THE ANALYSIS OF DNA AND MODIFIED PROTEINS BY EXPLOITING RESOLUTION IMPROVEMENTS IN MALDI-TOF MASS SPECTROMETRY

Steven M. Colby, Randy J. Arnold, Noah P. Christian, Chris T. Houston , and James P. Reilly
Dept. of Chemistry, Indiana University, Bloomington, IN 47405

One of the most time consuming steps of current DNA sequencing methods is the separation of DNA oligomers that have been prepared via the Sanger method[1]. This process is an important part of the Human Genome project which proposes to sequence the entire human genome. Current technology employs gel electrophoresis (PAGE) although other separation methods such as capillary electrophoresis are also being developed. An exciting alternative would be the separation of oligomers by mass spectrometry. This approach could be significantly more rapid than other techniques. A considerable amount of effort has therefore been directed at detecting oligonucleotides via mass spectrometry. Considerable progress has already been made. As pointed out by Tang et. al.[2] there are three principal advances required for DNA sequencing by mass spectrometry: 1. The detection of DNA fragments larger than 300 nucleotides; 2. Femtomole sensitivity for the detection of PCR products; and 3. Sufficient mass spectral resolution to distinguish a 500-mer from a 501-mer. Tang[2] and Bai et. al.[3] have already demonstrated the detection of large oligomers with significant sensitivity using Matrix Assisted Laser Desorption/Ionization and point out that the only element required for mass spectral sequencing of DNA is sufficient mass resolution.

We report the application of a mass resolution enhancement technique to the study of single stranded DNA oligomers ranging in size from 27 to 68 bases. This technique, called Space-Velocity Correlation Focusing, has been previously reported and is further described in another abstract at this conference.[4-6] It reduces the effect of the initial velocity distribution on the peak width of the detected signal. This distribution is one of the major factors affecting mass resolution. Others may include the presence of counter ions, metastable decay, gas phase collisions, and electronic limitations. The reduction of the effect of the initial velocity distribution permits for the first time the careful examination of these other factors. The work reported herein focuses on the study of counter ions in the analysis of DNA oligomers, specifically the use of desalting and ion exchange techniques.

We have explored the use of drop dialysis for the desalting of oligomers as well as the addition of the following salt solutions: ammonium chloride, ammonium citrate, and ammonium acetate. We have also used EDTA buffered with ammonium hydroxide as a chelating agent and examined the effect of aluminum and stainless steel substrates.

The effect of ammonium citrate on DNA mass spectra has been examined previously[7-9]. However, except for very short oligomers[7], the MALDI work was done without sufficient resolution to observe specific counter ions. The changes in peak width that were observed could therefore not be fully characterized. Fig. 1 compares the mass spectra of a 27-mer recorded with and without the addition of ammonium citrate. Counter ions or adducts corresponding to Na (b) , K (c), and Fe (d) are observed. Fig. 2A shows

another example of the effect of ammonium citrate. The counter ion distribution has changed slightly and potassium is now the strongest. This change is simply due to variations in handling of the sample. (The flight times are shifted due to differing operating conditions.) Fig. 2B illustrates the effects of drop dialysis (0.025μm) on the same sample. The signal intensity is dramatically reduced and we would appear to have lost the analyte in the membrane. However, Fig. 2C shows the result of subsequent re-addition of ammonium citrate. The resulting peak intensity is now almost 3 times greater than without membrane treatment. While we were originally concerned only with the cation in the buffer, we have found that the anion is also important. The use of ammonium acetate and chloride each produced progressively worse results. The use of dialysis and ammonium citrate on larger oligomers is shown in Fig. 3. As seen the treatment is less effective with longer polymers. This is to be expected since the number of counter ion sites increases with length. It should be noted that the change in peak width is not due to Space-Velocity Correlation Focusing. We are able to record mass spectra of proteins (trypsinogen) with mass similar to the 68-mer with 12 nanosecond wide peaks[5].

Applications of High Resolution MALDI TOF to Oligonucleotide Problems

Peter Juhasz, Marvin Vestal, Ed Takach, Mark Roskey, Igor Smirnoff,
Lawrence Haff and Stephen Martin
PerSeptive Biosystems, Inc., 500 Old Connecticut Path, Framingham, MA 01701

Matrix-assisted laser desorption ionization (MALDI) mass spectrometry has been vigorously explored recently for its potential use in high throughput DNA sequencing. Although speed of analysis is the main appeal of mass spectrometry, there are a number of issues which need to be addressed for mass spectrometry to be competitive with established biochemical methods. Major difficulties in MALDI which have to be overcome are the inherently low sensitivity of oligonucleotide desorption and ionization, and relatively poor mass resolution, in particular in the case of very complex mixtures such as sequencing ladders. Sensitivity of oligo- and polynucleotides to fragmentation is an additional complication rendering accurate molecular weight determination of large polynucleotides very difficult.

By means of a new ion source design considerable improvement of mass resolution has been achieved Inspired by the success of previous research on delayed ion extraction [1], an ion source was constructed utilizing three high voltage sources. In the two-stage ion source an extraction grid had constant electric potential while potential on the sample holder could be rapidly switched between the other two high voltage supplies. Thereby a well controlled extraction pulse could be applied following the ionization event which took place in a nearly field free environment. This ion source was used on two commercially available instruments - 1.3m and 2.1m long - both equipped with a coaxial, single stage reflector.

I. Basic performance. When tuned properly a mass resolution in excess of 1000 was obtained in the linear mode for mixed base oligomers up to 50mer. As a general rule, mass accuracy and sensitivity also increased in proportion with the resolution. Reproducibility of data was improved substantially, and high quality data could be readily generated with 3-hydroxypicolinic acid matrix: a matrix well known for hard to find sweet spots. Figure 1 demonstrates the typical performance on the delayed extraction (DE) linear instrument: a baseline separated pair of synthetic 31mers of different 3' termini but otherwise of identical sequence. C-T substitution corresponds to 15 Da mass difference, and the mass resolution in the figure is around 1,200. Even more dramatic increase in mass resolution was observed in the reflector mode. Figure 2 presents an RNA 12mer with 7500 mass resolution at *m/z* 3839.

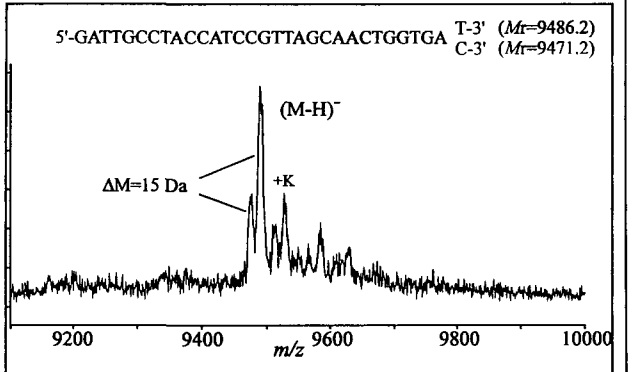

Figure 1 Pair of DNA 31mers differing by 15 Da. Mass resolution is 1200.

II. Sequencing applications. Improved performance by DE was extremely useful in sequencing applications dealing with complex mixtures. Sequence analysis of oligonucleotides up to 31mer was demonstrated based on failure sequences. Fast fragmentation processes were also reported earlier in delayed extraction experiments [1] and an 11mer could be completely sequenced based on its fast fragmentation when proper experimental conditions were used: picolinic acid matrix and 266nm irradiation.

Exonuclease degradation is the to be method of choice for sequencing ssDNA up to the 40mer range. 3'-Phosphodiesterase reactions exhibited more uniform digestion rates than those with 5'-phosphodiesterase. With a simple protocol, combination of the two digests yielded the sequence in less than 10 minutes when using delayed extraction (DE) MALDI with improved mass resolution. The strategy was successfully demonstrated on a 33mer and a 40mer.

