It is thought that the reaction of the electrophylic PAH metabolite with cellular DNA yields an adduct that is the initial step in the induction of mutants and neoplastic cell transformation Benzo[a]pyrene is the most extensively studied and best understood carcinogenic PAH. It is believed that Benzo[a]pyrene is metabolized *in vitro* to the diol epoxide, Benzo[a]pyrene-7,8-dihydrodiol-9,10-epoxide which then can react with various nucleophilic centers on DNA. The major alkylation product appears to be the reaction of the Benzo[a]pyrene diol epoxide with the N^2 position of guanine sites on DNA. Methods that can measure exposure and biological response to carcinogens such as PAH's are needed Human Blood can be separated into plasma, lymphocytes, and red blood cells The plasma should contain native PAH's which may yield some useful information about recent exposure The red blood cells contain hemoglobin and adducts of PAH's. Hemoglobin has an average lifetime of 120 days so quantification of hemoglobin adducts should give an average of a persons exposure over four months Also, the electrophilic metabolites that react with hemoglobin to form adducts are the same metabolites that form DNA adducts which can lead to mutations and cancer Lymphocytes contain DNA and therefore DNA adducts DNA adducts can be repaired by a series of enzymes so quantification of these adducts will only yield information about recent or non-repairable adducts. DNA adduct formation is believed to be the first important step in chemical carcinogenesis so quantification of these adducts should yield some information on exposure and a great deal of important data on biological response and risk from specific PAH's

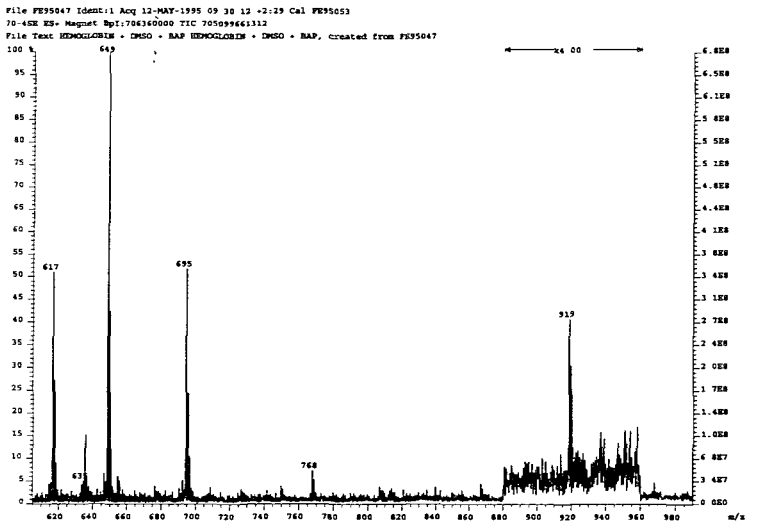
The levels of various PAH's in plasma can determined by isotope dilution high resolution mass spectrometry Two separate approaches are currently under development These are solid phase extraction of serum followed by high resolution GC/high resolution mass spectrometry and cloud point extraction with LC/MS analysis.

Hemoglobin has an average lifetime of 120 days The measurement of Hemoglobin-PAH adducts will therefore yield information of exposure over a four month period. Whole blood will be separated into plasma, lymphocytes, and red blood cells Hemoglobin will then be isolated from the red blood cells and the heme will be removed to yield globin. Acid hydrolysis will then release the adducts which can be partially purified by an organic extraction The final analysis and quantification will then be achieved by LC/MS or CE/MS The PAH-Hemoglobin adduct study started with the analysis of Benzo[a]pyrene adducts. The products released from hemoglobin for Benzo[a]pyrene are four different Benzo[a]pyrene tetrols Positive ion APCI yielded primarily an M^+ and negative ion yielded an $(M-H)^-$ We also have found from the analysis of the released heme that adduct formation on this portion of the protein can be

determined Treatment of hemoglobin with Benzo[a]pyrene followed by analysis with ESI MS showed that the initial adduct formation was actually on the heme (See Figure) Ions for the heme (m/z 617), Heme + dioxygen (m/z 649), heme + DMSO (m/z 695) and heme + B[a]P adduct (m/z 919) are all present. Treatment of hematin with Benzo[a]pyrene diol epoxide also produced these adducts

DNA adducts have a much shorter lifetime than Hemoglobin adducts due to the DNA repair mechanism, but are the most significant biological response for cancer risk The DNA adduct study would use DNA obtained from human lymphocytes isolated from blood The DNA would then be processed so that individual nucleotides with adducts could be isolated and analyzed by CE/ESI-MS.

The development of methods for the analysis of human exposure to PAH's in serum is important for the determination of health risk for the general population and exposed groups The extent of the risk to both low and high level exposures can only be determined by a correlation of health effects to measured body burden levels in humans. To aid in the understanding of human health effects due to PAH's, we are currently developing methods for the analysis of serum/plasma PAH's, PAH-Hemoglobin adducts, and PAH-DNA adducts.



MS Analysis of Pesticides by Combined On-line Photolysis and LC–MS

Dietrich A. Volmer* and Jon G. Wilkes

Food and Drug Administration, National Center for Toxicological Research, 3900 NCTR Drive, Jefferson, AR 72079

1. Introduction. The LC–MS spectra of many pesticides consist in general only of $[M+H]^+$ ions or simple adducts. The lack of structurally significant fragments limits the specificity of analysis. The problem can be overcome by the application of collision-induced dissociation (CID) either in MS/MS systems or by using in-source octapole lenses and cone-voltage fragmentation in API systems in conjunction with APCI and ESI. However, MS/MS systems are not readily available and inducing fragmentation with other ionization techniques such as thermospray (TSP) is more complicated. Furthermore, the sensitivity with CID is often not sufficient for trace level monitoring of pesticides. In this study we have used a different approach to overcome these limitations. An on-line photolysis ESI LC–MS system has been utilized for the analysis of several pesticide compound classes, *e.g.* carbamates, phenylureas and triazines.

2. Experimental. ESI LC–MS work was done with an Ultracarb 5 ODS 30, 5 μm, 150 × 3.2 mm column at a flow of 0.6 ml/min. The mobile phase consisted of a methanol-water gradient (initial 20% methanol; in 45 min to 95% methanol). An additional postcolumn flow (0.4 % formic acid in methanol) of 0.2 ml/min was applied. The mass spectrometer, a Finnigan TSQ 7000 equipped with an ESI source, was operated in the positive ion mode. Collision-induced dissociation (CID) was accomplished with argon at a collision-offset voltage of 20V and an argon pressure of 1.3 mTorr. The photolysis experiments were carried out in 5, 10 and 15 m × 0 25 mm knitted-reactor coils at irradiation wavelengths of $\lambda = 254$ nm and 366 nm. A mobile phase consisting of methanol/water = 50:50 (v/v) was used. Acetone and benzophenone were added postcolumn as photosensitizers at a concentration level of 1 % and 1 mM, respectively.

3. Results. An on-line photolysis electrospray LC–MS system has been used for the analysis of several pesticides with respect to the sensitivity and specificity of their ESI–MS detection. Experimental parameters such as irradiation time, irradiation wavelength and solvent composition have been investigated. Furthermore, the effect of postcolumn addition of photosensitizers on the degree and mechanism of photochemical degradation of the analytes and on the sensitivity of their detection has been investigated.

Carbamates: All investigated N-methylcarbamates produced significant amounts of methylamine after photolysis. Addition of acetone and benzophenone as photosensitizers significantly enhanced photolysis; i.e. the isocyanate and methylamine formation was greatly enhanced. Photosensitized UV degradation led to a > 90 % transformation in these experiments.

Phenylureas: LC-MS Analysis of photolysis products of phenylureas indicated a large number of degradation products with an unsatisfactory high noise level in the mass spectra. The major degradation pathway was loss of halogen and subsequent replacement by a hydroxyl group or hydrogen. Furthermore, loss of amines and formation of isocyanates was observed. By using photosensitizers, the noise level was substantially reduced. In general, photosensitized photolysis led to significantly reduced noise levels in all experiments conducted.

s-Triazines: Photolysis of *s*-triazines in the presence of solvent led to a number of photodegradation products. The chlorinated *s*-triazines readily underwent replacement of the chloro group by a methoxy or hydroxyl group, while in alkylthiotriazines the alkylthio group is replaced by hydrogen. Moreover, reactions in the alkylamine sidechain enabled characterization of isomers, *e.g.*, the isomeric triazines propazine/terbutylazine and prometryn/terbutryn could be distinguished by their photolysis LC–MS spectra. Photosensitizers can enhance the yield of these reactions (Figure 1a). Since the ESI sensitivity was not reduced in the photolysis mode, the system could readily be used for a very sensitive confirmatory analysis of triazines in sample extracts (Figure 1b).

4. Conclusions. It is demonstrated in this study, that the on-line combination of photolysis and LC–MS can increase spectral information for most pesticides and thus the specificity of their LC–MS analysis without loosing sensitivity, as is often observed in CID experiments. This is important for an unambiguous identification of pesticides in environmental or food samples, since several additional fragment ions are required for proof of presence. Most LC–MS ionization techniques, however, provide only mass spectra with little structural information, *i.e.* only $[M+H]^+$ ions or simple adducts are formed. Moreover, the utilization of on-line photolysis and LC–MS, especially in combination with tandem mass spectrometry, offers distinct possibilities for structure elucidation of transformation products formed by photochemical reactions, as is demonstrated in this paper.

Multiresidue Analysis of Pesticides by Electrospray LC–MS and LC–MS/MS

Dietrich A. Volmer* and Jon G. Wilkes

Food and Drug Administration, National Center for Toxicological Research, 3900 NCTR Drive, Jefferson, AR 72079

1. Introduction. The very low concentration limits set for pesticides in food and water has prompted the development of analytical techniques to determine these compounds at trace levels. Analysis of pesticides is not only complicated by the low detection limits required, but also by the fact that the regulated pesticides belong to very different compound classes which vary widely in their polarity. More important standard methods are an HPLC method with UV detection and a GC method with confirmation by GC–MS. Confirmatory analyses, however, are even more important for HPLC methods since the selectivity of these methods is lower compared to GC. Confirmation by UV is difficult because the UV spectra are often very similar and many thermally labile pesticides lack a strong UV chromophore for UV detection. Furthermore, co-eluting compounds cannot be distinguished by means of conventional UV or diode-array detection. When two compounds co-elute, LC–MS allows the identification and quantification of both, provided each has different characteristic ions. LC–MS has demonstrated its potential for analyzing a broad spectrum of pesticides [1-4]. At present, thermospray is most widely used because of its compatibility with conventional HPLC systems. In this study electrospray ionization (ESI) and tandem mass spectrometry (MS/MS) were evaluated with respect to their suitability for the LC–MS determination of a broad range of pesticides.

2. Experimental. ESI LC–MS work was done with an Ultracarb 5 ODS 30, 5 μm, 150 × 3.2 mm column at a flow of 0.6 ml/min. The mobile phase consisted of a methanol-water gradient (initial 20% methanol; in 45 min to 95% methanol). An additional postcolumn flow (0.4 % formic acid in methanol) of 0.2 ml/min was applied. The mass spectrometer, a Finnigan TSQ 7000 equipped with an ESI source, was operated in the positive ion mode. Collision-induced dissociation (CID) was accomplished with argon at a collision-offset voltage of 20V and an argon pressure of 1.3 mTorr. Liquid/liquid extraction was used for the preparation of food sample extracts.

3. Results. Electrospray ionization was evaluated in the LC–MS determination of a large number of pesticides having a wide range of chemical structures and polarities. The multiresidue method employs HPLC separation on a narrow-bore reversed-phase column with postcolumn addition of a reagent solution. An examples of an LC–MS separation of several triazines in the time-scheduled selected-ion monitoring (SIM) mode is shown in Figure 1a.

The multiresidue method is linear over at least 3 orders of magnitude with correlation coefficients $r > 0.998$. That is, quantitation is readily possible by using external standards. The precision is excellent, usually $< 5\%$ RSD, and the detection limits (LOD) are in the lower pg-range, typically 1–10 pg (time-scheduled SIM) thus enabling ultratrace analysis in environmental or food samples. Figure 1b shows the analysis of a lettuce extract.

Tandem mass spectrometry techniques such as constant-neutral-loss (CNL) scan and time-scheduled reaction monitoring (SRM) were applied to certain pesticide compound classes. The SRM detection limits obtained are in the range of 50–1000 pg.

4. Conclusions. The purpose of the present work was to evaluate a multiresidue electrospray LC–MS method used for determination and confirmation of a large number of pesticides with widely different chemical structures and polarities. The precision, linearities and detection limits obtained are adequate for monitoring a broad spectrum of pesticides by using reversed-phase gradient LC in combination with time-scheduled selected-ion-monitoring (SIM) or selected-reaction monitoring (SRM). For an unambiguous identification of pesticides in environmental or food samples, several additional fragment ions are needed, required for proof of presence. Because ESI is a soft ionization technique, mass spectra of almost all investigated pesticides usually consist of only $[M+H]^+$ and $[M+Na]^+$ ions. The selectivity of the method can, however, readily be enhanced by inducing fragmentation *via* the application of a collision-offset voltage to the built-in octopole rods of the source or by using MS/MS as demonstrated in this paper.

DETERMINATION OF CARBENDAZIM BY IMMUNOAFFINITY EXTRACTION AND LC/LC/MS/MS

Karen Bean and Jack Henion, Analytical Toxicology,
Diagnostic Laboratory, Cornell University, 927 Warren Drive,
Ithaca, NY 14850

Benomyl has been widely used as a systemic fungicide for disease control in crops for many years. Its mode of action and movement in the environment, however, are not clearly understood[1]. The primary reason for this is because benomyl readily decomposes in many common organic solvents[2] and also in water[3]. For this reason, benomyl is commonly determined as its primary degradation product, carbendazim The title method employs a high performance protein G immunoaffinity column coupled to a reversed-phase analytical column through the use of a trapping column and INTEGRAL™ Micro-Analytical Workstation. Carbendazim is enriched from soil extracts at the 100 ppb level and from lake water at the 25 pptr level and characterized by on-line mass spectrometric analysis

EXPERIMENTAL

Immunoaffinity extraction and coupled column chromatography were achieved using a PerSeptive Biosystems INTEGRAL™ Micro-Analytical Workstation equipped with an autosampler, two reciprocating HPLC pumps, and two automated switching valves The extraction itself was accomplished on a 2 1 mm i d. x 33 mm ChromatoChem Hi Pac Protein G column through which phosphate buffered saline (0 15 M NaCl, 0.01 M NaH_2PO_4) was pumped at 2.0 mL/min by pump 1 A 3 mm i d x 10 mm Regis Technologies SPS C_{18} guard column was used as the analyte trapping column when the 2% (v/v) acetic acid stripping buffer was pumped through the protein G column. Pump 2 delivered 40/60 MeCN/H_2O, 10 mM NH_4OAc at a flow rate of 200 µL/min through a Keystone Scientific Betasil C_{18} 2 mm i d x 150 mm column The effluent from the column was directly transferred to the ion spray interface which was maintained at 3 95 kV without post-column split The mass spectrometer, a PE-Sciex API-300, was operated in the positive ion detection mode Collision-induced dissociation (CID) reactions were accomplished with nitrogen and the collision energy was 23 eV in the laboratory frame Soil samples were extracted according to the procedure of Itak et al.[4] and 100 mL of the extract were pumped through the protein G column at 10 mL/min. Lake water samples were filtered prior to extraction.

RESULTS AND DISCUSSION

The specificity of immunoaffinity extraction makes it possible to detect low levels of carbendazim in soil samples without interference from matrix components The extracted ion current profile resulting from the SRM IAE/LC/LC/MS/MS analysis of soil fortified at 100 ppb with carbendazim is found in Figure 1 At sub-ppb levels, however, it is found that recovery of carbendazim from soil becomes more difficult This is most likely due to adsorptive losses of analyte on the soil The use of selected reaction monitoring allows for the achievement of the highest possible sensitivity with a minimum of chemical interference.

Figure 2 demonstrates that it is possible to detect trace levels of carbendazim in lake water samples This is probably due to fewer matrix interferences in water than in soil Very little sample preparation is required for environmental water samples The lake water samples analyzed for this work required only filtration prior to analysis to

remove particulate matter which could cause damage to the HPLC pumps and to the columns used for extraction and chromatography. The ability to pump sample through the protein G column at high flow rates (10 mL/min) and to automate the column-switching procedure makes the method rapid and efficient. Many samples can be analyzed in a relatively short period of time with minimum sample preparation Three samples can be analyzed per hour without operator intervention

ACKNOWLEDGEMENTS

We wish to thank PerSeptive Biosystems for the generous loan of the INTEGRAL™ Micro-Analytical workstation. Our gratitude also extends to PE-Sciex for the loan of the API-300 mass spectrometer We also thank Dr Richard Hammond of Chromatochem for providing the Protein G immunoaffinity column and Dr Robin Charlton of E I DuPont de Nemours for the use of the anti-carbendazim IgG Funding for this work is made possible by E I DuPont de Nemours.

Limitations and Challenges in the Determination of Carbofuran with Various LC/MS Interfacing Systems

Maarten Honing* and Damià Barceló, Ben L.M. van Baar[1], and Udo A.Th. Brinkman[2], Department of Environmental Chemistry, CID CSIC, Jordi Girona 18-26, 08034 Barcelona, Spain and Departments of Organic[1] and Analytical[2] Chemistry, Free University, De Boelelaan 1083, 1081 HV Amsterdam, The Netherlands

Most reports on LC-MS of carbamates deal with the use of thermospray (TSP) as the interfacing system. Problems with this type of interface may arise from the gas phase ion-molecule reactions between analyte molecules and ammonium ions. The abundances of the ions formed from these reactions appear to be dependent upon the ion source geometry in TSP-MS [1]. This especially holds true for the carbamate carbofuran. LC-TSP mass spectra of carbofuran reported in the literature, show large differences in the relatives intensities of the $[M+H]^+$ and $[M+NH_4]^+$ ions. It has earlier been proposed that the adduct ion formation observed is due to pH differences of the solvent stream [2]. For verification we analyzed 30 carbamates at pH values from 7 to 3 of the methanol-water (50:50) with 100 mM ammonium acetate as solvent stream. Table 1 shows the summarized results for carbofuran and dioxacarb and represents the our findings for carbamates in general: pH variation does not result in significant differences in relative abundances of protonated and ammoniated molecules.

Table 1 Relative abundances of $[M+H]^+$ and $[M+NH_4]^+$ ions of two carbamates at pH 3 and 7.

Compound	m/z	pH 3	pH 7
Carbofuran			
$[M+H]^+$	222	79	69
$[M+NH_4]^+$	239	100	100
Dioxacarb			
$[M+H]^+$	224	21	16
$[M+NH_4]^+$	241	100	100

An alternative explanation for the variance among literature reports lies in the variable effectiveness of the protonation or adduct ion formation in TSP-MS, which depends on the partial pressure of ammonia in the ion source and, therefore, on the ammonium salt concentration in the eluent. This was demonstrated by varying the eluent ammonium acetate concentration in the methanol-water (50:50) LC eluent(figure 1). Varying the concentration between 100 (A), 25 (B) and 1(C) mM results in a strong change of the $[M+H]^+$ ion (m/z 222) to $[M+NH_4]^+$ (m/z 239) abundance ratio. These results are in agreement with literature reports, where the $[M+NH_4]^+$ ion intensity was much lower at 8 mM than at 50 or 80 mM. A pressure dependence of the relative intensities of the $[M+H]^+$, and the, $[M+NH_4]^+$, ions of carbofuran was also observed in ammonia CI experiments (with a PB-MS system or desorption CI)[3]. An increase of the ion

source pressure resulted in a decrease of the total ion current and a strong increase of the relative abundance of the ammonium adduct ion. Ionisation in the API techniques takes place at atmospheric pressure. Thus no pressure dependence of the ion formation of carbofuran is expected. With regard to precision of the data, identification capability and sensitivity, the API techniques (APCI and ISP) have shown promising results [4, 5]. For some selected carbamates, and organophosphorus pesticides, combination of the LC/ISP-MS with novel preconcentration techniques results in detection limits between 10 and 50 pg [6, 7].

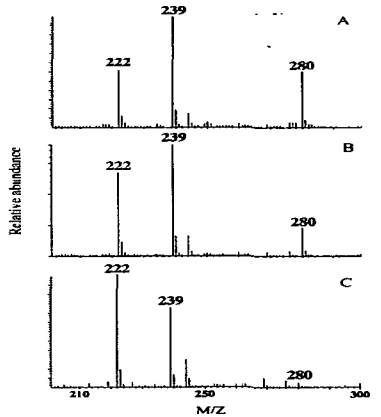

Figure 1 The full-scan (m/z 200-350) thermospray mass spectra (filament-assisted buffer ionization) of carbofuran, using a methanol-water (50:50) effluent with (A) 100, 2(B) 5 and (C) 1 mM ammonium acetate, 10 µl of a 50 mg/l standard solution in methanol-water (50:50) were injected.

The Analysis of Organophosphate Pesticides by a Trochoidal Electron Monochromator/Mass Spectrometer System

Paul H. Mazurkiewicz, James A. Laramee and Max L. Deinzer
Department of Agricultural Chemistry
and Environmental Health Sciences
Oregon State University
Corvallis Oregon

Organophosphate pesticides are in widespread use throughout the world making their low-level determination in environmental matrices and degradation mechanisms of utmost importance. Standard Electron Capture Negative Ion Mass Spectrometry (ECNIMS) is well suited for this task, but understanding of the electron capture processes is difficult because a buffer gas is present. The Electron Monochromator/Mass Spectrometer system (EM/MS) eliminates the need for a buffer gas, simplifies the number of electron-molecule and ion-molecule reactions present within the ion source and allows the experimentalist to tune to a specific electron energy allowing a more quantitative analysis than is possible with traditional ECNIMS[1]. EM/MS measurements of Negative Ion Resonances (NIRs) provide a new understanding of negative ion formation and have applications in biological, environmental and theoretical sciences.

Mechanisms of electron capture were probed by examining a series of novel parathion derivatives which possessed different electrophilicities. Pesticide samples were acquired from AccuStandard, tested for purity, and were found to be >99% pure. Derivatives of parathion were prepared using a classical coupling procedure[2].

Since parathion derivatives only differ in their *para* substitution, therefore they lend themselves to analysis using the Hammett equation which relates *para* substituents of aromatic compounds with the empirical Hammett substituent constant[3]. The constant represents all substituent electronic effects including resonance, through-space and inductive effects.

A linear correlation between electron energy and the Hammett constant implies a similar mechanism in the process under consideration. In the case of the parathion derivatives, all but one substitution correlates (Figure 1). A Hammett correlation was also discovered for the formation of fragment ion m/z 169. The di-ethoxythiophosphate anion is formed by cleavage of the phenolic oxygen carbon bond (Figure 2). Several of the derivatives correlate showing that the di-ethoxythiophosphate anion is formed in a similar mechanism for compounds that contain halogens and the unsubstituted derivative. Derivatives containing highly electron withdrawing or electron releasing substituents do not correlate. This fragment is important as it is the most intense spectral feature in most of the ion yield curves and appears in every derivative and compound similar to parathion. This fragment is not very intense in gas-mediated ECNIMS suggesting that the buffer gas interferes with its formation and lifetime.

Phosphothioate pesticides can capture a low-energy electron into a pi orbital to produce a radical anion which can rearrange to a spiro intermediate and can then fragment via pathway ***A*** to give the thiophenolate ion or pathway ***B*** to produce the phenolate ion (Figure 3). Since rearrangement mechanisms involve bond formation along with bond cleavage, the thiophenolate ion should have a lower activation energy than the phenolate ion. Indeed the NIRs for rearrangement ions occur at lower energies than for simple cleavage ions.

Analysis of Soil Metabolites Utilizing Narrow Bore LC/MS/MS Techniques

Steven R. McGown, Nelson Delgado
BASF Corporation
26 Davis Drive
Research Triangle Park, NC 27709

The trend for decreasing application rates of modern crop protection agents poses continuous new challenges for residue analysis. The agrochemical industry performs a wide variety of residue analyses, studies and tests so that the safety of agrochemicals to the consumer and the environment can be ensured. Metabolite analysis of crop protection agents in complex matrices, such as soil, poses difficulties for traditional analytical methods using HPLC/UV detection. The traditional methods can sometimes be long and tedious, requiring several days for sample preparation and analysis for more than one component. The use of API LC/MS/MS techniques on appropriate analytes can substantially reduce the analysis time per sample, increase LOD's, and raise confidence in data due to the added specificity of the mass spectrometer. The overall effect can also be a substantial cost savings for the analysis in terms of manpower and time. Here, we present an extraction and analysis scheme comparing two analytical approaches; the traditional HPLC/UV method and the API LC/MS/MS method.

The mass spectrometer used in these experiments was a PE/SCIEX API III Plus system manufactured in Thornhill, Canada. All HPLC analyses were performed using a Varian Star 9010 HPLC pump(Varian, Walnut Creek, CA), or a Thermoseparations P-4000 pump, and a Thermoseparations AS3000 autosampler, (Thermosepartions, Riviera, FL). Separations were performed on one of two types of narrow bore columns, either a 1 mm x 50 mm BDS-Hypersil C18, 5 µm or a 1 mm x 50 mm Prism, 3 µm, both supplied from Keystone Scientific, INC (Bellefonte, PA). The mobile phase was made using B & J HPLC grade methanol and water each containing 1% formic acid (Aldrich Chemical Co., INC), and 4 mM ammonium formate (Fluka Biochemika, Ronkonkoma, New York).

The mass spectrometer was operated in the MRM mode and was optimized by infusing a mixture of the 3 target molecules (Fig 1). Analytical standards were prepared in the mobile phase and extracts were prepared according to the extraction scheme shown. An isocratic system was used with a flow rate of 50 µl/min of the mobile phase. Injection volumes were normally 1µl.

Utilizing this type of approach to residue analysis has significant benefits when compared to traditional approaches. The LC/MS/MS method is capable of high through put (three analytes in under 5 minutes), has better limits of detection (LOD) than UV (<10 ppb vs 100ppb), and increased specificity. Normally an improvement in any one of these areas would be considered significant, but the combination makes this technique extremely powerful.

A traditional HPLC/UV method for each component was initially attempted since this type of equipment is generally more accessible to enforcement and contract laboratories. It should be noted that in the soil extract the 10 ppb fortification was totally masked by background interference. The extraction workup required about 16 man hours to complete and then each analyte had to be analyzed separately under two different chromatographic systems, approximately 20-30 min. each to satisfy federal regulations. The system worked well at the 100 ppb level but failed at the required 10 ppb lower limit.

Rather than spend additional effort on clean-up, a mass spectral solution was sought.Utilizing the power of MS/MS, appropriate parent/product ion transitions were chosen for each analyte. Analytical standards were prepared in the needed concentration range and analyzed. The three analytes are clearly separated in under 5 minutes with signal to noise ratios>25 :1 (Fig 2).Then control soils were extracted and analyzed to verify that there were no co-eluting components with similar transitions. These control soils were then spiked with known amounts of the analytes, extracted, and then analyzed (Fig 3). The end result was a short extraction/workup, about 4 manhours and a short HPLC run on a C18 BDS Hypersil narrow bore column, 1 mm x 50 mm, utilizing an isocratic mobile phase (80:20 MeOH/water, 4mM NH4CO2H, 1% Formic Acid). The recoveries were lower than expected for P-14 and this was probably due to suppression, since P-14 eluted in the void volume on the C 18 column After consulting with Keystone Scientific representatives, a 1 mm x 50 mm Prism RP column was tried and a more desirable separation was achieved (Fig 4). The mobile phase was altered to 90:10 (v/v) MeOH/water, 4mM NH4CO2H, 1% Formic Acid. There was a notable improvement in signal to noise ratio for all components, the suppression problem alleviated, a change in elution order, and some band broadening of the last component, PB-14.

The performance of the HPLC MS/MS methodology is far superior to that of the more traditional HPLC/UV methodology. Recent regulations require mass spectral confirmation of UV data making the analysis using traditional methods impractical. This method of analysis is more than fifty times faster than the traditional approach resulting in considerable savings in time and manpower. Data generated from the MS/MS approach has a higher confidence level due to the nature of the data. In addition to the retention times, there is the specificity of an MS/MS transition which gives the data an orthogonal dimension. In conclusion, the MS/MS approach has demonstrated its value in residue analysis.

LC/MS of Atrazine and its Hydroxylated Metaboilite by Using Electrospray

*Zongwei Cai[1], Ronald L. Cerny[1], and Roy F. Spalding[2], (1) Nebraska Center for Mass Spectrometry, (2) Water Center, University of Nebraska-Lincoln, Lincoln, NE 68588.

Atrazine (ATR) is one of the most widely used agricultural herbicides in the United States and has been identified along with its metabolites as contaminants in surface and ground water. Field-applied atrazine is known to undergo abiotic hydrolysis reactions leading to dechlorination and formation of hydroxyatrazine (HA). Methods currently used for the analysis of ATR and HA in water include HPLC (*1*) and fast atom bombardment mass spectrometry (*2*).

Liquid chromatography/mass spectrometry with electrospray ionization (LC/ESI-MS) has been employed for the quantification of small molecular species (*3*). However, LC/MS capability for atrazine and its metabolites as well as the quantitative aspects of the technique have not been investigated. The goal of this study is to develop a method using ESI-MS coupled with HPLC for the quantitative analysis of atrazine and its metabolites.

The electrospray mass spectra of ATR and HA are shown in Figures 1-2. In addition to the protonated molecular ions sodiated molecular and dimer ions were also observed at the mass spectrometric condition. Selected ion recording chromatograms for ATR and HA and their ^{13}C-labeled internal standards are demonstrated in Figure 3. The analytical method provides for a high throughput of samples as less than 6 min is needed per sample analysis.

A linear dynamic range over two orders of magnitude was obtained. The concentration of the calibration standards used ranged from 5 to 500 pg/uL and 25 to 1000 pg/uL for ATR and HA, respectively. The detection limits (S/N = 3) are 10 pg and 50 pg for ATR and HA, respectively, with the sample injection volume of 5 uL. Lower detection limits may be achieved if a larger volumes is injected. Injections of more than 30 uL, however, resulted in tailing of the HPLC peaks.

The quantification is based on the use of isotopically labeled internal standards, which increases accuracy and reliability of the analysis. Relative response factor for each of the native compounds relative to its corresponding internal standard was used to minimize the analytical error. Table 1 shows the analytical results for the surface water samples collected from York River, Nebraska after runoff events by using both electrospray LC/MS and FAB/MS methods. The results from both methods agree with less than 15% variation. The data profile shows that the levels of HA are approximately 5 times lower than those of ATR.

The method using solid-phase extraction with the carbon black cartridge and LC/ESI-MS is satisfactory for the trace analysis of atrazine and hydroxyatrazine in water. Quantification by using corresponding $^{13}C_3$-labeled compounds as internal standards was accurate and precise at ppt to ppb level. The method was successfully used to analyze ground and surface water samples for atrazine and its hydroxylated metabolite. The procedure can be expanded to other metabolites as well as to other related herbicides present in the environment.

DETERMINATION OF TRIAZINE HERBICIDES AND THEIR METABOLITES USING GC/MS/MS

DAVID L. HEIKES, Total Diet Research Center, Food and Drug Administration, P.O. Box 15905, Shawnee Mission, KS, 66285-5905

Triazine herbicides are some of the most widely applied pesticides in the U.S. The most common member of this class, atrazine, was the most heavily used pesticide in recent years. Many cleanup procedures with GC detection have been developed for the determination of these compounds in agricultural products. Several nitrogen-specific detectors have been utilized. However, a stringent cleanup procedure is required since nitrogen-containing compounds are ubiquitous in plant material.

The important practical benefits of ion trap MS/MS are it's inherent selectivity, sensitivity, and ease of routine operation. This unique and sensitive technique provides an approach to residue analysis which holds the very real potential to dramatically reduce labor-intensive cleanup and isolation steps while enhancing specificity.

Supercritical fluid extraction techniques have been employed to rapidly obtain an extract suitable for GC/MS/MS analyses. Although the parent triazine herbicides are relatively easily extracted using SFE, the more polar metabolites require more stringent conditions. Figure 1 depicts the extraction profiles of atrazine, desethylatrazine, desisopropylatrazine, and desethyl-desisopropylatrazine SFE-CO_2 at various pressures, 80° C, and a static-dynamic approach.

A Varian Saturn III has been upgraded to MS/MS capabilities. Unit mass isolation coupled with collision induced dissociation produced unique daughter ion spectra for each of eight triazine herbicides and three metabolites. After development of GC and MS/MS parameters (Figure 2) on a standard mixture, fortified samples were examined. Recoveries ranged from 89 to 103% at levels as low as 20 ppb on extracts of celery, pineapple, and wheat.

IDENTIFICATION OF BIODEGRADATION PRODUCTS OF CARBAZOLE BY MASS SPECTROMETRY

Jayasimhulu, K., Schneider, J., Xue, W., Grosser, R. and Warshawsky, D.
University of Cincinnati, Department of Environmental Health, Cincinnati, OH

ABSTRACT

Microbial degradation of harmful compounds opens the way for biodegradation of contaminated soils. A *Xanthomonas* sp. from former coal gasification site was isolated and its ability to mineralize carbazole was studied. The microorganism was incubated with carbazole for approximately two weeks. The resulting metabolites of carbazole were extracted from the media with ethyl acetate under acidic conditions. The pooled extract was concentrated and aliquots were injected on to a HPLC column for separation and collection of the fractions containing UV absorbing metabolites. The fractions were evaporated to dryness, methylated with diazomethane and analyzed by gas chromatography and mass spectrometry (GC/MS). The pooled total extract, after dryness, was also methylated and analyzed by GC/MS without prior separation by HPLC. A portion of the metabolite extract was also acetylated and methylated and analyzed by GC/MS. Elemental compositions obtained by high resolution mass spectral analysis and mass spectral fragmentation patterns made it possible for the identification of major metabolites detected in this study.

INTRODUCTION

Sites of former coal gasification plants constitute major health and environmental concerns in the U.S. These areas contain high levels of polycyclic aromatic hydrocarbons (PAH) and N-heterocyclic aromatic compounds (NHA) many of which are carcinogenic and/or mutagenic. Our overall aim is to isolate organisms which are capable of degrading these compounds, to elucidate degradative pathways and enhance the biodegradation rates. Towards that objective, we have isolated an organism, *Xanthomonas* sp. from a former coal gasification site which is capable of mineralizing ^{14}C-carbazole to $^{14}CO_2$. In this study we present data showing the metabolites of carbazole formed by this *Xanthomonas* sp.

MATERIALS AND METHODS

The bacterium was isolated from soil and growth and maintenance procedures have been published previously. Bacterial cells were maintained in minimal basal salts medium (MBS) with 37.5 $\mu g\ ml^{-1}$ of carbazole as the sole source of carbon. In order to obtain sufficient quantities of metabolites for mass spectral analyses, the bacterium *Xanthomonas* sp. was incubated in 1 liter of MBS with 900-1000 μg of carbazole. After two weeks of growth, the cultures were centrifuged to remove bacterial cells and the media was extracted twice with ethyl acetate (1:0.5, vol/vol) under acidic conditions. The ethyl acetate layers were pooled and evaporated to dryness. A portion of the isolated metabolites were derivatized with gaseous diazomethane to convert the carboxyl groups present to methylesters. Another portion was methylated and acetylated to methylate the carboxyl groups and acetylate the hydroxyl groups and amino groups. These derivatives were analyzed by gas chromatography and high resolution mass spectrometry. The samples were introduced onto a DB-5, 0.53 i.d., 30 m, 1 μm film thickness, capillary column of a Carbo Erba gas chromatograph interfaced with a Kratos MS-80 high performance mass spectrometer. The initial temperature of the oven is kept at 40°C and then is raised to 160°C after the introduction of the sample and is kept at that temperature for 3 minutes. The temperature was then raised to 280°C at a rate of 4°/min and kept at that final temperature for 20 min. The mass spectrometer was operated in the high resolution mode and the electron voltage, beam

current and the source temperature were maintained at 70 eV, 100 μA and 200°C respectively. The scan rate was 3 sec/decade and the data acquisition and processing was accomplished by DS-55 data system based on a Data General NOVA-4X computer.

RESULTS

The GC chromatograph indicates the presence of at least 16 peaks. GC-MS identified and confirmed 11 of these as metabolites of carbazole formed by *Xanthomonas* sp. The elemental compositions of the molecular ion ($M^{+\cdot}$) and fragment ions for these metabolites are consistent with the metabolites identified. Three of the peaks on GC (peaks 1,3,6) remain unidentified and are not products of biodegradation of carbazole by the bacterium. The identified metabolites include anthranilic acid, 2-aminophenyl acetic acid, 3-(2-aminophenyl)propionic acid, 4-(2-aminophenyl)butanoic acid, (1H)-4-quinolinone, 3-methylene-2-indole-carboxylic acid, 5-oxo-5-(2-aminophenyl)pentanoic acid, 6-oxo-6-(2-aminophenyl)hexanoic acid, indole-2,3-dicarboxylic acid and indole-2-carboxylic-3-acetic acid. The metabolite identified as anthranilic acid has been identified as a biodegradation product of carbazole by another bacterium, *Pseudomonas* sp. High resolution MS data of this metabolite formed by *Xanthomonas* sp. matches that of the standard anthranilic acid after methylation. Similarly, the MS data of the *Xanthomonas* sp. metabolite identified as indole-2-carboxylic acid matches that of the authentic standard after methylation. The carbazole metabolites of *Xanthomonas* sp. were also acetylated and methylated and these derivatives were analyzed by GC/MS. The data (not shown) further corroborated the assignments made for the methylated metabolites formed by *Xanthomonas* sp.

SUMMARY

GC-MS analyses identified at least eleven metabolites of carbazole formed by *Xanthomonas* sp. The formation of these metabolites by the bacterium is similar to other reports for another closely related bacterium, *Pseudomonas* sp. In particular, the formation of anthranilic acid was reported for this other bacterium. The formation of these carbazole metabolites by *Xanthomonas* sp. indicates that this species biodegrades carbazole and may be capable of degrading larger ring compounds.

ANALYSIS OF CARBAMATE AND PHENYLUREA PESTICIDES BY PARTICLE BEAM LC/MS

Ramesh Rao, VG Organic, Crewe Road, Wythenshawe,
Manchester, M23 9BE

Introduction

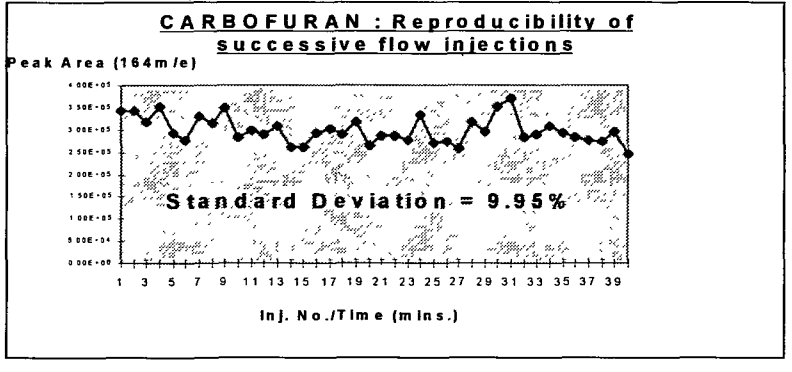
Carbamate and Phenylurea pesticides were introduced worldwide in the 1950's for use on a wide range of crops including potatoes, cotton and cereals.
In the following examples, HPLC is used combined with a dedicated benchtop Particle Beam Mass Spectrometer as the detector to obtain positive identification and structural information. The reproducibility and typical sensitivity is also shown along with an investigation of the linearity of response.

Methods

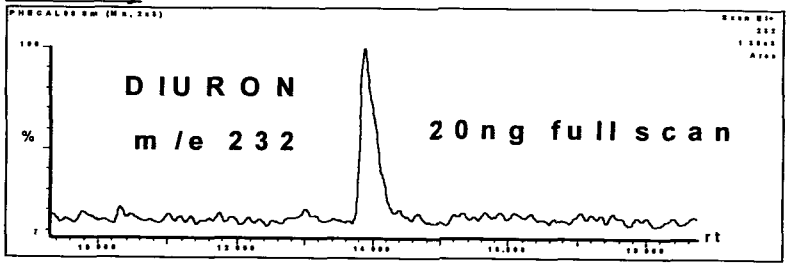
All analyses were carried out using the MD800 LCD (Liquid Chromatography Detector), a dedicated Particle Beam-LC-MS instrument. The MD800 LCD was operated in Electron Impact mode (EI+) scanning at 300amu/sec. The source temperature was set at 200°C and the desolvation temperature at 80°C.

Results

Reproducibility



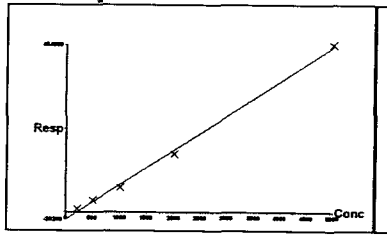
Sensitivity



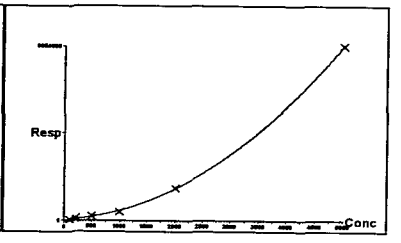
Linearity

The linearity of response can been shown to be compound dependent; for certain carbamates/phenylurea pesticides the response is linear, however, for others a non-linear response is seen.

Methomyl : linear



Linuron : non-linear



Conclusions

The combination of EI+ mass spectra and isotope distribution patterns from compounds containing naturally occurring isotopes gives excellent information for the identification of target analytes and other unexpected analytes in environmental analyses.
Typical detection limits are from about 5 to 50ng in full scan, equivalent to a 20µl injection of a 0.25-2µg/ml solution.
Particle Beam LC-MS using the MD800 LCD is a practical solution for the qualitative and quantitative analysis of carbamate and phenylurea pesticides as well as other common environmental contaminants.

Trace Determination of Sulfonyl Ureas in Soil

Lily Y.T. Li, Dale Campbell, Patrick Bennett, and Jack Henion
Advanced BioAnalytical Services, Inc., 15 Catherwood Rd., Ithaca, NY 14850

INTRODUCTION

The trace analytical determination of polar, involatile compounds in environmental samples remains a demanding analytical problem. The isolation, identification, and quantitation of labile analytes such as sulfonylureas (SU's) in soils is a representative challenge. Eight commonly used sulfonyl ureas (Accent, Harmony, Ally, Oust, Glean, Londax, Express, and Classic) and deuterium-labeled Accent (D6-Accent), used as an internal standard, were isolated from soils, and identified by ion spray LC/MS/MS under selected reaction monitoring (SRM) conditions. After several technical modifications (e.g., using a TurboIonSpray adapted LC/MS interface without a pre-column split and optimizing different MS/MS conditions for individual SU's), these eight SU's were qualitatively and quantitatively identified at the 0.05 ppb level in soil. This LC/MS/MS method demonstrates a twenty-fold increase in sensitivity from our earlier work and at least a four-hundred-fold improvement in sensitivity over other reports.[1]

EXPERIMENTAL

Soil samples were fortified with known levels of each of the eight SU's plus a fixed level of the internal standard. All analytes and the internal standard were then isolated from soils by a liquid/liquid extraction procedure. A gradient reversed-phase HPLC system using Keystone Betasil C_{18} columns (1 x 150 mm or 2 x 150 mm) provided separation of the eight SU's.

The LC/MS/MS analysis of the soil extracts was carried out using a PE Sciex API III ^{plus} tandem triple quadrupole mass spectrometer (MS) under SRM conditions in the positive ion mode. Data were acquired in four separate periods to optimize sensitivity for each analyte.

RESULTS AND DISCUSSION

The eight SU's were successfully isolated from soils by a liquid/liquid extraction procedure and were separated by an LC gradient program. Originally, a microbore Betasil C_{18} column (1 x 150 mm) was used to separate the SU's by running an eluent gradient with a pre-column split (~ 50 µL/min flow rate into column). The LC/MS/MS data were acquired using one period for the entire analysis to quantify and identify the eight SU's in soils at the 1 ppb level (Figure 1). Technical modifications, including the use of a TurboIonSpray adapted LC/MS interface, a 2 x 150 mm Betasil C18 column with an unsplit gradient and 200 µL/min flow rate directly to the mass spectrometer, and using four SRM periods to optimize the sensitivity for individual SU's, improved the method to allow the qualitative identification and quantitative measurement of the eight SU's at the 0.05 ppb level (Figure 2). This modified LC/MS/MS method demonstrates high selectivity, specificity, and sensitivity to unequivocally identify and quantify the eight SU's in soils.

Comparison of Electrospary and Thermospray for the Analysis of Herbicides

L. M. Shalaby, R. A. Croes, M. P. Wadsly and D. A. Armbrust, L. J. Mulderig and K. W.Ledeker
DuPont Agricultural Products, Wilmington, Delaware

The electrospary and thermospray LC/MS techniques have been evaluated for the study of the thermally labile sulfonylurea herbicides and metabolites. Both techniques were found to ionize those compounds and metabolites efficiently but the electrospary ionization enhances the protonated molecular ion and provides a complementary fragmentation pattern to thermospary. A typical thermospray mass spectrum of a sulfonylurea indicates a weak molecular ion and fragmentation ions characteristic of the sulfonamide and the heterocyclamine moieties. The sulfonamide moiety is detected in the protonated and ammonium adduct form. On the other hand the heterocyclamine and heterocyclurea are detected in the form of the protonated ion. A typical electrospray mass spectrum of sulfonylurea indicate the protonated molecular ion , the sodium and potassium adduct. Using the source collision induced dissociation produces mainly the protonated heterocycl isocyanate and heterocyclamine ion. The two ionization techniques were evaluated in the positive and negative ion mode. Results indicated that the negative ion electrospray ionization is more efficient than negative ion thermospray ionization for this class of compounds. Electrospray ionization was found to be more efficient in the ionization of metabolite conjugate as glucose, glucuronic acid, glutathione , amino acid and sulfate.

A typical spectrum for the sulfonylurea conjugate indicates the protonated molecular ion, the aglycone and few fragment ions. Preliminary evaluation of atmospheric pressure chemical ionization (APCI) has been carried out for sulfonylurea. Results indicated that both positive and negative ion APCI is applicable and spectral pattern indicated more intense fragmentation compared to electrospray ionization.

The electrospray ionization indicated an order of magnitude increase in sensitivity compared to themospray. The quantitative aspects of the two techniques were also evaluated for trace multi-residue analysis of several sulfonylurea and metabolites using conventional gradient LC and the selected ion mode for the mass detector. Eight sulfonylurea, rimsulfuron, bensulfuron, tribenuron, chlorimuron, nicosulfuron, thifensulfuron, metsulfuron methyl, and sulfmeturon methyl were separated and detected within 30 min in a single method(Figure 1). We used a

conventional 4.6mm o.d.x 250 mm Partisil 5 ODS column at a flow rate of 0.8 mL/min for the thermospray analysis and a 2.1 mm o.d.x 200 mm hypersil ODS at a flow rate of 0.3 mL/min and a 1:1 split with electrospray LC/MS. The selected conditions were found to give comparable separation while optimizing the sensitivity of each technique. While electrospray ionization is more sensitive and universal, thermospray was found to be more tolerant to matrices. Several instruments have been used to generate the electrospray LC/MS data, a Finnigan TSQ 700 , a Finnigan SSQ7000 and a Hewlett Packard Model 5989. For the thermospray LC/MS data we used a Finnigan SSQ700.

A study of the trace level thermospray and electrospray method precision indicated a relative standard deviation of 8-12% for thermospray and 4-8% for electrospray. The linear dynamic range for thermospray .and electrospray is in the 2-3 order of magnitude.

The method was evaluated for the analysis of those compounds in soil and wheat crop. The soil samples were extracted using 80% acetonitrile and the wheat grain samples was extracted using a C18 Empore disc. Using a simple sample preparation and eliminating the need for sample clean-up saved time and maximized the method efficiency The multiresidue method was applicable for all compounds down to 50 ppb. A method was developed to analyze for rimsulfuron, nicosulfuron and metabolites in Sassafras soil using electrospray LC/MS and simple extraction. The method was evaluated at fortification level of 0.02-0.2ppm and the average recovery was 94%. The mfThermospray LC/MS has been validated and used by several industrial and regulatory labs for multiresidue analysis the last few years. Multiresidue method validation using electrospray LC/MS is underway.

Colin Moore
Uniroyal Chemical Company
Benson Road
Middlebury, Connecticut 06749

The Analytical Chemistry Department at The Connecticut Agricultural Experiment Station analyzes large numbers of food samples annually for the presence of pesticide residues. The routine screening is conducted using conventional GC detectors such as electron capture (ECD), electrolytic conductivity (ELCD), and flame photometric (FPD) Recently we have been utilizing benchtop mass spectrometry to screen increasing numbers of samples

During a routine analysis, an unidentified peak was observed in the ECD and ELCD chromatograms of the extract from table grapes, suggesting the presence of a non-standard halogenated compound The extract was, therefore, analyzed using GC-MSD. The mass spectrum of the peak with the same RRT as the unknown peak from the ECD and ELCD analyses had a library match with a chlorinated triazole compound (see Figure 1) Discussions with colleagues at US FDA and California Department of Food and Agriculture indicated that the unknown compound might be Myclobutanil (Systane), a relatively new fungicide approved for use on grapes The RT and the mass spectrum of the unknown compound matched those of authentic Myclobutanil (see Figure 2)

There remained several unanswered questions from the low resolution mass spectrum which prompted us to investigate this fungicide in more detail. In particular (1) the library spectrum for the chlorinated triazole is missing the chlorine isotope pattern around m/e 179-181, (2) several alternate fragmentation schemes of Systane are possible to yield an m/e 179 ion, (3) several different structures for the m/e 179 fragment ion are possible

High resolution mass spectrometry of Systane provided data which showed that numerous m/e values observed as single ions in the low resolution mass spectrum are, in fact, resolved into two or more distinct fragment ions under high resolution. In particular the base peak is composed of two clearly resolved fragment ions at high resolution, each of which corresponds to a different fragmentation pathway (see Figure 3) In addition the cluster of ions at m/e 150-152 can be partially resolved into three different fragments (see Table 1)

In conclusion this study strongly suggests that fragmentation patterns deduced from low resolution mass spectra may be erroneous High resolution data are necessary to characterize fully compounds included in mass spectral libraries

NEGATIVE-ION UNIMOLECULAR DISSOCIATION OF ESTERS OF THE HERBICIDE DICLOFOP ACID IN A MASS SPECTROMETER SOURCE

J.V. Headley, and K. Peru. National Hydrology Research Institute,
11 Innovation Boulevard, Saskatoon, Saskatchewan, CANADA, S7N 3H5

INTRODUCTION

The transformation of some contaminants in the environment has been shown to correlate with unimolecular dissociations of gas-phase ions[1,2]. It is suspected that the internal energy (E) dependence of the transformation of chlorinated contaminants in the gas-phase may also correlate with the chemistry of neutral molecules in geological materials. To investigate the dependence of gas-phase transformations of a chlorinated herbicide relative to E, the unimolecular dissociations of three derivatives of diclofop acid (2-[4-(2,4-dichlorophenoxy)-phenoxy]propionate) were studied using electron capture negative-ion mass spectrometry (ECNIMS). Dissociation of the methyl, trimethylsilyl (TMS) and pentaflurobenzyl (PFB) esters in the ion-source was used to form a common precursor-ion, the carboxylate anion.

EXPERIMENTAL

Diclofop-methyl was purchased from Caledon Laboratories and the other two esters were prepared using derivatization procedures described in the literature[3,4].

The GC/MS experiments utilized a VG AUTOSPECQ mass spectrometer equipped with a 4000 VAX data system and OPUS 3.1X software. Identification of the derivatives for ECNIMS studies was based on retention time data, electron impact data and positive-ion chemical ionization data obtained for commercial and synthetic standards[2]. GC/MS experimental conditions were established as per Method 8270 guidelines : 30 m DB-5 column, internal diameter 0.33 mm, film thickness 0.25 μm, helium carrier gas 1 ml/min, injector 250°C, transfer line 300°C, temperature program 35°C/5 min at 10°C/ min - 280°C/7 min. For ECNIMS studies the ion-source was operated at 150°C, 35 eV and 0.3 μA emission current, using argon as the buffer gas at 2.0 - 2.5 x 10^{-5} torr.

RESULTS AND DISCUSSION

The carboxylate anion of the herbicide esters was observed to be stable to low energy collision induced dissociations (15-250 eV, laboratory frame of reference). However, the relative distribution of the E of the carboxylate ions formed in the ion-source was dependent on the chemical nature and size of the ester group. For the highest E (methyl ester) there was preferential formation of a chlorodibenzofuran oxide ion. In contrast, this dissociation was only a minor pathway for relatively low E (PFB ester) where loss of HCl only, was the preferred pathway. The distribution of E arising from dissociation of the TMS ester resulted in no preferred pathways. For this ester, the carboxylate ion was formed with E overlapping the range of E available for both the methyl and PFB esters. Dissociation of the carboxylate ion derived from the TMS ester was observed to be a mixture of the pathways for the methyl and PFB esters including a third pathway leading to full dechlorination.

The GC/ECNIMS data can be summarized by the mechanism given in Figure 1. This mechanism

highlights the importance of internal energy in switching on and off specific transformations. There was however, no evidence of chlorodibenzofuran as a metabolite in actual soil samples. Previous studies reported transformation of diclofop-methyl to chlorinated metabolites of benzoic acid, involving complex rearrangements and /or reactions with other contaminants present in the soil[5].

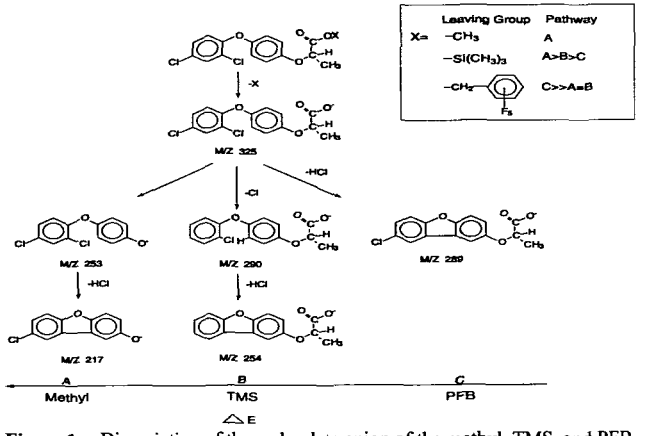

Figure 1 Dissociation of the carboxlate anion of the methyl, TMS, and PFB esters

CONCLUSION

For relatively high internal energies (methyl ester) there was preferential formation of a chlorodibenzofuran oxide ion, however at relatively low internal energies (PFB ester), elimination of HCl was the preferred pathway. In the case of the TMS ester there were no preferred pathways. Further work is warranted to develop models to predict the conditions under which the internal energy of contaminants can be manipulated to enhance remediation of contaminated sites.

Determination of Hydrolysis Degradates of Cloransulam-Methyl by Electrospray Liquid Chromatography Mass Spectrometry

Jesse L. Balcer, Stephen M. Brown, Paul Lewer
DowElanco, Indianapolis, IN 46268

During the course of plant metabolism studies, it is frequently necessary to extract the tissues under acidic and/or basic conditions. A necessary assumption of this approach is that the analytes of interest are not degraded by the extraction procedure. Cloransulam-methyl (CM), a new triazolo-pyrimidine sulfonanilide herbicide targeted for the control of broadleaf weeds in soybeans, and several of its known metabolites, were subjected to relatively severe acidic and basic hydrolysis conditions to validate this assumption in support of a nature of the residue study of CM in soybeans.

When extracting under severe conditions, compounds of interest may be converted to a single component or mixture of components. Since cloransulam-methyl was known to be both acid and base labile, standards of parent and several related compounds were treated separately with both acid (0.5M-hydrochloric acid) and base (0.5M-sodium hydroxide), reacted for two hours at 100°C, and the resulting products identified.

Cloransulam-methyl (CM), cloransulam-methyl-cysteine (CM-CYS), triazolopyrimidine sulfonic acid (TPSA), and methyl 3-chloroanthranilate (MCA) standards were chosen for testing. CM-CYS and TPSA had been identified as degradates of CM in soybeans. MCA was a hypothetical product from the bridge cleavage of CM.

Electrospray-LC-MS coupled with UV detection was performed on the reaction mixtures. Electrospray conditions consisted of a spray voltage at 4.5 kV, capillary temperature of 235°C, and nitrogen gas pressures of 70 psi and 20 mL/min for the sheath and auxiliary flows, respectively. A typical chromatogram showing products from the acid hydrolysis of CM is shown in figure 1. A typical spectrum derived from the chromatogram is shown in figure 2.

In all cases acid hydrolysis resulted in a mixture of more polar products plus a variable amount of residual starting material. In contrast, base hydrolysis gave a single product in high yield (> 94%) from each starting material. Therefore, these reactions showed that each test material was converted in high yield to a single product under basic, but not under acidic, conditions, and that the basic reaction was, therefore, preferred for the extraction of compound-related residues due to the formation of the fewest side-products. Figure 3 summarizes the basic reaction products.

The use of electrospray LC/MS allowed for the identification of all the major acid and base hydrolysis products of cloransulam-methyl without the need to isolate each individual component. This rapid screening experiment insured that products resulting from acidic or basic extractions of treated tissues were correctly identified.

DETERMINATION OF CLORANSULAM-METHYL AND ITS METABOLITES IN SOIL BY ESI LC/MS/MS

Stephen M. Brown, Jesse L. Balcer, Dennis O. Duebelbeis, and Angelea Thomas
Environmental Chemistry Laboratory, DowElanco, Indianapolis, IN 46268

Cloransulam-methyl is a new triazolopyrimidine sulfonanilide herbicide for the control of broadleaf weeds in soybeans. In order to register this new agricultural product for sale in the United States, a large number of metabolism, environmental, toxicological, and residue studies must be conducted. One of the required environmental studies follows the dissipation of the active ingredient and any known soil metabolites under actual field conditions. Usually, only the parent molecule and one or two similar metabolites need to be monitored throughout the soil core. Because of the small number (and similarity) of analytes, a derivatization procedure can usually be developed and GC/MS is often feasible for the analysis. However, cloransulam-methyl which has a more complex chemistry, breaks down in the environment to 5 different degradates (see **Figure 1**). Therefore, the parent molecule and 5 different metabolites may need to be determined. Due to the extreme variations in the nature and polarity of these metabolites, a single cleanup and derivatization scheme could not be developed. Because of this, electrospray LC/MS/MS was investigated for its feasibility as a possible analytical technique for cloransulam-methyl and metabolites in soil.

The extraction that we were forced to use due to analyte adsorption to the soil matrix, while very efficient at solubilizing the analytes of interest, also removed a significant amount of the organic matter present in the soil, resulting in a very viscous, "dirty" extract. The high background contamination precluded the use of LC/MS and necessitated the use of LC/MS/MS.

In order for an analytical method to be used for a soil dissipation study, it must meet certain reproducibility, linearity and sensitivity criteria. For reproducibility, the relative standard deviations of the method throughout the entire range of expected concentrations must be less than 20%. **Figure 2** shows typical reproducibility with this method for the six analytes. These data were not corrected through the use of an internal standard, and, with the exception of one analyte, meet the reproducibility requirements. The use of an internal standard was shown to improve this reproducibility by an average of about 5%.

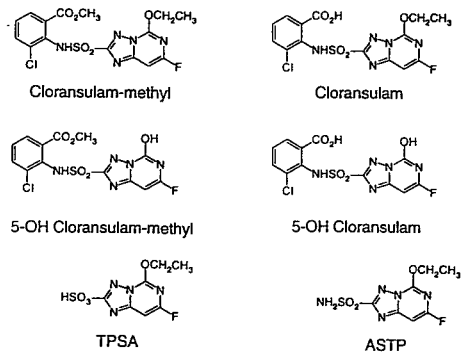
In terms of sensitivity, it is mandated that the method must be sensitive enough to quantify an analyte at 10% of application rate. For cloransulam-methyl, that means our method must have a limit of quantitation (LOQ) no greater than approximately 2 ppb. Therefore, a target LOQ was set at 1 ppb in soil. A chromatogram at the proposed LOQ of 1 ppb is given in **Figure 3**. The lowest signal to noise ratio seen in the chromatogram is about 20:1. The LC/MS/MS method, therefore, has more than adequate sensitivity for the analysis.

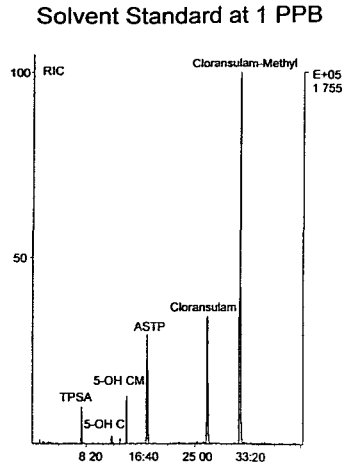
However, when control soil extracts that have been spiked with the six analytes are analyzed, the calculated LOQ suffers dramatically due to increased background from the soil matrix. **Figure 4** shows the chromatogram of an actual spiked sample at 1 ppb. It is quite obvious that there is a significant suppression of the signal by the soil matrix. In fact, the peak for 5-OH cloransulam cannot be detected. The calculated LOQ for this analyte has been determined to be about 5 ppb. However, the other analytes meet our target LOQ of 1 ppb.

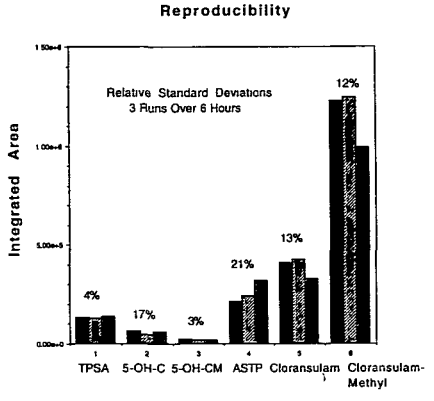
To conclude, the use of electrospray LC/MS/MS has allowed the determination of 6 analytes in a standard mixture in one run. The detection limit of the analysis is 1 ppb or better. The precision of the determination meets the mandated guideline of RSD<20%, with typical RSD's ranging from 3-20%. The use of isotopically labelled internal standards should lower this number.

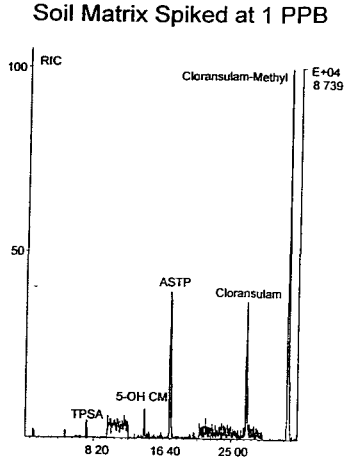
However, when soil extracts are analyzed by this method, the high background of the soil matrix (arising from our severe extraction procedure) causes significant signal suppression or enhancement. It should be noted that for other molecules where we used less severe extraction solvents (0.1N vs 1N HCl) the matrix effect was drastically reduced.

Although further clean-up will be necessary for this analytical method to be used in an actual study involving cloransulam-methyl and its metabolites, ESI LC/MS/MS has nonetheless proven itself to be a feasible alternative to the more traditional methods of residue analysis.









GC/MS ANALYSIS OF ALKYL METHYLPHOSPHONIC ACIDS

Dennis K. Rohrbaugh
U.S. Army Edgewood RD&E Center, APG, MD 21010-5423

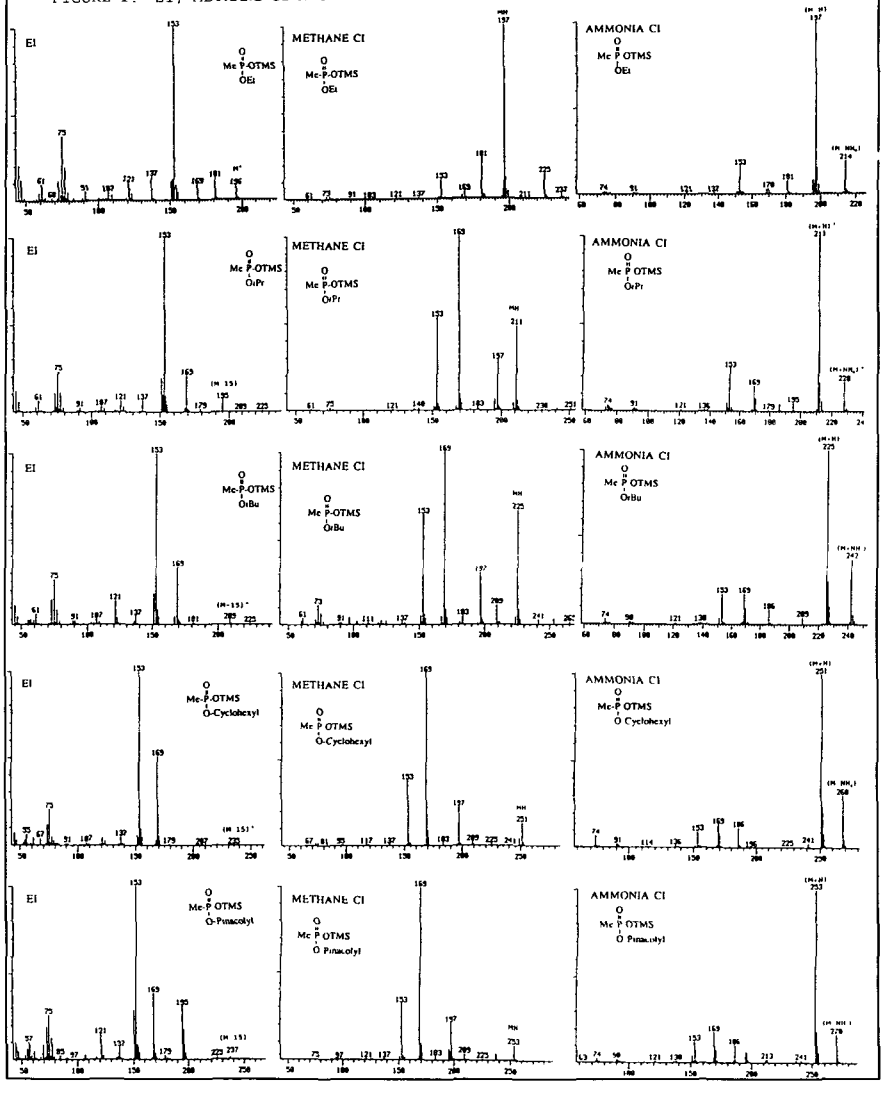
Detection of chemical warfare agent degradation products is important for assuring treaty verification compliance as part of the Chemical Weapons Convention and for monitoring chemical stockpile demilitarization efforts. Alkyl methylphosphonic acids [Me-P(O)(OR)OH], the primary environmental degradation products of organophosphorus agents, are not detected by direct GC/MS injection because of their acidity and low volatility and require derivatization prior to analysis. In this study, five acids resulting from the degradation of Schedule 1 compounds (R = Et, *i*Pr, *i*Bu, pinacolyl, and cyclohexyl) were converted to their trimethylsilyl (TMS) derivatives and analyzed using three methods of ionization (electron ionization, methane chemical ionization, and ammonia chemical ionization).

Each acid was derivatized by addition of 1 mg to 0.1 mL pyridine and 0.1 mL bis(trimethylsilyl)trifluoroacetamide (BSTFA) containing 1% trimethylchlorosilane (TMCS) and heating for 20 minutes at 60°C.

Derivatized samples were analyzed on a Finnigan 5100 GC/MS equipped with a 15m x 0.25mm DB-1701 or Rtx-5 capillary column. The oven was ramped from 60°C to 270°C at 10°C per minute. The injection port temperature was 200°C and the interface temperature was 230°C. Both methane and ammonia were used as CI reagent gases with a source pressure of 0.5 Torr. The mass range was scanned at 1 scan/sec from 45-450 amu for EI and from 60-450 amu for CI. The electron energy was 70 eV and the emmision current was 750 μA for both EI and CI. Retention times obtained for the TMS derivatives where R = Et, *i*Pr, *i*Bu, pinacolyl, and cyclohexyl were 263, 279, 370, 433 and 572 seconds, respectively, with the DB-1701 column, and 171, 188, 269, 337 and 465 seconds, respectively, with the Rtx-5 column.

The EI, methane CI, and ammonia CI mass spectra of the TMS derivatives of the 5 alkyl methylphosphonic acids are shown in Figure 1. The EI spectra of this class of compounds are characterized by ions at m/z 153 (base peak) and m/z 169 (10-50% of base peak), resulting from loss of OR and R, respectively, with subsequent protonation. The molecular ion is observed only for the ethyl ester. The similarity in spectra can make identification based on EI spectra alone difficult, especially at low concentrations. CI is particularly useful for the detection of these compounds. A protonated molecular ion is observed for all five compounds using methane CI, but the intensity decreases with increasing size of the R group and is only about 10% of the base peak for the cyclohexyl and pinacolyl esters. Ammonia CI is a superior method of ionization for detection of this class of compounds and provides enhanced protonated molecular ion formation, with the protonated molecular ion being observed as the base peak for all five compounds. A strong adduct ion $[M+NH_4]^+$ is also observed in all cases (20-50% of base peak).

FIGURE 1. EI, METHANE CI AND AMMONIA CI MASS SPECTRA OF ALKYL METHYLPHOSPHONATES



DETERMINATION OF TRIADIMEFON AND IMIDACLOPRID IN WHITE PINE BY GC/MS

Linda M. MacDonald[1], Bobbi-Jo Rainbird[1], Timothy R. Meyer[2]

Canadian Forest Service, Natural Resources Canada, Sault Ste. Marie, Ontario, Canada[1]
Ontario Forest Research Institute, Ontario Ministry of Natural Resources, Sault Ste. Marie, Ontario, Canada[2]

INTRODUCTION:

The white pine blister rust fungus (Cronartium ribicola Fisch.) and the white pine weevil (Pissodes strobi Peck) are the two most serious pest management problems in the production and reforestation of eastern white pine (Pinus strobi L.) in Canada. White pine weevil is also an important pest on other pines and spruces. To date reliable, cost-effective and environmentally acceptable methods of prevention and/or control are not available

In 1993, a major field study was undertaken by the Ontario Ministry of Natural Resources to evaluate the potential of applying, at the time of planting, a pesticide-impregnated, timed-release tablet containing the systemics triadimefon (fungicide) and imidacloprid (insecticide). The pesticides were incorporated into the tablet, individually and in combination, at various concentrations. Some treatments also contained a specially formulated fertilizer.

The triazoles triadimefon and its' major metabolite, triadimenol, are sterol-biosynthesis inhibiting fungicides which also exhibit plant growth regulating properties. The reduction of triadimefon to triadimenol may be regarded as an activation since the alcohol possesses greater fungicidal activity. Both have been registered for some time under the trade names Bayleton and Baytan respectively.

Imidacloprid is a new "nitroguanidine" insecticide with properties that make it very attractive as a tool in integrated pest management in today's world that demands enhanced environmental safety. These properties include favourable environmental/toxicological characteristics, excellent systemic activity against a wide range of insects on a wide range of crops, and a novel mode of action necessary to address the problem of insect resistance-it is an agonist of the nicotinic acetylcholine receptor

The timed-release tablet provides a delivery mechanism within the root zone, maximizing uptake of the chemicals while minimizing contamination of the surrounding soil volume and exposure of non-target organisms.

Pesticide distribution and persistence, over a period of several years, will be correlated with disease and insect incidence as well as with growth response data.

An analytical method has been developed for extraction of these pesticides from white pine needles, subsequent separation and quantitation by GC/MS. Triadimefon and triadimenol, are determined directly while imidacloprid is converted to the heptafluorobutyryl derivative. Quantification of all the analytes is performed by external standard comparison, in matrix, in selected ion monitoring mode.

METHODS:
SAMPLE PREPARATION:

White pine needles (1-5g) are macerated in acidified 7:3 methanol:water, filtered and the filtrate concentrated to the aqueous remainder under vacumn. The aqueous remainder is diluted with water then loaded onto a preconditioned C18 Sep-Pak. Co-extractives are removed by washing with 0.05M potassium carbonate. Following thorough drying, all analytes are eluted from C18 with methylene chloride.

Separation of triadimefon and triadimenol from imidacloprid is accomplished on activated Florisil. The triazoles are eluted in 20mL 75.25 ethyl acetate:hexane No attempt was made to separate the two on Florisil since they are easily resolved by GC. Imidacloprid, if present, is then eluted with 5mL of acetonitrile.

The 75:25 fraction is evaporated to dryness with nitrogen and triadimefon and/or triadimenol recovered in ethyl acetate for direct analysis by GC/MS.

The acetonitrile fraction containing imidacloprid is concentrated to 1.0mL and reacted with HFBA and pyridine (100uL each) at 60°C for 2hr. After cooling to room temperature, excess reagent is removed by evaporation to dryness with nitrogen and the derivative recovered in ethyl acetate for GC/MS.

ANALYTICAL CONDITIONS:

Analyses were performed on a Hewlett-Packard 5989A GC/MS. Samples were injected onto a DB-5ms column (J&W Scientific, 30m x 0.25mm ID x 0 1um film) with a deactivated fused silica guard column (1.0m x 0.32mm ID) at an injection port temperature of 250 °C.

For triadimefon and triadimenol the column temperature was programmed from 60 °C to 235 °C at 25 °C/min, then to 250 °C at 5 °C/min, and finally to 300 °C at 30 °C/min where it was held for 10 minutes.

For the HFB derivative of imidacloprid the column temperature was programmed from 150 °C to 300 °C at 12 °C/min and held for 10 minutes.

The transfer line and source temperatures were 280 °C and 275 °C, respectively

Confirmation and quantification were performed by selected ion monitoring of structurally significant ions.

Ions selected in the determination of triadimefon and triadimenol are indicated in Fig 1(a) and (b) with m/z 208 and m/z 168, respectively, used for quantification. Ion m/z 112, the base peak of triadimenol, could not be used reliably at low residue levels (<50ppb) due to the presence of this fragment ion at the same retention time in some matrix extracts

The EI spectrum of imidacloprid-HFB is shown in Fig 2. The ion pairs m/z 126/128, 210/212 and 407/409 were selected for confirmation, with m/z 407 used for quantitation.

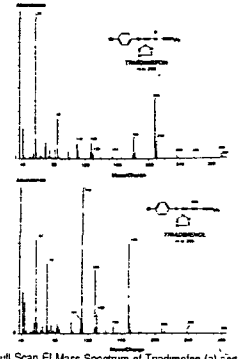


Figure 1 Full Scan EI Mass Spectrum of Triadimefon (a) and Triadimenol (b)

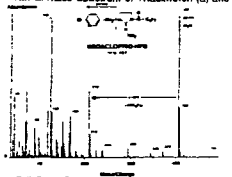

Figure 2 Full Scan EI Mass Spectrum of Imidacloprid - HFB

RESULTS and DISCUSSION:

This method has been validated for triadimefon and triadimenol in fortified white pine foliage at 10ppm, 1pmm and 100ppb. Limits of quantitation are 100pg on-column, with limits of detection conservatively set at 50pg.

Quantitation of imidacloprid was validated at the above levels as well as at 10ppb, equivalent to 10pg injected. LOD has been set at 5pg.

Overall mean recoveries were 84.14% + 6.22 (7.4%), n=50.

Figures 3 and 4 illustrate chromatograms obtained at 100ppb and 10ppb for triadimenol/triadimefon and imidacloprid-HFB, respectively.

During the course of our investigations, a variety of derivatization reactions were attempted with imidacloprid, including methylation, silyation and acylation. Acylation with HFBA provided the derivative most suitable for GC/MS, that is free from matrix interferences at environmentally significant concentrations.

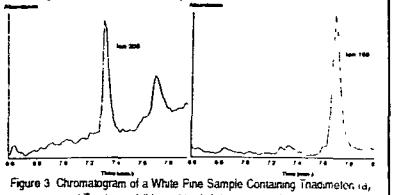

Figure 3 Chromatogram of a White Pine Sample Containing Triadimefon (a), and Triadimenol (b) at 100ppb (100pg injected)

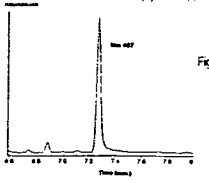

Figure 4 Chromatogram of a White Pine Sample Containing Imidacloprid at 10ppb (10pg injected as HFB derivative)

CONCLUSIONS:

Although this method was developed for a very specific application, we are confident it can be applied with little or no modification to the determination of triadimefon/triadimenol and imidacloprid in a variety of environmental matrices. It is our intention to extend it to seeding stem and root samples as well as to soils. Quantification of triadimefon and triadimenol by SIM at levels below 100ppb in white pine may be achievable with additional cleanup of the Florisil eluate to remove co-extractives. MS/MS to filter out the chemical background is certainly an option and could lower the LOQ to ppt levels.

Determination of Triclopyr and Metabolites in Environmental Matrices Using Solid-Phase Extraction and Capillary Gas Chromatography/Mass Spectrometry

INTRODUCTION

Triclopyr (3,5,6-trichloro-2-pyridinyloxyacetic acid) is a frequently used herbicide for the control of a variety of woody plant and broadleaf weed species. The compound is also under development for use as an aquatic herbicide. As such the chemical is active against a wide range of introduced aquatic nuisance species such as purple loosestrife and Eurasian milfoil, without adverse effect on desirable native plant species such as rushes and cattails (1). To support the registration for triclopyr as required under Subdivision N of the U.S. EPA Pesticide Assessment Guidelines, methodology is required for the determination of triclopyr and its two major metabolites in soil, sediment, and water.

Methods for the determination of triclopyr, 3,5,6-trichloro-2-pyridinol (TCP) and 2-methoxy-3,5,6-trichloropyridine (MP) were developed and validated over the concentration range 10-1000 ng/g in soil and sediment, and 0.10-10 ng/mL in water. This paper describes the methodology developed for the analysis of soil and sediment samples.

ABSTRACT

Residues of triclopyr, TCP, and MP are extracted from soil and sediment samples using acidified acetone. Aliquots of the soil extracts are purified by C_{18} solid-phase extraction (SPE) for triclopyr and TCP determination, while the MP determination requires a hexane extraction with an optional silica gel SPE. Following recombination of the purified extracts, the samples are derivatized to form the *tert*-butyldimethyl silyl (TBDMS) ethers, and analyzed by gas chromatography with mass selective detection.

For water samples, MP is first extracted with hexane and then purified using a silica gel SPE. Residues of triclopyr and TCP are then extracted using a C_{18} SPE. The subsequent sample preparation is the same as for the soil and sediment samples.

Analyses were performed by capillary GC/MS employing selected ion monitoring using a Hewlett-Packard Model 5971A benchtop mass selective detector. A splitless injection onto a J&W Scientific Durabond-1701 column was used for resolution of triclopyr and its metabolites from sample matrix components.

RESULTS

Compound	Validated Range, µg/g	Percent Recovery	Standard Deviation
Triclopyr	0.01-1.0	106	7 (n=32)
TCP	0.01-1.0	90	4 (n=32)
MP	0.01-1.0	95	7 (n=32)

CONCLUSIONS

The above method has proven reliable for the analysis of several thousand environmental samples from aquatic dissipation and field dissipation studies. Compared to existing methods (2,3), the advantages of this method include easier sample preparation, the formation of the TBDMS ethers for both the triclopyr and TCP (4), and the simultaneous determination of all three compounds in a single chromatographic run.

Because of the high specificity achieved for triclopyr and its metabolites by the use of capillary GC/MSD coupled with multiple ion detection, the usual requirement for a second independent confirmatory method for enforcement purposes is not necessary.

TITLE: Determination of Clopyralid in Soil Using Solid-Phase Extraction and Capillary GC/ECD and GC/MSD

AUTHORS: B. J. Harnick and E. L. Olberding
DowElanco, North American Environmental Chemistry Laboratory

INTRODUCTION

Clopyralid is the active ingredient in several broadleaf weed control products in use throughout the United States. As part of the reregistration process, methodology must be developed to determine clopyralid residues in various environmental and agricultural matrices.

A method for the determination of clopyralid residues in soil was developed and validated in the Residue Chemistry Group of DowElanco North American Environmental Chemistry Laboratories. The methodology employed a solid-phase extraction (SPE) with analysis by GC/ECD or GC/MSD.

ABSTRACT

Residues of clopyralid were extracted from soil samples using acidified acetone. A portion of each extract was evaporated to aqueous, diluted, and purified using C_{18} and alumina solid-phase extractions (SPE). After derivatization with acidified 1-propanol, the 1-propanol was evaporated and the clopyralid 1-propyl ester derivative (clopyralid PE) was partitioned from an aqueous sodium chloride solution into hexane containing clopyralid 1-butyl ester (clopyralid BE) as an internal standard. A portion of the hexane extract was then analyzed by capillary gas chromatography with electron capture detection (GC/ECD).

Capillary GC/ECD was performed using a Hewlett-Packard Model 5890 gas chromatograph equipped with an electron capture detector. A splitless injection onto a J&W Scientific Durabond-17 column was used for resolution of clopyralid from sample matrix components. The method was validated over concentration ranges of 5-250 ng/g in soil.

Capillary GC/MSD employing selected ion monitoring was used for confirmation of clopyralid residues. Capillary GC/MSD was performed using a Hewlett-Packard Model 5971A benchtop mass selective detector. A splitless injection onto a J&W Scientific Durabond-17 column was used for resolution of clopyralid from sample matrix components.

RESULTS

Validation of the above method produced the following results:

Matrix	Instrument	Validated Range	Percent Recovery	Standard Deviation
Soil	GC/ECD	5.0-250 ng/g	83	8 (n=29)

CONCLUSIONS

The use of solid-phase extraction with GC/ECD or benchtop GC/MSD for routine residue analysis has been demonstrated to produce excellent results. The above methods will be used for the analysis of environmental samples from field dissipation studies to provide data for re-registration of clopyralid.

THE EVALUATION OF A BENCHTOP API LC/MS/MS SYSTEM FOR ENVIRONMENTAL ANALYSES

Robert Bethem, ALTA Analytical Lab, 5070 Robert J. Mathews Pkwy., El Dorado Hills, CA 95762
and Takeo Sakuma and Bori Shushan*, Perkin-Elmer SCIEX Instruments, 71 Four Valley Drive, Concord, Ontario, Canada, L4K 4V8

INTRODUCTION

Atmospheric pressure ionization LC/MS is becoming a generally accepted and widely used analytical tool for quantitative environmental analysis. We have validated several environmental methods for the quantitation of pesticides and herbicides using a PE SCIEX API III+. We are currently using this data to assess the quantitative performance of the PE SCIEX API 300, a newly introduced benchtop LC/MS/MS system Two methods were chosen for the instrument comparisons The first method described is for the analysis of one carbamate (carbofuran) and two organophosphorous pesticides (methyl parathion and malathion) in rice field drainage water by LC-API/MS/MS These difficult samples provide us with an excellent opportunity to test method specificity and ruggedness. Although the quantitative statistics for the APCI method validation are excellent, methylparathion is thermally labile and does not give a molecular ion while in APCI mode. For this reason, we are also evaluating IonSpray™ for this analysis. We have generated instrument comparison data using APCI and IonSpray on the PE SCIEX API III+ and API 300. Sensitivity and linearity comparisons demonstrate similar performance. The second method is the analysis of hydroxytriazine degradates in groundwater by LC-APCI/MS/MS. The analysis provides quantitative analysis for all five analytes in a single injection with excellent sensitivity. The method uses strong cation exchange (SCX) chromatography and requires the use of volatile buffers for chromatographic retention. Due to the low molecular weight of the analytes (<200 amu), the use of ammonium acetate in the mobile phase, and the need to quantitate versus external standards, this method is a good candidate for evaluation of small molecule sensitivity, precision, accuracy and ruggedness. Comparison of APCI data from the API III+ and API 300 once again showed similar performance characteristics.