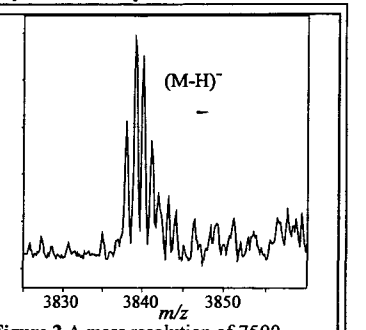

Figure 2 A mass resolution of 7500 observed in the reflector on an RNA 12mer at *m/z* 3839.

The Sanger method is used exclusively for high throughput sequencing of genomic DNA. A sequencing reaction amplified by thermocycling was devised to generate dideoxynucleotide terminated fragments at the 20-100 fmol level on a 40mer and 50mer template. While conventional MALDI failed on these samples, delayed extraction MALDI successfully reproduced almost the complete sequences. Mass spectrum of the "T" reaction of the 40mer is shown in Figure 3. From these applications it was obvious that adequate mass resolution has been obtained leaving sensitivity as the limiting factor for the routine use of mass spectrometry in DNA sequencing

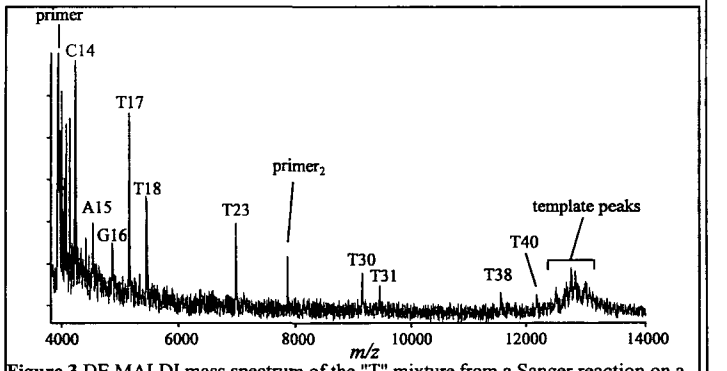

Figure 3 DE MALDI mass spectrum of the "T" mixture from a Sanger reaction on a 40mer template. The components are present at a 20-100 fmol/μL concentration.

Applications of MALDI/TOF in Polymer Chemistry

Paul O. Danis and Francois J. Huby
Research Laboratories, Rohm and Haas Company, Spring House, PA 19477

The application of MALDI to problems in polymer science is growing rapidly.(1-7) With molecular weight measurements as the obvious primary application, other areas where MALDI can play a role is in the structure elucidation of copolymers and the determination of end groups for the elucidation of polymerization mechanisms. Additionally coupling MALDI with a technique such as gel permeation chromatography [GPC] allows one to obtain direct measurement of polymer solution properties. From the comparison of MALDI data with GPC a greater understanding of the capability of both methods can be realized.

While aqueous(1) and non-aqueous(3) polar polymers can be readily analyzed, hydrocarbons are more difficult due to their low matrix solubility and lack of a dipole site for cation attachment. Using the matrix 1,4-di-(2-(5-phenyloxazolyl))benzene [POPOP] with silver acetoacetonate for cationization, polymers of styrene as well as isoprene and butadiene can be analyzed, Figure 1.

From the MALDI of poly(methyl methacrylate) [pMMA] prepared with a di-anion initiator several pathways of initiation are observed. These corresponding to the di-, tri-, and tetra-α-methylstyrene di-anion. It is also shown that the rate of initiation for the tetra- species is slower than that for the di-species.

From well-characterized standards of poly(methyl methacrylate), a comparison of MALDI data to that obtained from gel permeation chromatography, Figure 2, has allowed us to directly determine the band-broadening function of the chromatographic system. This important parameter is usually calculated with an analytical function containing assumptions of its independence on retention time and analyte composition. With MALDI the assumptions are removed and direct measurement is possible. The band broadening function for poly(methyl methacrylate) of 28k, 59k, 127k, and 260k Da is shown if Figure 3, and the lack of mass dependence on this function is obvious.

Polymer Characterization: A Comparison of MALDI vs Direct Laser Desorption

David A. Weil* and Cliffton B. Jacoby, 3M Company, St. Paul, MN 55144-1000

The characterization of high-mass polymers by MALDI have generally been from single component samples with narrow molecular weight distributions, and not from synthetic polymers routinely encountered in industry. A problem encountered in MALDI of high-mass, polydispersive polymers, is that the ion current is spread over a wide mass range, where as proteins have their ion current concentrated in a narrow mass range. Unlike reference standards, synthetic polymers encountered in industry are often mixtures of various molecular-weight distributions, monomers, initiators and end-cappers. At 3M we've found that present expectations are much higher than routine performance. The limitations in sample preparations, instrumentation, software and the fundamentals of MALDI-TOF may limit the practical application of MALDI to polymers with M_w < 50K Daltons. Both MALDI/TOF and LD/FTMS are extremely useful in characterizing low-molecular weight polymers, surfactants and oligomers. A comparison of the techniques was completed to determine the current strengths and weaknesses of the ionization methods and mass spectrometers. We have also compared the performance of MALDI/TOF and MALDI /FTMS systems.

The direct laser desorption ionization experiments were performed by using a pulsed high-powered CO_2 laser, at 10.6 micron, coupled to an EXTREL FTMS 3.0T, dual-cell system. Additional FTMS experiments were completed by using a similar system equipped with the nitrogen laser interface. The MALDI-TOF experiments were completed by using a Fisons TOFSPEC or TOFSPEC E systems, that utilize a pulsed N_2 laser. Standard sample preparation methods were utilized for the comparison.

In general, the strengths of MALDI/TOF are the ease-of-use, simple design, and wide mass range; while the weaknesses are the sample preparation, low-resolving power and high-chemical background at low mass. The strengths of LD/FTMS are high-resolving power, high mass accuracy, and ion manipulation methods; while the weaknesses are the space-charge effects, mass range limitations and more complex instrument design. The performance of the TOF mass spectrometer (dynamic range, mass resolution, detector type) in reflectron and linear mode may inhibit the identification of low-level components present in oligomer mixtures. In comparison, the high-resolution Fourier transform mass spectrometer can identify these low-level components, at the expense of mass range

MALDI has been shown to be a rapid and routine method for characterizing low-molecular weight polyethylene and polypropylene oxides in polymer extracts. With just a few micoliters of a solution of the polymer extract (even from an NMR sample tube), both the average molecular weight and the chemical composition information can be obtained within a few minutes from an extract. The MALDI/TOF mass spectrum (Figure 1) shows the presence of four different polymers. In LD/FTMS, one can detect low-mass fragment ions indicative of the initiator and monomer. While in MALDI, the chemical background from the matrix may inhibit the detection of these fragments.

The strengths and weakness of MALDI/TOF and LD/FTMS are illustrated in the characterization of modified polydimethyl siloxanes oligomers which contain end groups that vary by one mass unit and have overlapping isotope patterns. The broad mass-range capabilities of MALDI/TOF easily provide absolute M_w values (Figure 2), but the low resolving power inhibit determination of diamine and dibutyl levels from the isotope patterns. In comparison, the high-resolving power capabilities of LD/FTMS were used to determine the percent of monoamine, diamine and dialkyl end groups present (Figure 3). The mass spectral data was important since the proton NMR data can tell the ratio of the amine and the alkyl end groups, but not the amount of the dialkyl or

diamine groups. The LD/FTMS mass spectra also showed evidence for variations in the oligomerization process of these modified polydimethylsiloxanes (Figure 4).