ANALYSIS OF RICE FIELD DRAINAGE WATER BY LC-APCI/MS/MS

This example describes the preparation of water extracts by liquid-liquid extraction followed by the determination of the following compounds by LC-APCI/MS/MS. The method has been validated with rice field drainage water and is being used to assess the toxicity of rice field releases. Seven control sample aliquots were fortified with the analytes listed below at an estimated method detection limit (EMDL; fortification amounts varied for each analyte based on the sensitivity from standard injections). The samples were extracted using a concentration factor of 200 mL/2 mL and analyzed. The Method Detection Limit (MDL) for each analyte was calculated by multiplying the standard deviation of the seven replicate analyses by the Student value of 3.143. The Limit of Quantitation (LOQ) represents 10 times the standard deviation. See Figure 1 for the product ion mass spectra and Table I for a summary of results used for MDL and LOQ calculations.

An acidified water sample is extracted three times with methylene chloride. The combined aliquots are concentrated by rotary evaporation to less than 10 mL. The aliquot is transferred with methanol to a calibrated tube and concentrated to ~0.5 mL using nitrogen. The concentrate is diluted to a 2 mL final volume using 0.1% formic acid. Stable isotope internal standards for Carbofuran and Malathion are added prior to the extraction procedure. An internal standard for Methylparathion (d_{10}-Diethylparathion) is added just prior to bringing the extract to its final volume. For the analytical injection, all compounds are separated by reversed phase liquid chromatography (75mm x 4mm Nova-Pak C18) and introduced directly to the mass spectrometer using a heated nebulizer APCI probe. The analytes are analyzed by positive ion MS/MS using either the protonated molecular ions (carbofuran and malathion) or thermal degradation ions (Methylparathion and d_{10}-Deethylparathion) as precursors. See Figure 2 for a chromatogram of a matrix fortification analysis at the estimated MDL. A linear regression ($1/x^2$) is used for quantitation. Samples were quantitated using the area response ratios of the analytes/internal standards (y) versus the concentration of the native compounds (x) from all standards injected. Each analysis requires approximately 13 minutes. See Figure 3 for a comparison of results between API III ^{plus} and API 300.

TABLE I: LC-APCI/MS/MS Method Detection Limit Study

Precursor ions are indicated by an arrow. The Ion labeled "T" indicates a thermal fragment of Methylparathion used as the precursor ion.
The product ions used in the MRM analysis are indicated in bold

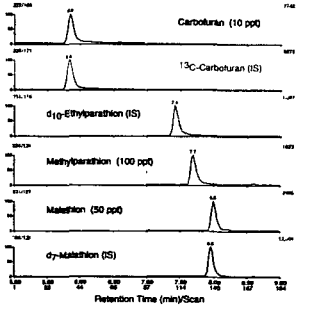

Figure 2:
APCI-LC/MS/MS (MRM) of rice drainage water matrix fortified at the indicated EMDL levels.

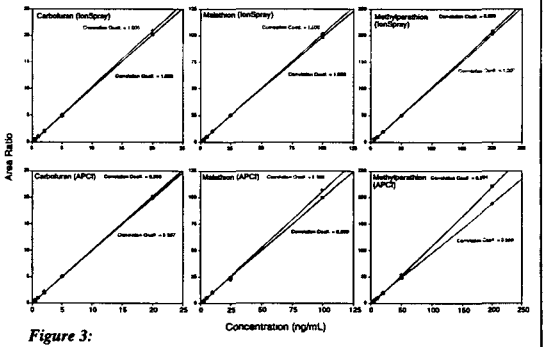

Figure 3:
Comparison of quantitative results between API III ^{plus} and API 300 (data shown in grey).All calibration curves use a $1/x^2$ linear regression and all correlation coefficients were between 0.997 and 1.000.

CONCLUSION

Atmospheric pressure ionization LC/MS/MS has been successfully applied to environmental analysis of several compound classes. Method Detection Limit studies demonstrate that accuracy and precision data equals or exceeds that obtained from traditional GC and LC methodologies with quantitative reporting limits in the low ppt level for water. The need for sample cleanup is dramatically reduced due to the inherent specificity of the technique. The methods are rugged and are capable of providing reliable results on a routine basis.The comparison of the results from the API III ^{plus} and the API 300 indicated similar response characteristics for the analyte classes studied.

Analysis of Pyrethoid Insecticides by Ion Trap GC/MS/MS

Gerald F. Bauerle, Jr., Kenneth L. Ray, and Jennifer S. Brodbelt*
Univerisity of Texas at Austin
Department of Chemistry
Austin, TX 78712

Pyrethoids are derivatives of pyrethrin, an extract of the Chrysanthemum family of plants, and are used as insecticides worldwide [1]. Many different methods have been used to analyze them including HPLC [2,3], and more commonly GC with appropriate detectors. Recent advances in ion trapping technology have promoted the development of sensitive and versatile bench-top gas chromatograph/tandem mass spectrometers which permit electron and chemical ionization of components in addition to collisionally activated dissociation of ions [4-6]. Detection limits as low as 0.5 ppb have been reported for standardized reference components, and complete mass spectra can be accumulated in a little as 80 ms [7].

Chemical Ionization and Collisionally Activated Dissociation of Compounds

The reactant ions of 43 and 57 u from isobutane were isolated after ionization, and were then allowed to react with the pyrethoids. For the CAD experiments typically the protonated pyrethoid was activated unless its abundance was too small, as for the cases of tetramethrin (331) and bifenthrin (422). Protonated tetramethrin dehydrated very efficiently and was used for CAD studies. For bifenthrin, none of the protonated structure remained intact. The ion at 361 u had a large intensity as well as a high mass to charge ratio, so it was used for CAD as well.

Since the Saturn 4D ion trap mass spectrometer is capable of performing CAD in real time on ions of different mass to charge ratios as they elute from the capillary column, experiments were performed to test the ability of the instrument to isolate and dissociate ions of different mass to charge ratios which elute closely. It was demonstrated that it was possible to successfully activate the dehydrated tetramethrin ion at 314 u, activate the ion from bifenthrin at 361 u, and switch back to activation of the 314 u ion.

Comparison of SECI/CAD to SECI and Interpretation of CAD spectra

The SECI/CAD spectra show several significant differences from the SECI spectra. For example, the SECI and the SECI/CAD spectra for bioallethrin (302) show several new ions, such as a fragment ion at 203 u which is one of the most abundant products in the CAD spectrum. Present in the SECI and SECI/CAD spectra is an ion at 285 u which indicates a loss of water. Ions appearing at 151 u and 123 u can be explained by a mechanism previously reported by Holmstead and Soderlund [8]. This cleavage to give a oxonium ion and an alcohol is characteristic in the CAD spectra of all the protonated pyrethoids.

A comparison of the SECI spectrum to the SECI/CAD spectrum, activation of $(M + H - 62)^+$, of bifenthrin shows numerous differences, having only the 181 u ion in common.

In the CAD spectrum of protonated cypermethrin (415), only two fragment ions are produced, 191 and 388 u. The ion at 191 u is from the ester cleavage of the protonated species [9]. The other is due to a loss of 28, possibly CO from the carbonyl group of the ester giving an ion at 388 u.

Tetramethrin does not show drastic differences in the SECI and SECI/CAD spectra as does bifenthrin. Thus, it is likely that many of the fragmentation processes include dehydration as the first step. Ions at 151 u and 123 u in the SECI spectrum, corresponding to the characteristic ester cleavage from protonated tetramethrin followed by the loss of carbon monoxide, are present. This combination is identical to the one seen for bioallethrin.

Limits of Detection

Limits of detection for bioallethrin and deltamethrin (503), corresponding to the first and last peak of the separation as well as the highest and lowest molecular weights, were determined. Upon isolation of the protonated bioallethrin analyte, the detection limit decreased to 50 ppb from 5 ppb, a loss of an order of magnitude, which can be explained by several factors. First, the ion at 303 u only represents 46 percent of the sum of the three most predominant ions used for determining the SECI limit of detection. In addition, upon isolation, the waveform generator incidentally ejects a portion of the desired ion. Using the CAD mode, the limit of detection decreases by a factor of four from the isolation mode. Since the three most predominant ions in the SECI/CAD spectrum comprise 46 percent of the total signal , it appears that half of the ions were lost.

The SECI limit of detection for deltamethrin was 0.5 ppm which represents an order of magnitude improvement over the detection limit previously reported for a quadrupole mass analyzer system [9]. The SECI-isolation technique showed a deterioration in the limit of detection similar to that of bioallethrin, but the fact that selected isolated ion only represented 2 percent of the total ion current in the original SECI product spectrum indicates an efficient isolation procedure. The SECI/CAD limit of detection was identical to that of the SECI-isolation technique, indicating nearly quantitative dissociation of the isolated precursor ion to the product ion at 281 u.

Compounds Produced by Motor Burnouts of Refrigeration Systems

Carolyn J. Koester*, Ruth A. Hawley-Fedder, and Linda Foiles
Lawrence Livermore National Laboratory, Livermore, CA 94568

Introduction: The phase-out of chlorofluorocarbons has necessitated the introduction of alternate refrigerants. R22 (CF_2ClH), R134a (CF_3CH_2F), and R507 (50/50 CHF_2CF_3/CF_3CH_3) are newer fluids which are used in cooling systems. Recently, concern over the possible formation of toxic compounds during electrical arcing through these fluids has prompted us to identify their electrical breakdown products by electron ionization GC/MS. For example, it is known that perfluoroisobutylene (PFIB), which has an threshold limit value of 10 ppb (set by the American Conference of Government Industrial Hygienists), is produced from the thermal and electrical breakdown of some refrigerants. We have used specially designed test cells, equipped with electrodes, to simulate the electrical breakdown of R22, R134a, and R507 in refrigeration systems.

Experimental: R22, R134a, or R507 were introduced into a test cell as gases. The test cell used for experiments at 15 PSI was made of epoxy, had a 93 mL volume, and had brass electrodes having a surface area of 0.8 in^2. The cell used for experiments at high pressure and temperature was made of vespel, had a volume of 77 mL, and had brass electrodes with a surface area of 0.3 in^2. The test cell had been previously filled with 1% by weight of the appropriate oil--Calgon C4 was used with R22 and EM Karate RL-327 was used with R134a and R507 Oil was added to the cells to simulate conditions expected in motors--oils are used to lubricate pistons in compressors and it is known that some contamination of the refrigerant by this oil will occur. The cell was then evacuated to 20 mtorr before being filled with the selected refrigerant. The refrigerant, as a gas, was subjected to up to 200,000 electrical pulses (30 µsec, 20 kV pulsed-breakdown at 100 Hz) and the resulting gas mixture was sampled and analyzed by GC/MS with a Hewlett-Packard 5989. The GC column (Restek RTX-1, 105 m, 250 µm i.d., 1 µm film thickness) was temperature programmed as follows: -30°C for 13 min, ramped at 5°C/min to 150°C, held for 10 min, ramped at 10°C to 300°C, and held for 10 min. The MS was operated in the electron ionization mode and scanned from 30u to 650u in 1.1 sec.

Results: The formation of many new compounds was observed; Table 1 shows the major compounds produced when R22 was subjected to electrical breakdown at 15 PSI and 20°C. Compounds were tentatively identified by using mass spectral data bases. Many of the compounds that were produced at 15 PSI and 20°C were also produced at 200°C and at higher pressures; however, the distribution of products changed slightly. The total amount of breakdown products increased with increasing arc exposure for experiments performed at 15 PSI and for experiments performed at higher pressures.

Conclusions: Many different compounds are formed at parts-per-thousand concentrations as electrical arcs are passed through refrigerants. PFIB was not present in sufficient quantities to be detected by GC/MS; thus, we plan to use the more sensitive GC/ECD to look for its presence. The variety of compounds produced suggest that interesting chemistry is occurring, including the formation and recombination of radicals to produce species which are larger than their parents. The electrical burnout of actual refrigeration motors will be performed to determine how well our test cells simulate processes that can occur in refrigeration systems.

Table 1. Major compounds present after 100,000 arcs passed through R22 at 15 PSI and 20°C. Each number represents the average of duplicate measurements.

Tentative Identification	mg/g R22
tetrafluoroethene	300
dichlorodifluoromethane (R12)	200
dichlorotetrafluoroethane	50
hexafluoropropene	40
dichlorohexafluoropropane	10
dichlorodifluoroethene	10
trichloropentafluoropropane	9
chloropentafluoropropene	8
chlorotrifluoropropyne	8
dichlorodifluoroethene	8
trichloropropene	8
dichlorodifluoroethene	7
chlorine & fluorine containing hydrocarbon	7
trichlorofluoromethane	6
dichloroethyne	6
trichlorofluoroethylene	6
chlorodifluoromethane	5
dichlorotetrafluorocyclobutene	5

Introduction. Chlorinated *n*-paraffins (CPs) are used as fire retardants, plasticisers in PVC, adhesives, and as extreme pressure additives in lubricants and cutting oils. They have also found use as replacement chemicals for more toxic and persistent chemicals such as PCBs.

There have been a few reports of the mass spectrometric behavior of CPs[1,2]. In these studies, efforts were made to resolve commercial mixtures by capillary gas chromatography (gc) columns, prior to introduction into the ion source. Because of the inherent complexity of commercial mixtures, most peaks eluting off the gc-column contained multiple components, and thus mass spectra were not of individual congeners.

Clearly then, there is a need for individual CP congeners. Methods of synthesizing individual CP congeners have already been developed in our laboratory[3]. In addition, the positive electron ionization (EI) and the electron capture negative ion (ECNI) mass spectrometry of these synthesized CP congeners have been described.

In this report, we describe the fragmentation behavior of two individual CP congeners by examining the results of a detailed study of metastable and collisionally induced dissociation (CID, argon) processes. Fragmentation pathways were determined by B/E, B^2/E and CNL linked-field scanning.

Mass Spectrometer. All studies were carried out on a Kratos Concept high resolution mass spectrometer controlled by a Mach 3 data system. EI mass spectra were scanned from 40 to 500 daltons at a scan rate of 0.7 seconds per decade. The ion source was maintained at a temperature of 220°C, the trap current was 500µA and the ion acceleration voltage was 8kV. The electron beam energy was adjusted for maximum sensitivity (~50eV). Ion decomposition was enhanced by collisional activation by introducing argon into the collision cell at a pressure sufficient to attenuate the m/z 231 ion of PFK by 50%.

Chromatography. GC separations were performed with a Hewlett Packard 5890 Series II gas chromatograph using a 60 m x 0.25 mm DB5 column, with He as the carrier gas. The initial column temperature was set at 80°C; it was ramped to 280°C at a rate of 10°C/minute and held there for 10 minutes. The injector and transfer interface were set at 200°C and 280°C respectively.

Results and Discussion. The EI positive ion mass spectra of one of the congeners, 1,2,9,10-tetrachlorodecane, $C_{10}H_{18}Cl_4$ (M_4) is shown in Figure 1. As reported earlier, the EI mass spectra of CP congeners do not show the presence of molecular ions; however, many fragment ions resulting from one, or several, losses of HCl and Cl· are observed[3].

Several fragmentation mechanisms for this compound have been determined (***Scheme I***). For the M_4 species, consecutive losses of 2 molecules of HCl lead to the $C_{10}H_{16}Cl_2^+$ ion, m/z 206, which is the precursor of a number of other significant ions. The mechanisms proposed involve known six-membered cyclic transition structures for the HCl losses, and 1,2 H-shifts for the subsequent decompositions. The dominant m/z 139 ion, $C_5H_9Cl_2^+$, had no identifiable precursor, so is assumed to be formed by rapid decomposition of $M_4^{+\cdot}$ in the ion source; the formation of a five-membered cyclic ion, as shown, is known to be a favored process.

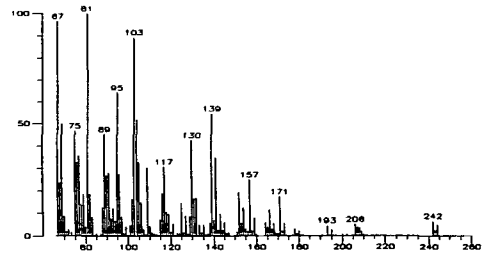

Figure 1. EI positive ion mass spectrum of M_4.

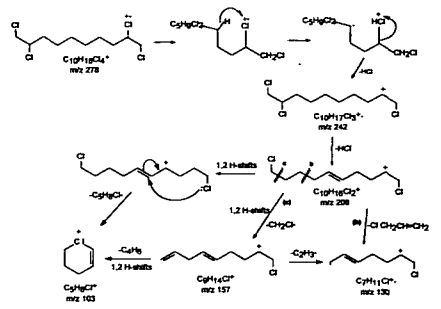
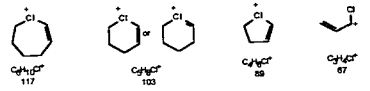


Scheme I. Decomposition mechanisms for M_4.

It is interesting to note that at low mass in the mass spectrum of M_4 there exist many even-electron odd mass ions To date, the precursors of many of these ions have not been established. The ions at m/z 117, 103, 89 and 75 correspond to the series $C_nH_{2n-2}Cl^+$. Proposed structures are shown below



Conclusions. The EI and CID mass spectrum of M_4 shows characteristic losses of HCl and Cl atoms, as well as some structure-specific ions. These results are a necessary step in the development of analytical techniques for characterization of complex CP mixtures.

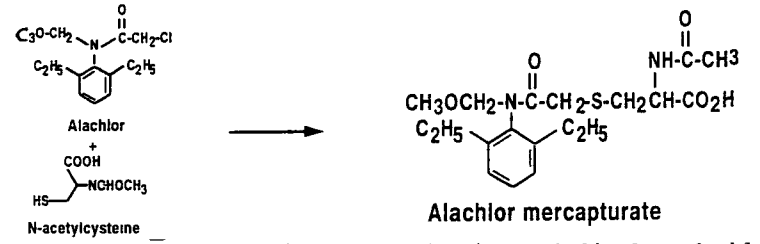
LC-MS/MS Identification and Analysis of a Major Human Urinary Metabolite of Alachlor

William J. Driskell[1], Robert H. HIll, Jr.[1], Dana B. Shealy[1], and R. Delon Hull[2]
[1]National Center for Environmental Health and Injury Control, Centers for Disease Control and Prevention, U.S. Department of Health and Human Services, Atlanta, Georgia 30333 USA
[2]National Institute for Occupational Safety and Health, U.S. Department of Health and Human Services, Cincinnati, Ohio 45242 USA

Alachlor (2-chloro-2',6'-diethyl-N-(methoxymethyl)acetanilide) is a commonly used preemergence herbicide on soybeans, corn and other crops. It is rapidly and completely metabolized to products that have not been characterized in human urine. Alachlor exposure has commonly been estimated by quantifying the base hydrolysis product, 2,6-diethylaniline (DEA), of alachlor metabolites in urine (Cowell et al 1987). In this study we attempted to identify alachlor metabolites by LC-MS/MS analysis of extracts of urine samples from subjects who were occupationally exposed to alachlor.

Four 25 ml samples from workers occupationally exposed to alachlor were obtained from the Environmental Protection Agency (EPA). To estimate the total concentration of alachlor metabolites in the samples, we used a base-pressure hydrolysis method, based on that of Cowell et al, 1987, that converts alachlor metabolites to 2,6-diethylaniline. We analyzed ethylacetate extracts of urine samples from the occupationally exposed subjects and unexposed control subjects with the Finnigan TSQ-7000 mass spectrometer by LC-MS/MS in the APCI mode. Our approach for identifying alachlor metabolites was to look, by means of MS/MS parent scanning, for parents of alachlor daughters with the presumption that some alachlor daughters would also be produced by alachlor metabolites. Two major alachlor daughters were present: A 238 amu dau was produced by a loss of a CH_3OH moiety and the 162 amu dau was produced by the loss of a $CH_3OC{=}OCH_2Cl$ moiety. There was a peak with a retention time of 5 min when the 162 amu daughter was analyzed in the parent scan mode in the samples from exposed subjects but no peak in the controls. Changing to daughter scanning, we found, in addition to the 162 amu daughter, two other major daughters of 365 amu and 130 amu. The 365 amu dau is a loss of methanol analogous to the 238 dau of alachlor; this implies that the amine methoxymethyl sidechain is still intact. We postulated that the 130 amu dau might be a product of an N-acetylcysteine moiety in which the sulfur-carbon bond is cleaved. From these data, a likely structure, analogous to that of some other pesticide metabolites, is the N-acetylcysteine displacement of the chlorine atom of alachlor to produce alachlor mercapturate. Based on mass spectrometry and chromatographic behavior of synthetic alachlor mercapturate, we identified this human metabolite of alachlor as alachlor mercapturate.



To estimate what proportion of alachlor is metabolized to alachlor mercapturate in humans, we analyzed exposed urine samples using the base hydrolysis method that quantitates DEA and, also, quantitated alachlor mercapturate in the same samples.

Sample	DEA (nanomolar)	Alamerc (nanomolar)
A	930	350
B	470	120
C	4320	2750
D	1120	475

In these four urine samples, alachlor mercapturate ranges between 25% and 62% of the concentration of DEA, the hydrolysis product that probably almost all alachlor metabolites produce.

In monkeys injected with radioactive alachlor, alachlor mercapturate was the major metabolite accounting for about 40% of the metabolite concentration (Carr et al, 1986). No free alachlor was detected in urine. Other pesticides besides alachlor, including lindane, cyanatryn (Aizawa 1982) and atrazine (Lucas et al 1993), and xenobiotics, including acrolein, benzene, vinyl chloride, and various allylic and benzylic halides (Stanek 1993), are metabolized to thioethers like alachlor.

Structural Characterization of Toxaphene Congeners by GC/MS

Frank M. Benoit[1], Alex Driega[2] and Murugan Malaiyandi[2]
[1]Environmental Health Directorate, Health Canada, Ottawa, Canada, K1A 0L2

Technical toxaphene is produced by chlorination of C10 terpenes and contains a highly complex mixture of polychlorinated bornane congeners that are difficult to isolate and characterize by GC/MS. Mass spectral characterization is hampered by the sheer number of congeners eluting into the ion source within a narrow time window, rendering it impossible to obtain a pure mass spectrum of an individual congener. Chlorination of 2-exo-,10-dichlorobornane produced a less complex mixture from which individual hepta-, octa- and nona-chlorobornanes were selectively isolated from the chlorinated mixture using a multistage purification scheme based on column chromatography and preparative HPLC. The nature and purity of each fraction were monitored by GC analysis at each stage of the fractionation until the purity of the sample was sufficient (> 90%) for congener characterization by GC/MS (EI and ECNI). Of the eight fractions isolated in this manner, six contained a single toxaphene congener and two contained minor components as well as one major toxaphene congener. Generally toxaphene congeners do not show molecular ions under electron impact ionization, however, very weak molecular ions may be observed when larger amounts are injected. ECNI (methane) produced simpler mass spectra consisting primarily of one cluster of ions resulting from the loss of chlorine from the molecular ion. The chlorine content of the original molecule was determined from the distribution of peaks within the fragment ion cluster. There is little structural information available in the ECNI mass spectra but the EI mass spectra of toxaphenes provides a complex array of ions which contains a wealth of structural information.

Table 1. Percent Distribution of Fragmentation Streams in High Mass Region

Congener (Knowns)	# of Chlorines	M-Cl -nHCl	M-HCl $C_2H_{4-x}Cl_x$	M-CH_2Cl -nHCl	M-$CHCl_2$ -nHCl

A1750	8	64	0	10	26
(Unknowns)					
G1380	7	46	40	14	0
I1482-1	7	49	10	0	41
I1482-2	7	42	30	0	28
01677-1	8	78	0	0	22
01677-2	8	68	15	0	17
J1648	8	49	28	23	0
R1728	8	59	18	23	0
01677-3	9	47	21	0	32
U1836	9	88	0	0	12

The primary fragmentations were the losses of Cl, HCl, CH_2Cl and $CHCl_2$ from the molecular ion and the secondary fragmentations were the losses of Cl, HCl, CH_2Cl, $CHCl_2$ and $C_2H_{4-x}Cl_x$ (Retro Diels-Alder). The major fragmentation streams consisting of a primary fragmentation followed by a series of secondary fragmentations were: M-HCl-$CH_{4-x}Cl_x$, M-CH_2Cl-nHCl, M-$CHCl_2$-nHCl and M-Cl-nHCl. Unlike other isomeric compounds, the isomeric chlorinated bornane congeners presented distinctive EI mass spectra; hence, the structural integrity of the ions was retained, at least through the initial fragmentation steps. The structure of the chlorinated bornane could not be completely determined from the EI mass spectrum alone. However, some structural features, such as the distribution of chlorine in the three possible locations within the molecule (ring, C10 and C8/C9) could be established. Based on the mass spectra of known toxaphene congener structures, the structures of unknown congeners were assigned as follows: The Retro Diels Alder fragmentation occured from either ring segment and provided information on the ring chlorine distribution: M-HCl-$C_2H_2Cl_2$ only indicated symmetric ring chlorines (2:2) whereas M-HCl-C_2H_3Cl indicated asymmetric ring chlorines (2:1). The Retro Diels Alder fragmentationwas absent in fractions A1750, O1677-1 and U1836 (Table 1). The structure of A1750 (as determined by x-ray crystallography - 2,2',5,5',8,9,10,10'-octachlorobornane) suggested that the loss of HCl from the molecular ion was forbidden when all the ring chlorines were geminal (CCl_2). The loss of $CH_{3-x}Cl_x$ provided information on the C10 chlorine distribution. Both CH_2Cl (C8) and $CHCl_2$ (C9 and C10) groups were present in TOX9. C8 and C9 are essentially equivalent positions and the loss of $CH_{3-x}Cl_x$ would be expected to occur from either position with equal probability. However, only the loss of $CHCl_2$ was observed. Therefore the loss of $CH_{3-x}Cl_x$ must occur primarily from the C10 position. The C8/C9 substitution was deduced by difference between the total number of chlorines and the sum of the ring and C10 chlorines. The structural features of the isolated toxaphene congeners are summarized in Table 2.

Table 2. Structural Features of Isolated Toxaphene Congeners

Congener	#Cl	C10	Ring	C8/C9
G1380	7	CH_2Cl	2:2	2Cl
I1482-1	7	$CHCl_2$	2:2	CH_2Cl/CH_3
I1482-2	7	$CHCl_2$	2:1	2Cl
A1750	8	$CHCl_2$	2:2 (g)	$CHCl/CH_2Cl$
01677-1	8	$CHCl_2$	2:2 (g)	2Cl
01677-2	8	$CHCl_2$	2:1	3Cl
J1648	8	CH_2Cl	2:2	3Cl
R1728	8	CH_2Cl	2:2	2Cl
U1836	9	$CHCl_2$	2:2 (g)	3Cl

(g) all chlorines are geminal

Characterization of Three Major Toxaphene Components in Ringed Seal Blubber

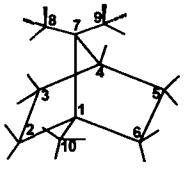
M.D. Loewen[1], G.A. Stern[2], D.C.G. Muir[2], J.B. Westmore[1], H. Parlar[3].

[1]Department of Chemistry, University of Manitoba, Winnipeg, MB, R3T 2N2, Canada. [2]Freshwater Institute, Department of Fisheries and Oceans, Winnipeg, MB, R3T 2N6, Canada. [3]Lehrstuhl fur Chemisch-Technische Analyse und Chemische Lebensmitteltechnologie der TU Munchen, D-85350 Freising-Weihenstephan, Germany.

Toxaphene, a complex pesticidal mixture consisting primarily of chlorinated bornanes (CHBs), was widely used in the US, Canada and other parts of the world before its ban in the early 1980's[1]. It's primary use was as an insecticide for cotton and soybean crops, and briefly as a piscicide in the late 1950's, and 1960's[1]. Although technical toxaphene is thought to consist of between two and three hundred penta- to undecachlorobornanes, a much more limited number have been shown to be environmentally significant[1]. At present only one Cl_9 compound, T12, and one Cl_8 compound, T2, have been structurally identified in marine environmental samples.[2,3]

We report here the isolation of three more environmentally significant CHB congeners, TS2, TS3 and TS4, extracted from Ringed seal blubber, and their structures as determined by mass spectrometry (GC-ECNIMS (CH_4), low resolution EIMS, and linked field scanning).

A Kratos Concept high resolution mass spectrometer, yielded mass spectra of TS2, TS3, and TS4. From ECNIMS we have determined that TS2, 3, and 4 are octachlorobornanes. Three major ion degradation pathways in the positive ion spectra, can be used to identify a given CHB congener First, is the loss of C_2H_3Cl, $C_2H_2Cl_2$, or C_2HCl_3 after an initial loss of HCl or Cl_2 from the molecular ion. This gives rise to an even mass odd-electron ion that is characteristic of the number of chlorine atoms located on C2-C3 and C5-C6. Elimination of a neutral fragment comprised of C7 and it's two attached substituents yields information regarding the bridging group's (C7, 8, 9) chlorine content. Observation of decompositions involving the elimination of CH_2Cl or $CHCl_2$ (eg $[M-CH_2Cl]^+$) gives evidence as to the identity of the substituted chloromethyl groups on C7, while the presence of CH_2Cl^+ or $CHCl_2^+$ ions at m/z 49 and 83 respectively provide information with regard to the chlorine substitution on C10.



Bornane skeleton

In the positive ion mass spectrum of TS2 the even mass odd-electron ion of m/z 244 is the result of two processes. Successive losses of Cl_2 and $C_2H_2Cl_2$, or of HCl and C_2HCl_3, from M^{+o} indicate that there must be five chlorine atoms on the ring, two on one side and three on the other. The exact positioning of these ring chlorines however could not be determined by mass spectrometry. An ion

giving rise to a peak at m/z 195 results from loss of $C_3H_4Cl_2$ from $[M-Cl_2-Cl]^+$ (m/z 305), indicating there is a total of two chlorines on the of successive losses of HCl and $C_2H_2Cl_2$ from M^{+o}. There is no other significant pathway resulting in an even mass odd electron ion and we can therefore conclude that there must be two chlorine atoms on bridging group. The observed losses of CH_2Cl from M^{+o} and $[M-Cl_2]^{+o}$ and not of $CHCl_2$, suggest the presence two monochloromethyl substituents on C7. The one remaining chlorine atom must be positioned on C10.

In the positive ion mass spectrum of TS3 a peak observed at m/z 278 is the result each of the C2-C3 and C5-C6 sides of the ring. By the high relative abundance of $[M-HCl]^+$ we can conclude that the chlorine substitution pattern on the ring is trans staggered (e.g. 2-exo,3-endo,5-exo,6-endo), but the actual substitution pattern cannot be verified by mass spectrometry. Loss of the neutral fragment $C_3H_4Cl_2$ from $[M-HCl-Cl]^+$ indicates the presence of two chlorine atoms on the bridging group. Loss of CH_2Cl from M^{+o} and $[M-HCl]^{+o}$ and the absence of losses involving $CHCl_2$ verify that the two chlorines in the bridging group are the result of two monochloro substituents on C7. The remaining two chlorine atoms must be positioned on C10. Support for a dichloromethyl group at C10 is shown by the presence of a peak corresponding to $CHCl_2^+$ at m/z 83.

A significant feature of the positive ion mass spectrum of TS4 is the very low relative abundance of the even mass, odd-electron ion at m/z 278, which results from the loss of $C_2H_2Cl_2$ from $[M-HCl]^{+o}$. As with TS3, the observed loss of $C_2H_2Cl_2$ indicates the presence of two chlorine atoms on both C2-C3 and C5-C6. Lack of a predominant even mass odd-electron ion would be consistent with a ring structure having a geminal dichloro-substitution and an adjacent unchlorinated carbon. Elimination of HCl in this case would be less likely while loss of Cl would be favoured. We cannot, however, verify the actual chlorine substitution pattern on the ring by mass spectrometry. Loss of $C_3H_3Cl_3$ is observed from $[M-HCl-Cl]^+$ This confirms the presence of three chlorine atoms on the bridging group. Decompositions involving the loss of CH_2Cl and $CHCl_2$ from M^+ and $[M-HCl]^{+o}$ indicate the presence of a dichloromethyl and monochloromethyl substituent on C7. The remaining chlorine must be located on C10.

Recently, Parlar *et al* were successful in isolating, and characterizing a number of CHBs in the technical mixture using mass spectrometry and NMR spectroscopy[4]. Based on their GC retention times and by comparison of full scan positive EIMS spectra, we found TS2, 3 and 4 to correspond to Parlar #39, 2,2,3-exo,5-endo-6-exo,8,9,10-octachloroborane; Parlar #40, 2-exo,3-endo,5-exo,6-endo,8,9,10,10-octachlorobornane; and Parlar #42, which is a mixture of 2,2,5-endo,6-exo,8,8,9,10-octachlorobornane, and 2,2,5-endo,6-exo,8,9,9,10-octachlorobornane respectively. The two compounds in Parlar #42 are identical except for the proximity of the substituted chloromethyl groups on C7 to the ring substituents. Since these two compounds would likely give the same mass spectrum we cannot conclude whether we have a single congener or a mixture of the two compounds.

WHERE IN THE GREAT LAKES IS TOXAPHENE GOING?

Michael J. Howdeshell, Susan T. Glassmeyer,
Tanya R. Myers, and Ronald A. Hites
School of Public and Environmental Affairs and Department of Chemistry
Indiana University, Bloomington, IN 47405

Toxaphene is a broad range pesticide which was used primarily on cotton in the southeastern United States. Its use was banned by the US Environmental Protection Agency in 1986 because of its persistence. Residues of technical toxaphene are found in biota far removed from sites of its application. Because toxaphene is an extremely complex mixture of hexa- to decachlorinated norbornanes and norbornenes and because few of its numerous congeners have been synthesized, toxaphene can only be analyzed effectively with a selective analytical technique. Various methods have been used; however, electron capture gas chromatographic mass spectrometry (EC GC/MS) gives the most reproducible results due to its selectivity and sensitivity. To determine the fate of this pesticide in the Great Lakes, we have used EC GC/MS to determine total toxaphene concentrations and chlorination level profiles in fish and sediment. In all cases, it was necessary to correct the toxaphene concentrations by subtracting contaminant contributions by using isotopic abundances for toxaphene and for the expected interferences.

Lake Erie walleye and trout from the other four Great Lakes were collected in 1982 and 1992. While both species occupy the same relative level in the food chain, they show markedly different bioaccumulation mechanisms. Additionally, the chlorination level profile for the fish from Lake Erie is significantly different from that of fish from the other four Lakes, suggesting that some unique process is occurring in Lake Erie. Figure 1 shows the average toxaphene concentrations for Great Lakes fish in 1982 and 1992. The error bars represent one standard deviation. The overall decrease in toxaphene concentrations can be attributed to the ban of its production in 1982. The increase in Lake Superior concentrations indicates that there are additional unknown sources.

We have also analyzed Lake Ontario sediment and found that toxaphene fluxes maximize in 1973 ± 6 years with a horizon year of 1945 ± 6 years. This compares well with the small amount of production and usage data that is available. Total toxaphene concentration profiles for the eight Lake Ontario sediment cores are plotted in Figure 2. From these profiles, sediment *in situ* density, and overall sedimentation rate for each core, fluxes to the lake were calculated. The maximum flux to Lake Ontario sediment was 22 ± 8 $\mu g/m^2$ yr in 1973 and the total toxaphene load in the lake is 10 ± 3 metric tonnes. By comparing the toxaphene burdens for the cores, we conclude that toxaphene is deposited to Lake Ontario sediment from both the Niagara River and from the atmosphere. We have developed a simple toxaphene decay model by using the ratios of the concentrations of hexachlorinated toxaphene (6-Cl) to heptachlorinated (7-Cl) toxaphene. By plotting the natural logarithm of 6-Cl to 7-Cl abundance ratios *versus* time since deposition, one obtains a pseudo first-order kinetic plot. Figure 3 shows this function plotted for all the core data and the overall regression line; in this case, the slope is 0.017 yr^{-1}. Taking the reciprocal of this slope gives a time constant of about 60 years.

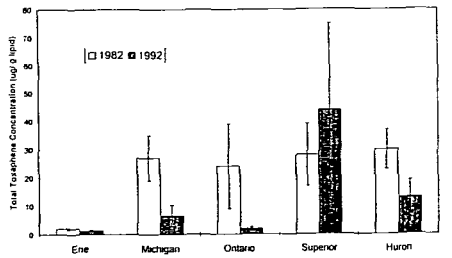

Figure 1. Average toxaphene concentrations in 1982 and 1992 Great Lakes fish.

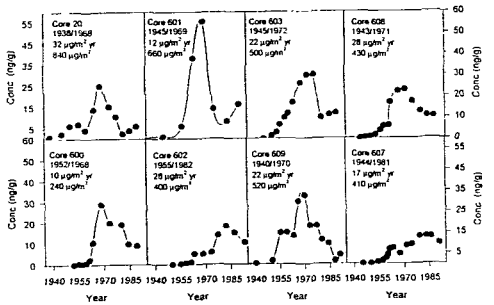

Figure 2. Toxaphene concentration profiles in Lake Ontario sediment cores with core identification, maximum and horizon years, maximum flux, and total burden listed on the plot. The cores are from the Niagara (core 20, 600), Mississauga (601, 602), Rochester (603, 609), and Kingston (607, 608) Basins.

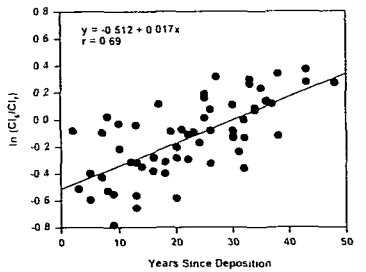

Figure 3. Plot of natural logarithm of the 6-Cl abundance divided by the 7-Cl abundance as a function of time since deposition for each core station; the regression is shown.

OPTIMAL ION TRAP MS/MS PARAMETERS FOR THE ANALYSIS OF DIOXINS AND FURANS

J.B. Plomley, R. S. Mercer* and R.E. March
Trent University, Department of Chemistry, Peterborough, ON. Canada K9J 7B8
***Dioxin/Furan Unit, Laboratory Services BranchOntario Ministry of Environment and Energy Etobicoke, ON, Canada M9P 3V6**

Introduction. Previously, one of the software limitations of non-research grade ion traps for analytical applications was the inability to quantitate using internal standards which chromatographically co-elute with their native analytes.[1] Further, the analysis by MS/MS of a number of different analytes which differ in parent ion mass was impossible in a single chromatographic run, since only one scan function could be applied per acquisition. These two impediments to quantitation have been alleviated on a number of commercially available GC/ion traps, thus making the ion trap suitable for dioxin and furan analysis using isotopic dilution techniques. An examination of those factors necessary for the optimization of an ion trap for dioxin and furan analysis by GC/MS/MS has been carried out. Specifically, three modes of resonant excitation were examined in an attempt to optimize the major dissociative channel (loss of COCl) from isolated parent ions. These modes were single-frequency irradiation (SFI), secular-frequency modulation (SFM), and multi-frequency irradiation (MFI). The last two resonant excitation modes obviate the laborious procedure required for empirically matching an applied single-frequency waveform to the fundamental secular frequency ($\omega_{z,0}$) of the ion.

Experimental. All data were acquired on a Varian Saturn 4D GC/ion trap with an EI/MS/MS scan function which consisted of (a) ionization at a low mass cut-off of 160 u, (b) waveform isolation of parent ions, (c) CAD using various modes of resonance excitation described below, and (d) mass analysis *via* an rf ramp. Saturn version 5.0 software was used for data acquisition while prototype software ("Toolkit") was required for the application of multiple-scan functions across a GC peak The ion trap was operated at 260°C with He buffer gas present at ≈1 mTorr. GC conditions for the separation of dioxins and furans have been described elsewhere.[1] The following were the conditions used for each mode of resonant excitation examined:
(a) **SFI**: Parent ions were irradiated at $q_z \approx 0.4$ for 30 ms with a single-frequency sine waveform.
(b) **SFM**: The rf applied to the ring electrode was varied over ranges of $4V_{0-p}$ and $6V_{0-p}$,with an ion dwell time of 5 ms/V_{0-p}. A single frequency sine waveform was applied at $\omega_{z,0}$ for an ion at $q_z \approx 0.4$.
(c) **MFI**: 1 kHz and 2 kHz bandwidth waveforms were applied to an ion at $q_z \approx 0.4$ for 30 ms.

Results and Discussion. Parent ion isolation efficiencies were on the order of 90% for all congener groups examined. Overall, each resonant mode of excitation accessed, to varying degrees, the energy channel corresponding to the loss of COCl. Under SFI conditions, waveform amplitudes required for optimal conversion efficiency (CE), corresponding to the loss of COCl, were larger for the furans (≈ $1.0V_{p-p}$) compared to the dioxins by as much as 400 mV_{p-p}; CE is defined as the sum of the daughter ion current divided by the abundance of the parent ion prior to dissociation. The larger waveform amplitude required for furan fragmentation compared to dioxin suggests that a larger activation energy barrier exists for the loss of COCl in the former species. Moreover, higher activation energy channels corresponding to the loss of $COCl_2$ and $COCl_3$ were observed for the furans;this contrasts with the high energy loss of 2(COCl) in dioxin. One noteworthy difference between the fragmentation channels of the dioxins and furans concerns the lowest energy channel, the loss of Cl. As much as 15% of the dioxin parent ion current (6% in furan) is conserved in the daughter ion resulting from loss of Cl. Thus the ion trap is more sensitive for furan detection than dioxin when the COCl channel is monitored. All the dissociation channels observed in the ion trap confirm those reported in earlier TSQ studies.[2]
Optimization of SFM required an examination of the ion dwell time and modulation range. For all congeners, a 5 ms ion dwell time/V_{0-p} was required for optimal CE, regardless of the modulation range. Furthermore, less than 5 CAD scan segments resulted in the incomplete dissociation of parent ions. The distribution of daughter ion current in SFM paralleled that of SFI when the optimal modulation range was used, and larger waveform amplitudes were required for furan dissociation compared to dioxin. In contrast to SFI, larger amplitudes were required for COCl loss using SFM, since the irradiating process was not continuous; $\omega_{z,0}$ is constantly changing. This can be rationalized as follows: When the frequency components of the ion are off-resonance with the applied waveform, collisional de-excitation can occur for internally excited ions which would otherwise undergo dissociation. Of course there will be instances when frequency components other than $\omega_{z,0}$ will be on-resonance. Since the amplitude of the applied waveform influences the collision energy by affecting the rate of increase in the amplitude of an ions trajectory, excitation at a frequency other than $\omega_{z,0}$ requires a larger waveform amplitude to achieve the same rate of increase in the amplitude of the trajectory. The optimal modulation range for SFM was not predictable. A $\pm 1V_{0-p}$ rf change corresponds to a ±200 Hz shift in $\omega_{z,0}$ at $q_z \approx 0.4$. Since empirically determined values of $\omega_{z,0}$ were never greater than +400 Hz from the waveform calculator utility, a $6V_{0-p}$ modulation range is extreme, though required in many instances for optimal CE. This suggests that a complex relationship exists between energy deposition and the ratio of time that an ion spends on- and off- resonance, and is the subject of further investigation using a thermometer molecule.

The following experimental observations characterize the MFI of dioxins and furans: (a) higher activation energy channels are more highly populated, (b) in contrast to SFI and SFM, larger amplitudes are required for optimal CE since each frequency component in the waveform only receives a portion of the specified voltage, (c) larger amplitudes are required to effect COCl loss in the furans (d) CE's for COCl loss are on average 5-15% less than observed with optimized SFI and SFM. Although the frequency pattern used to generate the waveform is designed to distribute the excitation power evenly over the bandwidth, the true power spectrum may contain an irregular power distribution that can lead to ion losses and reduced CE.

Preliminary results for the quantitation of dioxins and furans using toolkit software and optimal SFI conditions are impressive. The daughter ion extracted chromatograms for 1 pg of native 2,3,7,8-tetrachlorodibenzofuran and 1 pg of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, with their respective co-eluting $^{13}C_{12}$-internal standards) exhibited a Gaussian appearance, even though 4 scan functions were applied across each GC-peak (at a scan time of 0.5 s). S/N ratios of 15:1 for 1 pg of native analyte on the ion trap compared favourably with those observed on a TSQ 70 for the same calibration standard. Plots of response *vs* concentration were linear for many of the congener groups. For example, 2,3,4,7,8-pentachlorofuran analyzed with the ion trap by MS/MS over a concentration range of 2.5 pg-2,000 pg, had a correlation co-efficient of 0.99973 with a 17% RSD; analysis with the TSQ 70 also furnished a linear response, with a correlation co-efficient of 0.99975 and an RSD of 11%.

Conclusions. Both SFM and MFI represent resonant excitation techniques designed to overcome the shortcomings of automated frequency calibration and secular frequency shifting. The application of SFM for the analysis of dioxins and furans by MS/MS is unlikely; the CAD episode is too long (100-150 ms) and thus lowers the number of scan functions which can be applied across a GC-peak, as well as the number of μscans/scan. Parenthetically, we have found that a minimum of 4 μscans/scan are required to maintain the accuracy of each chromatographic data point. MFI is an alternative to SFM and satisfies the need for short CAD episodes, but CE's are lower and this may ultimately effect sensitivity.

While some fine tuning of the offset in SFI is required even after automated frequency recalibration, SFI with optimal irrradiating frequency offsets has initially produced satisfactory calibration results.

Determination of Elemental Compositions from Mass Peak Profiles of M, M+1 and M+2 Ions

Andrew H. Grange* and Joseph R. Donnelly
Lockheed Environmental Systems and Technologies, 980 Kelly Johnson Drive, Las Vegas, NV 89119
William C. Brumley and G. Wayne Sovocool

Mass peak profiles plotted from selected ion recording (SIR) data provide masses accurate to within 2.5 ppm for ions from trace components in complex mixtures. The number of elemental compositions with a mass within this error range increases rapidly with the ion's mass. At high mass resolution, 5 criteria for the M+1 and M+2 profiles are used to reject all but 1 composition.

Five criteria. At 20,000-25,000 resolution, interferences are usually separated from the M, M+1 and M+2 profiles. Four criteria, the relative abundances and masses of the M+1 and M+2 ions, are determined by using a split SIR descriptor to monitor across 60% of the M, M+1 and M+2 profiles simultaneously. The fifth criterion is the shape of the M+2 profile, which is observed using a SIR descriptor that monitors the full M+2 profile. SIR descriptors are prepared and data are processed by procedures written in Reflection™ 4.2, Lotus 1-2-3™ (2.2) and WordPerfect™ 5.1.

An example. An accurate mass of 423.2953 Da was obtained for an unknown compound in an environmental sample from a superfund site. Allowing up to 35 C, 74 H, 6 O, 6 N, 4 P, 4 S and 4 Si atoms and an error of ±2.5 ppm, 13 possible compositions were calculated. Of these, 5 were eliminated by invoking the nitrogen rule. The 8 remaining compositions are listed in Table I.

Table I. Error; M, M+1 & M+2 mass defects; relative abundances & ranges for 8 possible compositions

Error (ppm)	Composition	M	M+1		M+2	%M+1	%M+1 Range		%M+2	%M+2 Range		Shape M+2
-1.0	$C_{19}H_{45}O_4N_3Si_2$	.2949	.2969	x	.2937	30.2	(26.2-31.2)		8.8	(6.2-8.7)		x

+1.6	$C_{20}H_{40}NS$	.2960	.2992		.2980	32.5	(31.6-33.5)		6.0	(5.9-6.6)		

Hypothetical composition. A composition must be chosen before masses are calculated for the M, M+1 and M+2 profiles and used in a split SIR descriptor. After obtaining an M+2 profile, its shape and exact mass are compared to those predicted by the model to choose a hypothetical composition. If wrong, another composition with a similar M+2 profile will be identified as correct.

Model. A model was written in QuickBASIC™ and executed on a PC to calculate masses of M, M+1 and M+2 ions, estimates of the areas monitored by only 6 points about the center of the M, M+1 and M+2 profiles and a graphical representation of M+1 and M+2 profiles. The model also provides estimates of the range of %M+1 and %M+2 for the hypothetical and other compositions when the masses in the SIR descriptor are based on the hypothetical composition for shifts of ±5 ppm in the partial profiles' positions and ±10% changes in the resolution occur. The ranges also include the isotopic abundance errors possible for each element. The masses, relative abundances and their predicted ranges are listed in Table I at 21,400 resolution. An "x" next to an entry indicates that the criterion is useful for rejecting the composition based on an error of $\pm 2\sigma$.

Shape of the M+2 profile. In Figure 1 are shown M+2 profiles for 3 compositions from Table I calculated for 20,400 resolution. Each profile is plotted as the sum of contributions from all M+2 ions; those containing an M+2 isotope, two atoms of a single M+1 isotope or pairs of M+1 isotopes. The profiles for the compositions containing a S or Si atom are broad due to the large mass difference between the positive mass defect difference of ^{13}C vs ^{12}C and the negative mass defect differences of the M and M+2 isotopes (e.g., 2x0.00335-(-0.00420)=0.0109 Da for ions containing $^{13}C_2$ & ^{34}S). The shapes of the M+2 profiles shown are unique. The profiles obtained in Figure 2, acquired at (a) 20,400 and (b) 37,600 resolution, are similar to those predicted by the model (c) and (d) and identified the last composition as correct.

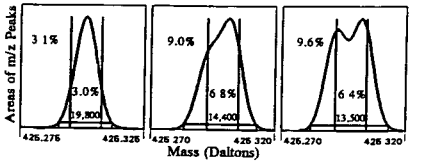

Figure 1.

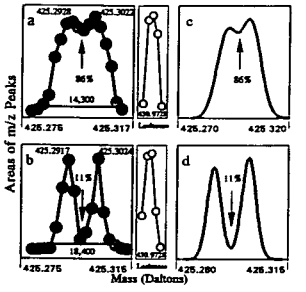

Figure 2.

Data. In Figure 3, partial profiles for the M, M+1, M+2 and PFK calibration ions plotted from SIR data acquired at (a) 10,100 and (b) 21,400 resolution are shown. After correcting the M+1 and M+2 masses for the error in the M mass, 1 and 3 compositions were rejected for falling outside the range of the observed M+1 mass ± 2.5 ppm at 10,100 and 21,400 resolution, respectively. Similarly, 4 compositions were rejected by the M+2 mass criterion at 10,100 resolution, but at 21,400 resolution, two maxima in the profile confused the issue.

In Figure 4 are plotted predicted ranges for (a) %M+1 and (b) %M+2 at 21,400 resolution for the 8 compositions. The dotted line marks the average %M+1 or %M+2 observed and the dashed box encloses 2σ. At 10,100 and 21,400 resolution, 5 and 7 compositions were rejected, respectively, by the %M+1 criterion. For the %M+2 criterion, 6 and 3 compositions were culled at 10,100 and 21,400 resolution.

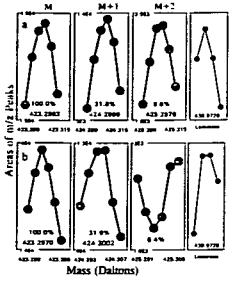

Figure 3.

Summarizing, at either resolution the correct composition was also identified by rejection of 7 of 8 compositions based on data acquired using the split SIR descriptor. Had another composition been correct, the 5 criteria would have confirmed the composition. These criteria can also be used to identify fragment ions.

Conclusion. Full and partial mass peak profiles plotted from data acquired with normal or split SIR descriptors at high mass resolution were used to identify the correct composition for a compound in a complex environmental extract. This technique is a valuable addition to the capabilities of double focusing mass spectrometers and is made possible by simple procedures executed on an ancillary computer.

DEVELOPMENT OF A MODERNIZED HRMS ENVIRONMENTAL METHOD FOR PCBS

J. R. Donnelly, A. H. Grange, G. R. Nichol, N. R. Herron,
J. L. Jeter, R. J. White, and W. C. Brumley*

Lockheed Martin-Environmental Systems & Technologies, 980 Kelly Johnson Dr., Las Vegas, NV 89119;
*U.S. Environmental Protection Agency (EPA), P.O. Box 93478, Las Vegas, NV 89193-3478.

The EPA Characterization Research Division at Las Vegas is developing a comprehensive screening and confirmatory method for monitoring PCBs, both as Aroclors and as individual congeners. About 130 PCB congeners are found in Aroclors.[1] This method includes extraction, extract cleanup, and analysis modules. Compatibilities of the modules are under investigation, and expected data quality and applicability for each technique will be included so researchers can select method features meeting cost, time, and data quality requirements.

Soxhlet, supercritical fluid (SFE), and accelerated solvent extractions (ASE) have been tested, and their performance characteristics have been determined. Both Soxhlet and the Dionex ASE™ provided high and reproducible recoveries. SFE required careful control of experimental variables, such as percent modifier (methanol) and cell temperature (not merely oven temperature), for adequate reproducibility. SFE also was less able to recover tightly-bound analytes from some soil matrices.

Carbon chromatographic cleanup procedures were elaborated with AX-21 (Anderson) and SK-4 (Alltech) to provide a chromatographic fraction enriched in the more toxic non-ortho and mono-ortho substituted congeners. Enrichment was realized with both types of carbon, however, SK-4 enabled a significant reduction in solvent usage.

The TCDD-like toxicity of an individual PCB congener is expressed as its toxicity equivalency factor (TEF) multiplied by its concentration in the sample. TCDD-like toxicity may be associated with structures that contain Cl atoms at both para positions, at least 2 meta positions and at no more than 2 ortho positions.[2] The 21 congeners suggested for TEF monitoring have assigned TEFs and are believed to contribute to TCDD-like toxicity in the Aroclors. Of these congeners, 14 have been found in human milk or blood serum.[3,4] The 21 congeners include three non-ortho substituted PCBs: 3,3',4,4' (#77); 3,3',4,4',5 (#126); 3,3',4,4',5,5' (#169); seven mono-ortho substituted PCBs: 2,3,3',4,4' (#105); 2,3',4,4',5 (#118); 2',3,4,4',5 (#123); 2,3,3',4,4',5 (#156); 2,3,3',4,4',5' (#157); 2,3',4,4',5,5' (#167); 2,3,3',4,4',5,5' (#189); and eleven di-ortho substituted PCBs: 2,2',3,3',4,4' (#128); 2,2',3,4,4',5 (#137); 2,2',3,4,4',5' (#138); 2,2',4,4',5,5' (#153); 2,3,3',4,4',6 (#158); 2,2',3,3',4,4',5 (#170); 2,2',3,4,4',5,5' (#180); 2,3,3',4,4',5,6 (#190); 2,3,3',4,4',5',6 (#191); 2,2',3,3',4,4',5,5' (#194); 2,3,3',4,4',5,5',6 (#205).

Congeners having IUPAC numbers 77, 126 and 169 are considered the most toxic, with TEFs of 0.01, 0.1 and 0.05, respectively. These congeners are present at trace levels in Aroclors and must be separated from interferences before they are quantified against carbon labeled standards. The separation of these congeners from mono-ortho and di-ortho PCBs was achieved as follows. The ortho congeners eluted in 20 mL of 2:1 CH_2CH_2:hexane from a 1 mL pipet packed with 60 mg of SK-4 carbon. The non-ortho congeners were then back-flushed off the

column with 20 mL of toluene. TEFs for the mono-ortho and di-ortho PCBs are 0.001 and 0.00002, respectively.

Immunoassay results using the Ohmicron RaPID™ PCB Assay kit were found to be comparable with GC-ECD results in the range 500 ppb to 100 ppm, when the appropriate Aroclor calibrator was used. A "decision tree" was developed to aid in Aroclor identification by low resolution mass spectrometry (LRMS). The LRMS detection limit for Aroclors was approximately 10 ppm. Linearity of response was verified to the level corresponding to 500 ppm in the sample.

A histogram-based technique was designed to allow visual Aroclor identification based on isomer-total areas. Automated high resolution mass spectrometry (HRMS) quantitations are conveniently based on areas of individual major peaks. Using HRMS, at least ten measurements are made across each chromatographic peak while using a 0.18 mm ID, 0.2 μm film, 40 m, RT_x-5 (or equivalent) GC column with an analysis time of under 50 minutes. Seven SIR descriptors are used to monitor 2 or 3 levels of chlorination each. Either non-labeled PCBs that are not found in Aroclors, or carbon-13 labeled standards may be used as internal standards. Most or all congeners should be quantitated against an internal standard within the same SIR window. For PCBs with three or more chlorines, two ion ratios from the molecular ion cluster are used for confirmation.

Validation of an HPLC-APCI-MS/MS Procedure for Diclofenac in Human Plasma

D. Thomas, S. Draper, H. Hill, M. Richards and J. Robson

Corning Hazleton, Otley Road, Harrogate, North Yorkshire, HG3 1PY, UK

Introduction

Diclofenac is a non-steroidal anti-inflammatory drug usually dosed at 75-100 mg/day. The drug is metabolized mainly via oxidative pathways followed by glucuronide conjugation. The resulting plasma levels are low, and therefore a sensitive and specific assay is needed to evaluate its pharmacokinetics.

In the present work, a method was developed and validated using high-performance liquid chromatography (HPLC) with tandem mass spectrometry (MS/MS) for the determination of diclofenac in human plasma following a single oral dose of 50 mg. The analytical procedure was validated according to current guidelines acceptable to international regulatory authorities i.e. inter- and intra-day precision and accuracy of calibration and quality control samples (QCs), stability to freeze/thaw cycles, stability at room temperature, recovery, sensitivity and specificity. Concentration of diclofenac in calibration standards and study samples was determined using least squares linear regression with a 1/x weighting factor to improve accuracy at low levels.

Experimental

Diclofenac and Indomethacin (used as internal standard) were purchased from Sigma. Standard solutions (1 mg/mL) of each analyte in methanol were used to fortify the calibration standards. A second set of solutions were prepared in the same manner and used to fortify the QCs. Control human plasma was obtained from Hazleton volunteers, pooled and used to prepare the calibration standards, QCs and plasma blank samples.

Extraction Procedure

Samples were removed from a freezer (-20°C), allowed to thaw at room temperature and mixed by vortex. Plasma (1 mL) was transferred to a borosilicate centrifuge tube and internal standard (50 μL, 10 μg/mL) added. Orthophosphoric acid (4 mL, 2.5 M) and hexane/IPA (5 mL, 90:10) were added and the tubes capped and mixed on a horizontal shaker. After mixing, the tubes were centrifuged for 5 min. The aqueous layer was frozen in dry ice/acetone and the upper organic layer transferred to a clean tube. The samples were evaporated to dryness under a stream of N_2 at 35°C. The extracts were dissolved in mobile phase (150 μL) and submitted for analysis.

HPLC-MS

HPLC-MS/MS quantitation was performed using a Perkin Elmer Series 400 LC pump, with a Perkin Elmer ISS 200 Autosampler. Aliquots (100 μL) of extract were injected onto a reversed phase column (10 mm x 4.6 mm i.d. with 3 μm particle size) and eluted with methanol:acetonitrile:water at a flow rate of 1 mL/min. The eluent from the column was conveyed into a SCIEX API *III* triple quadrupole mass spectrometer equipped with an APCI source. Mass spectra were acquired in the positive ion mode with the heated pneumatic nebulizer interface at a temperature of 480°C, the nebulizer pressure (UHP N_2) at 80 psi, a make-up flow of 1.5 L/min of UHP N_2, and the corona discharge needle maintained at a current-controlled 3 μA discharge. For the MS/MS experiments, Ar collision gas was used at a target thickness of 300 atoms/cm^2. The (laboratory frame) collision energy (nominal) was 10 eV for the singly charged ions studied here. The mass spectrometer was operated in the multiple reaction monitoring (MRM) mode with a dwell time of 100 ms per channel for diclofenac and the internal standrd.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Results

Calibration Curve

Calibration curves were obtained using the ratio of peak areas for the analyte and IS using a linear regression with a 1/x weighting factor over the concentration range 10 - 1000 ng/mL.

Specificity and Sensitivity

The chromatograms of six samples of control matrix from different individuals were examined, and the regions in the chromatograms corresponding to the retention time of the analyte and the internal standard checked for interferences. From these experiments, no interferent compounds were found in any of the control plasma samples analysed. Sensitivity (the lower limit of quantification (LLOQ)) was set at the concentration of the lowest calibration standard (10 ng/mL).

Recovery

Recovery was assessed using six replicates at each of the three QC levels used for the study. The peak areas of extracted samples were compared with the peak areas of direct injections of pure standards containing equivalent amounts of analyte and internal standard. The recovery of diclofenac from human plasma was approximatley 90% over the concentration range studied.

Stability

The stability of diclofenac was evaluated under various conditions: 1, 2, 3 freeze/thaw cycles; 1, 4, 24 h storage; stability of extracts in the autosasmpler. No apparent degradation of diclofenac was evident up to 3 f/t cycles or after storage described above.

Intra- and Inter-Day Validation

The procedure was validated as follows:-

Intra-Day - 1 x calibration standards, 6 x QC samples, 6 x matrix blanks from different individuals, 6 x calibration samples, matrix blank + IS, 2 x high standards and 2 x blanks to assess carry over, and a reagent blank.

Inter-day - 1 x calibration standards, 6 x QC samples, matrix blank, matrix blank + IS, reagent blank.

Intra-day precision of the calibration standards was determined from the coefficients of variation of the observed concentrations at each level. Intra-day precision of the calibration standards ranged from 13.2% at 10 ng/mL to 5.6% at 1000 ng/mL. Carry over was assessed by analysing blanks immediatley following high calibration standards and was found to be negligible.

Inter-day precision of the calibration standards and the quality control samples was determined from the coefficient of variation of the observed concentrations at each level from the three inter-day batch runs and from the intra-day validation. Inter-day precision for the calibration standards varied from 16.3% at the 10 ng/mL level to 3.0% at the 900 ng/mL level. Accuracy for the calibration standards ranged from 96.6 - 106.0% over the concentration range. The mean coefficient of determination of the inter-day calibration curves was 0.997905. The inter-day precision of the quality control samples was 6.7% at 30 ng/mL, 12.8% at 200 ng/mL and 6.7% at 800 ng/mL. Inter-day accuracy of the quality control samples was 109% at 30 ng/mL, 108% at 200 ng/mL and 95.6% at 800 ng/mL.

Conclusion

The method described was validated to current internationally accepted criteria and is capable of quantitating diclofenac in plasma which allows its pharmacokinetics to be described following a single oral dose of 50 mg to man.

Effects of Solution Additives and Denaturants on Peptide and Protein Electrospray Ionization Mass Spectrometry

Y. Smelyanskiy, R. R. Ogorzalek Loo, and P. C. Andrews
University of Michigan, Department of Biological Chemistry, Ann Arbor, MI 48109

Frequently detergents, urea or other additives are added to proteins to solubilize them and it is not always possible to avoid their use. Denaturants such as urea and formamide can be used to probe protein structure (e.g., in stability studies). It is of interest to understand the effects of these denaturants on charging and whether these reagents can be effectively used in conjunction with ESI-MS to probe protein conformation. We examine a practical issue: how much of a particular additive can be tolerated in electrospray ionization mass spectrometry (ESI-MS), and a fundamental issue: how do these additives affect charging.

Urea has a reputation for destroying protein signals in mass spectrometry, but its reputation may be overly tarnished, at least where ESI is concerned. We have employed urea to obtain spectra from inclusion bodies, formed when overexpressed proteins precipitate in the cell. Urea's performance with a standard protein is illustrated in Figure 1. Figure 1a was obtained with a 6 pmol/μL solution of myoglobin in 4% acetic acid/50% acetonitrile. Figures 1b and 1c were obtained under the same conditions, but with 0.1 M and 1.0 M urea, respectively. Note the reduction in ion signal, as well as the shift to lower charging with urea. Ion intensities and charging were reduced similarly when urea was added to hemoglobin and ubiquitin in 4% acetic acid/50% acetonitrile. Reduced charging in the presence of urea is also observed for peptides.

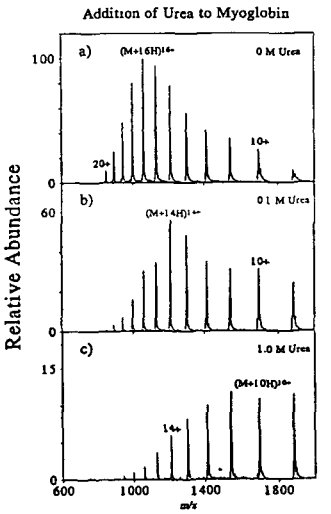
Charging is already reduced when ubiquitin or cytochrome *c* is sprayed from 100% H_2O relative to that observed when either protein is sprayed from 4% acetic acid/50% acetonitrile. When urea is added to a 100% aqueous solution, surprisingly no shift to higher charge was observed for either protein, even at up to 5 M urea. We had expected denaturation with its concomitant higher charging. It is possible that urea denaturation does not display higher charging for these proteins. Alternatively, the proteins may not have denatured in 5-6 M urea; other techniques must be applied to determine the protein conformation under these conditions. Still another possibility is that the urea breaks down to ammonia in the heated ion source. Gas phase proton transfer from the highest charge states to ammonia would yield similar spectra. Further studies were performed with formamide. Concentrations up to 1 M did not shift charge distributions for hemoglobin sprayed from 4% acetic acid/50% CH_3CN in contrast to the urea studies. Either formamide decomposes less to ammonia than urea or another explanation must be found.

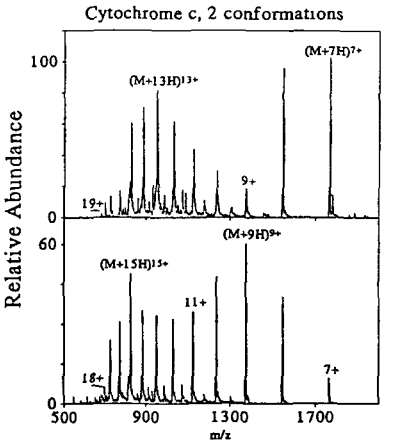
Myoglobin spectra were acquired in 5 mM NH_4OAc/H_2O, showing the heme-associated (*holo*) protein. Addition of formamide denatured the protein, yielding at least 2 forms, the *holo*-protein and the *apo*-protein (without heme). Higher charging was observed in the presence of formamide for both *apo*-myoglobin and *holo*-myoglobin, probably reflecting the denaturation.

ESI mass spectra obtained following addition of the nonionic saccharide surfactant n-hexyl glucoside at 0%, 0.01%, and 0.1% (w/v) to a solution of horse heart cytochrome *c* in H_2O showed increased charging as the amount of surfactant increased. Increased charging is general to nonionic saccharide surfactants for concentrations below and above surfactant

CMC's. Thus, the increased charging appears not to be a consequence of micelle formation or of its absence. Because surface tension does not continue to decrease with increasing concentration for concentrations exceeding a surfactant's CMC, the charge shifts cannot be attributed solely to surface tension effects, either.

It was demonstrated that the charge shift induced by addition of nonionic saccharide surfactants is not a consequence of protein unfolding, by examining solutions yielding 2 conformations (Figure 2). If the surfactant addition caused the analyte protein to unfold, the bimodal conformation would have collapsed to a single, high charge state distribution. Instead, the surfactant caused charge shifts without regard to higher order structure; both portions of the bimodal charge envelope shifted to higher charge (lower *m/z*). Circular dichroism studies have also provided no indication of denaturation for cytochrome *c* and ubiquitin in nonionic saccharide surfactant solutions.





Desolvation of Noncovalently-Bound Complex Ions for ESI-MS Analysis

Joseph A. Loo, Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, 2800 Plymouth Road, Ann Arbor, MI 48105

Rachel R. Ogorzalek Loo, Department of Biological Chemistry, University of Michigan, Ann Arbor, MI 48109

INTRODUCTION. The gentleness of electrospray ionization (ESI) has allowed MS to detect several examples of noncovalently-bound complexes. To preserve the proper protein conformation and/or complexation upon transfer from solution to the gas phase, ESI of aqueous solutions is often necessary. Although the ESI process depends on efficient desolvation of the highly charged droplets prior, it is sometimes difficult to completely remove *all* solvent molecules from the protein complex ions without affecting the gas phase complex (i.e., dissociation of the complex may occur). The resulting mass spectra can show variable amounts of solvation, depending on several experimental factors, such as collisional activation in the atmosphere/vacuum interface, drying gas flow rate and temperature, pressure in the high vacuum region, and ESI needle position.

EXPERIMENTAL. ESI-MS analyses were performed with a Finnigan MAT 900Q (EBqQ) mass spectrometer equipped with a PATRIC focal plane array detector. An ESI interface based on a heated glass capillary inlet was used. Droplet desolvation was aided by a countercurrent stream of warm nitrogen and by collisions in the interface controlled by adjustment of the voltage difference between the tube lens at the metalized exit of the glass capillary and the first skimmer element (ΔV_{TS}).

RESULTS AND DISCUSSION

Effect of Nitrogen Countercurrent Flowrate. For many ESI interfaces, the use of a gas flow (e.g., N_2) countercurrent to the electrospray axis is necessary for efficient ion desolvation. The N_2 flowrate can influence not only ESI sensitivity, but also the amount of solvation observed for the multiply charged ions, especially for ESI of aqueous solutions. For avidin, a 64 kDa tetrameric protein, peaks for the protein tetramer are broad and shifted to higher *m/z* than expected with the N_2 flowrate of 2.5 L min^{-1}. Increasing the N_2 flowrate to 10 L min^{-1} produces sharper peaks and shifts the peaks to lower *m/z*, consistent for more desolvated ions.

Effect of Energetic Collisions and Pressure in the ESI Interface. Optimizing the voltage difference between the various lens elements in the vacuum region of the ESI interface is critical for removing remaining solvent molecules from the ions. Solvated ions can also be desolvated by increasing the pressure in the vacuum region of the interface. Residual solvation can be effectively stripped from the molecules with only a slight loss in sensitivity (factor of ~ 2).

Effect of Electrospray Position. The position of the electrospray source can also influence the amount of solvation observed for the protein ions. Optimum sensitivity with our system for the myoglobin complex (16.9 kDa polypeptide noncovalently-bound to heme) is achieved with the spray situated ca. 5.2 degrees "off-axis" (off the axis of the capillary inlet). Directing the ESI source "on-axis" results in very broad peaks and an increase in low *m/z* background ions. The use of an on-axis electrospray results in "wet" ions because larger droplets are sampled by the MS inlet. Similar results were obtained for trypsin (23.3 kDa) complexed with an inhibitor (BPTI, 6.5 kDa).

Spray conditions also play a role in the analysis of peptide mixtures. For an equimolar mixture of two similar mass peptides, $P(K_2G)_9K_2$ and dipalmitoyl-$K(KG)_{13}K$, high flow rates and on-axis spraying favor desorption of the surface active peptide (the dipalmitoyl-modification is extremely hydrophobic, making the dipalmitoyl-peptide surface active). Lower ESI voltages and lower countercurrent desolvation flows also favor desorption of the dipalmitoyl-peptide. All of these conditions yield larger droplets.

Solvation Shielding Effect? The amount of dissociation of the noncovalently-bound complex observed in a mass spectrum is affected by a variety of factors, including the solvation state. Figures 1 and 2 compares the effect of increasing ΔV_{TS} at two different spray angles for myoglobin. Starting off with "wet" ions and subjecting them to energetic collisions results in less solvated ions for the myoglobin complex (Fig. 1). Starting with "dry" ions and subjected them to the same energy collisions results in dissociation of the complex (Fig. 2). *Solvation can act as a shield around the protein complex, "protecting" them from further dissociation in the ESI interface.*

CONCLUSION. For a more accurate molecular weight determination of protein complexes, efficient desolvation is required. Solvated ions can yield higher mass values than expected. However, there is a fine balance in experimental conditions for producing desolvated complex ions versus the dissociated complex. Careful control of all experimental factors affecting droplet/ion desolvation is necessary for successful detection of weakly-bound complexes by ESI-MS.

c Analytical Research and Development, Pfizer Central Research, Sandwich, Kent, UK.

We are interested in the use of cyclodextrins (CDs) as chiral selectors in capillary electrophoresis (CE) and HPLC. We have studied the chiral separation of tioconazole using these techniques, and determined the binding constants for the complex[1]. Tioconazole is a racemic pharmaceutical, used in the topical treatment of fungal infections. Tioconazole has been shown by NMR to form a 1:1 complex with CD. When tioconazole was analyzed in solution with α-, β- and γ-CD by ESI-MS, host-guest complexes were observed in each case (Figure 1). For each CD, the fraction complexed was calculated from the ratio of the peak height of the complex to the sum of the heights of the complexed and free CD. In Figure 1 these are 0.28, 0.53 and 0.73 for α- β- γ-CD respectively. This implies an order of binding strength of $\alpha > \beta > \gamma$.

CE is an analytical technique in with ionic species in solution are separated according to their mobilities, μ. When there is a dynamic equilibrium, μ is the weighted average value of the bound and unbound forms of the analyte. The mobility of tioconazole was measured with 5 mM of α- β- and γ-CD in the background electrolyte This provides a measure of the extent of binding in the liquid phase, for comparison to the mass spectrometry data With no cyclodextrin in the background electrolyte the mobility was 1.18×10^{-8} $m^2 V^{-1} s^{-1}$. With α-, β- and γ-CD the mobilities were 1.04×10^{-8} $m^2 V^{-1} s^{-1}$, 0.83×10^{-8} $m^2 V^{-1} s^{-1}$ and 0.71 10^{-8} $m^2 V^{-1} s^{-1}$ respectively. The order of mobilities CE therefore agrees with the ratios observed in the mass spectrometer. This provides strong evidence that we are, indeed, observing true inclusion complexes and not just associations in the gas phase.

Mass spectra were collected at constant tioconazole concentration (1.1 mM) and varying β-CD concentration (0.5 mM to 1.9 mM), and the peak height of tioconazole was measured. By only monitoring this single species, differences in the ionization efficiency of the complex could be ignored. The peak height of tioconazole diminished with increasing β-CD concentration. The concentration of the complexed and free β-CD was then calculated using mass balance, and used to estimate K, the binding constant. The average binding constant of the complex from the data points was found to be 230 ± 50 M^{-1}. Binding constants from CE for a 50:50 aqueous:methanol buffer were calculated to be 68 ± 1 M^{-1}. From previous work[1] it is known that the binding constant of the tioconazole:β-CD complex increases with decreasing methanol content. Therefore can we postulate that at the time of expulsion of the complex from the droplet, the composition of the droplet was 25 % methanol?

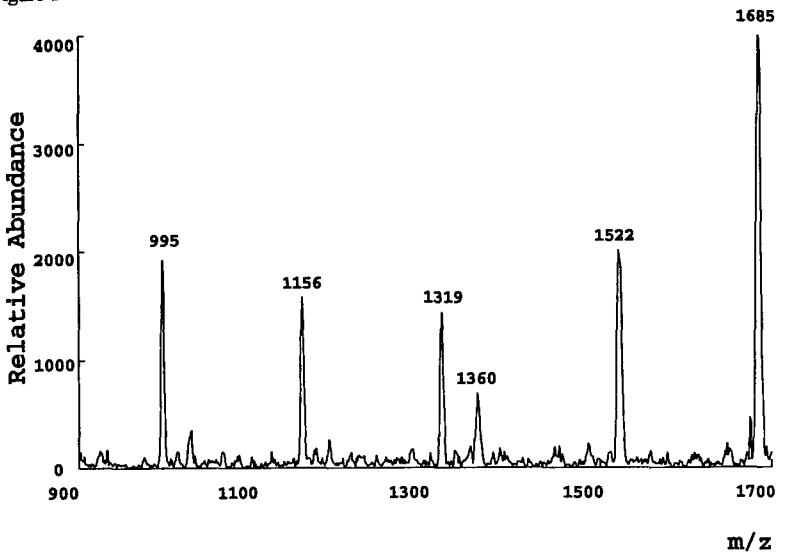
43rd ASMS Conference on Mass Spectrometry and Allied Topics

Figure 1



Electrospray ionization mass spectrum of tioconazole (6 5 mM) with equimolar quantities of α-, β- and γ-CD (1.0 mM) in a 50 50:1 water:methanol:acetic acid solution. Mass assignments given in table below.

Mass	Assignment
995	$[\alpha\text{-CD} + Na]^+$
1156	$[\beta\text{-CD} + Na]^+$
1319	$[\gamma\text{-CD} + Na]^+$
1360	$[\alpha\text{-CD} + \text{tioconazole} + H]^+$
1522	$[\beta\text{-CD} + \text{tioconazole} + H]^+$
1685	$[\gamma\text{-CD} + \text{tioconazole} + H]^+$

Non-Covalent Complexes formed between Acyl CoA Binding Protein and CoAs

Carol V. Robinson, Birthe Kragelund, Jens Knudsen,
Robin T. Aplin and Christopher M. Dobson
Oxford Centre for Molecular Sciences,
South Parks Road, Oxford, OX1 3QT, UK.

Introduction

Acyl coenzyme A binding protein (ACBP) is an 86 residue protein present in a wide range of eukaryote organisms. Since the protein binds long chain acyl-coenzyme A esters (acyl CoAs) with high affinity, it is thought to have a role in the transport and storage of acyl CoAs in the cell. The protein and acyl CoA associate by electrostatic and non-polar interactions and have been the subject of an investigation by NMR.(B.B. Kragelund *et al* ,.J. Mol. Biol. 1993, **230**, 1260-1277).

The non-covalent complexes formed between ACBP and a variety of acyl CoAs have been studied by electrospray ionization mass spectrometry (ESI MS). Whilst initial experiments clearly demonstrate an interaction between the protein and its non-covalent CoA ligand a number of control experiments were used to examine the specificity of the interaction.

Results and Discussion

The following experiments were used to study the interaction between the binding protein and its ligand:

(1) Increasing the ratio of ligand to protein from 1:1 up to 1:10.

(2) Denaturing the protein or disrupting the complex using heat, organic solvent or a high voltage difference between the needle and skimmer.

(3) Varying the binding affinity of the ligand.

(4) Monitoring the hydrogen exchange of the *apo* and *holo* proteins.

(5) A competition experiment in which a mutant protein which lacks a critical residue involved in the binding interaction is mixed in a 1:1 ratio with the wild type protein and the CoA ligand added to the protein mixture.

In the first control experiment the effect of increasing the ratio of the ligand to the free protein was examined using a stepwise increment from 1:1 to 1:10. In all cases increased amounts of the complex were observed with increased concentrations of the ligand. This observation suggests that even with the high binding affinity of the palmitoyl CoA ligand, K_D = 0.5+/-0.2x10^{-13}M, dissociation in the gas phase is a relatively

facile process. Furthermore, increasing the concentration of the ligand in the electrospray droplets increases the probability of observing the complex.

In the second experiment 50% acetonitrile was added to the aqueous solvent to denature the protein and the interface heating increased to 50C. Under these conditions no complex was observed in the ESI mass spectrum indicating that the tertiary structure of the protein is indeed required for observation of the complex.

Further evidence for the preservation of tertiary structure was obtained from hydrogen exchange kinetics. If a fully deuterated sample of ACBP and a deuterated complex formed between ACBP and an acyl CoA ligand are diluted into water at pH 5 and the hydrogen exchange kinetics monitored over a period of 10 hours, increased protection from exchange is observed for the complexed protein. This increase in protection from exchange was observed for both the palmitoyl and the octanoyl CoA ligands (K_D=0.2+/-0.1x10^{-6}M) and was not found to differ despite the large difference in binding affinities measured for these two ligands in solution.

If the electrospray mass spectrum was a reflection of the situation in solution it would be predicted that a mixture of acyl CoAs added to the protein would yield a complex for the highest binding affinity CoA. However, addition of a 1:1:1 mixture of CoAs with ACBP gave rise to complexes for all three acyl CoAs despite their widely differing binding constants. This result was surprising and indicated a lack of specificity in complex formation or some interaction between the CoAs. However, if a mutant of ACBP is prepared in which the essential tyrosine residue is mutated for an asparagine residue and mixed with the wild type protein a molar equivalent of palmitoyl CoA added; the complex is only observed for the wild type protein. This is in complete agreement with observations in solution.

Conclusion

The observation of the intact complex and the increased hydrogen exchange protection, detected for the *holo* protein in comparison with the *apo* protein, indicate that the ligand is indeed in the correct binding site of the protein. However, the lack of specificity observed for the different acyl CoA ligands suggests that the complex in the spectrum is not a reflection of the relative binding affinities of the ligands but infers some non-specific association or interaction of the ligands in the mixture. Nevertheless, the lack of a complex for the mutant protein indicates some specificity. Further work will establish if the observations made on this system are applicable to the study of a wider range of non-covalent complexes by ESI MS.

An Iron Carboxylate Oxygen-Centered-Triangle Complex Detected During Use of "TFA-Fix": A Comment on the Finnigan TSQ-700 Electrospray Inlet System

Carl F. Ijames, Robert C. Dutky*, and Henry M. Fales*

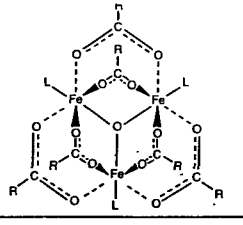
Section on Analytical Biochemistry, Laboratory of Clinical Science, National Institute of Mental Health, and * Chemical Structure Section, Laboratory of Biophysical Chemistry, National Heart, Lung, and Blood Institute, Bethesda, Maryland 20892

The deleterious effect of small amounts of hydrochloric, sulfuric, phosphoric, and especially trifluoroacetic acid (TFA) on electrospray mass spectra of basic compounds such as peptides is well known, although its cause is still a matter for some speculation. With TFA the effect is particularly unfortunate since many of the most useful HPLC systems rely on this additive. Apffel et al. (abstracts # 642 and #772, Proceedings of the 42nd ASMS Conference on Mass Spectrometry and Allied Topics, Chicago, Illinois, May 29-June 3, 1994, Hewlett-Packard "Ion Notes", **1994**, 9, #2, 4-5) reported last year that addition of a solution of 75:25 propionic acid-isopropanol ("TFA-Fix"), added one-third by volume post-column via a mixing tee at a total flow rate of 300 μL/min before the pneumatic nebulizer nozzle, increases by 15-30 fold the signal of basic compounds (peptides and alkaloids) whose signals had been drastically reduced by 0.1-0.2% TFA.

We attempted to extend the technique to simple infusion analysis of peptides at low flow rates (1-3 μL/min) by adding the ingredients of "TFA-Fix" to peptides prior to analysis. After tuning our triple quadrupole instrument with a standard mixture of 5 μM equine apomyoglobin and 20 μM MRFA in 50% aqueous methanol containing 0.5% acetic acid, we observed the not unexpected loss of maximum apomyoglobin signal by a factor of 19 and MRFA by 13 after addition of TFA to a final concentration of 0.1%. Addition of 25% v/v of "TFA-Fix" reduced the signal loss of apomyoglobin to a factor of 14 even though the degree of adduct tailing became severe. The effect of "TFA-Fix" on the MRFA component of the tuning solution was impressive, actually increasing its intensity by a factor of 1.8 over the original solution. However, an intense peak was noted at m/z 622 and inspection of its isotope pattern suggested it contained three atoms of iron. This was confirmed by mass measurement on an FTMS instrument yeilding 621.9722 ($C_{18}H_{30}O_{13}Fe_3$). The presence of at least 4 propionoxy groups in the cluster is clear from its fragmentation pattern in the TSQ. Six propionoxy groups would account for twelve of the oxygen atoms while the presence of the extra oxygen suggests the ion at m/z 622 is derived from a "basic iron carboxylate" as shown in structure **1**. These compounds are known as "oxygen centered triangles" since their three metal atoms and lone oxygen form a nearly planar triangular unit, and they have the general formula $Fe_3O(O_2CR)_6(L)_3$ where L is a ligand such as water or pyridine. They are thought to have relevance to the ferritin iron storage protein. When acetic acid was substituted for propionic acid in the above experiment an analogous ion formed at m/z 538. As the tube lens-skimmer potential

was reduced from 66 to zero volts, ions containing up to three acetic acid ligands replaced m/z 538 as expected for its structure. Similar results were obtained with a wide variety of other cosolvents including water, acetonitrile, and tetrahydrofuran all of which adducted in combinations with the carboxylic acid totalling three molecules of ligand. The intensity of these adducted ions is affected not only by reduction of the tube lens potential, but also by the presence of auxiliary gas in the spray region. The ion is most likely derived from dissolution of iron from the stainless steel needle surrounding the fused silica capillary, either by direct or subsequent reaction with the carboxylic acid. The inlet system of our Finnigan TSQ-700 spectrometer regularly produces a more conventional electrolytic process which greatly exceeds the true electrospray current. Indeed, the current displayed on the computer terminal is actually a combination of the true electrospray current plus a conventional electrolysis current running back through the solvent-filled fused silica capillary to the grounded stainless steel fitting. When the grounding connection is removed from the stainless steel fitting virtually no current is observed even in the presence of a strong electrospray ion signal since the first small division on the software current display represents 0.32 μA, which greatly exceeds the true electrospray current. With the ground connection in place as recommended by Finnigan, solutions of moderate conductivity supply an erratic ion signal and spray due to formation of hydrogen gas bubbles by electrolysis of the solution at the grounded fitting We now routinely operate with the ground connection removed, although this presents a safety concern when the high voltage is on.