Figure 1. MALDI mass spectrum of a polymer extract showing the detection of four different PEO and PPO polymers.

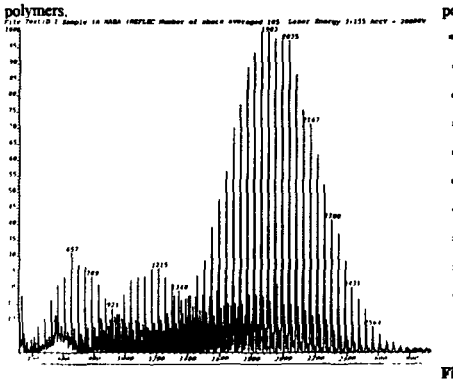

Figure 2. MALDI mass spectrum of a modified polydimethyl siloxane polymer with differing end groups. The low resolving power of MALDI/TOF makes end group polymers

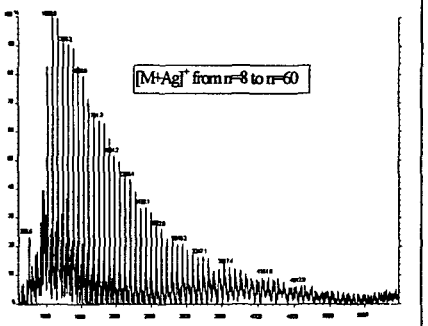

Figure 3. A narrow portion of the LD/FTMS mass spectra of a modified polydimethyl siloxane. The relative amounts of the different end groups can be estimated from the isotope ratios.

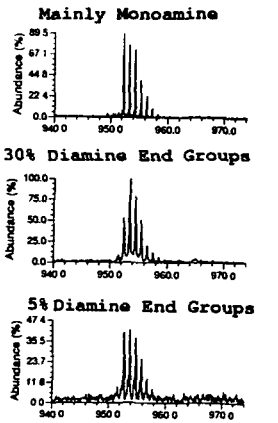

Figure 4. LD/FTMS mass spectra showing the characteristic differences in oligomerization processes of polydimethylsiloxanes

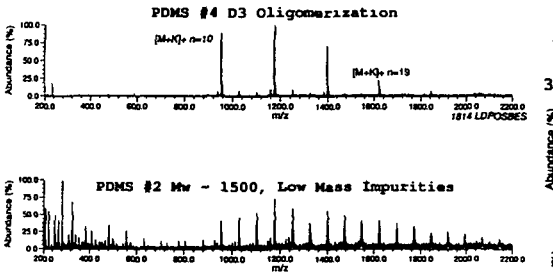


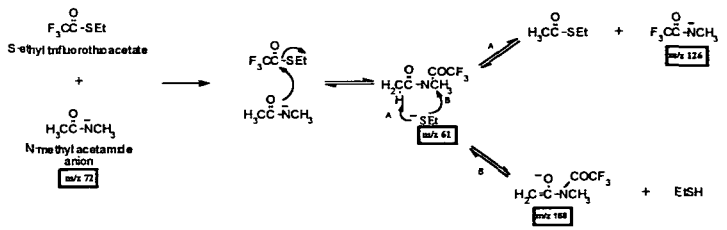
In summary, both MALDI and direct laser desorption ionization techniques are useful, routine and rapid methods for characterizing low-molecular weight oligomers and surfactants. The high-mass expectations of polymer chemists overshadow the current capabilities of the techniques. More research into sample preparation, mechanisms, and improvements in MALDI/TOF systems are needed to make MALDI a routine analytical tool for polymer characterization.

CHEMICAL REACTIONS VS. CID TO CLEAVE AMIDE BONDS

Tracie L. Williams, James L. Stephenson, and Richard A. Yost
Department of Chemistry, University of Florida, Gainesville, Florida

The structural analysis of biological molecules by tandem mass spectrometry has relied primarily on collision-induced dissociation (CID), in which precursor ions undergo low-energy collisions with a neutral target gas. This technique, however, suffers as the m/z of singly charged ions increases due to the limited energy available in center-of-mass coordinates. Therefore, collisions with low mass collision gas is unable to deposit sufficient internal energy to cause fragmentation. An attractive alternative to CID would be the use of a chemical reagent which would drive an exothermic bimolecular reaction to cleave selected bonds to form fragments bearing structural information specific to both the analyte and the reagent used. Cheng and coworkers have shown in a flowing-afterglow study that S-ethyl trifluorothioacetate and hexafluorobenzene react with deprotonated anions of model amide compounds to cleave the carbonyl-nitrogen bond (1). This reaction scheme is shown in Figure 1. In work to be presented, we investigate the feasibility of using these chemical reagents to selectively cleave the amide bond of peptides.

Figure 1



All experiments were performed on a quadrupole ion trap. The rationale for using this instrument is its ability to mass-select the ion of interest and its capability of controlling ion/molecule reactions by varying the storage time. In addition, MALDI and electrospray ionization sources can be interfaced with the ion trap. In our preliminary studies, negative chemical ionization in the trap was used to ionize small model amide compounds. An electrospray/ion trap instrument was then utilized to extend the reactions to small peptides.

NEGATIVE CHEMICAL IONIZATION

The negative CI experiment involves the use of the hydroxide ion from water as the reagent ion. The hydroxide ion abstracts a proton from the neutral amide molecule generating the $[M-H]^-$ ion. This ion is mass isolated and allowed to react with the neutral reagent which is introduced through a pulsed valve

mounted within the vacuum manifold. A negative DC voltage is placed on the endcaps of the ion trap in order to operate outside the stability region of positive ions (2). This eliminates the possibility of ion-ion recombination which would occur if the trap were operated in its normal mode in which both positive and negative ions are stable and efficiently stored. The spectra illustrating the sequential steps for the reaction between S-ethyl trifluorothioacetate and $[M-H]^-$ ion of N-methyl acetamide are shown in Figure 2.

ELECTROSPRAY IONIZATION

In order to extend these studies to peptides, it is necessary to use an ionization technique suitable for labile molecules. However, forming the anion of the peptide in which the negative charge is present on the amide group poses a problem. Instead, the most likely site of deprotonation is the terminal carboxylic acid or side chain of an acidic amino acid. If the reaction of the anion formed from an underivatized peptide is allowed to react with S-ethyl trifluorothioacetate, the product ion is that shown in Figure 3. Derivatization of the acidic groups with tert-butyl ester will protect these acidic functionalities, but the ability to subsequently deprotonate the amide group by electrospray has yet to be demonstrated.

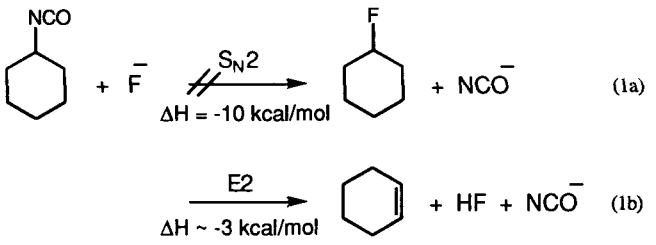
Neutral Products From Ion-Molecule Reactions: F^- + 5-Chloro-1,3-Pentadiene

Michael Baschky and Steven Kass
Department of Chemistry
University of Minnesota, Minneapolis, MN 55455

Ion-molecule reactions generate new ionic species which are readily detected with mass spectrometers. The neutral byproducts, however, often contain the information of interest, but they are much more difficult to identify. In this paper we describe how these compounds formed in a flowing afterglow device can be collected and identified.

Cyclohexyl isocyanate reacts readily with fluoride to afford isocyanate ion (eq 1). Analysis of the neutral products from this reaction reveals that cyclohexene is formed and that cyclohexyl fluoride is not observed (i.e. elimination is favored over substitution).



(1a)

(1b)

5-Chloro-1,3-pentadiene reacts with fluoride at the collision controlled rate to afford chloride ion (eq 2). Several different reaction channels can readily be envisioned to be responsible for the formation of the chloride ion. Identification of the neutral products from this reaction indicates that all three pathways (i.e. S_N2, S_N2', and E2) take place, and that $S_N2 > S_N2' > E2$. Molecular orbital calculations (Table 1) are consistent with this observation. They also reveal that the double bond does not activate the nucleophilic substitution reaction, and that it has a flexible orientation (i.e. conjugation of the double bond with the incipient p-orbital of the carbon atom bearing the leaving group is unimportant in contrast to conventional

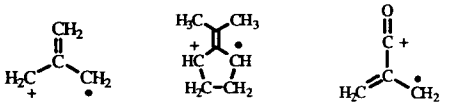
Ion-molecule Reactions of Trimethylenemethane Radical Cations

Phillip K. Chou[1], Sherry L. Painter[2], Silas C. Blackstock[2], and Hilkka L. Kenttämaa[1]

[1]Department of Chemistry, Purdue University, 1393 BRWN Building, West Lafayette, IN 47907-1393. [2]Department of Chemistry, Vanderbilt University, Nashville, TN 37235.

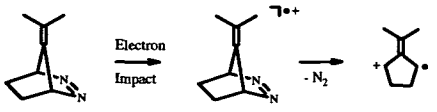
Radical cations that have charge and radical sites separated by one or more atoms are defined as distonic ions. Utilizing an Extrel Model 2001 Fourier transform ion cyclotron resonance mass spectrometer, studies were carried out on an unusual class of distonic ions (**1-3**) possessing the trimethylenemethane radical cation ($TMM^{+\bullet}$) structure.



1 **2** **3**

These ions are unique in that both the radical and charge sites are potentially delocalized throughout the ion. Electron impact ionization of methylenecyclopropane (MCP) produces an ion corresponding to the molecular formula of $TMM^{+\bullet}$ (**1**), $C_4H_6^{+\bullet}$. Recombination energy (RE) bracketing experiments indicated that $RE(C_4H_6^{+\bullet})=9.3 \pm 0.1$ eV. In comparison, the ionization energy (IE) of MCP was bracketed to be 9.4 ± 0.1 eV. These results suggest that most of the $C_4H_6^{+\bullet}$ ions generated from MCP have a cyclic structure. The $C_4H_6^{+\bullet}$ ions react with CH_3SSCH_3, $CH_3SeSeCH_3$, and benzeneselenol to yield abundant charge exchange products. However, a small amount of radical abstraction products were also observed in each case. This suggests that the $C_4H_6^{+\bullet}$ ions consist of a mixture of ionized MCP and $TMM^{+\bullet}$.

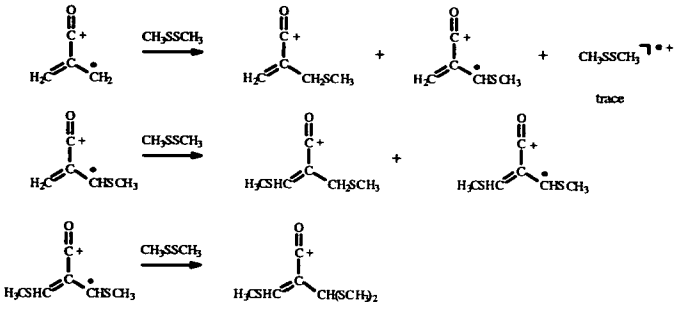
A cyclic derivative of $TMM^{+\bullet}$, the radical cation of isopropylidenecyclopentan-1,3-diyl ($IPC^{+\bullet}$, **2**) was generated from the fragmentation of an azo precursor (eq 1). In contrast to $TMM^{+\bullet}$, $IPC^{+\bullet}$ does not react with CH_3SSCH_3 and benzeneselenol. The RE of $IPC^{+\bullet}$ was



(1)

bracketed to be 7.8 ± 0.3 eV. This is consistent with the expected RE for $TMM^{+\bullet}$-type radical cations.

Dimethyleneketene radical cation ($DMK^{+\bullet}$, **3**) was formed from the fragmentation of α-methylene-γ-butyrolactone. The reactivity of $DMK^{+\bullet}$ was consistent with that of a distonic species; radical abstraction reactions were observed with CH_3SSCH_3, $CH_3SeSeCH_3$, and benzeneselenol. These reactions are very efficient, $Eff.(CH_3SSCH_3)=0.61$, $Eff.(CH_3SSCH_3)=1$, Eff.(benzeneselenol)=1, which is likely due to a mechanism that involves charge catalysis. Molecular orbital calculations (BVWN5/6-31G*//BVWN5/6-31G*) indicate that in $DMK^{+\bullet}$ the unpaired electron is delocalized over the allylic carbon atoms while the charge is localized on the carbonyl carbon. Clearly, delocalization of the radical does not diminish ion reactivity. The $DMK^{+\bullet}$ ion also displays unique reactive behavior in that it can undergo sequential abstraction of up to three $CH_3S^{\bullet}$ groups during reactions with CH_3SSCH_3 (Scheme 1).



Scheme 1

Reactions of Small Carbon Cluster Ions with Nitrogen Containing Compounds

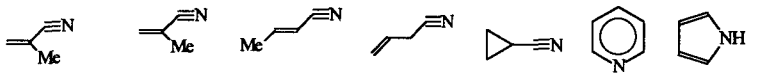
Robert C. Dunbar and Boguslav P. Pozniak
Chemistry Department, Case Western Reserve University, Cleveland, OH 44106

Introduction

Reactions of carbon cluster cations in the range C_{10}^+ to C_{24}^+ were studied,

$$C_n^+ + M \rightarrow C_n^+ \cdot M \; [\rightarrow \text{Fragmentation products}]$$

These cluster ions are believed to be monocyclic, and could be expected to obey Huckel-type aromaticity rules Previous work has showed striking cluster-number selectivity and aromaticity effects in reactions with benzene[1], and in some partial reaction series with acrylonitrile[2] and crotononitrile[3]. A more extensive set of nitrogen-containing substrates was examined here, using the complete series of cluster ions.



Acrylonitrile ACN | Methacrylonitrile MeCN | Crotonitrile CRN | Allyl cyanide ALC | Cyclopropyl cyanide CCN | Pyridine | Pyrrole

Experimental

Ions were produced by laser desorption/ionization of graphite at 532 nm, and trapped in the FT-ICR cell (Fig 1). Fig 2 shows a typical cluster ion production spectrum. After isolation of the desired cluster ion by rf ejection pulses, the reactions were followed by FT-ICR detection Pressures ranged from 1-100 x 10^{-8} Torr. Early in the reaction period ions had excess kinetic and internal energy ("hot ions"), while later, after 5-10 ion-neutral collisions, the ions were presumed to be thermalized Reaction rates and products were different in these two time regimes, and were recorded separately

Results

In most cases, the only reaction of thermalized cluster ions was simple association with neutral Exceptions were C_{10}^+, C_{12}^+ and C_{14}^+reacting with ALC and CRN, which gave some fragmentation products. Figs. 3 and 4 show the rate constants. Hot ions showed a wide variety of fragmentation products, and a greatly reduced association channel. CID of C_{11}^+ C_4H_5N and C_{15}^+ C_4H_5N gave only regeneration of the carbon cluster ion.

Discussion

Aromaticity effects. For the nitrile substrates, strongly enhanced reactivity is seen for the antiaromatic series of ions C_{13}^+, C_{17}^+, C_{21}^+ (Fig 3). This extends the previous observation of antiaromaticity enhancement of reactivity seen for benzene.[1] Enhanced ion production was seen for the aromatic series C_{11}^+, C_{15}^+, C_{19}^+, C_{23}^+ (Fig 2).