Returning to the evaluation of "TFA-Fix" for the infusion electrospray of peptides, we analyzed a 50 μM solution of a mixture of peptides (angiotensin I, angiotensin II, physalaemin, aprotinin, and insulin) in 50% aqueous methanol. As with the tuning solution, making this solution 0.1% in TFA reduced the average signal (sum of all intensities) by a factor of ~69. Addition of 25% by volume of the "TFA Fix" solution increased the signal strongly so that it was now only reduced by an average factor of 2.3 from the original, confirming the results of Apffel et al. Addition to the TFA solution of the same volume of a 1:1 mixture of methanol and acetic acid was not as effective as "TFA-Fix", and the signal was still reduced by a factor of 28 from the original intensity (not shown).



Electrospray of Borane Salts; High Molecular Weight Clusters and Reactions

Cornelis E.C.A. Hop,* Dovas A. Saulys and Donald F. Gaines, Department of Chemistry, University of Wisconsin-Madison, 1101 University Avenue, Madison, WI 53706.

The recent development of electrospray ionization (ESI) has revolutionized the biochemical applications of MS. In comparison, much less attention has been paid to the use of electrospray for analysis of inorganic compounds. Here,[1] we will demonstrated that ESI is a valuable technique for identification of borane salts, which cannot be analyzed with conventional MS ionization methods such as EI, CI and liquid SIMS.

A VG AutoSpec triple sector (EBE) mass spectrometer equipped with the mark II ESI source was operated in the - or + ion mode. The samples were dissolved in CH_3CN, CH_3OH, H_2O or THF (200 ng.μl^{-1}) and the flow rate was 15 μl.min^{-1}. All experiments were performed with a resolution of 1,250 to obtain maximum signal strength. N_2 was used as both the nebulizer gas and the bath gas. The following borane salts were examined: $[(Me)_4N][B_3H_8]$, **I**; $Cs[B_3H_8]$, **II**; $Na[B_{10}H_{13}]$, **III**; $[Ph_3PMe][B_{11}H_{14}]$, **IV**; $[Ph_3PMe][B_{11}H_{13}\text{-}C_6H_{13}]$, **V**; $Na_2[B_{12}H_{12}]$, **VI**. The ^{11}B NMR spectra of these compounds showed only resonances attributable to the cations and/or anions.

The most remarkable feature of the - ion mode ESI mass spectrum of $[(Me)_4N][B_3H_8]$, **I**, in CH_3CN is the extensive clustering displayed by **I**. Up to 1,000 Dalton all signals correspond to cluster ions having the formula $[C_{x-1}A_x]^{1-}$ (C = cation; A = anion). Indeed, the observed isotope patterns of these signals match the calculated patterns. Above m/z 1,000, multiply charged ions are visible and the onsets of the various charge states are listed below.

charge	2-	3-	4-	5-
m/z	1015	1454	1903	2425
composition	$[C_{17}A_{19}]^{2-}$	$[C_{37}A_{40}]^{3-}$	$[C_{65}A_{69}]^{4-}$	$[C_{104}A_{109}]^{5-}$

In contrast, the - ion mode ESI mass spectrum of $Cs[B_3H_8]$, **II**, in CH_3CN shows mainly singly and doubly charged cluster ions; the first doubly charged cluster ions are observed at m/z 1688 ($[C_{19}A_{21}]^{2-}$). Thus, the onset of doubly charged cluster ions in terms of the number of $B_3H_8^-$ units is similar for **I** and **II**. The + ion mode ESI mass spectra of CH_3CN solutions of **I** and **II** are compatible with those obtained in the negative ion mode. Again, the most remarkable feature of the spectra is the formation of singly and multiply charged cluster ions; the onsets of the various charge states for **I** are listed below.

charge	2+	3+	4+
m/z	1049	1488	2052
composition	$[C_{19}A_{17}]^{2+}$	$[C_{40}A_{37}]^{3+}$	$[C_{73}A_{69}]^{4+}$

The + mode ESI mass spectrum of a CH_3CN solution of **II** shows mainly singly and doubly charged cluster ions; the first of the doubly charged cluster ions is observed at m/z 1954 ($[C_{23}A_{21}]^{2+}$). Thus, again the onset of doubly charged cluster ions in terms of the number of $B_3H_8^-$ units is similar for **I** and **II**.

The + ion mode ESI mass spectra of the CH_3OH solutions of **I** and **II** differ substantially from those of the corresponding CH_3CN solutions: cluster ions containing B_3 units are not present in these spectra! (Degassing the solution with Ar prior to use did not change the spectra, implying that the presence of residual O_2 is irrelevant.) Since ^{11}B and ^1H NMR spectra clearly indicated that the methanol solutions of **I** and **II** are stable and pure, an electrochemical reaction during the ESI process is implied. To resolve this issue, we removed the electrospray needle

assembly from the source [2] and collected an electrosprayed CH_3OH solution of **II** in a flask mounted around the needle. The CH_3OH was then pumped away and the residual solid was dissolved in CD_3OD. The NMR spectrum of the latter solution exhibits resonance positions corresponding to the presence of $B(OCH_3)_4^-$ (37 molar %) as well as $B_3H_8^-$ (63 molar %). Complete conversion of $B_3H_8^-$ into $B(OCH_3)_4^-$ under ESI conditions explains all signals observed in the + ion mode ESI mass spectra of the CH_3OH solutions of **I** and **II**. Differences in nucleophilicity and/or basicity alone are insufficient to rationalize the observed reactivity; more specific aspects of the solvents must be invoked. As the hydrogen atoms in the borane anions are negatively polarized with respect to the boron atoms, protic bases, such as CH_3OH, are capable not only of nucleophilic attack on boron, but also of concurrent elimination of H_2, a pathway not available to aprotic reagents, such as CH_3CN.

The - mode ESI mass spectra of CH_3CN solutions of $[Ph_3PMe][B_{11}H_{14}]$ (**IV**), $[Ph_3PMe][B_{11}H_{13}\text{-}C_6H_{13}]$ (**V**) and $Na_2[B_{12}H_{12}]$ (**VI**) and a THF solutions of $Na[B_{10}H_{13}]$ (**III**) gave spectra characteristic for the borane salts, even though some of these borane salts are extremely air sensitive. The borane anions as well clusters of these anions with the corresponding cations were observed. The - mode ESI mass spectrum of $Na_2[B_{12}H_{12}]$), **VI**, in CH_3CN is presented below; the onsets of the various charge states (2-, 3-, 4-, 5-, 6- and 7-) are indicated. The most intense signals are due to $[B_{12}H_{12}]^{2-}$ and $\{Na[B_{12}H_{12}]\}^{1-}$. Cluster ions with a charge of 6- or 7- are clearly visible. The enhanced ability of cluster ions from **VI** to support negative charges correlates with the larger size of the closo $[B_{12}H_{12}]^{2-}$ anions in **VI** compared to the arachno $[B_3H_8]^{1-}$ anions in **I** and **II**.

In conclusion, we have shown that electrospray is a valuable technique for identification of borane salts. However, it is crucial to consider the influence of various experimental parameters (e.g. the solvent) on the electrospray mass spectra.

COMPARISON OF ESI AND LSI MS/MS IN THE ANALYSIS OF NEWBORN BLOOD SPOTS

Donald H Chace, Steven L. Hillman, David S Millington, Robert D. Stevens
Duke University Medical Center, MS Facility, RTP, NC, USA

Analysis of amino acids and acylcarnitines by liquid secondary ionization MS/MS (manual introduction FIB) has previously been shown to be a simple, rapid, accurate, and reliable method for the early detection of numerous metabolic diseases (Chace et al ASMS '93 & '94). Much of the sample preparation has been successfully automated using simple, commercially available equipment. Automation of the MS/MS analysis using dynamic LSI MS/MS (Flow FIB) for amino acids was achieved. However, this method was seriously compromised by sample retention, sample carry-over, frequent cleaning of the probe tip and difficulty maintaining reproducible conditions Electrospray ionization offers the potential to overcome many of these problems. A preliminary investigation of the ability of electrospray ionization to attain full automation of these analyses for newborn blood spots is presented as well as a quantitative comparison of acylcarnitine and amino acid profiles by ESI MS/MS with LSI MS/MS.

Filter paper blood spots from normal patients (newborns or adults) were used in this comparative study Sample preparation consisted of extracting two 3/16" diameter filter paper blood spots with 400 µL of methanol containing 13 stable isotopically enriched (99 9%) internal standards (9 amino acids and 4 acylcarnitines) and esterifying with 3N HCl in *n*-butanol at 65°C for 15 min For the comparison study of static LSI MS/MS and ESI MS/MS, 10 control blood spots were prepared These samples were split into two aliquots and either 35µL of 50:50 methanol:glycerol + 0 1% Na-Octylsulfate (LSI) or 50-100µL of 50:50 acetonitrile:water + 0.02% Formic acid (ESI) was used For comparison studies of dynamic LSI MS/MS with electrospray, random blood spots for each analysis were used. A VG Quattro I fitted with a Cesium Ion gun was used to analyze samples by LSI. A VG Quattro II was used to analyze samples by ESI. An amino acid profile (*m/z 125-300)* was obtained by each tandem mass spectrometer using the neutral loss (NTL) of 102 amu scan function An acylcarnitine profile (*m/z 250-550)* was obtained by each tandem mass spectrometer using the parents (PAR) of 85 amu scan function A Gilson 231 automated sample injector fitted with an interchangeable low dispersion Rheodyne loop (1, 2 or 5µL) was used for automated analysis An ISCO Model 500D syringe pump delivered solvent at 10 -15 µL/minute.

Acylcarnitine profiles obtained by ESI MS/MS and LSI MS/MS are presented in Figures 1a and b. A comparison of amino acids produces similar results (see accompanying ASMS poster, Chace et. al) This comparison of acylcarnitine and amino acid profiles by LSI and ESI MS/MS shows that these modes of ionization produce similar results. Different absolute intensities of many amino acids and acylcarnitines are observed. However, there are few differences in the intensities of specific amino acids or acylcarnitines relative to their internal standards. Detection of long chain fatty acylcarnitines (C14-C18) is approximately 10 fold greater by ESI. Higher molecular weight amino acids are better detected in ESI whereas lower molecular weight amino acids are better detected using LSI. Automated analysis of 60 blood spots is significantly better by ESI. Using ESI, the sample analysis time is 1 sample per minute versus 1 sample per 2 minutes using dynamic LSI. Excellent peak shape and sensitivity were maintained throughout the ESI analysis. Good sensitivity for the detection of amino acids was observed using both ionization modes. A satisfactory acylcarnitine analysis by dynamic LSI could not be achieved because of low sensitivity.

The analysis of newborn blood spots using electrospray ionization compares well with static (manual) LSI and is superior to dynamic LSI. Each method produces similar qualitative and quantitative data in normal patients. We have demonstrated that electrospray ionization clearly

offers the potential to fully achieve automated analyses of blood spots for amino acids and acylcarnitines Other improvements of the assay, such as increased sensitivity of diagnostically important long chain acylcarnitine metabolites, were noted. This study shows that either mode of ionization can be used in the application of tandem mass spectrometry to diagnose disease

Monitoring Reactions of Nitric Oxide with Peptides and Proteins by Electrospray Ionization Mass Spectrometry.

*Urooj A. Mirza[φ], Harry M. Lander[δ] and Brian T. Chait[φ]
[φ]The Rockefeller University, 1230 York Ave, New York, NY. 10021,
[δ]Cornell University Medical College, 1300 York Ave, New York, NY. 10021

Introduction: The interaction of nitric oxide (NO) with proteins is known to play a critical role in regulating blood pressure, host defense and neurotransmission. Known targets of NO on proteins are cysteine and tyrosine residues and metals such as heme-Fe^{2+}. Although much work has been performed in characterizing NO-Fe interactions there is considerably less data on the reaction of NO with cysteine. One reason for this paucity of data is the labile nature of the nitrosothiol (RSNO) bond. In an effort to observe these labile products, we have employed the gentle technique of electrospray ionization mass spectrometry (ESI-MS)[1].

Experimental: 20mM bicarbonate solution (pH 8.0) was sparged for 15 min with N_2 then for 15 min with NO gas to produce a saturated solution of NO. Electrospray ionization mass spectra were obtained on a Finnigan-MAT TSQ-700 quadrupole instrument.

Results. A peptide (KNNLKECGLY MW = 1181.4) (Fig. 1a) was treated (Fig. 1b) with a 10 fold molar excess of NO. Treatment with NO for 5 min at pH 3.0 resulted in formation of new species with mass 29 Da greater than the starting peptide, indicative of a substitution reaction. Derivatization of the cysteine sidegroup of the peptide with N-ethyl maleimide (NEM) a blocked all reaction of NO with the peptide. This result indicates the cysteine residue is the primary site of NO reaction. We also carried out a detailed ESI-MS examination of the reaction of NO with the peptide as a function of time over extended time periods. The results demonstrated that NO reacts with the cysteine thiol to form a nitrosothiol (RSNO) derivative. Additional chemical modifications such as oxidation of cysteine to sulfonic acid and nitration of tyrosine residue are also observed but these are much slower processes. The order of formation of reaction products was RSNO >> Tyr-NO_2 = SO_3H. We also studied the nature of the RSNO bond by varying the energy input into the peptide ions during transit through the metal capillary transfer tube of the electrospray ionization source. Our results showed that very gentle mass spectrometric conditions are required for the detection of intact nitrosated derivatives, and that elevated transfer capillary temperatures lead to homolytic cleavage of the nitrosothiol bond to produce thiyl radical (R-S$^{\bullet}$) with the loss of NO$^{\bullet}$. Reactions of NO with the peptide at physiological pH demonstrated that dimerization of the peptide is the favored process. Bacterially expressed $p21^{ras}$ has 5 reduced cysteines residues available for nitrosation. ESI-MS analysis (Fig. 2a,b) demonstrates that only one of the five free cysteines in $p21^{ras}$ is nitrosated. Thus, this technique also allows for the determination of stoicheometry of the nitrosothiol formation in proteins.

INTRODUCTION

Imidocaptate (IC) was developed for experimental boron neutron capture therapy for cancer. Electrospray ionization mass spectrometry(ESI-MS) was used to characterize the IC by using various counter ion pairs. The best results were obtained with ion paired with triethylamine, and tetraethylammonium cations.

EXPERIMENTAL

Imidocaptate was prepared by coupling the dicesium salt of dodecaborane sulfhydryl with 1-(2-bromoethyl)-5-nitroimidazole in dimethylformamide-water (1:1) buffered with sodium bicarbonate. The molecule was purified by reversed - phase HPLC using a triethyl ammonium acetate methanol solvent system. Different salt forms were obtained by Dowex 50 exchange. ESI-MS was done on a Finnigan -MAT 900 equipped with Analytica Source, and PATRIC array detector Sample was dissolved in 1 1 0.01 in methanol water. acetic acid at a concentration of 30pmol/ul. The flow rate was set at 1.7 ul/min and 1.5ul/min, the skimmer voltage at 65v, and 55v, and the needle voltage at -2.7kV and -2.6kV for triethyl ammonium and tetraethyl ammonium cations respectively. In the IC with the triethyl ammonium cation pair, isopropyl alcohol was used as a sheath liquid with a flow rate of 1 7ul/min, the skimmer voltage set at 65v, and the needle voltage at 2.5kV for negative ion detection. The tetraethyl ammonium did not require sheath liquid for negative ion detection The skimmer was set at 55v, and the needle at 2.2 kV. The data was acquired at the scan rate of 30sec/decade.

RESULTS

The IC with the three different counter ion pairs showed complementary results. The triethyl ammonium ion pair Imidocaptate in negative ion detection showed an ion at 317 daltons $[M-2(102)]^-$ or IC minus the ion pair triethyl ammonium, and the ion at 419 daltons represents the IC minus one triethyl ammonium. In positive ion detection $[M+H]^+$ was present at 522 daltons. The IC (with the cation pair) plus sodium or $[M+Na]^+$ gave an ion at 544 daltons. The Imidocaptate ion pair molecule which was treated with excess of triethyl ammonium indicated a base peak at 624 daltons, which corresponds to $[M+Triethyl]^+$ ion In the tetraethyl ammonium Imidocaptate we observed a peak at 707 daltons corresponding to $[M+Et4n]^+$ ion.

DISCUSSION

The result obtained for the IC with the various paired ion indicated the presence of whole molecules (ion pairs plus the molecule) as the dominant ionic specie in ESI-MS. In the sample which the triethyl ammonium was exchanged with the tetra ethyl ammonium the base peak was at 707 daltons. This peak showed the successful exchange of paired triethyl ammonium moiety with a paired tetraethyl ammonium specie, plus a tetraethyl ammonium ion $[M+tetraethyl]^+$. The initial IC showed a base peak at 544 daltons or $[M+Na]^+$ [M= molecule +2(triethyl ammonium), after a successful exchange of the sodium with a triethyl ammonium ion the base peak shifted to 624 daltons or $[M+triethl\ ammonium]^+$. The labile IC was preserved with its adduct ion paired species in ESI-MS and was the dominant specie.

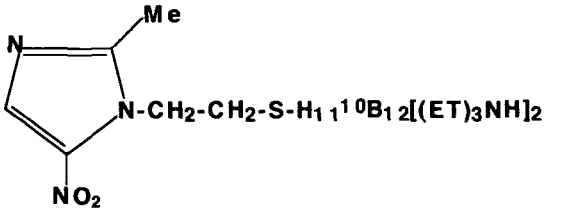
Structure of Imidocaptate



Negative-Ion ESI/MS of Primary Amines with TFA/TFE Derivatization

Hideji Fujiwara, Ronn G. Nadeau, Robert C. Chott, R. Thomas Solsten

Life Sciences Research Center, Monsanto Company
700 Chesterfield Parkway St. Louis, MO 63198

The study of glyphosate metabolism over the past 20 years, has been complicated by the difficulties associated with obtaining pure samples. Typically, identification required many chromatographic separations and purifications prior to MS analyses. Derivatization of these herbicidal compounds significantly improves the ease of MS analyses.

The derivatization of glyphosate and AMPA for GC/MS was initially developed at Monsanto. Several additional studies have since reported quantification of these compounds through derivatization. The derivatization makes these compounds to be less polar and volatile. The derivatization, however, is not always complete and some of the partial derivatives are not volatile enough for GC analysis. It is, therefore, desirable to use HPLC for the analysis.

Recently, we discovered that a trifluoroacetyl and trifluoroethanol (TFA/TFE) derivative of glyphosate was about 25 to 50 times more sensitive to negative ion electrospray ionization mass spectrometry (ESI/MS) than underivatized glyphosate. The derivatization increased the molecular weight of the metabolite and also improved the reverse phase LC chromatographic properties.

Since herbicides are generally metabolized in soils, plants, and animals into carboxylic (or sulfonic) acids, amino acid (or peptide) conjugates, and sugar conjugates, we have now extended this derivatization technique to amino acids & small peptides, nucleosides, amino alkyl(or aryl) sulfonic acids, and primary amines. We anticipate that this technique will be a valuable tool for analyzing metabolites of chloroacetanilide and sulfonylurea herbicides.

Selectivity and Binding Mode of DNA Interacting Molecules Studied by ESI-MS

David C. Gale, David G. Camp II, and Richard D. Smith
Chemical Sciences Department, Pacific Northwest Laboratory, Richland WA, 99352

An area of interest to a number of scientists are small organic molecules that bind to or interact with DNA, thereby exhibiting antitumor, antiviral, or antibacterial activity.[1] Recently, the noncovalent complex formed between an oligonucleotide duplex and a minor groove binder was observed by electrospray ionization mass spectrometry (ESI-MS).[2] In this report, we address two important areas where by ESI-MS may be utilized in the study of minor groove binding molecule/oligonucleotide duplex noncovalent complexes. First, can the binding motif of a minor groove binding molecule be determined by ESI-MS? Second, can differences in the solution binding affinity of minor groove binding molecules to different duplexes, be observed in ESI mass spectra?

Shown in Figure 1 is the ESI mass spectrum of a self complementary oligonucleotide, 5'-dCGCAAATTTGCG-3' (M), with the minor groove binder distamycin (Dm). A charge state distribution for the 1:1 Dm/oligonucleotide duplex is observed. Shown in Figure 2 is the ESI mass spectrum of a duplex comprised of two sequence specific oligonucleotides, 5'-dCGCCTCGTCCGC-3' (T1) and 5'-dGCGGACGAGGCG-3' (T2), with Dm. No peaks for a 1:1 Dm/oligonucleotide duplex are observed in Figure 2. A charge state distribution for a 2:1 Dm/oligonucleotide duplex is however observed in Figure 2. It is important to note that the concentration of Dm and duplex are approximately the same in both Figures 1 and 2. These results demonstrate that Dm has a different binding motif with the two different oligonucleotide duplex sequences.

It is known that Dm has a high binding affinity for long AT regions (4 to 6 base pairs in length).[3] Shown in Figure 3 is the ESI mass spectrum of a solution containing the self complementary oligonucleotide, 5'-dCGCAAATTTGCG-3' (M), and two sequence specific oligonucleotides, 5'-dCGCCTCGTCCGC-3' (T1) and 5'-dGCGGACGAGGCG-3' (T2), without Dm Peaks composed of **both** Duplexes are observed at *m/z* 1214, 1457, and 1822. Distamycin was added to the solution used to acquire Figure 3, this data is shown in Figure 4. In comparing Figures 3 and 4, a charge state distribution for the 1:1 Dm/oligonucleotide duplex is observed. This is consistent for the binding of Dm to the 5'-dCGCAAATTTGCG-3' oligonucleotide duplex, as observed in Figure 1.

These results indicate that ESI-MS may be useful as an analytical technique in the analysis of small molecule/oligonucleotide duplex noncovalent complexes. As demonstrated in Figures 1 and 2, different binding motifs can be observed for different oligonucleotide duplex sequences. In addition, with carefully constructed experiments, binding affinity information of at least qualitative utility can be obtained by ESI-MS. This can be observed in Figure 4, where Dm binds only to the oligonucleotide duplex containing the long AT base pair region, as expected based on solution binding affinities.[3]

CHARACTERIZATION OF LARGE GLYCOPROTEINS USING HPLC/ELECTROSPRAY MASS SPECTROMETRY

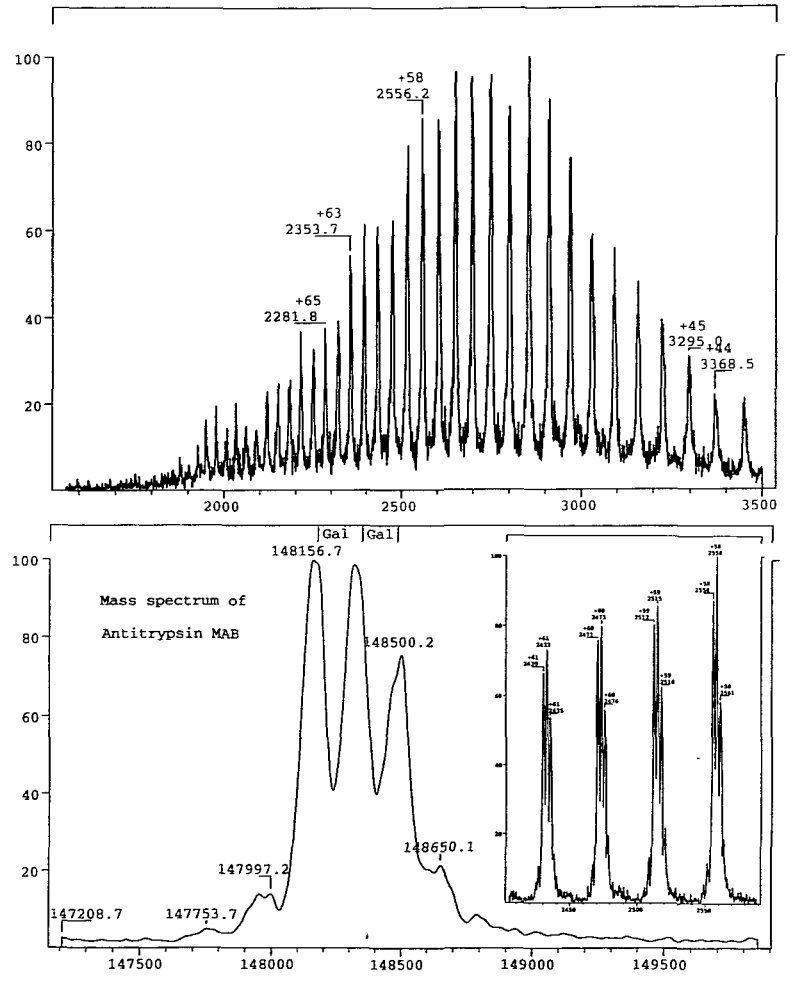
Lee Q. Huang, Anthony Paiva, Ramadas Bhat*, Mel Wong*, Bayer Research Center, Pharmaceutical Division,Bayer co., 400 Morgan Lane, West Haven, CT 06516,
*Biological Division, Bayer co., Berkeley, CA 94701

HPLC coupled to mass spectrometry (MS) using electrospray ionization (ESI) has been widely used recently in the biological sciences for the characterization of proteins and peptides. Analysis of large glycoproteins by MS is, however, still challenging due to heterogeneity of the cabohydrates on the proteins. In this presentation, we describe the successful application of HPLC/ES/MS to the analysis of glycoproteins as large as 150,000 Da, determining not only the molecular weight, but also detailed heterogeneity for the first time. It is found to be crucial to use a synthetic peptide of MW 3259.6 for the optimiztion and calibration of the instrument in the high mass range up to 4000 amu, where the multiply charged envelopes of the 150,000 Da proteins are found. Further tuning of the instrument at relatively high mass resolution enabled us to resolve single monosaccharide deletions for the glycoproteins.

Electrospray ionization was performed on a Finnigan TSQ 7000 triple quadrupole mass spectrometer (Finnigan MAT, San Jose, CA) fitted with a Finnigan ESI source. Protein samples were introduced without any splitting into the electrospray source through a 0.10 mm id untreated fused silica column coupled to the HPLC with a PEEK zero dead-volume union (Upchurch Scientific, Oak Harbor, WA). A voltage of 4500 V - 5000V for the positive ions was maintained on the ESI electrode throughout all the experiments. The capillary was heated to 220° C. Nitrogen was introduced as a sheath gas at a pressure of 50 psi. Auxilliary Nitrogen gas at 40 cm/min was also introduced to improve sensitivity and reproducibility.

Q1 was operated in high mass range and was scanned from 1800-4000 amu over 5 seconds. The electron multiplier was run at 1200 - 1400 V. This resulted in a typical TIC (total ion count) of 1×10^{8} counts. A DEC 5000/25 data system running Finnigan ICIS software (version 8.0) was used to control the TSQ 7000. All spectra for proteins were acquired in profile mode. Profile data was averaged using a peak width of 100 mmu on a DEC 5000/133 data system. A mass defect of 0 mmu at 0 AMU and 300 mmu at 1000 AMU was used for data processing. Mass deconvolution of multiply charged ions was performed using Finnigan Biochemistry software.

With the improvement of instrumentation and sample introduction, it is demonstrated here that HPLC coupled to a quadrupole mass spectrometer with electrospray ionization can detect both molecular weight and microheterogeneity for 150,000 Da glycoproteins. High mass capability of the instrument facilitates the studies and is of importance for the characterization of large glycoproteins. Complementary information from Carbohydrate Analysis or Amino Acid Analysis are important to understand the glycosylation of large proteins. Together, the application of this method should have an impact on future glycoproteins research.



Cone Voltage Fragmentation and Collision-Induced Decomposition Electrospray Mass Spectra of Antineoplastic Drugs.

John Roboz, Longhua Ma and Qitao Yu, Division of Neoplastic Diseases, Department of Medicine, Mount Sinai School of Medicine, New York, NY, 10029, USA

OBJECTIVES. The prospective objective has been to explore electrospray ionization as a general technique for the quantification of antineoplastic drugs and for the identification of their metabolites in body fluids and tissues. The present objective was to obtain comparative data on the cone voltage fragmentation (CVF) and collision-induced decomposition (CID) electrospray (ESP) spectra of 12 compounds, selected to represent different classes of antineoplastic agents.

EXPERIMENTAL. Samples: 5-Fluorouracil (247 Da), cis-platin (298 Da), mitomycin C (335 Da), tamoxifen (371 Da), medroxyprogesterone acetate (387 Da), amsacrine (394 Da), doxorubicin (544 Da), homoharringtonine (545 Da), etoposide (589 Da), vincristine (825 Da), dactinomycin (1256 Da), bleomycin (1427 Da) Samples were dissolved in methanol/water (1:1 v/v) containing 1 % formic acid, to yield 5-100 ng/uL analyte concentration. ESI: Positive ESI spectra were obtained using a triple quadrupole mass spectrometer (Model Quattro, Fisons). Sample flow rate into the source was 5 µl/min. In CVF experiments spectra were obtained in the 70-300 V cone voltage range in 7 steps of 20-50 V increments. In CID experiments, argon was used as collision gas, using 50 V and 150 V collision energy Scan speed was 10 sec/scan, mass range from 100 to 500-1500 depending on the analyte. Spectra were obtained by summing 5 scans for CVF and 10 scans for CID.

RESULTS At 70 V cone voltage (normal condition) all drugs gave protonated molecules, actinomycin, bleomycin and vincristine gave both singly and doubly charged ions Medroxyprogesterone acetate and tamoxifen have relatively rigid structures with MH^+ at base peak intensity even at cone voltages of 220 V and 300 V, respectively. For bleomycin, high cone voltage (220 V) permitted identification of all analogs in the drug mixture. Increasing cone voltage led to considerable fragmentation providing structural information comparable to CID, e.g., doxorubicin (Fig. 1) and amsacrine (Fig. 2). High voltage CVF was often fully compatible with CID but with 2-5 times higher sensitivity, e g , etoposide. When fragment ions obtained at 250-300 V cone voltage were subjected to CID, additional structural information could be obtained from second and third generation product ions, e.g , mitomycin C, dactinomycin.

DISCUSSION. In the ESI of antineoplastic drugs, the CVF technique often produces structural information complementary to that provided by CID. Advantages of CVF include: simplicity (programmable), high sensitivity, both molecular and fragment and isotopic ions detectable, MS/MS-like spectra with single quadrupoles, intense fragments for second generation subsequent CID, and no loss of resolution. Disadvantages of CVF include less specificity than CID, and inapplicability to mixtures.

CONCLUSIONS. Judicious selection of experimental conditions provide intense protonated molecules for quantification by selected ion (CVF) or reaction (CID) monitoring, as well as structurally significant fragment ions to be used in strategic schemes for metabolite detection. Factors Affecting ESI-MS of Nucleobases and Nucleosides

Ten-Yang Yen[1], Robert D. Voyksner[2] and M. Judith Charles[1]
[1]Department of Environmental Sciences and Engineering, University of North Carolina Chapel Hill, NC 27599-7400
[2]Analytical and Chemical Sciences, Research Triangle Institute, Research Triangle Park, NC 27709-2194

Introduction:

Electrospray ionization mass spectrometry (ESI-MS) has enhanced our capability to analyze thermally labile polar biomolecules including nucleobases and nucleosides, but the mechanism of electrospray ionization is not well understood. The ESI response is greatly affected by several physico-chemical parameters such as the concentration, pK_a of analytes and acids, as well as the nature of solvent[1]. Further understanding these factors can help us to improve the sensitivity of ESI needed for its application to analyze DNA adducts. In this study, we present data to demonstrate that the $(M+H)^+$ ion does not greatly increase (< 2 fold) by acidifying the solution, and a dramatic decrease in response was observed from organic bases in solutions acidified with HCl or CF_3COOH. From conductivity measurements data, we propose that the dramatic suppression of response is due to the ion-pair interactions between the $(M+H)^+$ ion of organic bases and the anion of HCl or CF_3COOH. A model for the ESI droplets formation of acidified solution related to the $(M+H)^+$ ion response is also proposed.

Experimental:

Solutions of analytes (500 μM) dissolved in 50% methanol/water were infused into ESI source at a flow rate of 2 μL/min. The ESI-MS mass spectra were acquired on a Finnigan 4000 quadrupole mass spectrometer retrofitted with an Analytica of Bradford, Inc. ESI source and a Teknivent Vector 2 data system. A tensiometer (CSC scientific Company, Inc.) was used to measure the surface tension of the solution. The conductance measurements were performed with an YSI conductivity meter and an YSI dip cell.

Results and Discussion:

Analytes with higher pK_a generally have greater response of the $(M+H)^+$ ion in ESI. The response of 1-methyladenosine, N^6-methyladenosine, thymine and uracil as a function of concentration of acetic, formic, hydrochloric and trifluoroacetic acid showed that the $(M+H)^+$ ion does not greatly increase (< 2 fold) by acidifying the solution. Moreover, a rapid decrease in response for organic bases such as 1-methyladenosine and N^6-methyladenosine was observed in solutions acidified with HCl or CF_3COOH. This dramatic suppression was not observed for neutral compounds such as thymine or uracil. According to results of conductivity measurements, the concentration of H^+ ion are nearly equal for those acidified solution with the same conductivity. The response of $(M+H)^+$ ion as a function of the solution conductivity for organic bases in solutions acidified with HCOOH or CH_3COOH is different than for solutions acidified with HCl or CF_3COOH (Figure 1). We propose that the dramatic suppression of response for organic bases is due to the ion-pair interactions between the

43rd ASMS Conference on Mass Spectrometry and Allied Topics

$(M+H)^+$ ion and anion of HCl or CF_3COOH. Because we did not observe a rapid decrease in response either from the solution acidified with HCOOH or CH_3COOH containing the same concentration of H^+ ion, or from neutral compounds (thymine, uracil) in any of acidified solution examined (Figure 2). The surface tension determined by tensiometer in any of acidified solutions was similar (33-34.5 dyne/cm). From these data, we infer that the response of $(M+H)^+$ ion is related to the ESI droplet formation processes. The competition of excess charge on the droplet surface between $(M+H)^+$ of analyte and H^+ of acid affects the observed response in ESI. Higher concentration of H^+ suppresses the $(M+H)^+$ ion signal and also reduces the size of droplet[2]. The decrease in response for neutral analytes in high conducting solutions is possibly due to the formation of smaller droplets during ESI processes. Fewer coulombic explosions occur in smaller droplets[3], and thus less response in the $(M+H)^+$ ion.

A NEW APPROACH TO DETERMINE MODIFICATIONS IN DNA CZE/MS OF OLIGONUCLEOTIDES

P. Janning[1], W. Schrader[1], R.Pesch[2], H. Münster[2] and M. Linscheid[1]
[1]*ISAS - Institut für Spektrochemie, P.O.Box 10 13 52, D - 44013 Dortmund, Germany*
[2]*Finnigan MAT Bremen*

Chemical modifications of DNA by xenobiotic compounds are regarded to play a major role in mutagenicity and carcinogenesis. The structural determination of such modifications of covalent and non covalent nature is difficult, since the compounds are normally rather polar and labile and the amount of material is small. In addition, the development of convincing experimental models was handicapped by the normal procedures, which require to cleave the DNA into nucleosides or nucleobases. Thus, all the sequence and topological information of the modification reaction is lost. We have now established a procedure which allows the *investigation of DNA modifications on the* oligonucleotide level. An unspecific nuclease is used to cleave DNA into mainly di-, tri-, tetra- and some penta- and hexanucleotides. In the next step, the 5'- phosphate is removed with alkaline phosphatase. The resulting mixture can be separated using CZE into groups of the same chain length. With electrospray MS, the different species are detected within the groups[1].

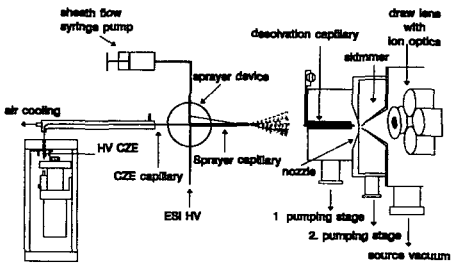

Fig. 1: Home build ESI source for a MAT 90 comprising static quadrupoles as focusing elements; interfaced to a CZE instrument

We have used this approach in two studies. In the first, the reaction of the potentially carcinogenic styrene oxide with DNA is explored aiming at the determination of nucleobase preferences and sequence specificity. In a second study the known reaction of cisplatin with DNA is used to detect the limits of this approach with respect to applications in drug development. For both, the detection power of the system is of major concern due to very low levels of adducts formed in DNA. Thus we have compared the results from a MAT 90 with a home built ESI source and from a MAT 900 equipped with an ESI II ion source and a PATRIC detector as one of simultaneous detections systems available.

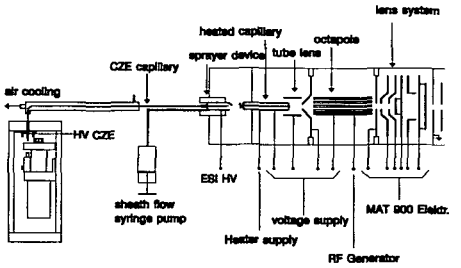

Fig.2: *ESI II ion source interfaced to the laboratory built CZE instrument*

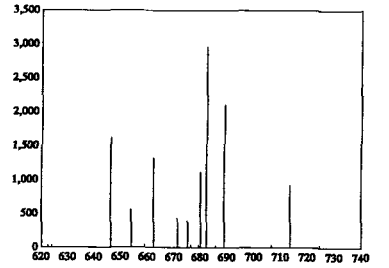

Fig.3: *Single scan of the mass range for adducts of styrene oxide to dinucleotides, home build ion source, MAT 90*

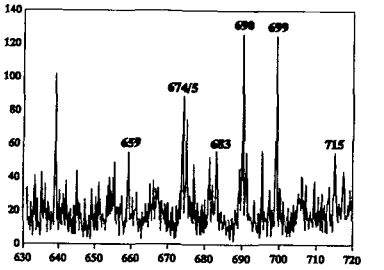

Fig.4: *Adducts of styrene oxide to dinucleotides, single scan, PATRIC detector*

The same capillary zone electrophoresis instrument was interfaced to the mass spectrometers. In figures 1 and 2, the schematics of both sources are given. For the styrene oxide adducts we have been able to detect the styrene oxide adducts (negative ions) at low levels with the PATRIC detector, whereas with the MAT 90 no signal at all was to discover. As an example a single spectrum from the MAT90 (Figure 3) covering the mass range in question and of a MAT 900 (Figure 4) is shown. In principle the same effect was obtained with the positive ions for the detection of cisplatin adducts to oligonucleotides, although the higher chemical background limited the gain in sensitivity to some extend. We were able to detect previously unknown complexes of the drug with two and three dinucleotide moieties. It is evident that the use of simultaneous detection systems can be crucial for the method to become a viable tool for the determination of modifications at the low level, which are to expect in real world samples. On the basis of these experiments it appears feasible to use this approach for biomonitoring programs e.g. for the control of occupational hazards. A second field of application envisaged is the study of genotoxic reactions of drugs in early stages of the development. But it seems inevitable that it is not sufficient only to use the best detection systems available; rather, the development of optimized sample introduction schemes for the CZE separation such as combinations with isotachophoresis or liquid chromatography and sample stacking procedures are required and experiments along that line are under way[2].

STRUCTURE ELUCIDATION OF OLIGONUCLEOTIDES USING CZE/ESI-MS AND SKIMMER CID

Chr. Siethoff[1], W. Schrader[1], R.Pesch[2], H. Münster[2] and M. Linscheid[1]
[1]*ISAS - Institut für Spektrochemie, P.O.Box 10 13 52, D - 44013 Dortmund, Germany*
[2]*Finnigan MAT Bremen*

The determination of adducts of xenobiotic compounds in DNA is one of the major steps towards an understanding of chemical carcinogenesis as well as of the role of DNA modifying cytostatic drugs. We have developed a mass spectrometric approach using enzymatic digestion of DNA into oligonucleotides and the separation with CZE/ESI-MS into groups of the same chain length[1]. The oligonucleotides are detected as negative ions with the number of charges depending on the chain length.

In a study with the potential carcinogen styrene oxide and DNA we have been able to separate the adducts to dinucleotides and trinucleotides and to obtain the molecular weight information with ESI-MS on sector field mass spectrometers (MAT 95/MAT 900). From the molecular ions the location of the reaction with respect to the nucleobases, riboses or phosphates cannot be determined, only the preference to the purine bases is evident (see Figure 1). To obtain a more detailed view of the reactions at the different oligonucleotides, we have attempted to use skimmer CID to get fragments from modified nucleotides[2] and from several di- and trinucleotides as well.

In analogy to earlier studies we have optimized the fragmentation conditions with a series of dinucleotides[3]; in Figure 2, as one example the fragments of the dinucleotide d(ApC) as a function of the skimmer voltage are shown. It is possible to distinguish isomeric dinucleotides on the basis of the intensity of fragments. We have then used skimmer CID during a CZE separation of oligonucleotides to detect the fragments of the di- and trinucleotides and of the modified species. Since the modification occurs in a few percent of the unmodified material only, we have used single ion detection at the relevant m/z values only to determine the adducts of the nucleobases. In Figure 3, the result for the purines is given; reactions at Cytosine was very low, Thymine did not react at all.

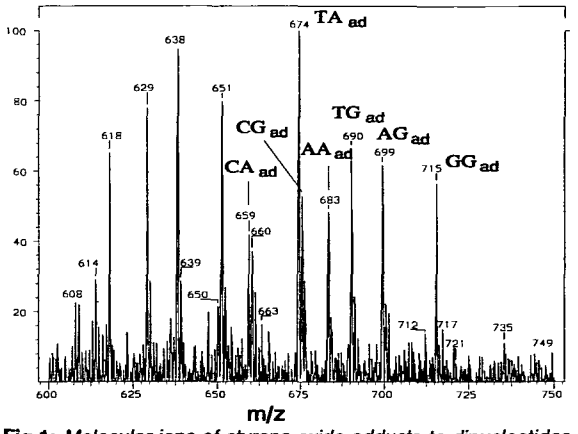

Fig.1: *Molecular ions of styrene oxide adducts to dinucleotides*

The first peak in both electropherograms appears always and is a result of N-7 adduct formation causing chemical depurination of the oligonucleotides. The second broader peak is a CID fragmentation product and indicates the reaction at the purines at site yielding chemically stable products. The loss of a modified nucleobase cannot be detected with our current procedure, because the signals are identical to those of unmodified dinucleotides. Since with the separation scheme used so far the oligonucleotides are separated according to the number of nucleobases only, it can become difficult to further elucidate the relation of the different precursor and product ions. To solve this problem, two approaches are conceivable: either using MS/MS experiments or a refinement of the electrophoretic separation.

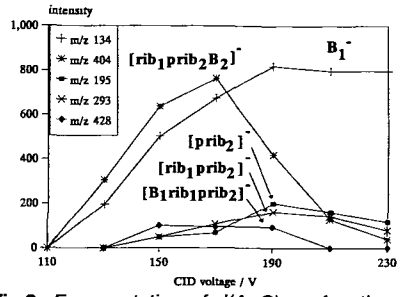

Fig.2: *Fragmentation of d(ApC) as function of skimmer voltage; [M-H] was omitted*

We have begun to modify the separation scheme in order to isolate the different oligonucleotides within the groups. First experiments confirm that this is possible at least at the di- and trinucleotide level, which makes the interpretation of skimmer CID experiments straight forward. Since the levels of adducts in real samples are low, the superior detection capabilities of skimmer CID compared to linked scan makes this a very valuable option to obtain further structural information on the modified DNA components.

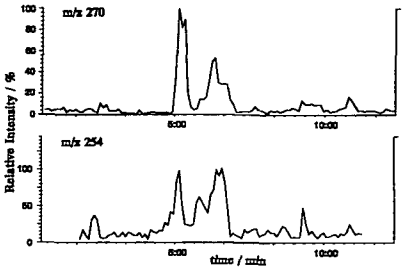

Fig.3: *Single ion electropherograms ESI/CID MS of adducts of guanine (upper trace) and adenine (bottom trace)*

With an improved separation scheme and the superior detection capabilities of a PATRIC detector this approach may allow to discover adducts in DNA down to the level required for the analysis of samples from people exposed to occupational hazards and to determine endogenous modifications.

THERMODYNAMIC STUDIES OF METAL SELF-ASSEMBLED COMPLEXES BY ESMS.

A. Dupont[1], E. Leize[1], A. Marquis-Rigault[2], D. Funeriu[2], J.-M. Lehn[2], and A. Van Dorsselaer[1]
[1] Laboratoire de Spectrométrie de Masse Bio-Organique, URA 31 CNRS-Université Louis Pasteur Strasbourg, France. [2] Laboratoire de Chimie Supramoléculaire, URA 422 CNRS-Université Louis Pasteur, Strasbourg, France.

INTRODUCTION :

Self-assembly, which consists of the spontaneous formation of a well-defined architecture from a given set of molecules able to recognize, orient and assemble themselves, is one of the basis of life chemistry [1]. Polynuclear metal complexes formed by self-assembly of different small synthetic ligands around metal ions are models allowing to approach the driving forces involved in self-assembly. ESMS has already been successfully used for the characterization of these molecules [2]. Quantization of **all ionic species present in a solution** is necessary to determine the thermodynamic parameters of a system and are important to understand the basic principles of the formation of these complexes.
In this work, we will evaluate the possibilities of ESMS for quantitative studies. We first study alkali ions solutions to determine key parameters for the response factors in ESMS. We show then an example of copper self-assembled complexes with identical desolvation energies. Their formation is studied by ESMS and results compared with NMR.

RESULTS :

1. Comparison of ESMS response factors of alkali ions : In this simple model, all the ions (same state of charge, very close m/z values, no fragmentation in the interface) are in equimolar concentration but show very different response factors (fig. 1). Such differences in response factors necessary originate from the ion evaporation itself. It is possible to correlate the response factor k of each cation and its hydration energy E, with a simple mathematical relationship (fig. 2). Such an effect of the hydration energy has already been qualitatively mentionned [3] but never mathematically described.

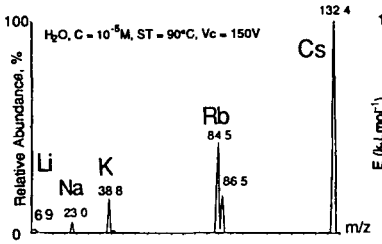

Fig. 1 : ESMS of an equimolar mixture of LiCl, NaCl, KCl, RbCl and CsCl.

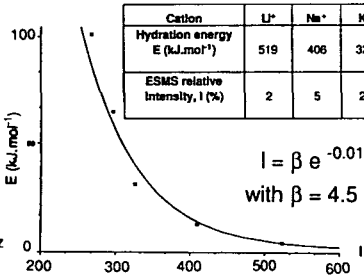

Cation	Li+	Na+	K+	Rb+	Cs+
Hydration energy E (kJ.mol-1)	519	406	322	293	264
ESMS relative intensity, I (%)	2	5	20	60	100

Fig. 2 : Correlation between desolvation energy and ESMS response factors of the alkali ions.

This result demonstrates that the **solvation energy of the ions is a key parameter** for the response factors of ionic species by ESMS. A quantitative study is then only possible whether the solvation energies of the different compounds under study are known or if they are identical.

2. Application to the study of Cu(I) self-assembled complexes : We have investigated **molecular recognition** between 2 types of ligands which are expected to form homohelicates [4] rather than

heterohelicates (fig. 3). For this study the ES mass spectrum is expected to give an exact image of the different species in solution because they have very close structure and hence comparable desolvation energies and response factors. Figure 4 shows the ES mass spectrum of the mixture of the heterodimer ($L^1L^2Cu_3$) and the homodimers ($(L^1)_2Cu_3$, $(L^2)_2Cu_3$) obtained by mixing 2 equiv. of L^1 and L^2 with 6 equiv. of $CuPF_6$. From this spectrum it is clear that ligands L^1 and L^2 are capable of self-recognition. Indeed a statistical repartition would have led to 50% of the heterohelicate instead of 23% as measured by ESMS.
This quantization obtained by ESMS is in perfect agreement with a quantization performed by NMR (at 10^{-3}M), which validates the use of ESMS for quantization of this series of compounds. A similar work has been performed on another model : a self-assembled capped complex [5], where the ESMS quantization of the intermediate species is in good agreement with the UV-Vis spectrophotometric data.

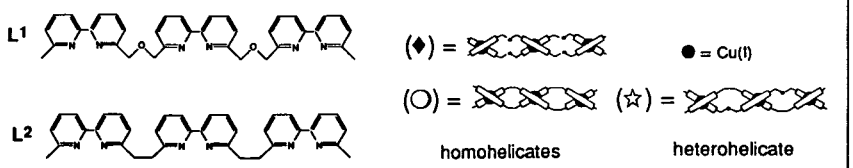

Fig. 3 : Structure and symbolism of the helicates

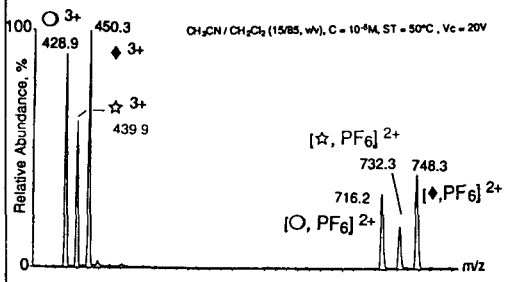

Species	% ESMS	% NMR
O	37	40
♦	41	40
☆	23	20

Fig. 4 : ES-mass spectrum of a mixture of 2 eq. L^1, L^2 and 6 eq. $CuPF_6$: comparison with NMR data.

CONCLUSION :

ESMS appears to be a very valuable technique for the analysis of metal complexes in thermodynamic equilibrium in diluted solutions. Indeed, in each case either NMR or UV-vis spectrophotometry could correlate with the relative intensities on the ES mass spectra for each molecular species present in solution. However it appears that quantization is possible only provided some precautions : no fragmentation, same charging rules and same solvation energy of all molecular species.

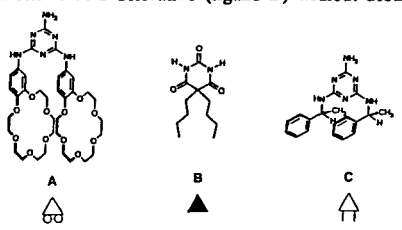
ION LABELING STUDY OF SELF-ASSEMBLED SUPRAMOLECULAR SPECIES BY ESMS

Leize E.[1], Russell K.C.[2], Lehn J.M.[2] and Van Dorsselaer A.[1]
1 Laboratoire de Spectrométrie de Masse Bio-Organique,URA 31 CNRS-Université Louis Pasteur,
2 Laboratoire de Chimie Supramoléculaire, URA 422 CNRS-Université Louis Pasteur, Strasbourg, France.

INTRODUCTION :
ESMS has recently emerged as a suitable technique for understanding supramolecular self-assembly processes by following their formation. [1]
When supramolecular assemblies formed by hydrogen bonds are neutral, their study by ESMS is difficult because charges cannot be brought by protonation since acidity would disrupt the supramolecular complexes. In this case the study of these assemblies by ESMS needs the use of an ion label as ionization agent. The ion label used is a triaminotriazine attached to a crown-ether able to complex metal cations (ligand A) and allows the detection by IL (Ion Labelling)-ESMS of the species formed through hydrogen bonding with a complementary barbituric acid derivative (ligand B) without destroying the species obtained.



RESULTS AND DISCUSSION :
Characterisation by IL-ESMS of the complexes obtained by self-assembly of A and B :
The ES mass spectrum of S_1 (= equimolar mixture of A and B in CH_2Cl_2 at 10^{-2} M, saturated with KPF_6) shows major peaks corresponding to the different charged states of the ligand A and the A_3B_3 complex (Fig. 1). As ligand B was not ionized, it was not detected. A less intense peak is also observed corresponding to the doubly-charged ion of A_2B_3.
The charge state of these peaks was confirmed by the ESMS study of S_2 (= equimolar mixture of A and B in CH_2Cl_2 at 10^{-2} M, half saturated with KPF_6). S_2 contains half the KPF_6 than does S_1 and this fact increases the number of peaks (Table 1) corresponding to species, by the loss of one and several KPF_6 units. A m/z difference of 61.2 Da/e (= KPF_6 molecular weight/3) obtained between the peaks indicates that these peaks are indeed triply-charged ions, a m/z difference of 92.5 Da/e (= KPF_6 molecular weight/2) confirmed the doubly-charged state of the corresponding ions.
These ESMS studies have thus allowed the characterization of three complexes in solution: A_3B_3, A_2B_3 and A_3B_2. A_3B_3 was the predominant species detected. Since no larger complexes were observed, we can attribute to A_3B_3 a closed structure of the supramolecular macrocycle D, similar to that observed in the crystal for related systems.[3] Such a structure could explain the higher stability of A_3B_3 in comparison to A_3B_2 and A_2B_3. Three possible structures for A_3B_2 and A_2B_3 in solution again could be a linear ribbon (a), a bent ribbon (b), or a partial rosette (Fig. 1).
Characterisation by diluted IL-ESMS of the complexes obtained by self-assembly of B and C :
By extension, the IL-ESMS could be applicable to the study of any self-assembled structure in solution capable of incorporating the labelling agent A added in trace amounts. In the presence of a salt, A coordinates a cation and label ion containing species become visible by ESMS. This was tested by the introduction of five percents of A into a preformed assembly of B•C to obtain information by ESMS about the neutral entities formed (solution S_3 = 1 eq. A (5.10^{-4} M), 20 eq. B (10^{-2} M) and 20 eq. C (10^{-2} M), in CH_2Cl_2 saturated with KPF_6). The ES mass spectrum of S_3 (Fig. 2) shows two major species : the ion label A and the AB_3C_2 complex, as well as two other complexes : the ABC complex and AB_2C_2 complex. Again in this case, the six-components complex is the major species observed, suggesting that the assembly of B and C also prefers a macrocyclic rosette architecture.

CONCLUSION :
In conclusion, the IL-ESMS that we describe in this work allows the characterization of non-covalent complexes involving few hydrogen bonds which corresponds to particulary low energy interactions. Thanks this new IL method, it is possible to use ESMS for the investigation of the self-assembly processes of neutral and labile complexes.

RETROSPECTIVE ANALYSIS OF HYPERPHENYLALANINEMIAS BY LSI AND ESI MS/MS

Donald H. Chace[†], Steven L. Hillman[†], Takeo Sakuma*, Yves Le Blanc*, Bori Shushan*
[†]Duke University Medical Center, MS Facility, RTP, NC, USA;
*PE Sciex, Concord, Ontario, Canada

Phenylketonuria (PKU) is a genetic disorder of phenylalanine (Phe) metabolism that results from the accumulation of this amino acid in blood. Early detection through infant screening and subsequent dietary changes prevents mental retardation. Presumptive diagnosis of this disorder relies on the quantitative measurement of an elevated Phe in blood Most methods used currently have a false positive rate that is at best 0.1%. Tandem mass spectrometry with liquid secondary ionization (LSI) has been used recently to screen for this form of hyperphenylalaninemia (1). Using isotope dilution techniques, this method is very accurate and precise for Phe quantitation. Calculation of Phe to Tyr ratios improves the diagnostic accuracy such that false positive analysis are reduced to less than 0.1% In this study, we have compared in retrospective analyses the accuracy of both LSI and ESI MS/MS to diagnose PKU.

Sixty filter paper blood spots containing normal, positive, and false positive samples were analyzed in a blinded fashion Sample preparation has been described previously(1) The samples were divided in two equal aliquots, dried, and the following matrices were added:

LSI: 35µL of 50.50 methanol:glycerol + 0.1% Na-Octylsulfate.
ESI: 50µL of 50:50 acetonitrile:water.

A VG Quattro I fitted with a Cesium Ion gun was used to analyze 2 µL aliquots by manual sample introduction. A PE Sciex API III was used to analyzed 5µL aliquots by flow injection techniques. An amino acid profile (*m/z 125-300)* was obtained by each tandem MS using the neutral loss (NTL) of 102 amu scan mode

Amino acid profiles from a blood spot of a patient with PKU using LSI and ESI MS/MS is shown in Figures 1a and b, respectively For each profile, internal standards are marked with an asterisk. A quantitative comparison for all samples that were analyzed by LSI and ESI MS/MS for measurement of Phe concentration and the µmolar ratio of Phe to Tyr was made A plot of Phe concentration by LSI versus Phe concentration by ESI showed that these two ionization modes produced similar results and closely correlate with each other (r = 0.97). The slope of the concentration data set is 0 66, which suggest that a higher estimate of the Phe concentration by LSI MS/MS is a observed when compared to ESI MS/MS. It is unlikely that different ionization efficiencies of Phe would account for this difference because the concentration is calculated from the ratio of Phe to d_5-Phe. Differences in the data processing software (baseline subtraction, smoothing, centroiding) could account for some of these differences Correlation of the Phe:Tyr ratios is also excellent (r=0.95) while the slope of the data set is 1 08 suggesting that these two ionization methods are producing similar Phe:Tyr ratios We have found previously that calculating Phe/Tyr ratios is the best method for diagnosing PKU resulting in a reduction in false positive diagnosis (1) In each case, both techniques differentiated normal patients from patients with PKU This comparative analysis demonstrates that it is MS/MS and its application to selective detection of key diagnostic amino acids that is the basis for the diagnosis of phenylketonuria regardless of the ionization method.

Electrospray Ionization Mass Spectrometric Study of Host-Guest Complexes

Ragulan Ramanathan and Laszlo Prokai

University of Florida, Center for Drug Discovery, Gainesville, FL 32610-8186

Recent studies have shown, that noncovalently-bound receptor-ligand, enzyme-substrate, and heme-protein complexes, formed in solution can be studied in the gas-phase using electrospray ionization (ESI) mass spectrometry (1). In the experiments reported here, an ESI mass spectrometer was used to demonstrate the applicability of this technique in the study of host-guest complexes. Cyclodextrins (α-, β-, γ- and heptakis(2,6-di-O-methyl)-β-CD) were selected as host molecules along with protonated amino acids (AA) (*L*-tryptophan, *L*-phenylalanine, *L*-tyrosine, and *L*-valine) as guest molecules. For the second part of this study, we selected protonated Ala-Leu-Gly [(TP)H^+] and Tyr-Gly-Gly-Phe-Leu [(PP)H^+] as guest molecules in order to investigate whether the peptide with all aliphatic amino acid residues formed less stable complexes than the peptide with aromatic amino acid residues.

All experiments were performed using a Vestec 200 ES single quadrupole mass spectrometer, equipped with an ESI source (2). The ESI was achieved by applying 2-2.5 kV to a flat tipped stainless steel needle. Sample solutions were delivered to the ESI source via syringe pump at a flow rate of 2-5 μL/min. The mass spectrum shown in Figure 1 was obtained via electrospraying equimolar mixtures of α-, β- and γ-CD's (1.0×10^{-4} M) with (Trp)H^+ (1.0×10^{-5} M). The results suggested that a better match between the cavity diameter of the host and the size of guest molecules increases the net complex stabilization. Mass spectra obtained by electrospraying equimolar mixtures of *L*-Trp, *L*-Phe, *L*-Tyr, *L*-Val and β-CD suggested that β-CD encapsulates protonated AA's in the order of Trp > Phe > Tyr > Val. The striking difference between ESI mass spectra obtained by using β-CD and DM-β-CD is the enhanced complexation (>90%) of protonated amino acids by DM-β-CD. However, the trends observed in complexation are similar for both host molecules. The encapsulation of (Trp)H^+ by both CD's is favored greatly over (Val)H^+, (Phe)H^+ and (Tyr)H^+. In order to understand the relationship between complex stability in solution versus gas-phase, a series of experiments were performed varying the DM-β-CD concentrations. Figure 2 represents a graph obtained by plotting the normalized ion intensities of each amino acid complexed as a function of the log of DM-β-CD concentration in the sample solution. The concentration of the amino acid was kept constant at 5.0×10^{-5} M and the concentration of DM-β-CD was varied between 3.7×10^{-8} and 7.5×10^{-4} M. Analysis of the curve indicates that the selectivity of DM-β-CD for protonated amino acids is (Trp)H^+ > (Phe)H^+ > (Tyr)H^+ > (Val)H^+.

Repeller/collimator CID experiment was performed on each (DM-β-CD)--(AA)H^+ to obtain relative stabilities and fragmentation information. For example, at lower repeller/collimator potential difference (2-10 V), collisional activation is low, and peaks due to (DM-β-CD)--(AA)H^+, (DM-β-CD) + (CH_2)--(AA)H^+ and (DM-β-CD) + $(CH_2)_2$--(AA)H^+ were observed. when the repeller/collimator potential difference was increased to 15 V, peaks due to the loss of $[(CH_3)_2C_6H_8O_5]_n$ (n = 1-2) units from the protonated host molecule (formed during or after the dissociation) were observed at *m/z* 1142 and 952. However, direct loss of the protonated AA, such as (Trp)H^+, from the complex, is not predominant. Step-wise loss of glucopyranose units from protonated DM-β-CD was common at higher repeller/collimator CID potentials with all the (DM-β-CD)--(AA)H^+ complexes studied. Increasing the potential difference >90 V produced $[(\text{DM-}\beta\text{-CD})\text{-}[(CH_3)_2C_6H_8O_5]_6\text{-}(H_2O)_2 + H]^+$ at *m/z* 155 as the most abundant fragment ion. The energy required for the dissociation of the complexes varied in the order of (DM-β-CD)--(Trp)H^+ > (DM-β-CD)--(Phe)H^+ > (DM-β-CD)--(Tyr)H^+ > (DM-β-CD)--(Val)H^+.

Repeller/collimator CID was performed on (DM-β-CD)--(TP)H^+, (DM-β-CD)--(PP)H^+, (TP)H^+ and (PP)H^+. At lower repeller/collimator potential difference, direct loss of the protonated peptide from complex was detected. At higher repeller/collimator potential difference, step-wise loss of glucopyranose units from the protonated (DM-β-CD) and the appearance of sequence ions were predominant. As shown in Figures 3-4, the appearance of sequence ions was monitored as a function of the repeller/collimator potential difference. The shift, between the fragmentation curve obtained from the complexed and uncomplexed peptide, correlates to the energy required to dissociate the host from the DM-β-CD cavity.

Studies of on-line coupling of electrochemistry with mass spectrometry, i.e., "electrochemical mass spectrometry" (EC/MS) date back to work by Bruckenstein et al. in the 1970's [1]. In these and other early experiments, porous working electrodes or permeable membranes were usually used as the interface between the cell and the MS ionization source which exclusively employed electron ionization (EI). As a result, only volatile products of electrochemical reactions could be detected by the mass spectrometer.

An important development in on-line electrochemistry/mass spectroscopy was the coupling of an electrochemical cell to a thermospray (TS) mass spectrometer (EC/TS/MS) reported by Hambitzer and Heitbaum [2], and Volk et al. [3]. Employing an aqueous ammonium acetate thermospray buffer solution, all detected species appeared as either protonated or ammoniated species in the positive ion mode or as deprotonated or acetate adduct species in the negative ion mode. Radical cations or anions were not detected.

Although "electrochemically assisted electrospray mass spectrometry" has been progressing for a few years, chiefly due to the pioneering efforts of Van Berkel and coworkers [4,5], on-line coupling of electrochemistry with electrospray mass spectrometry (EC/ESMS) is still a developing area because of the experimental difficulties involved, such as high voltage hazard to the electrochemistry hardware (e.g. potentiostat), and MS signal suppression caused by the presence of high concentrations of supporting electrolytes.

We report the coupling of an electrochemical device on-line with electrospray mass spectrometry (EC/ESMS) to extend the potential of ESMS to detect non-polar neutral compounds, and to monitor and identify intermediates and products generated by electrochemical reactions. Under favorable conditions, EC/ESMS can be used for the detection of radical cations of polycyclic aromatic hydrocarbons (PAHs) as first reported by Van Berkel et al. [5]. We find that PAHs can be divided into three groups according to the stability of the radical cations. The first group of compounds includes anthracene, phenanthrene and pyrene. Their radical cations are extremely reactive and undergo rapid irreversible reactions with solvent or impurities. Therefore, these radical cations were not detectable, or were only barely detectable under the applied potential. The second group includes 9,10-diphenylanthracene, perylene and rubrene. Their radical cations are very stable because the most reactive sites (e.g., carbon atoms at 9, 10 positions of anthracene) have been blocked by substituents. In addition, the resonance effect of phenyl substituents greatly increases the stability of radical cations. As a result, the radical cations of this group of compounds were detected by ESMS, even without use of the electrochemical cell (cell off). In this case, the electrospray capillary and counterelectrode functioned as an electrochemical cell which generated detectable amounts of radical cations. With an applied potential (+1.5 V), however, the radical cation abundance increased about 3-6 fold. The third group includes 9-methylanthracene, 9,10-dimethylanthracene, chrysene and benzo[a]pyrene. The stability of their radical cations lies between the above two groups. The radical cations could not be detected or were only barely detectable with the cell off, but high abundances of radical cations appeared in ESMS spectra with the cell on (+1.5 V).

One of the most important applications of the EC/ESMS system is to determine intermediates and products from solution chemical reactions of radical ions. Here we report the EC/ESMS study of the electrochemical oxidation of benzo[a]pyrene an extremely carcinogenic PAH.

[5] Van Berkel, G. J.; McLuckey, S. A.; Glish, G. L., *Anal. Chem.*, 1992, 64, 1586.
[6] Jeftic, L.; Adams, R. N., *J. Am. Chem. Soc.*, 1970, 92, 1332.

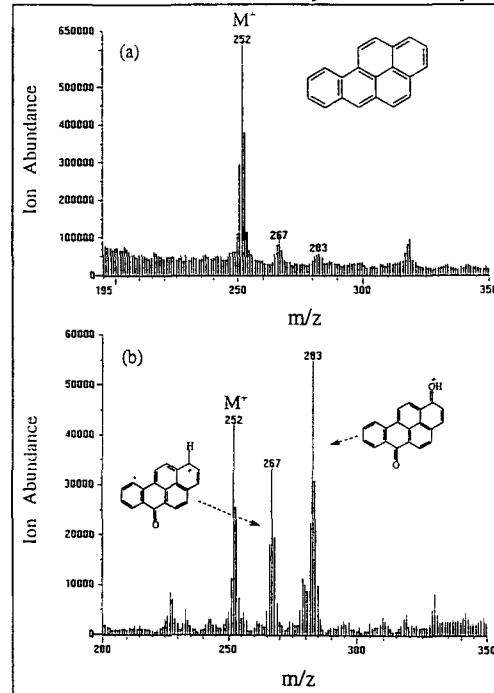

Figure 1. EC/ESMS studies of the oxidation of benzo[a]pyrene. (a) In dried 95% CH_2Cl_2 + 5% CH_3CN solvent, a high abundance of BaP $M^{+\cdot}$ (m/z=252 was detected with +1.5 V applied). (b) After adding 0.1 M H_2O to the solution, the abundance of m/z 267 and 283 increased sharply while $M^{+\cdot}$ abundance decreased.

Table 1. EC / ESMS Data for PAHs

Compound (M.W.)	$E_{1/2}$ (ox) vs. SCE (V)	$M^{+\cdot}$ abundance cell off	$M^{+\cdot}$ abundance cell on
Anthracene (178)	1.09	-	25,000
Pyrene (178)	1.16	-	-
Phenanthrene (178)	1.50	-	22,000
9-methyl-anthracene (192)	0.96	-	40,289
9,10-dimethyl-anthracene (206)	0.87	-	653,615
Chrysene (228)	1.35	-	93,473
Benzo[a]pyrene (252)	1.27	-	577,557
9,10-diphenyl-anthracene (330)	1.22	13,782	35,500
Perylene (252)	0.85	10,500	59,620
Rubrene (532)	0.77	5,100	24,500

This result demonstrates that the solvent composition plays an important role in determining the pathway of electrochemical reactions. Addition of a small amount of water introduced a series of solution chemical and electrochemical reactions which led to the formation of the ionic intermediate 6-oxobenzo[a]pyrene cation (m/z=267), and the "final" products 1,6- 3,6- and 6,12- benzo[a]pyrene quinone in accordance with the mechanism of Jeftic and Adams [6]. One should note that 6-oxobenzo[a]pyrene and the benzo[a]pyrene quinones are not radical cations implying that they cannot be detected by EPR spectrometry, but they are readily detected by ESMS.

This study demonstrates that on-line coupling of electrochemical / electrospray mass spectrometry allows identification of intermediate ions (radical or even electron) and products generated from electrochemical and ensuing solution-phase reactions. EC/ESMS offers much potential as a novel tool for studying the mechanism of complicated electrochemical reactions such as those occurring in biological redox systems or in electrochemical organic synthesis. EC/ESMS also enables the analysis of neutral compounds which are otherwise difficult to analyze by ordinary electrospray mass spectrometry.

THE EFFECTS OF ANION ENCAPSULATION BY KATAPINATES ON ELECTROSPRAY MASS SPECTRA

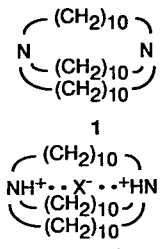
Anne B. Giordani
Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company
2800 Plymouth Road, Ann Arbor, MI 48105

Introduction Numerous factors affect the sensitivity of electrospray (ES) mass spectrometry and the appearance of ES spectra. The presence of salts in ES solutions may cause a reduction in analyte signal. Mirza and Chait have shown that the nature of the anionic species present in the analyte solution can influence charge state distributions in positive ES spectra.[1]

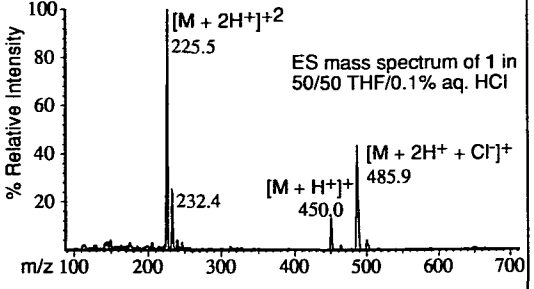
Addition of a cation-binding-macrocyclic compound, 18-crown-6 ether, to sodium-chloride-contaminated electrospray solutions decreases the sodium-cationized analyte levels and can increases sensitivity through an improvement in analyte signal-to-noise.[2] Katapinates are macrobicyclic diamines. Doubly protonated katapinate molecules form ion pairs with halide ions by encapsulation of the anion into the macrobicyclic hydrocarbon cavity.[3]

This poster reports the use of electrospray mass spectrometry to observe interactions of halide ions with the C_{10} katapinate: 1,12-diazabicyclo[10.10.10]decacosone,**1**, extends the study of Mirza and Chait to encompass the full halide anion series and reports the effects of ion pair formation by this katapinate with halide anions on positive electrospray mass spectra.

Observation of katapinate binding to halide anions ES-MS spectra of 1,12-diazabicyclo[10.10.10]decacosone are consistent with the literature NMR data showing facile Cl^-, Br^- and I^- ion pair formation with the doubly-protonated diamine.[3] The relative intensity of the peak corresponding to the $[M + 2H^+ + I^-]^+$ ion is lower than that of the chloride or bromide, which may be due to the larger ionic radius of I^-. Iodide ion was not observed to bind with the *[9.9.9]*diamine in the NMR studies, and this was attributed to the size of the hydrocarbon cavity relative to the radius of I^-. Fluoride ion binding to the katapinates was not observed. The lack of fluoride ion binding has been attributed to the high heat of hydration of fluoride ion, and bifluoride ion formation.[3] Product ion spectra of the $[M + 2H^+ + X^-]^+$ ions show ready losses of neutral HX to form the singly-protonated bicyclic diamine.



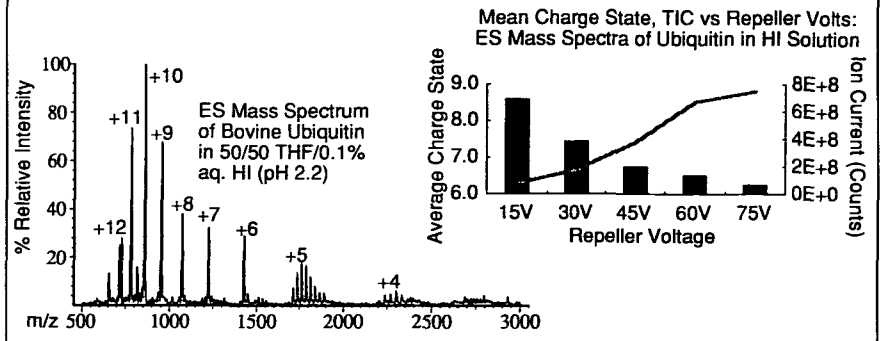
Halide anion- katapinate ion pair



The effects of halide anions on ES mass spectra of some peptide and proteins ES mass spectra of peptides and proteins from solvent solutions of 50/50 THF/0.1% aqueous HX show a decrease in the average charge state across the halogen acid series. (The measured pH of the hydrochloric, hydrobromic and hydriodic acid solutions was 2.2.) The observed order of halide anion effectiveness in shifting charge state distributions to lower charge states is: $I^- > Br^- > Cl^- > F^-$. This order parallels the acetate

anion series studied by Mirza and Chait.[1] The trend was consistent for TRH precursor peptide, melittin, ubiquitin and myoglobin, although the mean charge states observed from HCl/aqueous THF solutions were lower than those reported by Mirza and Chait for the same peptides and proteins from HCl/aqueous methanol.

The ES spectrum of ubiquitin exhibits the narrowest peak widths from HCl solution compared to HF, HBr and HI, indicating that there is the least amount of adduction. Adduction of HI and HBr is particularly apparent for the +5 peaks in the spectra from their respective solutions. An overall increase in ion current and decrease in the average charge state is observed in the spectra of ubiquitin from HI-containing solution, as the degree of adduction is reduced at higher repeller voltages.



Effects of halide anion-katapinate ion pair formation on positive electrospray mass spectra Considerable suppression of ES signal is observed in the presence of a relatively large concentration of katapinate. The average charge states are lower than in solutions without katapinate, probably because the diamine's presence causes an increase in the solution pH. Despite the halide anion-katapinate ion pair formation and the severely suppressed protein signal, the trend toward decreasing mean charge across the halogen ion series is still evident.

Conclusions

- Halide anion-katapinate ion pair formation is readily observed by electrospray mass spectrometry.
- The observed order of halide anion effectiveness in shifting charge state distributions to lower charge states is: $I^- > Br^- > Cl^- > F^-$.
- Katapinate addition to ES solutions does not diminish the effectiveness of halide ions in shifting charge state distributions to lower charge states.

4-Oxalocrotonate (4OT) tautomerase is an enzyme used by certain soil bacteria to help degrade aromatic hydrocarbons to intermediates in the Krebs cycle. The enzyme is a hexamer of identical 62 amino acid subunits which catalyzes the 1,3-allylic isomerization of 2-oxo-4-trans-hexenedioate to 2-oxo-3-trans-hexenedioate through the intermediate 2-hydroxymuconate. We have established access to 4OT by total chemical synthesis and are interested in studying the structure and function of this highly efficient enzyme by exploiting the advantages afforded by total chemical synthesis. Here we have used electrospray ionization time of flight (ESI-TOF) mass spectrometry to establish the multimeric state of our synthetic enzyme. The technique has also proven very useful in studying the non-covalent nature of several 4OT analogs including the D-enantiomer of the enzyme as well as several analogs containing modifications to the active site at the N-terminus of the enzyme.

All mass spectra were acquired using an ESI-TOF instrument constructed at the University of Manitoba and described previously(1). ESI-TOF analysis was performed under both native (5 mM ammonium bicarbonate, pH 7.0) and denaturing (5 mM ammonium bicarbonate, 0.02% formic acid, pH 4.0) conditions at concentrations of approximately 10 µM.

Under native electrospray conditions strong ion signals corresponding to the multiply charged monomer and hexamer complex of the enzyme (MW 40,866) were observed in the ESI-TOF mass spectrum of synthetic 4OT (Fig. 1A). Only weak signals representative of the dimer and pentamer were detected and there was no evidence for trimer or tetramer in the spectra. Analysis of the enzyme under denaturing conditions yielded only multiply charged monomer ions and confirmed the specific, noncovalent nature of the hexamer that is formed under native conditions (Fig. 1B). Increasing the declustering voltage from 120 V to 250 V also fragmented the hexamer. Significantly, however, the major decomposition product (the pentamer) appears to be unusually stable.

We have also used native ESI-TOF to assess the structural integrity of several 4OT analogs including the D-enantiomer, a truncated construct (2-62), and a derivative where the N-terminal proline was replaced with cyclopentane carboxylate (CP). Native ESI-TOF mass spectra of D-4OT and CP were similar to those obtained with L-4OT and show that these analogs appropriately fold to form a hexameric enzyme complex resembling that of L-4OT (Figs. 2A and 2B). Only monomer ions were observed in the native mass spectrum of (2-62) indicating that this 4OT construct does not fold appropriately (Fig.2C).

Our native ESI-TOF results with L-4OT, D-4OT, (2-62), and CP were also consistent with structural data obtained from circular dichroism experiments on these samples. Multimeric (hexamer) complexes were only observed in the native mass spectra of samples that showed significant helical content by CD spectroscopy (Fig. 3). Furthermore, our ESI-

TOF results with (2-62) and CP were instrumental in establishing the mechanistic and structural significance of the catalytically important Pro1 residue in 4OT. The absence of multimeric (hexamer) complexes in the native mass spectrum of (2-62) suggests that Pro1 is essential for enzyme folding. From our studies with CP we also conclude that 4OT requires an N-terminal amine for activity as the CP analog apparently folds correctly but is inactive (Table 1). Therefore, we conclude that the N-terminal proline residue of 4OT is both chemically and structurally significant.

Investigation of Cyclodextrin-Metal Cation Complexes Using ESI/FTICR-MS

David E. Kage, Clifford H. Watson, [1]Laszlo Prokai, John R. Eyler
Department of Chemistry, University of Florida, Gainesville, FL 32611-7200
[1]Center for Drug Delivery, University of Florida, Gainesville, FL 32611

Cyclodextrins were discovered by Villiers near the turn of the twentieth century. They were isolated as enzymatic degradation products of starch.[1] Not long after their discovery, Schardinger characterized them as cyclic oligosaccarides.[2] Freudenberg et al. revealed that the cyclodextrins were held together by the formation of α(1,4)-linked glucose units[3] (Figs. 1 and 2). The products of the enzymatic degradation contain α-, β-, and γ-cyclodextrins with traces of cyclodextrins ranging up to thirteen glucose units. The three that are produced to an appreciable extent are α-, β-, and γ-cyclodextrin which contain six, seven, and eight glucose units, respectively.

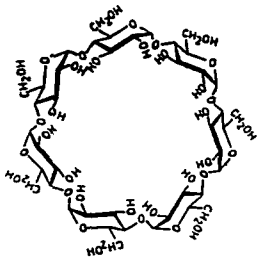

Figure 1

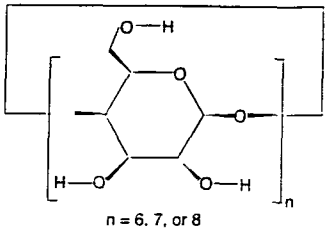

Figure 2

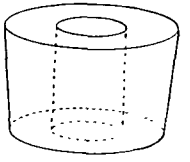

Figure 3

Figure 1 depicts the chemical structure of α-cyclodextrin where the glucose units are in the C1 chair conformation and are linked by α(1,4) bonds. Their overall geometry leads to a shape that is described as a truncated cone (a lamp shade if you will). The wider side of the molecule contains the secondary hydroxyl groups, while the narrower side contains the primary hydroxyl groups. The dimensions of the cavity are governed by the number of glucose units in the ring (Fig. 3). Due to the arrangement of the functional groups, the cavity created by the cyclodextrins is hydrophobic (relative to water), while the external faces of the cone are hydrophilic.

Cyclodextrins have a number of unique properties as a result of their structural features. The most important property, or at least the one that has generated the bulk of the literature, is the ability of cyclodextrins to form inclusion complexes with a large variety of guest molecules. The guests can be organic or inorganic, neutral or ionic, or even gaseous in nature. The limiting factor is that the guest must "fit" (even if only partially) into the host cavity created by the cyclodextrins. The alkali and alkaline earth metal cations are well suited for the formation of inclusion complexes based on their size.

In these studies, cyclodextrins (α-, β-, and γ-) have been investigated as potential host molecules for small metal cation guests ($M^{+1,2}$). Our interests start with understanding and measuring the affinity and binding strengths of different metal guests to different cylodextrin hosts. The experiments were performed on a 7-T

FTICR mass spectrometer equipped with an external electrospray ionization source. Samples of cyclodextrins were dissolved in 50/50 ($MeOH/H_2O$) and brought to ca. 1-5x10^{-4} M. Salt solutions were prepared using the same solvent system. The capillary, cylinder, and needle of the ESI source were kept near -4kV, -3kV, and 0V, respectively Standard pulse sequences written into the software were used to detect ions in the ICR cell.

Preliminary results have shown that alkali and alkaline earth metal cations (specifically Li^+, Na^+, K^+, Cs^+, and Ca^{+2}) will bind to α-cylodextrin (see Figs. 4 and 5 for examples). The results are promising and prove to us that our instrumental design is suitable for studying these species in the gas phase. Work on this project is ongoing in our laboratory. We are working toward a better understanding of the binding of these metal guests to the cylodextrin hosts. Are the metal cations truly encapsulated within the host cavity, or merely stuck to the outside walls electrostatically as recently suggested by Vouros et al?[4] Collisionally activated dissociation (CAD), laser photodissociation, and ion-molecule reaction experiments will be conducted on these host-guest complexes.

HPLC - ESI - MS of Flavonoid Glycosides in Hops

Martin Sàgesser and Max L. Deinzer, Oregon State University, CORVALLIS, OR

INTRODUCTION

The objective of this work was to determine the content of flavonoids in hops (*humulus lupus*).

Flavonoids[1], also known as tannins or polyphenols, include a wide range of compounds, suchs as catechins, anthocyanidins, flavonols, flavones and their different glycosides. They are widely distributed in the plant world and are common in the human diet. They ere found in barley and hops[2,3], in honey, black tea, fruit, vegetables and other plants These naturally occurring flavonoids (aglycones and glycosides) can be separated using reversed-phase HPLC[4].

RESULTS

Extraction and HPLC

One gram of dried hop pellets and 50ml of water were placed in a flask and homogenized. The extract was filtered after 24h and used for the following RP-HPLC Initial experiments by HPLC showed differences in flavonoid content of different hop varieties

Mass Spectrometry

The mass spectrometry analyses were performed using a SCIEX API III triple-quadrupole mass spectrometer (Thornhill, Ontario, Canada) with an ionspray interface and a Macintosh data system The MS was operated in the positive ion mode under conditions of unit mass resolution. Profile spectra were obtained by acquiring data points every 0.2 Da with a dwell time of 2ms. Purified air was used as the nebulizing gas at 24-48 psi and the ionspray voltage was to +5000V. The curtain gas was nitrogen and the orifice voltages were set at +80 -120V. Collision induced dissociation (CID) experiments were performed using argon as target gas with a thickness of 2-3x10^{14} atoms cm^{-2}. The step size was 0.5 amu and the mass range 400-900 Dalton. The mass spectrum of Rutin in Fig. 1 shows not only the protonated molecular ion, but also information about the glycosidic residue - glucose (Δm. 162Da) and deoxyglucose(Δm· 146 Da) - and also the aglycone unit of the molecule.

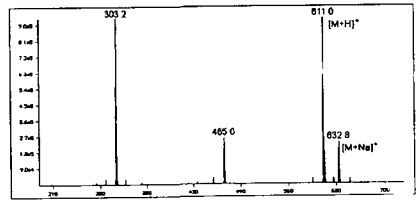

Fig 1: ESI-MS of Rutin (Quercetin-3-rutinoside)

LC - ESI - MS

A typical LC-MS basepeak chromatogram (BPC) of a hop extract is shown in Figure 2

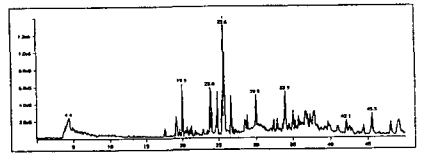

Fig 2· BPC of Hallertau hop extract

The mass spectra of the different HPLC peaks show molecular ion and fragments which could be derived from proanthocyanidins and flavonol glycosides.