Mechanism. For thermal ions, the rate-limiting process is believed to be association to form an electrostatically bound complex, while rearrangements, insertions and fragmentation channels open up for hot ions. Supporting the complex-formation mechanism are (1) the fact that all the C_4H_5N isomers react at similar rates, (2) the tenfold lower reactivity of C_3H_3N than C_4H_5N, and (3) the CID results suggesting retention of carbon cluster ion identity in the complex. Pyrrole and pyridine showed fast reactions and little selectivity, and a different mechanism is believed to govern these kinetics.

Conclusions

Very large selectivity of reaction rates was observed depending on the size of the cluster ion, but little selectivity based on neutral substrate isomeric form. The selectivity strongly supports the hypothesis of aromaticity effects in carbon cluster ions, and reactivity enhancement for the antiaromatic cluster ions

ION-MOLECULE REACTIONS OF 18-CROWN-6 WITH ITS FRAGMENT IONS

Nanzhu Shen, Chadin Dejsupa, Marshall Pope, and David V. Dearden
Brigham Young University, Department of Chemistry, Provo, Utah 84602

Introduction

The mass spectrum of the macrocyclic ligand 18-crown-6 is well-known.[1-3] Under 70 eV EI, the protonated molecular ion M+1 peak (m/z 265) is not observed, while under more gentle conditions such as NH_3 CI or ESI it is prominent. The remainder of the spectrum is dominated by fragment ions characterized by losses of $(C_2H_4O)_n$ from the protonated parent. Notably, the loss of C_2H_4O to yield m/z 221 is not observed, consistent with losses of neutral *p*-dioxane.[4] This pattern of fragmentation results in fragment ions which are isobaric with protonated molecular ions of smaller members of the simple crown ether family, such as 12-crown-4 (m/z 177), 9-crown-3 (m/z 133), and *p*-dioxane (m/z 88). Our interest in 18-crown-6 stems from our use of proton attachment kinetics to measure the pressure of the neutral ligand. In this paper we probe some of the chemistry of 18-crown-6 chemical ionization, both using ammonia as a reagent and using "self-CI."

Experimental

All experiments were performed in a Fourier transform ion cyclotron resonance mass spectrometer (model APEX 47e, Bruker Instruments) equipped with an ion source external to the high-field region of a 4.7-Tesla superconducting magnet. EI, CI, and ESI were all performed with ion sources provided by the manufacturer, and which are readily interchangable. Electrostatic focusing and injection techniques were used to transfer ions from the source to the field-corrected ("Infinity") trapping cell of the instrument. Ion-molecule kinetics experiments were performed using ions isolated using conventional FTICR techniques (chirp and shot ejection of unwanted ions). Studies of the reactivity of m/z 177 also involved extensive collisional cooling by pulsing 10^{-5} mbar Ar into the trapping cell immediately after ion injection, followed by 90 sec cooling / pumpdown delay prior to isolation. Neutral pressures were measured using a magnetically-shielded ionization gauge (Balzers).

Results and Discussion

The molecule is surprisingly fragile. Reaction of NH_4^+ with 18-crown-6 gives extensive fragmentation, even though the proton affinity of 18-crown-6 is only 26 kcal mol^{-1} greater than that of NH_3.[5] The most prominent ion initially is a fragment at m/z 89, but fragments at m/z 133 and 177 are also produced. All eventually decay so at long reaction times the protonated molecular ion dominates. A small amount of 18-crown-6•NH_4^+ adduct also forms.

The pattern in self-CI is similar, but with some intriguing twists. The m/z 133 fragment reacts with the parent neutral to yield m/z 45, 89, 177, and, eventually, 265. Similarly, m/z 177 reacts with 18-crown-6 yielding m/z 45, 89, 133, and 265 (Figure 1). No adduction is evident in the reactions of either m/z 133 or m/z 177. Closer examination of the decay of these fragment ions shows that neither can be described by simple exponentials. A double exponential fits the decay of m/z 133 reasonably well, but fails to fit the decay of m/z 177. This suggests two or more isobaric ions at m/z 133, and three or more at m/z 177.

The observation of both smaller and larger fragment ions, as well as the inability to fit the decay curves using single exponentials, suggest that reactions of m/z 133 result in products at m/z 133, and that reactions of m/z 177 yield products at m/z 177. Since 18-crown-6 is a stable molecule, it follows that the structures of the isobaric reactant and product ions must differ.

We will focus on the m/z 177 fragment. It has generally been assumed that this fragment is protonated 12-crown-4. Is this really so? Collision-induced dissociation of the m/z 177 fragment, generated using 70 eV EI, NH_3 CI, and ESI from 49:49:2 methanol:water:trifluoroacetic acid, are similar. When EI is used to generate it, m/z 177 fragments to yield m/z 89, 45, and 40. From CI-generated m/z 177, only the m/z

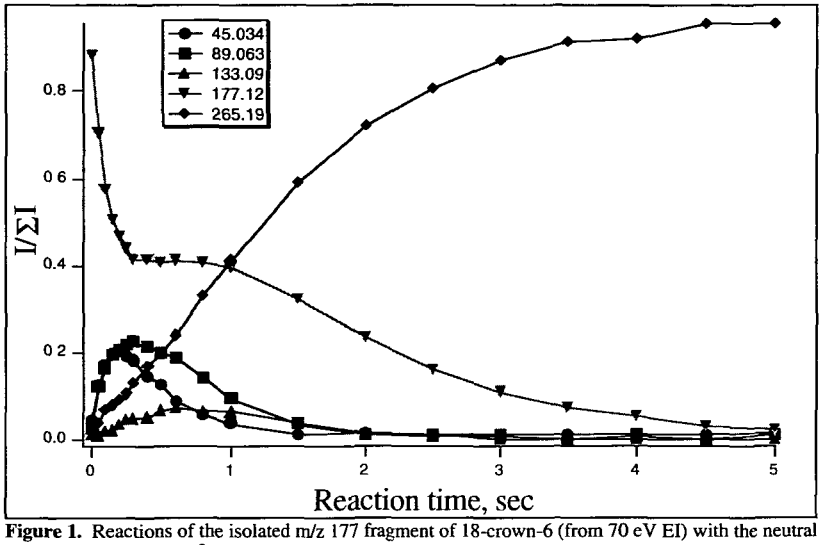

Figure 1. Reactions of the isolated m/z 177 fragment of 18-crown-6 (from 70 eV EI) with the neutral parent. $P_{18C6} = 5 \times 10^{-8}$ mbar.

89 fragment is seen, while the ESI-generated m/z 177 yields both 89 and 45. Thus, the CID spectra suggest that the three ionization methods produce ions which are energetically or structurally different.

Reactivity can be a sensitive probe of ion structural differences. We investigated the chemistry of protonated 12-crown-4, generated by electrospray from 49:49:2 methanol:water:acetic acid, with NH_3. In all of these experiments, $P_{NH_3} = 5 \times 10^{-8}$ mbar. The only observed reaction was formation of a 12-crown-4•NH_4^+ adduct at m/z 194; no proton transfer was observed, consistent with the fact that the proton affinity of NH_3 is 17 kcal mol^{-1} less than that of 12-crown-4.[6] (Similarly, the acyclic analog of 12-crown-4, triglyme, reacts exclusively by adduct formation.) EI-generated m/z 177, on the other hand, reacts primarily by proton transfer, with a very slow reaction to yield adducts. CI-generated m/z 177 also proton transfers to ammonia, but adducts were not observed. The ESI-generated fragment ion is unreactive even after 120 sec.