LC - Tandem Mass Spectrometry

The mass spectra in the positive ion mode of glycosides of quercetin and kaempferol show signals for the protonated molecular ion and for the different possible losses of the sugar residues as shown in Figure 1. All spectra have in common a peak with m/z 303 Da or 287 Da, both of which are due to the protonated aglycones. These ions were scanned in order to identify the parent ions. To get the most useful information out of one LC run, both the parent ion scans of kaempferol and quercetin were performed simultaneously

By analysing these scans we found 12 different glycosides related to these flavonols The amount of each glycoside was different in the various hop varieties.

The mass spectrum of compound A is shown in Figure 3 This compound must have quercetin as the aglycone because it is a parent scan of m/z 303 The peak at m/z 757 Da could be the $[M+H]^+$-ion of quercetin with one hexose and two desoxyhexose sugar units. The difference between m/z 757 and 611 and between m/z 611 and 465 is in both cases 146, which corresponds exactly to a desoxyhexose unit. The remaining fragment has a mass of 162, a hexose unit The mass spectrum alone is not enough to determine the correct structure. Either reference compounds or further isolation and NMR analysis would help to get the right structure.

Direct analysis of beer samples

Without any concentration or purification, samples of beer were directly injected into the LC-MS. The same type of scan as described above (parent ion scan)

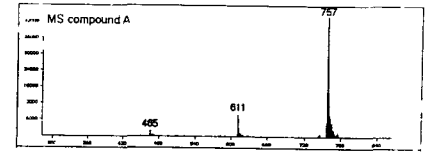

Fig 3 Mass Spectrum of compound A

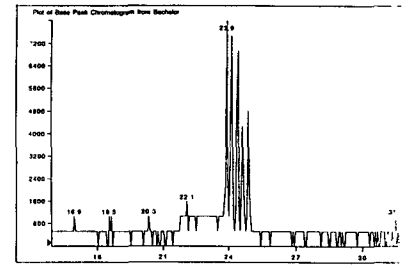
was used to search for flavanol glycosides in these samples. Figure 4 shows a fraction of the chromatogram of a commercial beer.



igure 4 Chromatogram of a commercial beer

The intensity is about ten times smaller than in the hop extracts, but the mass spectra allow one to determine the different compounds

CONCLUSION

- HPLC-electrospray mass spectrometry is a powerful method for the investigation of these polyphenols in hops The technique provides molecular mass information and some structural data with a minimum of sample preparation
- Tandem mass spectrometry is even more useful to get specific information on one class of compounds, as shown here with the flavanol glycosides

POTENTIALITY OF MASS SPECTROMETRY FOR THE ANALYSIS OF SULFATED POLYSACCHARIDES OF HIGH POLYMERIZATION DEGREE

F. UZABIAGA[1], C. MONTEIRO[1], M. PETITOU[1], C. PONTHUS[1], J.C. PROME[2] and C. PICARD[1]

INTRODUCTION

Mass spectrometry analysis of highly sulfated oligosaccharides derived from Heparin is complicated by their strongly ionic and hydrophilic character. Because of their strong interaction with the surrounding (solvent, matrix), it is very difficult to volatilize these molecules intact from the sample, in particular when increase polymerization degree (PD), degree of sulfation (SD) and number of anionic charges (AC)

Attachment of small cations to the anionic groups also interferes with molecular weight determination.

In a previous study (1), we first demonstrated the potentiality of mass spectrometry using LSIMS AND ESI-MS for the analysis of synthetic sulfated oligosaccharides (up to 10 mer with a degree of sulfation 16).

We concluded that ESI-MS was a more sensitive technique which allowed molecular weight determination of oligosaccharides with higher polymerization and sulfation degree than LSIMS did.

In this study, we present the ESI-MS results obtained for several new synthetic sulfated oligosaccharides with higher polymerization degree (PD - up to 20 mer) higher sulfation degree (SD - up to 31) and higher number of anionic charges (AC - up to 41) However when the size, number of sulfate groups and number of anionic charges increased, interpretation of the ESI data were becoming more and more intricate due to overlaps between multicharged molecular species and multicharged fragments (loss of Na^+ or $NaSO_3$ groups).

Thus, it seemed interesting to evaluate the potentiality of MALDI-TOF-MS applied to the MS analysis of such higher charged and higher masses oligosaccharidic compounds with the hope that this technique could lead to more comprehensive experimental data and, hence, could be more routinely applied to synthesis follow-up of these compounds by mass spectrometry.

MATERIALS AND METHODS

Chemicals

The various compounds were obtained from one of us (M. Petitou). They were analysed in aqueous solution.

- LSIMS : Negative LSIMS analyses were performed on a ZAB-2E (VG Organic Fisons) using a magnet scanning over a mass range of 600 to 2400 amu. Spectra were acquired in the continuum mode and 4 to 8 scans were summed. The caesium ion gun energy was set to 35 keV and the source accelerating voltage was 8 kV

Oligosaccharides were analysed in this mode up to 6- mer (SD = 10 , AC = 13). 1 µl of 100 µg/µl solution (*45 nmoles*) was added to 2 µl of triethanolamine matrix.

- ESI-MS : Negative ESI spectra were obtained on a VG-Platform instrument (VG Organic Fisons). 10 µl loop injections were performed using a mobile phase isopropanol/water (8/2) at 10 µl/min

Polysaccharides (from 12-mer and up to 20 mer) were injected at a concentration ranging from 1 to 2 µg/µl in water (*7 nmoles* injected). A 3 kV ESI potential was applied to produce the spray .

Spectra were acquired in the MCA mode over a mass range of 200-1200 amu with a scanning rate of 10 sec/scan. Sample cone voltage was optimised in the 15-30 V range

- MALDI-TOF-MS : Negative MALDI-MS was tried on a VG-TOF-SPEC (VG Organic Fisons) in linear mode. A N2 laser radiating at 337 nm with 4 ns pulses was used

Ions were accelerated to 18 KeV. Spectra were acquired over 0-5000 amu and the calibration performed with Glucagon and Bombesin

The various matrices tested were used at a concentration of 50 mM in H_2O/CH_3CN (2/1) Only a pentamer compound (average MW = 1731 , PD = 5 ; SD = 8 ; AC = 10) was tested at a concentration ranging from 10 pmol/µl to 100 pmol/µl in H_2O/CH_3CN (2/1) 2 µl of the tested matrix and 2 µl of the sample were premixed 2 µl of the mixture were then deposited on a stainless steel target and then dried at atmospheric pressure and room temperature before analysis.

RESULTS

- LSIMS

⇨ LSIMS spectra for polysulfated polysaccharides showed a base-peak pseudo molecular ion $[M - Na]^-$ and a fragment ion corresponding to the loss a sulfate group $[M - Na_2SO_3 + H]^-$. *Increasing polymerization and sulfation* degrees up to the hexasaccharide decasulfated leads to very weak ion signal showing losses of sulfate groups without evident pseudo molecular ion.

- ESI-MS

⇨ ESI spectra : On the well defined spectrum (obtained for the 12 mer with 19 sulfates and 25 anionic charges), we observed multiply charged ions from the 4^- up to the 11^-. On this spectrum, each multiple charged state shows a rather complex profile in which the desodated ion dominates. After deconvolution with sodium adduct ion, the obtained molecular weight is 4296.8 which is very closely related to the expected molecular weight (Table 1) *Increasing polymerization and sulfation degrees leads to more intricate spectra.*

The ESI spectrum obtained for the 20 mer is presented on figure 1 The spectrum presents ions from 6^- to 14^- giving an experimental molecular weight of 7077 amu as expected.

In this case, the polycharged ions coming from the only losses of Na^+ counter-ions do not appear as the most intense ones within a defined polycharged state profile. Indeed ions resulting from an additional loss of a sulfate *group predominate. Other ions corresponding to the losses of 2 or 3 sulfate groups are also observed, thus giving* overlaps between multicharged molecular species and multicharged fragments

The maximum state charge observed in the ESI spectra decreased as the anionic charge number increased. The measured molecular weights were always found comprised between the monoisotopic and the average values. A few nanomoles were necessary to obtain these results by ESI-MS

- MALDI-TOF-MS

In the present work, we tried to obtain a direct MALDI-TOF mass spectrum of a pentasaccharide compound (average MW 1731 , PD = 5 ; SD = 8 , AC = 10). This compound was analysed either directly in different matrices (2.5-dihydroxybenzoic acid, 3-amino-quinoline, sinapinic acid, caffeic acid, anthranilic acid) or after treatment with cation exchange beads (AGMP50, Biorad) to convert the salts into free acids In neither case a direct MALDI spectrum could be obtained and trials were not extended to other higher molecular weight derivatives.

These negative results were in good accordance with the work of Juhasz et al (2) who also failed to obtain direct MALDI spectra from polysulfated oligosaccharides. These authors suggested an indirect measurement by the observation (in positive MALDI-TOF-MS) of complexes between these highly acidic compounds and highly basic proteins and peptides (with high Arginine content).

Hence, the "complex formation" concept appears to be the only alternative for using MALDI-TOF-MS as a tool for mass measurement of polysulfated oligosaccharides

DP	SD	AC	Expected MW monoisotopic average	Measured MW	State Charge observed
12 (dodeca)	19	25	4297.5 4300.7	4296.8 +/- 0.9 amu	$5^- \rightarrow 11^-$
14 (tetradeca)	22	29	4991.4 4995.2	4993.0 +/- 2.2 amu	$5^- \rightarrow 12^-$
16 (hexadeca)	25	33	5685.3 5689.6	5687.6 +/- 2.3 amu	$5^- \rightarrow 13^-$
18 (octadeca)	28	37	6379.2 6384.1	6381.4 +/- 3.2 amu	$6^- \rightarrow 13^-$
20 (icosa)	31	41	7073.1 7078.5	7077.3 +/- 3.2 amu	$6^- \rightarrow 14^-$

Table 1 : **Main characteristics of the various oligosaccharides analysed by ESI-MS.**

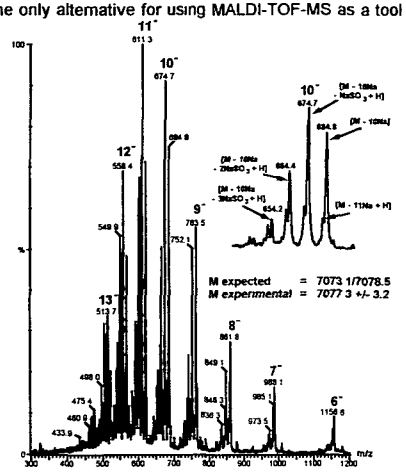


Figure 1 : **ESI mass spectrum of the 20 mer compound (DP 20, DS 31, 41 Na).**

CONCLUSION

This comparative study of LSIMS, ESI-MS and MALDI-MS for the analysis of sulfated polysaccharides shows that :

⇨ LSIMS give the most accurate mass determination but could be only used up to the hexamer with 8 sulfate groups.

⇨ ESI allows direct observation of molecular weight up to 20 mer (SD = 31 ; AC = 41) with good accuracy and sensitivity We have not reach the limits of this technique. However the spectrum becomes more intricate with higher polymerization degree.

⇨ MALDI failed to give any interpretable data by direct measurement in accordance with Juhasz. P et al. (2)

Detection of Photosubstitution Intermediates of Ru(II) Diimine Complexes using On-line Electrospray Mass Spectrometry

Ryuichi Arakawa, Satoshi Tachiyashiki,[a] and Takekiyo Matsuo[b]
Department of Applied Chemistry, Osaka University, 560 Japan
[a]Laboratory of Chemistry, Kagawa Nutrition University, 350-02 Japan
[b]Department of Physics, Osaka University, 560 Japan

In thermal- and photo- ligand substitution of a metal complex with bidentate ligands the substitution is considered to proceed stepwise and thus an intermediate with a η^1 bidentate (one-legged) ligand is proposed (Fig. 1). However it has not yet been possible to demonstrate the existence of such an intermediate, at least for tris(bidentate)type chelates. However, we have recently been able to identify an intermediate with a one-legged bidentate ligand in the photosubstitution of $Ru(bpy)_2(dmbpy)^{2+}$ (Fig. 2a) by ^1H nmr and HPLC separation.

Here, we report studies of photosubstitution of Ru(II) diimine complexes by on-line ES-MS in order to obtain direct evidence of intermediate formation and to observe some mechanistic details of the photoreaction, such as the effects of solvent and intensity of irradiation. Through this study it is hoped that on-line electrospray mass spectrometry will be demonstrated to be a powerful tool for the study of photochemical reactions in solution.

Two different modes of irradiation (λ >420nm) were used for photoreaction: cell mode and spray mode irradiation. For the cell mode irradiation a cylindrical quartz cell (1mm i.d.) was installed in the middle of a syringe needle. The spray mode irradiation was carried out 3mm from the tip of the electrospray needle, i.e., the charged droplets were irradiated.

Figure 2a shows an ES mass spectrum of the complex in acetonitrile (AN) solution without photoirradiation. The spectrum is simple, showing only two peaks of RuL_2B^{2+} and RuL_2BX^+, where L, B, and X represent bpy, dmbpy, and ClO_4^-, respectively. No apparent difference in the photosubstitution reaction was observed either in the cell mode (Fig. 2b) or in the spray mode (Fig. 2c), although the photoreaction enviroments were fifferent (ordinary solution vs. microscopic charged droplets). The photoproducts were divalent $RuL_2(AN)_n^{2+}$ (n=0-2), monovalent $RuL_2(AN)_2X^+$, and BH^+, the protonated dmbpy liberated

Figure 1. Photosubstitution

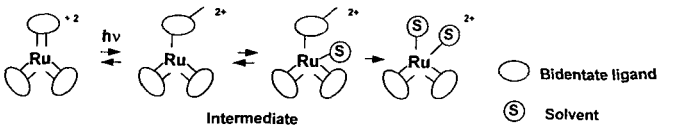

Figure 2.

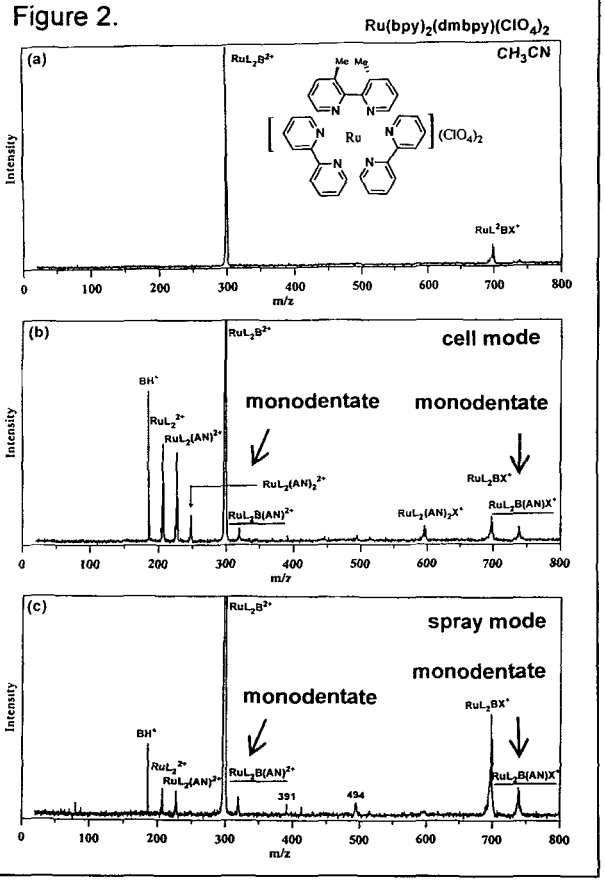

from the complex. $RuL_2B(AN)^{2+}$ and $RuL_2B(AN)X^+$ were also observed; they must be reaction intermediates with a monodentate B ligand since AN is expected to coordinate to Ru in these species. Such a signal was not detected in the on-line ES mass spectra obtained after photoreaction of $Ru(bpy)_3^{2+}$ and $Ru(bpz)_3^{2+}$.

The larger intensities observed for the 4- and 5-coordinate ions than for the 6-coordinate ion must be due to a facile dissociation of acetonitrile molecules from the 6-coordinate ion by collision-induced dissociation (CID).

FORMATION OF COMPLEXES BETWEEN ANGIOTENSIN II AND FIRST-ROW TRANSITION-METAL(II) IONS BY ESI: SOLUTION VS GAS PHASE

M. Cameron Sullards, Jeanette Adams, and Alex Reiter, Department of Chemistry and the Emory University Mass Spectrometry Center, Emory University, Atlanta, GA 30322

Experiments were conducted to determine: (1) the binding affinities between first-row transition metal(II) ions and angiotensin II; (2) whether angiotensin II-Me^{2+} complexes in which Me^{2+} = Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} reflect solution or gas-phase formation. Narrow scan range (*m/z* 515-615) electrospray ionization (ESI), full scan range (*m/z* 200-1200) ESI, and MS^2 experiments were performed using a JEOL JMS-SX102/SX102A/E five-sector tandem mass spectrometer.

The narrow scan range data show that the relative ion abundances of $(M + Me)^{2+}$ ions change with metal(II) ion. Furthermore, the absolute ion intensities of the $(M + Me)^{2+}$ ions change with metal(II) ion. The absolute ion intensities increase from Mn^{2+} to Cu^{2+} then decrease sharply from Cu^{2+} to Zn^{2+}. This follows the Irving-Williams series of transition metal(II) ion binding to ligands [1].

The full scan range data reveal that the $(M + Me)^{2+}$ ions are the predominant metal ion-peptide species (Figure 1). The singly charged $(M + Me - H)^{+}$ ions are not detected. Furthermore, the triply charged $(M + Me + H)^{3+}$ ions are only weakly abundant. The absolute ion intensities of $(M + Me)^{2+}$ ions are the same as in the narrow-scan data (brackets in Figure 1).

MS^2 metastable ion decomposition spectra of the $(M + Me)^{2+}$ precursor ions show abundant product ions (Figure 2). Singly charged product ions arise from complexes that contain zwitterionic peptides coordinated to the metal ion. Spectra of Co^{2+}, Ni^{2+}, and Zn^{2+} complexes show abundant $(b_6 + Me - H)^{2+}$ ions. Complexes that contain Cu^{2+} bind differently than other transition metal(II) ions.

In solution at pH 5-8, complexes between angiotensin II and Mn^{2+} contain no deprotonated amides [2]. The Mn^{2+} is bound to either the Asp or C-terminal carboxylate. The resulting solution complex is doubly charged, and thus highly abundant $(M + Mn)^{2+}$ ions are expected by ESI if ESI reflects solution. In this same pH range, Ni^{2+} and Cu^{2+} form 3N complexes with the His side chain and two deprotonated amides toward the N-terminus [3,4]. The resulting solution complexes have no net charge. Thus, highly abundant $(M + Ni)^{2+}$ or $(M + Cu)^{2+}$ ions are not expected by ESI if ESI reflects solution. The ESI data, however, do not reflect these expected solution results.

The ESI data reveal that complexes between angiotensin II and first-row transition metal(II) ions are readily formed. The $(M + Me)^{2+}$ ions are the predominant metal ion-peptide species. The complex formed with Cu^{2+} is of significantly greater abundance than that formed with Mn^{2+}. The ion abundance trends are not related to solution chemistry. Furthermore, the MS^2 data show that the gas-phase complexes of Cu^{2+} and Ni^{2+} do not reflect expected solution species.

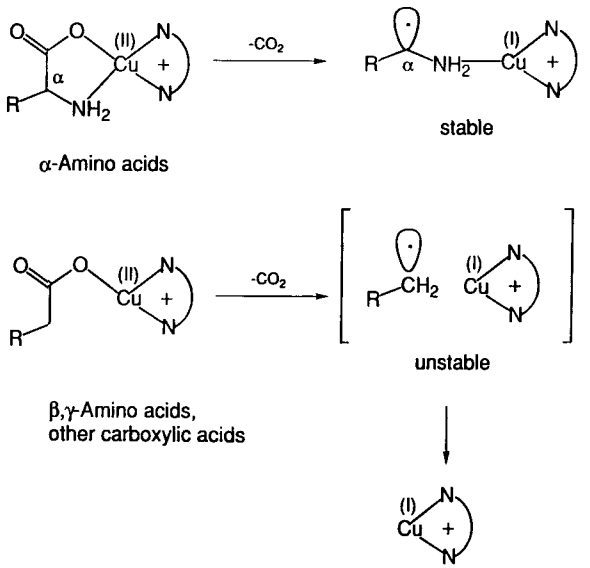
Amino Acid Coordination to Cu(II)-Diimines: Structures and CAD Mechanisms

Christine L. Gatlin,[1] *Frantisek Turecek,*[1] *Tomas Vaisar*[2]
[1]Chemistry Dept., Box 351700, University of Washington, Seattle, WA 98195-1700
[2]Molecumetics, Ltd , Bellevue, WA 98102

Coordination of Cu(II) to amino acid residues (eg. His, Cys, Met) in highly ordered protein structures has been well documented. However, much less is known about the intrinsic properties of Cu(II) interactions with free amino acids Tetracoordinate complexes of Cu(II) and diimines with amino acids are known to be stable in solution.[1] We report[2-4] the ES-MS detection of singly and doubly-charged ions of Cu(II)-diimines with all 20 essential amino acids Low-energy CAD of the resulting gas-phase ternary complexes ($[Cu(AA-H)L]^+$, L=bpy, phen, dmphen) show several common features which can be rationalized in terms of free radical-induced dissociations and used to distinguish isomers (Leu and Ile) and isobars (Gln and Lys).

REDUCTIVE DECARBOXYLATION

Reductive decarboxylation to form stable $(M-CO_2)^+$ ions is a common first step resulting in an aminoalkyl radical residue coordinated to Cu(I) by the amino group $Cu(bpy)^+$ complexes of other carboxylic acids do not form stable $(M-CO_2)^+$ ions stressing the importance of the α-aminoalkyl radical for binding to copper.



RADICAL β-FISSION

For aliphatic amino acids, further dissociations of the aminoalkyl radical complex involve β-fission of the alkyl chain which gives information on its branching, as shown for Leucine and Isoleucine

Peptide Coordination to Cu(II)-diimines: Structures and Sequence Information

Christine L. Gatlin,[1] Ramesh D. Rao,[1] Frantisek Turecek,[1] Tomas Vaisar[2]*
[1]Chemistry Dept., Box 351700, University of Washington, Seattle, WA 98195-1700
[2]Molecumetics, Ltd., Bellevue, WA 98102

The analytical utility for peptide sequencing by MS has been of growing interest.[1] Most studies have been based on the gas-phase fragmentations of *protonated* peptide ions. Sequencing of these ions is based on a series of charge-induced fragmentations ideally occurring at random along the peptide backbone Difficulties have been encountered, however, with peptides containing amino acids with basic side groups which can impede backbone fragmentation.[2] In contrast to "random" fragmentations, *metallated* peptide ions have shown specific fragmentations depending on the nature of the metal ion and its binding site. Most studies have involved FAB-induced (*high energy*) fragmentations of negatively-charged alkali or alkaline-earth cationized peptides.[3] However, there are a few reports discussing gas-phase peptide interactions with *bare* transition-metal ions which typically provide a few sequence fragment ions upon CAD.[4]

We report the formation of gas-phase ternary complexes of the transition-metal Cu(II), and a diimine co-ligand (such as bpy) with a number of isomeric dipeptides[5] and tripeptides upon electrospraying their methanol-water solutions. Low-energy CAD of the resulting Cu-diimine-peptide complexes show (1) the distinction of peptide isomers differing in their amino acid positions, (2) the sharp differentiation of C-terminal leucine and isoleucine, and (3) specific fragmentations that can be induced starting at either the N- or C-terminus of the coordinated peptide.

Three dipeptide isomeric pairs (LF, FL; AL, AI; MF, FM) and three tripeptide isomers (GGI, GGL, LGG) were selected for detailed comparison For the $Cu(bpy)^+$ of Ala-Leu and Ala-Ile (*next page*), low energy CAD clearly distinguishes the isomers The $'a_1$ fragment at *m/z* 262 is indicative of N-terminal Ala. Reductive decarboxylation followed by β-fission of the C-terminal aliphatic side chain distinguishes Leu (loss of C_3H_7) from Ile (loss of C_2H_5).

ANALYSIS OF METAL CHELATES BY ELECTROSPRAY IONIZATION MASS SPECTROMETRY

K. L. Wahl, R. W. Stromatt, and D. L. Blanchard
Pacific Northwest Laboratory, P.O. Box 999 Richland, WA 99352

Solubilized metal ions pose a potential environmental threat for many waste-disposal sites. Understanding the behavior of metal ions in complex organic matrices and the possible metal-chelate complexes that could form may aid in developing remediation techniques. For example, waste tanks on the Hanford Site are known to contain large amounts of chelators such as ethylenediaminetetraacetic acid (EDTA). These chelators may be responsible for difficulties in removing some of the radioactive metals, such as ^{90}Sr. One possible method for examining these metal-chelate complexes is electrospray ionization mass spectrometry (ESI-MS). The goal of this project is to examine the behavior of strontium (Sr) in complex mixtures containing a variety of inorganic and organic components that simulate tank waste constituents. Preliminary results presented suggest that ESI-MS can be used to study the behavior of chelators, such as EDTA, N-(2-hydroxyethyl)ethylenediaminetriacetic acid (HEDTA), and nitrilotriacetic acid (NTA), in the presence of metals such as iron (Fe) and Sr.

Negative ESI-MS of a solution containing EDTA and Sr in a 20:1 molar excess of EDTA exhibits ions from the Sr-EDTA complex, in addition to doubly and singly charged EDTA with various amounts of sodium (Na) adduction. These concentrations were chosen because they resemble those estimated to be present in the waste tanks at the Hanford Site. Increasing the concentration of Sr relative to EDTA increases the intensity of the Sr-EDTA ion relative to the Na adducted EDTA. As expected, adjusting the capillary-skimmer offset voltage in the interface region affects the observation of the Sr-EDTA ion. Adding $Fe(NO_3)_3$ to the solution mixture creates a competition between Fe and Sr for complexation with EDTA. Both metal-EDTA complexes are observed by negative ESI-MS as shown in Figure 1. The relative ratios of Fe, Sr, and EDTA were chosen to represent typical relative concentrations in tank waste. Further studies of adjusting the solution conditions to verify that ESI-MS is probing solution specific complexation behavior are in progress.

When citrate, another potential chelator that is present in the tank wastes, is added to a solution of EDTA and Sr, only the Sr-EDTA complex is observed by ESI-MS (Figure 2). No evidence of a Sr-citrate complex is observed. The order that the solution components are added and the solution pH needs to be adjusted to substantiate these preliminary results Other chelators, such as NTA and HEDTA, show significant complexation with Sr when individually studied. The next step is to combine different chelators in the same solution to determine if competition for complexation based on known stability constants of different metal-chelate complexes can be observed by ESI-MS.

Preliminary results indicate that negative ESI-MS can provide insight into the chelation of Sr by compounds such as EDTA and HEDTA. The next step is to study the effects of solution conditions, such as pH, mixing order, and solvent composition, in addition to the electrospray conditions on the complexes observed by ESI-MS. Future work will expand these studies to more complex solutions and focus on adding on-line separations such as capillary electrophoresis.

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under Contract DE-AC06-76RLO 1830.

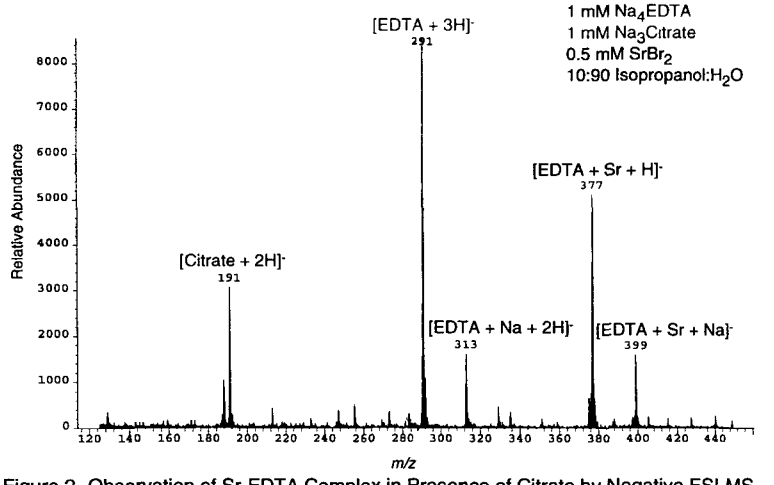

Figure 2. Observation of Sr-EDTA Complex in Presence of Citrate by Negative ESI-MS.

PRODUCTION OF COORDINATED 3D TRANSITION METAL IONS BY ESMS

Yaodong Xu, Xin Zhang, Alfred L. Yergey
LTPB, NICHD, National Institutes of Health, Bethesda, MD 20892

We have investigated first-row transition metal ions, Cu(II), Ni(II), Zn(II) and Co(II), coordinated with model amino acid and/or simple peptide systems, glycine (gly) and glycylglycine (gly-gly), by means of electrospray ionization mass spectrometry (ESMS). The purpose of this investigation is to study the formation of these complex ions under electrospray ionization conditions and the relationship between the electrospray mass spectra of these ions and their solution chemistry. These preliminary results will serve as the basis for more detailed studies of the coordination chemistry and interactions of proteins with transition metal ions by ESMS.

Experiments were carried out in the apparatus consisted of a home-built electrospray ionization source interfaced to a component based quadrupole mass analyzer. A 500 mm ID, 26 cm long stainless steel capillary that is resistively heated were employed. Multiply charged droplets were produced from solutions flowing at 1.8 μL/min from a syringe pump through the discharge needle held at +2.6kV. The capillary was maintained at the lowest temperature possible consistent with detection of ions. The discharge needle is separated from the capillary by about 6.0mm. The 0.5mm aperture skimmer is 3.5mm away from the capillary end. The average pressure in the region between the capillary and skimmer is 1.2 torr maintained by a 600 l/min mechanical pump. The ion beam exiting the skimmer passes through an einzel lens held in a differentially pumped chamber evacuated by a 4-in., 1200 liter/sec oil diffusion pump. The ion beam passes through a 5mm diameter aperture into the quadrupole analyzer. Operating pressure in the latter is 1x10-6 torr. A Model 4752-G continuous dynode electron multiplier is used for ion detection.

The electrospray mass spectrum of a mixture of Cu(II) and gly solutions is shown in Fig. 1a. We have identified the pairs of ions at 138/140, 173/175, 212/214 and 287/289 Da as the singly-charged ions $[Cu(I)\cdot gly]^+$, $[Cu(II)\cdot(H_2O)_2\cdot(gly^-)]^+$, $[Cu(II)\cdot gly\cdot(gly^-)]^+$ and $[Cu(II)\cdot(gly)_2\cdot(gly^-)]^+$. In addition, we have identified the pairs of peaks at m/z 87/88 and 106.5/107.5 Da as the doubly-charged ions $[Cu(II)\cdot(H_2O)_2\cdot gly]^{2+}$ and $[Cu(II)\cdot(gly)_2]^{2+}$. The fractional abundances of ^{63}Cu and ^{65}Cu at 0.692 and 0.308 were reflected in the ion intensities of these species. Replacing gly with gly-gly led to analogous singly- and doubly-charged ions. When a mixture of the solutions containing Cu(II) and equal amounts of both ligands was used, the singly- and doubly-charged ions of both ligands as well as mixtures were observed. The mass spectrum of Ni(II)/gly solution is shown in Fig. 1b.

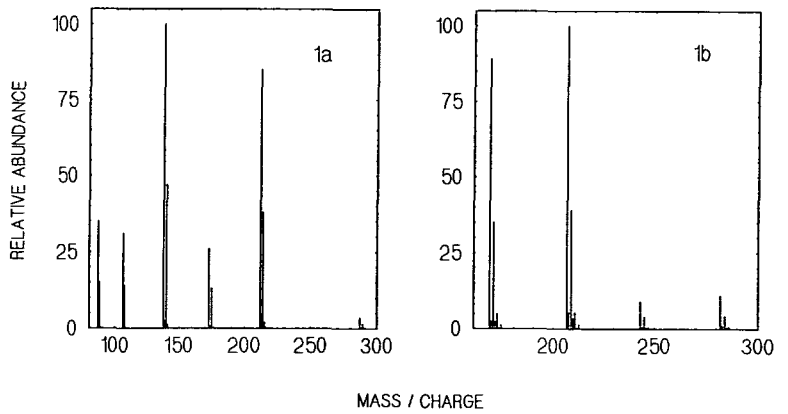

Figure 1. Electrospray ionization mass spectrum of complex ions. flow rate = 1.8 μL/min, the capillary was heated to 60°C. (a) 5.0×10^{-4} M Cu^{2+} and 1.0×10^{-3} M glycine in deionized water. pH=3.92. (b) 5.0×10^{-4} M Ni^{2+} and 1.0×10^{-3} M glycine in deionized water. pH=5.00.

The metal·gly and metal·gly-gly complex ions can be divided into two groups that differ in their formation mechanisms. The first group is a novel type of ion for ESMS, and is taken to be a consequence of direct desorption of a complex that originated in the solution and was protonated [1], if necessary, during ESI. The second group results from a number of possible gas phase reactions including charge transfer and ligand replacement [2]. Most of the complex ions we observed are believed to belong to first group.

The aqueous solution chemistry of 3d transition-metal ions and gly and gly-gly has been well established in electrochemical studies. Comparing our results with previous data, we conclude that the electrospray spectrum may not be a quantitative representation of the aqueous solution for these complex ions, but it does show that the spectrum is a qualitative representation of the bulk phase compositions.

Characterization of Transition Metal Organometallic Complexes by ESI/Sector MS

H. Tong, K. Ng, R. Rodebaugh, C. Kuell, S. Shum and S. Pastor
Ciba-Geigy Corporation, 444 Saw Mill River Road, Ardsley, NY 10502-2699

The study of organometallic chemistry is important to life science, catalysis and many other fields. Mass spectrometry, especially via FAB, has been a useful tool for these studies. But FAB has serious limitations, particularly in ionizing large molecules while preserving their fragile bonds. The emergence of ESI/MS, with its unique ion formation mechanism and its "softness", has provided an unprecedented opportunity for the characterization of a small amount of large organometallic compounds in solution. This is demonstrated through the study of cyclic phosphite-Rh complexes in solution at pmole levels.

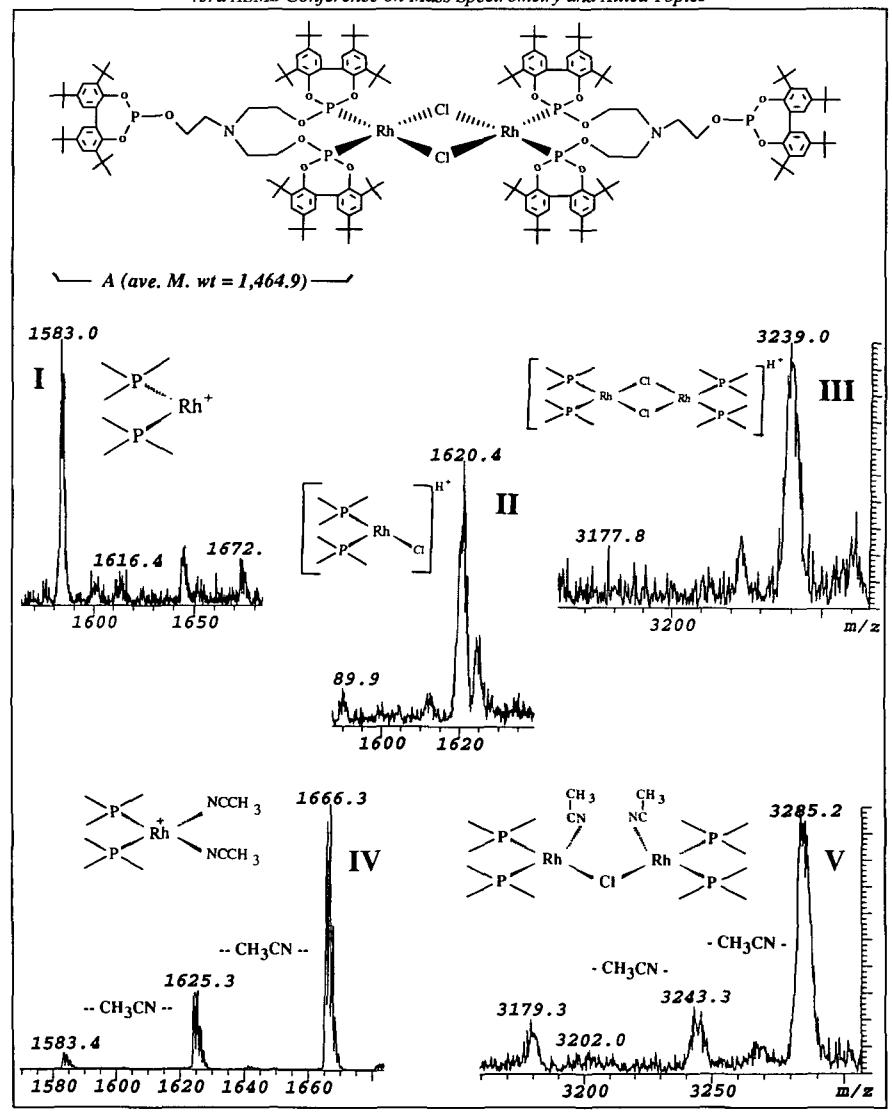
The metallic complexes in this study were synthesized in the Ciba Additives research laboratories. The ESI/MS analyses were performed on a Fisons AutoSpecQ hybrid (EBEqQ) MS with a m/z range up to 9,000 under the ESI condition. High- and low-energy collision-induced dissociation (CID) MS/MS techniques were also used in the analyses. The NMR data of these complexes were obtained from Varian Gemini 300 and UNITY 500 MHz NMR instruments.

The target complex of this study was the [A-Rh-Cl_2-Rh-A] dimer (see the diagram). The NMR data (P31, 1 and 2D) of the synthetic product in $CDCl_3$ clearly showed the P-Rh-P binding unit, but could not affirm the presence of Cl as a ligand The P31 NMR explicitly failed to show the dimer because the increased P31 spectral complexity expected from the virtual coupling of the two rhodium was not seen. The dimer structure was proposed on the basis of the synthetic path followed and literature precedent.

In the ESI/MS spectrum I of the sample in CH_2Cl_2/MeOH, the major complex component is $[A'Rh]^+$ observed at m/z 1,583 (A' = A with one P oxidized, only the structures associated with Rh are given in all the spectra) No complex dimer was detected When the sample solution was acidified with 0 5% CH_3COOH, an ion at m/z 1,620 emerged (spectrum II), indicating that Cl has rejoined the complex. At the same time, an ion was observed at m/z 3,239 (spectrum III), corresponding to the Cl-bridged dimer. Both [A'RhCl] and the dimer were able to be charged via protonation, but produced weak signals. However, the spectra of the complex can be dramatically changed when the solvent is altered. This is illustrated in spectra IV and V which arose upon a replacement of CH_3COOH with a small amount of CH_3CN. The chloride is displaced; an intense ion at m/z 1,666 and weak ion at 3,284 represent [A'Rh+2CH_3CN] and [dimer+2CH_3CN], respectively. The easy detection of these four-coordinate species of Rh^I is likely due to their stabilities in the solution. Under the CID conditions, as shown in spectra IV and V, the CH_3CN ligands can be consecutively removed, and other bonding properties can be explored (which will be detailed in the full paper) *To ensure that the dimers detected were not the result of ion* clustering phenomena commonly encountered in ESI, the sample solution was scanned up to m/z 9,000 and no species above m/z 4,000 was observed.

The ESI/MS data provide a "dynamic" picture of these complexes in solution, as opposed to a static one from X-ray crystallography. The phosphite ligand binds to Rh^I tightly, whereas Cl associates with Rh^I loosely. The role of Cl within the complex, and its participation in formation of the "dimer bridge" can be manipulated through careful control of solvation. Furthermore, we were able to successively displace Cl with other ligands more strongly electron donating in nature. Through these, an array of novel, subtly varied, charged species in solution can be realized by ESI/MS. The volatile nature of Cl participation in these complexes may explain the difficulties of NMR in developing evidence for the dimer.

43rd ASMS Conference on Mass Spectrometry and Allied Topics



Accurate Mass Measurement of Peptides Ions with a Magnetic Sector Instrument

P.A. D'Agostino, J.R. Hancock and L.R. Provost, Defence Research Establishment Suffield, P.O. Box 4000, Medicine Hat, Alberta, CANADA, T1A 8K6

The use of magnetic sector instruments for high resolution mass measurement of peptide molecular and product ions is limited, with prior publications dealing with the electrospray (ESI) analysis of pure peptides available from commercial sources. High resolution ESI-MS enables the confident assignment of charge state to multiply charged isotope clusters, the calculation of monoisotopic molecular weights, and aids in the interpretation of primary sequence data following collisional activated dissociation (CAD) in the ESI interface.

ESI-MS Conditions follow: Instrument, Autospec-Q with Mark II ESI interface; Electrospray needle, 7.8 kV; Acceleration voltage, 4 kV; Sampling cone voltage, 0 to 250 volts; Nitrogen bath gas (80°C), 500 L/hr; Nitrogen nebulizer gas, 14 L/hr; Source/Analyser vacuum, $2x10^{-6}$ / $3x10^{-8}$ Torr; Scan functions, 1550 to 400 Da (25 sec/dec) or 1000 to 400 Da (30 sec/dec); Resolution, 2500 to 9000 (10% valley); Calibration, external calibration with PEG; LC, Applied Biosystems 140B pumping 1:1 mixture of water (with 0.05% TFA) and 20% water/80% acetonitrile (with 0.05% TFA). Samples: 0.02 to 0.1 mg/mL range in distilled water.

High resolution ESI-MS data were obtained for unknown synthetic peptides and toxic peptides of particular interest to the defence community. Accurate monoisotopic molecular weights were obtained for peptides up to 7500 Da during magnetic sector scanning over a wide mass range. Figure 1 illustrate the ESI-MS data obtained for one of the Conus snail toxins, w-Conotoxin MVIIC. Figure 2 illustrates the ESI-MS data obtained for synthetic peptide #29 at a sector resolution of 6000. A 37 ppm difference between the theoretical and observed molecular weight was obtained. Errors between observed and theoretical monoisotopic molecular weights were typically in the 5 to 60 ppm range at sector resolutions between 2500 and 9000 (10% valley definition).

CAD/MS was investigated under a number of different cone voltage settings, LC flow rates and bath gas temperatures in an attempt to increase product ion formation. Product ion formation, as anticipated, increased with increasing cone voltage settings. Cone voltages above 175 volts resulted in significantly reduced signal strengths. LC flow rates of 20 μL/min and bath gas temperatures of 80°C, recommended for the ESI interface, were used successfully during loop injections. Increasing the LC flow rate to 50 μL/min, to be compatible with 1 mm I.D. LC, resulted in a lack of product ion formation. Incomplete desolvation in the ESI interface was suspected. Increasing the bath gas temperature to 100°C (maximum) resulted in only a modest improvement in product ion formation. The best CAD/MS analyses were obtained at lower flow rates, 10 to 20 μL/min., with cone voltage settings in the 100 to 150 volt range. Full or partial sequencing of unknown peptides below 2000 Da was demonstrated for the synthetic and bioactive peptides used in this study. The complete primary sequence for an unknown was determined and the value of high resolution MS was demonstrated by the differentiation of Lysine from Glutamine, two amino acids differing in residue mass by 0.0364 Da.

Acknowledgement: The authors thank Dr. R. Hodges and Mr. P. Semchuk (University of Alberta) for the unknown synthetic peptides used in this study.

Some important effect in protein and peptide analysis by MALDI*

Y.F. Zhu, K.L. Lee, K. Tang, S.L. Allman, N I. Taranenko, and C.H. Chen

Oak Ridge National Laboratory
P.O. Box 2008, Bldg 5500, Oak Ridge, Tennessee 37831-6378, U.S.A.

During the past few years, tremendous progress has been achieved in the analysis of proteins and peptides by Matrix-Assisted-Laser Desorption Ionization spectroscopy (MALDI). Observations of protein ions with molecular weights greater than 100,000 Da by MALDI have been reported. The detection of peptides and proteins by MALDI is beginning to be accepted as an effective analytical technique. But, on the other hand, the desorption and ionization mechanisms of MALDI process are not well understood despite extensive study. Many questions in this area remain unanswered, and the selection of good matrices for MALDI analysis of biomolecules relies on "experience" rather than scientific analysis. For example, is there any specific ionization channel which is enhanced by the presence of a certain functional group in a protein or peptide chain? If there is, what is the preferred ion form (positive or negative), and how does it relate to the molecular weight? In this work, we present the MALDI results of proteins and peptides to answer some of these questions.

The MALDI experiments were conducted in a recently built reflectron time-of-flight mass spectrometer (Jordan) with 15 and 16 kV for linear and reflectron voltages respectively Two ion detectors have been installed, one for the linear signal and an other for the reflected signal. An interesting effect was observed in our preliminary MALDI results of insulin, insulin A chain and insulin B chain. The MALDI signal of insulin B chain was found to be much larger than the one of insulin A chain under identical experimental condition even though the molecular weight of the B chain is much larger than that of A chain. Further experimental results imply that the weak MALDI signal of insulin A chain was not due to suppression by contaminants, insulin B chain, or matrix molecules This intensity difference between A and B chains indicates that the ionization efficiency depends on the molecules themselves, i.e. the type of amino acids they contain. In comparing the types of amino acids in insulin A and B chains, we notice that there are several basic amino acids (arginine, histidine, and lysine) in B chain which are not in A chain. To confirm the effect of enhanced ionization efficiency by these basic amino acids, we made MALDI measurements of many small peptides which contain either one basic amino acid or none in their chains. These small peptides are similar in molecular weight and amino acids other than the basic amino acid. Comparing the ionization efficiencies of these peptides in MALDI spectroscopy, we discovered several important effects.

1) For positive ion detection, the MALDI intensity of the peptides containing one basic amino acid are generally 10-100 times greater than the MALDI intensity of the peptides containing no basic amino acid. This conclusion is based on the measurement of 15 peptides which contain one basic amino acid, and 6 peptides which do not contain any basic amino acid Figure 1 shows the MALDI spectra of Allatostatin IV (contains one arginine) and Allatostatin III (no arginine).
2). For negative ion detection, the MALDI intensity of the peptides containing one basic amino acid are almost negligible. The ratios of positive ions vs negative ions of these peptides are approximately $10\text{-}10^2$ using laser energies of 1 to 4 mJ/cm^2. (See Figure 2)
3). No double charged peptide ions have been detected in the peptides containing one basic amino acid even under high laser energy (~10 mJ/cm^2). On the other hand, double charged peptide ions have been detected in the peptides containing more than one arginine at the threshold laser energy (1 mJ/cm^2).
4) The ratios of the positive ion vs negative ion signals for matrix molecules are approximately $10\text{-}10^{-2}$, which is opposite to the ratio of peptides that contain one basic amino acid.
5). The positive ion signals of peptides containing one basic amino acid are greatly suppressed when a small amount of NH_3 is used to neutralize 25% of H^+ in matrix molecule. This result indicates that the ionization of these peptides containing basic amino acid is H^+ related.

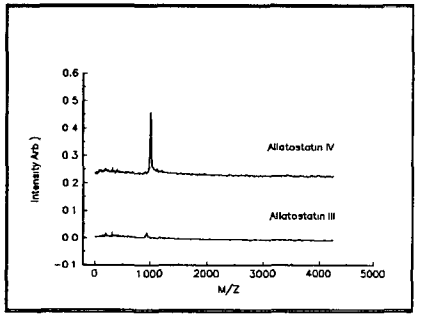

Figure 1 The MALDI spectra of Allatostatin IV and Allatostatin III.

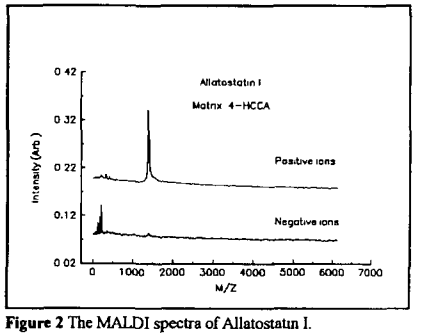

Figure 2 The MALDI spectra of Allatostatin I.

All these results strongly indicate that the ionization mechanism of the peptides or proteins containing basic amino acid is different from that of the peptides or proteins containing no basic amino acid The basic amino acid in protein or peptide chains can react with the protons of matrix molecules to form stable ions during the MALDI process. The ionization mechanism is dominated by the proton transfer from matrix molecule to peptide. Due to the low energy barrier of the acid and base reaction, large numbers of peptide ions are formed and the MALDI intensities of these peptides are greatly enhanced. When a peptide only contains one basic amino acid, the single charged ion is formed. When a peptide contains more than one basic amino acid, both the single charged ion and the double charged ion are observed. Due to the mechanism of proton transfer, if the H^+ concentration of the matrix solution is reduced by the presence of an other base, the MALDI intensity of these peptides should be greatly decreased, which is consistent with experimental results

Matrix Solution Effects of the MALDI-MS of Peptides & Proteins

*S. L. Cohen and B. T. Chait
The Rockefeller University, 1230 York Avenue, NY, NY 10021

MALDI-MS is a powerful tool for evaluating mixtures of peptides and proteins. In this study we have found that the details of the sample/matrix preparation have profound effects on the quality of the MALDI response using 4HCCA (4-hydroxy-*alpha*-cyano cinnamic acid).

First, the matrix solution composition strongly influences the MALDI response. We investigated sixteen different matrix solution compositions and have determined that there are solution-dependent mass discrimination effects. **Fig. 1** shows the positive ion MALDI-MS of a partial V8 digest of an 11 kDa recombinant protein (the transcription factor Max; five Glu residues) [**1**]. The spectra were run in two matrix preparations using the conventional dried drop method [**2**] with a linear time-of-flight instrument. The top spectrum was taken with a saturated 4HCCA solution made from formic acid-water-isopropanol (FWI) (1:3:2 v/v), pH 1.3. Note the strong presence of intermediate- and high-mass components of the digest. The bottom spectrum of **Fig. 1** was run with 4HCCA made with water-acetonitrile (2:1 v/v), pH 2.5. In contrast to the FWI spectrum, note the dominance of low mass peptide fragments and the distinct lack of components above m/z 6000. These results, along with our studies of other 4HCCA matrix solutions, suggest that the observed mass discrimination effects are strongly pH-dependent.

A second matrix solution effect involves the time scale of matrix/analyte crystallization. **Fig. 2** shows the MALDI-MS of a complete V8 digest of the protein Max. A total digest of the protein results in six V8 fragments (labeled 1-6). The matrix solution used was 4HCCA / water-acetonitrile (2:1 v/v). Two different crystallization procedures are compared. In the dried drop technique [**2**] (TOP spectrum) the matrix/analyte solution droplet air dries on the MALDI probe in about two minutes. Using this method, all six V8 fragments are observed. In the slow crystallization method [**3**], analyte-doped matrix crystals where grown for 12 hr. in the matrix solution. For this method (BOTTOM spectrum) only the two high-mass V8 fragments (5 and 6) appear in the spectrum. We have found this low-mass discrimination effect to occur regardless of the composition or pH of the matrix solution.

In conclusion, we have shown that there are pH-, solution composition-, and time-dependent mass discrimination effects observed in MALDI-MS using the matrix 4HCCA. These effects add a "chromatographic" dimension to the sample/matrix preparation procedures that can be suitably exploited to optimize the analysis of mixtures of peptides and proteins.

STUDY OF OXIDATION REACTION OF SELENOMETHIONINE PEPTIDES BY MASS SPECTROMETRY

Rong Wang[1], Urooj A. Mirza[1], Steven Birken[2], and Brian T. Chait[1]
The Rockefeller University, New York, NY 10021
College of Physicians & Surgeons of Columbia University, New York, NY 10032

A powerful variation of multiwavelength anomalous diffraction that is extremely useful for determining the three-dimensional structures of proteins involves the substitution of selenomethionine for methionine in the proteins of interest[1]. Unfortunately, selenomethionine has a high sensitivity to oxidation. Because protein crystals take a long time to grow, this sensitivity to oxidation may produce a heterogenous product that diffracts poorly. Therefore, it is important to have a reliable method for analyzing the oxidation of selenomethionine residues in proteins -- to ensure that a homogenous product is produced. oxidation of free selenomethionine was studied in the early 70's.[2] The oxidation product was identified as selenoxide by NMR. However, it is much more difficult to analyze oxidation of selenomethionine residues in peptides and proteins. In the present study, we tested several mass spectrometric approaches for assaying the oxidation of selenomethionine in peptides, which includes matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS), californium-252 plasma desorption mass spectrometry (PDMS) and electrospray ionization mass spectrometry (ESI-MS).

Selenomethionine-containing peptide (SeMet-peptide, Arg-Ala-Ala-Ala-SeMet-Asn-Pro-Thr-Leu-Glu) and methionine-containing peptide (Met-peptide, Arg-Ala-Ala-Ala-Met-Asn-Pro-Thr-Leu-Glu) were chemically synthesized by the solid phase method. The Oxidation was induced by hydrogen peroxide. Peptides were reacted with hydrogen peroxide in the molar ratio of 1:100 to 1:1000 (peptide/hydrogen peroxide) and the reaction products were either directly analyzed by mass spectrometry or separated by reverse-phase high performance liquid chromatography (HPLC) and analyzed by mass spectrometry.

MALDI-MS results indicate that the Met-peptides undergo oxidation to the Met-sulphoxide and a small amount of sulphone, while oxidation of the SeMet-peptides gives no selenoxide. Rather, the original peptide is observed together with product that arises from loss of the selenomethyl group and homoserine derivative (Figure 1).

PDMS gives the same results as MALDI-MS. In addition, when the selenomethionine peptide is exposed as a solid film to air, loss of the selenomethyl group is observed. The major product from an oxidation of the Met-peptide is the Met-sulfoxide.

The oxidation reaction products were analyzed by ESI-MS. When the reaction mixture was infused into the mass spectrometer in the presence of hydrogen peroxide, a selenoxide derivative of the peptide and a fragment arising from the loss of the oxidized methylseleno group were detected (Figure 2). The presence of hydrogen peroxide in the spray solution appears to accelerate the loss of the oxidized methylseleno group. The ratio of the fragment to the selenoxide increases in proportion to the concentration of hydrogen peroxide.

Two product peaks were readily resolved in reverse-phase HPLC from the oxidation reaction mixture (Figure 3). These two peaks were analyzed by MALDI-MS and gave almost identical spectra. By doing LC/ESI-MS, these two peaks were identified as methionine selenoxide peptide derivative and original SeMet-peptide (Figure 4).

Our experiment results shown that great care should be taken when studying labile compounds by mass spectrometry. For selenomethionine residue oxidation studies, electrospray ionization mass spectrometry is the method of choice.

Mapping of the β-Amyloid Peptide from Alzheimer Disease Brain by Gelatinase A using MALDI.

A.S. Woods and R.J. Cotter
Johns Hopkins School of Medicine Baltimore, MD 21205

M.J. Ball A.E. Roher
Wayne state University School of Medicine Detroit, MI 48201.

In Alzheimer disease (AD), the β-Amyloid (Aβ) peptide accumulates in the gray matter, leading to destruction of brain cells, cortical vessels, and occlusion of capillary networks resulting in dementia (1). The 39-42 amino acid long Aβ polymerizes into 10 nm filaments which are very insoluble and resistant to proteolytic degradation. The Aβ peptide is derived from a larger molecule that resembles a cell surface receptor, the β-amyloid precursor protein (βAPP), is expressed by a gene in chromosome 21. By alternative mRNA splicing molecules made of 695, 751 or 770 amino acid residues (aa res) are generated. The N-terminus of the 42 aa res form of Aβ results from hydrolysis between Met_{596}-Asp_{597} of the 695 aa res βAPP ($βAPP_{695}$) by β-secretase. The C-terminus of Aβ is produced by hydrolysis of the bond Ala_{638}- Thr_{639} located within the transmembrane domain of βAPP. An alternative cleavage of $βAPP_{695}$ can be made by the enzyme α-secretase between Lys_{612}- Leu_{613}, generating a secreted large N-terminal βAPP domain and a non-amyloidogenic C-terminal peptide(3).

It was reported that the proteolytic enzyme gelatinase hydrolyzed the Lys_{16}-Leu_{17} peptide bond of a synthetic peptide (YEVHHQKLVFF) representing the soluble Aβ sequence of amino acid residues 10-20. The proteolytic activity of gelatinase A appears to be inhibited by a 28 kDa domain located at the C-terminal region of the secreted βAPP. Thus βAPP seems to have a dual role in its interaction with gelatinase A since it can function as its enzymatic substrate and its proteolytic inhibitor(4).

The purpose of this work was to test if this enzyme could also degrade the insoluble 40-42 residues long Aβ peptides purified from AD brain.

Human brains with severe deposits of vascular amyloid as well as large numbers of neurofibrillary tangles were used to extract the insoluble 40-42 residues long Aβ peptides (2). The extract's supernatant was applied to a FPLC-Superose 12 column. Fractions containing Aβ were pooled, dialyzed and concentrated. Digestion of Aβ by gelatinase was done at an S:E ratio of 20:1, at 37°C, for both 4 and 16 hours. The fragments generated by the digest were separated by reverse phase HPLC using a C_4 column.

Aliquots of the fractions were lyophilized and resuspended in 10 ul 20% CH_3CN, 0.1% TFA. 0.3 ul of each fraction was spotted on a target site of a a sample slide, followed by addition of 0.3 ul of matrix solution (saturated alpha-cyano-4-hydroxy-cinnamic acid in 1:1 ethanol:water). The sample-matrix mixture was allowed to dry at room temperature. The samples were analyzed by matrix assisted laser desorption/ionization (MALDI) mass spectrometry using a Kompact MALDI III(Kratos Analytical, Manchester, England).

Aβ peptide was purified, digested with gelatinase A, the resulting peptides were separated by Reverse phase HPLC using a C_4 column and characterized by MALDI (Table I). The results indicated that within the hydrophobic sequence of res 30-38 (AIIGLMVV) of both $Aβ_{1-40}$ and $Aβ_{1-42}$ numerous peptide bonds were hydrolysed. Gelatinase A preferentially cleaves hydrophobic sequences. Gelatinase A hydrolyzed $Aβ_{1-40}$ and $Aβ_{1-42}$ peptides at Lys_{16}-Leu_{17}, Leu_{34}-Met_{35} and Met_{35}-Val_{36} peptide bonds. These results suggest that Gelatinase A is capable of degrading the purified Aβ by hydrolysing this peptide *(in vitro)* at the α-secretase site and even more efficiently in the middle of its C-terminal domain. If This hydrolysis occured in the brain's extracellular matrix, the enzymztic action of gelatinase A could prevent generation of amyloidogenic $Aβ_{1-40(42)}$. The proteolytic activity of enzymes that occur natyrally in the extracellular space and that are capable of degrading Aβshould be further investigated in the search for a possible therapeutic tool in the treatment of Alzheimer's disease.

Electrospray Ionization Mass Spectrometric Studies on Brain Delivery of Neuropeptides

Laszlo Prokai, H.-S. Kim, K. Prokai-Tatrai, and N. Bodor
Center for Drug Discovery, College of Pharmacy
University of Florida, Gainesville, FL 32610-0497

The major obstacle to the use of neuropeptides in the pharmacotherapy of brain diseases is their delivery to the central nervous system (CNS) because of the existence of the blood-brain barrier (BBB -- a continuous lipid bilayer in the brain capillary endothelium). To cross this physical component of the BBB, the solute must possess sufficient lipid solubility. Most peptides are water soluble and, without specific transport system, are excluded from the brain. The BBB also contains highly active neuropeptide-degrading enzymes forming an enzymatic barrier that rapidly cleaves peptides and prevents them to reach the brain.

We have recently developed a strategy for brain delivery of neuropeptides by chemical/enzymatic means [1,2]. Covalent modifications are employed to the peptides (**P**) such as an enkephalin analog (Tyr-Ala-Gly-Phe-Leu) and the progenitor sequence of a thyrotropin-releasing hormone (TRH) analog (Gln-Leu-Pro-Gly) to increase lipophilicity through biolabile functional groups susceptible to enzymatic removal: a bulky, lipophilic ester (**L**) at the C-terminus, and a lipoidal 1,4-dihydrotrigonellyl (**T**) at the N-terminus that also serves as a redox targetor, because it is converted to a membrane-impermeable pyridinium ion (**T**$^+$) by enzymatic oxidation ($NAD^+ \leftrightarrow$ NADH coenzyme). A spacer (**S**) residue is applied that allows for the removal of **T**$^+$ by specific peptidase(s). In addition, the molecular architecture of the chemical delivery system (CDS) also disguises the peptide nature preventing the recognition and degradation by the enzymatic component of the BBB. Brain delivery occurs by the following sequence: (1) the CDS crosses the BBB by passive transport, and within the CNS (2) the targetor is converted to a membrane-impermeable form, and (3) the lipophilic protection (**L**) is removed to yield a relatively stable peptide conjugate that is retained (locked-in) in the CNS. Finally, (4) peptidases process the conjugate to release the desired peptide.

Electrospray ionization (ESI) mass spectrometry (Vestec/Perseptive Biosystems 200 ES quadrupole instrument) was used to verify that the peptide derivatives reach the brain in significant concentration after intravenous administration to rats [1]. However, the release of the peptide could not be directly determined because of the complexity of the (*post mortem*) rat brain samples. Therefore, metabolism of the peptide conjugate accumulated in the brain was studied *in vitro* (incubation in rat brain homogenate) and *in vivo* (microdialysis in living tissue [3]). Fig. 1 and 2 show that the sustained release of the biologically active peptide (Tyr-D-Ala-Gly-Phe-D-Leu, YAGFL, *m/z* 570) is confirmed. The advantage of cerebral microdialysis has been that the samples are free from interfererence by the brain tissue (endogenous peptides/proteins, self-proteolysis during incubation, etc.). Hence, metabolites can be easily identified (Fig. 2).

Characterization of Iron-Binding Exochelins of *Mycobacteria tuberculosis*

Bradford W. Gibson[1], Christopher H. Moore[1], Diane Wong[1], Jovana Gobin[2], Joseph R. Reeve Jr.[2], and Marcus A. Horwitz[2], [1]Department of Pharmaceutical Chemistry, University of California, San Francisco CA and [2]Department of Medicine, University of California, Los Angeles CA

Mycobacterium tuberculosis, the primary agent of tuberculosis, is a human pathogen that infects up to one-third of the world population. Recent cases caused by multiple-drug resistant strains of *M. tuberculosis* has made this organism a particular lethal pathogen, especially for immunocompromised patients. In order to better combat this re-emerging pathogen, a better understanding of the molecular mechanisms of *M. tuberculosis* host-pathogen interactions needs to be obtained.

Almost all bacteria need to acquire iron from their environment for the proper functioning of a number of key enzymes necessary for growth and survival. This requirement poses a significant problem for infectious bacteria which must meet their iron needs from the host where iron is quite limited. In an effort to understand the molecular basis of how *M. tuberculosis* acquires iron from the host, we have isolated and characterized a class of secreted iron-binding compounds, or "siderophores", from *M. tuberculosis*.

We have shown that these secreted siderophores, called "exochelins" (1), exist as a complex group of related compounds that are similar to the iron-binding molecules immobilized in the cell wall, the "mycobactins". Our studies include data from LSIMS, MS/MS, GC/MS and HPLC/electrospray ionization mass spectrometry (2). LSIMS of the HPLC separated exochelin mixture initially identified two separate series of potential iron-binding species. In most fractions, peaks were observed in pairs of roughly equal abundance 53 Da apart that was indicative of the iron-free and iron-bound molecular forms, i.e., $(M + H)^+$ and $(M - 2H + Fe^{III})^+$, in addition to other metal-containing species such as Mg and Al adducts. High energy CID MS/MS analysis of the non-iron binding forms of the exochelins was critical in defining the conserved core and variable components of these structures (see Figure 1A), and these des-ferri forms were only observed under LSIMS conditions. Under HPLC/ESI-MS conditions, the exochelins appear almost exclusively as their iron-bound forms (see Figure 1B) which do not undergo CID fragmentation nearly as readily as the iron-free forms. The lack of fragmentation and single ion species per component observed under ESI-MS conditions, however, provided an ideal method to identify the complete set of exochelins.

Overall, the exochelins were found to be more polar and smaller in mass compared to the water-insoluble mycobactins due the presence of a methyl ester terminating small alkyl chain attached to the N^{ε}-hydroxylysine group, i.e., $-N-CO-(CH_2)_nCOOCH_3$, compared to the much longer unmodified alkyl chain of the mycobactins, i.e., $-N-CO-(CH_2)_nCH_3$. We also observed some amounts of the corresponding free acid exochelins, $-N-CO-(CH_2)_nCOOH$, which likely arise through ester hydrolysis. However, we also observed that the methyl ester-containing exochelins could be quantitatively converted to the free acids forms by esterase treatment, suggesting the possibility of their *in vivo* conversion these acidic forms. These structural difference are likely to be important factors relating to the extracellular transport of exochelin through the *Mycobacteria* cell wall and their presumed interactions with the human host iron-binding proteins such as lactoferrin and transferrin. Moreover, the structural similarity of these two iron-binding compounds suggests that the mycobactins and exochelins share a common core biosynthetic pathway.

Figure 1. Opposite page. Top (**A**) MS/MS spectrum under high energy CID conditions of the major saturated serine-containing exochelin with $(M+H)^+$ at m/z 720.3. Fragment ions are assigned as structural moieties ***A-F*** arising from one or more cleavages about the amide or ester bonds. Bottom (**B**) On-line HPLC-ESI/MS analysis of exochelins. Note that only ferri-exochelin species are seen by ESI-MS, i.e., $(M-2H+Fe^{III})^+$, while LSIMS analysis yield numerous species for each exochelin component.

HEMORPHINS, HEMOGLOBIN-DERIVED PEPTIDE FRAGMENTS, IN BLOOD AND BRAIN STUDIED BY IN VIVO MICRODIALYSIS/MICRO-ELECTROSPRAY MASS SPECTROMETRY

Per E. Andrén[1], Katarina Sanderson[2], Fred Nyberg[2], Richard M. Caprioli[1],
[1]Analytical Chemistry Center and Dept. of Biochemistry and Molecular Biology, University of Texas Medical School, 6431 Fannin, Houston TX 77030, and [2]Div. of Biological Research on Drug Dependence, Uppsala University, Box 591, S-75124 Uppsala, Sweden

INTRODUCTION

The hemorphins are peptides with opioid activity, which are enzymatically released from hemoglobin. They have an inhibitory effect on the angiotensin converting enzyme (ACE)-activity, an enzyme known to be involved in blood pressure regulation. The hemorphins are quite stable in tissue extracts containing ACE, and are therefore proposed to be naturally occuring ACE inhibitors. A decapeptide, LVV-hemorphin-7, identical to the sequence 32-41 of the beta-chain of hemoglobin has been isolated from human ventricular cerebrospinal fluid (CSF).

In the present experiments we have studied the *in vivo* metabolism of LVV-hemorphin-7 (LVVYPWTQRF) in rat blood and brain by using microdialysis in combination with micro-electrospray mass spectrometry (micro-ES MS). In addition, we have examined the metabolism of LVV-hemorphin-7 in human plasma and CSF by using *in vitro* microdialysis and micro-ES/MS.

METHODS

In vivo metabolism of LVV-hemorphin-7 in rats

Rats were anesthetized with an intraperitoneal (ip) injection of pentobarbital (45 mg/kg) and a microdialysis probe was implanted either in the jugular vein or the striatum of the brain by stereotaxic technique (coordinates were AP +2.4, ML +3.0, DV -6.5 mm). The microdialysis probes used were CMA/20, 4mm membrane (blood) and CMA/10, 4 mm membrane (brain). The probes were perfused with artificial CSF at a flow-rate of 0.3 µL/min and were allowed a two hour equilibration period before the experiment was started.

LVV-hemorphin-7, 1.0 or 10 pmol/µL was infused for 10 min at a flow-rate of 0.3 µL/min and samples were taken every 10 min. The microdialysis probes were used to both introduce LVV-hemorphin-7 into the blood and brain as well as to collect reaction products.

In vitro metabolism of LVV-hemorphin-7 in human plasma and CSF

Microdialysis probes (CMA/10, 4 mm) were placed in 1.0 mL of human plasma or CSF. The probes were perfused with artificial CSF at 0.3 µL/min. LVV-hemorphin-7 was added to plasma and CSF to yield a concentration of 1.0 pmol/uL. Samples were taken every 30 min for 2 hours.

Capillary liquid chromatography/micro-electrospray mass spectrometry

Mass spectra were obtained with a TSQ70 triplequadrupole mass spectrometer (Finnigan MAT, San Jose, CA) equipped with a modified micro-ES source. A capillary-LC/C18-packed column (50 µm i.d., 40 nL bed volume) was used for the concentration and desalting of the peptides. The dialysate samples were loaded on to a 10 µL loop on a 10-port valve and washed onto the capillary C-18 column at a flow rate of 2 µL/min. The mobile phase contained 2% methanol/0.25% acetic acid in distilled water. After washing at 2 µL/min, LVV-hemorphin and its fragments were eluted with 50% methanol/0.25% acetic acid in distilled water at 0.82 µL/min directly into the mass spectrometer.

CONCLUSIONS

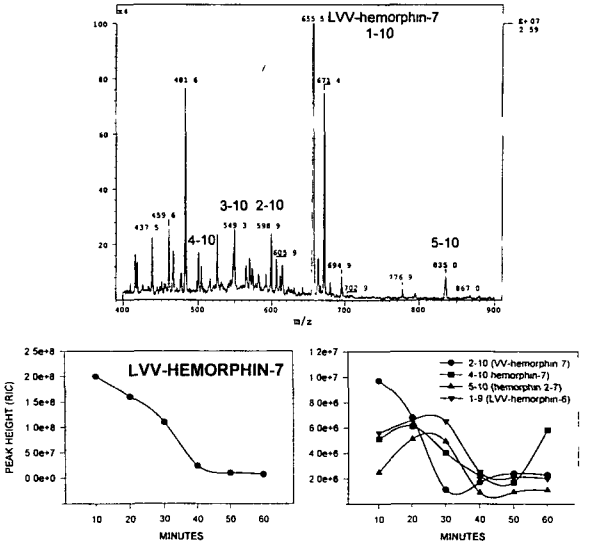
This study has demonstrated that LVV-hemorphin-7 is metabolized *in vivo* by proteolytic enzymes in the brain extracellular fluid as well as the blood.

The result showed that LVV-hemorphin-7 was metabolized mainly from the N-terminal end of the peptide. The fragments found were N-terminal fragments 2-10, 3-10, 4-10, 5-10, 7-10, C-terminal fragment 1-9, and internal fragments 5-8 and 4-9.

LVV-hemorphin-7 was relatively stable in human CSF, but more readily metabolized in human plasma.

Microdialysis in combination with micro-ES/MS is advantageous in studying dynamic chemical processes in vivo in that microdialysis provides a highly filtered, low-volume, aqueous solution of polar analytes. This technology is clearly advantageous and is the method of choice because of its unique mass specificity.

***IN VIVO* METABOLISM OF LVV-HEMORPHIN-7 IN RAT STRIATUM**



Mass Spectrometric Detection of β-Endorphin-containing Proteins in Bovine Pituitary

Dominic M. Desiderio, Lin Yan, and Jih-Lie Tseng

Charles B. Stout Neuroscience Mass Spectrometry Laboratory, University of Tennessee, Memphis, 800 Madison Avenue, Memphis, TN, 38163.

Non-secreting pituitary tumors provide difficult clinical problems because no hormone is excessively secreted. During the past several years, we found in non-secreting human anterior pituitary tumors a hypometabolism of the β-endorphin (BE)/proopiomelanocortin (POMC) system by our MS/MS quantification of BE. This significant discovery will facilitate future clinical diagnosis for non-secreting human anterior pituitary tumors.

To clarify the molecular processes that are involved in the formation of human anterior pituitary tumors and to indicate any defects in the metabolism of the BE/POMC system in tumors versus control pituitaries, we have developed a new analytical strategy,[1-3] including chromatography separation, enzyme and chemical digestion, RIA detection, and mass spectrometry characterization, to analyze endogenous BE-containing peptides and proteins that derive from POMC. The bovine pituitary is chosen as the model tissue for this research.

Trypsin digestion of BE-containing proteins will produce the following specific "marker" tryptic peptides: BE_{20-24} (=$POMC_{254-258}$, molecular weight = 557) and BE_{10-19}(=$POMC_{244-253}$, molecular weight = 1133) have favorable LSIMS properties. Therefore, the MS detection of the $(M+H)^+$ ions of those marker peptides in the trypsin-digested gel permeation (GP) and RP-HPLC fractions would guide us to find new BE-containing proteins. For the first time, two putative intermediate-sized BE-containing proteins, with molecular weight of *ca.* 9855 and 8350, were found in bovine pituitary.

A partially-purified fraction, which was different from the BE fraction, but which also showed BE-li (Figure 1), was obtained by C_{18} Sep-Pak and RP-HPLC. ESIMS analysis of this immunoreactive fraction showed the presence of a mixture of peptides and proteins. Trypsin digestion of this mixture, when analyzed by LSIMS, yielded the ions at *m/z* 558 and 1134 (among others); those two ions correspond to the $(M+H)^+$ of tryptic peptides BE_{20-24} (=$POMC_{254-258}$) and BE_{10-19}(=$POMC_{244-253}$). That immunoreactive fraction was subjected to further HPLC separation, and two components in different fractions, corresponding to molecular weight of *ca.* 9855 and 8350, showed the presence of the ions at *m/z* 558 and 1134 after treatment with trypsin (Figure 2 and 3). The component with a M.W. of *ca.* 9855 has been reported previously as a putative BE-containing protein[1]. The other component with a M.W. of *ca.* 8350 is a new putative BE-containing protein in bovine pituitary. NIH GM26666

Introduction

Endogenous Motilin is a gastrointestinal peptide hormone containing 22 amino acid residues that is involved in the regulation of fasting motility of the small intestine. A fourteen amino acid Motilin analog has been synthesized which seems to produce similar effects on the small intestine. A sensitive and selective LC/ESI/MS/MS method for the quantitative determination of a Motilin analog, extracted from human plasma, has been developed and validated. The fourteen amino acid residue peptide was quantitated using a d_{10}-analog as the internal standard. The validated method was linear from 100 to 5000 pg/mL. A three day study was performed to assess linearity, precision, and accuracy for intra-and inter-day assays.

Experimental

The peptide was isolated from 1.0 mL of heparinized human plasma using Spec microcolumn solid phase extraction. Reverse Phase chromatography of 200 µL of sample extract was performed on a Hewlett Packard Series II 1090 liquid chromatograph using a YMC Basic column (2 x 100 mm) with a flow rate of 0.5 mL/min. Mobile phases consisted of 0.01% TFA in Water (A) and 0.01% TFA in Acetonitrile. A gradient, with an initial 1 minute hold, from 0% B to 100% B in 3 minutes, followed by a 2 minute hold and a 3 minute re-equilibration. Co-elution of the test article and the internal standard was achieved at a temperature of 60°C with a typical retention time of 4.5 minutes. Detection was achieved on a Finnigan MAT TSQ700 equipped with a Finnigan electrospray interface. The mass spectrometer was operated in the positive daughter ion mode with 1.6-2.0 mtorr of argon as the collision gas. The collision energy was set at -40 ev. SRM of the singly charged product ions, formed from the triply charged parent ions, were used for quantitation.

Results

The limit of quantitation was defined as that concentration having intra-day variability less than 20%, mean accuracy of back-calculated values which was within 20% of the expected values and provided a signal to noise ratio greater than 5:1 . The signal-to-noise (baseline) ratio was always greater than 5:1. A representative chromatogram for a 100 pg/mL standard is displayed in Figure 1. The mean back-calculated value for the 100 pg/mL standards analyzed within the same day in replicate (n=4) was 98.4 pg/mL; within 2% of the expected value. The relative standard deviation was 17.4% for the 100 pg/mL Standard.

Linearity and sensitivity were assessed by replicate (n=5) analyses of extracted analytical standards over the range 100 to 5000 pg/mL for the Motilin analog using a d_{10}-analog at 2000 pg/mL. All acceptable standard concentrations produced a %CV and a mean difference from expected value (accuracy) of no greater than 15% except at the LOQ where 20% was acceptable. The method was linear from 100 to 5000 pg/mL of the Motilin analog in extracted human plasma using analytical standards from duplicate determinations at seven concentrations. The mean correlation coefficient (r^2) from the regression analysis was 0.996. The mean slope and slope %CV for 9 individual standard curves performed over three days for the Motilin analog were 6.83E-04 and 4.6%, respectively.

The precision and accuracy were evaluated in both intra- and inter-day studies. Intra-day and inter-day precision and accuracy data were provided by replicate analyses (n=5) of QC samples prepared at 250, 800, and 4000 pg/mL plasma for the Motilin analog on three separate run days. Reported concentrations of the QC's were calculated from an "aggregate" regression of duplicate standard curves (n=2 at each of seven concentrations for the Motilin analog) which were analyzed daily at the beginning and end of each analytical run. The intra-day precision (%CV) for the Motilin analog at the medium and high QC levels on each of the three days never exceeded 6%, except for the Day 1 medium QC level which was 16.2%. The intra-day precision (%CV) for the Motilin analog at the low QC level on each of the three days never exceeded 17%.The inter-day precision was less than 12% for the medium and high QC levels and less than 14% for the low QC level. Intra- and inter-day precision for replicate QC standards at low, medium, and high concentrations of the Motilin analog are displayed graphically in Figures 2. The intra- and inter-day mean values for the low, medium and high QC levels were always within ±10% of the expected concentration for the QC's.

Discussion

A specific and sensitive method for the quantitation of a Motilin analog in human plasma using solid phase extraction followed by HPLC-ESI/MS/MS has been validated. The method was linear between 100 and 5000 pg/mL. It was demonstrated that accurate and precise quantitation using freshly prepared standards in plasma and stored QC samples (-70°C) could be accomplished in a production fashion (80 or more samples/24 hr). The validity and reproducibility of the assay was determined by examining precision and accuracy in the QC's. Intra-day and inter-day precision were acceptable at all concentrations of QC's between 100 and 5000 pg/mL for the Motilin analog. The LOQ was determined to be 100 pg/mL on the basis of acceptable bias and variability, and acceptable signal-to-noise ratio.

Mass spectrometric analysis of impurities in peptide synthesis

I.A. Papayannopoulos, B. Chao, K Jiang
Biogen Inc., 14 Cambridge Center, Cambridge, MA 02142

The eicosapeptide Phe-Pro-Arg-Pro-Gly-Gly-Gly-Gly-Asn-Gly-Asp-Phe-Glu-Glu-Ile-Pro-Glu-Glu-Tyr-Leu (Hirulog™) was built by rational design as a direct thrombin inhibitor using the protein hirudin as a model (1,2). For the purposes of evaluating the therapeutic potential for this peptide in the management of thrombotic disease with regard to its tolerability and anticoagulant activity, studies in humans were carried out (3). The material used for the clinical trials was made by solution-phase synthesis, the final step of which involved the coupling of two fragments, each of which had, in turn, been made from smaller fragments. The product, including all impurities, was characterized in detail.

All impurities present at the 0.1% level or higher compared (by UV absorption) to the main product were first analyzed by neutral gradient reversed-phase (rp) high performance liquid chromatography (HPLC) and fractions were collected Each of these fractions was re-injected into a rp-HPLC and eluted using an acidic gradient; often the second round of HPLC resulted in further separation of peaks which had co-eluted under the neutral gradient conditions For all HPLC separations a C-18, 0 46 x 25 cm column was used. Typically, a substantial amount of material (*ca.* 0 25 mg) was loaded onto the column in order to generate enough (50-200 pmol) of the low-level impurities for further analysis.

The fractions collected by HPLC were analyzed by fast atom bombardment (FAB) or electrospray ionization (ESI) mass spectrometry In cases where the measured molecular weight did not allow for unambiguous assignment of an impurity to the eicosapeptide amino acid sequence, collision-induced dissociation (CID) tandem mass spectrometry was employed. FAB mass spectrometric analyses were carried out on a four-sector magnetic deflection tandem mass spectrometer (JEOL HX110/HX110) installed at the M.I.T. mass spectrometry facility. ESI mass spectrometric analyses were carried out on a triple quadrupole instrument (VG Quattro II) installed at Biogen.

The commercial scale product was directly analyzed by ESI mass spectrometry as well as by FAB mass spectrometry. In the FAB spectrum in addition to an ion at m/z 2180, due to the protonated peptide molecule, an ion at m/z 650 was also present, which, from its CID tandem mass spectrum, was found to be a peptide with the sequence Pro-Glu-Glu-Tyr-Leu; these are the last five amino acids of the eicosapeptide being analyzed. In order to establish whether the ion at m/z 650 were due to fragmentation during FAB ionization, or to an impurity, the sample was acetylated with a mixture of acetic acid and acetic anhydride (10:1) and the FAB mass spectrum of the acetylated material was acquired. An ion at m/z 2222, corresponding to the acetylated eicosapeptide (the only possible acetylation site is the peptide N-terminus), was present, but the pentapeptide Pro-Glu-Glu-Tyr-Leu, was shown not to have been acetylated, because the ion at m/z 650 did not shift by 42 u (as a control, synthetic Pro-Glu-Glu-Tyr-Leu was readily acetylated under the same conditions). It is clear that the ion at m/z 650 was a fragment, generated during FAB ionization, and this situation illustrates the difficulty of attempting to establish purity of peptide samples by mass spectrometric analysis alone.

Mass spectrometric analysis of the fractions collected (and, when it was necessary, tandem mass spectrometry) allowed for the identification of a number of impurities, most of which could be readily matched by their molecular weights to contiguous amino acid segments of the eicosapeptide sequence.

Tandem mass spectrometry was utilized when it was not possible to identify a contiguous amino acid segment in the eicosapeptide amino acid sequence, that corresponded to a peptide with molecular weight matching the value measured by mass spectrometry. For example, comparison of the low-energy tandem collision-induced dissociation (CID) mass spectra of the correct peptide (Figure 1A) and of an impurity 71 u higher in mass (Figure 1B), revealed that Phe-12 in the impurity had been modified by the addition of a group, either by alkylation of the amine nitrogen, or by a Friedel-Crafts type acylation of the aromatic ring during the highly acidic conditions employed for the removal of amino acid protecting groups at the end of the synthesis

In conclusion, mass spectrometry has been used to carry out the identification of impurities, isolated by two different HPLC gradients and present at very low levels, of a synthetic eicosapeptide. It was possible to assign all impurities that were missing one or more amino acids to the expected peptide sequence either from their molecular weights alone or from their tandem CID mass spectra, and to obtain, from the latter data, information on impurities containing modified amino acids.

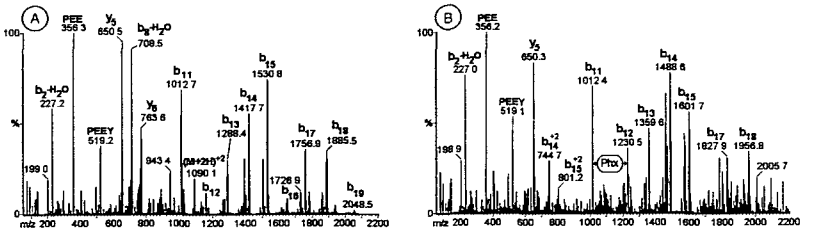

Figure 1. Low-energy, tandem mass spectra of the eicosapeptide Phe-Pro-Arg-Pro-Gly-Gly-Gly-Gly-Asn-Gly-Asp-Phe-Glu-Glu-Ile-Pro-Glu-Glu-Tyr-Leu (**A**) and an impurity 71 u higher in mass (**B**). Both spectra were obtained after CID of the respective doubly protonated molecules. The impurity contains a modified Phe at position 12 (indicated as "Phx" in the spectrum).

ANALYSIS OF CRUDE SYNTHETIC PEPTIDE MIXTURES BY IONSPRAY MASS SPECTROMETRY

Lydia M. Nuwaysir, Jacqueline McCandless, Richard Noble, Ling Chen
Perkin Elmer Applied Biosystems Division, Foster City, CA 94066

INTRODUCTION

The characterization of synthetic peptides is straightforward using mass spectrometry. Since the sequence of the desired product is known, an accurate mass can be calculated and compared to the mass spectrometric results. Frequently, however, the synthetic peptide product will contain additional products produced *via* side-reactions, incomplete deprotections, and/or insufficient couplings. Often times it is desirous to characterize these side products in order to eliminate or minimize their production in the future. Normally, these products are collected from an HPLC purification and submitted for mass spectrometric analysis. An easier solution is to submit the entire crude peptide mixture for LC/MS analysis. This, in combination with high/low orifice scanning, allows the entire mixture to be analyzed for molecular weights, possible contaminants, and confirmation of structure. High/low orifice scanning entails using a programmed set of scan conditions such that intact ions and fragment ions are alternately generated every other scan. Thus, both molecular weight information and sequence information are obtained within the same LC/MS run. In this study, several examples are shown of the use of alternate high/low orifice scanning for the LC/MS analysis of crude synthetic peptides.

EXPERIMENTAL

A PE SCIEX API 300 benchtop triple-quadrupole mass spectrometer was used for this study and operated in the single MS mode. Data were acquired using a step size of 0.25 mass units, a dwell time of 0.5 ms, and a scan range from 100 Daltons to 1500 Daltons. An orifice potential of either 50 or 150 Volts was used, alternating the voltage every other scan. On-line LC/MS was accomplished using a PE ABI 140B LC pump. Crude peptide mixtures were dissolved in an aqueous solution of 5% acetic acid and injected onto an Aquapore OD-300 1 x 100 mm C18 column and eluted using a gradient from 5% to 75% B. Buffer A = 95% H_2O, 5% ACN, 0.05% TFA; Buffer B = 80% ACN, 20% H_2O, 0.0425% TFA. Peptides #1, #2, and #3 were synthesized on a PE Synergy® Peptide Synthesizer using HBTU activation and the Fmoc protecting strategy. Peptides were cleaved according to the ABD User Bulletin No. 40. All reagents were from PE Applied Biosystems Division Peptide #4 was from an outside source.

RESULTS

Figure 1 displays the LC/MS analysis of crude peptide #1. Two main products were produced during the synthesis, the expected peptide (DN1) and a peptide 15 Daltons less than the expected peptide (DN1*). Inspection of the sequence data generated by the high orifice scans reveals that the DN1 peptide has the correct sequence while the DN1* peptide contains a residue in place of the lysine with a nominal mass of 113 Daltons, indicating a leucine, isoleucine, or norleucine in this position (Figure 2). Edman sequencing revealed that this residue was in fact a leucine, and was due to the use of a degenerate cartridge containing equal amounts of Fmoc-Lys(Boc)-OH and Fmoc-Leu-OH during the synthesis.

As further observed in the TIC, Both DN1 and DN1* undergo side reactions to produce additional products. These side reactions result in the formation of a peptide 18 Daltons lower than the expected molecular weight, and a peptide 67 Daltons higher than the expected molecular weight. Closer inspection revealed that this was due to aspartimide formation at the Asp residue (loss of 18 Daltons) followed by formation of a piperidide adduct during the piperidine deprotection steps of the synthesis (addition of 67 Daltons).[1,2] In order to test the sensitivity of the -DN- sequence for aspartimide and piperidide formation, peptide #2, "DN2", was generated (a truncated peptide containing only the first five residues DNGKA). Piperidide formation was suppressed as a result of fewer deprotection steps (only one) following coupling of the Asp residue. However, a small amount of the aspartimide-containing peptide was still observed.

Aspartimide formation and piperidide adduction were also observed for peptide #3. In fact, virtually all of the peptide had reacted during the synthesis to produce these two side products. Treatment of the mixture with base opened up the aspartimide to reform the desired peptide. However the piperidide peptide was unaffected. Thus, in order to limit piperidide formation, the aspartimide must be limited first.

Many peaks were observed to elute very closely in the TIC for the analysis of crude peptide #4. High/low orifice scanning during the LC/MS run indicated that the peptide with the correct sequence eluted last, while other peaks were due to oxidation of methionine and insufficient couplings.

CONCLUSION

Alternating low and high orifice scans during a single LC/MS run speeds analysis of peptides by providing both molecular weight information and sequence information of entire crude mixtures within the same time frame. The technique is easily implemented using the standard software and provides sequence data without the need for a triple-quadrupole instrument.

Tandem Mass Spectrometry of Metal-Peptide Complexes.

Scott G. Summerfield, Vanessa C. M. Dale, Dominique Despeyroux and Keith R. Jennings.
Department of Chemistry, University of Warwick, Coventry, CV4 7AL, U.K.

Collisional activation of metal-peptide complexes provides a complementary source of information to the more traditional studies of the $[M+H]^+$ ion. Charge remote fragmentations are common from protonated peptide complexes when highly basic residues are present. This study has been undertaken to gain more information about the charge remote processes occurring in Group 1 metal complexes of the type $[M+Cat]^+$ and $[M-H+2Cat]^+$. High energy collision induced dissociation has been performed using a Kratos 'Concept' Four-sector instrument equipped with a liquid SIMS source, floated collision cell and scanning array detector. The results described suggest that at high collision energies, small losses from the side chains of certain amino acids occur *via* charge remote processes. These losses can be characteristic of the presence of residues such as those of arginine, lysine and methionine [1].

Collision induced losses from the arginine residue are typified by the behaviour of the metal complex shown in Figures 1a and 1b. The $[M+K]^+$ complex of Arg-Pro-Pro-Phe-Leu-Ser-Pro-Phe, m/z 942.4 Da. (Figure 1a), generates a number of sequence-specific product ions including the N-terminal a_n series and the C-terminal y_6 and y_7 ions. Figure 1b shows the upper mass range of the spectrum where the neutral losses of the **100**, **87**, **73** and **59** Da from the precursor ion are due to fragmentation along the pendant chain of the arginine residue.

These observations may be rationalised by postulating a series of elimination reactions. Loss of **87** Daltons from the metal complex occurs by a 1,4 elimination where the α-hydrogen of the arginine side chain is involved in the rearrangement. The losses of **73** (inset) and **59** Daltons arise from similar reactions further along this side chain. As a result, the arginine side chain, $-(CH_2)_3NHC(NH)NH_2$ is converted to a shorter alkene chain. Loss of **100** Daltons occurs by radical cleavage of the α-β bond of the pendant chain and results in the loss of the entire $[C_4H_{10}N_3]^+$ group.

Many cation peptide complexes undergo analogous rearrangements [1]; the methionine residue may lose **62** or **48** Da; the side chain of the lysine residue may lose **59**, **45** or **31** Da.

Similar fragmentations occur on CID of certain $[M+H]^+$ ions such as for the peptide Tyr-Phe-Met-Arg-Phe-NH_2. The expected site of protonation is the arginine residue and the high energy collision induced decomposition results in losses of **62** and **48** Daltons from the methionine side chain. These data suggest that these fragmentations occur remote from the site of proton attachment and similarly, fragmentations of this type from metal complexes may also be charge remote in nature. This suggestion is consistent with other studies of alkali metal-peptide complexes where the major interactions are thought to occur between the metal and the carbonyl oxygens of the peptide backbone [2], leaving the amino acid side chains playing a less important role in charge stabilisation.

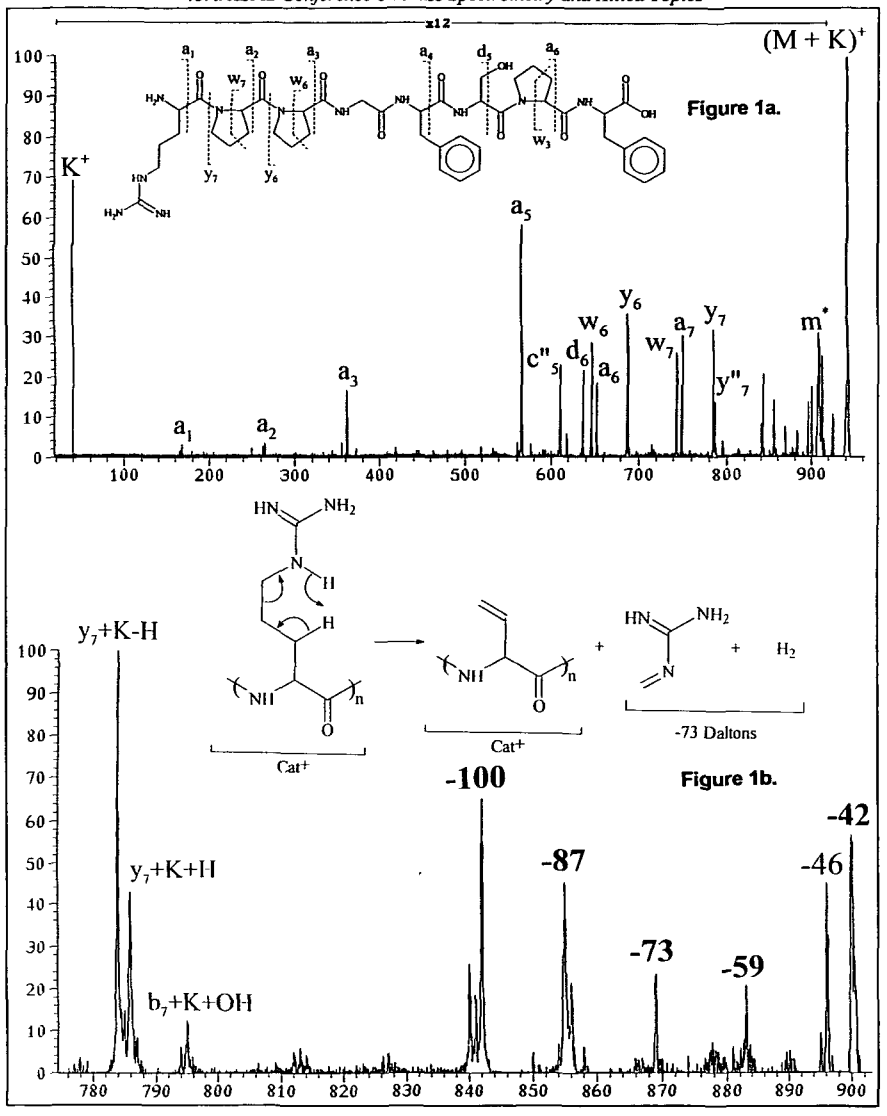
43rd ASMS Conference on Mass Spectrometry and Allied Topics



LOSS OF THE C-TERMINAL AMINO ACID FROM COMPLEXES BETWEEN TRANSITION METAL IONS AND PEPTIDES

Alex Reiter, Jeanette Adams, and M. Cameron Sullards, Department of Chemistry and the Emory University Mass Spectrometry Center, Emory University, Atlanta, GA 30322

Experiments are conducted: (1) to investigate the mechanism for metastable ion loss of the C-terminal amino acid from complexes between transition metal ions and peptides; (2) to relate this chemistry to that of complexes between alkali metal ions and peptides; and (3) to demonstrate the occurrence of this chemistry for multiply-charged complexes between peptides and transition metal ions formed by electrospray ionization (ESI). ESI, MS^2, and MS^3 experiments are performed using a JEOL JMS-SX102/SX102A/E, five-sector tandem mass spectrometer.

Loss of the C-terminal amino acid results in formation of $(b_{n-1} + OH)$ ions. MS^2 spectra show that precursor $(M + H)^+$ ions give $(b_{n-1} + OH)^+$ ions [1]; $(M + Li)^+$ ions give $(b_{n-1} + Li + OH)^+$ ions [2,3]; and $(M + Me^{2+} - 3H)^-$ ions give $(b_{n-1} + Me^{2+} - 3H + OH)^-$ ions. MS^3 experiments show that first-generation $(b_{n-1} + Me^{2+} - 3H + OH)^-$ ions have the same structures as $(M_{n-1} + Me^{2+} - 3H)^-$ ions of peptides that are missing the C-terminal amino acid (Figure 1). Furthermore, the $(b_{n-1} + Me^{2+} - 3H + OH)^-$ ions decompose to give second-generation $(b_{n-2} + Me^{2+} - 4H)^-$ products [4] (Figure 1A). The only mechanism that can explain formation of both first- and second-generation product ions is the mechanism originally proposed by Westmore [5] (Scheme I).

Loss of the C-terminal amino acid to give $(b_{n-1(2)} + Me^{2+} + OH)^{2+}$ ions also occurs for $(M + Cu)^{2+}$ complexes of angiotensin II that are formed by ESI (Figure 2A). Although these ions are weakly abundant in the MS^2 spectrum (Figure 2A), they are predominant in the MS^3 spectrum of the first-generation $(M + Cu - 44)^{2+}$ ions. The $(M + Cu - 44)^{2+}$ ions arise by loss of CO_2 from the precursor complexes. The MS^3 spectrum indicates that $(b_7 + Cu + OH)^{2+}$ and $(b_6 + Cu + OH)^{2+}$ ions must arise from precursor structures that contain the metal ion bound toward the N-terminus but not to the deprotonated Asp side chain. Furthermore, the precursors must contain a neutral C-terminal carboxylic acid.

The mechanism in Scheme I explains all the data for $(M + H)^+$, $(M + Li)^+$, $(M + Me^{2+} - 3H)^-$, and $(M + Cu)^{2+}$ ions. In contrast, the mechanism originally proposed by Renner and Spiteller [6] cannot explain all the data. This strongly suggests that the Westmore mechanism [5] is the correct one.

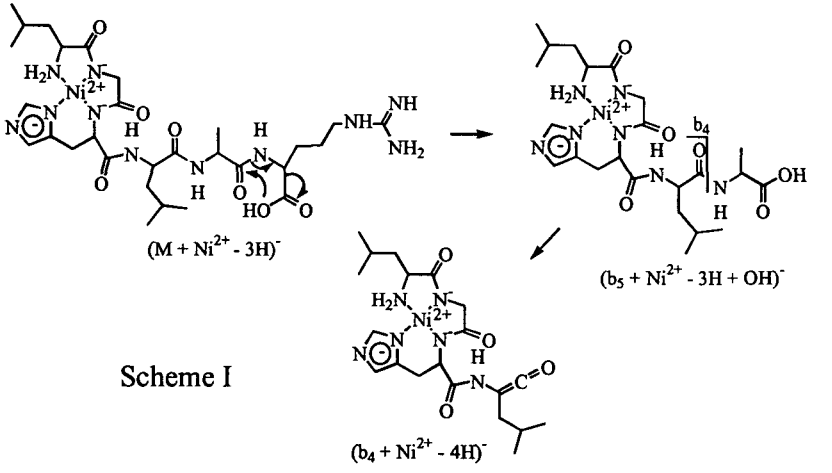

Scheme I

INTRINSIC COORDINATION BETWEEN CO(II) AND NI(II) AND HISTIDINE PEPTIDES

Alex Reiter and Jeanette Adams, Department of Chemistry and the Emory University Mass Spectrometry Center, Emory University, Atlanta, GA 30322

We previously studied gas-phase anionic complexes between Co^{2+} and Ni^{2+} and peptides that contain hydrocarbon amino acids.[1] The complexes decompose metastably to give abundant $(b_4 + Me^{2+} - 4H)^-$ ("b_n") ions. It was shown by MS^3 experiments that precursor ions that give rise to the $(b_4 + Me^{2+} - 4H)^-$ ions contain the Me(II) ion in a N-terminal square planar complex.

We extend this study to investigate the gas-phase anionic complexes between Co^{2+} and Ni^{2+} and peptides that contain His side chains. Seven hexapeptides (HLGLAR, LHGLAR, LGHLAR, LGLHAR, LGLAHR, DTHAAA, and ADTHAA) that contain His in varying positions are investigated by MS^2 and MS^3 experiments using a JEOL JMS-SX102/SX102A/E, five-sector tandem mass spectrometer.

For the HLGLAR series, Ni^{2+} complexes metastably decompose to give more abundant b_n ions than Co^{2+} complexes. Co^{2+} complexes generally decompose to give more abundant $(y_n + Me^{2+} - 2H)^-$ ("y_n") ions than Ni^{2+}. These trends demonstrate that Ni^{2+} prefers N-terminal binding more so than Co^{2+}. Complexes of LGLHAR and LGLAHR show an increase in $(y_3 + Me^{2+} - 2H)^-$ and $(y_4 + Me^{2+} - 2H)^-$ ions. MS^3 experiments show that these ions arise from precursor structures that contain the metal ion bound internally to the His side chain. Unique $(a_3 + Me^{2+} - 4H)^-$ ions are observed for LGHLAR (Figure 1). These ions arise from N-terminal square planar complexes. Precursor ions that give rise to $(b_4 + Me^{2+} - 4H)^-$ ions contain the metal ion bound to the N-terminus and three deprotonated amides. Precursor ions that give rise to $(a_3 + Me^{2+} - 4H)^-$ ions, however, contain the metal ion bound to the N-terminus, two deprotonated amides, and a deprotonated His side chain. This type of binding by His is similar to that which occurs in solution.[2]

The only cleavages of the peptide backbone that occur for Co^{2+} and Ni^{2+} complexes of DTHAAA and ADTHAA give b_n and y_n ions (Table I). Ni^{2+} complexes (Figure 2A and 2B) give both b_n and y_n ions, whereas Co^{2+} complexes give only y_n ions (Table I). The lack of b_n ions for Co^{2+} complexes indicates that no N-terminally bound complexes are formed. MS^3 experiments show that the precursor ions that give y_n ions have the metal ion bound internally to the His side chain.

This study shows that three major factors determine the extent and type of binding that occurs for complexes between Co^{2+} and Ni^{2+} and His-containing peptides: metal ion, position of His, and neighboring residues. Co^{2+} binds to the His side chain more than it binds to the N-terminus. Ni^{2+}, however, generally prefers to bind to the N-terminus more than it binds to the His side chain. Effects of neighboring residues are illustrated by comparing the MS^2 spectra of Ni^{2+} complexes of LGHLAR and DTHAAA (Figure 1 and 2A). LGHLAR binds simultaneously to both the His side chain and the N-terminus to form a square planar complex, whereas the metal ion binds internally to the His side chain of DTHAAA. These structures are verified by MS^3 experiments.

PEPTIDE ADSORPTION AT GAS-LIQUID INTERFACES PROBED BY FAB MASS SPECTROMETRY

Richard B. van Breemen, Department of Medicinal Chemistry & Pharmacognosy, College of Pharmacy, University of Illinois at Chicago 833 S. Wood Street, Chicago, IL 60612-7231

Any compound that will adsorb preferentially to an interface is surface active. In particular, amphiphilic molecules may adsorb at the interface between hydrophilic and hydrophobic bulk phases, such as the air-water interface. The only method which can directly quantify adsorbed molecule concentrations is the radiotracer method.[1] The basis for this technique is that the radiation emitted by a weak β-emitting nuclide is attenuated much more by solvent than by air. This results in surface-adsorbed radiolabeled species contributing more to the radiation measured by a detector directly above the solution than do species in the bulk solution. The disadvantages of this technique are the requirement of tritiated or ^{14}C labeled solute and length of time (several hours) per measurement. In this investigation, fast atom bombardment (FAB) was evaluated as a method for probing the surface activity of peptides or other surfactants in a glycerol matrix, and the surface activities of several peptides were compared in glycerol and water.

Although several studies have investigated the mechanism of FAB ionization, none have compared the abundance of analyte ions desorbed by FAB directly to their surface excess concentrations. The only related study was carried out by Allmaier,[2] who used a de Nouy ring tensiometer to measure surface tension of several peptide solutions in glycerol and then from these measurements estimated surface excess concentration. Allmaier found a rough correlation between estimated surface concentration and abundance of protonated peptide.

METHODS

The isomeric peptides, $Gly_4Lys_4Phe_4$ and $(GlyLysPhe)_4$, were synthesized using Fmoc chemistry using a solid support and then deprotected and released from the resin. Radiolabeled peptides were synthesized using ^{14}C-labeled Fmoc-glycine. Semi-preparative reversed-phase HPLC was used to purify each synthetic peptide. Positive ion FAB mass spectrometry with collision induced dissociation and linked scanning at constant B/E were used to confirm peptide molecular weights and sequences.

Standard solutions of each peptide in glycerol or water were prepared by serial dilution. Peptide concentrations ranged from 7.0 mg/ml to 0.35 μg/ml. Radiotracer measurements were carried out using a Teflon sample cell in a thermostatted environmental chamber. A solid scintillator β-detector was positioned immediately above the glycerol (or water) surface. The radiotracer apparatus has been described in detail.[3]

Positive ion FAB mass spectra were acquired using a Finnigan MAT 90 double-focusing mass spectrometer at 1000 resolution. Aliquots of 1 μl each were loaded onto the FAB probe, inserted into the ion source, and analyzed by FAB using xenon fast atoms at 8 kV. The FAB gun was turned on exactly 10 s after the sample was introduced into the vacuum system.

RESULTS

In order to determine if peptide surface activities in glycerol differ significantly from those in water, the surface excess concentrations of several peptides were measured in water and glycerol using the radiotracer method. The radiotracer measurements demonstrated that surface activities of peptides in glycerol are considerably different than in water. Therefore, the surface excess concentration of a peptide in glycerol may not be predicted based on its properties in water. For example, the two isomeric peptides, $Gly_4Lys_4Phe_4$ and $(GlyLysPhe)_4$, showed different surface activities in water, but the isotherms measured in glycerol were indistinguishable.

Isotherms were plotted showing surface excess concentration (determined using the radiotracer technique) or intensity of protonated peptide signal (obtained using positive ion FAB) versus bulk concentration. Whether obtained using the radiotracer method or FAB mass spectrometry, each pair of isotherms showed that same slopes and inflection points, which indicated that the mechanism of FAB desorption/ionization of peptides is primarily a surface desorption technique (see Figure 1).

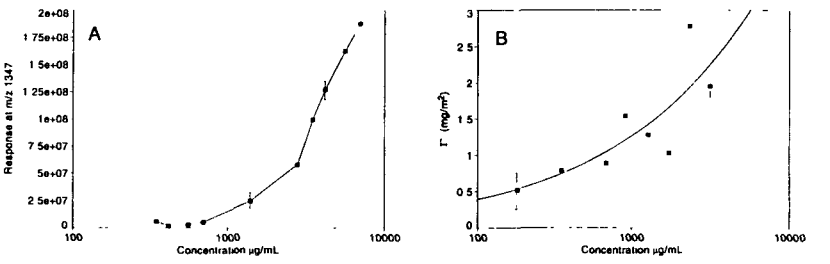

Figure 1. (A) Positive ion FAB SIM of $[M+H]^+$ at m/z 1347 of peptide $Gly_4Lys_4Phe_4$ in glycerol. (B) Surface excess concentration of $[^{14}C]$-$Gly_4Lys_4Phe_4$ in glycerol using the radiotracer method.

Additional evidence supporting FAB as a surface desorption technique was provided by the shape of the FAB isotherm. If FAB primarily sampled the bulk of the peptide solution instead of the surface, than the mass spectrometer response should increase linearly with increasing bulk concentration of peptide in glycerol. Instead, the mass spectrometer response increased sharply at high concentrations as the peptide surface excess concentration increased more rapidly than the bulk concentration. Finally, these results suggest that FAB mass spectrometry can be used as a much faster technique than the radiotracer method to compare surface activity of peptides in glycerol solutions.

ACKNOWLEDGEMENTS

Neurohypophysial hormones oxytocin (OT) and arginine vasopressin (VP) belong to a class of peptide hormones. The main function of VP is the regulation of diuresis and blood pressure; OT regulates birth action and lactation. In the last decade attention was paid to a synthetic analog of OT namely deamino- oxytocin (d-OT) which differs from natural hormone by absence of NH_2 group at the Cys-1. The biological oxytocin-like activity of d-OT on tissues-targets is 2-4 times higher than that of natural hormone [1].

Recently the experimental proofs appeared which allow to explain the biological activity of neurohypophysial peptides by their direct action on the membrane lipid phase. In particular, the formation of ion channels was observed in model lipid membranes under effect of peptides [2,3]; the change of phase transition temperatures [4,5] and the direct effect of peptides on membrane bound enzymes [6]. The idea of the present work is the FAB MS study of individual peptide hormone molecules and their equimolar mixtures in comparison with physico-chemical properties and biological activity.

The samples of oxytocin, (1006.5 dalton for the lowest isotope), deamino-oxytocin (991,5 dalton) and arginine vasopressin (1083,6 dalton) samples were synthesized and purified in the Institute of Organic Synthesis (Riga, Latvia). FAB mass spectra were obtained on a MX-1310 double focusing instrument (Chernogolovka, Russia) of 2000 dalton mass range at 5 KV accelerating voltage and resolution 10 000. The design and performance of original FAB MS ion source using argon atom beam were published earlier elsewhere [7]. The details of experimental procedure of peptide studies were described previously [8]. Parameters of peptide surface activity were studied according to the well known Wilhelmy method in a glass trough [9].

RESULTS AND DISCUSSION

"Monoisotopic" FAB spectra in the mass interval (M-H), (M+4H) were computed, for which all elements are represented by their lowest isotopes only. The deconvolution procedure of obtaining "monoisotopic" mass spectra proposed by K. Vekey [10] was used, including the substraction of "chemical" background (usually 2-4% of main peak intensity).

The most interesting feature of oxytocin FAB mass spectrum is abundant (about 40% to protonated molecule) satellite group of lines 15 dalton heavier than molecular cluster ions. The distribution of relative ion intensities in this group is similar to distribution of molecular cluster ions. Observed effect may be explained by replacement of a hydrogen atom by an amino group in molecular cluster.

The only source of amino groups availiable in a FAB liquid matrix (glycerol + water) is the nearby peptide molecule. It seems that under FAB conditions the disproportion reaction between two peptide molecule may occur resulting in attaching eighther a proton or a charged amino group ion to a peptide molecule. No analogous satellites were observed for deamino-oxytocin and arginine vasopressin.

The experiments with equimolar mixtures of peptides in all possible combinations were proceeded in order to discover possible ionization of intermolecular associates and/or products of their decomposition. No such species was observed. In all cases the mass spectra of mixtures looked like a superposition of individual peptide mass spectra and relative abundances of species observed did not depend on pH value. But contributions of different peptides to the mass spectrum of mixture was not equal. The mean ratio of molecular ions abundances estimated from all the equimolar experiments was approximately 5:4:1 in the raw OT:d-Ot:VP; the same ratio was 7:4:1 if satellite ion of OT (M+15) was taken into account.

The maximum Gibbs adsorption Γ on (KCl solution)-atmosphere interface and on the azolectine monolayers (integral phospholipide fraction of soy-bean with lipid composition similar to biological membranes) gave in both cases the sequence OT>d-OT>VP which coincide with ion yield in FAB mass spectra of mixtures.

The comparison of the effects of natural neurohypophysial hormones on lipide membranes shows good correlation with physiological activity, surface activity and abundance of cluster ions in FAB mass spectra of mixtures. It was found out, for example, that OT, in contrast to VP, is able to create ion channals in bilayer lipid membranes [11] and that VP action is limited by vesicles surface [12] whereas OT effects the whole structure of bilipid layer [13]. This may be the reason of dramatic difference in effect of OT and VP on liposomes: both peptides increase the permeability of phosphatidylcholine liposomes to Ca ions, but to uncommensurate levels.

CONCLUSIONS

In FAB study of d-OT, OT and VP and their equimolar mixtures the resulting mass spectra of mixtures were the superposition of individual peptide mass spectra. No intermolecular association of different peptides was observed. The ion yield from mixtures in FAB glycerol matrix decreased in the row OT> d-OT>VP, similar to their surface activity. The ion yield from natural peptides mixtures in glycerol (OT and VP) correspond both to surface and membranotropic biological activity. The ion yield in the pair of natural (OT) and synthetic (d-OT) peptides was inverse to biological activity. Natural hormone (OT) posesses less physiological and membranothropic activity in spite of its higher surface activity. The specific behaviour of OT may be explained by structure peculiarities of OT molecule resulting in dimer formation and aminogroup exchange in the surface layer of glycerol matrix.

PROCESSING OF DYNORPHIN A (1-17) IN HUMAN AND MONKEY BLOOD STUDIED BY MS

Jim Yu, Eduardo R. Butelman*, James H. Woods*,
Mary Jeanne Kreek, and Brian T. Chait
The Rockefeller University, New York, NY 20021, and
*The University of Michigan, Ann Arbor, MI 48109

Studies of the endogenous neuropeptide dynorphin A [Dyn A (1-17)] have indicated that this peptide may attenuate the behavioral signs and objective measurements of the opioid withdrawal syndrome in morphine-dependent rodents and may be useful as a therapeutic agent for the treatment of opioid dependent patients [1,2]. It has also been shown that Dyn A peptides can modulate morphine tolerance in morphine-dependent mice [1,2]. Dyn A peptides have been demonstrated to have analgesic properties and may have potential application in the management of chronic pain [3]. Also both opioid and non-opioid dynorphin peptides have been shown to alter the immune function of natural killer cell activity [4].

Isolation and characterization of the processing of dynorphin A in tissues and brain regions [5-8], spinal cord [9] and cell cultures [10] have been studied. However, there is still relatively little information about the dynamics and nature of dynorphin A biotransformation in biological systems [11,12]. The processing of Dyn A (1-17) produces various opioid and non-opioid peptides, which are potentially biologically active. In order to find a suitable model for invasive studies of the biotransformation of Dyn A (1-17), and to further evaluate the potential therapeutic effects of this peptide, the rhesus monkey was chosen as a primate model. Comparative studies of *in vitro* biotransformation of Dyn A (1-17) in rhesus monkey and in human blood were conducted.

Human blood was obtained from eight healthy volunteers, 6 males and 2 females with an average age of 30.8 years (range 22-47). Monkey blood was obtained from three healthy adult female rhesus monkeys, average age 8.3 years (range 7-10). Dyn A (1-17) in an amount of 0.59 mg/ml was added to freshly drawn blood from each subject and incubated at 37°C. Samples were taken from the incubated blood at specific time intervals. Plasma was separated from blood cells by centrifugation at 4°C for 5 min (4,000 rpm). Two hundred-µl of plasma containing the biotransformed dynorphins was added to 1.8 ml of 1% trifluoroacetic acid (TFA) aqueous solution, along with 100 µl of 315 µM somatostatin in 0.05% aqueous TFA as the internal standard. The solution containing plasma, biotransformation products from Dyn A (1-17), somatostatin and TFA, was centrifuge-filtrated with concentrators (Centricon-SR3, Amicon Inc., Beverly, MA), having molecular weight cutoff of 3,000 Da. After filtration, 100 µl of filtrate was evaporated in a Speed Vac concentrator (Savant Instruments, Farmingdale, NY) for 20 min to reduce the total volume to approximately 40 µl. Twenty-µl of the solution was mixed with 10 µl of acetonitrile. Ten-µl of this solution was mixed with 20 µl of matrix (α-cyano-4-hydroxycinnamic acid) solution. The mass spectrometer employed in this study is a matrix-assisted laser desorption ion source and a linear time-of-flight mass analyzer, which was constructed at the Rockefeller University. Every MS spectrum employed an average of 200 laser shots.

It has been demonstrated that Dyn A (1-17) *in vitro* biotransformation in human and rhesus monkey blood is very similar. One major pathway is the non-specific or specific enzymic cleavage of tyrosine from position one of Dyn A (1-17) to yield Dyn A (2-17). This is a slow process with prolonged presence of Dyn A (1-17) in both human and rhesus monkey blood. Intact Dyn A (1-17) was detected in human and rhesus monkey blood at 180 min and 90 min, respectively. Dyn A (2-17) is the major and long-lasting biotransformation product of Dyn A (1-17) *in vitro* both in human blood and in rhesus monkey blood. However, there are some variations in the formation of minor products between human and monkey and among individual subjects. It has been shown that Dyn A (2-17), which is a non-opioid peptide, has many effects including prevention or reversal of opioid withdrawal in rodent models; analgesic properties for chronic pain; and alteration of natural killer cell activities [1,2,4]. Another major pathway is the specific enzymic cleavage between Arg(6) and Arg(7) to produce the opioid peptide, Dyn A (1-6), and the non-opioid peptide, Dyn A (7-17). Our results indicate that rhesus monkey may be a good model for further *in vivo* pharmacological studies. However, dynorphin A processing occurred at a faster rate *in vitro* in monkey blood than that in human blood, indicating any use of rhesus monkey as a model for pharmacokinetic studies for humans will need to be carefully evaluated.

ANALYSIS OF HETEROGENOUS PEPTIDE MIXTURES BY LC/MS

Manfred Raida, Gabi Heine, Peter Schulz-Knappe, Wolf-Georg Forssmann
Lower-Saxony Institute for Peptide Research (IPF)
Feodor-Lynen-Strasse 31, D - 30 625 Hannover, Germany

The analysis of heterogenous peptide mixtures, as present in blood or urine, by immunological methods has become an important technique in diagnostics to detect markers which are present or absent due to disease or a genetic variation. Immunological detection is limited to known markers, thus an overview of the peptide pattern to compare healthy and sick persons cannot be performed by this method Nevertheless, a comparative analysis of the peptide pattern with respect to a certain disease could help to detect those peptides which are related to the disease. This comparative analysis can lead to the detection of new markers which are helpful for early diagnosis.

The main problem in the comparative analysis of the peptide pattern of serum is the presence of high concentrations of proteins, like albumin and globulins, the large number of peptides up to appr 30 kD, and their low concentration in the solution. More than several 100 000 different peptides are present in the serum, besides bioactive peptide hormones these are mainly fragments of larger proteins like albumin, fibrinogen or collagen, ranging from low fM / l to nM / l in concentration. The analysis of complex mixtures has to be performed by the combination of different chromatographic or electrophoretic separation techniques with highly sensitive detection methods, like electrospray mass spectrometry

Two dimensional techniques, like consecutive chromatographic separation by ion exchange chromatography and chromatography of subfractions by reversed-phase chromatography are suitable to resolve even very heterogenous mixtures. A third independent parameter is introduced to every component in the mixture by electrospray mass spectrometric detection. Therefore every single peptide in a complex mixture can be defined by three parameters, the charge, the hydrophobicity, and the molecular weight. This method will be denoted as 2D-LC/MS in the following

Firstly 2D-LC/MS analysis has been performed using the peptides from human hemofiltrate. Human hemofiltrate was obtained by blood filtration of patients with final stage renal disease. The hemofiltrate contains all peptides present in the blood, but no larger proteins, cells and cell fragments which are retained by the filter with a 20,000 D cut-off. For further analysis the hemofiltrate was desalted by batch extraction using alginic acid as a week cation exchanger and the peptides lyophilized. This crude extract served as the starting material for further analysis.

In the first separation step, the hemofiltrate is fractionated by strong cation exchange chromatography using volatile buffer systems Fractions were collected and lyophilized prior to reversed-phase chromatography The reversed-phase chromatography was connected on-line with the electrospray interface of the mass spectrometer. In the experiments shown here 1 x 250 mm C-18 columns (YMC, Japan) were used for the separation. The flow rate was 20 µl / min, the column outlet was directly connected through a variable UV-detector equipped with a capillary flow cell with the electrospray interface of the mass spectrometer (API III, SCIEX, Toronto, Canada) No postcolumn splitting was performed. The mass spectrometer was run in single MS mode.

About 40 fractions from cation exchange chromatography of human hemofiltrate peptides were analyzed by LC/MS. The raw data were analyzed manually. More than 1.000 peptides could be determined with respect to their charge, hydrophobicity and molecular weight. These peptides represent the abundant peptides in the hemofiltrate, equivalent to concentrations in the pM / l. The molecular weights of the peptides detected ranges from about 600 D to over 25,000 D, and even low amounts of serum albumin, due to large pores in the hemofiltrate membrane and restraint filtration were detected

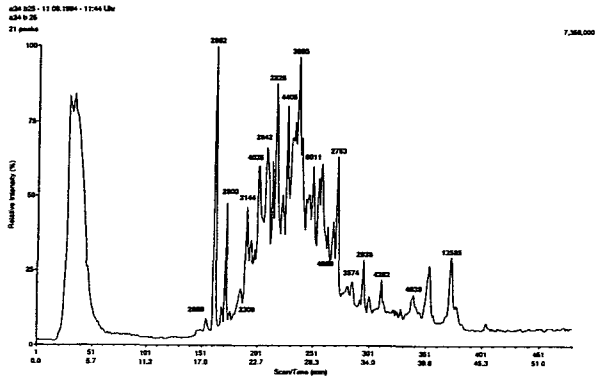

Figure Total ion chromatogram of one fraction from human hemofiltrate (see text) The molecular weights indicate those peptides which could be clearly identified.

The 2D-LC/MS analysis allows the detection of a single peptide in the complex mixture As shown with human hemofiltrate the total analysis of the peptide pattern becomes possible ussing this method In addition, peptides which could be obtained as pure fractions were identified by N-terminal sequencing or other methods.

Nevertheless, efforts have to be made to increase the sensitivity, reduce the time of analysis, and increase the separation in the second step With the 2D-LC/MS method, very heterogenous mixtures can be analyzed and data bases, equivalent to the 2D-gel electrophoresis databases can be created allowing the comparison of peptide patterns.

We wish to thank Ulrike Ballnus, Jutta Barras-Akhnoukh, and Ilka Uhrlandt for their excellent and experienced help in the analysis shown here

Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry as a Tool in the Characterization of E. Coli RNA Polymerase

The core enzyme of Escherichia coli RNA Polymerase (RNAP) has the subunit composition of ($\alpha_2\beta\beta'$). The α subunit is a 329 amino acid long protein which consists of two domains each capable of independently folding and dimerizing: αCTD (C-terminal domain) and αNTD (N-terminal domain). The αNTD dimer plays an important role in initiating RNAP assembly by binding to the beta subunit. The αCTD dimer makes specific protein-DNA interactions with promoters containing an UP element (e.g., *rrnB P1*) and specific protein-protein interactions with activator proteins at promoters with activator sites (e.g., *lac{CAP}*). For specific binding to promoters and initiation of transcription the core enzyme has to bind to a σ factor. The σ factors, in addition to binding specifically to promoters, also responsible for melting of the DNA double helix. In this paper we present results exemplifying how mass spectrometry can be used in combination with molecular biological techniques to increase the understanding of the structure and function of RNAP.

Limited proteolysis using trypsin was performed on the σ^{70} factor and the β subunit to determine domain boundaries. The SDS-PAGE gel of tryptic fragments of σ^{70} using different trypsin concentrations is shown in Figure 1a. The fragment at 40 kDa was purified and its mass was measured with Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry (MALDI MS). It consisted of two components with molecular masses of 39785 Da and 38651 Da (Figure 1b). The relative intensity of the peaks was very sensitive to trypsin concentration and digestion time. To determine the identity of the fragments, they were digested with CNBr in 0.1 N HCl for 30 minutes. The positive ion MALDI spectrum of the digest of a sample dominated by the larger fragment is shown in Figure 1c (the corresponding spectrum of a sample dominated by the smaller fragment is very similar). The peaks in the mass spectrum are labeled with the position number of the first and last residues of the corresponding peptide in the σ^{70} sequence Peaks corresponding to peptides between residues 278 to 448 were identified. Since residue 448 is an arginine, it is likely the C-terminal of the fragment to be identified. The only N-terminal agreeing with the molecular weight measurement of the larger and the smaller fragments are 104 and 114, respectively. That residue 104 is the N-terminal of the larger fragment was confirmed in another experiment where the sample was digested with endoproteinase Glu-C. We conclude that the 40 kDa fragment of σ^{70} is residues 104-448 or 114-448. Other tryptic fragments of σ^{70} [1] and of β were also identified using MALDI MS in combination with N-terminal sequencing. The polypeptide corresponding to residues 114-448 of σ^{70} was expressed and is being crystallized to determine its 3D structure.

To confirm and quantify in vivo experiments that show that the side chain of amino acid 261 of αCTD is essential for CAP-dependent transcription, in vitro transcription experiments with wild type RNAP ([Glu^{261}]α) and with RNAP reconstituted using [Gly^{261}]α and [Lys^{261}]α were performed [2]. In order to produce mutant RNAP substantially free from wild-type α, the mutant α genes were subcloned into T7 RNAP expression vector pET3a and the mutant α's were overproduced to the extent of ~30% of total cell protein. The mutant α's were purified and the mutant RNAP was reconsituted from purified mutant α and purified wild-type β, β', and σ^{70}. The contamination of wild-type RNAP was measured by MALDI MS. The wild-type and mutant α subunits were prepared from the reconstituted RNAP by denaturing centrifugal ultrafiltration and digested with endoproteinase Glu-C and the reaction products were analyzed with MALDI MS. Since residue 261 is a glutamic acid in wild-type α but not in the mutants endoproteinase, Glu-C can digest wild-type α but not the mutants at residue 261. Figure 2 shows a part of the mass spectra of wild-type α and of [Gly^{261}]α. Peaks labeled A and B correspond to residues 289-319 and 287-319, respectively and the peak labeled C correspond to residues 230-261. The intensity ratio of peaks A and B does not change significantly between the mass spectra of wild-type α and of [Gly^{261}]α while the relative intensity of peak C is dramatically different. This is expected since the mutant α cannot be digested by endoproteinase Glu-C at residue 261. Therefore the ratio of the relative intensities of peak C and B is taken as a measure of

the content of wild type α in RNAP. In Figure 2C the measured content of wild-type α is shown together with the CAP-dependent transcription initiation activity at the lac promoter for wild type and mutant RNAP. The activity of the mutant RNAP can be explained with the contamination of wild-type RNAP. From this result we conclude that amino acid 261 is essential for CAP-dependent transcription.

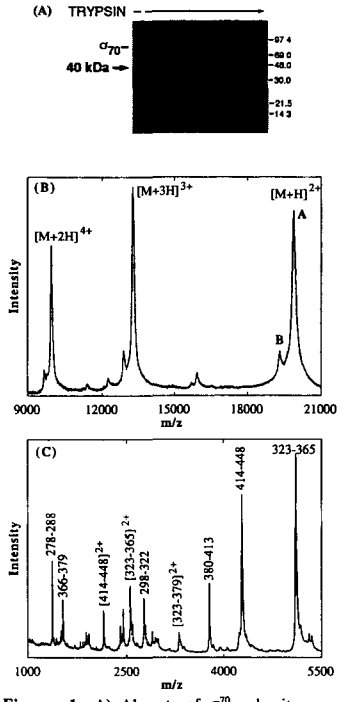

Figure 1. A) Aliquots of σ^{70} subunit were treated with increasing amounts of trypsin and the reaction products were separated on a 10% Tris-Tricine SDS-polyacrylamide gel. B) MALDI spectrum of the purified 40 kDa fragment. C) MALDI spectrum of the purified 40 kDa fragment digested with CNBr.

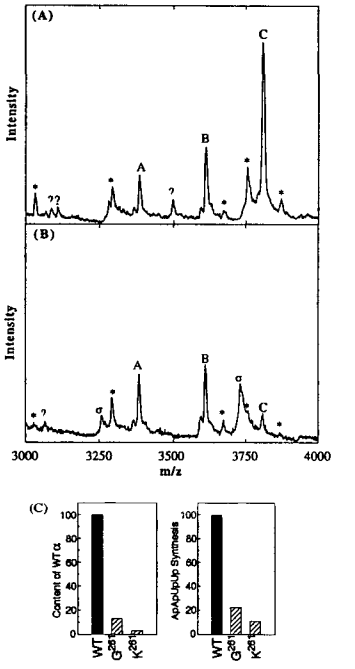

Figure 2. Endoproteinase Glu-C digest of the α subunit purified from reconstituted RNAP. A) Wild type α subunit. B) α subunit with glutamic acid at residue 261 replaced with glycine. Peaks A, B, and C correspond to residues 289-319, 287-319, and 230-261, respectively. Other fragments of the α subunit are marked with * and fragments due to contamination of σ^{70} are marked with σ C) Purity and in vitro CAP-dependent transcription activity at lac promotor for wild-type RNAP, [Gly^{261}]α-RNAP, and [Lys^{261}]α-RNAP.

Introduction

Peptide mapping using mass spectrometry, especially MALDI-TOFMS and LC/ESIMS, are now widely used for the structural characterization of proteins. Mass spectrometric peptide mapping can be carried out well when the molecular weight of a protein is not so large. In the case of a large protein, such as IgG, however, molecular weight of a peptide generated by the cleavage is sometimes attributed to more than two positions of the amino acid sequence only by its molecular weight and the specificity of the cleavages. One more serious problem is that the differentiation of leucine and isoleucine residues is impossible only by the molecular mass information. Leucines and isoleucines cannot be differentiated by low-energy MS/MS, too. From this point of view, new methodology utilizing ^{2}H-labeled leucine (Leu(D10)) was developed and applied for the peptide mapping of mouse monoclonal IgG2b.

Methods

^{2}H-Labeled leucine was purchased from Euriso-top. Labeled and unlabeled mouse monoclonal anti-dansyl antibody IgG2b were obtained by the cultivation of a culture fluid containing a Leu or a Leu(D10). Labeled and unlabeled mouse IgG2b was reduced and carboxymethylated, and then digested with lysyl-endopeptidase. RCM-IgG2b(mix), an equivalent mixture of the labeled and the unlabeled RCM-IgG2b was prepared in the same manner. FABMS (JEOL HX110/HX110) was applied for the confirmation of the number of the ^{2}H-labeled atoms. Peptide mapping by MALDI-TOFMS was carried out by Shimadzu-Kratos Kompact. Peptide mapping by capillary LC/ESIMS was achieved by Finnigan-MAT TSQ700. MS/MS experiments were carried out by JEOL HX110/HX110 (high-energy CID) and Finnigan-MAT TSQ700 (low-energy CID).

Results

It was recognized that the mass difference between the labeled and the unlabeled leucine residue in the protein was 9 mass units, not 10 mass units, by FABMS analysis, while the mass difference between a Leu and Leu(D10) was 10 mass units. One mass unit decrease of the molecular mass of a leucine residue must be derived from a deuterium-hydrogen exchange caused by the racemization by racemase during the cultivation. Figure 1 shows MALDI-TOF mass spectrum of the lysyl-endopeptidase digested peptides of RCM-IgG2b(mix). Considerably many splitted twin peaks could be observed. For example, twin peaks were observed at *m/z* 2333.5 and *m/z* 2360.4. Mass value of *m/z* 2333.5 could be attributed to the protonated molecular mass of two peptides, TDSFSCNVRHEGLKNYYLK (H420-438) and GLVRAPQVYILPPPAEQLSRK (H341-361), by the specificity of the enzyme. It was impossible to assign the mass value to the peptide certainly only by molecular mass information. On the other hand, the mass difference of the observed twin peaks indicated the number of the leucine residues in the peptide. In the case of the above mentioned peptide, the mass difference of the twin peaks were 26.9, which suggested that this peptide contained three

leucine residues in the sequence. The peptide H420-438 contained three leucine residues while the peptide H341-361 contained two leucine residues. Accordingly, it could easily be determined that the peak at *m/z* 2333.5 was a protonated molecular ion of the peptide H420-438, not H341-361. Similarly, certain assignment of all the observed mass values in MALDI-TOFMS peptide mapping could be carried out by referring the number of leucine residues. The differentiation of leucine and isoleucine residues could be achieved by MS/MS. Tandem mass spectrum with high energy collision, of course, could differentiate a leucine and an isoleucine residue in a peptide. When a leucine residue was labeled by deuterium, clearer differentiation could be carried out by MS/MS with high energy collision, and in addition, these two amino acid residues could be distinguished by MS/MS with low energy collision. Figure 2 shows ESI-MS/MS spectra of the isolated peptides DVLNISLTPK (H249-258) and DVL*NISL* TPK (H249-258) with low energy collision. The y series ions were clearly observed and the sequence could easily be identified.

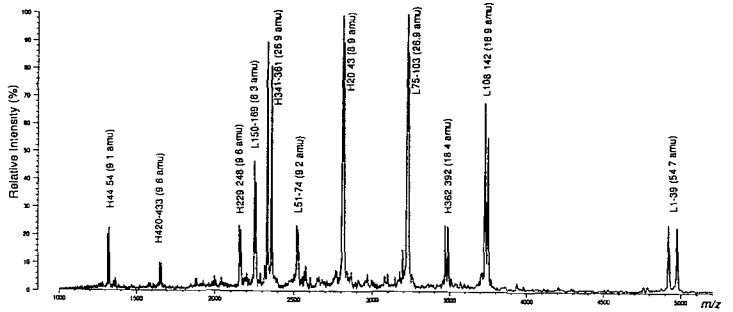

Fig. 1 MALDI-TOF mass spectrum of the lysyl-endo-peptidase digest of RCM-IgG2b(mix).

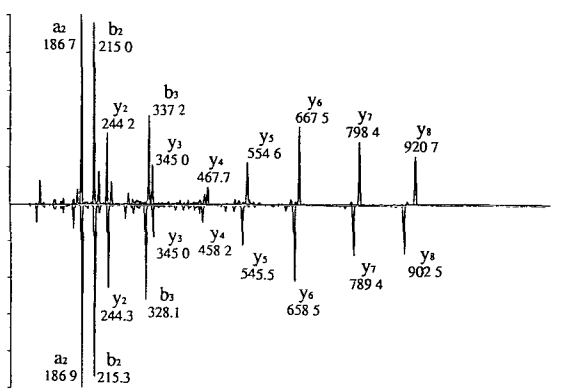

The mass difference between y_5 and y_6 ions in the both spectra is 113 amu. This indicates the exsistence of a Ile residue at the 5th position from the N-terminus.
The mass difference between y_3 and y_4, and y_7 and y_8 ions in the upper spectrum is 122 amu while those in the lower spectrum is 113 amu. This indicates the existence of a Leu residue at the 3rd and 7th positions from the N-terminus.

Fig.2 ESIMS/MS spectra of the labeled (upper) and the unlabeled (lower) peptides DVLNISLTPK.

Structural Characterization of IgG Carrying Allotype-j

Introduction

A family of switch variant, which produce mouse anti-dansyl monoclonal antibodies with the identical V_H, V_L and C_L in conjunction with different heavy chain constant regions, have been generated by Dangl et al.. This family of switch variant antibodies contains IgG1, IgG2a, IgG2b and IgG2a(s). This paper reports the structural characterization of switch variant IgGs produced by haplotype-j mice. Among these four IgGs, only IgG2a is classified into allotype-j and the other IgGs are classified into allotype-a by the serological properties. It has been believed that there must be some structural difference which suggests the existence of allotypic markers.

Methods

The cells which produced mouse switch variant IgGs were from C3H/SW mice (haplotype-j). Switch variant IgGs were reduced and carboxymethylated prior to the peptide mapping. Peptide mappings were carried out by MALDI-TOFMS (Shimadzu-Kratos KOMPACT) and capillary-LC/ESIMS (Finnigan-MAT TSQ700) after the digestion with lysyl-endopeptidase or *S. aureus* V8 protease. When a peptide with an unexpected molecular weight calculated from the reference sequence was found, it was isolated by HPLC and subjected to the amino acid sequencer and FABMS analysis (JEOL HX110). After the determination and confirmation of the sequences of switch variant IgGs, investigation on the allotypic markers was carried out by computer graphics.

Results

Figure 1 shows MALDI-TOF mass spectra of lysyl-endopeptidase digest of RCM-IgG1. A peak at *m/z* 6559.7 could not be attributed to any peptide, by referring the sequence of IgG1 of the other allotype. It was impossible to detect all of the protonated molecular ions of the peptides by MALDI-TOFMS. The peptide with molecular weight of 6558.7 was isolated and sequenced after the capillary-LC/ESIMS analysis. It was clarified that Pro193H and Arg194H were substituted by Thr and Trp, respectively. In like manner, all of the sequences of other switch variant antibodies produced by haplotype-j mice could be confirmed, by referring the sequences of IgG grouped in other allotypes. It was recognized that the C-terminal Lys residue of the heavy chain was sometimes missing in the sequences of switch variant IgGs. Several amino acid residues in the CH1 domain of IgG1 and IgG2a were found not identical to the reference sequences. No other modification except for the above mentioned could be recognized.

In IgG1, Thr and Trp were found instead of Pro193H and Arg194H, respectively, and Ser was found instead of Thr136H in IgG2a. Considering the fact that only IgG2a is classified into allotype-a, Ser136H was supposed to be related to the allotypic marker. The environment of Ser136H was investigated by computer graphics (Fig. 2), using the atomic coordinates of the human immunoglobulin molecule obtained from the Protein Data Bank (code:2IG2).

Antibodies are components of the basic defense mechanism in our immune system, their formation being an immunological response to the presence of foreign substances (antigens). In general, the interaction of an antibody with an antigen results in the noncovalent formation of an antigen/antibody complex. An antibody elicited by a specific antigen (hapten) exhibits shape and charge complementasity to that hapten. This was exploited by chemists to design catalytic antibodies capable of catalyzing specific chemical transformations. Catalytic antibodies are produced by introducing haptens that structurally resemble a reactions transition state species into mice. Antibodies produced by accordingly immunized mice may, in effect, catalyze the reaction by binding and stabilizing the true metastable transition state.

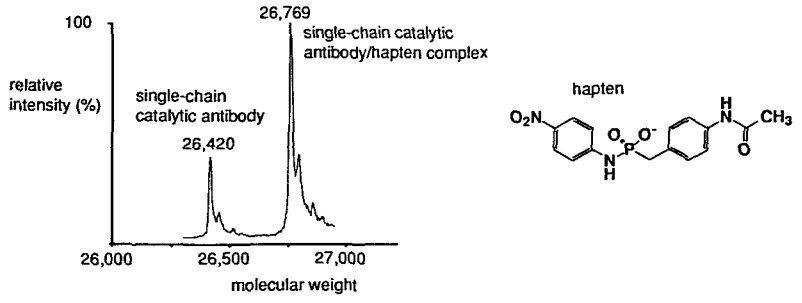

Figure 1. ESI of catalytic antibody and noncovalently bound hapten.

In the first study, a single-chain catalytic antibody was used with a molecular weight of 26,419.9 Da. Although ESI (API III PE SCIEX) cannot be used for the intact catalytic antibody due to its high molecular mass (~ 150 kDa), it is ideally suited for examining smaller fragments such as the single-chain Fv fragment. Antibodies generally exhibit high affinities (<1 nM) for the haptens they were elicited by and are excellent candidates for the study of noncovalent gas phase interactions. The antibody-hapten complex observed with ESI is shown in Fig. 1.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

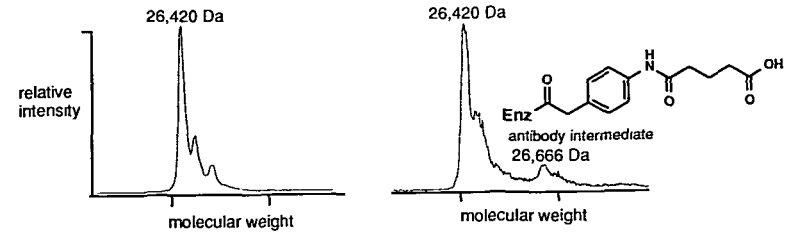

Figure 2. ESI of catalytic antibody and acyl intermediate.

The same catalytic antibody was used to study the hydrolysis of an anilide for which this antibody was designed (Fig. 2). The antibody was first analyzed alone, and then in the presence of substrate. Upon addition of substrate, a peak consistent with an adduct mass of 26,666 Da was observed. The observed mass increase of 247 Da is identical (within error) to the mass of the acyl functionality of the substrate. These spectra were acquired with declustering potentials of 175 - 250 V, under conditions where even high affinity (≤ 1 nM) noncovalent complexes are separated. Additional experiments with an antibody mutant, devoid of catalytic activity, showed no accumulation of the intermediate. These experiments provided the first direct evidence for the acyl-antibody intermediate previously proposed for this antibody.

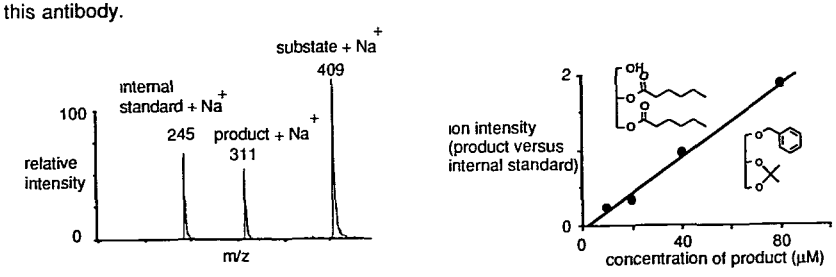

Figure 3. Reaction catalyzed by lipase quantitatively monitored by electrospray ionization.

Electrospray was also used to investigate the reaction kinetics of lipid hydrolysis, Fig. 3. Selected ion monitoring was used to perform the calibration and kinetic studies. The electrospray measurement of the rate of triacylglycerol hydrolysis by the lipase was consistent with rates determined through colormetric and derivatization techniques.

Investigation of Mouse Urinary Proteins Using ESI and MALDI

One of the most important forms of communication in mice is through the use of olfactory signals originating from the mouse urine. Mouse urine has been shown to mediate many behavioral responses such as inter-male aggression and mate selection. Although the actual scents are caused by small hydrophobic ligands (pheromones),[1] the regulation of the pheromones is controlled by a series of proteins known as major urinary proteins (MUPs). These acidic proteins, in the molecular weight range of 18.6 to 18.9 kDa, are the products of a multi-gene family, and variation exists in the types and amounts of proteins found in different mouse strains.[2] This results in mixtures of closely related proteins in the urine. Electrospray ionization mass spectrometry (ESI-MS) is highly amenable to the analysis of these mixtures.[3] Direct analysis of MUPs from the urine is possible with only minimal sample preparation and MaxEnt processing allows resolution of two proteins separated by only 15 Da at mass 18,700 Da. Although the mechanisms involved in ligand binding are not yet fully understood, small differences in the primary structures of individual MUPs may influence binding specificity. Selected proteolytic digests have been used to probe the primary structure of two MUPs. MALDI-Reflectron TOF is highly suited for the analysis of these peptide mixtures, resulting in detection of all major fragments and allowing the identification of a novel MUP.

Proteolysis Study

MUP mixtures from the species BALB/C and BALB/K consist of primarily three proteins (MW 18,647, 18,710 and 18695 Da). Initial studies involving the proteins from BALB/C mice indicated that the proteins degraded when incubated over time (37°C, 1 mM MES buffer). Although an FTIC-Casein proteolytic assay confirmed that proteolysis was occurring in the protein mixtures, gel electrophoresis was insufficient to characterize the nature or extent of proteolysis. However, analysis of these samples by ESI-MS and processing by MaxEnt showed the progression of proteolysis, revealing clear formation of lower mass products after 7 days corresponding in mass to the loss of the first 4 N-terminal amino acids in each sequence.

Initially proteolysis was believed to occur due to the endogenous protease, meprin, in the urine. Incubation of the mutant MUP strain BALB/K (no meprin) should have shown no cleavage. However, variable amounts of cleavage were observed throughout the incubation time. Further duplicate incubations showed variable amounts of cleavage. When the incubation study was repeated using sterile conditions, no cleavage was observed, indicating that the source of the proteolytic activity was not endogeneous to the protein mixture.

Identification of Allelic Variation

An anion exchange profile of the MUPs found in the C57BL/6 mouse strain showed four prominent peaks. The masses of these species (determined by ESI-MS) indicated that the two later eluting peaks (III and IV) had the same mass, suggesting an isobaric amino acid substitution, which changed the overall charge properties of these species, but not the mass. The Swissprot database contained one relevant cDNA sequence corresponding to the mass observed. An isobaric substitution of lysine to glutamine would sufficiently change the overall charge properties of these species to allow their chromatographic resolution. This substitution was investigated by the use of a selective proteolytic agent, endoproteinase Lys-C, which cleaves at the C-terminal side of the lysine residues in the proteins.

The digestion mixtures were analyzed by reflectron-MALDI-TOF with only minimal sample preparation. The resulting spectra (below) showed Lys-C fragments encompassing 96% of the protein structure. MUP III (Figure 1) contained a Lys residue at position 140 and gave a cleavage product at m/z 1123 corresponding to residues 132-140. A smaller peak is also observed at m/z 2535 corresponding to residues 141-162. In contrast, digestion of MUP IV (Figure 2) resulted in a prominent peak at m/z 3642 corresponding to residues 132-162, confirming a $Lys_{140} \rightarrow Glu_{140}$ substitution, and therefore identifying a new MUP species.

The Analysis of a Therapeutic Monoclonal Antibody by HPLC, MALDI-TOF/MS and ESI/MS

Department of Analytical Research & Development @ and Biopharmaceutical Development#
R.W. Johnson Pharmaceutical Research Institute
Route 202, P.O. Box 300, Raritan, New Jersey 08869

The analysis of monoclonal antibody molecules, with a typical molecular weight at around 150,000 amu, generally requires many months of labor-intensive laboratory work involving multiple steps of tedious sample separation, sample collection and Edman degradation sequencing. For the purpose of screening specific sites of modification due to product aging and other causes, sequencing the entire antibody molecule may not be necessary. In this work, we have explored an analytical strategy based largely on enzymatic digestion, HPLC and mass spectrometry to quickly extract the critical information about the amino acid sequence of these molecules.

We have analyzed therapeutic monoclonal antibody samples using a combination of HPLC and mass spectrometry (MS) involving both matrix-assisted laser desorption (MALDI) and electrospray ionization (ESI). The ESI/MS experiments were performed on a Finnigan-MAT TSQ-70/0 triple stage quadrupole mass spectrometer. All the MALDI experiments were done on a Finnigan-MAT LaserMAT linear time-of-flight mass spectrometer using sinapinic acid as the ionization matrix. The MALDI laser power was optimized for maximum signal to noise ratio. For HPLC/ESI/MS, the solvent flow rate of 1.00 ml/min was split 1:1 for both UV and mass spectrometric traces.

The antibody samples were first checked by MALDI for sample integrity. Each sample was then reduced and alkylated with 4.5 mM dithiothreitol and 10 mM iodoacetamide, respectively. These samples were found to produce intense ions at m/z 51,000 and 23,000 which correspond to the reduced and alkylated heavy and light chain molecules, respectively (Figure 1). The method of using disodium 2-nitro-5-thiosulfobenzoate (NTSB) as a sulfitolysis reagent was also attempted to reduce the heavy and light chain molecules. When separating the heavy and light chain molecules by size exclusion chromatography (SEC), molecules undergone reactions with the sulfitolysis reagent appears to have a much better resolution for the heavy and light chain molecules than other reagents (Figure 2). For amino acid sequence analysis, the reduced and alkylated antibody molecules were subjected to either tryptic or lys-C digestion. In our case, the tryptic peptide map provided fragments which are more compatible with the mass spectrometric characterization.

**College of Veterinary Medicine
The University of Georgia
220 Riverbend Road, Athens GA 30602, USA

Introduction:

Indirect evidence has linked the presence or absence of certain cytokines in tears to a number of pathological events that occur in the anterior segment of the eye. Despite the apparent clinical importance of identifying these proteins, techniques for their direct detection in tears have not been developed. Multiple problems are encountered in the detection of these proteins in tears. For example, a large number of proteinaceous components (>100) are known to be present in tears. Furthermore, the quantity of these cytokines is extremely limited. Current thinking places the concentration of these cytokines at roughly the attomole to femtomole per microliter level. However, only a few microliters, (2-5) of tears can be obtained from each collection, and the total quantity of each cytokine that can be obtained from an individual tear sample is limited to at most ~500 femtomoles. Although we have not yet achieved the sensitivity necessary to detect cytokines reproducibly and with acceptable intensity, we have developed a new technique that provides affinity separations directly on the surface of the matrix assisted laser desorption/ionization mass spectrometer (MALDI-MS) probe. This strategy which we call "probe affinity MS" (PAMS) provides both *in situ* identification of biomolecules through biospecific antibody/antigen interactions and molecular weight information in a rapid and facile manner.

Methods:

Separation:

Capture agents specific for molecules of interest are immobilized on a gold surface by covalent attachment through reductive amination with a self assembled monolayer of dithiobis succinymidylpropionate (DSP), (see Figure 1).

MALDI Detection:

The mass spectrum shown here (Figure 2) was acquired on a Hewlett Packard LDI 1700XP MALDI TOF mass spectrometer, using α-cyano-dimethoxy-4-hydroxy cinnamic acid. Each dried sample on our eight mesa gold plated probe tip was reconstituted using 80% acetonitrile, 19% ultra pure water, (Continental), and 1% TFA. The instrument was operated at an accelerating voltage of 30 kV and an extractor voltage of 9 kV. The goat anti-biotin and the DSP was purchased from Sigma, and the human anti lysozyme was purchased from BTI.

Results and Discussion:

A conventional MALDI spectrum of a mixture of biotinylated insulin and myoglobin is shown in Figure 2A. The MALDI spectrum obtained following PAMS analysis is shown in figure 2B, with ion peaks corresponding to singly, doubly, and triply biotinylated insulin. Comparison between the PAMS spectrum and the normal MALDI spectrum of the protein mixture serve to illustrate the success of the PAMS experiment in separating an analyte of interest. Figure 2C illustrates the minimal amount of non-specific binding seen of analyte on the gold surface.

Characterization of Recombinant Human Interferon α-2 by Electrospray LC/MS

Larry Heimark, Eric Huang, Birendra Pramanik
Schering-Plough Research Institute, 2015 Galloping Hill Road, Kenilworth, NJ 07033

The recombinant protein, human interferon α-2 (Hu-IFN), marketed under the trade name Intron A, is an important cytokine with broad spectrum antiviral, antiproliferative and immunomodulatory properties. As a result, Intron A has been approved for the treatment of hairy cell leukemia, selected cases of condylomata acuminata, AIDS-related Karposi's Sarcoma, chronic hepatitis B and chronic hepatitis non-A , non-B/C. In this work, Hu-IFN is characterized by ESI of the intact protein and ESI LC/MS of the trypsin digest using 1.0 mm and 0.5 mm I.D. columns, and a 0.32 mm I.D. packed capillary column.

Hu-IFN is a 165 amino acid protein with 2 disulfide bonds and no other post-translational modification. The theoretical average molecular weight for the reduced protein is 19,266 Da. An observed MW of 19, 265.4 Da was recorded by ESI analysis (Figure 1). Figures 2-4 present the base peak chromatograms of the Hu-IFN trypsin digest separated on 1.0 mm, 0.5 mm and 0.32 mm ID columns, respectively. The chromatographic peaks representing the various tryptic peptides are labeled in each chromatogram. The molecular weight and amino acid sequence of all expected tryptic fragments are shown in Table 1. The scan range was m/z 500-2400, therefore, all digest fragments below 500 Da representing one or two amino acids were not detected.

An examination of the chromatograms for the 1.0 mm, 0.5 mm and 0.32 mm columns reveals that most of the expected tryptic peptide fragments, except T-10, are detectable regardless of column dimension. Fragment T-10 was not eluted under the gradient conditions used for this study. The chromatograms differ primarily in peak resolution. All chromatograms were run using the same gradient program with no attempt to optimize elution conditions for each column. These results demonstrate that, even without extensive optimization of elution conditions, similar information can be obtained using both conventional microbore and packed capillary columns. The major difficulty encountered with smaller diameter columns is in column setup, plumbing and maintenance of a stable flow rate and reliable gradient mixing. The 1.0 mm ID column required no special setup. The flow rate and gradient stability were provided by using a pump with small piston volume (250 µl) and a small volume (10 µl) mixer. The 0.5 mm and 0.32 mm columns required pre-column flow splitting after the gradient mixer then post-column flow measurement and adjustment of the pump flow rate to achieve the optimal flow rate for the two columns. Despite the additional setup time required with the smaller columns, the enhanced sensitivity provided by the lower flow rates used with smaller diameter columns can be especially advantageous when sample amount is limited.

Mass Spectrometric Characterization of the rhM-CSF Receptor Binding Site

M. Kalkum[1], R. Yamamoto[2], J Schreurs[2], M.L. Deinzer[3] and M O Glocker[1]

[1]Faculty of Chemistry, P.O. Box 5560M732, University of Konstanz, 78434 Konstanz, Germany. [2]Chiron Corp 4560 Horton Street, Emeryville, CA 94608, USA. [3]Department of Agricultural Chemistry, Oregon State University, Corvallis, OR 97331, USA.

Macrophage Colony Stimulating Factor (M-CSF) is a cytokine of pharmaceutical interest because of its ability to stimulate innate host defenses in immunocompromised patients It is a hematopoietic growth factor that stimulates the survival, proliferation, differentiation, and function of mononuclear phagocytes. Three human cDNA clones, each encoding a M-CSF polypeptide of different length, have been isolated and expressed as active protein. The recombinant human M-CSF (rhM-CSF) studied here was cloned and expressed from *E. coli* as a truncated form (aa4-221) of the longest cDNA clone (M-CSF ß) [1]. rhM-CSF forms a disulfide linked homodimer with a molecular weight of 49029 Da The inter- and intramolecular disulfide bonds were assigned using mass spectrometric methods [2]. M-CSF dimers contain the cytokine-specific four-helix bundle in each monomer at their N-terminal regions [3] In order to investigate substructures of the receptor interacting four-helix bundles, histidine residues, which occur in the A-helix of the molecule and not in one of the other three helices (B - D), were selected as targets for chemical modification

In this study we report the use of diethyl pyrocarbonate (ethoxyformic anhydride, diethyl dicarbonate, DEP) for selective modification of histidine residues, combined with mass spectrometric peptide mapping analyses, as a tool for the characterization of the receptor recognition region of rhM-CSF. DEP is a commonly used reagent for the specific modification of histidine residues in proteins [4] The product of the modification is considered to be an N-carbethoxy-histidine derivative (CEt-His) Mass spectrometric analyses have shown that with excess DEP the reaction of imidazole or histidine residues in peptides proceeds through Bamberger cleavage to N,N'-dicarbethoxy-N-formyl-1,2-diaminoethenes (FCEt) which then slowly decompose to urethane-derivatives, N,N'-dicarbethoxy-1,2-diamino-ethenes, (UCEt) DEP reacts with protein histidine-residues in a narrow pH range Below pH 5 5 the imidazolyl-nitrogens will be protonated and reaction is very slow, and above pH 7 5 hydrolysis of both, DEP and the CEt-His derivative will play a major role Our investigations have shown, that modification of histidine residues in proteins with DEP best be carried out in ammonium acetate buffer at pH 6.5 in which the selectivity of the reaction, the stability of the product, and the hydrolysis-side reactions, all

43rd ASMS Conference on Mass Spectrometry and Allied Topics

are optimized to yield in a 1 . 1.16 stoichiometry of the CEt-His derivative, with respect to the starting amount of imidazolyl groups.

Using the above mentioned conditions, the chemical reactivities of the histidine residues of rhM-CSFß (5 His / monomer; His9, His15, His98, His176, His210) were monitored. Increasing conversion of histidine-residues was observed with increasing excess of DEP by MALDI-MS molecular weight determination. After tryptic digest of the modified protein derivatives MALDI-MS peptide-mapping analyses showed that histidines were converted to CEt-His and UCEt-His, respectively The degree of the chemical modifications at His9/15 are correlated to the biological activity of the protein derivatives. A substantial decrease (>60%) of the biological activity and receptor binding of rhM-CSF was found in *in-vitro* bioassays. Although histidines 176 and 210 were modified to a comparable extent than the histidines 9 and 15, only the latter two are located in the A-helix of the 4-helix bundle and, thus, the histidine residues from the C-terminal areas are not important for biological activity. Site specific mutagenesis experiments in wich His8 and His15 were replaced by alanine residues exhibited a decrease in specific bioactivity [5]. Also, His98 seems not necessary for biological activity, as was deduced by comparison of human and mouse M-CSF, where His98 is replaced by Gln [6].

Two types of histidine residues were differentiated by chemical modification reactions. His176 and His210 were found to react to UCEt-derivatives to a greater extent than His9 and His 15 For the formation of UCEt both nitrogen atoms of the imidazolyl-group must be accessible to the reagent In rhM-CSF the surface accessibilities (SA) of the imidazolyl-nitrogen atoms of His9, His15, and His98 are very asymmetric, indicating, that only one of the two nitrogens is accessible The predominant mono-derivatization to CEt-His of these residues is in agreement with the calculated values from the X-ray structure [3] SA values from nitrogen atoms of His176 and His210 are not available, however, our results suggest that both nitrogen atoms should be accessible to the surface.

COMPARISON OF THE WATER-SOLUBLE CRYSTALLINS FROM NORMAL AND AGE-RELATED CATARACTOUS HUMAN LENSES

S. He,[1] S. Pan,[2] K. Wu[2] and R. Orlando[1*]
1. Complex Carbohydrate Research Center and Department of Biochemistry and Molecular Biology, University of Georgia, Athens, GA
2. Zhongshan Ophthalmic Center, Sun Yat-sen University of Medical Science, Guangzhou, China

To better understand the mechanism(s) for cataractogenesis, we have begun an investigation into the *in vivo* transformations that occur to the primary structure of human lens crystallins upon cataract formation. In this study, the *in vivo* post-transtlational modifications found in the water-soluble lens crystallins from a 65-year-old cataractous individual were compared to those of a normal human fetus by high performance liquid chromatography/mass spectrometry (HPLC/MS).

The water-soluble crystallins, prepared by homogenization of the lenses, were directly analyzed by HPLC/MS. This technique permits separation of crystallins while simultaneously determining the molecular weight of each component to within a few Daltons.

These HPLC/MS experiments determined that the molecular weights of the water-soluble crystallins in the normal and age-related cataractous lenses were virtually identical (table 1, figure 2), implying that there are no significant differences between the *in vivo* post-translational modifications found in the water-soluble crystallins of normal and age-related cataractous lenses. These experiments also demonstrated that the quantity of βB1 and several γ-crystallins are significantly reduced in the water-soluble fraction of the age-related cataractous lenses (figure 1), presumably these crystallins have become water-insoluble.

These result demonstrate that post-translational modifications do not appear to accumulate in the water-soluble crystallins fraction, providing evidence that alterations in the primary structure of the crystallins that remain water soluble do not play a role in age-related cataract formation. Alternatively, the disappearance of several crystallins appears to be associated with age-related cataractogenesis; however, the fate of these missing crystallins could not be determined by these experiments.

Identification of Modified Human Water Insoluble Lens Crystallins by MS

Anders L. Lund, Jean B. Smith and David L. Smith
Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304

Cataract is the number one cause of blindness worldwide, and the cost of cataract surgery is 11 % of the Medicare budget. One hypothesis for the formation of cataract is that opacification arises from aggregation of the modified lens crystallins. The eye lens crystallins can be separated into water soluble and water insoluble fractions. Initial work on the water insoluble fraction indicates that there are multiple modifications of several crystallins in this fraction.

The water insoluble monomers are very complex mixtures. Two dimensional polyacrylamide gel electrophoresis can resolve the mixture into its components, but the proteins cannot be easily removed for analysis. We were unable to use ESIMS to analyze the fractions solely isolated by reversed phase HPLC. The crystallin composition of the fractions was too complex. Ion exchange chromatography is needed prior to the reversed phase separation to add another dimension to the fractionation of the monomers.

Many of the modified crystallins constitute a very small portion of the total protein in the water insoluble fraction. To increase the amount of trace components in the monomer fraction, the monomers from three lenses were combined. Prior to combining the monomers, the UV traces from the three lenses were compared to examine the variability of the lenses. The combined sample was fractionated on a Pharmacia Mono Q 5/5 ion exchange column.

The fractions collected from ion exchange chromatography were further purified by reversed phase HPLC on a Vydac C4 column. The gradient was started at 30% B to ensure the crystallins would stay in a denatured state after the urea was removed. The peaks were collected and concentrated.

ESIMS was used to analyze the fractions isolated from reversed phase HPLC. The ESI mass spectrum in Figure 1 is of the fraction designated α-A. (The inset spectrum in Figure 1 is of water soluble α-A crystallin.) The water insoluble protein in this fraction coelutes with water soluble α-A crystallins on reversed phase HPLC. The MW of unmodified α-A is 19952. Approximately 10 pmol of sample was analyzed by on-line LC/ESIMS. The effective resolution was enhanced three fold with the maximum entropy algorithm. Two ions corresponding to novel *in vivo* degradation products were immediately observed. The minor components of this fraction are still associated with the parent crystallin after extensive chromatography. The mass difference between the water soluble and water insoluble α-A crystallin is 2 mass units.

To determine where the water insoluble crystallin was modified, the sample was digested with trypsin. To perform LC/ESIMS, the effluent from a C8 microbore column was split 10:1, 5μl was directed into a Fisons VG Platform quadrapole mass spectrometer with an ESI source. The other 45μl was directed into a UV detector and fractions were collected for later analysis.

The information obtained from the digest includes: two sites of deamidation, confirmation of the loss of serine from the C-terminus, a doubly charged ion and triply charged ion that correspond to the peptide sequence 120-145 (this sequence may contain a disulfide bond), and possibly an oxidized methionine in the amino terminus.

To determine the amount disulfide bonding present in the peptide 120-145 we analyzed 5 μl of the fraction containing the peptide 120-145 on a Fisons VG AutoSpec. This fraction was collected during the LC/MS analysis described previously. The array detector of the AutoSpec provided increased sensitivity at the resolution required to analyze the sample. The spectrum was compared to the calculated isotopic pattern (Figure 2). The doubly charged ion from the spectrum matched the isotopic pattern of the disulfide bonded peptide, suggesting that all of the protein is disulfide bonded.

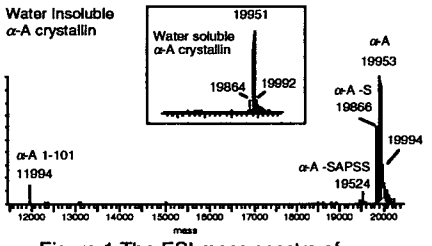

Figure 1 The ESI mass spectra of water soluble and water insoluble α-A crystallins.

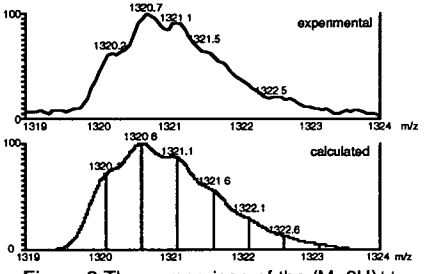

Figure 2 The comparison of the $(M+2H)^{++}$ peak from the ESI mass spectrum of the peptide 120-145 to the calculated isotopic distribution at the same resolution.

Additional evidence for the complete disulfide bonding of α-A was obtained from the AspN digest of the crystallin. The digest was analyzed by on-line LC/ESIMS; the total ion current is displayed in Figure 7. A selected ion plot for the peptide 125-135 (DQSALSCSLSA) disulfide bonded to 136-150 (DGMLTFCGPKIQTGL) shows a strong single peak at scan 165. Selected ion plots for the individual peptides 125-135, and 136-150 did not show any peak in the chromatogram.

The following modifications are found in both the water soluble and water insoluble α-A crystallins: deamidation of several asparagine and glutamine residues, phosphorylation of serine 45 and 122 (either or both), and partial loss of the C-terminal serine. Two major modifications of the α-A crystallins in the water insoluble fraction were identified. First, the water insoluble fraction is completely disulfide bonded, whereas the water soluble fraction is less than 10 % disulfide bound. Next, peptide bond cleavage occurred between Asn 101 / Glu 102 and Thr 167 / Ser 168 only in the water insoluble fraction. These modifications may cause the transfer of the crystallins from the water soluble fraction to the water insoluble fraction. Deamidation at Asn 101 was readily observed in the water insoluble fraction. Peptide bond cleavage at this site may be associated with this event. It is not known if this site is just prone to hydrolysis, or if there are external factors catalyzing the hydrolysis at this site.

PROBLEMS AND SOLUTIONS IN SEQUENCING A MUSSEL FOOT PROTEIN FROM *MYTILUS EDULIS*

Vladimir V. Papov and Klaus Biemann
Dept. of Chemistry, Mass. Inst. of Technology, Cambridge, MA 02139

The marine mussel, *Mytilus edulis*, is particularly adept at attaching its foot to underwater surfaces through the byssus, which can be described as a bundle of threads ending in adhesive pads or plaques.[1] The process of this surface bonding is of considerable technological and scientific interest since it is quite strong, rugged, persists while completely immersed in seawater, and finally, is naturally occurring and presumably environmentally benign. Waite and coworkers at the University of Delaware have previously isolated at least four distinct families of polymorphic proteins thought to be involved in this adhesion process.[2] These proteins are derived from *Mytilus edulis* foot and byssal adhesive plaques and have been named mefp (for *Mytilus edulis* foot protein).

The third protein family (mefp-3) is unusual in that all of its variants (at least nine have been isolated) contain short sporadic repeat sequences. In addition, mefp-3 is composed almost exclusively of 3,4-dihydroxyphenylalanine (DOPA), Gly, Asn, Trp, Arg, and an unknown basic amino acid. The unusual composition of these proteins, no doubt due to their unusual biological role, complicated the sample handling and analysis of mefp-3. The primary sequence of mefp-3 is based on a variant F (mefp-3F) which appeared to be the most chromatographically pure as determined by acid-urea-PAGE analysis.

Although the identity of 4-hydroxyarginine (the unknown basic amino acid) was ultimately determined by fast atom bombardment (FAB) tandem mass spectrometry, peptides derived from mefp-3F ionized poorly by FAB due to their high content of DOPA, Arg, and 4-hydroxyarginine. Conversely, both mefp-3F and peptides derived thereof ionized well by matrix-assisted laser desorption ionization time-of flight mass spectrometry (MALDI-TOF-MS). The MALDI mass spectrum of native mefp-3F contained a cluster of $(M+H)^+$ ions that differed from the most highly hydroxylated form, $(M+H)^+ = m/z$ 6135.2, in multiples of -16 mass units due to incomplete post-translational hydroxylation.

Endoproteinase cleavage of mefp-3F was complicated by the tendency of this protein to oxidize, polymerize, and degrade while in solution, especially at alkaline pH. Trypsin digestion in particular resulted in an inordinate amount of peptides making analysis difficult. On the other hand, Endo-Lys-C retained its specificity producing a very simple digest consisting of only three peptides. Although the Endo-Lys-C peptides (LC-1, 2, and 3) were partially sequenced using automated Edman degradation (Waite *et al.*), the unusual composition of mefp-3F did not allow unambiguous determination of the C-terminus by this method. Ultimately, the C-terminal sequences of peptides LC-2 and LC-3 were identified by separately digesting each peptide with carboxypeptidase P and directly analyzing aliquots at different time points by MALDI-TOF mass spectrometry. For example, Figure 1 shows a MALDI-TOF mass spectrum of peptide LC-3 [$(M+H)^+ = m/z$ 1606.7] incubated with carboxypeptidase P for 30 seconds. All of the C-terminal lysine has been released at this time but the four major peaks at m/z 1478.6, 1421.4, 1249.3, and 1077.1 (loss of 128.1, 57.2, 172.1, and 172.2 Da) correspond to the consecutive loss of K, G, **R**, and **R** (where **R** is 4-hydroxyarginine), respectively.

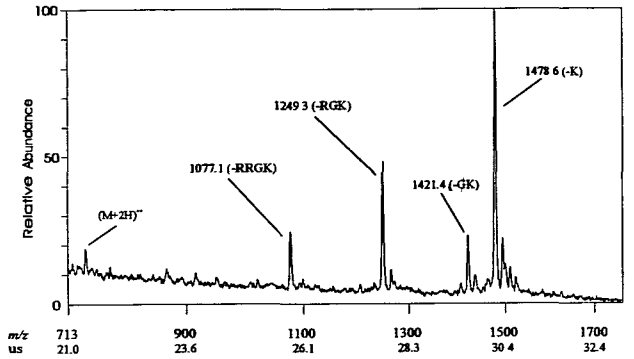

Figure 1. MALDI-TOF mass spectrum acquired after 30 sec of carboxypeptidase P digestion of peptide LC-3 from mefp-3F. The mass differences indicate that **RRGK** are the last four C-terminal residues of this peptide (undigested LC-3 has $(M+H)^+ = m/z$ 1606.7 as measured with an internal standard).

Similarly, the N-terminal peptide sequence was determined (and confirmed) by incubating the peptide with aminopeptidase M and analyzing the aliquots by MALDI-TOF-MS. In this manner, it was possible to determine the sequence of peptide LC-3 entirely by mass spectrometry. The alignment of the peptides in the final sequence was accomplished by digesting native mefp-3F with carboxypeptidase P in combination with MALDI-TOF-MS.