The structure of the m/z 177 fragment ion is still not known, but it is clearly *not* protonated 12-crown-4, and its reaction kinetics suggest ions of two or perhaps three different structures are present. Further interpretation awaits investigation of possible structures using theory.

We are grateful for support of this work by NSF, PRF, and Alcon Laboratories.

Structural Rearrangements and Reactions of the Trimethylene Sulfide Dimer Radical Cation. An Experimental and Theoretical Study

Michael Peschke, Michael L. McKee and Andreas J. Illies
Department of Chemistry
Auburn University

Abstract:

An experimental and computational study of the ion-molecule reactions of the trimethylene sulfide dimer radical cation, formed from the monomer and its monomer cation, has been carried out. The experiments were done mainly in a hybrid drift tube / ion source under chemical ionization conditions. MS/MS experiments were also done in a modified VG ZAB-1F mass spectrometer. The most abundant species under virtually all conditions is m/z 106 $S_2C_3H_6^+$. Computations suggest a cyclic structure with the sulfur inserted into the ring rather than an exocyclic sulfur attached to the trimethylene sulfide ring or an open chain. This is analogous to an earlier study of thiirane in which m/z 92 $S_2C_2H_4^+$, m/z 124 $S_3C_2H_4^+$, and m/z 156 $S_4C_2H_4^+$ were observed in the mass spectra. Those masses were attributed to sulfur insertion into one of the rings of the thiirane dimer parent cluster and subsequent ejection of ethylene followed by further ring expansion up to the six membered ring. In the present case, computations indicate a mechanism in which the trimethylene sulfide dimer cation undergoes several rearrangements resulting in sulfur insertion into the trimethylene sulfide ring. After a few more steps, including two hydrogen transfers, propylene is ejected. All of the intermediates and transition states are exothermic with respect to the monomer plus monomer cation (Figure 1). In addition, computations indicate a very stable eight-

membered ring, 1,5-dithiacyclooctane radical cation, as an intermediate which has the same mass as the dimer, m/z 148. MS/MS results support the presence of 1,5-dithiacyclooctane radical cation as well as the hydrogen transfer steps in the dimer rearrangement. Further ring expansion, analogous to the thiirane case, is not observed. Computationally, it is found that the six-membered ring $S_3C_3H_6^+$ plus propylene is endothermic with respect to m/z 106 cation plus trimethylene sulfide monomer neutral, explaining the end of the ring expansion with the five-membered ring.

Ion Molecule Reactions of Organophosphorus Compounds

Michael W. Wensing, Brad E. Forch, Robert A. Fifer

A. P. Snyder and C. S. Harden
U.S. Army, Edgewood Research, Development and Engineering Center
Aberdeen Proving Ground, MD 21010

Organophosphorus compounds (OPCs) have many important commercial applications: in plasticizers, pharmaceuticals, nerve gas agents, and pesticides. Their detection and differentiation is becoming of great commercial importance.

Sensitive detection of OPCs is achieved by atmospheric pressure chemical ionization triple quadrupole mass spectrometry (APCI-TQMS) due to the high proton affinities associated with these compounds. Characterization of the dissociation pathways of these compounds can result in selective detection schemes, and ion molecule reactions may be used to differentiate the dissociation pathways of different organophosphorus compounds. It has been observed that selected product ions produced from the dissociation of phosphonate and phosphate parent ions are subject to nucleophilic attack, while no product ions of phosphites are subject to nucleophilic attack. Ion molecule reactions may therefore be used to distinguish certain classes of compounds. In addition, these ion molecule reactions may be to differentiate isobaric daughter ions produced in the the dissociation of phosphonate, phosphate, and phosphite compounds. This work focused on characterizing different classes of compounds based on the interaction of their daughter ions with water.

The compounds analyzed included dimethyl methyl phosphonate (DMMP), diethyl ethyl phosphonate (DEEP), diethyl methyl phosphonate (DEMP), diethyl propyl phosphonate (DEPP), diethyl butyl phosphonate (DEBP), diisopropyl methyl phosphonate (DIMP), trimethyl phosphate (TMP), triethyl phosphate (TEP), tripropyl phosphate (TPP), tributyl phosphate (TBP), trimethyl phosphite (TMPI) and dimethyl phosphite (DMPI).

Neat samples were introduced by headspace analysis, protonated via a corona discharge, and travelled through a 2 mm orifice, N_2 curtain gas, a smaller 0.1 mm orifice, and into the high vacuum of the triple quadrupole mass spectrometer. Parent ions were selected with Q1, and product ions were detected with Q3. Collisions between water molecules and the product ions occured in Q2. The intensity of the product ions were monitored at increasing Ar pressures in the collision cell. The water was present as an impurity in the UHP 99.999% Ar gas. As the CAD gas thickness increased the amount of H_2O increased as well as the amount of product ions.

Selected phosphonate and phosphate product ions both show a great tendency to form water adducts. Phosphonate product ions form water adducts more extensively, phosphate product ions form water adducts less extensively. The phosphite product ions analyzed do not form water adducts. From the results obtained it appears that quadvalent phosphonate and phosphate ions react with water extensively. Product ions that have a lone electron pair on the phosphorus atom do not form water adducts.

Vibrational-energy dependence of the reactions of N_2^+ with Ar, Kr, O_2 and H_2 at thermal energies

Joost A. de Gouw, Li Ning Ding, Shuji Kato, Veronica M. Bierbaum and Stephen R. Leone

JILA, National Institute of Standards and Technology and University of Colorado, Department of Chemistry and Biochemistry, University of Colorado, Boulder, Colorado 80309-0440

In the study of ion-molecule reactions much attention has been paid in recent years to the role of the initial state of the molecular ions. Depending on the vibrational or electronic excitation of the ion, the reaction rate constants may vary considerably.

The apparatus used to study these processes consists of a selected-ion flow tube (SIFT) combined with either laser-induced fluorescence detection of the molecular ions, or mass spectrometric analysis of the reactant and product ions[1]. The quadrupole mass spectrometer identifies the reaction pathways, and the LIF technique provides a state-selective measurement of rate constants at thermal energies.

In reactions between $N_2^+(v)$ and Ar or Kr the charge transfer,

$$N_2^+(v) + \mathrm{Ar\ (or\ Kr)} \longrightarrow N_2 + Ar^+\ (\mathrm{or}\ Kr^+), \qquad (1)$$

is the most important channel[2] The rate constants measured for reaction (1) are shown in Fig. 1a. Charge transfer between $N_2^+(v)$ and Ar is endothermic for $v = 0$, but becomes exothermic for $v = 1$, which explains the increase of the rate constant by two orders of magnitude. Although charge transfer between $N_2^+(v)$ and Kr is exothermic for all v, the rate constant increases, though more gradually, by a factor of 100 in going from $v = 0$ to $v = 4$. These observations can be explained qualitatively by considering the Franck-Condon overlap and the energy difference between the possible initial and final states, but the calculations give no quantitative agreement.

In the $N_2^+(v) + O_2$ system both charge transfer and the vibrational deactivation process,

$$N_2^+(v) + O_2 \longrightarrow N_2^+(v') + O_2 \qquad \text{with } v' < v, \qquad (2)$$

are important reaction channels[3]. The rate constants for reaction (2) even exceed the charge-transfer rates. Unlike rare gas atoms a diatomic molecule can easily absorb the vibrational energy of N_2^+, especially if the vibrational frequencies of the ion and the molecule are similar.