In conclusion, the mussel foot protein, mefp-3F, presented unique challenges to the determination of the amino acid due to its unusual composition. Furthermore, the post-translational hydroxylation of mefp-3F complicated the conventional sequencing method of Edman degradation. The complete sequence of the most highly hydroxylated form of mefp-3F was finally determined to be (where **Y** and **R** are DOPA and 4-hydroxyarginine, respectively)

ADYYGPNYGPP**RRY**GGGNY**NRY**NRY**GRRY**GGYKGWNNGWNRGRRGKYW

by using a combined approach of Edman degradation sequencing and mass spectrometry.

MASS SPECTROMETRY OF MARINE BIOMOLECULES

Mark M. Ross[1], Steven W. Taylor[2] and J. Herbert Waite[2]
[1]Code 6113, Naval Research Laboratory, Washington, DC 20375
[2]Dept. of Chemistry, University of Delaware, Newark, DE 19716

The growth of marine organisms on surfaces in the ocean is a serious problem for the Navy. This "biofouling" phenomenon is the focus of chemical, biological and materials science research aimed at determining the adhesive agents, adhesion chemistry and strategies or new materials that will prevent the adhesion.

This project is focused on marine mussels, which stick to surfaces via a strong, durable thread and a versatile plaque. Some of the proteins produced and secreted by mussels have been characterized, and some of these are speculated to be involved in the adhesion [1]. However, the exact identities of the binding molecules and the adhesion chemistry are unknown.

In this work, the marine mussel, *Mytilus edulis*, is grown on different substrates, cold-shocked, harvested and the feet or plaques are extracted [2]. These extracts are fractionated by HPLC, and the components of these complex mixtures are analyzed using MALDI and ESI mass spectrometry. The objective is to identify the proteins that are contained in the mussel foot and plaque. Because it is the plaque that sticks to a substrate, the biomolecules in this part of the mussel are of primary interest. One unique aspect of this work is that the adhesive side of intact plaques were subjected to MALDI in an attempt to probe directly the species used to adhere.

The HPLC fractions of an extract of 5,000 plaques showed a wide variety of species by MALDI, from 2-15 kDa. Of particular interest are variants of Mefp-3 (the 3rd family of Mytilus edilus foot proteins), which have molecular weights in the 5-6 kDa range and are suspected adhesive agents. Figure 1 shows the MALDI mass spectrum of one plaque extract fraction, which contains many species and some with masses in the correct range for Mefp-3.

It is known that the plaque contains Mefp-3 proteins, but it is not known which of the many variants are used in adhesion. Figure 2 shows a MALDI mass spectrum taken directly of the adhesive side of a plaque. Some of the most abundant ions are in the 5-6 kDa range, and the narrower peak widths, relative to those of the extract species, indicate specific variants.

The next step is to determine the sequence of those species observed directly from the plaque. It may then be possible to determine if the adhesive agents used by the mussel vary with the substrate.

INTRODUCTION :

Molecular machinery of sex determination is understood in details only in few cases. In crustacea the sex differentiation of young animals is totally under control of the androgenic glands (AG). It has been clearly demonstrated that a protein isolated from AG was responsible from sexual differentiation. This protein is the Androgenic Hormone (AH).(1,2)

Our goal was to determine the primary structure of AH. We have used mass spectrometry and Edman degradation in conjonction to determine not only the sequence but also the possible post-translational modifications. We have also isolated and characterized its precursor (prohormone) and a C-peptide. To follow the biological activity of AH on female woodlouse, two kinds of bioassay were performed. A rapid one, which revealed a biological response within 8 to 10 days and a second one (sex reversal and mating experiments), which required several months but which led to the complete convertion of females to sexually active males.

RESULTS :

1-MALDI-TOF spectrum from a single crude Androgenic Gland. (Fig 1)

A single gland was isolated and directly submitted to MALDI-TOF analysis.

2-Purification and characterization of the androgenic hormone. (Fig 2)

The extract from 1200 androgenic glands was injected on a phenyl rp-HPLC column (4 x 300 mm). Three peaks were shown to be active. After several chromatography, each peak was analysed by MALDI-TOF. The MALDI spectrum of peak 1 and 2 were characterized by a broad peak ranging from 10 to 12 kDa. Peak 3 showed a large peak ranging from 16.5 to 18.5 kDa and a strong peak at 5kDa.

For Peak 1 and 2 the same primary structure was observed by Edman Degradation and MALDI-TOF. Both proteins are heterodimers made of 2 chains linked by 2 disulfide bonds. The 2 highly active proteins named AH1 and AH2 were only differentiated by the size and the heterogeneity of glycan chain on Asn 18 from chain A. This glycosylation was characterized by MALDI-TOF.

3-MALDI-TOF characterization of the glycan moiety of AH. (Fig 3)

Chains A, from AH1 and AH2 were isolated by reduction-alkylation and analysed by MALDI-TOF. Digestion with Lys-C allowed to isolate a small peptide (17-29) with the glycan chain. Fig 3 shows the MALDI-TOF spectrum after partial hydrolysis with MeOH/HCl 0.5N of the peptide 17-29 of chain A. Different peaks could be attributed to the core structure of the complex type N-glycosylation. GC-MS data confirmed the presence of N-acetylglucosamine, galactose and fucose.

CONCLUSION:

We have determined for peak 1 and 2 the same primary structure. AH1 and AH2 were both an heterodimer N-glycosylated on Asn 18 of chain A. The glycosylation is heterogeneous. From active peak 3, we have isolated the precursor of AH (17kDa) and the C-peptide (45 residues) linking chain B to chain A. All the peptides characterized after purification could be observed in the preliminary MALDI-TOF analysis of a single crude Androgenic Gland.

SEQUENCE CHARACTERIZATION OF PEPTIDES FROM A SPIDER SILK PROTEIN BY ELECTROSPRAY MS/MS

Bernice Yeung & Paul Vouros
Chemistry Department and Barnett Institute, Northeastern University, Boston, MA 02115
Charlene M. Mello & David L. Kaplan
Biotechnology Division, US Army RD& E Center, Natick, MA 01760

INTRODUCTION Silks are fibrous proteins spun by biological systems. Unlike silkworms, spiders produced a variety of silks which has not been well characterized. The dragline silk of *Nephila clavipes* is the most studied of all spider silks, and it has been found to possess a unique balance of mechanical strength and elasticity [1]. Sequence characterization of this silk will lead to an understanding of its structure-function relationship, and ultimately to its application as bioengineered materials.

The focus of our work is on the direct sequencing of this dragline protein. Due to difficulties with solubility and the lack of basic amino acids in its composition, a chemical digest using N-bromosuccinimide (NBS) was opted over the conventional enzymatic methods for the digest of this protein. Digest protocol using NBS has been optimized for generating peptides suitable for sequencing by MS/MS and Edman degradation. The results are presented below.

EXPERIMENTAL

(1) Sample Preparation: Digest protocol and sample preparation are outlined in Figure 1.

(2) SDS-PAGE: All electrophoresis was carried out using precast 10-20% Tricine gels (Novex), running under a constant voltage of 125V for 100 minutes.

(3) HPLC: Peptide mapping was done on a Waters 625 LC system, using a H_2O/ACN/TFA gradient system on a Delta-Pak C18 column. Fractions were collected manually and concentrated to a final volume of ~50μL each.

(4) ESI MS: All work was done using a Fisons Quattro triple quadrupole instrument coupled to a Carlo Erba Phoenix 20 capillary HPLC system. A C18 packed capillary LC column (LC Packings) was utilized in the gradient mode, using a H_2O/IPA/TFA system.

RESULTS

Fraction 26: The full scan ESI mass spectrum is shown in Figure 2. CID analysis of m/z 768 and m/z 455 were performed, and their sequences were determined to be (Q/K)GGAGGHG(Q/K) and GGY, respectively. The CID spectrum of the latter peptide is displayed in Figure 3, where the tyrosine residue is shown to be NBS-modified and bears the characteristic fragmentation pattern as previously discussed [2].

Fraction 13: Figure 4 shows the full scan mass spectrum of this fraction, where an MH^+ ion is seen at m/z 304, along with its $[2M+H]^+$ and $[3M+H]^+$ ions. CID data of m/z 304 (Figure 5) indicates two possible sequence assignments: GGGGG and GG(L/I)G. Finally, Edman degradation of this fraction established the sequence to be GGLG.

The internal structural proteins of retroviruses are formed by proteolytic processing of the Gag precursor polyproteins in the last stages or after budding of the virus particle from the infected cell. In all retroviruses the proteins into which Gag is proteolyzed include (in order from the Gag N-terminus) MA (matrix protein), CA (capsid protein), and NC (nucleocapsid protein). In avian retroviruses the Gag precursor also encodes the protease (PR) that is responsible for processing the precursor (for a review on the form, function, and use of retroviral Gag proteins see reference 1). Cleavage of Gag leads to a morphological change in the virus particle called maturation, which is essential for the virus to become infectious.

In the mature virus particle, CA forms the protein shell or "core" that encapsulates the viral RNA genome and RNA-associated proteins, including NC and the replication enzymes reverse transcriptase and integrase. In the newly infected cell, the core is delivered to the cytoplasm, where reverse transcription (replication of the genome) occurs. In the avian sarcoma and leukemia viruses, typified by Rous sarcoma virus (2), the major Gag proteins are MA, p10, CA, NC, and PR. In addition, several small peptides are produced, from Gag proteolysis between MA and p10 (peptide p2), and between CA and NC (spacer peptide).

In earlier studies (3) it was found that mature viruses contain multiple forms of the CA protein that differ by proteolytic processing of the C-terminus. We have now definitively identified three forms of CA in mature virions, and have investigated the proteolytic processes by which these forms are generated *in vivo*, using electrospray ionization mass spectrometry (carried out on a VG Quattro II instrument) to analyze various Gag-derived proteins of the Prague C strain Rous sarcoma virus (PrC-RSV) and avian myeloblastoma virus (AMV). Each protein generated from *in vivo* processing of Gag was collected and analyzed by ESI MS. The results for PrC-RSV are tabulated as follows:

Protein	Position[1]	Calculated MW	Measured MW
MA	[1-153]	16574.1	16653[2], 16574
p10	[176-237]	6044.6	6044
CA	[238-477]	25815.9	25815, 25684[3], 25543[3]
NC	[487-575]	9492.6[4]	9492
PR	[586-699]	13609.9	13609

1 Positions refer to the sequence of the Gag precursor polyprotein.
2 MA is known to be phosphorylated; MW 16653 corresponds to the phosphorylated protein
3 The CA variability is discussed below.
4 The calculated MW corresponds to one of the known isoforms of this protein.

The ESI mass spectra of PrC-RSV and AMV CA proteins, along with the corresponding transformed data, are shown, in Figure 1. PrC-RSV (Figure 1A) consists of two major components of MW 25542 and 25815; the latter agrees with the molecular weight predicted for CA from the nucleotide sequence, while the former corresponds to the predicted sequence minus the last three amino acids (Ala-Ala-Met). A minor component of MW 25684 corresponds to the predicted CA sequence minus the C-terminal Met residue. All three components are generated during proteolysis of the Gag precursor molecule. Unlike PrC-RSV,

AMV is a mixture of closely related viruses, thereby resulting in a mixture of CA species, consisting of at least three CA proteins (Figure 1B). Nevertheless, for each component the same processing, including relative abundances, was observed as for the PrC-RSV CA protein.

Recombinant viruses that were designed to contain the CA protein missing its last three amino acids (AAM) were found to undergo proteolytic maturation but were non-infectious. Earlier results (4) had demonstrated that deletion of the nine amino acids (spacer) that are present between CA and NC sequences in Gag (see Figure 1) had a similar effect (i e., CA is not processed further to the shorter form lacking the three C-terminal amino acids).

The processing of Gag to CA minus the C-terminal three amino acids was a previously unrecognized event. Two experiments were designed to test if this shorter form of CA were indeed a Gag PR product. The first experiment involved *in vitro* cleavage with the PR protease of a synthetic peptide (LTDGIAAAMSSAI) consisting of the last nine amino acids of CA and the first four amino acids of the spacer sequence. The second experiment involved digestion with PR of a fusion protein encompassing CA, the spacer peptide, and NC In both cases cleavage analogous to that observed *in vivo* took place. Furthermore, the synthetic peptide (LTDGIAAAM) comprising the last nine amino acids of CA did not cleave with the PR protease. These results clearly demonstrate that if the spacer region between CA and NC is present (as in Gag) then the protease will process CA *in vitro* in a manner similar to the *in vivo* processing, and that the shorter form of CA is not generated from C-terminal trimming of CA.

Although the full significance of multiple processing sites between CA and NC is not known, it is apparent from our experiments that the region between CA and NC is required for proper processing of the CA protein and, presumably, the interactions between the various CA forms affect the infectivity of the virus. It is interesting that certain features of the CA maturation in PrC-RSV are also found in other retroviruses, such as HIV-1 (5,6).

Peptide phosphorylation site identification: A new method based on ion trap mass spectrometry.

Beth L. Gillece-Castro, David P. Arnott, Mark E. Bier*, Adrian P. Land*, and John T. Stults ; Genentech, Inc., 460 Point San Bruno Blvd., South San Francisco, CA 94080 and *Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

Phosphorylation of proteins is an enzymatically-controlled method of signal transduction within cells. Importantly, the sites and level of phosphorylation determine the activity of these signals. To identify these sites, a number of mass spectrometric methods have been developed in recent years. Many of the methods rely measuring Δ 80 Da on peptides or proteins, and have been demonstrated using LSIMS (1), ESI (2) and MALDI ionization techniques. Alternatively, phosphopeptides can be isolated from non-phosphorylated species by TLC or affinity chromatography (eg. iron binding) (2). Some characteristic fragments may be produced in tandem mass spectra which further confirm the presence of phosphorylation on particular peptides. In positive ion mode phosphoric acid is often lost from phosphoserine and phosphothreonine residues (- 98 Da). Fragment ions of this type have been observed in high-energy CID (1), low-energy CID (3) and MALDI-TOF post-source decay. In negative ion mode, low mass fragments of $H_2PO_4^-$ and HPO_3^- (97 and 80 Da, respectively) are produced by CID, and have been used for on-line LC/MS identification of phosphorylated peptides (4). Finally, the sequence of *phosphorylated peptides can be determined from CID to identify the specific site within a peptide (1).*

We developed a new method for identification of protein phosphorylation sites using a single LC/MS run on an ion trap mass spectrometer (Finnigan LCQ). Ion trap mass spectrometers can acquire multiple mass spectra in a data dependent manner in which ions detected in a full scan mass spectrum are selected by the data system for further MS experiments. The presence of an intense ion in the normal mass spectrum triggers the aquisition of scans further identifying this ion. These MS experiments include determination of charge state by narrow mass scan at high (>1000) resolution. Unique to the ion trap method is the MS^3 scan, shown in Figure 3. The double protonated peptide ion (m/z 418.9, Figure 1) was isolated and induced to dissociate (MS^2 scan, Figure 2). The abundant fragment ion at *m/z* 370 was selected for the MS^3 scan (Figure 3) from which the P-Thr site was deduced.

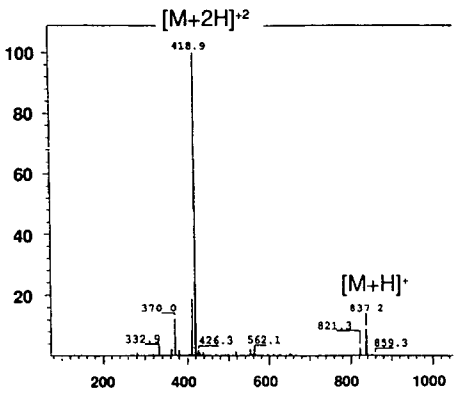

Figure 1. Peptide LKRA(p)TLG-amide analyzed by ESI-ion trap mass spectrometry.

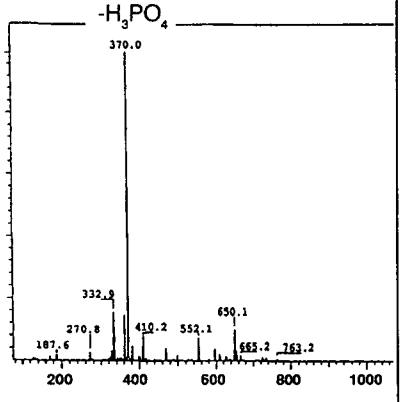

Figure 2. MS^2 scan of the doubly charged peptide LKRA(p)TLG (*m/z* 418.9) shown in Figure 1.

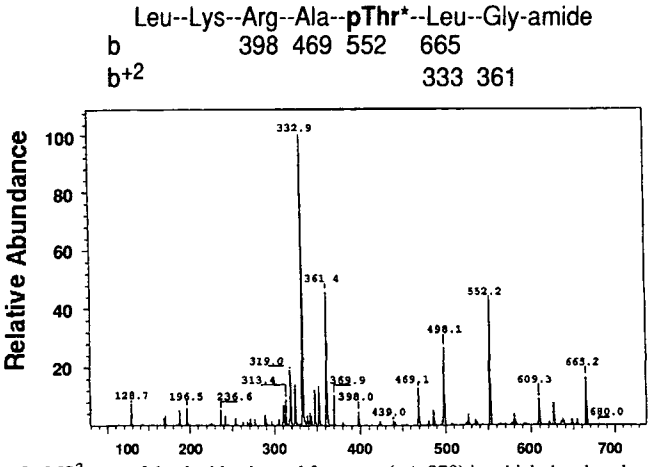

Figure 3. MS^3 scan of the doubly charged fragment (*m/z* 370) in which the phosphate group was lost by elimination forming a new residue, dehydroaminobutyric acid (pThr*).

Capillary HPLC was connected for on-line electrospray ionization mass spectrometry with a quadrupole ion trap analyzer. Peptides, including those produced by protein digestion were injected using from 0.1 to 10 pmol of each. Four types of mass spectra were obtained in a sequential manner with data-dependent scans First a scan from *m/z* 300-2000 is obtained. The most abundant ion detected in the MS scan above a preset threshold was selected for a second narrow higher resolution scan to determine the charge state of this ion. This same ion is then isolated for CID and the third, product ion spectrum (MS^2) obtained with the scan width calculated from the MW determined from the m/z and charge state. Finally, the most abundant ion observed in the MS^2 spectrum was isolated for a MS^3 scan. Total time for the series of MS scans was 3 to 4 seconds depending on the MW of the peptides observed. The MW of peptides was determined from the full scan mass spectrum and charge state determination. From the MS^2 scan the sequences of P-Tyr containing peptides were determined by the residue mass difference of 243 Da. Partial sequence of P-Ser and P-Thr containing peptides were also observed in MS^2 spectra, but the most abundant species were the $[M-H_3PO_4]^{+2}$ ions. These fragment ions now have dehydroalanine or dehydroaminobutyric acid where the P-Ser or P-Thr residues resided. MS^3 scan of this product ion typically gives sequence information with the phosphorylation site identified by residue mass differences of 69 Da or 83 Da. Occasionally, the MS^2 scan produces sufficient sequence ions to identify a site of phosphorylation in addition to the loss of phosphoric acid.

Advantages to the ion trap method for phosphopeptide identification are that the complete identification can be done in a single LC/MS run with peptides in any charge state. Singly, doubly and triply charged ions have been identified as phosphopeptides by the loss of phosphoric acid (98, 49, or 32.67 Da respectively) and/or sequence ions in the MS/MS spectra.

BACKGROUND AND OBJECTIVE

Hirudin [1] is a natural antithrombotic peptide of 65 amino acids containing three disulfide bridges. Recombinant hirudin (rHV-1) is produced by a process using genetically modified saccharomyces microorganisms. The biotechnological process also yields some byproducts with chemical properties similar to those of rHV-1. Six peaks named M(1)-M(6) in order of their retention time were separated by preparative HPLC and their major and minor constituents analyzed by electrospray ionization (ESI) mass spectrometry.

EXPERIMENTAL

Liquid chromatography: The byproducts were separated on a reversed phase C-18 type column (Vydac) using gradient elution. The mobile phase was water-acetonitrile (with 0.1% TFA). Flow rate was 1 ml/min, UV detector was at 220 nm. The collected samples were dissolved and introduced directly into the ESI source in acetonitrile-water (1:1, v/v) containing 1% formic acid. Mass spectrometry: ESI source in positive mode (Model Quattro, Fisons). Settings: capillary 3.50 kV, source temperature 80 °C, mass range 700-1900 Da, scanning speed: 0.1 sec/decade. The peak intensities reported are the averages from 5-10 consecutive spectra.

RESULTS AND DISCUSSION

Fig.(1) shows the HPLC separation of the raw sample: ESI spectra were obtained for all separated components. Fig.(2) shows, from up to down, the ESI spectra of samples rHV-1, M(1), M(2), M(3), M(4) and M(6), respectively. In addition to the base peaks, sodium addition peaks were also detected in all samples. The molecular mass of rHV-1 was 6963.33 Da, within 0.20 Da from the theoretical value. The molecular mass of major component of M(1), was 5059.49 Da (within 0.16 Da) corresponding to the 1-49 fragment of rHV-1, starting from the N terminal. Two minor components of M(1) were identified as 1C, the fragment of 1-51 of rHV-1 (m/z5284.08 Da, 0.27 Da from theoretical) and 1D, the fragment of 1-53 of rHV-1, (m/z5512.55 Da, 0.46 Da from theoretical) a third minor component, 1B was not identified. HPLC peak M(2), a single component, corresponded to the fragment 1-46 of rHV-1 (m/z4706.21 Da, 0.00 Da from theoretical). HPLC peak M(3) had three components, the first (3A) corresponding to fragment 1-61 of rHV-1 (m/z6429.95 Da, 0.0 Da from theoretical), the second (3B) corresponding to 1-62 fragment of rHV-1 (m/z6558.43 Da, 0.63 Da from theoretical), 3C was not identified. HPLC peak M(4), a single component, was identified as fragment 1-63 of rHV-1 (m/z6723.06 Da, 0.82 Da from theoretical). HPLC peak M(5) did not show ESI activity. The major constituent of HPLC peak M(6) was fragment 1-64 of rHV-1(m/z 6834.88 Da, 0.52 Da from the theoretical), a minor constituent had the molecular mass of rHV-1. A pictorial summary of the results with the structural significance is shown in Fig.(3).

CONCLUSION

The ESI technique was suitable for the determination of byproducts obtained in preparation of recombinant hirudin. The results suggest that the presence of carboxypeptidase and/or carboxydipeptidase enzymes may be responsible for the formation of byproducts during the biotechnological process.

Introduction

A certain strength of Matrix-assisted Laser Desorption/ Ionization Time-of-Flight Mass Spectrometry (MALDI/TOF-MS) compared to other MS techniques is its capability to analyze very heterogeneous mixtures of biopolymers Therefore, it is very suitable for investigations on extracts of biological material We applied MALDI for mapping of bovine and rat brain proteins. Conventionally, this is done by 2D-PAGE. However, the identification of the different components is often difficult there because of the limited accuracy of the MW determination. We fractionated an extraction of brain rougly by HPLC and analyzed the resulting fractions subsequently by MALDI. HPLC was coupled off-line to MALDI, i e. the different fractions have been collected and mixed with matrix outside of the MS instrument. To perform the mapping time-efficiently and to avoid a too excessive dilution, that might lead to the loss of components with low concentrations, each fraction still contained a smaller number of different components How effectively can a protein map of the many brain proteins, having very different concentrations in the extract, be established by the combination of HPLC and MALDI? Besides the number of detected proteins also the accuracy of their mass determination is a main criterion

Methods

1. Homogenization of bovine/ rat brain with 4 vol. of 0 1M potassium phosphate buffer (pH 7 1), 1.38M $(NH_4)_2SO_4$, 1mM EDTA ("solution 1") Centrifugation at 10,000g (30 min) Adding of powdered $(NH_4)_2SO_4$ to 85% saturation at pH 4 7 Collection of the precipitate by centrifugation, redissolution in a minimal volume of solution 1.
2. Desalting. injection of 50 µl crude brain extract into a reversed-phase C18 HPLC column and elution with a linear gradient from 0 1% aequeous TFA to acetonitrile Collection of the eluates into 42 different fractions (fig 1) Adjustment to equal volumes with 0.1% TFA / MeCN.
3. Mixing of 0.5 µl of each fraction with 0 5 µl matrix solution on the MALDI target. Matrix was a 9 1 mixture of salicylic acid and 5-methoxysalicylic acid, dissolved at 10 g/l in 9·1 0.1% TFA / MeCN
4. Mass analysis of the fractions in a VISION 2000 reflector-type MALDI/TOF-MS (Finnigan MAT) MALDI spectra were calibrated by Insulin, Cytochrome C or BSA due to the measured sample MW

Results

Each HPLC fraction analyzed by MALDI contained up to 10 different peptides and proteins (fig 2) MALDI provides for a high sensitivity for the detection of all components, which were in the fractions with quite different concentrations. Summarizing all MS spectra, about 160 different brain proteins were detected, of which ca 70% could be identified by comparison with databases. So, a detailled and accurate map of brain proteins and peptides could be established that is more detailed and more accurate than the conventioal 2D-PAGE (fig.3) The identification of all components is easier because of the much higher mass accuracy of MALDI-MS that was about 0 04% in average over the entire mass range. By comparison of the respective maps of different species, similiarities and differencies between their peptides and proteins can easily be revealed Off-line HPLC/MALDI has been demonstrated to be a powerful tool for mapping of complex biological samples like a brain extract.

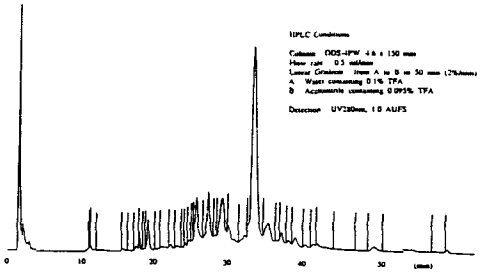

Fig. 1: Fractionation of Brain proteins using a Reversed-Phase HPLC Injection of 50 µl of Brain Extract into the column 42 fractions have been collected

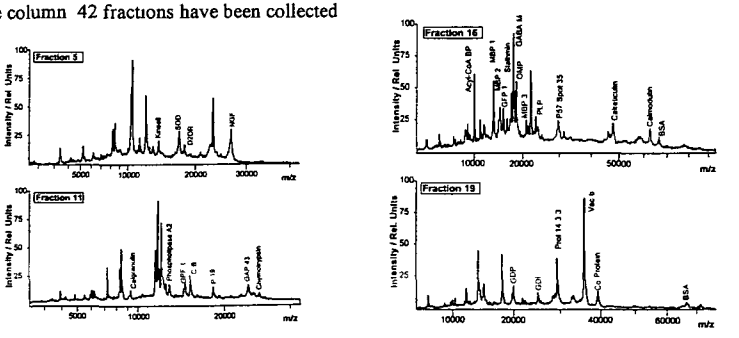

Fig. 2: MALDI spectra of the HPLC fractions #5, 11, 16, 31 from bovine brain as examples. Sum of 50 shots As can be seen, each fraction still contained up to 10 different proteins

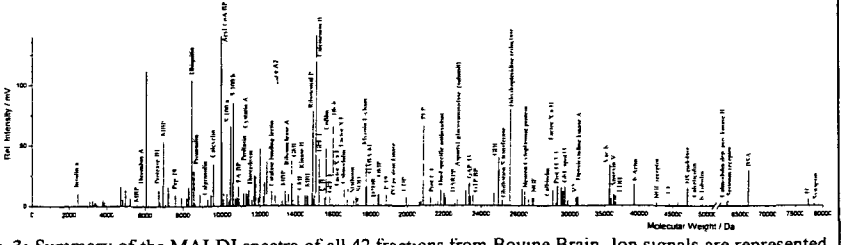

Fig. 3: Summary of the MALDI spectra of all 42 fractions from Bovine Brain Ion signals are represented by columns. About 160 different components have been detected which we tried to identify by comparison with databases The proposals for about 70% of all components are written on the columns

Mass Determination of Large Proteins Exceeding 200 kDa by UV-MALDI/TOF-MS

A. Ingendoh, H. Ikezawa, K. Seta, M. Kanai, Y. Yamakawa*, T. Omori-Satoh*, T Isobe# and T. Okuyama#
Finnigan MAT Instruments Inc., 2-5-8 Hatsudai, Shibuya-ku, Tokyo 151, Japan
*Japanese National Institute of Health, Shinjuku-ku, Tokyo 162, Japan
#Tokyo Metropolitan University, Department of Biochemistry, Hachioji-shi, Tokyo 192-03, Japan

Introduction

Molecular weight determination of large molecules is widely still done by SDS-PAGE, regardless of its by far insufficient accuracy. Moreover, by SDS-PAGE it is impossible to determine the MW of proteins above 200 kDa, as those large molecules cannot migrate sufficiently in the gel. GPC-HPLC, that is used more often in that case, is also very inaccurate and influenced by many factors Among today's MS methods, only Matrix-assisted Laser Desorption/ Ionization (MALDI) is able to analyze molecules with a mass exceeding 200 kDa. Few attempts have been made by ESI-MS also, but as most large biomolecules contain a distribution of carbohydrates or consist even of different species, the various highly charged ion signals of each species overlap and cannot be separated sufficiently. Moreover, MALDI has advantages in terms of a quite high sensitivity in the upper mass range and of a high tolerance against contaminants or biochemical additives which often cannot be removed completely from the sample solution. Here, we report about the successful analysis of biomolecules with MW between 200 and 400 kDa by MALDI.

Methods

Sample Preparation: Bov Catalase (Sigma), SCRI, Human α_2-Macroglobulin and Protease Inhibitor (Erinaceus europaeus) were dissolved at about 10^{-6} M in 0.1% aequeous TFA (some mM of phosphate buffer in some cases). Sample amount loaded onto the target was about 1pmol. Matrix was 9:1 salicylic and 5-methoxysalicylic acid, dissolved at 10 g/l in 9:1 0.1% aequeous TFA / acetonitrile.

Experimental Setup: The MALDI instrument used was a VISION 2000, Finnigan MAT, equipped with a N_2-laser emitting at a wavelength of 337 nm. All spectra have been taken in the reflectron mode. As even in the high mass range the transmission of the used reflectron is in the range of at least 80%, its advantage of a higher resolution compared to the linear mode can still be utilized. A specially designed post-acceleration dynode in front of a SEM is used for an effective detection of the striking large ions. All spectra have been calibrated externally by using BSA (MW 66,430 Da) as a calibrant.

Results

The MW determination of different macromolecules up to a mass of 350 kDa by MALDI has been demonstrated (fig.1). Most of the investigated macromolecules consist of several identical, non-covalently bond subunits. Although an acidic matrix solution has been used, in some cases at least a part of these subunits remained associated, giving ion signals of the entire biomolecule. Dimer ions up to at least 500 kDa have been clearly detected, proving the unrivaled high mass range of MALDI/ TOF-MS (fig.2). Because of the non-uniformity of most large biomolecules due to different species or a heterogeneous glycosylation, it is difficult to specify the accuracy of mass determination in this high mass range. However, by a careful estimation it was presumed in the range of 0.5%. Because this still means a deviation of 1500 Da at a molecular weight of 300 kDa, it is obvious that the mass accuracy has to be improved to give more reliable results. As the reproducibility of the calibration could be shown to be already within 0.2%, better calibration standards with MW closer to those of the large biopolymers might improve the mass accuracy easily. Such standards are highly demanded.

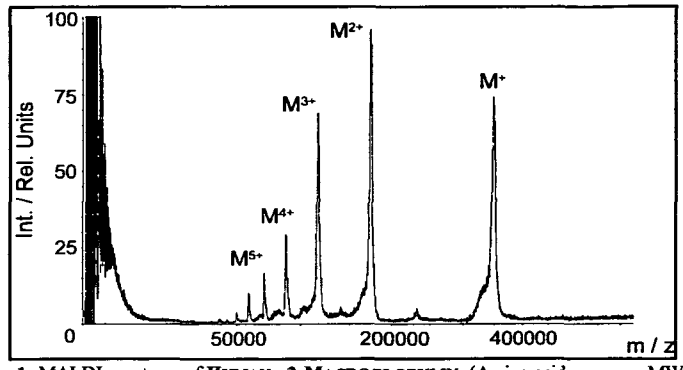

Fig. 1: MALDI spectrum of **HUMAN α2-MACROGLOBULIN**. (Amino acid sequence MW 643,148 Da). 100 laser shots. α2-MG consists of 4 non-covalently bond subunits and is a highly glycosylated protein. Averaged measured MW 349,730 Da, i.e. 2 of 4 subunits stay together despite of the acidic matrix solution. The mass difference between the measured and the amino acid sequence value indicates a glycosylation of Human α2-Macroglobulin in the range of 8 5%.

Subunit amino acid sequence of the **HUMAN α2-MACROGLOBULIN** (MW 160,787 Da - 1450 AA):

CHARACTERIZATION and QUANTITATION of CHONDROITINASE I (MW 112.5 kDa) and II (MW 111.7 kDa) by ESI/MS and MALDI/MS

Marshall M. Siegel[1], Kiran M. Khandke[1], Keiko Tabei[1], Stefan Berkenkamp[2], Arnd Ingendoh[2], Franz Hillenkamp[2]

[1]American Cyanamid Company, Medical Research Division, Lederle Laboratories, Pearl River, NY 10965
[2]Institute of Medical Physics, University of Münster, D-4400 Münster, FRG

INTRODUCTION Chondroitinase is an enzyme that digests chondroitin sulfate (a sulfated polysacchride) which is part of a proteoglycan that binds the vitreous humor to the retina. Chondroitinase is being developed as a chemical scalpel to separate the vitreous humor from the retina for medical purposes by replacing the conventional scalpel used for this ophthalmic surgery.

RESULTS Two forms of chondroitinase have been discovered and are referred to as chondroitinase I and II. Wide scan ESI and IR-MALDI mass spectra for chondroitinase II are illustrated in Figures 1A and 1B, respectively. Similar spectra were obtained for chondroitinase I. Likewise, mixtures of chondroitinase I and II can be resolved and analyzed by both ESI/MS (Figure 2A: narrow scan data; Figure 2B: transformed maximum entropy data) and IR-MALDI/MS (Figure 2C and 2D: singly and doubly charged molecular ions, respectively). The molecular weights for chondroitinase I and II, computed from the ESI and IR-MALDI mass spectral data, are 112.5 kDa and 111.7 kDa, respectively, which are consistent with predicted molecular weights based upon DNA sequencing data. The estimated molecular weights obtained from SDS-PAGE gels were of the correct magnitude but in reverse order. Table 1 summarizes the measured molecular weight for chondritinase I and II. The mass difference between chondoitinase II and I is 795 Da.

Chondroitinase I and II are produced simultaneously during bacterial fermentation. The relative amounts of both materials were quantitated by ESI/MS and MALDI/MS. Concentration studies by ESI/MS showed that each of the pure chondroitinases had similar linear responses from 0 to 4 pmoles/μL and saturated above 5 pmoles/μL. ESI/MS studies of chondroitinase mixtures of known concentrations, falling within the linear or saturated response regions, showed that the relative responses for chondroitinase I and II are always proportional to the relative concentrations of the components. The saturation effect coupled with a linear relative response is due to the limited number of charges available in the ESI source which randomly ionize the analytes. The rate of formation of chondroitinase mixtures was

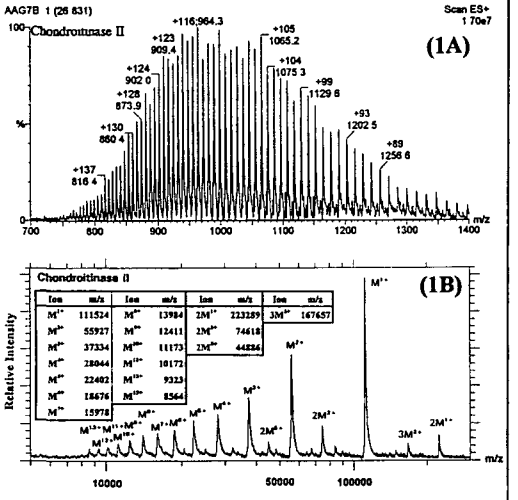

Table 1

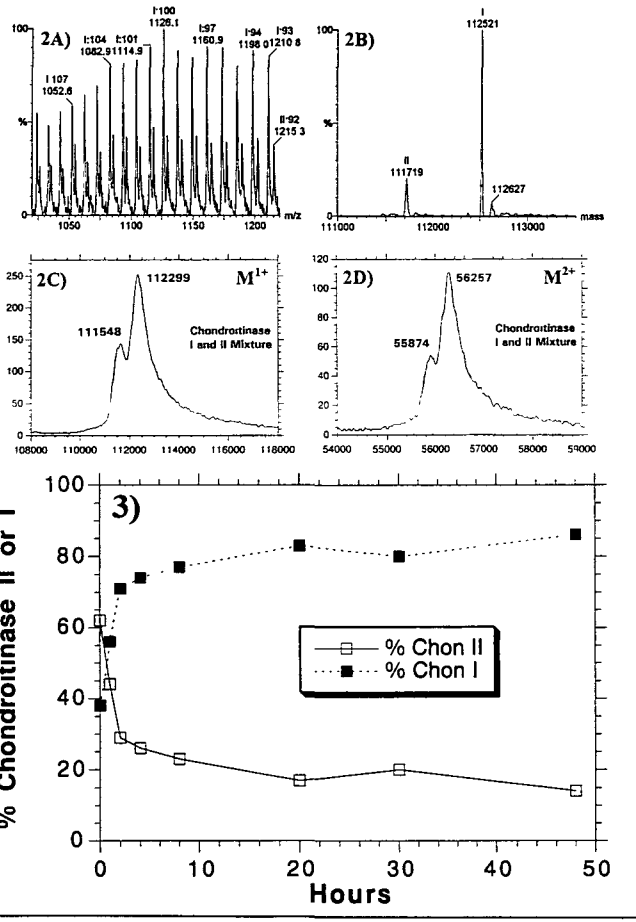
Method	Chondroitinase I MW	Δ (Error)	Chondroitinase II MW	Δ (Error)	I - II
DNA	112,507.82	-	111,713.33	-	+795
ESI/MS	112,553 ± 3 (0.003%)	+45 (0.04%)	111,750 ± 1 (0.001%)	+37 (0.03%)	+803
IR-MALDI/MS	112,324	-183 (0.16%)	111,525	-188 (0.17%)	+799
GELS	110 kDa		112 kDa		

Δ = Observed MW - Theoretical MW
I - II = Chondroitinase I MW - Chondroitinase II MW

quantitatively studied by ESI/MS as illustrated in Figure 3. Preliminary quantitative studies by IR-MALDI/MS were consistent with the ESI/MS results.

Degradation products of chondroitinase I were characterized by UV-MALDI/MS (MW 95,370±60; MW 16,630±50) and correlated with corresponding amino acid residues of chondroitinase I (AA 158-997, MW 95,022.4; AA 1-157, MW 17,503.4). Note that these two fragment ions correspond to cleavage of the amide linkage between AA residues 157 and 158 of chondroitinase I.

Chondroitin sulfate was degraded by chondroitinase. Isolated fractions were analyzed by ESI/MS and found to be only sulfated disaccharides and tetrasaccharides with from 1 to 3 sulfate moieties present.



DISTRIBUTION and LOADING of CALICHEAMICIN DERIVATIVES CONJUGATED to MONOCLONAL ANTIBODIES by IR-MALDI/MS and ESI/MS

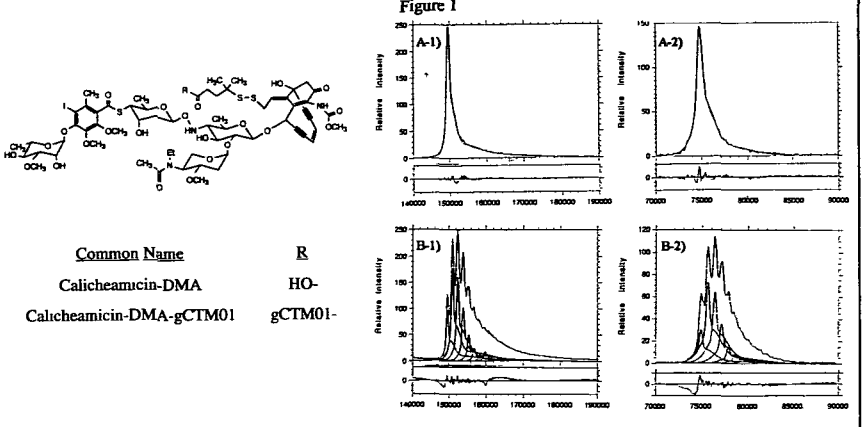
INTRODUCTION Calicheamicin and its derivatives are potent enediyne-containing antitumor antibiotics which function by cleaving DNA. Calicheamicin derivatives (MW ~1.5 kDa) conjugated to monoclonal antibodies (MoAbs, MW ~150 kDa) are being developed as targeting agents for anticancer therapy and have shown promising results in irradicating solid cancer tumors in laboratory animals and are presently undergoing clinical trials in leukemia patients. The average loading values for calicheamicin conjugates studied to date by UV-MALDI/MS were 2-5 times less than the values obtained by UV absorption spectrometry, immunoassay and biological assays [1]. In addition, the distribution of calicheamicin derivatives conjugated to MoAbs were not obtainable from these assays. These poor correlations with accepted biochemical assays prompted us to seek out the causes of these failures. Previous work [2] demonstrated the lability of calicheamicin derivatives and calicheamicin MoAb conjugates under UV-laser irradiation and that calicheamicin loading values as well as drug distributions can be obtained using IR-lasers in the MALDI/MS experiments with succinic acid. We now demonstrate that neutral glycerol is a better IR-MALDI matrix and the limitations of ESI/MS for determining accurate loading values and distributions for calicheamicin conjugates with stable linkers.

EXPERIMENTAL The IR-MALDI mass spectrometer was a reflector-type time-of-flight mass spectrometer. The IR laser system used was an Er-YAG, wavelength 2.94 mm (3401 cm^{-1}), pulse width 150-180 ns (electro-optically Q-switched) (Schwartz Electro Optics, Orlando, FL). The spot size diameter was ~200 μm (focused by a ZnSe lens having a 127 mm focal length) with irradiance of about 10^{+6} - 10^{+7} W/cm^2. The acceleration voltage was 12.3 kV. Electrospray ionization mass spectra were obtained with a VG Quattro triple quadrupole mass spectrometer equipped with a VG electrospray source, rf hexapole lens and Megaflow gas nebulizer probe.

RESULTS Figures 1A-1 and 1A-2, respectively, illustrate the singly and doubly charged parent ion peaks for pure gCTM01 MoAb using (frozen) glycerol as the matrix. An unusual feature of the MALDI mass spectra of MoAbs is that resolutions up to ~200 are achieved routinely in the IR-MALDI mode which is

Figure 1



Common Name	R
Calicheamicin-DMA	HO-
Calicheamicin-DMA-gCTM01	gCTM01-

about 2 times greater than can be achieved in equivalent measurements in the UV-MALDI mode. Figures 1B-1 and 1B-2, respectively, illustrate the singly and doubly charged parent ion peaks for low levels of calicheamicin-DMA conjugated to gCTM01 MoAb using (frozen) glycerol as the matrix. All the IR-MALDI/MS peak profiles in the observed spectra of the MoAbs conjugated to calicheamicin derivatives are broadened relative to the pure MoAb peak widths and are modulated. The mass difference between each maximum in the modulated peak corresponds to 1,460 daltons which is the mass change for the covalent addition of different numbers of calicheamicin-DMA molecules to the MoAb. The distributions of the calicheamicin derivatives conjugated to the MoAbs were calculated by deconvoluting the modulated peak profiles of the IR-MALDI spectra of the MoAb conjugates (See Figures 2A and 2B) using the peak profiles of the pure MoAbs as the basis functions. IR-MALDI/MS (with glycerol matrix) average distribution loading values (1.95) computed for MoAb conjugates made with the stable DMA linker were very similar to those computed from UV absorption spectrometry data (2.00). UV absorption spectrometry loading values correlated poorly with ones obtained using UV-MALDI/ MS with nicotinic acid matrix and using IR-MALDI/MS with succinic acid matrix [2].

Wide and narrow scan ESI/MS spectra are illustrated respectively in Figures 2 and 3 for pure gCTM01 MoAb and for low levels of calicheamicin-DMA conjugated to gCTM01 MoAb. Unique features of the spectra are the broad charge distribution and partial resolution (modulation) of the peaks. The transformed and integrated maximum entropy (resolution enhanced) spectra are illustrated in Figure 3. The modulation of the molecular ion peak is due to the heterogeneity of the polysaccharide present in the MoAb which corresponds to mass increments of 162 Da consistent with the addition of mannose or galactose units to the lowest mass immunoglobulin glycan. For the MoAb-conjugate sample, note the appearance of a new series of peaks each ~1,460 Da apart. relative to the peaks in the corresponding spectra for pure gCTM01 MoAb. This mass difference corresponds to the mass change of the MoAb after the covalent addition of calicheamicin-DMA via an amidation reaction. These ESI/MS distribution average loading value (1.28) is lower than the UV absorption average loading value (2.00) and less reliable than the IR-MALDI/MS result (1.95) due to the difficulty in resolving the overlapping multiply charged peaks arising from the heterogeneity of the covalently bound calicheamicin-DMA drug and the polysaccharide in the monoclonal antibody.

FHA is a major adhesion protein of *Bordetella pertussis*, the etiological agent of whooping cough. This protein is a component of a number of acellular pertussis vaccines. The MW of FHA was estimated from SDS-PAGE gels to be approximately 220 kDa. FHA was analyzed by ESI/MS (Figure 1A) and IR-MALDI/MS (Figure 2A) and found to have a molecular weight of 230,544±11 and 230,240±60 kDa, respectively. The ESI/MS MW value was computed from narrow scan data (Figure 1B) by minimizing the average mass error in the average MW by systematically varying the charge assignments to the observed multiply charged peaks (Figure 1C). Figure 1D illustrates the transformed ESI mass spectrum for FHA.

Lysyl-FHA, developed as a more soluble form of FHA, was prepared by mixing FHA with a very large molar excess of L-lysine followed by titration with formaldehyde. Lysyl-FHA was formed by linking lysine to FHA via a methylene group by the reaction of the addition product of lysine and formaldhyde with the active hydrogen atoms in FHA. The amount of lysine covalently bound to the FHA was quantitated by IR-MALDI/MS. Figure 2A, 2B and 2C illustrate respectively the singly, doubly and triply charged molecular ion regions of the IR-MALDI mass spectra for the pure FHA and the Lysyl-FHA components. (SDS-PAGE was incapable of distinguishing between FHA and Lysyl-FHA.) Mass centroids were computed for both components. (The mass centroid for Lysyl-FHA was computed from the sharp peak in the spectrum. The ions on the low mass side of the sharp peak are degradation products present in the impure FHA used in this preparation and were ignored for this calculation.) The IR-MALDI/MS loading values for lysine is computed from the difference in the mass centroids between Lysyl-FHA and pure FHA divided by the mass change upon the addition of one methylene-linked lysine moiety to FHA (158 Da). Figure 2D illustrates the data used for the loading calculations. The lysine loading value by IR-MALDI/MS was found to be 15.2±2.3 and the average MW for this batch of Lysyl-FHA was 232,640±360.

Fragment A, a recombinant protein containing the putative carbohydrate recognition domain of FHA which is critical for bacterial adherence, was purified from *E. coli*. ESI mass spectra obtained at the pH's of 3 and 10 (Figures 3A and 3B, respectively) revealed that Fragment A has a molecular weight 29,659.0±1.0 which is about twice that of the 14,812.4 kDa MW predicted from the DNA sequence. The ESI experiment was performed at the basic pH to demonstrate that the experiment at the acidic pH did not induce dimerization. Upon reducing the protein with dithiothreitol, the molecular weight computed from the ESI mass spectrum (Figure 3C) was 14,822±2.0, confirming that Fragment A is produced as a dimer.

Observation of holoprotein molecular ions of several ferredoxins by electrospray-ionization mass-spectrometry .

Yves Pétillot[1], Eric Forest[1], Jacques Meyer[2], Jean-Marc Moulis[2]
[1]Institut de Biologie Structurale (CEA/CNRS), [2]Departement de Biologie Moleculaire et Structurale (CEA), 38 Grenoble, France.

In order to characterize **iron-sulfur proteins**, we have defined experimental conditions leading to their holoprotein state detection by **ESI-MS**. For this purpose we took advantage of the fact that most ferredoxins and rubredoxins are negatively charged at neutral pH, where their stability is highest. Thus, the implementation of the negative-ion detection mode (**ESI⁻**) at neutral pH has already proved to be more successful than the positive-ion detection mode (**ESI⁺**) at acidic pH: in negative-ion detection mode, the mass spectra displayed contributions of only the protein with its bound metallic ion (1). We report here an extension of these studies to several proteins containing iron-sulfur clusters(2).
High-potential [4Fe-4S] ferredoxin (HiPIP) extracted from *Chrom. vinosum* (Cv. Fd) was analysed in **ESI⁺** and in **ESI⁻**, as shown in **Fig.1a** and **1b**, respectively. The relatively low charge state observed in **ESI⁻**, indicates that the deprotonation sites react less easily in this slightly basic solution than the protonation sites under the conditions of **ESI⁺**. The measured masses are in good agreement with the calculated mass of the holoprotein (M=9252.6)
Low potential 2[4Fe-4S] ferredoxins extracted from *Clostr. pasteurianum* (Cp. Fd), *Clostr. acidurici* (Cau.Fd), *Chrom. vinosum* (Cv.Fd), did not yield satisfactory results in **ESI⁺**, but in **ESI⁻** no evidence for degradation of these unstable proteins was found and the mass mesured for each protein fits closely with the calculated mass of the holoforms (M=6194.5, M=6234.5 and M=9750.4, respectively).
[2Fe-2S] spinach ferredoxins: two isoforms (Sp.Fd-I and Sp.Fd-II) have been evidenced in spinach chloroplasts. In **ESI⁺**, both isoforms give a coherent series from 6 to 11 charges which could correspond to the protonation of all basic residues plus the four glutamines; these data suggest a complete unfolding of the polypeptide chain with the loss of the iron-sulfur cluster. The reconstrusted spectra in insets yielded molecular masses which are in good agreement with the calculated values (M=10,482.5 and M=10,334.4, respectively) for the apoproteins. In **ESI⁻**, the mass spectra of the two isoforms are different and display a serie from 5 to 12 charges for Sp.Fd-I and only two charge states for Sp.Fd-II which are both well below the number of potential negative sites (23 and 22, respectively): this can be explained by the proteins remaining folded and limiting acces of the solvent to the deprotonation sites. Reconstructed mass spectra indicate molecular mass in good agreement with those calculated (M=10,654.3 and M=10,506.2, respectively) for the holoforms .

PROTEOLYTIC PEPTIDES OF RHODOPSIN ANALYZED BY MALDI-TOF

David Barnidge, Ed Dratz, and Jan Sunner

Dept. of Microbiology
Montana State University, Bozeman, MT 59717
email: UCHJS@EARTH.OSCS.MONTANA.EDU

Integral membrane proteins play a vital role in a variety of cell functions. Their part in signal transduction has prompted a great deal of research into the mechanisms involved in transporting a signal across a membrane and in promoting cell response to stimuli such as chemotaxis. In order to study these events, techniques including affinity labelling, fluorescent probes, and peptide mapping have been used.

The use of mass spectrometry to identify proteolytic peptides from integral membrane proteins modified by biological techniques has been limited due to the hydrophobicity of the fragments. Digestion of an integral membrane protein followed by analysis of the mixture using MALDI-TOF does not produce an adequate map of the protein due to aggregation of the peptides and the subsequent loss of ionization. The use of LC-ESI with standard water:acetonitrile gradients will not elute hydrophobic fragments.

In order to utilize mass spectrometry as a tool to analyze a mixture of proteolytic peptides we have been using a technique that separates a mixture of hydrophobic peptides prior to mass analysis. The separation method was developed by Tomich et. al. *[1]* and involves RP-HPLC using a C_4 column and mobile phase containing octyl-β-glucoside (OG). The digest is made 20mM (2 x CMC) in SDS and 2% formic acid prior to injection to reduce aggregation and loss of peptides to the column.Samples are fractionated, concentrated, and analyzed by MALDI-TOF using ACHCA matrix.

The objective of this method is to have a mass analysis technique that will allow the identification of modified sites on an integral membrane protein including post-translational modifications. It will also be used to identify structural information such as transmembrane fragments and extramembrane loops. We present here identification of transmembrane segments and the heterogeneously glycosylated N-terminus of the G protein-coupled receptor rhodopsin.

Table 1 is a list of tryptic peptide fragments from rhodopsin. The model by Dratz and Hargrave [2] list each fragment as having at least one transmembrane sequence. The peptides with an asterisk * have been identified using detergent modified RP-HPLC and MALDI-TOF.

Figure 2 is a chromatogram from a tryptic digest of affinity purified rhodopsin in 0.1% OG. The peptides represented are listed next to the retention times.

Figure 3 is a MALDI-TOF spectra from the peak at 48.59 min. It is from the #1 transmembrane peptide. The peak at 5462.46Da is the #1 fragment plus an additional lysine due to incomplete digestion. Late eluting hydrophobic peptides having the mass of transmembrane peptide #5 were found however due to the closeness in mass to fragment #1 the true identity of the fragment was not conclusive. Work with absorbance spectra of these fragments is ongoing. Spectra

containing the mass of fragment #2 plus a formyl group were found but the parent ion was not. This may be fragment #2 due to the formic acid used in this procedure.

Analyses of Hydrophobic Peptides and Proteins using ESI- and APCI-MS

Bernhard C. Pellascio, Urs P. Schlunegger, Institute of Organic Chemistry, University of Berne, Berne, Switzerland

Johann Schaller, Donald Kaesermann, Institute of Biochemistry, University of Berne, Berne, Switzerland

INTRODUCTION: Over the past few years electrospray (ESI) and atmospheric pressure chemical ionization (APCI) have been playing an increasing role in the characterization of biomolecules. Up to day analyses have been performed mainly with biopolymers soluble in aqueous solutions; therefore data of hydrophobic peptides and proteins are seldomly reported in the literature [lit. 1].

The hydrophobic membrane protein bacteriorhodopsin (BR) forming the proton pump in the lipid bilayer of the bacterium *Halobacterium halobium* consists of the chromophore retinal and the protein bacterioopsin (BO). We present here mass spectrometric data of BO and its fragments. BO was cleaved with protease V8 from *Staphylococcus aureus* into two fragments, V-1A/B (Glu-1 to Glu-161/166) and V-2A/B (Glu-161/166 to Glu-232). Cyanogen bromide cleavage of V-2 at Met-209 produces two fragments ψ, ψA (Ser-162 to Hse-209) and ψB (Val-167 to Hse-209) and a fragment ω (Val-210 to Glu-232).

MATERIALS AND METHODS: The spectra were acquired on a VG Platform II (Fisons/VG, Manchester UK). The mass spectrometer was scanned from m/z 700 to 2500 in 10 s. For one analysis ten scans were used. The samples were dissolved either in the carrier solvents or in hexafluoroisopropanol. The flow rate was 10 µl/min. Typical used sample quantities were 100-200 pmol per analysis. The separations were carried out on a HPLC system from Applied Biosystems with a 759A absorbance detector, a 140B solvent delivery system and a phenyl aquapore column. After the isolation of BR the chromophore retinal was removed by bleaching to leave the protein BO. BO was cleaved with protease V8 and cyanogen bromide to produce the fragments V-1, V-2, ψA/B and ω (according lit. 2).

RESULTS: Influence of carrier solvents: The samples BO, V-2A/B, ψ and ω were dissolved in hexafluoroisopropanol and subjected to ESI-MS and APCI-MS with three different carrier solvents: **1. neat formic acid; 2. chloroform:methanol:water (2:5:2, v/v/v) with 2% HOAc; and 3. acetonitrile:water (1:1, v/v).** The carrier solvent chloroform:methanol:water gave excellent results for V-2A/B whereas neat formic acid was best for BO. With the carrier solvent usually used in ESI-MS, acetonitrile:water (1:1, v/v) no good spectra could be obtained. FIG. 1 and FIG. 2 show the maximum entropy processed spectra and in the inset the transformed

mass (calculated mass: V-2A 7147.6 Da; V-2B 7747.3 Da; BO 26785 Da).

Similar experiments were also carried out with APCI-MS but no good results could be obtained. It seems that APCI-MS is not the appropriate method for hydrophobic peptides and proteins.

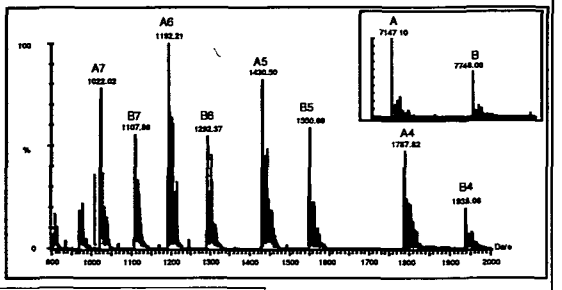

FIG. 1 Electrospray mass spectrum of the fragments V2-A/B (A calculated mass: 7147.6 Da; B calculated mass: 7747.3 Da) with chloroform:methanol:-water (2:5:2, v/v/v) containing 2% HOAc as carrier solvent. The transformed spectrum is shown in the inset.

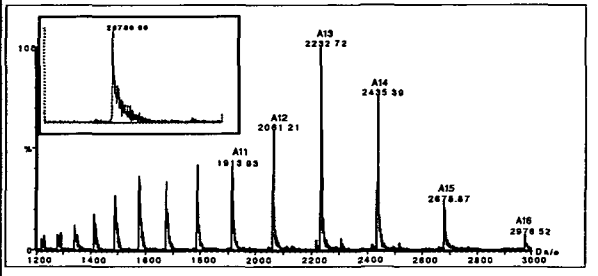

FIG. 2 Electrospray mass spectrum of bacterioopsin with neat formic acid as carrier solvent (calculated mass: 26785 Da). The transformed spectrum is shown in the inset.

Influence of source temperature: All fragments of BR were measured under the same conditions as described above except the source temperature: **a) 60°C; b) 100°C**. For all fragments the results were better at a source temperature of 60°C (spectra not shown).

CONCLUSIONS: Formic acid is well known to be an excellent solvent for hydrophobic peptides and proteins. We were able to show that formic acid is as well a very powerful carrier solvent for ESI-MS. However, care must be taken not to allow samples to remain in neat formic acid. The chloroform:methanol:water mixture is especially useful for smaller fragments and peptides. The solvents usually used in ESI are useless for hydrophobic peptides and proteins because of their insolubility in conventional solvents without detergents. The results of the APCI-MS experiments show that this method is not yet fully developed to analyse hydrophobic peptides and proteins. It will be an aim in the future to continue the development of the APCI-MS technique. A source temperature of more than 60°C is disadvantageous with a substantial loss of sensitivity.

HEREGULIN / EPIDERMAL GROWTH FACTOR CHIMERAS: A STRUCTURAL STUDY

K.J. Rosnack, J.G. Stroh, B.C. Guarino, D.H. Singleton, E.G. Barbacci, J.D. Moyer, G.C. Andrews
Pfizer Inc, Central Research, Eastern Point Road, Groton, CT 06340

The heregulins (HRGs) are a family of proteins that stimulate the tyrosine phosphorylation of p185^{erbB2} and have a region of high homology to EGF. Although HRG was initially proposed to act as a ligand for p185^{erbB2}, subsequent studies revealed that binding of HRG did not correlate with p185^{erbB2} expression. Further studies have demonstrated that *erb*B4, *erb*B3, and their heterodimers are receptors for HRG. These receptors and EGFR have substantial homology both in the intracellular and extracellular domains and therefore may bind ligands that also share common structural features.

Although there are multiple receptors for the HRGs, both EGF and HRG bind to breast cancer cells with complete specificity (EGF does not block HRG binding nor does HRG block EGF binding.). This specificity is obtained despite topological similarity generated by three conserved disulfide bonds in their core domains. A 65 amino acid EGF-like domain of heregulin β1, amino acids 177-241, was shown to be sufficient for high affinity binding. The receptor binding domain of heregulin β and heregulin α have been synthesized, and a series of truncated synthetic HRGs and EGF/HRG chimeric peptides were utilized to determine the essential structural elements of HRG receptor binding.

Mass Spectrometry was used in this project to determine molecular weight for each peptide using direct infusion electrospray ionization (ESI) mass spectrometry (MS). Disulfide bond determination was accomplished for HRG and HRG chimeras using chemical and enzymatic digestion followed by liquid chromatography mass spectrometry (LCMS).

Direct Infusion ESI Mass Spectrometry was used to confirm the molecular weights of each of the synthesized peptides. Disulfide bond analysis was accomplished using chemical and enzymatic digestion followed by LCMS analysis. Two peaks of interest were observed in the LCUV trace from a Heregulin α (177-227) tryptic digest. The observed MW (1679 1 Da) for Peak #1 corresponds to the tryptic fragment shown in Figure 1C (right) while the observed MW (2131.3 Da.) for Peak #2 corresponds to the tryptic fragment shown in Figure 1C (left). From the information contained in this experiment, one disulfide bond was confirmed. A Glu-C digest of the tryptic digested material was necessary to confirm the remaining disulfide bonds.

The LCUV trace from the Glu-C digest of the previous sample gave one peak of interest. The observed molecular weight (1349.6 Da.) corresponds to the fragment shown in Figure 1D (right). Results from this experiment confirmed a second disulfide bond. The third disulfide bond shown in Figure 1D (left) was not observed but can be inferred.

Other Heregulin chimeras were analyzed in the same fashion. Complete disulfide bonding patterns could not be determined for EGF and EGF chimeras by this method. These compounds were then subjected to the binding and phosphorylation testing.

For both HRGα and HRGβ, a 50 amino acid region (177-226) was fully active both for binding to cellular receptors and for stimulation of p185 phosphorylation. Further truncation by a single amino acid or two amino acids reduced both the receptor binding and phosphorylation by > 100-fold. Thus the critical binding and activation are contained within a 50-amino acid portion of the heregulins beginning at amino acid 177 and ending with amino acid 226.

Alignment of the core regions of HRGα with HRGβ and EGF with HRGβ shows the extensive homology within this family. On the basis of the results with the truncated HRG's, we examined chimeras of EGF 1-48 and the core 50-amino acid region of HRGβ to determine the essential structural elements of HRG receptor binding and the basis for receptor binding selectivity.

Substitution of any single cysteine bound region of EGF or the EGF C-terminus into HRG produced a chimera that retained full affinity for the HRG receptor and the ability to stimulate the p185 phosphorylation in cell. It had no affinity for the EGF receptor. All the HRG chimeras were potently active. Even the region 197-209 of HRG, postulated to be involved in receptor binding, can be replaced with EGF 21-30 without loss of binding affinity. Results indicate that neither the regions between cysteine residues nor the C-terminus contribute to the specificity of binding for EGFR vs. HRGR.

Substitution of the HRG 177-181 (SHLVK) for the N-terminus of EGF produced a chimera which bound both receptors with high affinity. Specific binding of both EGF and HRG could be completely blocked by this chimera. This chimera was as active as EGF in the EGFR autophosphorylation and was highly active in the stimulation of p185 phosphorylation. The EGF chimera with the HRG 191-195 had moderate affinity for both receptors.

Substitution of individual amino acids had little effect on the affinity for the HRG receptor. However, removal of amino acids 177 & 178 reduced affinity for the HRG receptor by >10-fold, without a corresponding effect on affinity for the EGF receptor. This supports the conclusion that amino acids 177-181 are of specific importance for binding to the HRG receptor. While the region comprising residues 177-181 of HRG are important elements for binding specificity, additional regions are also necessary for high affinity binding -- most notably, loss of the C-terminal residues at 225-226 ablated activity.

Mass Spectrometry confirmed the molecular weights of all synthesized products. Sequential digestion followed by LCMS analysis confirmed the disulfide bond pattern of the heregulins and heregulin chimeras. The complete disulfide bond analysis of Epidermal Growth Factor and EGF chimeras was not possible. Substitutions of EGF sequences for HRG regions bound by conserved cysteine residues, or substitution of the EGF C-terminus for that of HRG, had no effect on binding affinity for the HRG receptor. Several amino acids in EGF shown to be important in EGFR binding such as Tyr13, Tyr37, and Arg41, are either conserved or replaced with conservative substitutions (Tyr to Phe) in the HRG's Results suggest that the conserved residues in the intracysteine regions of EGF and HRG together with the unique HRG N-terminus are essential elements of HRG binding. Results suggest that the specificity for the HRG receptor is entirely generated by the HRG N-terminus. Findings also suggest that it may be possible to design compounds that combine activity for the two receptors at various ratios.

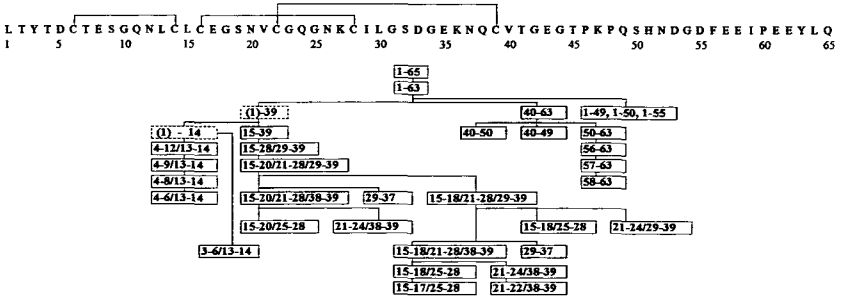
LC-MS PEPTIDE MAP OF HIRUDIN BY USING THE UNSPECIFIC PROTEASE THERMOLYSIN

Harald A. Zilg * and Birgit Schultz **
*Research laboratories of Behringwerke AG, D- 35001Marburg, Germany
**FH Ostfriesland, Dept. of Biotechnology,D- 26723 Emden, Germany

Peptide mapping of a recombinant therapeutic protein generally is performed using highly specific proteases. The ruggedness of the method justifies its use for quality control, as any structural deviation is most probably seen in the peptide map, e.g. by appearance of a new peptide peak.However limitations sometimes are: a) the peptides obtained are not small enough to reveal structural deviations, b) the cleavage sites are not domains of the protein where they are mostly needed, e.g. when analysing disulfide pairing in native protein digest.

Hirudin, the highly potent thrombin inhibitor from the leech HIRUDO MEDICINALIS *is also* being expressed in yeast. Part of our aim to confirm the structure of a variant of hirudin was devoted to cystine bridge positions. These should link the cysteines in amino acid position 6-14, 16-28 and 22-39 in the core domain of the 65 amino acid peptide. The only protease found to cleave the hirudin amino acid chain between C(14) and C(16) was thermolysin with its broad specificity to cleave at the N-terminus of the following amino acids in the order of decreasing activity: L > F > I, V, M, A > Y, G, T, S. Some cystine bridge containing peptides have been described (1).

Complete identification of hirudin peptides obtained by thermolysin digest was possible *using reversed phase HPLC combined with Electrospray MS. The large number of* cleavage sites including some unexpected sites allowed the identification of numerous cystine bridged peptides and to prove correct disulfide pairing. Due to slow and fast cleavage reactions along the amino acid chain a pathway in the formation of individual peptides can be derived from thermolysin digest kinetics followed by LC- MS:



Some of the intermediates were not found as indicated by dotted lines, but were derived from occurrence of others. A number of peptides were identified with the expected cystine bridges. A few peptides exhibited even two. It is evident that the correct disulfide pairing in hirudin is confirmed by these results.

For a therapeutic protein absence of structural variants with mismatched cystine bridges has to be shown. Thermolysin digest yield is nearly quantitative for cystine bridge C(6)- C(14) containing peptides. However peptides derived from the domain of the molecule containing the intertwined two other cystine bridges C(16)- C(28) and C(22)- C(39) are either not formed in considerable amount by the digestion or the digestion did produce peptides too small to be seen in Electrospray- MS. The identification cut- off is near 300 amu which means that penta- to hexapeptides with two charges are not detectable by and large. Thus digest yield is no promising approach.

We then focussed our attention on the positive identification of structural variants with mismatched disulfide pairing. This was based on the observation that rapid reoxidation of completely reduced hirudin is leading to structure variants with higher retention than hirudin in RP- HPLC, but identical molecular mass by direct Electrospray- MS. Similar behaviour was described for a hirudin core peptide, which indeed exhibited structural properties of a mismatched variant (2).

When the thermolysin peptide map is performed on the higher retention fraction of hirudin according to the procedure for hirudin itself, we observed several unusual peptides in the chromatogram. To identify these peptides we used a list of all thermolysin peptides derived from the 14 structural variants of hirudin with mismatched disulfide pairing (F1- F14). Some of the peptides found definetely are not expected with hirudin. For example at 30.77 min retention an m/z signal of 824 originates most probably from a peptide with C(16)- C(22) or C(22)- C(28) disulfide pairing:

Peptide analysis of a mismatched hirudin variant - chromatogram segment 27- 33 min

RT (min)	Mass (theory)	variant	peptide	m/z found	Intensity	m/z found	Intensity
27,667	639,30	F2, F11, F14	15-18<->21-22	639,00	127500		
		F1, F5, F12	21-22<->25-28

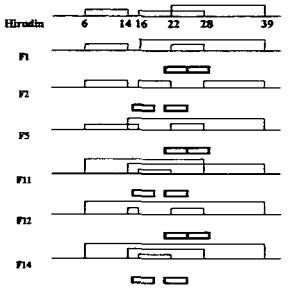
	1625,70	Hir, F4, F9	18-22<->30-40	813,50	18750		
29,060	1099,50	Hir, F1, F2	04-08<->10-14	551,00	15000	1100,50	11667
30,765	644,00	Hir, F1- F14	50-55	644,00	16667		
	1287,50	F9, F10, F11	13-18<>21-24<>38-39				
	819,40	Hir, F1- F14	30-37	-	-		
	824,40	**F1, F5, F12**	**21-24<->25-28**	412,50	3571	824,50	17857
		F2, F11, F14	**15-18<->21-24**				
32,351	1473,60	F9, F10, F11	13-17<>21-22<>34-39	737,50	31667		



However a straigthforward assignment of these peptides to one specific mismatched variant was not possible at this stage of the analysis. Probably the search for simultaneous appearance of specific peptides shall lead to the final interpretation. An appropriate software could possibly ease the evaluation.

In our view the question raised can be answered at the level reached, since high retention peptides can easily be monitored by standard RP- HPLC once their identification as mismatched variants is achieved.

Advances in Peptide Mapping by MALDI-TOF-MS

O. Vorm, P. Roepstorff and M. Mann
European Molecular Biology Laboratory

Mass Spectrometric peptide mapping is often a necessary step in protein characterization. It follows the molecular weight determination of the intact protein (where possible) and precedes sequencing (where needed). Matrix assisted laser desorption ionization (MALDI) time-of-flight (TOF) mass spectrometry holds great promise for peptide mapping because it is fast, sensitive, and relatively tolerant against many buffers. Furthermore, spectra of peptide mixtures are simple to interpret since each component is present only as the singly charged species. Disadvantages of peptide mapping by MALDI TOF MS have been its moderate mass accuracy and resolution. More seriously, we and others have frequently noticed the absence of peptides that were expected to be seen in the MALDI spectrum when compared to HPLC and/or LC-MS data. Here we show how all three drawbacks are alleviated by some recent improvements in sample preparation techniques for MALDI MS.

We obtain much better resolution, mass accuracy, sensitivity, and a more qualitative representation of peptide components in MALDI TOF than previously possible (ref 1-3). Reflector TOF data enable routine peptide mixture analysis with better than 0.01% mass accuracy without the use of internal calibration standards and isotope resolution up to 2 kDa and beyond. The total peptide amounts needed for mapping are around 10 fmole per component making the method competitive with LC-MS and in any case attractive as a prescreening technique. With the new methods we observe significantly less variability between peptide maps when analyzed under different experimental conditions as well as a higher degree of consistency between MALDI spectra and data obtained by other forms of analysis such as LC-ES-MS and HPLC.

These results have enabled us to quickly pinpoint sites of suspected sequence inaccuracy without the use of LC/MS. Apart from greatly facilitating the mapping of known sequences, the increased mass accuracy also increases the specificity of database searches of previously unidentified proteins by a large factor. In many cases the new techniques lead to certain rather than probable assignment of a protein on the basis of a peptide map alone. Examples show a large sequence coverage and unambiguous protein identification achieved from isotope resolved, high mass accuracy peptide maps of small amounts of peptides obtained from 2 dimensional protein gels.

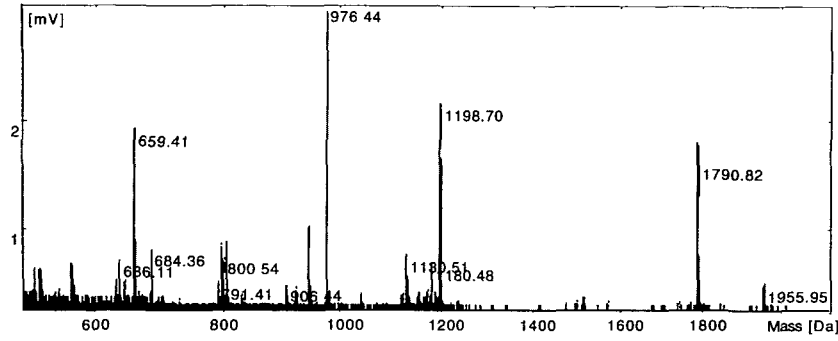

Fig. 1 MALDI reflector TOF mass spectrum of peptide map obtained by tryptic digestion of a protein isolated by SDS-PAGE. The measured peptide masses were used for database search, which lead to unambiguous identification of actin.

USE OF ESMS FOR THE STUDY OF THE MECHANISM OF RESISTANCE TO β-LACTAMS

O. Burlet-Schiltz, I. Saves, J.-P. Samama, J.-M. Masson, and J.-C. Promé
Laboratoire de Pharmacologie et Toxicologie Fondamentales, C.N.R.S., 205 Route de Narbonne, 31077 Toulouse Cedex, FRANCE

Resistance to β-lactam antibiotics is becoming an increasingly alarming problem for the treatment of bacterial infections. Resistant strains generally appear a few years after the extensive use of a new β-lactam, such as a penicillin or a cephalosporin. The major cause of resistance of Gram-negative bacteria is the production of enzymes, β-lactamases, which hydrolyze the β-lactam ring of these antibiotics, and thus inhibit their action. The class A β-lactamase TEM-1 and mutants derived from TEM-1 represent the most frequently encountered β-lactamases in clinical isolates.

The emergence of resistance is usually due to point mutations at one or a few positions on TEM-1 sequence. Thus, the mutation of a glycine into a serine at position 238 (G238S) is responsible for cefotaxime resistance, a third-generation cephalosporin. It has also been shown that this mutation decreases the penicillinase capacity of TEM-1. At the molecular lever, however, the effect of the G238S mutation remains unclear. We have developed an approach, based on electrospray mass spectrometry (ESMS), to access elementary rate constants of the catalytic mechanism. Comparison of these constants for the hydrolysis of penicillins and cefotaxime by TEM-1 and the G238S mutant provides valuable information to understand the global effect of the mutation on the resistance to cefotaxime.

Enzymes were produced by *Escherichia coli* strain XaC-1 transformed by the plasmids pAra 15 and T28C2+ for TEM-1 and the G238S mutant, respectively. They were then extracted, concentrated, desalted, and purified. Michaelis-Menten constants, k_{cat} and K_m, were determined by UV measurements. ESMS analyses were performed with a TRIO 2000 quadrupole mass spectrometer equipped with an electrospray source. Enzymatic reactions were quenched by acidification to pH 2.5 before analysis by ESMS.

The general mechanism for the hydrolysis of penicillins or cephalosporins by class A β-lactamases may be decomposed into three elementary reactions. After formation of a reversible non covalent complex, conversion of this complex into a covalent acyl-enzyme intermediate (acylation), and then hydrolysis of the acyl-enzyme to liberate the free enzyme and the hydrolyzed product (deacylation). The deacylation rate constant, k_3, can be determined knowing the concentration of acyl-enzyme at the steady-state of the reaction (ESMS and UV) and the rate of product formation (UV). The acylation rate constant, k_2, can then be calculated knowing the catalytic rate constant, k_{cat}.

ESMS analyses of the hydrolysis of penicillins by TEM-1 (oxacillin and cloxacillin) and the G238S mutant (oxacillin and penicillin G) show that the acyl-enzyme intermediate is the only enzyme species in solution during the steady-state. The determination of acylation and deacylation rate constants

for these reactions indicates that the rate-determining reaction is deacylation (Table). ESMS analyses of cefotaxime hydrolysis by TEM-1 and the G238S mutant show that the free enzyme is the only enzyme species observed during the steady-state. However, the product of the reaction is formed, as it is observed by ESMS (Figure). Thus, hydrolysis occurs and acylation is rate-determining for cefotaxime hydrolysis. These results, combined to the catalytic properties and to computer modeling of TEM-1 and the G238S mutant, allow to understand the effect of this mutation at the molecular level. Modeling of the G238S mutant suggests an enlargement of the active site and a misplacement of the deacylating residue (E166). These structural hypotheses are in agreement with a better catalytic efficiency of the G238S mutant toward cefotaxime by facilitating its access to the active site, and with a less efficient deacylation of penicillins due to the misplacement of the E166 residue.

TABLE: ELEMENTARY RATE CONSTANTS FOR TEM-1 AND THE G238S MUTANT

	TEM-1					G238S				
Substrate	T (°C)	K_m (μM)	k_{cat} (s^{-1})	k_2 (s^{-1})	k_3 (s^{-1})	T (°C)	K_m (μM)	k_{cat} (s^{-1})	k_2 (s^{-1})	k_3 (s^{-1})
Penicillin G	-	-	-	-	-	2.5	7	16	>> 16	16
Oxacillin	2.5	25	30	143	38	37	9	0.7	>> 0.7	0.7
Cloxacillin	2.5	30	6	24	8	2.5	-	< 0.1	-	-
Cefotaxime	37	1100	1.8	$k_2 < k_3$		37	180	20	$k_2 < k_3$

Analysis of Bovine Insulin (SBI) and Reduced SBI in a Glucose Film by ^{252}Cf-Plasma Desorption Mass Spectrometry (PDMS)

S. Song, S. Cockrill, R. D. Macfarlane, Department of Chemistry, Texas A&M University, College Station, TX 77843

Glucose films have been developed as a liquid matrix for sample analysis in PDMS.[1] The deposition of sample molecules in a well defined chemical environment results in high sensitivity and efficiency for PDMS detection. Salts, amino acids and peptides have been analyzed in the glucose films. Glucuronic acid as co-matrix provides higher molecular ion yield for peptide samples.

The positive ion spectra of SBI using Nitrocellulose (NC) or glucose/glucuronic acid film give the molecular ion peaks (MH^+, MH_2^{2+}), and B chain and A chain ion peaks. The negative ion spectrum of SBI in NC matrix gives little information, the negative ion spectrum of SBI in glucose/glucuronic acid gives the A chain ion peak with low intensity.

The analysis of reduced SBI was conducted by mixing the sample solution into the matrices (electrosprayed NC, glucose/glucuronic acid film, and glucose/TFA film), or directly depositing the sample solution onto the aluminized Mylar foil. Bovine insulin was reduced by 0.06 M ammonium bicarbonate and 0 08 M dithiothreitol at room temperature for 30 minutes.[2]

The positive molecular ion region for reduced SBI is shown in Figure 1 Using the NC matrix the B chain molecular ion is observed The spectra for the glucose/TFA film and the directly deposit sample show both A chain and B chain molecular ions. The spectrum for the glucose/glucuronic acid film shows high intensity A chain molecular ions, the B chain molecular ion intensities were suppressed by the presence of the A chain molecules. The observation of a B chain molecular ion in the glucose/TFA indicates that the surface activity is affected by the matrix component.

In the negative ion mass spectra, the A chain and B chain ion peaks are observed using the glucose/TFA film. Only the A chain ion peak is present in the spectra for the glucose/glucuronic acid film and the directly deposit sample. No informative ion peaks are observed in the negative ion spectrum for the NC matrix.

The fragment ions from the NC matrix originate from the B chain which has basic residues. It has been proposed that the Arg residues direct the fragmentation process by a charge-remote mechanism.[3] The same positive fragmentation pattern is observed in the glucose/glucuronic acid film. For the reduced bovine insulin, the NC matrix produces only B chain positive fragment ions and no negative fragment ions. When glucose/glucuronic acid is used as the matrix, fragment ion peaks from the A chain are present in both the positive and negative ion mass spectra, although there is no Arg residue in the A chain. The glucose/TFA film produces positive fragment ions from the B chain and negative fragment ions from the A chain. The details on fragment ion type from all those matrices are listed in Figure 2.

In conclusion, glucose films with a co-matrix provide a matrix system capable of producing different molecular ion profiles and fragmentation patterns for reduced SBI sample. The negative fragment ions, which is not observable with the NC matrix, are present in the spectra with glucose matrix for negative fragmentation mechanism study.

MOLECULAR RECOGNITION IN DRUG DISCOVERY

David J Bell and A.West, SmithKline Beecham Pharmaceuticals, Great Burgh, Epsom, Surrey KT18 5XQ, UK.

In addition to the characterisation of both potential therapeutic agents and target proteins, mass spectrometry can be used to study the interactions between such entities. The formation of a covalent inhibitor-enzyme complex can be studied by electrospray ionisation mass spectrometry to yield information relating to rate of formation and/or stability of the complex by monitoring the change in molecular mass as a function of time. We have found that certain steps must be taken when using high ratios of inhibitor:enzyme, i.e. 10:1 or greater, as the formation of adducts in the mass spectrometer ion source can give rise to ambiguous data. Prior separation of excess inhibitor by reverse phase HPLC or size exclusion methods will avoid such effects, the latter being essential for the determination of complex stability. Other data that can be readily determined by mass spectrometry is the point of binding by the use of proteolytic digestion of the complex followed analysis of the resulting peptides using mass spectrometic techniques and Edman sequencing. Conformational changes in proteins upon binding can be observed by comparing the rate of change in molecular masses of the complex and the native enzyme as a result of hydrogen/deuterium exchange when dissolved in deuterated buffer solution.

Non-covalent interaction can be characterised by the formation of free inhibitor upon denaturation, i.e. such a complex will give rise to separate protein and inhibitor spectra when analysed by reverse phase HPLC/MS. To ensure that the origin of the inhibitor is from the complex, unbound material were removed by non-denaturing techniques prior to such analyses. Determination of the binding sites is however more difficult but the methodolgies that have been developed based on the protection of the area around the binding sites from modifications. The techniques used included the comparison of the degree and rate of deuterium exchange by monitoring the change in molecular mass using electrospray ionisation. Whilst the deuterium exchange experiments can produce a profile that will differentiate complexes, chemical modification of the complex by the use of selective reagents produced information relating to the sites of interaction as the amino acid residues protected from derivatisation were identified.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

ESI-MS/MS for the Identification of Modifications of Intact Proteins

M. Busman, M.D. Wilcox, W.E. McIntire, J. Millsap*, H.E. Hamm*, J.D. Hildebrandt, and K.L. Schey, Dept. of Pharmacology, Medical University of South Carolina, Charleston, SC 29425, *Dept. of Physiology and Biophysics, University of Illinois, Chicago, Chicago IL

Posttranslational modifications play important roles in cellular processes including cell signalling and molecular recognition. Biochemical methods for identifying these covalent structures are often laborious. With the introduction of electrospray mass spectrometry, ionization of large proteins is easily achieved. Furthermore, the use of tandem mass spectrometry (MS/MS) provides an opportunity for structural studies on these large ions. Previously, proteins as large as bovine serum albumin have been dissociated by the ESI-MS/MS method[1].

Heterotrimeric GTP-binding proteins play critical roles in signal transduction pathways. The gamma subunits of these proteins have been reported to be isoprenylated by farnesyl group in the case of retinal γ_t (transducin) and geranylgeranylated in the case of brain γ subunits. Based on MALDI mass measurements, predictions of posttranslational modifications of brain γ subunits have been published[2]. In this report we utilize ESI-MS/MS on intact protein ions to identify posttranslational modifications. In addition, a sample preparation method for generating ESI signals for proteins provided in complex matrices including salts, detergents, DTT and glycerol is presented.

Samples were acetone precipitated by adding 9 volumes of ice cold acetone and placing on ice for 20 minutes. After centrifuging for 10 min. at 10,000 rpm, the supernatant was removed and excess acetone blown off. Pellets were resuspended in water/methanol/acetic acid 48/48/4. MS/MS experiments were carried out using an API-III Sciex triple quadrupole instrument.

Figure 1 shows the ESI mass spectrum of bovine transducin. Strong signals are observed for the γ subunit having a molecular weight of 8330. The $[M+8H]^{8+}$ ion at m/z 1042 was selected by Q1 and the product ion spectrum is shown in Figure 2. The most abundant product ion, m/z 1161, can be assigned to loss of the farnesyl group and loss of one charge. In addition, in the low mass range, a series of b ions is observed. These b ions confirm that the N-terminus begins with a proline residue. Finally, a series of multiply charged y ions is observed corresponding to cleavage at proline residues. The facile loss of farnesyl group is also observed in nozzle/skimmer collisions.

Figure 3 shows an ESI-MS/MS spectrum of the $[M+8H]^{8+}$ ion, m/z 968 of the bovine brain γ_2 subunit. As was observed for γ_t, facile loss of the isoprenyl group, geranylgeranyl, is the most prominent product ion observed. The low mass b ions confirm that the N-terminal methionine is cleaved and the resulting glycine is acetylated. Also, cleavage at proline residues is observed in the form of multiply charged y ions.

In summary, acetone precipitation allows proteins presented in complex matrices to be examined by ESI-MS. Significant structural information can be obtained from ESI-MS/MS experiments on intact proteins. More specifically, facile loss of isoprene modifications is observed. In addition, low mass b ions confirm N-terminal sequence and y ions confirm C-terminal sequence.

Mass Spectrometric Analysis of Recombinant Stromelysin and Collagenase

Mark D. Bauer, Yiping Sun, Melanie V. Anastasio and Cathy E. Snider
The Procter and Gamble Company, Miami Valley Laboratories
P.O. Box 538707, Cincinnati, OH 45253-8707

Introduction Stromelysin and collagenase are metalloproteases that are key targets for osteoarthritis therapy. Ionspray mass spectrometry is a powerful analytical technique for the structural characterization of these proteins. Ionspray MS provides high sensitivity (low picomoles), high mass accuracy (0.01%) and high speed (5-10 min. for flow injection analysis and 30-60 min. for on-line LC-MS analysis). In this presentation, the structural characterization of recombinant, truncated human collagenase, stromelysin, $^{13}C/^{15}N$-labeled stromelysin, and biotinylated stromelysin is demonstrated. In addition, the detection of non-covalent stromelysin-metal complexes under non-denaturing conditions is presented.

Experimental Both stromelysin and collagenase were expressed in *E. coli* grown in LB broth containing ampicillin. Protein expression was IPTG induced. p-aminophenyl mercuric acetate was used for protease activation. CNBr digestions were carried out in 0.1N HCl for 2 hours at 37°C in the dark and stopped by the addition of 4 volumes of H_2O. Biotinylation was performed using the NHS-LC-Biotinylation Kit (No. 21430, Pierce). Isotope enriched stromelysin was generated by substituting M9 minimal salts media composed of $^{13}C/^{15}N$ labeled components in place of LB broth. All ionspray MS analyses were carried out on a PE-Sciex API-III LC/MS/MS triple quadrupole instrument (PE-Sciex, Thornhill, Canada). On-line microbore LC-MS analysis was carried out on a Waters 600-MS system at a flow rate of 0.8 ml/min in the gradient mode. A pre-injector split ratio of 9:1 was established by splitting one side to a balance column (Waters Delta Pak C18, 3.9x150 mm) and splitting the other side to a 1x150 mm C4 microbore column (Vydac, 300 Å, 5 µ) with an in-line Rheodyne injector (model 7125). For the detection of non-covalent stromelysin-metal complexes, the delivery solvent was neat water at 5 µl/min. Sample solutions, which were passed through a 10,000 MW cut off microconcentrator, were introduced using a Rheodyne loop injector (model 7125).

Results and Discussion On-line microbore LC-MS was used to accurately measure the molecular weights for both recombinant, truncated human stromelysin (MW=19396.6) and recombinant, truncated human collagenase (MW=18992.8) to within 0.01%. Although collagenase gave a single peak by HPLC (RT = 19.6 min), it was found to be a mixture of intact material and two N-terminal truncated forms involving the loss of either the first residue or the first and second residues (Figure 1). CNBr mapping, along with on-line microbore LC-MS, confirmed the native structures of both stromelysin and collagenase. On-line microbore LC-MS analysis confirmed that biotinylation of stromelysin was successful. Furthermore, from one to five biotin molecules were added to the native protein (Figure 2). The degree of $^{13}C/^{15}N$ incorporation into stromelysin was measured to be 98% (Figure 3). That is, the mass of native stromelysin increased by 1087 Da out of a possible 1110 Da mass unit shift if all of the ^{12}C and ^{14}N atoms were replaced by their ^{13}C and ^{15}N counterparts. Figure 4 is the mass spectrum for stromelysin complexed with 2 Zn and 2 Ca atoms (Measured MW=19597.7). The binding of two zinc atoms to stromelysin is consistent with NMR data (1). There is, however, still some debate as to whether stromelysin (or other metalloproteases) binds one or two calcium atoms (2,3). In addition to the non-covalent complex, an autolytic fragment corresponding to residues 1-80 (MW=9250.5) was observed. This fragment was generated during the filtration step where stromelysin spent several minutes in conditions ideal for autolytic processes.

Characterization of Recombinant NMDA Receptor Regions with ESIMS

Klaus Eckart, Andreas K. E. Koepke, and Joachim Spiess; Department of Molecular Neuroendocrinology, Max Planck Institute for Experimental Medicine, Hermann-Rein- Str. 3, D-37075 Goettingen;

INTRODUCTION

NMDA receptors (NR) are involved in diseases such as epilepsia and scizophrenia and may also play an important role in memory and learning. For a functional understanding the three-dimensional structure including the transmembrane localization is of great interest. These questions were approached by using regiospecific antibodies directed against different domains of various NMDA receptor subunits (1). These receptor regions were produced using an *E. coli* overexpression system. All receptor regions carry an N-terminal leader sequence. This includes a His_6 sequence used for affinity purification on a Ni^{2+}-chelate column and an enterokinase cleavage site. The A-regions are expected to represent the N-terminus of the receptor subunit, whereas the location of the D-region is discussed controversially (2). These fusion proteins are analyzed with electrospray ionization mass spectrometry (ESIMS).

METHODS

Overexpression and purification of the proteins were described recently (1). The purity of the proteins was initially assessed by SDS polyacrylamide gel electrophoresis. In cases of low expression rates the Ni^{2+}-chelate column purification was repeated one time. Dialyzed proteins were completely desalted by 5 successive water washes on microcon 10 (amicon) ultrafiltration devices. Electrospray ionization mass spectra were recorded on a Fisons VG AutoSpec-T mass spectrometer equipped with the Fisons electrospray interface. Measurements were carried out using the following parameters: spray chamber temperature: 60°C, needle voltage: 8000 V, counter electrode voltage: 5000 V, accelerating voltage/skimmer voltage: 4000 V, bath gas: 300 l/h nitrogen. The sampling cone voltage and ring electrode voltage were adjusted according to the best conditions of each sample. Samples were continuously infused with 1 µL/min from an infusion syringe pump (Harvard model 22). The D-region proteins were dissolved in a mixture of 49.5% water, 49.5% methanol and 1% acetic acid, whereas the A-region proteins were measured and desalted in a mixture of 47.5% water, 47.5% methanol and 5% acetic acid. ESI mass spectra were recorded with an exponential magnet down scan from m/z 6000 to m/z 600 using a scan rate of 5 seconds/decade. Mass spectra were calibrated with 0.1 mg/ml myoglobin or a 1 mg/ml polypropylen glycol 2000 solution The instrument was operated with a fully opened collector slit. Data acquisition and analysis including the maximum entropy deconvolution were performed with the OPUS data system.

RESULTS

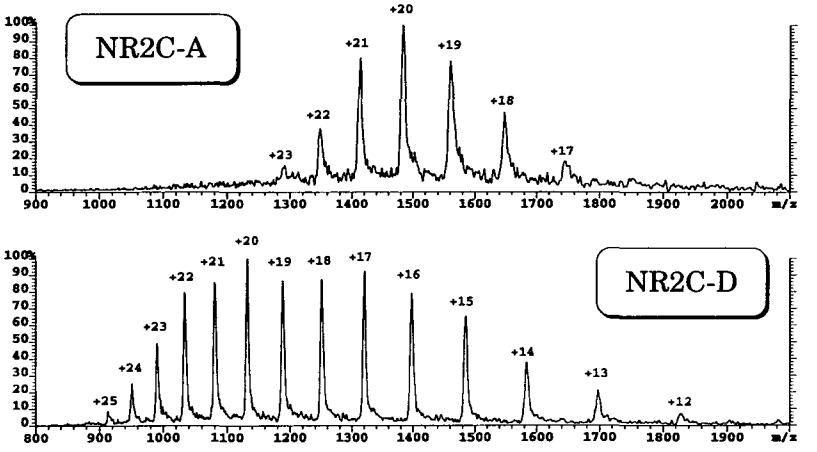
The purity of the overexpressed proteins assessed by SDS polyacrylamide gel electrophoresis was usually better than 80%. Nevertheless further purification for ESIMS using ultrafiltration on microcon devices was necessary to remove the excess of urea, which gave rise to extensive clustering and suppression of the protein ions.

Table 1: NR protein regions subjected to ES mass spectrometry

Protein	Subunit	Region	MW measured	MW calculated	Difference
NR1a-D	1a	D	20,290 Da	20,288 Da	+0.10 ‰
NR2A-A	2A	A	31,039 Da	31,079 Da	-1.28 ‰
NR2C-A	2C	A	29,648 Da	29,594 Da	+1.83 ‰
NR2C-D	2C	D	23,752 Da	23,746 Da	+0.25 ‰

The molecular masses for both D-region proteins determined by maximum entropy charge deconvolution (Tab. 1) showed the typical experimental errors. In contrast to this the molecular masses for both A-region proteins (Fig. 1) deviate significantly from the calculated values. The molecular masses of the overexpressed proteins were calculated on the basis of the DNA sequence of the plasmid used for overexpression. The mass differences are therefore most likely to be the result of posttranslational processing in the *E. coli* overexpression system.

Figure 1: Electrospray Ionization Mass Spectra of the NMDA Receptor Regions NR2C-A and NR2C-D



Both A-region proteins were insoluble in a methanol water mixture containing 1% acetic acid. Therefore, the handling of these proteins had to be carried out in a methanol water mixture containing 5% acetic acid after the proteins were predissolved in pure acetic acid. The hydrophylicity analysis reveals a relatively high degree of hydrophobicity of these proteins. This property is also reflected in the ESI mass spectra (Fig. 1). Both A-region proteins exhibit a larger ratio of molecular mass per proton attached to the proteins compared to the D-region proteins. Furthermore, the number of different charge states is relatively small. Both effects may be interpreted as less unfolding induced by solvent and pH of the A-region proteins compared to the D-region proteins.

It must be pointed out that the proteins were purified by a simple and straightforward one-step procedure. The essential step is the affinity purification of the proteins using the specific binding of the His_6 sequence to Ni^{2+} ions. The incomplete removal of urea from the 8M urea containing elution buffer by dialysis presented some difficulty to ESIMS. Desalting of the proteins on microcon ultrafiltration devices provided salt-free proteins which produced much more abundant and less broadened signals in ESIMS.

Enhanced Nucliophilicity of N-terminal Proline. Zhonghua Yu[1,2], Charles Craik[1], Patrick Jones[2], Alma L. Burlingame[1], Dept. of Pharmaceutical Chemistry, UCSF, San Francisco, CA 94143, and [2]Dept. of Chemistry, Univ. of the Pacific, Stockton, CA 95211

Proteolytic activity is high in living organisms and the activities of the many proteases must be balanced to maintain normal physiological conditions of homeostasis. Strategies to stop the maturation of the HIV virus include efforts to block the action of the HIV protease, a homodimeric aspartate protease, with a 99 amino acid monomer.

Various peptide based inhibitors and nonpeptide inhibitors of HIV protease have been considered. A non-selective inhibitor of aspartate protease, EPNP, was shown to be effective in binding covalently to HIV-1, HIV-2 and SIV proteases (Yu, 1995). Various workers have sought selective inhibitors. Haloperidol was found to be highly complementary to the binding pocket of HIV-1 protease (DesJarlais, 1990) and was shown to have an 8:1 selectivity for HIV-1 protease over cellular proteases (Rose and Craik, 1994). Irreversible inhibitors of the HIV-1 protease based on the haloperidol framework have been developed (see **Figure 1**).

The products of the irreversible inhibition reaction were separated by HPLC. Electrospray mass spectra of the intact HIV-2 and the UCSF-86 modified protease showed an increase in mass of 354 corresponding to the addition of one molecule of the haloperidol. The modified protease molecules were subjected to a digest, separated by HPLC, and the masses of the peptides were determined by mass spectrometry. The peptides including covalently bound modifiers were separated using a C-18 analytical column. The HPLC fractions containing the inhibitor were analyzed by tandem mass spectrometry as shown in **Figure 2.** In this case, the inhibitor was found only to be attached to the proline at the N-terminus. Mass fragment assignments were confirmed by selecting first the ^{35}Cl and then the ^{37}Cl containing parent ion using MS1. High energy CID provided the unambiguous assignments shown in Figure 2. Other CID spectra demonstrated irreversible binding of the haloperidol derivatives to Cys-95 of the HIV-1 protease and to Cys-67 and Pro-1. Pro-1 was not modified as much in HIV-1 protease as in HIV-2 and SIV. Possible mechanisms for the attachment of the haloperidol derivatives suggest the involvement of hydrogen binding between the haloperidol and the N-terminal proline.

In conclusion, we note that (1) Certain haloperidol derivatives prove to be efficient inhibitors of HIV-1, HIV-2 and SIV proteases. X-ray studies show the N-terminal proline to be at the surface. This work demonstrates the access of the modifier to Pro-1 and not to other nucleophilic centers under these conditions. The attachment to Pro-1 may inhibit protease activity by interfering with dimer formation or by altering the tertiary structure. (2) Mass spectrometry is very useful in the development of selective and potent irreversible inhibitors of targeted enzymes by unambiguously identifying the sites of binding. (3) Binding at the N-terminus is not as effective as binding at the cysteines of HIV-1, but suggests another strategy for designing drug molecules to inhibit the protease activity.

Calcium Binding Properties and Sequence of Frog (*Rana tegrinka*) Parvalbumin as Determined by Electrospray Ionization - Mass Spectrometry

Peifeng Hu, Scott D. Buckel, Margaret M. Whitton and Joseph A. Loo Chemistry Department, Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, 2800 Plymouth Road, Ann Arbor, MI 48105

Recently, we applied ESI-MS to the analysis of Ca^{2+} - binding proteins.[1] The Ca^{2+}-binding stoichiometries for calmodulin, parvalbumin, and α-lactalbumin were readily determined to be 4, 2, and 1 respectively, in agreement with results obtained by other methodologies. Of particular interest, the distribution of Ca^{2+} ions among the protein molecules were also revealed. Rabbit and rat parvalbumins were found to bind either zero or two Ca^{2+} ions, suggesting strong cooperativity between the two calcium- binding sites.[1] The ESI-MS analyses of frog parvalbumin (R. tegrinka), however, showed that the protein retains one Ca^{2+} ion and binds to two Ca^{2+} ions only at high Ca^{2+} concentration levels (Figure 1). The sequence of this parvalbumin remained unknown and therefore, should be of interest for future studies on the structure - Ca^{2+} binding relationships for calcium - binding proteins.

The strategy used to determine the protein primary structure was to sequence the tryptic peptides and the protein with a free N-terminus by Edman degradation to obtain the majority of the protein sequence, and to use ESI-MS to screen Asp-N and Protease V8 digests for peptides that provide overlapping sequences (Figure 2). Mass spectrometry was used in three areas: 1) confirming the sequences of peptides by measuring the molecular weight of the peptides; 2) determining the C-terminal residue of peptides left out by Edman chemistry; 3) determining the N-terminal blocking group of the protein. The mass accuracy provided on our sector instrument is generally better than 0.3 amu. Thus, the masses of the peptides provided information that confirms the sequence assignments. For peptides whose C-terminal residue is missing the mass difference between the measured mass and the mass deduced from the known part of the seqence reveals the identity of that residue. The N-terminal blocking group was determined by tandem mass spectrometry. The N-terminal tetrapeptides with/without the blocking group were separated from Asp-N digest. All N-terminal product ions produced by the $(M+H)^+$ ion of the modified peptide are 42 u higher than those produced from the tetrapeptide. The C-terminal product ions from both peptides have the same mass to charge ratios.

The protein contains two cysteines, with one conserved at position 34 and the other located at the C-terminus (residue 110). This justifies its propensity to dimerizes. However, the question whether this structure chracteristics affects the Ca^{2+} affinity and the interacting relationships of the two Ca^{2+} sites awaits to be addressed.

Determination of the Sites of Non-Labile HNE-Adduction to Proteins

Mark S. Bolgar and Simon J. Gaskell

The Michael Barber Centre for Mass Spectrometry, UMIST, Manchester, M60 1QD, U.K.

Structural changes that accompany oxidation of low density lipoprotein (LDL) are believed to be responsible for the increased atherogenicity of oxidized LDL. Among the modifications demonstrated to occur are adduction of protein amino acids by lipid peroxidation products. One of the lipid oxidation products implicated in the modification of LDL is 4-hydroxy-2-nonenal (HNE). In vitro studies have suggested that HNE modifies primarily lysine, histidine and cysteine residues of proteins (1-2). In a previous study we demonstrated that histidine and cysteine residues of a series of short model peptides are readily modified by HNE and that adduction occurs via an addition type reaction (3). In the current study, techniques have been developed for the identification of the number and sites of non-labile HNE-adductions to protein using apomyoglobin as a model system.

Data presented here from the analyses of apomyoglobin provides clear evidence that histidine residues are the major sites of non-labile HNE-adduction to protein. Electrospray MS analysis revealed that incubation of apomyoglobin with 2 mM HNE for 2 hours resulted in the addition of up to 10 HNE adducts, consistent with adduction solely to apomyoglobin's 11 histidine residues. A mass increase of 156 Da per HNE-adduct was observed indicating modification occurred by an addition reaction. Examination of the unfractionated tryptic digest by ESI MS (Fig 1) provided a rapid technique for the localization of the sites of HNE-adduction. The spectrum was extremely complex due to the presence of 19 identifiable components, most of which were represented by more than one charge state. This analysis, which consumed 45 pmol of sample, yielded coverage of ca. 80% of the amino acid residues and revealed a precise correlation between the number of histidine residues contained in the fragment and the maximum number of HNE-adducts. For all of the tryptic fragments the number of HNE-adducts detected equaled the number of histidine residues. We previously reported that peptides which contained an HNE- adducted histidine residue, when subjected to collisional activation, gave an abundant fragment ion at m/z 266 (3). This ion corresponded to the HNE-adducted histidine immonium ion and we demonstrated that scanning a mixture for precursors of m/z 266 was an effective method for selectively detecting peptides which contained an HNE-adducted histidine residue. Analysis of the tryptic digest of HNE-adducted apomyoglobin by scanning for precursor of m/z 266 (Fig 2) resulted in the detection of all of the HNE-modified tryptic fragments observed in the full scan spectrum (Fig 1). In addition to providing conclusive evidence for extensive adduction specifically to histidine residues, the precursor ion spectrum was greatly simplified compared to the full scan mass spectrum due to elimination of the ions from native tryptic fragments.

Protease-catalyzed Incorporation of ^{18}O into Protein Fragments

Martina Schnölzer, Paul Jedrzejewski,* Wolf D. Lehmann*

Dept. of Cell Biology and *Central Spectroscopy Dept.
German Cancer Research Center, Im Neuenheimer Feld 280,
D-69120 HEIDELBERG, Germany

Normally, the preparation of an enzymatic digest containing a set of smaller peptide fragments is the first step in protein sequence analysis. Since proteolytic cleavage proceeds via incorporation of oxygen from water into the newly formed peptides, the reaction can be used to generate a set of carboxyl-^{18}O labeled peptides by using buffers containing $H_2{}^{18}O$. MALDI- and ESI-MS are the most powerful techniques for studying the incorporation of ^{18}O in digest mixtures with or without LC separation of the peptide mixture.

Proteolytic digests in $H_2{}^{18}O$ buffers can be analyzed using FAB-MS, and the C-terminal peptide can in general be recognized as the only nonlabeled peptide fragment in such digests.[1-3] However, the extent of ^{18}O-incorporation catalyzed by endoproteinases has not been studied in detail. We report here on an investigation of endoproteinases commonly used for protein sequence analysis and their incorporation of ^{18}O into peptide fragments. Analytical applications for this approach are shown.

Enzyme-catalyzed protein cleavage in highly enriched $H_2{}^{18}O$ buffers (>95 atom% ^{18}O) using various endoproteinases results in two distinctly different ^{18}O incorporation patterns (Table 1).

Table 1: Incorporation of ^{18}O from highly enriched $H_2{}^{18}O$ buffers into enzymatic protein fragments catalyzed by some endoproteinases frequently used for peptide sequencing.

enzyme		no. of ^{18}O atoms incorporated after 18 h
trypsin		2
Lys-C	(major activity Lys/)	2
Lys-C	(minor activity Arg/)	1
chymotrypsin		1
Glu-C		1
Asp-N		1

Trypsin and the major activity of Lys-C lead to incorporation of 2 atoms of ^{18}O into the newly formed carboxyl group. This indicates that following hydrolytic cleavage this labeled fragment undergoes repeated covalent binding/hydrolysis cycles on the enzyme leading to a complete equilibration of ^{18}O between solvent and both oxygens of the carboxyl group. In contrast chymotrypsin, Glu-C, Asp-N and the minor activity of Lys-C only incorporate 1 atom of ^{18}O under identical experimental conditions, indicating that these enzymes only interact with their substrates in a single covalent binding/hydrolysis step with incorporation of 1 atom of ^{18}O.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

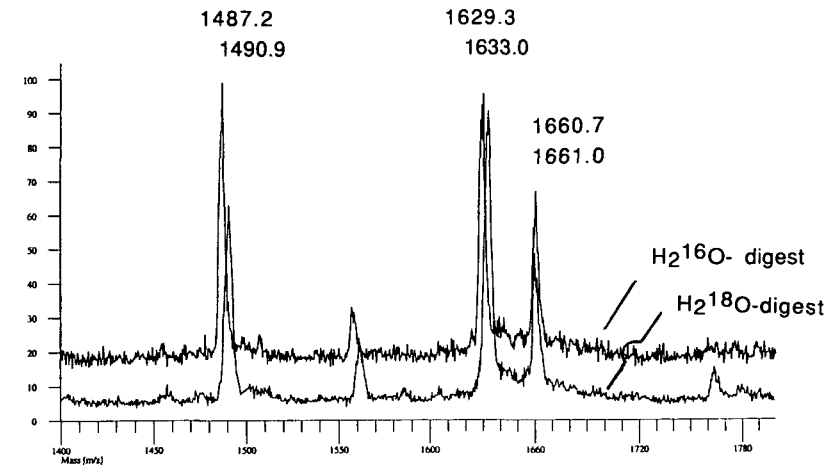

Fig. 1: Partial positive-ion MALDI spectra of a total tryptic digest of ß-lactoglobulin performed in $H_2{}^{16}O$ and $H_2{}^{18}O$, respectively. The C-terminal fragment at m/z 1661 (LSFNP TQLEE QCHI, calculated average m/z for $[M+H]^+$ = 1659.86) is recognized by the absence of a mass shift, whereas all other proteolytic fragments in the $H_2{}^{18}O$-digest show a mass shift of + 4 D. The sample amount was 0.25 pmol.

For determination of the C-terminal peptide, tryptic digests of ß-lactoglobulin were prepared in both $H_2{}^{16}O$ and $H_2{}^{18}O$ buffers and a 0.25 pmol aliquot of each digest was investigated by positive-ion MALDI-MS (Figure 1). The ion signal at m/z 1661, which has the same position for the $H_2{}^{16}O$ and $H_2{}^{18}O$ digests, can be clearly identified as the C-terminal peptide LSFNP TQLEE QCHI. Two other ion signals in Figure 1 show a mass shift of + 4 D, typical for peptide fragments generated by trypsin digestion in $H_2{}^{18}O$ buffer.

The use of $H_2{}^{18}O$ buffers for enzymatic digests has two additional applications in protein sequence analysis: (i) identification of MS/MS fragment ions as either C-terminal or N-terminal fragment ions, since exclusively the C-terminal fragment ions are shifted, and (ii) recognition of the charge state of ions in ESI-MS.

Methodology to Identify Proteins using LC-Ion Trap Mass Spectrometry

John R. Yates, Jimmy Eng, David Schieltz, Andrew Link
Department of Molecular Biotechnology, University of Washington, Seattle, WA 98195

The ability to obtain sequence information from peptides contained in a complicated mixture by MS/MS analysis enables the identification of individual proteins in the mixture. Proteolysis of the entire mixture of proteins creates peptide "identities" for each protein. In addition to the determination of the amino acid sequence of antigens or other peptides, an MS/MS spectrum can be used to search protein databases directly, to determine the protein origin of the peptide. This approach benefits from instrumentation capable of rapidly acquiring large numbers of tandem mass spectra. The LC/Q ion trap was examined for its ability to rapidly acquire tandem mass spectra of LC separated peptides. Results are presented for the identification and characterization of proteins from *E. Coli* and *S. Cerevisiae* by using the Ion trap mass spectrometer to generate MS/MS data and correlation analysis of the ion trap data with sequences in the databases (Eng et. al. JASMS **5**, 976 (1994), Yates et al *Analytical Chemistry* **67**, 1426 (1995)). The peptide sequence represented in the tandem mass spectrum serves as a pointer to the protein sequence in the database. This allows proteins contained in a mixture to identified.

Proteins were isolated from the periplasmic membranes of *E. Coli* and by heparin chromatography of *S. cerevisiae* lysates. Selected fractions were digested with trypsin subjected to LC/MS/MS analysis on the LC/Q. Peptides were separated on a 1 mm x 150 mm C_{18} column with a 50 µL/min flow rate and a 0-65% 20 min linear gradient (water/acetonitrile/TFA; 10/90/0.09). Peptides eluted over 700 scans and MS/MS data were collected, on average, every other scan.

Tandem mass spectra were acquired on a newly designed and built tandem mass spectrometer, LC/Q (Finnigan MAT, San Jose, CA). Ions are trapped in the RF field and selected by creation of broad field with a frequency notch at the frequency corresponding to the m/z value of the ion of interest. This ion is then excited by resonance excitation and the resulting fragmentation products are scanned out of the trap. High resolution mass spectra are obtained by ion selection, and slowing the scan speed over a narrow mass range as previously described by Schwartz et al (*J. Am. Soc. Mass Spectrom.* **2**, 198 (1991)) This process is automated with Ion Trap Control Language (ICTL).

Database searches were conducted with previously described software on a DecStation 3000/900 computer (Eng et. al. *J. Am. Soc. Mass Spectrom.* **5**, 976 (1994), Yates et al *Analytical Chemistry* **67**, 1426 (1995)) using the OWL database.

As part of an effort to identify proteins from *E. coli* and correlate the results from the genome (A. Link, Ph.D. Dissertation, Harvard University, 1994), proteins from the periplasmic space were fractionated on a Mono Q column. Fraction 24 was digested with trypsin and analyzed by using LC/MS/MS on the LC/Q. A representative tandem mass spectrum and the amino acid sequence represented therein is shown in Figure 1. By searching the database with this tandem mass spectrum a sequence of ELNADDVVFSFDR was found to belong to the periplasmic dipeptide transport protein. Proteins enriched from S. cerevisiae cells by using heparin chromatography were also digested and analyzed. A list of peptide sequences and their proteins sources are listed in Table 1.

In both analyses approximately 250-350 tandem mass spectra were acquired over the course of a 35 minute reversed-phase HPLC analysis. Due to limitations in the prototype data acquisition software and data file formats, only a hand full of the spectra were retrieved and submitted for data analysis. A majority of the peptides represented in the spectra were identified. Analyzing the large volume of data that can now be acquired

requires more sophisticated data analysis techniques. By pre-filtering all spectra through the databases spectra matching known sequences can be identified. Those spectra not matching any known sequences can be submitted to de novo computer interpretation software for further analysis.

CROSS LINKING OF GLUTATHIONE-S-TRANSFERASE pi DIMER BY ORGANIC MUSTARDS

Yetrib Hathout and Catherine Fenselau
Structural Biochemistry Center, Dept of Chemistry and Biochemistry,
University of Maryland Baltimore County, Baltimore, MD 21228

Glutathione-S-transferases (GST's) are a family of protein which catalyze the conjugation of reduced glutathione to a large variety of electrophilic compounds. Numerous studies (1) suggest that overexpression of GST's in tumor cells may contributes in resistance to nitrogen mustards (alkylating agents) used in chemotherapy. GST class pi is one of the overexpressed protein in many human tumors (2). Human placenta GST class pi is formed by two identical subunits. Each subunit has a molecular mass of 23.2 Kda and contains four reduced cysteines residues. The objective of the present study is to test the hypothesis that pi class GST can inactivate the therapeutic mustard chlorambucil (CHB) by covalent sequestration.
Human placenta GST pi (43 μM) was treated with CHB (172 μM) in vitro at pH 7. The complex formed was purified by HPLC and characterized by Matrix Assisted Laser Desorption (MALDI) using 2-(4'-hydroxyazobezen)-benzoic acid as a matrix and bovine α-chymotrypsinogen (M.W. 25657 Da) as internal calibrant. To test reproducibility products from 5 different reactions were analyzed. The molecular mass obtained from the complex was 46676 Da while molecular mass obtained from GST control was 23223 Da. This result indicates that one CHB molecule has cross linked two subunits of GST. Based on the difference between molecular mass of the complex obtained and molecular mass of GST dimer without the drug attached (46446 Da) one molecule of CHB bonds each protein dimer. To characterize the chlorambucil alkylation site on GST, the protein was digested with trypsin and the resulting peptides were separated by HPLC. One chlorambucil modified peptide was detected. Close examination of this peptide using MALDI and FAB/MS/MS indicates that the alkylation site occurs on the Cys47 of one subunit and Cys101 of the second subunit. This result can be explained by the fact that these two cysteine residues are proximal in the three-dimensional structure of the dimeric protein (3). This result is consistent with the idea that covalent sequestration of this and other drugs by GST's contributes to the acquired resistance of tumors to chemotherapy.

Applications of MS/MS to the Study of *S*-Linked Conjugates of Isocyanates

Margaret R. Davis* and Thomas A. Baillie*
Department of Medicinal Chemistry, School of Pharmacy, University of Washington, Seattle, WA 98195

Isocyanates (R-N=C=O) are highly reactive, electrophilic compounds which are formed as products of the metabolic activation of certain drugs and other xenobiotics. In general, conjugation of electrophiles with the tripeptide, glutathione (GSH) serves as an important detoxification process. In certain cases, however, conjugation of a xenobiotic with GSH results in the formation of a reactive, and thus potentially toxic, conjugate. The GSH adducts of isocyanates represent one such class in that they are formed reversibly and thus may serve as *in vivo* "carriers" of the isocyanates from which they are derived.

N,N'-bis(2-chloroethyl)-*N*-nitrosourea (BCNU) is a widely-used antineoplastic agent which decomposes under conditions of physiological temperature and pH to alkylating and carbamoylating intermediates (Figure 1). The carbamoylating species, 2-chloroethyl isocyanate (CEIC), is believed to be responsible for the pulmonary toxicity associated with the parent drug through its ability to covalently modify the active site of glutathione reductase (GR). Inactivation of this enzyme, which is crucial to maintaining a normal cellular redox state, produces oxidative stress which, in turn, has been linked to the development of the potentially-fatal pulmonary fibrosis associated with long-term BCNU therapy.

GR is a 118 kDa protein, the sequence of which has not yet been fully elucidated. It is known, however, that two cysteine residues are present in the active site and are directly involved in the catalytic conversion of glutathione disulfide (GSSG) to GSH. It has been proposed that carbamoylation of one of the active site sulfhydryl groups by CEIC is responsible for the inactivation of the enzyme observed following administration of BCNU.[1] Interestingly, the GSH conjugate of CEIC (SCG, Figure 2) has been shown to be an inhibitor of GR, equipotent to BCNU, in isolated rat hepatocytes.[2] In the present studies, oxytocin, a nonapeptide with two cysteine residues, was chosen as a peptide model of the active site of GR to probe the reactivity of BCNU, CEIC and SCG towards nucleophilic centers. Ionspray MS provided molecular weight information on the products of reaction between these carbamoylating agents and oxytocin *in vitro*. These adducts afforded doubly-protonated molecular ions, CID of which provided product ion spectra which were characterized by many doubly- and singly-charged fragment ions which resulted primarily from cleavages of the peptide bonds in the oxytocin-derived backbone. From these spectra, the structures of a number of products formed by the reaction of BCNU, CEIC and SCG with the peptide were characterized, thus providing valuable insight into the potential nature of the covalent interaction of these carbamoylating agents with GR.

Strategies for Analyses of Drug Metabolite Mixtures by CE-MS and CE-MS/MS

Stephen Naylor, Linda M. Benson, and Andy J. Tomlinson, Biomedical Mass Spectrometry Facility and Department of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN 55905, USA

Investigation of the metabolic fate of therapeutic agents ultimately requires structural characterization of unknown metabolites. However, such products are often minor components of a complex biologically derived mixture that may also contain a large excess of parent drug. Good sensitivity and high dynamic range are basic requirements of the analytical methods to be used in these studies. In the present study, we demonstrate a systematic method development of CE separation media and describe the instrumental requirements of on-line CE-MS. Furthermore, we discuss the practical aspects of performing CE-MS and CE-MS/MS in the structural characterization of drug metabolites.[1] We investigate the *in vivo* metabolism of haloperidol which is a widely used neuroleptic agent to treat psychiatric disorders such as schizophrenia.

Various CZE conditions for the separation of haloperidol and six structurally similar analogs were investigated involving consideration of 1) pH; 2) % organic modifier (MeOH); and 3) ionic strength. Optimal separation conditions were determined to be 50 mM NH_4OAc, 10% MeOH and 1% AcOH. Furthermore for CE to be coupled to the MS, the following points must also be considered: 1) good electrical contact at the outlet of the CE capillary in the MS; 2) position of the CE capillary within the ion source; 3) use CE separation media of low ionic strength containing volatile salts.

Using this CE-MS approach, we have previously determined the metabolic fate of haloperidol after guinea pig and mouse hepatic microsomal incubations. However, due to the limited loading capacity of a conventional CE capillary, only limited information was obtained. In order to overcome this problem, we have developed on-line preconcentration-CE-MS (mPC-CE-MS)[2]. This allows both on-line analyte concentration as well as sample cleanup prior to elution and subsequent electrophoretic analysis. This is demonstrated in Figure 1 for a mPC-CE-ESI-MS analysis of a rat microsomal incubation of haloperidol where six metabolites were detected.

The isolation and analysis of haloperidol metabolites by mPC-CE-MS only results in a tentative identification. However, by employing tandem MS (MS/MS) where a molecular ion is selected and subjected to collision with an inert gas and the subsequent fragment (product) ions are analyzed can result in a more compelling determination.

We report for the first time the use of mPC-CE-MS in conjunction with high energy (5 kV) fast linked scanning (FLS) to obtain structural information of metabolites. The use of mPC-CE-FLS-MS/MS enables selection of a specific molecular ion and also allows detection of isotope ions. This is demonstrated in Figures 2 and 3 for the haloperidol metabolite HP^+ (M^+= 354) found in both a rat liver microsomal incubation and human urine sample respectively.

It has been recognized that mutagenic and carcinogenic chemicals tend to be reactive electrophiles capable of modifying biological macromolecules such as DNA and proteins.(1) Despite much progress, a full understanding of the mechanisms of modification of biomolecules by reactive electrophiles at the molecular level remains elusive.(2,3) This is due to the complexity of these systems, whereby the actual electrophile(s) responsible for modification are often uncertain, the roles of solvent and counter ions are usually unknown, and the exact fate of the initially formed adduct(s) between the biological macromolecule and electrophile is unclear. In our work, two of the complicating factors, viz. the solvent and the counter ions are removed.(4) Thus the *intrinsic* reactivity of biomolecules with electrophiles in the gas phase are determined. The regioselectivity of these reactions are determined by analyzing the unimolecular fragmentation reactions of the product ions formed by reacting biomolecules with electrophiles in the CI source of a tandem mass spectrometer (all experiments were performed on a Fisons/VG (Manchester, UK) Autospec-Q; for details see ref. 4). Further insights into the thermodynamics and mechanisms of these reactions are gained by performing *ab initio* calculations on both the reactants and products of these reactions.

Specifically, we have determined that glycine undergoes a non- regioselective S_N2 reaction with $(CH_3)_2Cl^+$, with methylation occurring at both nitrogen and oxygen. This is consistent with the relative methyl cation affinities (MCAs) of CH_3Cl (MCA (CH_3Cl) = 62.0 kcal /mol) and those calculated via *ab initio* calculations (at the MP2/6-31G*//HF/6-31G* level) for the three nucleophilic sites in glycine: MCA (H_2N group) = 116.0 kcal/mol, MCA (C=O group) = 90.8 kcal/mol and MCA (HO group) = 80.6 kcal/mol. In contrast, the ambident electrophile $CH_3OCH_2^+$ reacts almost exclusively via a regiospecific pathway involving addition at nitrogen followed by elimination of CH_3OH to form a $[M + CH]^+$ ion with the structure $CH_2{=}NHCH_2CO_2H^+$. The experimental results are consistent with the *ab initio* calculated (at the MP2/6-31G*//HF/6-31G* level) relative stabilities of isomeric $[M + CH]^+$ ions.(4)

$(CH_3)_2Cl^+$ methylates cysteine (**1**) and the 2-hydroxypyridine (**2a**)/ 2-pyridinone (**2b**) system (a model for the tautomerism exhibited by nucleobases) at the sites indicated with a * in Scheme 1. The largest system studied to date is glutathione (Figure 1), which seems to be

methyated by $(CH_3)_2Cl^+$ at the sulfhydryl group. Our work is currently being extended to include the reactivity of other electrophiles (such as NO^+) and other biomolecules.

INTRODUCTION

β-Adrenergic agents are used illegally to enhance the lean body mass of livestock by repartitioning metabolic energy from fat deposition to muscle accretion. This creates the potential for misuse in commercial meat production. These compounds, commonly referred to as β-agonists, have produced acute toxicity (cardiac, central nervous system) in humans consuming liver from illegally treated cattle. Because of high potency, the doses of β-agonists used in treating farm animals are in the μg/kg range and very low residue levels remain in tissues. Residues are cleared from the plasma, urine and muscle before liver and pigmented retinal epithelium, roughly in that order. The high potency, rapid elimination from animal tissues, and the large number of β-agonists available for misuse requires multiresidue screening methods that incorporate efficient extraction from tissues with long clearance times, chromatographic separation and sensitive, selective detection coupled with unequivocal identification.

EXPERIMENTAL

Untreated bovine eyeballs were obtained from a slaughterhouse and eyeballs from clenbuterol-treated animals were obtained from a pharmacokinetic study conducted by USDA. β-Agonist standards were obtained from commercial sources. Pigmented retinal epithelium was dissected and residues were extracted using sonication in aqueous HCl (0.01M) and solid-phase extraction using C18 cartridges. Recoveries of clenbuterol, salbutamol and terbutaline spiked into control tissue were 80-110%. Incurred residue levels of clenbuterol in treated eyeballs were comparable to those found by USDA researchers who used liquid-liquid extraction and GC/MS quantification. LC separations were made using a C18 NovaPak cartridge or C4E column flowing at 1.0 ml/min with 90% acetonitrile/10% 1 mM ammonium acetate or 20% acetonitrile/80% 20 mM ammonium acetate, respectively. MS measurements were performed using a VG Platform single quadrupole mass spectrometer or a VG Quattro II triple quadrupole mass spectrometer (VG Organic, Altrincham, U.K.). The entire effluent from the LC column was introduced into the mass spectrometer using an APCI interface and positive ion data collected. MS/MS measurements were obtained using Ar as the collision gas at a pressure of 2×10^{-3} mbar. A collision energy of 15 eV was used for multiple reaction monitoring (MRM).

RESULTS AND DISCUSSION

We previously developed a multiresidue extraction and separation of 5 β-agonists from plasma using LC-APCI/MS and MS/MS (*J. Mass Spectrom.*, in press). In the present study, we extend these results to bovine retinal epithelium, a tissue with an extended clearance time for β-agonist residues, to provide a method that can support regulatory surveillance of livestock. The basis for the method is an isocratic LC separation of 9 currently available β-agonists. In this study, we focused on three t-butyl-substituted compounds thought to be used in livestock: terbutaline, salbutamol and clenbuterol. A goal of this work was to develop MS and MS/MS methods with high sensitivity and the specificity required for regulatory confirmation. In the MS experiments, data from a minimum of three ions: $(M+H)^+$, $(M+H-H_2O)^+$ and $(M+H-t\text{-}Bu-H_2O)^+$ were acquired for each compound in selected ion monitoring mode (SIM). The cone voltage was varied throughout the acquisition such that a particular ion was monitored under the condition that maximized the respective intensity (e.g., acquisition of MH^+ ions was made at a low cone voltage, etc.). In this way, the intensity ratios for a given compound were approximately equivalent (i.e., as close to 1.0 as possible). This minimized the influence of data variation, especially on low intensity peaks. This technique was used to confirm the presence of incurred clenbuterol residues in eyeballs (72-100 ppb). Table 1 shows the ion intensity ratios for injection of standards (1 ng) vs. those from clenbuterol-dosed eyeballs. The high degree of reproducibility and the close agreement between ratios for standards and incurred samples meets current regulatory guidelines for confirmation (≥ 3 ions, ± 10%). Furthermore, the estimated LOD (S/N = 3) was 1-2 ppb (100-200 pg on-column) in retina using the method described here.

TABLE 1. Ion intensity ratios determined from the areas under the respective SIM chromatogram for clenbuterol residues from dosed cow retina (72-100 ppb) and an equivalent amount of clenbuterol standard.

RATIO	277/277	259/277	203/277
Standards (n=4)	1.0	0.82 ± 0.01	0.95 ± 0.06
Incurred Retina (n=4)	1.0	0.79 ± 0.02	0.90 ± 0.03

On-line LC-MS/MS techniques were also used to increase specificity and sensitivity of detection for the 3 t-butyl-substituted compounds. Constant neutral loss (CNL) of 74 ($-H_2O$, - t-Bu) was monitored to perform class-specific detection. Similar scans could be performed for iPr-substituted compounds using loss of 60. The estimated detection limit for this technique was 8-16 ppb (1-2 ng on-column) in retina. MRM of the most prominent transition for each t-butyl-substituted compound yielded the highest sensitivity detection (16-80 ppt, 2-10 pg) of β-agonist residues in retina.

These techniques can be combined in a strategy to detect, confirm and quantify misuse of β-agonists in livestock: 1) use retinal tissue because of long clearance times for residues; 2) employ the multiresidue extraction and LC separations described; 3) use CNL scans to identify t-Bu or i-Pr substituted compounds; 4) quantify target residues using low cone voltage MS-SIM using external standards or isotope dilution; 5) confirm target residues using intensity ratios of at least 3 characteristic ions or transitions in comparison with those from standards using MS-SIM or MRM, respectively; 6) for very low level detection, use MS/MS with MRM to monitor one specific transition and quantify residues using external standards or isotope dilution.

THE USE OF GC-MS TECHNIQUES TO EVALUATE BIOLOGICAL LIPID PEROXIDATION

W. Rodney Mathews, David Guido, Rose McKenna, Rachel Laskey.
Biochemistry, The Upjohn Company, Kalamazoo MI.

Reactive oxygen species such as superoxide anion, hydrogen peroxide and hydroxyl radical have been implicated in a variety of human diseases. Reactive oxygen species attack biological membranes resulting in a chain reaction referred to as lipid peroxidation. Lipid peroxidation results in damage to cellular membranes as well as the production of toxic compounds. The role of reactive oxygen species in many human pathologies remains speculative however since most currently used methods for quantifying lipid peroxidation lack adequate sensitivity and specificity. We have developed two GC-MS methods for quantifying lipid peroxidation products that can be used both in vitro and in vivo. The first method involves the use of electron impact GC-MS to measure various hydroxy-arachidonic acids (HETE assay,(1)). This method is especially useful for tissue samples. The second method employs negative ion chemical ionization GC-MS to quantify F2-Isoprostanes as first described by Roberts and coworkers (2) and is especially useful for measuring lipid peroxidation in plasma and urine samples. These assays have been used to determine lipid peroxidation in a variety of different systems.

The HETE assay has been used to investigate the role of nitric oxide (NO) in lipid peroxidation. NO has been reported to be a pro-oxidant by virtue of its reaction with superoxide anion to generate the powerful oxidant peroxynitrite anion ($ONOO^-$). Phosphatidylcholine (2 mg/ml) liposomes were incubated at 37 C with various NO sources (NO gas, Sin-1, diethylamine NONOate) or $ONOO^-$. After one hour, internal standard (25 ng 16-hydroxy-heneicosatetraenoic acid) was added and the samples analyzed by GC-MS as described previously(1). The results are shown in figure 1. Ferrous ammonium sulfate (FAS) used as a positive control and $ONOO^-$ caused significant lipid peroxidation. The NO donor Sin-1 which generates NO and O_2^- simultaneously with subsequent $ONOO^-$ formation caused a slignt increase in lipid peroxidation. Interestingly NO not only does not cause lipid peroxidation of PC liposomes but blocks iron-induced lipid peroxidation. Therefore, whether NO acts as a pro- or anti-oxidant in vivo will depend on the nature of the biological milieu into which it is released.

The HETE assay has been used to evaluate the role of lipid peroxidation in an in vitro model of oxidant induced damage to vascular function. Rings of rabbit aorta were suspended in bioassay baths and exposed to hydrogen peroxide or $ONOO^-$ and tested for endothelium dependent relaxation in response to acetylcholine. Both oxidants completely abolished ACh relaxations. Strips of rabbit aorta were exposed to the same concentration of oxidant species and the endothelial cells removed and assayed for HETE content. As shown in figure 2, the functional damage to the endothelial cells caused by these oxidants was not associated with a significant increase in lipid peroxidation. These results indicate that oxidant stress can cause significant alterations in cell function by mechanisms other than membrane lipid peroxidation.

MACROLIDE ANTIBIOTIC RESIDUES IN DISTILLER'S GRAIN AND MILK BY ESI LC/MS

Rick A. Flurer, John A. Tomlinson, and R. Duane Satzger
Forensic Chemistry Center, U.S. Food and Drug Administration
1141 Central Parkway, Cincinnati, OH 45202

The Forensic Chemistry Center has recently been involved in the investigation of large numbers of beef cattle deaths in several midwestern states. The factor linking these deaths is currently thought to be the consumption of contaminated dried distillers grain (DDG), a feed additive. During the course of this investigation, it was determined that the DDG had been contaminated with antibiotic residues at an ethanol production facility. These residues originated from waste stream ethanol that had been sent to the ethanol production facility for removal of high levels of dissolved solids before use in the production of gasohol. The solids remaining after distillation of the waste stream ethanol were then combined with the DDG produced by the firm's standard process for production of ethanol. The residues consisted of erythromycin A, clarithromycin, and a variety of side-reaction products or decomposition products (analogs) from a process wherein clarithromycin is synthesized from erythromycin A. Ethanol is used as a solvent in this synthetic process. We have developed an electrospray LC/MS method for the analysis of these antibiotic residues in DDG. The investigation also revealed that dairy cattle were also fed the contaminated DDG; however, they did not suffer any effects from exposure to the macrolide residues. In spite of this fact, it was necessary to check several tank trucks of milk from these cows for macrolide antibiotic residues to prevent possible exposure of the public to these residues. The level of concern was approximately 10 ppb. Therefore, we have also developed an electrospray LC/MS/MS method for confirmation of macrolide antibiotic residues in bovine milk at the 1-10 ppb level.

The total ion chromatogram (TIC) and several reconstructed ion chromatograms (RIC) for a contaminated DDG sample are shown in Figure 1. More than two dozen components are present, and the RIC's indicate that many components share the same nominal masses. The product ion spectra for erythromycin A, clarithromycin, and decladinosyl-clarithromycin (Declad) standards contain an ion at m/z 158. The commonality of the presence of the ion at m/z 158 suggests that a precursor ion LC/MS/MS experiment for precursors of m/z 158 would be useful as a screen for clarithromycin analogs. The precursor ion LC/MS/MS TIC and the LC/MS TIC for contaminated DDG are compared in Figure 2. Clearly, there is one-to-one correspondence between the chromatographic peaks in each TIC, indicating that virtually all of the peaks represent macrolide antibiotic species. Most have been identified through their product ion spectra, the mass of their $[M+H]^+$ ions, and knowledge of possible side-reactions or decomposition pathways. In general, the analogs in the DDG samples were present at the 1-100 ppm level, as determined by a single point calibration versus a clarithromycin standard.

The selected reaction monitoring (SRM) data for a mixed 25 ppb clarithromycin and declad standard are shown in Figure 3. Declad elutes at retention time 7:23 and clarithromycin elutes at retention time 9:32. The corresponding data for a 1 ppb milk spike are shown in Figure 4. The data exhibit a signal-to-noise ratio > 3:1, and the peak maxima in the RIC for each reaction monitored occur at the retention time of the corresponding standard. The SRM data for a negative control milk sample are shown in Figure 5; they demonstrate the absence of interferences at the retention times of the standards. The average recoveries for declad at the 1 ppb and 10 ppb spike levels are 79±12% and 82±5 (n=5), respectively. The corresponding recoveries for clarithromycin are 69±5% and 77±2% (n=5). Clearly, this method is more than adequate for the determination of macrolide residues in milk at the 1-10 ppb level.

ISPROSTANE FAMILIES FOLLOWING FREE RADICAL OXIDATION OF ARACHIDONIC ACID

Russell J. Waugh and Robert C. Murphy
National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson Street, Denver, CO 80206

INTRODUCTION

A great deal of interest has centered around the role of lipid peroxidation in diseases which range from cancer, atherosclerosis to ischemia reperfusion injury (1). Typically, very small molecules have been measured to assess lipid peroxidation; these small molecules include pentane, malonyldialdehyde, and 4-hydroxynonenal (2). Recently, structures of more complex free radical oxidation products have been identified, in particular the compounds isomeric to the cyclooxygenase-derived prostaglandins that have been termed *isoprostanes* (3). As seen in Figure 1, the free radical formation of these isoprostanes are initiated by formation of a stable bisallylic product which reacts with triplet oxygen to form a hydroperoxy adduct. This can cyclize and further react with another molecule of triplet oxygen yielding a hydroperoxy endoperoxide. Arachidonic acid has three bisallylic positions which can form, in theory, four different structural family subtypes of hydroperoxy cyclic endoperoxides (Figure 1). We have undertaken studies to investigate the formation of these families by free radical oxidation of arachidonic acid and obtained mass spectra of different family subtypes.

RESULTS

Using Fenton chemistry (4), oxidation of arachidonic acid with hydrogen peroxide and Cu^{++} was carried out to form a host of free radical products. Following HPLC separation of these products, catalytic reduction using Rh/Al_2O_3 with hydrogen gas, methylation, and trimethylsilylation products were analyzed by electron ionization GC/MS. One component from the initial HPLC separation is shown in Figure 2A which was identified as a Type-IV family member based upon the characteristic α-cleavage ions identical to authentic $PGF_{2\alpha}$ derivatized in the same manner. Another HPLC fraction yielded a component with the EI mass spectrum shown in Figure 2B. The α-cleavage ions were identical to those predicted for a Type I family member.

A method for direct detection of isoprostanes eluting from the HPLC was developed using electrospray ionization mass spectrometry. Isoprostanes have a unique structural characteristic, namely a 1,3-diol moiety within a cyclopentane ring. The carboxylate anion from $PGF_{2\alpha}$ (*m/z* 353) was previously shown to decompose with the loss of 44 u (C_2H_2O) to form *m/z* 309 (5,6). Selected reaction monitoring was employed for *m/z* 353 during HPLC/MS/MS analysis of the oxidation products of arachidonic acid as described above. The elution of isoprostanes were readily detected and three major HPLC peaks identified (Figure 3). Structural analysis of these isoprostanes using the GC/MS techniques of the reduced methyl ester trimethylsilyl ether derivative described above, revealed the presence of two predominant family members, Type IV and Type I.

The free radical oxidation of arachidonic acid using Fenton chemistry conditions resulted in the predominate formation of family Type IV (cylooxygenase-like products) and family Type I which has the free hydroxyl group at carbon 5 of arachidonic acid. This latter family type is structurally unique in that members are not enzymatically derived from cyclooxygenase-mediated oxygenation of arachidonic acid.

Introduction. Beclomethasone 17,21-dipropionate (BDP; figure 1) is an anti-inflammatory steroid used for the control of the symptoms of rhinitis or bronchial asthma. A sensitive assay was needed for the simultaneous determination of BDP and three potential metabolites, beclomethasone (BEC), beclomethasone 17-propionate (17-BMP) and beclomethasone 21-propionate (21-BMP) in plasma of several species. The technique of HPLC combined with atmospheric pressure chemical ionization (APCI) tandem mass spectrometry (MS/MS) was found to provide the necessary sensitivity and selectivity to develop and validate this analytical methodology.

Experimental. A Finnigan-MAT TSQ 700 or 7000 triple stage quadrupole mass spectrometer equipped with the Finnigan APCI source was used for the study. Plasma samples (0.4 to 1.0 ml; depending on species) containing mometasone furoate as an internal standard (IS) were subjected to liquid-liquid extraction. Separation of the four analytes and the IS was achieved by a reverse phase HPLC column connected directly to the APCI inlet. The MS analysis was performed using the selected reaction monitoring (SRM) technique. In each case, the protonated molecule $[MH]^+$ was chosen as the parent ion by Q1 and a molecule-specific fragment ion selected for the progeny ion by Q3. Collision gas energies in Q2 were optimized for each of the compounds (see figure 2.)

Results and Discussion. The HPLC-APCI/MS/MS analytical methodology was sensitive and specific for the simultaneous determination of BDP and three metabolites. The method was validated and found to be linear over the range of 50 to 5000 pg/ml for BDP and 17-BMP and 100 to 5000 pg/ml for BEC and 21-BMP in 1.0 ml human plasma samples. Accuracy and precision of the method were evaluated using quality control (QC) samples. Back calculated values for all analytes at each concentration of the standard curve were within 8% of the expected values. Relative standard deviation was less than 13% for standards below 100 pg/ml and less than 11% for values 100 pg/ml or higher. Samples were found to be stable during multiple freeze-thaw cycles.

The assay was also validated in dog and rat plasma. Lower limits of quantitation were 2-fold higher due to smaller sample volumes of 0.5 and 0.4 ml, respectively.

Column-Switching sample preparation for quantitative analysis by LC-MS

G. Hopfgartner, M. Zell, C. Husser
F. Hoffmann-La Roche, Pharma Division, Department of Drug Metabolism & Kinetics, CH-4002 Basel

Introduction

Atmospheric pressure ionisation (API) tandem mass spectrometry combined with liquid chromatography (LC-MS/MS), becomes a powerful analytical tool in respect to sensitivity and selectivity that arising with the use of HPLC with UV-detection for the quantification of pharmaceutical compounds.

Due to high selectivity of tandem mass spectrometry fast analysis time in the range of one to five minutes are possible and over 300 samples can be analysed on a daily basis assuming that several people or automates are involved with sample preparation. Limiting factors became sample preparation and data handling. For sample preparation the following techniques are widely used : liquid-liquid extraction or solid-phase extraction.

An elegant alternative to off-line sample preparation is column-switching (1,2), where large amount of samples (up to 1 ml) were injected onto a standard bore pre-column where the analytes are retained while salts and endogenous compounds were washed out. After this preconcentration and wash step the analytes are eluted in backflush onto a standard, narrow or microbore analytical column. Plasma or plasma samples after protein precipitation can directly be injected into the fully automated system. The setup is simple, low cost, universal and can be used either with ion spray or the heated nebuliser interface reducing development and optimisation time of a given analytical problem.

Using the same strategy two assays have been developed for the quantification of the benzodiazepine agonist Ro 48-6791 and its depropyl metabolite Ro 48-6792 or the platelet aggregation inhibitors : Ro 48-3856 and Ro 44-3888 in human plasma.

Experimental

The HPLC system used in this work was constituted by two Merck Hitachi L6200A and 6000 pump and an AS-4000 autosampler (Merck) equipped with a 2 ml injection loop. For column switching a high speed Reodhyne six port switching valve was used. The analytes were separated on a 150 x 2 mm or a 150 x 1 mm i.d. Inertsil ODS-2, 5 µm column.The eluant was 1% HCOOH/MeOH (60/40, v/v and the flow rate was 0.2 ml/min for 2 mm i.d. column or 0.05 ml/min for the 1 mm i.d. column. For the analysis of Ro 48-6791 and Ro 48-6792 plasma proteins (0.5 ml plasma) were precipitated with acetonitrile. After partial evaporation of acetonitrile, a buffer solution was added and 1 ml of the supernatant was injected into the HPLC system.

All analyses were performed on an API III^{plus} (PE Sciex) triple quadrupole mass spectrometer equipped with a home-made autogate for automated recycling.
The MS analysis was performed using ion spray in positive mode with selected reaction monitoring (SRM). The following precursor-to-product ions reactions were monitored with dwell times of 200 and 400 msec : m/z 371 to 300 (Ro 48-6792), m/z 375 to 300 (d4 IS) and m/z and m/z 413 to 114 (Ro 48-6791), m/z 417-118 (d4 IS). The collision energy was set at 10 eV and argon was used at a collision gas thickness of 270 x 10^{13} atoms/cm^2.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Results

The column-switching approach was found to be robust and sensitive. Over 700 samples could be analysed with the same trapping pre-column. The lower limit of quantification was 20 pg/ml for Ro 48-6791 and 50 pg/ml for Ro 48-6792, respectively. The assay was liner for both compounds up to 20 ng/ml. The precision and accuracy derived from QC samples, concomitantly assayed along with unknown samples from clinical studies, was found to be better than 8.1 % and 94.7 % in the concentration range of 100 pg/ml to 10ng/ml, respectively. By adding a second switching valve and a second trapping pre-column the sample throughput can be increased from 100 samples per day to 150 samples per day without compromising analytical performance. A quantification limit of 2 pg/ml in human of plasma was achieved by transfering from the standard bore trapping column to a microbore (1 mm i.d.) analytical column.

The column-switching system can be used with analytes of different polarities and a sensitive method was also developed with the same strategy for the quantification of the platelet aggregation inhibitors (Ro 48-3856 and Ro 44-3888) in human plasma.

Direct Measurement of Steroid Glucuronides and Sulfates with HPLC/MS and HPLC/MS/MS

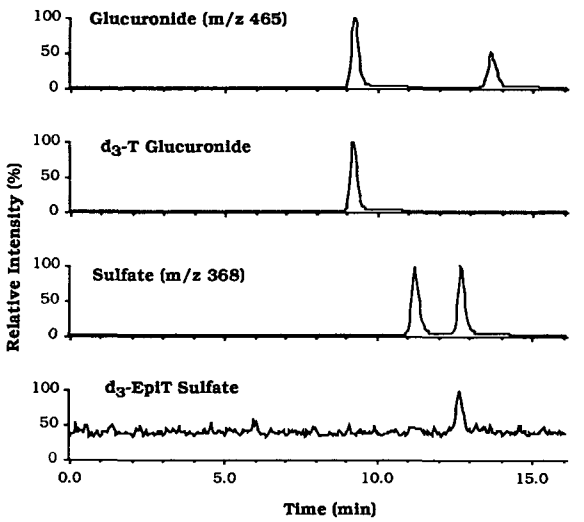
Sanaullah and Larry D. Bowers
Department of Pathology and Laboratory Medicine
Indiana University Medical Center
Indianapolis, IN 46202-5120

The measurement of steroids in urine is an important aspect of doping control in sports, as well as diagnosis of disease and genetic metabolic disorders. Steroids are excreted in urine as conjugates with glucuronate and sulfate. The present analysis of steroids requires hydrolysis, derivatization, and GC/MS detection; this approach has a number of limitations. One area of steroid measurement which is of great interest in doping control is measurement of the testosterone-epitestosterone (T/E) ratio. The IOC requires sanctions for T/E ratios greater than six. Recent work by Dehenin and Matsumoto suggests that differences in glucuronidation and sulfation could result in variability of the T/E ratio. We have developed HPLC/MS and HPLC/MS/MS methods for direct quantitation of T-sulfate, T-glucuronide, E-sulfate, and E-glucuronide in urine.

We have synthesized ES, EG, d_3-TG, and d_3-ES in our laboratory. The T labeling procedure began with androstendione. d_3-E was synthesized from d_3-T using the Mitsunobu reaction. We have used a modified version of the Köenig-Knorr reaction to improve the yield of glucuronidation. Using the synthesized standards and deuterated internal standards, we have developed a method for extraction and quantitation using HPLC/MS. The steroid conjugates were extracted from urine using a modification of the reported by Weidolf and Henion.

The HPLC/MS method makes use of a PE Sciex API III tandem mass spectrometer. The IonSpray interface was used in conjunction with both 1 mm id and 320 um id HPLC columns. Using the packed capillary, detection limits of 20 pg on column were achieved. The orifice voltage is very important in achieving a sensitive analysis. TG and EG behave very differently, with EG fragmenting to yield predominanatly the aglycone at orifice voltages of 60 V. The sulfate conjugates are much more rugged. In fact, the inability to significantly fragment these compounds in the positive ion mode is a drawback in terms of the utility of the technique to provide information about the identity of the steroid.

Measurement of the T and E conjugates in urine showed that although significant inter-individual differences in the conjugation do occur, they do not appear to affect the T/E ratio.



Haloacetic Acid Drinking Water Disinfection By-Products

William L. Budde, Jean W. Munch, David D. Kryak, and Thomas D. Behymer

U. S. Environmental Protection Agency, Office of Research and Development, National Exposure Research Laboratory, Aquatic Research Division, 26 W. Martin Luther King Drive, Cincinnati, OH 45268

Humic material from decaying vegetation, etc. in surface and ground waters reacts with chlorine which is added to drinking water for microbiological disinfection. A series of well-characterized drinking water disinfection by-products (DBPs) are formed including the well-known trihalomethanes, mono-, di-, and trihaloacetic acetic acids, haloacetonitriles, and other substances. Depending on the concentration of bromide ion in the water, brominated and mixed bromochloro DBPs are also produced.

$$\text{humic substances in source water} \xrightarrow[Br^-]{Cl_2} Br_xCl_yC\text{-}COOH + Br_xCl_yCH + Br_xCl_yC\text{-}CN + \text{others}$$

This work focused on the haloacetic acids which are usually determined with EPA Methods 552 or 552.1. In Method 552, a 100 mL drinking water sample is extracted with methyl tert-butyl ether (MTBE), the acids are converted to methyl esters with diazomethane in MTBE, the esters are separated with capillary column GC, and measured with an electron capture detector (ECD). Because it is highly desirable to reduce laboratory worker exposures to solvents like MTBE and reagents like diazomethane, alternative Method 552 1 was developed. In this method, a 100 mL drinking water sample is passed through an anion exchange column, the retained acids are eluted with acidic methanol, the acids esterified by heating with a small amount of MTBE, partitioned into MTBE, separated with capillary column GC, and measured with an electron capture detector (ECD). Unfortunately, haloacetic acids are not extracted efficiently by the ion exchange column from waters with a high ionic strength, and particularly from those waters with relatively high concentrations of sulfate ion which displaces the acid anions from the resin Both methods suffer from a reliance on retention times for identifications and the potential for many coeluting electron capturing substances.

We are exploring alternative approaches to the measurement of haloacetic acids which have been proposed for regulation in drinking water. Use of a high sensitivity mass spectrometer in place of the ECD would eliminate at least one of the shortcomings of Methods 552 and 552.1. High sensitivity in the full mass scan mode is required to ensure that the concentrations of acids are below proposed regulatory levels and to ensure correct identifications of the haloacetic acids. An instrument detection limit of 20 pg or less was obtained for the methyl esters using an ion trap mass spectrometer. The methyl esters of mono-, di-, and trichloroacetic acids, mono-, and dibromoacetic acids, and bromochloroacetic acid chromatograph on standard bonded phase fused

silica capillary columns with retention times in the 5-15 min range. Tribromoacetic acid and several other mixed bromochloroacetic acids may be present in some drinking waters but were not included in our studies because of problems with stability, purity, availability of standards, and chromatography. The methyl esters of the compounds studied are readily identified by their 70 eV electron ionization spectra, although molecular ions are very weak or not observed.

A completely different approach is being investigated as a means of overcoming all the deficiencies in Methods 552 and 552.1. In this approach, no extraction is used but the water sample is concentrated by a factor of 10-20 by lyophilization. The acid anions are separated at pH > 10 by ion chromatography , introduced into the mass spectrometer (MS) by pneumatically assisted negative ion electrospray, and measured by time scheduled selected reaction monitoring (SRM) in a tandem MS system The ions used in the SRM mode are given below:

Anion	Q_1 m/z		Q_3 m/z
$ClCH_2\text{-}COO^-$	93		35
$BrCH_2\text{-}COO^-$	137		79
$Br(CH_2)_2\text{-}COO^-$ (IS)	151		79
$Cl_2CH\text{-}COO^-$	127	$\xrightarrow{-CO_2}$	83
$Br_2CH\text{-}COO^-$	217	"	173
$BrClCH\text{-}COO^-$	173	"	129
$Cl_3C\text{-}COO^-$	161	"	117

On collision induced decomposition (CID), chloroacetate, bromoacetate, and the internal standard 2-bromopropionate give primarily chloride and bromide ions respectively, and these reaction products are monitored in Q_3. On CID, the other haloacetate molecular anions lose carbon dioxide and the residual anions are monitored in Q_3. Instrument detection limits are in the range of 0.1-3 ng which may be adequate for monitoring these acids in drinking water. Further details on this approach are given in Wednesday poster (WPF) 136.

Investigating Oxidation Reactions in Environmental Systems

M. Judith Charles[1], Thomas N. Feinberg[1], and Susan D. Richardson[2]
[1]Department of Environmental Sciences and Engineering, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599-7400; [2]U.S. Environmental Protection Agency, Environmental Research Laboratory, Athens, Georgia 30605-2720.

Introduction: Research in the environmental sciences strives to understand processes such as chemical oxidation reactions that influence the formation transport and transformation of chemicals in environmental systems. Explorations of chemical mechanisms is a critical component of these studies. We present two research stories highlight the contribution of mass spectrometry to understanding environmental issues affecting everyday life, and exemplify the interplay between the emergence of significant environmental issues and the development of analytical technologies to cope with these issues.

Chemical mechanisms affecting the formation of worrisome chemicals in disinfected waters: In 1974, the finding that halogenated methanes are present in chlorinated waters by Rook and Bellar *et al.*, (1,2) led these and other researchers to investigate the formation of these compounds. Bellar *et al.*, 1974 suggested that chloroform resulted from the step-wise oxidation of ethanol to acetaldehyde, chloral and chloral hydrate. This hypothesis failed to account for the ubiquity of disinfection by-products as little evidence was found to support the notion that ethanol is present in all natural waters (3). Rook was the first to suggest that humic substances are precursors for trihalomethanes in drinking waters. Rook evoked the "haloform reaction", a series of base-catalyzed halogenation and hydrolysis reactions explains the production of chloroform from methyl ketones such as acetone (4,5). The half-life for haloform formation for acetone at pH 7 is too long (almost a year; 7500 hr) (4) and the concentration of acetone in waters is insufficient to account for the high levels (200 μg/L) of chloroform (1). Rook then suggested, based on chlorination studies of model compounds that fast chlorination occurs on resorcinol or resorcyclic acid moieties incorporated causes ring rupture of the humic macromolecule to produce methylene chloride, dichloroacetic acid, chloroform and butenoic acid (6). Chemical degradation studies advanced the idea that humic substances are comprised of aromatic and aliphatic components and the identification of unchlorinated aliphatic and aromatic compounds highlights the oxidation capabilities of chlorine (7,8). The identification of saturated molecules and 3,5,5-trichlorocyclopent-3-ene-1,2-dione as the primary intermediate in the reaction of chlorine with resorcinol led Christman and co-workers (7) to dispute Rook's hypothesis. Ring rupture mechanisms similar to those proposed by Rook effect the formation of unsaturated molecules and OCl^- attack on side chains of aromatic molecules produces saturated molecules (9). Tretyakova *et al.*, (10) observed the formation of cyclopentadione intermediates, compounds observed to occur during the formation of chloroform from resorcinol and thought to be too unstable to be reaction intermediates by Rook. The identification of toxicologically worrisome chemicals has fostered research on the use of disinfectants, such as monochloriamine, ozone, chlorine dioxide, and TiO_2/UV. These disinfectants do not produce high levels of trihalomethanes, but do produce polar oxygenated molecules that may be hazardous to human health.

Chemical mechanisms for the transformation of volatile organics affecting tropospheric ozone formation: Volatile organic hydrocarbons participate in the photochemical cycle by reacting with the hydroxyl radical to form organic radicals that combine with molecular oxygen and nitric oxide to form other radical species and nitrogen dioxide. The photodissociation of nitrogen dioxide releases ground state oxygen that recombines with molecular oxygen to form ozone. Because ozone dissociates to form hydroxyl radicals, this process is a chain reaction. On a global scale the emissions of biogenic hydrocarbons exceed that of all anthropogenic sources of non-methane organic gases. Isoprene (2-methyl-1,3-butadiene) constitutes a major fraction of all vegetative non-methane hydrocarbon emissions. Hence, the atmospheric photochemistry of isoprene is a critical component of understanding tropospheric ozone formation. Gu *et al.* (11) proposed that 1,2- and 3,4-addition reactions leads to the formation of alkoxy radicals that degrade to form methacrolein and methylvinylketone. 3-methylfuran and formaldehyde, also reaction intermediates were proposed to form by other chemical mechanisms. Subsequent FTIR work done by Tuazon and Atkinson (12) confirmed the formation of intermediates previously observed and second generational species, including hydroxyacetone, methylglyoxal and glycoaldehyde. The total product yield uncertain because only $\approx$55% of the carbon containing products can be positively identified. The remaining "unknown" composition was determined from its IR spectrum to consist of carbonyls and only a small fraction from organic nitrates. From data obtained by using PFBHA derivatization in combination with ion trap mass spectrometry, Yu *et al.* (13), established that hydroxyl radical oxidation of isoprene process by many types of addition reactions. 1,2-addition of ·OH to isoprene forms alkoxy radicals that degrade to methylvinylketone and hydroxymethylketone. Second generational species formed include methylglyoxal, glycoaldehyde and hydroxymethyl glyoxal. 3,4-addition, 2,1-addition and 4,3-addition reactions are also important and also leads to the formation of multi-functional carbonyl compounds.

Summary: After 20 years of research, we now know that humic substances are complex materials that cannot be elucidated by a simple drawing; and that chlorination of these materials effects chlorination and oxidation reactions that degrade humic substances. At present more than 50% of the total organic halogen in chlorinated humic samples and in chlorinated water supplies remain unidentified. After 9 years of research, we now understand that many types of addition reactions effect degradation of isoprene. The "missing carbon" formed from degradation of the humic macromolecule or photooxidation of isoprene is believed to be low-molecular weight polar and oxygenated molecules. New analytical methodologies are needed to further advance our understanding of chemical mechanisms in aquatic and atmospheric systems. Electrospray mass spectrometry, derivatization techniques in combination with ion trap mass spectrometry and the development and application of novel chemical ionization reagents will likely allow deeper and better research questions to be answered in the environmental sciences.

High Speed Analysis of Total Trihalomethane (TTHM) Content in Drinking Water using Membrane Introduction Mass Spectrometry (MIMS)

Scott Bauer, Jan Bauer, MIMS Technology Inc.
1900 S. Harbor City Blvd. Suite 115
Melbourne, FL 32901

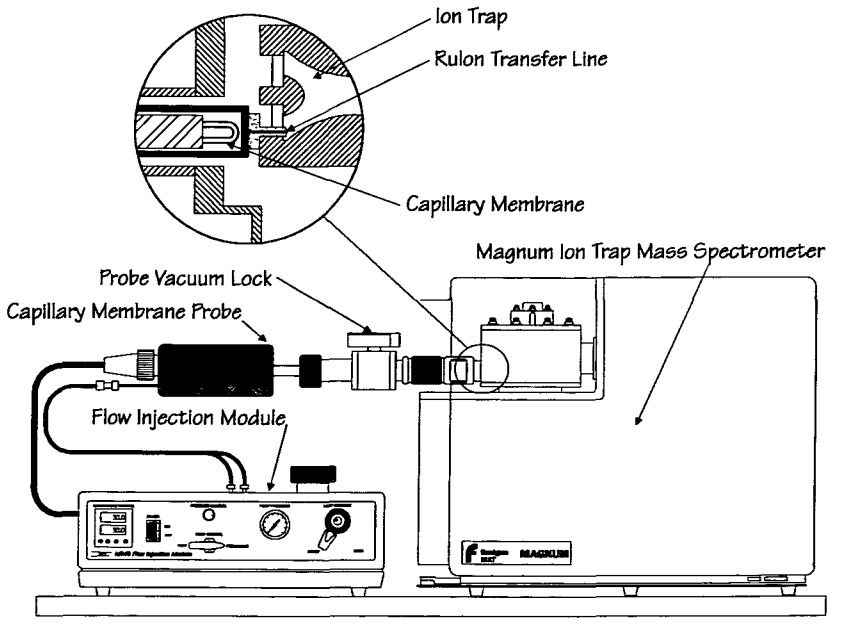
Traditional methods for the determination of total trihalomethane content in drinking water by purge and trap gas chromatography (GC) is slow, expensive, and requires specialized training to interpret the results. An alternative method using membrane introduction mass spectrometry (MIMS) is presented here. MIMS provides an analysis method that is fast, simple, inexpensive, and requires little training to derive meaningful results. Furthermore, due to the high speed nature of MIMS analyses, use of this technique on-line as a drinking water treatment process monitor is also discussed. Dedicated software is under production to automate the analysis and provide a means for feed-back control of the treatment process. Simultaneous use of the MIMS system to screen for the presence of other volatile organic compounds of environmental interest is also discussed.

Traditionally, trihalomethane analysis is performed by gas chromatography wherein the individual trihalomethanes, chloroform, bromodichloromethane, dibromochloromethane, and bromoform are separated in time, individually quantified, and the results are added together to arrive at the total trihalomethane content of the sample. This procedure is intuitively inane. One may ask, why bother separating the compounds in time by GC/MS and then add the results together again at the end of the analysis? The answer lies in the fact that at the time this method was written, there was no other way to remove the analytes from the water matrix for introduction into a detector. Today, there is MIMS.

MIMS is a direct introduction sampling method that utilizes a semi-permeable membrane which separates the liquid sample from the vacuum of the mass spectrometer. Volatile organic compounds, like trihalomethanes, diffuse across the membrane into the source of the mass spectrometer where they are ionized and mass analyzed. Water is excluded from passage across the membrane so there is an increase in analyte concentration in the mass spectrometer source compared to that in the bulk sample solution. This makes the technique very sensitive. Detection limits at or below 100 parts per trillion are routine. Additionally, other potential interfering components of the sample such as acids, bases, salts, metals, suspended solids, and biological materials are also excluded from passage into the mass spectrometer. This means that no sample preparation of any kind is required to achieve optimum performance. This is one of the chief advantages in MIMS. Other direct inlet technologies such as capillary direct, thermospray, and electrospray techniques are plagued by constant problems associated with the build-up of salts and other non-volatiles on the mass spectrometer source and inlet components.

The presented experiments demonstrate the ability to directly determine total trihalomethane content in drinking water using MIMS and flow injection analysis techniques. Samples are injected into the FIA-TC1 flow injection module where they are carried to the 1900-C1 capillary membrane probe. Trihalomethanes diffuse across the membrane directly into the mass spectrometer source. All of the volatile components of the sample enter at the same time. Extraction of the ion current chromatograms for m/z 83, 129, and 173 in summation form allows for direct determination of the total trihalomethane content in one step. Identification of the trihalomethanes is easily accomplished without separation from the mass spectrum.

Experiments described here demonstrate that trihalomethane analysis may be performed by MIMS in less than five minutes per sample, with percent RSDs of 1.12%, detection limits of 100 parts-per-trillion, and average percent recoveries of 98.9%. This performance rivals that of the best purge and trap GC systems and details productivity as much as one order of magnitude higher than conventional systems.



CHEMISTRY AND TOXICOLOGY OF POULTRY CHILLER WATER

WILLIAM F. HADDON, R. G. Binder, Leslie A. Harden, R.Y. Wong, R. Wilson and K. L. Stevens, Western Regional Research Center, USDA, Albany, CA 94710. e-mail haddon@pw.usda.gov

Introduction: Chlorination of poultry chiller water using hypochlorous acid (bleach) is an effective sanitation process for reducing the levels of pathogenic bacteria in poultry chiller water (PCW). However the chemistry of chlorination of PCW and the toxicology of its many chlorine disinfection by-products have not been thoroughly studied, and there has been some concern that bacterial mutagens may be formed at increased chlorination levels (Masri, 1986). As in water disinfection, there is interest in alternative disinfectants (Richardson, et al, 1994), and use of chlorine dioxide has recently been approved for poultry processing.

Results and Discussion: There is a dose-response relationship between the level of chlorination and the bacterial mutagenicity of PCW in several Ames tester strains. Systematic fractionation and chromatographic purification of chiller water from a simulated PCW, followed by mass spectrometry, has allowed us to characterize the Ames-active components that are formed. Remarkably, a single compound, 2,5-pyrrolidinedione-3,3-dichloro-4-dichloromethylene, 2, accounts for most of the mutagenicity in tester strain TA-100 for the pH 2 extract of the simulated chiller water after chlorination. A related compound, 3,4-dichloromaleimide 1, appears to co-occur in the chlorination mixtures (Haddon, et al, 1995).

An especially interesting aspect of the work is the similarity in molecular structure between 2 and the chlorofuranone "MX", which is the principal mutagenic product formed in when chlorine is used to bleach paper. This relationship links our toxicology study of PCW to the much larger area of drinking water, where chlorination in the presence of humic material produces "**MX**".

The Ames mutagenicity for 2 in TA-100, without metabolic activation, is 1850 revertants per nanomole, making it the second most potent bacterial mutagen so-far discovered from chlorination; the mutagenicity of MX under comparable conditions of testing is about 5500 rev/nmole. Both **MX** and 2 should be potent electrophiles.

We are exploring these toxicology relationships through computational chemistry approaches which attempt to link molecular structure information to biological activity. For 2 (E), and a related synthetic tri-chloro imide 3 (D), the computed (negative) energy of the lowest unoccupied molecular orbital correlates with molecular mutagenicity and falls on the same curve developed by Lalonde, et al for MX and several of its structure analogs. ECNI mass spectra may provide a similar indication of electrophilicity for these molecules.

Pulmonary hemosiderosis is a rare and serious disease characterized by spontaneous pulmonary hemorrhage and associated with iron deficiency anemia. The disease is so rare that from 1983 to 1993 only three cases were identified at a referral hospital in Cleveland, Ohio. Despite the low incidence of this disease, in January 1993 to November 1994, eight cases of idiopathic pulmonary hemorrhage/hemosiderosis (IPH) were identified among previously healthy infants at the same hospital mentioned above .[1] During the investigation of the Cleveland cases, an additional seven cases of IPH were identified at a children's hospital in Chicago, IL (from April 1992 - November 1994).[2] Cases have continued to be reported since then, with a total of 15 cases in Cleveland and 12 cases in Chicago. Examination of the infants at the hospital and laboratory testing did not indicate the cause of the illness. Urine samples from infants with IPH and some of their parents were collected, frozen and stored at CDC for analysis.

A black mold was found in homes of some of the sick infants. The mold was growing on walls, wall paper, ceiling or other areas in the homes that had been water-damaged and remained moist. Samples were collected with scotch tape and the tape fixed on glass slides. A mold called *stachybotrys* was identified on some of the slides. *Stachybotrys atra* (*S. atra*) produces a macrocyclic trichothecene called satratoxin (Figure 1) that has been shown to be toxic. It was proposed that the IPH occurring in the infants may be associated with satratoxin or another previously unidentified toxicant produced by *S. atra*. Human and animal illnesses have been associated with *S. atra* in the past (Stachybotrytoxicosis); however, illnesses involving infants have not been reported previously.

Based on the hypothesis that satratoxin was linked to IPH, our laboratory developed a method to measure the satratoxin exposure. Little is known about the metabolism of satratoxin in the human body. Metabolism usually involves attachment of glucuronides or sulfates to a toxicant in an attempt to increase its solubility in urine and thereby increase its excretion. We assumed that at minimum glucuronide attachment occurred during the metabolism of satratoxin, and that satratoxin and all its metabolites were hydrolyzed to verrucarol (Figure 1). Since the number of glucuronides that may associate with any toxicant is unknown, it is usually helpful to strip the glucuronides from the analyte prior to analysis. Removal of glucuronides from metabolized compounds is normally accomplished using acid, base or enzyme hydrolysis. Further base hydrolysis of satratoxin produces verrucarol. Since verrucarol production from satratoxin is an easy reaction, it was chosen to be the target analyte to determine whether satratoxin had been present.

The sample preparation method for hydrolysis of urine and satratoxin urinary metabolites is described in Figure 2. Initial experiments with verrucarol-spiked urine showed that verrucarol is not destroyed by this method and is recovered between 60-70%. Strong base hydrolysis was used to hydrolyze satratoxin in the urine to verrucarol. Recovery for satratoxin converted to verrucarol is approximately 40%. Atmospheric pressure chemical ionization and tandem mass spectrometry was used to measure verrucarol in the extracts. The molecular ion of verrucarol $(M+H)^+$ 267 and its daughter ion at m/z 219 were monitored. This fragmentation constitutes the loss of OH and CH_2OH from the molecular ion. An isotopically labeled internal standard was unavailable and a suitable non-labeled internal standard could not be identified, therefore urine samples spiked at varying concentrations were used to construct a standard curve and determine the limit of detection and limit of quantitation for this method. The LOQ for verrucarol is 59 ppb in urine, or 11.8 ng on-column injection, the LOD for verrucarol in urine is 23.6 ppb, or 4.72 ng on column injection.

Very small volumes of urine from infants were available, therefore we decided to first analyze urine collected from the parents of the ill infants. The parents should be exposed to the same environment as the infants, and their urine specimens should document this. Four parental urine samples were available, and ten milliliters of each was hydrolyzed and extracted. There were no positive detects made for verrucarol in these urine samples.

The results imply that these parents were not exposed to *S. atra* or satratoxin in amounts large enough to result in detectable amounts of verrucarol in these urine samples. There are however, many assumptions that have been made throughout the course of these analyses: a) exposure to *S.atra* occurred; b) *S. atra* produced satratoxin; c) satratoxins are metabolized to compounds which hydrolyze to verrucarol (in basic solution); d) concentrations of satratoxin are great enough to be detected. In addition to these assumptions, we do not know if in fact satratoxin is the prinsiple toxicant in *S. atra*. It has been suggested that other compounds could be present in *S. atra* (spirolactones and lactams), or that a synergistic effect may be occurring with these compounds or other environmental factors that may be associated with this illness. Presently, fungus samples from the homes of ill infants are being analyzed to determine the types of toxicants present in them. Once these results become available, that information will be used to improve our present method, and provide direction for future studies to identify the cause of IPH.

Arvada, CO 80002

The production, storage, and disposal of nitroaromatic and nitramine explosives and propellants at military installations worldwide present serious environ-mental problems. Several of these explosives and their degradation products are hazardous to human and ecosystem health [1,2] and are subject to Federal regulatory statutes. These water-soluble compounds have been demonstrated to be environmentally mobile by their presence in ground-water samples [3]. Thus, nitroaromatic and nitramine explosives and propellants are significant site-specific water contaminants.