In the $N_2^+(v) + H_2$ reaction the dominant channel is the transfer of a hydrogen atom[4]:

$$N_2^+(v) + H_2 \longrightarrow N_2H^+ + H. \qquad (3)$$

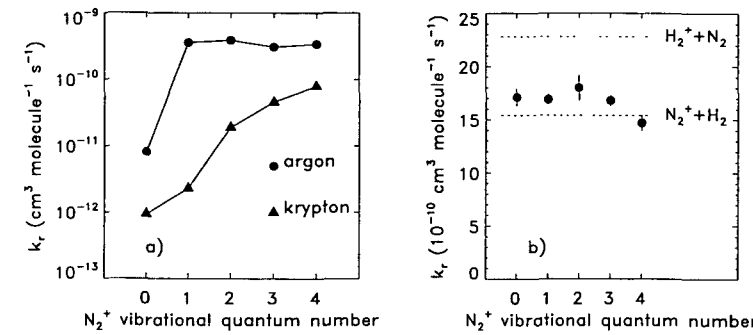

Figure 1: The rate constant as a function of the vibrational excitation of N_2^+. a) for the charge-transfer reaction with Ar and Kr, and b) for the hydrogen-atom transfer reaction with H_2.

The two other reaction channels, charge transfer and vibrational deactivation, are of minor importance. The measured rate constants for reaction (3) are shown in Fig. 1b The rate constant is almost independent of the vibrational excitation of the N_2^+ ion. The lower dashed line represents the classical Langevin rate for this system and it is clear that the results exceed this rate These observations are explained by a simple reaction model in which the first step of the hydrogen-atom transfer consists of a charge transfer at large internuclear distances. After this first step the Langevin rate is higher, since the polarizability of N_2 is larger than of H_2. The experimental results are below this second Langevin rate, as indicated in Fig. 1b. Moreover, as a result of the first step, a number of different intermediate states can be reached, which qualitatively explains the weak state-dependence of the rate constant.

Symmetry Induced Kinetic Isotope Effects in the Formation of $Ar{\bullet}CO_2^+$

R. K. Yoo and Gregory I. Gellene
Department of Chemistry and Biochemistry
Texas Tech University, Lubbock, TX 79409-1061

During the past decade evidence has been mounting for the existence of a new type of kinetic isotope effect which is dependent on symmetry considerations and is thus qualitatively and quantitatively different from those usually considered in chemical kinetics. Our interest in Symmetry Induced Kinetic Isotope Effects (SIKIE) was motivated by the observation of SIKIE in the formation of O_4^+ from O_2 and O_2^+. In that study [Griffith and Gellene, JCP **96**, 4403 (1992)], ^{17}O and ^{18}O were equivalently incorporated into O_4^+ to levels up to 100 times their natural abundance. This result could not be explained by any existing theory and a new theoretical approach [Gellene, JCP **96**, 4387 (1992)] was developed which both rationalized the O_4^+ results and provided a framework for identifying new systems where SIKIE might be observed. In particular, a potential system is required to have an asymptotic electronic degeneracy arising from either (1) one or both of of the reactants being in a degenerate electronic state or (2) identical reactants in different electronic states. Application of this theory to the association reaction: $He^+ + 2He \rightarrow He_2^+ + He$, lead to the prediction that $^7He_2^+$ formation should be enhanced by SIKIE which was subsequently experimentally observed [Gellene, JPC **97**, 34 (1993)].

A particularly interesting conclusion of the application of the theory to the O_2/O_2^+ system, was the prediction different SIKIE for the loss of molecular centrosymmetry and the loss of the asymptotic degeneracy. That point was addressed by the study of $(CO_2)_2^+$ formation where ^{13}C substitution lifts the asymptotic degeneracy while preserving molecular centrosymmetry and $^{17,18}O$ substitution removes both symmetries. The results confirmed the theoretical predictions with unique and independent SIKIE being observed for ^{13}C and ^{18}O [Yoo and Gellene, JCP **102**, 3227 (1995)]. Because the observed ^{18}O SIKIE is attributed to the loss of the centrosymmetry of CO_2^+ ion, it was suggested that an ^{18}O SIKIE might still be observed if CO_2 is replaced by another closed shell species. This conjecture is explored in the present study.

CO_2^+ was produced by 21 eV electron ionization of Ar/CO_2 mixtures (with natural isotopic abundances) at an ion source inlet pressure of 10-150 mTorr and an ion source temperature of -55° C. The ions were accelerated to 5 keV, magnetically mass resolved and detected by a Channeltron electron multiplier operating in the single ion counting mode.

The primary data was used to calculate the statistically normalized enhancement fac[illegible] EF) for ^{13}C and ^{18}O by the procedure described previously [Yoo and Gellene, JCP **102**, 3227 (1995)]. The results are shown in Fig. 1. In agreement with the theoretical predictions no enhancement of ^{13}C is observed (i. e., $EF(^{13}C) = 1$) whereas a substantial enhancement of ^{18}O is observed (e. g. $EF(^{18}O) > 20$ for $Ar:CO_2 = 1:15$). Because the measurements were taken under conditions where Ar^+ can be produced, the loss of $EF(^{18}O)$ with increasing $Ar:CO_2$ ratio suggests that CO_2^+ ions produced by $Ar^+/CO2$ charge transfer are preferentially produced in those states for which no symmetry restrictions to $Ar{\bullet}CO_2^+$ cluster formation are

predicted. Noting that these quantum states of CO_2^+ are precisely those for which no symmetry restrictions to $(CO_2)_2^+$ formation were predicted [Yoo and Gellene, JCP **102**, 3227 (1995)], the present results imply that CO_2^+ ions produced by Ar^+/CO_2 charge transfer will more efficiently produce $(CO_2)_2^+$ cluster ions than will CO_2^+ ions produced by electron impact. This remarkable prediction was tested by monitoring the intensity of $(CO_2)_2^+$ cluster ions produced in the presence of Ar under conditions where Ar^+ could (E_e = 21 eV) and could not (Ee = 15 eV) be produced. The results shown in Fig. 2 clearly demonstrate that $(CO_2)_2^+$ are strongly promoted when the CO_2^+ ion is produced by Ar^+/CO_2 cha ge transfer.

Fig. 1. Isotopic Enhancement Factors (EF) in $Ar{\bullet}CO_2^+$ Formation

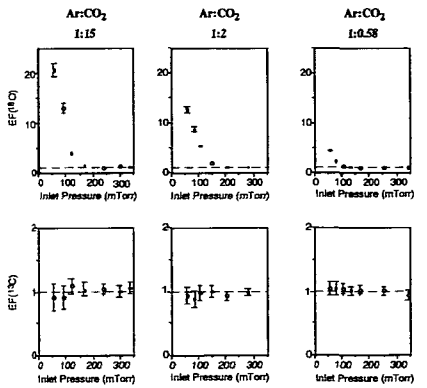

Fig. 2. Effect of Ar on $(CO_2)_2^+$ Formation

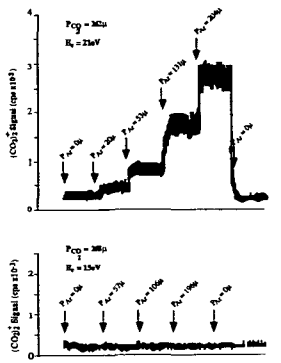


Conclusions

1. SIKIE has been observed for the first time in a chemical system where the reactants have no atoms in common. This effect can be understood (indeed, it was anticipated) by the theory of the phenomena being developed in this laboratory.

2. Unanticipated quantum state propensities are inferred for Ar^+/CO_2 charge transfer.

3. Ar acts as a catalyst for $(CO_2)_2^+$ cluster ion formation.

Structural Aspects of Metal-Oligonucleotide Binding Studied by ESI-CID-MS

Xueheng Cheng, Qinyuan Wu, Quanyin Gao, Steven A. Hofstadler, Richard D. Smith
Chemical Sciences Department and Environmental Molecular Sciences Laboratory,
Pacific Northwest Laboratory, Richland, WA 99352.