Typically, explosives are separated by high-performance liquid chromatography (HPLC) and identified by ultraviolet photodiode-array detection (PDA). Consequently, the identification of most explosives is not definitive, particularly for the determination of unknown degradation products in environmental matrices. A new analytical method was developed to (1) improve the specificity and reliability of identification, and (2) develop an experimental design to en-hance identification of unknown compounds in surface-water, ground-water, and soil matrices.

An HPLC with PDA was coupled to a triple-stage-quadrupole mass spectrometer using a thermospray interface. Selected compounds were separated under isocratic conditions using an octadecylsilane liquid-chromatographic column (5-micrometer particle size, 4.6-millimeter internal diameter, 250-millimeter length). Electron-capture negative ionization (ECNI) HPLC-thermospray mass spectrometry (HPLC/MS) and HPLC-thermospray tandem mass spectrometry (HPLC/MS/MS) were applied to determine molecular weight and confirm molecular structure.

For optimal detection of known compounds, selected-ion-monitoring (SIM) MS was used. Calibration curves fit quadratic models, with correlation coefficients typically exceeding 0.995 over two orders of magnitude. Instrument-detection limits ranged from 2.5 to 10 nanograms per injection, resulting in estimated method-detection limits from 50 to 200 nanograms per liter for typical water samples. The identities of nitroaromatic explosives were confirmed by combining optical absorbance and ECNI/SIM/MS spectral evidence, improving reliability and selectivity.

Mass spectra produced by HPLC/MS were characteristically simple, usually consisting of molecular ions and acetic acid or acetate ion adducts (Figure 1). In order to elucidate com-pound structures, MS/MS spectra of many explosives were collected. Product-ion (PI) MS/MS spectra were dominated by neutral losses of OH, NO, and 2(NO). Nitrobenzene, 2-, 3-, and 4-nitrotoluene, and 4,6-diamino-2-nitrotoluene PI spectra were dominated by the presence of NO_2^-. 2,4,6-Trinitrotoluene, 2-amino-4,6-dinitrotoluene, and 2,4-dinitrotoluene exhibit a pri-mary loss of OH, characteristic of ortho-substituted nitrobenzene ions [4]. 1,3,5-Trinitroben-zene, 3,5-dinitroaniline, 1,3-dinitrobenzene, 4-amino-2,6-dinitrotoluene, and 2,6-dinitrotoluene PI spectra are dominated by the loss of NO. 2-

Amino-4,6-dinitrotoluene also has an approx-imately 50 percent larger 2(NO) loss relative to total-ion-current intensity than 4-amino-2,6-dinitrotoluene. PI/MS/MS spectra and the relative abundances of specific ion fragments provide tools for unknown compound identification, including isomer specific identification.

Unknown compounds were first indicated by optical spectra. Molecular ions were identified by full-scan MS on the sample extract. A PI/MS /MS experiment was performed to elucidate structure when molecular ions were identified. Following tentative identification, a compound's identity was confirmed with a standard, if available. Molecular ions for compounds from a settling-pond sample are shown in Figure 2. These compounds were tentatively identified as 2-amino-6-nitrotoluene, 4-amino-2-nitrotoluene, and 2-amino-4-nitrotoluene.

Low detection limits and reliable identification of explosives and related degradation products using SIM/HPLC/MS were developed into an analytical method applicable to ambient concentrations in surface-water, ground-water, and soil matrices. Using ECNI, this method is relatively free of interferences restricting detection to compounds capable of electron capture. An experimental design is proposed to facilitate the identification of unknown nitroaromatic compounds and degradation products. The suitability of selected-reaction-pair HPLC/MS/MS as a detection method for selected compounds is also discussed.

MS/MS CID FRAGMENTATION PROCESSES IN SOME PESTICIDES

Jehuda Yinon

Weizmann Institute of Science, Department of Environmental Sciences and Energy Research, Rehovot 76100, Israel.

Because of their widespread use, pesticide residues and their degradation products are currently detected in various environmental matrices, such as soil, water and air. Analytical methods for trace detection of these pesticides and their degradation products require high sensitivity and selectivity. Tandem mass spectrometry (MS/MS) with collision induced dissociation (CID) is able to identify trace amounts of organic pollutants in a variety of matrices with a high degree of selectivity. The recorded daughter-ion spectrum will enable the characterization of the analyzed compound by providing structural information leading to its unambiguous identification.
We have studied the MS/MS CID fragmentation processes of a series of pesticides, including atrazine, simazine, linuron, diuron, alachlor, aldicarb and carbofuran. CID mass spectra of the molecular and major fragment ions were recorded with a Finnigan MAT TSQ 70 triple quadrupole.
Fig. 1 shows the CID fragmentation map of simazine, which was deducted from the CID mass spectra. An example of the use of the CID data is the GC/MS/MS of carbofuran, which has a very small molecular ion. Fig. 2a shows the MS/MS mass chromatograms of the EI fragment ion at m/z 164 (precursor ion), and the main daughter ion at m/z 149. Fig. 2b shows the the CID mass spectrum of the ion at m/z 164. These were recorded on a Varian 3D GC/MS -ion trap, equipped with MS/MS capability and a Septum Programmable Injector (SPI).

Spray application is one of the most familiar operations connected with pesticide use, resulting in large losses of pesticides to the atmosphere. Photodecomposition or photochemical stability are important factors influencing the pesticide composition and residence time in the atmosphere, and determining the distance over which pesticides are transported in the atmosphere. It is therefore of great interest to be able to predict the stability and/or decomposition of pesticides exposed to UV sunlight.
We have found that there seems to be a possible similarity between UV chemical degradation products of pesticides and CID fragment ions of the same compounds. An example is given in Fig. 3 which shows the UV decomposition [1] and CID fragmentation of atrazine. A similar UV decomposition product [2] and CID fragmentation ion was also found in alachlor.
More work has to be done on UV chemical degradation in order to determine whether CID mass spectra can be used to predict the decomposition of pesticides exposed to sunlight.

The widespread use of pesticides in agriculture has led to a ubiquitous presence of these compounds in the environment. The health effects of non-persistent pesticides in exposed and general human populations is not yet known. The extensive use of these compounds has created a great interest in developing laboratory and epidemiology studies on possible health risks. We have recently developed methods for a pilot study to analyze blood samples collected from farmers and their families in two states. These samples were collected before, during, and after pesticide application. A target group of non-persistent insecticides, herbicides, and fungicides have been identified and isotope dilution mass spectrometric methods have been developed.

The analysis of these pesticides in serum requires an efficient sample preparation procedure followed by high resolution chromatography and high resolution mass spectrometry so that interferences do not hinder the analysis. The method developed for the quantification of this complex mixture of non-persistent pesticides includes a solid phase extraction of serum that has been treated with an equal amount of saturated ammonium sulfate (Figure 1). This procedure yields an extract which is analyzed by GC/MS. A DB-1701 column is employed for the GC separations and the pesticides are recorded on a high resolution magnetic sector mass spectrometer (VG 70-4SE). Specificity and sensitivity are obtained by ionization with low energy electron impact (30 eV) and selective ion monitoring at a resolution of 10,000. Employing this procedure with isotope dilution mass spectrometry allows for an accurate and sensitive method of quantification. Parts-per-trillion (ppt) levels of many of the non-persistent pesticides were found in the serum pools from the general population . An example of the data from a farm is shown in Figure 2. Serum levels tended to be in the low ppt for pre-application season. During application, pesticide levels typically rose to parts-per-billion in applicators and were then eliminated from the body in subsequent days. Spouses levels also tended to rise during the pesticide application. In addition to the current analytical methods, new approaches such as ultra-sensitive, fast, multidimensional GC/high resolution MS (2DGC/MS) are currently being developed. An example of a 2DGC/MS chromatogram of a pesticide mix is shown in Figure 3

ESI MS/MS Determination of a New Cationic Surfactant in River Water

Thomas R. Mertens, Jocelyn C. Dunphy[1], Karen M. Kershner, and Samuel J. Morris, III
Laundry & Cleaning Products Development, Analytical Sciences Department
The Procter & Gamble Company
5299 Spring Grove Avenue, Cincinnati, OH 45217

Introduction: The need to quantify trace levels of surfactants in environmental samples is critical for the environmental safety assessments of new laundry and cleaning product chemicals and the long-term environmental defense of existing chemicals. New liquid introduction MS techniques (Flow-FAB, electrospray) have significant advantages over conventional methods (usually pre-concentration followed by HPLC) for measuring trace levels of surfactants in environmental samples. These include high throughput, high selectivity, less sample preparation required, and ultimately lower detection limits, especially for compounds that lack a chromophore, like most cationic surfactants. We needed to develop a rapid, sensitive method to determine the new cationic, di-(ethanolester)dimethylammonium chloride (DEEDMAC), in river water to support exposure levels of this biodegradable material during aquatic toxicity studies. (DEEDMAC structure given in Figure 1).

Experimental: Using a Finnigan TSQ-700 with a Finnigan API source in the ESI mode, ESI/MS/MS conditions were developed and optimized to determine DEEDMAC in river water samples. DEEDMAC gave excellent ESI response in the positive ion mode using 50:50 v/v mixture of n-propanol and water containing 7.5 mM $NH_4^+HCOO^-$. Figure 1 shows a spectrum of DEEDMAC derived from soft tallow fatty acid. The C16,C18:1 homolog (most abundant) was chosen to act as a tracer for the complex mixture of homologs that are present in commercial grade DEEDMAC. Low energy MS/MS (29 ev) of DEEDMAC (parent ion 636.6) and a pure deuterated (C16,C18) homolog (parent ion 641.6) provided fragments corresponding to the esterified fatty acids. M/z 308.3 and 310.3, respectively, were chosen for selected reaction monitoring (SRM). Typical ESI conditions for this instrument, (4500v ESI spray) were used. Due to the selectivity of SRM, no chromatography or extensive sample preparation was needed for the river water samples. Thus, a simple scheme was developed in which river water samples are taken, acidified to pH 3, filtered using 0.45 um filters, and diluted 1:1 with n-propanol with 15 mM $NH_4^+HCOO^-$, and injected using an HPLC pump (100 uL inj. volume, flow rate 0.1 mL/min) following addition of the deuterated internal standard. Quantitation (peak areas) is performed using a linear fit to calibration curves constructed to bracket expected sample levels. A typical calibration curve is shown in Figure 2.

Results: We have found that the simple sample preparation serves both to prevent any adsorption to containers (due to addition of organic solvent) and also preserves samples for at least two weeks when stored frozen. We make the use of a low and high calibration curve to ensure optimal quantitation of DEEDMAC by having the standards and internal standards at a concentration near the concentration of each sample. Blanks must be injected between each sample/standard injection to minimize carryover. Validation (spike/recovery) results are outlined in the following table. The MS detection limit was found to be ~0.020 ppm, which corresponds to 0.040 ppm in river water samples.

	10 ppm Sample	1.6 ppm Sample	0.05 ppm Sample
Avg. Concentration	10.7	1.67	0.064
Percent Recovery	107.1	104.1	127.5
Std. Dev.	0.18	0.045	0.005
Relative Error %[1]	3.0	4.97	9.02
number of samples	4	4	6

[1]Calculated as $100(t' s_n)/n$*avg. conc., where t' is at the 95% confidence level

Conclusions: A rapid, sensitive method was developed for DEEDMAC at trace levels in river water. The specificity of selected-reaction monitoring makes sample preservation simple, and the sensitivity obviates the need for sample concentration techniques, which are challenging for cationic surfactants. This method was successfully used for the analysis of over 300 samples for 5 river water aquatic studies. Variations of this methodology can be used for other environmental applications with cationic surfactants.

Figure 1: Electrospray MS Spectrum of DEEDMAC.

Advantages and Applications of Mass Peak Profiles Plotted from Selected Ion Recording Data

Andrew H. Grange* and Joseph R. Donnelly
Lockheed Environmental Systems & Technologies Co., 980 Kelly Johnson Dr., Las Vegas, NV 89119
William C. Brumley and G. Wayne Sovocool
U.S.E.P.A., Environmental Monitoring Systems Laboratory, PO Box 93478, Las Vegas, NV 89193-3478

Advantages. Exact masses of molecular ions can provide unequivocally, the elemental composition of unknown compounds, provided the error and precision in the mass determinations are small. In Figure 1, a mass peak profile is plotted as the areas under the chromatographic peaks in the ion chromatograms for m/z ratios monitored across the profile. Compared to KVE scanning at a mass resolution of 10,000 using a VG70-250SE double focusing mass spectrometer, plotting mass peak profiles from selected ion recording data (MPPSIRD) provides 3 times greater scan speed with 17 times more sensitivity while operating at 20,000 resolution. Error limits for exact masses computed as the weighted average of several points across the profile are ±2.5 ppm, ±1.5 ppm and ±1.0 ppm when 3, 7 or 15 determinations are made. This high precision greatly reduces the number of possible compositions, which increase rapidly with the mass and number of elements an ion might contain. Preparation of SIR descriptors and processing of the data are done automatically by procedures written in the RSX and VG languages on the data system and in Lotus 1-2-3™, Reflection 4.2™ and WordPerfect 5.1™ on an ancillary personal computer.

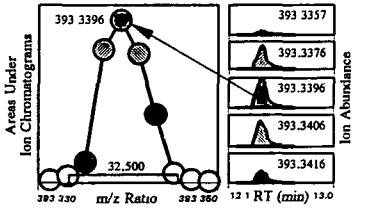

Figure 1.

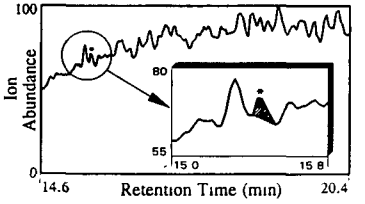

Figure 2.

Applications. Shown in Figure 2 is part of the total ion chromatogram for a GC/MS run of an extract from a Superfund site sample that contained a high level of PCBs. Four poor library matches were found for the background subtracted mass spectrum of the trace component responsible for the chromatographic peak marked with an asterisk. For each match, the molecular ion weighed 266 Da.

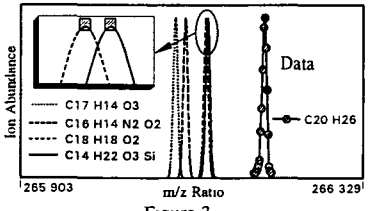

Figure 3.

The profiles for the four molecular ions were calculated at 20,000 resolution and plotted in Figure 3. The boxes on top of the two profiles closest in mass shown in the insert correspond to an error limit of ±2.5 ppm. Hence, any of the 4 compositions could have been identified from its exact mass. The profile obtained and shown in Figure 4 was also plotted in Figure 3 and corresponded to $C_{20}H_{26}$, which might be an alkylated biphenyl. This composition for the trace component in the complex mixture rejected all four library matches. Thus, MPPSIRD is a powerful technique for proving that no compounds with targeted compositions are present to a very low detection limit.

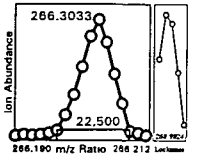

Figure 4.

MMPSIRD is an important quality assurance tool. It can be used to document the resolution required to avoid interference from coeluting compounds that yield ions with masses similar to an analyte ion. In Figure 5, the profiles for the molecular ions of acridine on the left and of anthracene and/or phenanthrene containing a ^{13}C atom on the right are well separated at 22,000 resolution. Lower resolution would result in interference for quantification of acridine in creosote containing soils if a single m/z ratio atop the acridine profile were monitored. In addition, the resolution during elution of each analyte is routinely determined from the profile width at 5% of its maximum.

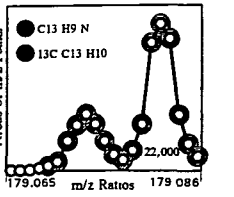

Figure 5.

M+1 and M+2 profiles. Multiple compositions are often calculated for large ions within the error range for exact mass determinations. The shape of the M+2 profile, the exact masses of the M+1 and M+2 profiles, and the relative abundances of the M+1 and M+2 profiles provide 5 criteria for rejection of erroneous compositions. Because only 22 m/z ratios are used, a split SIR descriptor simultaneously monitors the top 60% of the M, M+1 and M+2 profiles with 6 m/z ratios each and the top 40% of the lock mass profile with 4 m/z ratios. A model based on the Gaussian distribution, written in QuickBASIC™, provides plots of the full M+1 and M+2 profiles, labeled with predicted masses and relative abundances for the partial profiles. For an unknown compound found in an extract of a Superfund site sample, one of eight compositions ($C_{28}H_{41}NS$) was identified based on the unique shape of the M+2 profile and confirmed by rejection of the other seven compositions based on the exact masses and relative abundances of the M+1 and M+2 profiles. For a minor component in another environmental extract, a good library match suggested the compound was bis(2-bromophenyl)diazene ($C_{12}H_8N_2Br_2$). But the exact mass and %M+1 identified $C_{13}H_8OBr_2$ as the composition and the full scan spectrum was consistent with a dibromomethylfuran.

Larger Mass Ions. For four standards with molecular weights between 536 and 766 Da, 15 mass and relative abundance determinations were made using probe introduction into the ion source. The mass error was <1.0 ppm for the M, M+1 and M+2 profiles for all 4 standards. This table shows the errors in averaged masses and relative abundances for the correct compositions and the compositions most difficult to reject, which are italicized. The emboldened errors failed the criteria and eliminated incorrect compositions.

Mass of M (Da)	Composition	ΔM	ΔM+1	ΔM+2	Δ%M+1	Δ%M+2
		----(ppm)		-----	(% %M+1 &	%M+2)
536.2621	C28 H40 O10	-0.3	-0.0	+0.5	+0.1	-0.1
536.2635	*C29 H36 O6 N4*	-2.9	-2.1	-2.1	-1.9	+0.1
536.3151	C34 H40 O2 N4	+0.1	-0.2	-0.2	+0.1	-0.0
536.3138	*C33 H44 O6*	+2.5	+1.8	+2.5	+2.1	-0.1
622.2791	C36 H38 O6 N4	+0.6	+0.2	-0.95	-0.0	+0.0
622.2796	*C38 H45 N2 P3*	-0.2	-0.7	-2.2	-1.5	+0.4
766.3942	C44 H54 O8 N4	-0.6	+0.1	+0.5	-0.7	+0.1
766.3946	*C46 H61 O2 N2 P3*	-1.02	-0.6	-0.4	-2.2	+0.3

When multiple compositions remain possible for a large molecular ion, fragment (F), F+1 and F+2 profiles are monitored. Because their masses and the masses of neutral loss fragments obtained by difference are smaller, unique compositions are obtained and the molecular ion is identified as the sum of its parts. Compositions are determined without knowledge of the sample's history.

Conclusion. MPPSIRD is an important new analytical technique for double focusing mass spectrometers. The basic capabilities needed to perform MPPSIRD are already included in the data system software. Custom procedures permit automation of the technique, and a simple model allows planning of experiments and interpretation of the data obtained.

BIMOLECULAR GAS-PHASE EXCHANGE OF ALKALI METALS BETWEEN CATIONIZED BIOMOLECULES AND NEUTRAL CROWN ETHERS

Marshall Pope*, Steven Hofstadler‡ and David V. Dearden
Department of Chemistry and Biochemistry, Brigham Young University, Provo, UT
‡Pacific Northwest Laboratories, Battelle, Richland, WA

Introduction

Electrospray ionization of polypeptides and nucleic acids often yields ions containing sodium or potassium charge carriers. These alkali adducts are frequently the residue of ionic buffers used to preserve protein conformation in solution or artifacts of a natural matrix such as blood plasma. Measures taken in solution to desalinate these samples are hindered by the desire to maintain native conformation. We show here that ion-molecule chemistry is an alternate means of removing alkali metal ions from multiply-charged biomolecules. Ion-molecule reactions of multiply charged polypeptides with crown ethers result in adduction of the crown if protons are the only charge bearing species, or desalting (removal of an alkali cation) if alkali metals are among the attached charge carriers. Both product ions, the desalted peptide and the crown/alkali metal complex, are observed in the latter case.

Experimental

All experiments were performed in a Fourier transform ion cyclotron resonance mass spectrometer (model APEX 47e, Bruker Instruments) equipped with an Analytica electrospray ion source external to the high-field region of a 4.7-Tesla superconducting magnet. Neutral crowns (12-crown-4, 15-crown-5, 18-crown-6) were purchased from Parish Chemical (Orem, UT). 12-crown-4 and 15-crown-5 were purified by sequential freeze-pump-thaw cycles prior to introduction on a Varian leak valve. 18-crown-6 was used unaltered and introduced on an unheated solids probe. Twelve hours of gentle bake out were sufficient to eliminate methanol and reach a stable pressure of ~6 x 10^{-8} mbar. Proton transfer kinetics for the reaction of acetone and 18-crown-6 (assuming unit efficiency) have been used to coarsely determine a response factor for our Balzers IMG 233 ionization gauge[1]. Nozzle skimmer voltages varied from 50 to 80 V. Extensive adduction may be observed in neutral water solutions containing millimolar concentrations of alkali metals. Electrostatic focusing and injection techniques were used to transfer ions from the source to the field-corrected ("Infinity") trapping cell of the instrument. Ion-molecule kinetics experiments were performed with ions isolated using conventional FTICR techniques (chirp and shot ejection of unwanted ions).

Results and Discussion

The trapped-ion mass spectrum of electrosprayed gramicidin S (GS) c[Val-Orn-Leu-Phe-Pro-Val-Orn-Leu-Phe-Pro] shown in figure 1 is typical of peptides sprayed from alkali metal containing solutions. To the far right, the envelope of the +1 charge state is dominated by $NaGS^+$ at 1163 m/z. Protonated gramicidin S appears at 1141 m/z. Impurities resulting from leucine or isoleucine substitution for valine shadow each peak at +14 m/z in the +1 charge state and +7 in the +2 charge state. Although the magnification of the inset clips the isotopic distribution of H_2GS^{2+}, four sodium adducts are easily identified within the +2 charge state. A .5 m/z isotopic spacing confirms a net charge of +2. The individual metal adduct states are separated by 11 m/z, indicating that each adduct displaces a proton.

The progress of the charge shifting reaction following isolation of the +2 charge state is illustrated in figure 2. Each of the doubly-charged, multiply-sodiated peaks gives rise to a corresponding singly-charged gramicidin with one less metal adduct. In addition, the other stripping product, the crown-sodium complex, accumulates. If sodium is not present as in H_2GS^{2+}, adducts of the crown ether and peptide ion form.

Gross and Williams[2] have demonstrated that the protons attached to gas phase H_2GS^{2+} are on the terminal amine groups of the two ornithine side chains. It is possible that these functional groups also participate in alkali metal binding, however the smaller extent of charge transfer associated with alkali metal cations suggests that these metals prefer harder Lewis bases or multidentate bases. Another explanation for the loading we observe is coordination to tautomerized peptidic oxygen. Proton displacement from amide sites along the peptide backbone would result in a zwitterionic cation without a shift in charge state. If such sites actually exist, the group I binding affinity of the peptidic oxygen anion is expected to exceed that of 12-

THE IMPORTANCE OF CHARGE-SEPARATION REACTIONS IN ELECTROSPRAY IONIZATION TANDEM MASS SPECTROMETRY

Jeanette Adams, Fred H. Strobel, and Alex Reiter, Department of Chemistry and the Emory University Mass Spectrometry Center, Emory University, Atlanta, GA 30322

Research was conducted to determine: (1) why low-mass complementary ions from charge-separation reactions are missing in ESI/MS-MS spectra acquired using B/E scans; (2) whether the kinetic energy release (KER) in metastable ion charge-separation reactions can be related to intercharge distance; and (3) whether the information from the KER can be used to understand structure and reaction mechanisms. MS-MS B/E and MS-MS MIKES experiments of $(M + 2H)^{2+}$ ions of angiotensin II were performed using a JEOL JMS-SX102/SX102A/E five-sector, tandem mass spectrometer.

The MS-MS B/E spectrum shows abundant doubly charged product ions and one weakly abundant b_6^+ singly charged product ion (Figure 1). The low-mass $y_2^{\cdot+}$ complementary ion is missing. In contrast, the MS-MS MIKES spectrum shows a highly abundant b_6^+ ion and a relatively highly abundant $y_2^{\cdot+}$ ion (Figure 1). Narrow MIKES scans of these two ions show that they are broad and dished (Figure 2). The kinetic energy release distributions (KERDs) give a most probable KER (T_{mp}) of 0.902 eV (Figure 3).

Using Coulomb's Law and assuming a dielectric constant of 1.0, the T_{mp} gives an intercharge distance of 16.0 Å. This value can be compared to distances obtained from SYBYL molecular dynamics calculations when one proton is fixed on the C-terminal amino acid and the other is placed in various positions in the peptide (Figure 4). The calculations give an intercharge distance of 15.8 Å for having one proton on the Arg side chain, which is in accord with the experimental measurement.

The intercharge distance can be used to address possible mechanisms for formation of the $b_6^+/y_2^{\cdot+}$ complementary ion pair. The accepted mechanism for formation of b^+ ions, which gives an N-terminal acylium ion, is not in accord with the experimental data In contrast, a "charge-remote" rearrangement mechanism, which is commonly accepted for formation of y^+ ions, is in agreement.

The experimental data reveal that product ions from charge-separation reactions are severely discriminated against in B/E scans, and partially discriminated against in MIKES experiments. Consequently, MIKES experiments provide a better, but not accurate, estimate of relative product ion abundances. The agreement between the measured KER and the calculated value suggests that these types of charge separation reactions can be used to address structure and reaction mechanisms.

The Correlation of Fragmentation and Structure of a Protein

Qinyuan Wu, Xueheng Cheng, Steven Van Orden, Ray Bakhtiar and Richland D. Smith*
Pacific Northwest Laboratory, Richland WA 99352

Characterization of proteins of similar structures is important to understanding the biological function of the proteins and the processes with which they are involved. Cytochrome *c* variants typically have similar sequences, and have similar conformations in solution with almost identical absorption spectra and redox potentials. We chose cytochrome *c* 's from bovine, tuna, rabbit and horse as a model system in studying large biomolecules using MS^n of multiply charged ions generated from electrospray ionization (ESI).

All of the experiments reported here used an external source ESI-FTICR (7 T) instrument. SORI-CID pulses were placed at +/- 1500 Hz of the cyclotron frequency of the parent ions and the irradiation time was 300 ms. N_2 gas was pulsed into the cell for trapping and dissociation. For each stage of MS, the precursor ions were isolated using SWIFT. Cytochrome *c* samples were dissolved in 5% HOAc and the 15+ state ions were studied.

Due to the high resolution capability, we can assign over 95% of the product ion peaks from SORI-CID with an accuracy better than 10 ppm. All four variants were effectively dissociated and showed distinctive, but complicated MS/MS spectra. Fig. 1 shows the relative probability of fragmentation along the amino acid sequences for bovine and horse cytochrome *c*, whose sequences are only different by three residues at position 47, 60, and 89. In general, fragmentation does not appear at charge sites (basic residues, shown as full length lines in Fig. 1). The silent regions in residues 10-20 and around residue 80 correspond to the heme-binding pocket. Fragmentation mainly occurs at the N-, C-, 60's helices and residues 40-50. Such a fragmentation pattern seems to correlate to the known feature of denatured cytochrome *c* in solution, and is consistent with gas phase H/D exchange results. We tentatively attribute the dramatic difference (Fig. 1) between bovine and horse cytochrome *c* patterns as arising mainly from replacing Gly with a charged Lys at the 60th position. Lys^{60} and Lys^{79} have been shown to be close in space in X-ray structures of the native state cytochrome *c*. Our observation suggest that their charge repulsion causes changes in 3-D structure, resulted in the changes in fragmentation at Pro^{76} and residues 40-70.

We have also succeeded in performing up to four stage of MS without using quadrupole cooling technique. In Fig. 2, 15+ state tuna cytochrome *c* ions are dissociated and the resulting b_{102} fragment is then selected to be further dissociated. At MS^4, b_{98} ions generate complimentary ions with isotopic resolution. Such MS^n techniques are very useful not only in identifying internal fragmentation of the known structures, but also in analysis of proteins having small structural modification or unknown sequences.

These results indicate that the dissociation of the cytochrome *c*'s is influenced by the higher order structures and charge location, in addition to the amino acid sequence. Low energy CID may be useful in probing small structural differences of proteins in the gas phase.

This work was supported by Laboratory Directed Research and Development funds by Pacific Northwest Laboratory through the U.S. Department of Energy. Pacific Northwest Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy under Contract DE-AC06-76RLO 1830.

Quadrupole Ion Trap Study of Ion-Ion Chemistry of Multiply-Charged Ions

William J. Herron, Douglas E. Goeringer, and Scott A. McLuckey
Oak Ridge National Laboratory

The gas phase ion chemistry of multiply-charged biological polymers, such as oligonucleotides and proteins is a new and growing field of research. Understanding the gas phase chemistry of these species is important both to obtaining information on ion mass, structure and reactivity and to determining the relationship between gas phase and condensed phase chemistry. Gas phase ion chemistry studies to date have principally emphasized unimolecular fragmentation following some form of activation and ion-molecule chemistry, primarily proton transfer and hydrogen/deuterium exchange. The experiments described here constitute an important first step in understanding the ion-ion chemistry associated with the reactions of multiply-charged ions with oppositely charged ions in the gas phase.

We have adapted an electrospray/quadrupole ion trap combination to incorporate a means for generating positive ions in the ion trap to interact with negative ions injected into the ion trap from an external source. The reaction (mutual neutralization) of O_2^+ and NO_2^- provided an initial confirmation of ion-ion recombination in the ion trap. (1) However, our long range interest lies in observing ion-ion reactions between singly-charged positive ions and multiply-charged negative ions. The unique advantage of studying such reactions is the ability to observe and further study both the reactants and the product ions.

We have studied ion-ion proton transfer reactions (Figure 1) involving protonated pyridine and multiply-charged anions of short single-stranded poly A deoxynucleotides. (2) More recently we have expanded the scope of our studies to include ion-ion electron transfer reactions (Figure 2). We have examined multiply-charged anions of short single-stranded poly A deoxynucleotides with singly-charged rare gas radical cations. (3)

Figure 1. Isolated multiply-charged oligonucleotide anions were allowed to react with protonated pyridine cations for 1 s within a quadrupole ion trap mass spectrometer. The isolated triply-charged reactant anions $d(A_4 - 3H)^{3-}$ (a) undergo ion-ion proton transfer with protonated pyridine to form doubly-charged product anions $d(A_4 - 2H)^{2-}$ and (b) isolated doubly-charged product anions from the first ion-ion proton transfer, react with protonated pyridine to form singly-charged product anions $d(A_4 - H)^{1-}$.

Figure 2. Isolated multiply-charged oligonucleotide anions were allowed to react with xenon radical cations for 200 ms within a quadrupole ion trap mass spectrometer. The isolated triply-charged reactant anions $d(A_4 - 3H)^{3-}$ undergo ion-ion electron transfer with Xe^+ to form doubly-charged product anions $d(A_4 - 3H)^{2-\cdot}$. Although in this example, the doubly-charged product anion is not observed, the extensive fragmentation is consistent with the doubly-charged radical anion fragmenting either by charged base loss and subsequent fragmentation along the phosphodiester linkage or by neutral base loss and fragmentation along the phosphodiester backbone.

ISOMERIC STRUCTURES FOR UBIQUITIN IONS PRODUCED BY ELECTROSPRAY FTMS

Carolyn J. Cassady and Nigel Ewing
Department of Chemistry, Miami University, Oxford, OH 45056

The determination of gas-phase ion structures is an active area of research which increases our understanding of the processes that occur inside a mass spectrometer. Historically, this work has been limited to singly charged ions because these species were readily generated by common ionization techniques. The recent development of electrospray ionization mass spectrometry (ESI MS), however, has made possible the formation of large multiply charged ions from samples such as proteins and peptides. The current investigation demonstrates that the same MS/MS techniques utilized to elucidate isomeric structures of singly charged ions can be successfully applied to multiply protonated ions, $[M+nH]^{n+}$, generated by ESI. Conclusive evidence for at least two structures of $[M+12H]^{12+}$ from the protein ubiquitin has been obtained by deprotonation reactions, hydrogen/deuterium (H/D) exchange reactions, and collisionally activated dissociation (CAD). In addition, it is found that the $[M+12H]^{12+}$ population generated directly by ESI is not identical to the $[M+12H]^{12+}$ population formed by gas-phase deprotonation of $[M+13H]^{13+}$.

Electrospray ionization was achieved using an Analytica of Branford source in the external ion source of a Bruker CMS-47X Fourier transform mass spectrometer. Ubiquitin ions, $[M+nH]^{n+}$, containing 7-13 attached protons were produced. $[M+12H]^{12+}$ were m/z-selected by resonant frequent ejection techniques. For ion/molecule reaction studies these ions were allowed to react with static pressures of neutral reagents present in the FTMS cell. In CAD experiments, sustained off-resonance irradiation (SORI)[1] was used to induce low energy fragmentation.

Ubiquitin (M_r = 8564.8) is a monmeric peptide containing 76 amino acid residues. It has 13 basic sites that may be preferentially protonated in the gas-phase. We recently reported that $[M+12H]^{12+}$ of ubiquitin were rapidly deprotonated by compounds having gas-phase basicities (GB) greater than or equal to that of n-propylamine (GB = 210.1 kcal/mol^2).[3] These reactions exhibit linear pseudo-first-order kinetic behavior and provide no evidence for more than one $[M+12H]^{12+}$ structure. In contrast, deprotonation reactions of ESI-generated $[M+12H]^{12+}$ with the less basic ammonia (GB = 195.6 kcal/mol^2) and 2-fluoropyridine (GB = 202.8 kcal/mol^2) reveal non-linear pseudo-first-order kinetic behavior that suggests the presence of at least two ion structures. With ammonia, 60.4($\pm$9.6)% of $[M+12H]^{12+}$ react with a rate constant (k_{exp}) of 8.4($\pm$4.4) x 10^{-12} cm^3 molecule^{-1} s^{-1}, while the remaining 39.6($\pm$9.6)% of the ions are slower to react with k_{exp} = 5.4($\pm$2.0) x 10^{-13} cm^3 molecule^{-1} s^{-1}. For 2-fluoropyridine the difference is more pronounced: fast-reacting ions account for 45.8($\pm$4.5)% of the $[M+12H]^{12+}$ and have k_{exp} = 3.8($\pm$1.5) x 10^{-10} molecule^{-1} s^{-1}, while 54.2($\pm$4.5)% of the ions react with k_{exp} = 2.8($\pm$0.2) x 10^{-12} cm^3 molecule^{-1} s^{-1}. Interestingly, this behavior appears to be unique to n = 12 and was not seen with n = 13 and 11.

In addition to production directly by ESI, $[M+12H]^{12+}$ were formed by removal of a proton from "fully protonated" $[M+13H]^{13+}$ with 2-fluoropyridine. Surprisingly, these ions show kinetic evidence for only one $[M+12]^{12+}$ population and react with a rate constant of 5.1($\pm$0.8) x 10^{-12} cm^3 molecule^{-1} s^{-1}. This suggests that deprotonation of $[M+13H]^{13+}$ (which yields exclusively slow-reacting ions) produces a more homogeneous and energetically stable ion population than the ESI process itself. Thus, ESI is less selective than ion/molecule reactions at protonating (or deprotonating) basic sites on proteins.

The presence of two ubiquitin $[M+12H]^{12+}$ populations is also indicated by reactions with D_2O and CD_3OD. These species do not deprotonate $[M+12H]^{12+}$; instead, H/D exchange occurs. The ions that are rapidly deprotonated also rapidly exchange the first 11$\pm$1 hydrogens. The ions that are slower to deprotonate are slower to H/D exchange. Again, this behavior is not found with n = 13 and 11.

Additional confirmation of at least two different $[M+12H]^{12+}$ structures was provided by SORI CAD experiments performed as a function of reaction time with ammonia and with 2-fluoropyridine. The reaction time, during which ubiquitin's fast-reacting $[M+12H]^{12+}$ is selectively depleted, occurs before SORI activation. The spectra reveal a gradual shift in the relative abundances of several fragment ions as the deprotonation reaction progresses. After the reaction has removed the fast-reacting $[M+12H]^{12+}$ population, this shift ceases and the CAD spectra remain virtually unchanged as the reaction time is increased. For example with the y_{58} product ions, the first 1.0 second of the reaction time yields marked changes in the relative abundances of y_{58}^{8+}, y_{58}^{9+}, and y_{58}^{10+}; however, beyond 1.0 second the ratios remain relative stable. Based upon k_{exp} and the experimental conditions, 94 % of the fast-reacting $[M+12H]^{12+}$ should be removed within the first 1.0 second. Therefore, after longer reaction times only the slow-reacting $[M+12H]^{12+}$ still remains for study by SORI CAD. In addition, the CAD spectra do not change as a function of reaction delay when the amine is replaced with argon. This is important because it indicates that collisional thermalization is not responsible for the phenomenon of changing product intensities as a function of reaction — and thus collision — time.

The SORI CAD spectra for $[M+12H]^{12+}$ formed by deprotonation of $[M+13H]^{13+}$ resemble the spectra of the slow-reacting ions and are independent of reaction delay with 2-fluropryidine or ammonia. This agrees with the deprotonation reaction results that indicated that protonation of $[M+13H]^{13+}$ produces only the slow-reacting $[M+12H]^{12+}$.

The two ubiquitin $[M+12H]^{12+}$ ion structures may be conformational isomers, isomers related to differences in protonation site, or both. In considering the CAD spectra for $[M+12H]^{12+}$, several notable changes occur as the fast-reacting ions are selectively removed by deprotonation reactions. For example, the abundances of y_{58}^{8+} and y_{24}^{4+} are highest when both $[M+12H]^{12+}$ isomers are present at short reaction times but decrease as the fast-reacting ions are depleted. In contrast, production of y_{58}^{9+}, y_{58}^{10+}, and y_{24}^{5+} increases as the reaction progresses, meaning that these fragments are formed in greater abundance from slow-reacting $[M+12H]^{12+}$. The y_{58} fragment contains amino acid residues 19 through 76 of ubiquitin, which have 10 of the preferred basic sites; y_{24} contains residues 53 through 76 with 5 basic sites. In the CAD spectrum of "fully protonated" $[M+13H]^{13+}$, y_{58} has a maximum charge of 10+ and y_{24} has a maximum charge of 5+. Thus, the preferential formation of y_{58}^{10+} and y_{24}^{5+} for slow-reacting $[M+12H]^{12+}$ suggests that these ions may be protonated at all 10 basic sites of residues 19 through 76 and all 5 sites of residues 53 through 76, respectively. That is, for slow-reacting ions the absent proton is near the N-terminus. For fast-reacting $[M+12H]^{12+}$, the more abundant y_{58}^{8+} supports loss of a proton from a basic site between residues 19 and 76, while the more abundant y_{24}^{4+} suggests that a proton is absent between residues 53 and 76. Therefore, fast-reacting ions may be missing a proton near the C-terminus. These changes in protonation site could also induce changes in 3-dimensional conformation.

Ubiquitin $[M+12H]^{12+}$ is the only multiply charged ion systems to date that has been subjected to structural studies that combine ion/molecule reactions and CAD. This combination should be a powerful tool for solving structural problems for proteins relating to sequence, conformation, and protonation site.

Electrostatic Interactions in Multiply Protonated Gas-Phase Ions

Evan R. Williams, Deborah S. Gross, Paul D. Schnier, Sandra E. Rodriguez-Cruz, Clifton K. Fagerquist
Department of Chemistry, University of California, Berkeley, CA 94720

Coulomb repulsion in multiply protonated gas-phase ions, such as those produced by electrospray ionization, dramatically increases the reactivity of these ions. Increased rates of proton transfer (1) and dissociation (2) are observed with higher charge state ions. We have developed a method for determining the Coulomb energy in multiply protonated ions through measurements of apparent gas-phase basicities (GB^{app}, equation 1).

1) $$GB^{app} = GB_{Intrinsic,t} - \sum_{i=1}^{n} \frac{q^2}{(4\pi\varepsilon_o)\varepsilon_r r_{it}}$$

where ε_r is the effective shielding between charges in these gas-phase ions, and $GB_{intrinsic}$ is the basicity of a molecule protonated at a site *t*. All experiments are performed in an external ion source Fourier-transform mass spectrometer that uses electrostatic ion lenses to guide the electrospray generated ions through the fringing fields of a 2.7 T superconducting magnet into the ion cell (3). Ions are thermalized with N_2 gas introduced through a pulsed valve and mass selected with SWIFT. Reactions with reference bases at a pressure of ~1 x 10^{-7} Torr are measured with varying reaction times. Rates of proton transfer are obtained from these data and the GB^{app} of the ions is obtained.

Initial evaluation of this method was done with doubly protonated 1,*n*-diaminoalkanes (*n* = 7-10, 12) (4) and doubly protonated gramicidin s (3). For the diaminoalkanes, singly protonated monoaminoalkanes were used as references to obtain values for $GB_{intrinsic}$; distances between charge sites were obtained from molecular modeling. Measured GB^{app} values for this series fit equation 1 using an ε_r = 1.01 ±0.07 indicating that these reactions accurately follow a point charge Coulomb potential. For gramicidin s, intramolecular charge solvation occurs. We make the approximation that if charges are independently solvated, that the difference, $GB^{app}(MH_n^{n+})$ - $GB_{intrinsic}$ will reflect differences in Coulomb energy and that entropies and enthalpies of cyclization will cancel. For this peptide, we find ε_r < 1.2. (3).

For larger more complicated ions, such as proteins, information about where charges are located must be obtained so that an estimate of the $GB_{intrinsic}$ of the site of deprotonation can be obtained. For this, we model the most energetically favorable configuration of charges using a pseudo random-walk algorithm (5,6). By comparison of these calculated values to our measured values, ε_r for proteins is obtained. For the 3+ to 15+ charge states of cytochrome c, we find a best fit to our experimental values using a fully denatured ion structure and an ε_r = 2.0 (5). Our calculations show that the charge state for which our calculated GB^{app} is lower than the GB of the solvent from which the ion is formed corresponds to the maximum charge state observed experimentally. For 15 proteins commonly analyzed by ESI, our calculated maximum charge state based on gas-phase reactivity is within 6% of the maximum charge state observed in the literature (6). The maximum charge state for peptides (ε_r = 1.3) with many basic sites also appears to be determined by the gas-phase chemistry. For peptides with few basic residues, we find that the maximum charge state is better correlated to the charge state in solution.

Because of the long range 1/*r* distance dependence (where *r* is the intercharge separation), accurate measurements of Coulomb interactions should provide a sensitive probe of ion conformation. Lysozyme contains four disulfide linkages that are readily cleaved in solution. The GB^{app} of the 3+ - 15+ ions formed from denaturing and native solutions was measured (7). For some charge state, the proton transfer kinetics required two or more rate constants for an accurate fit (Figure 1), indicating the presence of more than one ion conformation for the charge state. Significant differences in reactivity between ions formed from "native" and denaturing solutions are observed for several charge states (Figure 2) For example, the most reactive isomer of the 9+ ion formed from a "native" solution is 23 kcal/mol more reactive than the least reactive isomer of the 9+ ion formed from a denaturing solution. The reactivity of these two ion structures is consistent with our calculated values for ions that are in a crystal structure and

fully denatured conformation, respectively. Lower charge state ions are formed by proton transfer to neutral base. The low charge state ions formed from denaturing solutions are *more* reactive than those formed from native solutions. This indicates that these ions have a more compact structure than disulfide intact ions. Since these low charge state disulfide reduced ions are formed by removal of protons from higher charge states that are initially denatured in the gas-phase, this indicates that these ions must be *folding in the gas-phase.*

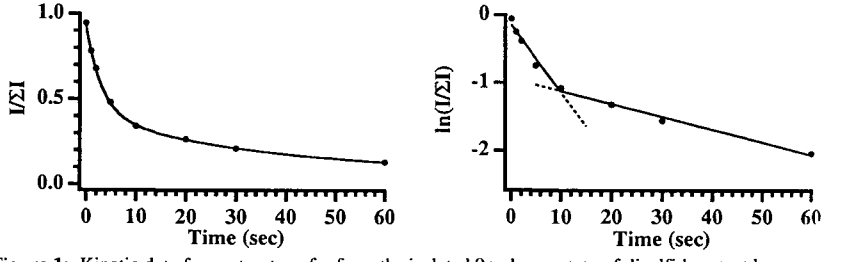

Figure 1: Kinetic data for proton transfer from the isolated 9+ charge state of disulfide-intact lysozyme to neutral triethylamine (GB = 227.5 kcal/mol). The decrease of 9+ ion abundance with time is fit using three rate constants (semi-log plot of these date are shown on right).

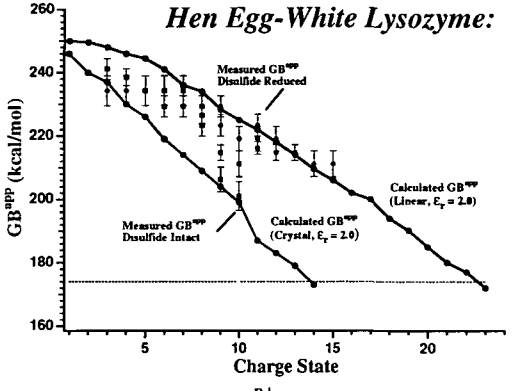

Figure 2: Apparent gas-phase basicities of $(M+nH)^{n+}$ ions of disulfide-intact and disulfide-reduced hen egg-white lysozyme. Calculated values of apparent GB of these ions modeled using the X-ray crystal structure coordinates, and modeled as a fully denatured one dimensional string are shown. The dashed line indicates the GB of methanol (174.1 kcal/mol).

Surface-Induced Dissociation of Multiply-Charged Peptides

Ashok R. Dongré, Árpád Somogyi and Vicki H. Wysocki

Department of Chemistry, Virginia Commonwealth University, Richmond VA 23284-2006

Surface-induced dissociation has proved to be an effective technique to elucidate structure and study mechanisms of peptide fragmentation for peptide <2000 u.[1] Side-chain specific sequence namely "d" and "w" ions which are high energy charge remote fragmentation processes, are observed in low energy SID spectra of peptides. The advantages afforded by SID such as high energy deposition can also be utilized to study fragmentation of large (>2000 amu) protonated peptides. The goal of the current investigation is to study fragmentation of multiply-protonated peptides in the molecular weight range of (2000-5000 amu). The experiments were carried out on a custom designed tandem mass spectrometer for ion surface collisions.[2] A fluorinated alkanethiolate monolayer surface was used in the current investigation, as it yields higher energy deposition and greater scattered ion efficiency than observed on the octadecanethiolate monolayer surface.

All the different charge states from the electrosprayed peptide solution were mass selected, in separate experiments and made to collide with the surface to observe fragmentation and obtain sequence information. Figure 1 illustrates a SID spectrum of doubly-charged insulin B-chain (oxidized). The SID spectrum yields a complete series of "b" and "y" type ions. Complete sequence information for insulin B-chain can be obtained from this spectrum. Other peptides, such as glucagon, melittin, human parathyroid hormone, and ACTH 1-39 were also investigated. Except for Insulin B-chain, the spectra for all the other peptides are either dominated by a "b" ion series or a "y" ion series. The position of the basic amino acid residues (namely Lys and Arg) along the peptide backbone affects which of the ion series predominates. If the basic amino acids are towards the C-terminus as in melittin, a "y" ion enevlope is observed. The charge state of ions observed in SID spectra are one lower than the mass selected ion, even the mass selected ion losses a proton on collision with a surface to yield a lower charge state intact peptide ion. The fragment ion

intensities may also be dictated by the sequence and conformation of these multiply protonated peptide ions.

In summary, surface-induced dissociation can be utilized to obtain sequence information from these large (>2000 amu) peptides and also to study the fragmentation mechanisms of these multiply-protonated peptides.

DEPROTONATION REACTIONS OF SMALL PEPTIDE IONS PRODUCED BY ELECTROSPRAY

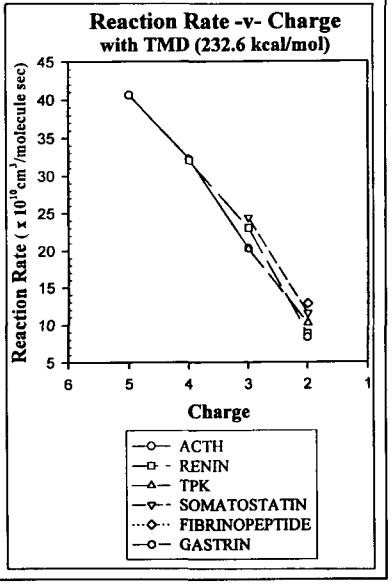
Scott R. Carr and Carolyn J. Cassady
Department of Chemistry, Miami University, Oxford, OH 45056

Gas-phase reaction chemistry of multiply charged small peptide ions produced by electrospray ionization (ESI) has been examined. These ions were allowed to undergo gas-phase deprotonation reactions with neutral bases in a Fourier transform ion cyclotron resonance mass spectrometer (FT-ICR). The peptides that were examined had 13 or 14 amino acid residues, but varied in composition as well as sequence of the residues These include· ACTH (11-24), fibrinopeptide B, human gastrin I (1-14), renin substrate (1-14), somatostatin, and tyrosine protein kinase. Deprotonation reactions have been done by this lab on a larger peptide, namely, ubiquitin[1], under similar conditions.

The peptides were dissolved in a 49.49.2 mixture of methanol, water and acetic acid Individual solutions of ~10^{-5} M were delivered by a syringe pump at 2-3 μL/min. The solution then passed through an electrospray needle and across ~5 kV A Bruker CMS-47X FT-ICR was used for all experiments. The Analytica of Branford ESI source was at atmospheric pressure and the analyzer cell at ~10^{-9} Torr. The m/z-selected peptide ions were reacted with various amines held at a static pressure (2-20 × 10^{-8} Torr) in the cell. These amines had a wide range of varying known gas-phase basicities (195.6 to 232 6 kcal/mol)[2] and are listed in order of increasing gas-phase basicity· ammonia, 2-fluoropyridine, n-propylamine, di-n-propylamine, tri-n-propylamine, and N,N,N′,N′-tetramethyl-1,4-diaminobutane. See the example spectra on the following page.

The number of charges that were present on the individual multiply charged peptide ions produced by ESI had a close correlation with the number of inherently basic amino acid residues, namely, histidine, lysine, arginine and the N-terminal residue. For example, ACTH has two arginines and four lysines, one of which was at the N-terminus, and was seen to have six different charge states

Upon examination of the rates of deprotonation, it is seen that as the charge state of the peptide and the gas-phase basicity of the amine increased, the rate did likewise. Most of the peptides exhibited linear pseudo-first-order kinetics with only a few exceptions The reactions occurred very fast and often approached the collisional rate as calculated from ADO theory The small peptides with the same number of residues and charge appeared to be deprotonated at nearly equivalent rates once the reactions had become thermodynamically favorable (see neighboring figure). This implies that, with the possible exception of adjacent residues, composition and sequence is not actually a determining factor in the deprotonation rate based on the studied peptides



Example spectra are shown **A**, all ions in a reaction of somatostatin with n-propylamine are being detected without isolation The large peak present is the +3 charge state **B**, all ions except that of the +3 state have been removed by resonant frequency ejection techniques **C**, the product ions of the deprotonation reaction after 0 2 seconds at a static pressure of 4 8 × 10^{-9} Torr.

Competitive binding of two mixtures of inhibitors to bovine carbonic anhydrase II (BCAII) was studied using electrospray ionization mass spectrometry (ESI-MS). The first mixture contained inhibitors with hydrocarbon/fluorohydrocarbon linker groups and with an 800 fold span of binding constants. The second contained inhibitors with dipeptide extensions synthesized using the solid phase method. Noncovalent enzyme-inhibitor complexes were observed from solutions in 10 mM ammonia acetate having abundances consistent with their relative binding constants measured in solution. The inhibitor with highest affinity was readily identified in an equimolar mixture. The inhibitors with very low affinity were identified to form specific complexes as well. Several control experiments including acidifying the solution or removing the Zn metal from the enzyme resulted in the disappearance of the enzyme-inhibitor complexes, demonstrating the specificity of the (mass spectrometrically) observed complexation and the reliability of ESI-MS in the characterization of biomolecular binding. Good correlation between gas phase inhibitor ion abundances and their binding constants in solution were observed (Fig. 1). Structural information and relative binding constants of inhibitors of close or degenerate masses were obtained using Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS) through multi-stage dissociation experiments (Fig. 2). These results support the role of ESI-FTICR-MS in the study of specific noncovalent associations from solution, and show that its unique capabilities can be exploited to extend studies to large mixtures of inhibitors in drug leads discovery.

Pacific Northwest Lab is operated by Battelle Memorial Institute for the U.S. Department of Energy under Contract DE-AC06-76RLO 1830.

Compounds That Elude FAB Analysis: It All Begins in Solution!

Kate Noon and John Allison
Department of Chemistry, Michigan State University, East Lansing, Michigan

This presentation is an unusual one for this session on multiply-charged ions in that it does not concern electrospray ionization, but fast atom bombardment. Also, it is a story about "compounds that don't work", those that traditionally elude analysis by FAB. In FAB, some have reported that if an analyte is ionic in solution, a "preformed ion", then it is more likely to result in a successful FAB analysis, with strong analyte signals. One group of molecules for which FAB does not yield strong signals are those which form anionic species in solution. One would predict that negative ion FAB would be the method of choice, but it is not. The most challenging compounds form *polyanionic* species in solution, and include molecules such as inositol hexaphosphate, glutathione coenzyme A (sodium salt), and gangliosides, expecially those that contain multiple sialic acid residues. To enhance our ability to detect these compounds, as well as to investigate the relationship between the ionic species formed in solution and those observed in the negative ion mass spectra, we use the matrix additive octylnicotinium bromide, ON^+Br^-. It is believed that the octylnicotinium cation, ON^+, is surface active. Because it is cationic, it attracts negatively charged analytes to the surface, increasing the desorption probability and altering the environment from which the analyte desorbs.

It is not unreasonable to assume that, if an analyte exists in a glycerol matrix in a polyanionic form, it will not appear in the gas phase as a multiply charged species. Consider for example the phosphate ion, PO_4^{3-}. We estimate that approximately 285 kJ/mol is required to desorb the singly charged speices, $H_2PO_4^-$, from glycerol, but an energy of more than 2500 kJ/mol would be required to desorb the intact phosphate anion in the 3- form. A variety of other experiments suggest that energies of that magnitude are not available in the desorption process in FAB.

While many compounds that form polyanionic species in solution do not form strong signals in negative ion FAB experiments, we observe that citric acid does. Citric acid is a small triprotic acid, which we will designate as H_3Cit. We have introduced citric acid into the glycerol matrix via various citric acid/trisodium citrate mixtures, each keeping the total citrate concentration constant. The spectra are complex because the citrate ion appears in many forms such as H_2Cit^-, $HNaCit^-$ and Na_2Cit^-. From this work it is clear that the sodium ion concentration in the solution influences the form in which the citrate desorbs, so we have studied a range of citric acid/sodium citrate mixtures (buffers) with a constant sodium concentration, to minimize the variables influencing the ions formed. In the "buffer" solutions prepared at various pH's, the ionic forms observed in the mass spectra do change with pH. The H_2Cit^- form always dominates over those containing sodium. It appears that, at low pH values, the analyte mainly forms H_3Cit in the FAB sample solution. It may desorb in neutral form, and react via ion/molecule reactions with ions such as $(G\text{-}H)^-$ to form H_2Cit^-. At high pH, when the dominant solution form is Cit^{3-}, direct desorption is not energetically possible. At high pH's where multiply charged forms of the citrate dominate the solution, more H_2Cit^- is formed in the gas phase. The 3- ion can form an ion pair with Na^+ to lower its charge, or react with neutral glycerol and extract a proton. Both lead to species with lower charge. The process can again happen, yielding 1- ions that can desorb (see Figure 1). For the systems studied, the concentration of the glycerol matrix is higher than any ionic species such as Na^+, and this may influence the relative rates of H^+ vs Na^+ capture by the polyanionic citrate.

When the same systems are studied in the presence of ONBr, the major ion at all pH's is H_2Cit^-. ONBr creates a very different environment for desorption of the anions, and in the process it appears to displace alkali ions from regions close to the surface. With ONBr present , citrate signals are highest at high pH values, suggesting that the 1- ions observed evolve from the 3- ions in the solution. We have performed similar studies with the tartaric acid/sodium tartrate system (Figure 2). Tartaric acid, H_2Tar, is a diprotic acid. While the Tar^{2-} ion need not undergo as many steps to obtain a 1- state as citrate, the results are quantitatively similar.

The collected results and observations indicate that polyanionic molecules in the FAB matrix glycerol have a rich chemistry during the desorption process. Atom bombardment results in local temperature increases. As T increases, density and dielectric constant decrease, and rates for ion pair formation (involving Na^+) become high. The polyanionic materials also can extract protons from the matrix. This process is endothermic, but the resulting anion has a lower net charge and requires less energy for desorption. Presumably, polyanionic species can scavenge positive charges through a variety of mechanisms to lower their net charge, can become completely neutralized, and can even acquire a net positive charge through similar processes. The rate for each process seems to reflect relative reactant concentrations in a straightforward way. Thus, while "preformed ions" may in some cases yield strong signals, this is not necessarily the case for many polyanionic species in solution These compounds appear to undergo charge-changing reactions at high rates, and may be extensively neutralized by the time they leave the interfacial region (the space above the FAB target between the solution and high vacuum).

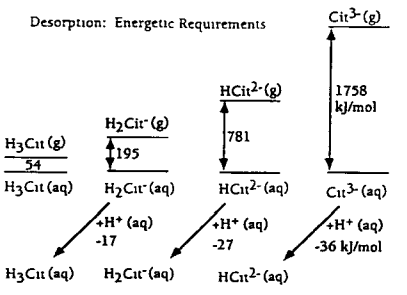

Figure 1. Thermochemical estimates for energies required for the desorption of the various forms of citric acid from glycerol. Also shown, protonation during the desorption process from an acidic environment leads to lower charge states, which require less energy to desorb.

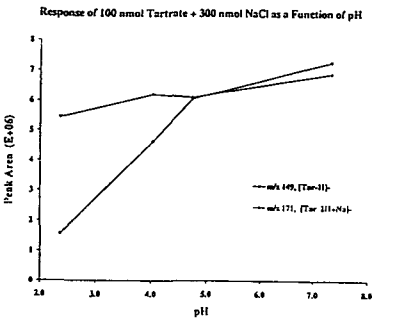

Figure 2. Changes in the ionic species of tartaric acid observed in the mass spectrum as the pH of the analyte solution is varied.

MALDI-MS IN THE INFRARED: A CRITICAL EVALUATION

Franz Hillenkamp, Michael Karas and Stefan Berkenkamp
Institute for Medical Physics and Biophysics, University of Muenster, Germany

Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry (MALDI-MS) has become a widely used technique for the analysis of large biological molecules Lasers emitting in the ultraviolet (UV) wavelength range of 260 - 360 nm and matrices absorbing strongly in this range are almost exclusively used in MALDI instruments. First reports about the use of lasers emitting in the infrared (IR) at wavelengths around 3 µm (ER-lasers) and 10 6 µm (CO_2-lasers) have appeared as early as 1990 (1, 2) A host of potential matrices are available with a strong absorption at these wavelengths, mainly that resulting from O-H and N-H vibrational modes at 3 µm. Several of them such as succinic acid, glycerol or urea have been proven to be functional matrices yielding spectra of a quality comparable to those obtained in the UV The current state of our knowledge on the experimental parameters and the performance data of IR-MALDI with Er YAG lasers will be presented.

An in-house built single stage reflectron TOF instrument of 3.5 m equivalent flight length and a 12 kV acceleration potential was used for all experiments (3) Working pressure in the sample chamber is 3×10^{-4} Pa Ions are detected by a conversion dynode (ion impact energy 20 - 27 kV, depending on ion mass) mounted 1 cm in front of a venetian blind secondary electron multiplier (EMI R2362). Signals are processed by a transient recorder with a time resolution of 10 ns (LeCroy 9400A) and then transferred to a PC for storage and further evaluation Single pulses of two different ER.YAG lasers (SEO 1-2-3, Schwartz Electro Optics, USA, Spektrum GmbH, Berlin, Germany) of respectively ca 150 ns and ca. 80 ns duration at a wavelength of 2 94 µm are focused to a spot diameter of 180 µm (with a 45° angle) onto the sample The instrument is equipped with a liquid nitrogen (LN) cooling stage The temperature of the stainless steel substrate is monitored with a thermocouple with an absolute accuracy of ± 5 K; it may be possible that the actual temperature of the top layer, even of very thin samples, is slightly higher than the measured substrate temperature. As in UV-MALDI, the results depend strongly on matrix and preparation techniques chosen for a given analysis. Different combinations will be discussed For the results obtained with an ice matrix, the reader is referred to poster abstract ThPF233 (this volume)

The reproducibility of IR-MALDI spectra from shot to shot has been a major concern in the past This reproducibility depends predominantly on two factors the variation of the laser pulse energy from shot to shot and the sample homogeneity. For ER.YAG lasers of recent design, the energy variation can be minimized at ±2%, comparable to that of the best UV-lasers. Sample homogeneity depends critically on the type of matrix and the preparation technique Solid matrices such as succinic acid typically form heterogeneous microcrystalline patterns. This can be more problematic in IR- vs. UV-MALDI, because only 3-4 single spectra can typically be obtained from a given sample spot due to the IR-radiation penetration into the sample between 1 and 10 micrometers. Liquid matrices such as glycerol or water form very homogeneous layers and for these matrices the reproducibility is as good, if not better, than for comparable UV-preparations.

All other parameters being equal, at least a factor of 100 - 1000 more material is consumed per spectrum as compared to the UV, because of the deeper penetration of the radiation into the sample. For succinic acid, this does not necessarily result in more material needed for a single preparation, but less spectra can be obtained from any given sample Normally 0.5 µl of a 10^{-5} M protein solutions are used, but the minimum amount of sample material necessary has not yet been explored for this matrix Substantially higher amounts of protein are needed for preparations with liquid matrices such as glycerol The ion signal intensity of IR-MALDI spectra is quite comparable to that of UV-MALDI spectra. Considering that much more material is ablated per laser pulse in the IR, the material is either primarily removed as clusters and

small particulate matter, or the ion yield is smaller by two to three orders of magnitude.

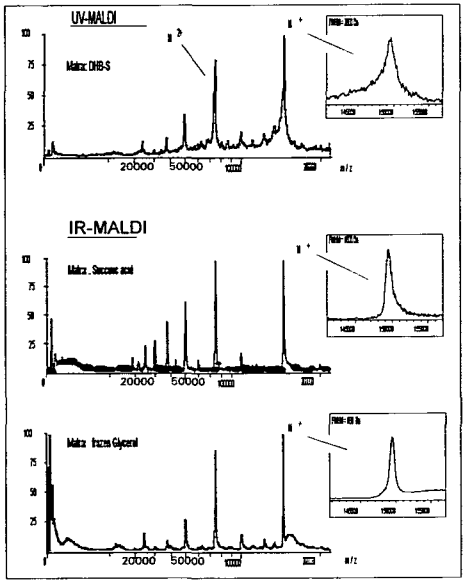

Figure 1 Mass spectra of a Monoclonal Antibody (MW ca 150,000Da)

In the mass range below ca 20 kDa the mass resolution for most of the matrices was equal to that found in UV-MALDI spectra recorded with the same instrument Above 20 kDa the mass resolution of the IR-MALDI spectra is substantially better than that of comparable UV-MALDI spectra as demonstrated in Figure 1 for spectra of an IgG monoclonal antibody It is interesting to note that mass resolution increases for glycerol if the temperature is lowered to 150 K. This increased mass resolution has been used to determine the distribution of a specific conjugate to monoclonal antibodies (4). The superior mass resolution of the IR-MALDI spectra is mainly a result of significantly less metastable fragmentation as evidenced by less low mass tailing og the peaks. the steep low mass edge of the peaks Succinic acid and glycerol tend to form adducts, broadening the peaks on the high mass side. For frozen glycerol these adducts appear to separated from the protein peak, leading to the above mentioned increase in mass resolution An important task for future work will be the search for other matrices with less tendency for adduct formation. Preliminary results indicate that, for yet unknown reasons, the decrease in metastable decay is accompanied by an increase in prompt fragmentation. The different fragmentation behavior is also the suspected reason for fact that the upper mass limit appears to be higher for IR-MALDI. A spectrum of Gramicidin S synthease at mass 510,000 Da has been recorded with a quite acceptable S/N-ratio and a mass resolution of ca. 50.

So far the absolute mass accuracy has been limited to 10^{-3} - 5×10^{-4} for two main reasons First, only external mass calibration has been used for example with lysozyme clusters. The second problem has been the jitter of the trigger signal for the transient recorder due to the shot to shot variation of the laser pulse energy The latter problem seems to be resolved with the new 80 ns ER:YAG laser A major advantage of IR-MALDI over UV-MALDI is the availability of physiological matrices such as TRIS-HCl. Excellent spectra of myoglobin samples have been recorded, showing peaks of the apoprotein as well as the protein itself. Particularly in combination with this buffer matrix, physiological concentrations of NaCl are tolerated without a significant degradation of the spectrum quality.

Sequencing electroblotted proteins by tandem mass spectrometry

D. Fabris[1], M.M. Vestling[1], M.M. Cordero[2], V.M. Doroshenko[2], R.J. Cotter[2], and C. Fenselau[1]

1) Structural Biochemistry Center, University of Maryland Baltimore County, Baltimore, MD 21228
2) Middle Atlantic Mass Spectrometry Laboratory, Johns Hopkins University, Baltimore, MD 21205

Gel electrophoresis, particularly SDS-PAGE, is routinely used to separate protein mixtures. Electroblotting the separated proteins to membranes makes available small amounts of relatively pure samples for further analysis. Specific antigen detection (Western blotting), *in situ* reduction, alkylation, digestion, Edman sequencing, and mass spectrometric analysis can be performed directly on the membrane or after extraction. On-membrane cleavage followed by accurate molecular weight determination of a few tryptic peptides allows the identification of a protein if it is present in an appropriate database. The objective of the present work was to further support the database identification with sequence information obtained from the tryptic peptides by tandem mass spectrometry. The broad applicability of this approach was evaluated using MALDI on both a curved field reflectron (CFR) TOF-MS[1] and a quadrupole ion trap[2] developed "in house" at the Middle Atlantic Mass Spectrometry Laboratory of the Johns Hopkins University. High energy collision-induced dissociations (CID) were performed at the Structural Biochemistry Center of the University of Maryland Baltimore County on a HX110/HX110 (JEOL, Tokyo, Japan) high performance four sector mass spectrometer equipped with both a FAB (JEOL) and a massive cluster impact (MCI) ion gun (Phrasor Scientific Inc., Duarte, CA).

Following SDS-PAGE of 1.2 nmoles of cytochrome C, the protein was blotted onto nitrocellulose and digested *in situ* with trypsin. The peptides were extracted with 60:40 iso-propanol·water, 0.1% TFA. Tryptic peptides were mapped by MALDI CFR TOF-MS and eight molecular weights were used to search the MOWSE[3] protein database succesfully. For sequencing, precursor ions were selected by a voltage gate and post source decay (PSD) spectra were obtained by analyzing the decomposition products on the CFR TOF-MS. The fragmentation observed in PSD spectra of peptide [88-91] (m/z 533.3) and peptide [28-38] (m/z 1168.6, Fig. 1) showed good correlation with the known sequences. The PSD spectrum of m/z 659.3 confirmed its identification as a trypsin autolysis peptide [44-49].

In an analogous manner, the tryptic digest was mapped by MALDI in a quadrupole ion trap. Precursor ions were selected using the SWIFT[4] technique and collided with Xe for 50-500 msec. The MS/MS spectra of cytochrome C peptide [28-38] (m/z 1168.6, Fig. 2) and trypsin peptide [44-49] (m/z 659.3) showed good agreement with the expected patterns.

For the sector analyses, cytochrome C was deposited on PVDF (polyvinylidene difluoride), digested on-membrane, and directly loaded onto the FAB probe. Both FAB and MCI gave good mapping and sequencing data. The m/z values of the fragments observed for cytochrome peptide [28-38] (m/z 1168.6) were in good agreement with the calculated values.

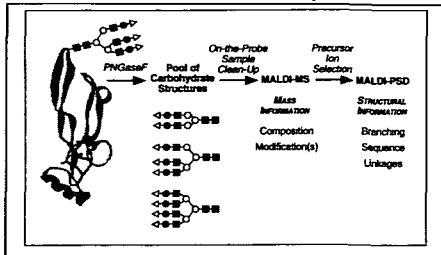
MALDI AND PSD CHARACTERIZATION OF RELEASED CARBOHYDRATES FROM GLYCOPROTEINS

Jason C. Rouse, James E. Vath, and Hubert A. Scoble, Genetics Institute, Inc., One Burtt Road, Andover, MA 01810*

The potential for carbohydrate structural heterogeneity at individual glycosylation sites on a glycoprotein is vast due to the permutations generated from differing monosaccharide compositions, branching sites, and linkages. In the case of CHO-expressed glycoproteins, the heterogeneity typically observed experimentally is not as large as theoretical considerations would suggest. Many common carbohydrate structures can be recognized based on composition information (i.e., molecular mass) provided one has prior knowledge regarding the glycosylation phenotype(s) of the host cell. While this approach is often structurally conclusive, a remaining challenge for carbohydrate analyses utilizing mass spectrometry is the differentiation of isomeric structures. MALDI-post-source decay (PSD) (i.e., gas-phase ion fragmentation) of carbohydrates has the potential to quickly provide isomeric structural information on small amounts of underivatized, minimally purified material.

The heterogeneous carbohydrate structures from a particular protein glycosylation site were enzymatically released and directly analyzed as a mixture by MALDI-MS to prevent sample handling loss and to speed analysis time (see Scheme 1). On-the-probe sample clean-up strategies employing small in situ amounts of chromatographic media, instead of traditional protein removal and desalting procedures, were applied to minimize interferences from cations, anions, and/or detergents. In Figure 1, on-the-probe chelex treatment (or small cation removal) shifts the distribution of multiple sodium adduct ions to $[M+Na]^+$ and improves the signal-to-background ratio greater than 2 fold. For MALDI-PSD, each carbohydrate component in the mixture can be mass spectrometrically isolated with a precursor ion selection device in place of traditional chromatography.

A library of MALDI-PSD spectra was assembled using a variety of highly purified, previously characterized N-linked complex, hybrid, and oligomannose carbohydrates, and interpreted as a whole to identify the rules and trends associated with carbohydrate $[M+Na]^+$ low-energy fragmentation. The primary structural information extracted from these spectra was carbohydrate branching patterns. The key fragmentation that reveals the branching patterns are branch loss ion types ($y_{\alpha/\beta n}$) and internal ion types ($b_{\alpha/\beta n/n}$) which arise from single and multiple glycosidic bond cleavages at branch points, respectively (see Figure 2). For the oligomannose 7 library spectra in Figure 3, the peak intensity ratios among the branch loss ion types and among the internal ion types are consistent with expected isomeric structures and ratios. This knowledge base of MALDI-PSD carbohydrate fragmentation was successfully applied to the interpretation of oligomannose 7 with unknown isomeric structures and distributions. The distribution of isomers in this unknown mixture was validated by HPAE isolation and PSD of each individual isomer. This "PSD knowledge-based isomeric differentiation" strategy allows comparison of fragment ion abundance ratios in unknown and library MALDI-PSD spectra to identify the location of structural variations, to recognize isomerically pure carbohydrates from isomeric mixtures and estimate the distribution of isomers.



Scheme 1. MALDI-MS based characterization of N-linked carbohydrates.

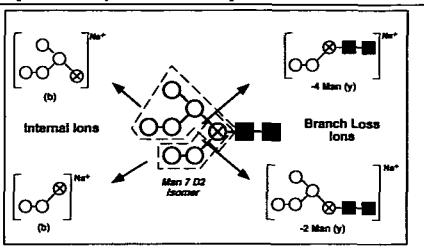


Figure 2. The key fragment ions in oligomannose carbohydrates that contain the isomeric information are the branch loss ion types ($y_{\alpha/\beta n}$, Na^+ retained on reducing end) and internal ion types ($b_{\alpha/\beta n/n}$, Na^+ retained on non-reducing end), which arise from single and multiple glycosidic bond cleavages at branch points, respectively

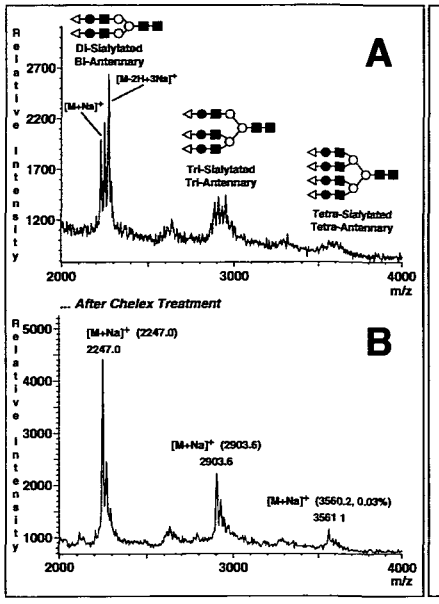

Figure 1. In both spectra, an equimolar mixture of commercially available, sialylated complex carbohydrates (7 pmol each) were analyzed by MALDI. These acidic carbohydrates have a high affinity for Na^+ given the signal for each component is divided by the multiple sodium adduct ions in (A). After on-the-probe chelex treatment (small cation removal) in (B), $[M+Na]^+$ becomes the dominant form and the S/B increases two fold or greater

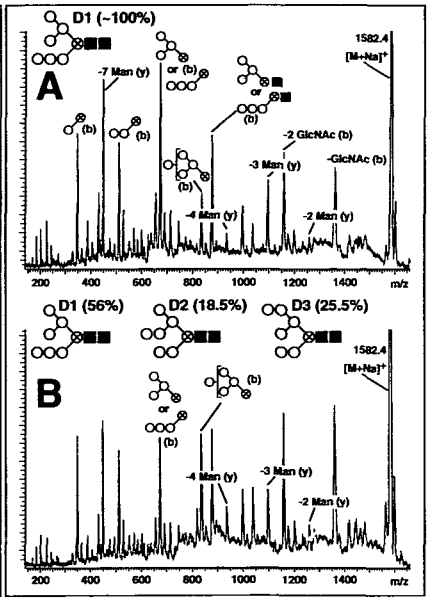

Figure 3. Both oligomannose 7 library MALDI-PSD spectra above were obtained from 40 pmol (i.e., material on the probe) of commercially available material in super DHB matrix. For the D1 isomer of Man 7 in (A), the -3 Man (y) branch loss fragment ion abundance is greater than that of -2 and -4 Man (y), and the internal "b" type ion containing the 3 mannose branch plus mannose core is more abundant than the 4 mannose branch plus mannose core "b" internal ion, which is consistent with the branching structure of the D1 isomer. For the Man 7 isomeric mixture in (B), the abundances of the 4 mannose branch plus mannose core "b" internal ion and the -4 Man (y) branch loss ion increase 2 fold indicating the D2 and D3 isomers represent ~50% of the total isomeric content while D1 represents the other 50%. The ratios listed are derived from chromatographic separation.

MASS SPECTROMETRY IN PROTEIN AND GLYCOPROTEIN STRUCTURE ELUCIDATION

Howard R Morris, Anne Dell, Maria Panico and Roy McDowell
Department of Biochemistry, Imperial College, Exhibition Rd., London SW72AZ, U K.

Whilst the relatively new ability to determine an intact protein or glycoprotein molecular weight has value, for example in determining whether or not a protein may be post-translationally modified, the critically important objective of determining the precise covalent structures involved is still dependent upon the "mapping" of low molecular weight (approx 3kD) fragments from digest mixtures, a strategy first introduced in the late 1960's and early 1970's - then called "mixture analysis" mass spectrometry (1,2) What has changed in modern research is the ability through instrumentation development to execute this strategy at the pico or femtomole level rather than the tens of nanomole level necessary for studying unknowns twenty five years ago. The intervening years have seen instrumentation developments of FAB, Electrospray and MALDI ionisation techniques, as well as High Field Magnet, Quadrupole, TOF and Cyclotron separation methods, and the introduction of MCP Array Detection. Various combinations of these technologies seem to work better or worse for solving particular problems with respect to sensitivity, mass accuracy, mass range and resolution.

Some years ago (1987) we suggested the building of a wide angle (1 5 mass ratio) magnetic sector focal plane detector instrument for mapping studies with high sensitivity and mass accuracy, and although the raising of funds for that instrument proved impossible, sufficient funding was available to commission a pseudo-focal plane version built to our specifications around ZAB2SE optics (3). This novel "dual array" mass spectrometer is compatible with most if not all ionisation methods including FAB, FD, Electrospray and MALDI, and the combination of Array Detection with Double Focusing allows high sensitivity with good resolution and mass accuracy Our instrument incorporates a low resolution wide-angle survey array for "mapping" and post-translational modification analysis of unknowns, and most data is first acquired on Array 1. This allows single shot data at a mass ratio of 1 5.1 e.g. 4,000 to 6,000 daltons, with wide mass range (up to 15 kD) data created in real time (interscan) by software stitching of consecutive shots. Peaks of interest may then be consecutively switched to a second high resolution array (Array 2) at the conventional double focusing point of the instrument within the timeframe of a single sample loading to give isotopically resolved data (>8,000 RP) with mass measurement accuracy of better than 0.2 Daltons for biopolymer characterisation.

Some examples of the instrument performance taken from our biopolymer research studies are shown below FAB remains probably the simplest and fastest way of mapping biopolymers if partial suppression or sample quantity are not limiting, giving good data down to 1 picomole on pure samples. The resolution of our instrument on Array 2 is illustrated in Figure 1 showing a FAB spectrum of Insulin giving a resolution of around 8,000 (FWHM). To exploit the inherent sensitivity of the Array it is of course necessary to chose a relatively low chemical background noise ionisation technique such as F D. or MALDI. Here, the quality of data far exceeds FAB with respect to signal to noise, even with relative sample loadings of less than one per cent Figure 2 shows the MALDI spectrum on this magnetic sector instrument (MAGNETIC MALDI to distinguish it from conventional MALDI TOF) of a relatively impure sample of 1 picomole of a human Calcitonin Gene Related peptide. The fully resolved data showing good mass accuracy illustrate some advantages of this MAGNETIC MALDI double array technique. In our studies of carbohydrate and peptide mapping by MALDI, we have determined that for small sample loadings in the 10 femtomole to 1 picomole range, the variability of ion beam intensity for consecutive laser firings on the same spot is incompatible with collection of wide mass range (multi-step) array data. However, excellent MALDI mapping data can be achieved simply by collecting array data in individual

steps, and switching the laser to different sample spot locations as and when sample is consumed An example of Array 1 low resolution MAGNETIC MALDI data acquired in this way is shown in Figure 3 allowing the location of the N-terminal polypeptide (F-1 to R-30), in one of the steps of a seven step experiment, in a digest of a glycoprotein from N. meningitidis

Nucleotide analogs increase the stability of DNA for MALDI-MS analysis

Klaus Schneider and Brian T. Chait

The Rockefeller University, 1230 York Ave., New York, N.Y. 10021

The use of matrix-assisted laser desorption mass spectrometry (MALDI-MS) has been suggested as an ultrafast readout of Sanger DNA sequencing ladders in a manner analogous to that used with sequencing gels. Currently, a serious limitation of MALDI-MS for the analysis of DNA results from the tendency for oligonucleotides to undergo facile fragmentation in the gas phase. The present study was undertaken to gain an understanding of the influence of various chemical structural features of purine bases on the stability of oligodeoxynucleotide ions produced by MALDI. The study focused on the stability of model compounds of the type d(TTTTT TTTTT X TTTTT TTTTT TTTT), where T designates deoxythymidine and X a purine-containing 2'-deoxynucleotide analog.

In a first set of experiments, we chose guanine, hypoxanthine, adenine, and 2-amino-purine as the base in the nucleotide X. Two types of mass spectrometric fragments were observed. The first was a fragment occurring through the loss of the purine base from the intact molecule. The second were fragments that arise by cleavage of the sugar-phosphate backbone. We found that the relative tendency for fragmentation of the four model compounds decreased in the order of the bases guanine > hypoxanthine > adenine = 2-amino-purine. This order correlates with the decrease in basicity of the N7 nitrogen of the purine.

We therefore carried out a second set of experiments in which the nucleotide X contained bases with the N7 nitrogen replaced by carbon C7, i.e., 7-deaza-guanine and 7-deaza-adenine. The mass spectra of the model compounds containing 7-deaza analogues of guanine and adenine reveal a significantly increased stability compared to the 7-aza analogues under the conditions of MALDI-MS. The previously reported incorporation of the 7-deaza-2'-deoxy-adenosine triphosphate and the 7-deaza-2'-deoxy-guanosine triphosphate into DNA by polymerases suggests their use in a Sanger dideoxy sequencing experiment. The dideoxy termination products with the 7-deaza-purines instead of the 7-aza-purines might be sufficiently stable to allow the separation and detection of the sequencing ladder by MALDI- MS. Thus an ultrafast (seconds) read-out of DNA may become feasible.

Identifying the presence of a specific DNA fragment is becoming increasingly critical to many applications in medical, clinical, forensic and other research laboratories. At present, regions of interest in DNA are amplified using the Polymerase Chain Reaction (PCR) or other reactions to produce fragments containing a specific number of nucleotide units that are diagnostic for the targeted genetic disease, person, or pathogen. These fragments are then typically analyzed by slab gel electrophoresis. Mass spectrometry has the potential of characterizing the DNA fragments faster and more confidently than chromatography-based methods

We have evaluated matrix assisted laser desorption (MALDI) time-of-flight (TOF) and electrospray (ES) quadrupole ion trap (QIT) mass spectrometry for the rapid analysis of PCR fragments. Synthetic oligomers and PCR products from human and bacterial genomic DNA were used in these initial studies. The human samples studied represent a mutation, ΔF508, in a gene that involves the cystic fibrosis transmembrane conductance regulator; this mutation is caused by a three base deletion. PCR primers containing 18 bases were prepared that would result in a 75-base fragment for a normal individual and a 72-base fragment for an individual with the 3-base deletion. The bacterial sample was isolated from a region from the gene that codes for 5S rRNA in bacteria of the genus *Legionella*, and the amplified product contained 108 bases

ES spectra of synthetic oligomers and $tRNA^{Phe}$ showed that methanol solutions generally yielded 100 to 1000 fold lower detection limits than aqueous solutions. Removal of alkali metal counter-ions was found to significantly improve sensitivity and resolution of charge states. Figure 1 shows the ES spectra of synthetic 75-base single-stranded oligonucleotides in which alkali counter-ions have been replaced by ammonium ions. Double stranded DNA fragments, which are produced by the PCR amplification, could be analyzed intact by ES.

MALDI spectra, using 3-hydroxypicolinic acid as the matrix, were also obtained on the synthetic 72- and 75-base oligomers, Figure 2. Removal of alkali metal counter ions was also found to be necessary to enhance both sensitivity and resolution. For DNA of this size, oligomers that differed in mass by three bases (approximately 900 Daltons), could be readily distinguished, resolution of single base differences, however, was limited to oligomers containing about 40 bases. Because MALDI sensitivity falls off with mass, it was also necessary to remove the PCR primers. A spectrum of a 75-base PCR product from human genomic DNA (after removal of a majority of the 18-base primers and salt) is shown in Figure 3. We have used similar approaches to detect the 108-base PCR fragment that is diagnostic of the *Legionella* species (not shown)

In general, it was found that both ES and MALDI are capable of analyzing of DNA fragments; however, several areas need to be addressed before either may be used in a routine method.

Both techniques are useful for analysis of DNA fragments containing at least 100 bases at present. To extend this technology to larger PCR fragments, current limitations in mass resolution and mass range need to addressed. As stated previously, both ES and MALDI require removal of cations and primers for optimum detection of the DNA fragments. Finally although detection of low- to sub-picomoles of the DNA fragments is currently achievable, higher sensitivity is desirable to reduce the extent of PCR amplification required for the analysis. We are currently developing approaches to circumvent these limitations, including enhancements in instrument performance, investigation of microsample handling techniques, and development of methods for rapid on-line sample preparation.