INTRODUCTION

Metal ions play important roles in biological system. Not only are they often required as cofactors for enzymes, but they also associate with RNA and ribozymes (i.e. catalytic RNA). Similarly, interaction of the negatively charged DNA backbone with certain metal counterions have been known to affect the DNA's polyelectrolyte behaviors and to stabilize certain structures such as DNA quadruplexes. Some metal complexes have also been used for DNA cleavage as potential methods for DNA sequencing or as alternatives for DNA-protein footprinting. On the other hand, the effects of cation binding on dissociation behaviors of oligonucleotides in mass spectrometry are closely related to the fragmentation mechanism and the application of MS to characterization of oligonucleotide structures.

EXPERIMENTAL

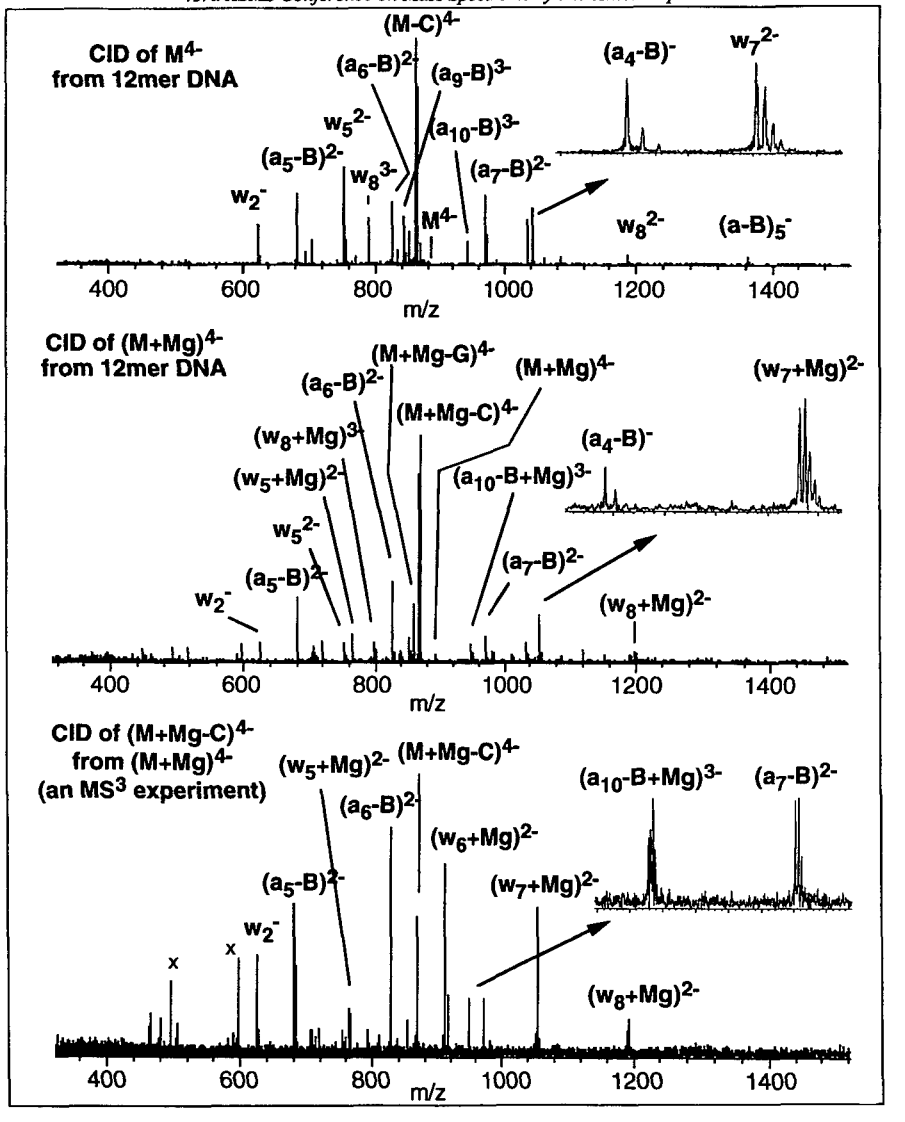
Multiply-charged ions of oligonucleotides and their complexes with Na^+, Mg^{2+} and UO_2^{2+} ions were generated by electrospray ionization (ESI). The collision induced dissociation (CID) experiment was done on a 7-T FTICR instrument (IonSpec). The experiments on tRNA were done on a Finnigan MAT TSQ 7000 triple-quadrupole mass spectrometer. A home-built microspray emitter optimized for very low sample infusion rate (0.2-0.5 ul/min) was used on both instruments. The DNA and tRNA samples was desalted using Centricon 3 or Centricon10 filters twice with 100 mM triethylammonium acetate or 10 mM ammonium acetate. The amount of residue metals in the DNA and RNA was determined using ESI-MS before addition of specific metal ions to be studied.

RESULTS

We have probed the structures of metal-bound oligonucleotides using collision CID. The CID of negative ions from two oligonucleotides (8mer: 5'-pGCTTGCATp-3' and 12mer: 5'-TTGGCCCTCCTT-3') with and without metal adduction were studied. The results of the 8mer DNA indicate that cleavage at the 3'-side of T is the least facile process. In the CID of metal containing species, the position of the metal can be inferred from an analysis of the distribution of the metal containing fragments. The results suggest that in the 8mer DNA, UO_2^{2+} is localized in the middle of the sequence possibly binds to the TT position while Na^+ is more mobile. The 12mer DNA also showed a clear absence of 3'-side dissociation for all the T residues while abundant fragments were observed for all other positions. The low dissociation propensity of T will impose certain limitations on the use of CID for DNA sequence determination. The CID spectra of the metal adducted ions of the 12mer DNA (Mg^{2+} and UO_2^{2+} studied) also suggested that the metals are localized in the middle of the sequence involving the T_8 position. Multi-step dissociation experiments (up to MS^4) revealed the dissociation sequence and aided the assignment of fragment ions. These results on the dissociation of metal-bound DNA showed the potential of using CID to determine binding location and possibly higher order structures of metal-bound DNA in the gas phase. The effect of divalent metal Mg^{2+} and monovalent cation NH_4^+ on the conformation of tRNA was also examined. The addition of both cations induced a charge state shift of tRNA from around m/z 1500 to m/z 2500, indicaitng the formation of a folded structure, while triethylammonium cation did not show such an effect. These results are consistent with the effect of cations on the conformation of tRNA studied in solution and suggest that gas phase dissociation of metal adduct of tRNA may eventually reveal the position of cation binding in tRNA.

Pacific Northwest Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy, through Contract No. DE-AC06-76RLO 1830.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

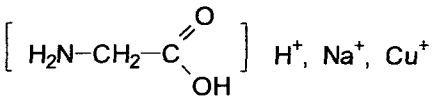


GAS PHASE CHEMISTRY OF MX$^+$ IONS, (X = H, Na, Cu), FROM GLYCINE

Sarka Beranova, Blas A. Cerda, and Chrys Wesdemiotis

Department of Chemistry, The University of Akron, Akron, OH 44325-3601.

Interactions of biomolecules with cations play a crucial role in biological systems. Mass spectrometry has been established as a powerful tool for studies of these interactions in a solventless environment. Elucidation of detailed gas phase chemistry of cationized amino acids can help understand the behavior of peptides and proteins and is, therefore, of fundamental interest. This investigation concerns the unimolecular reactivity of the FAB generated glycine complexes with three different cations: H^+ [1], Na^+, or Cu^+. Their chemistry is probed by collisionally activated dissociation (CAD), and neutralization-reionization mass spectrometry (NRMS). The NRMS methodology allows (a) the evaluation of the complementary neutral fragments generated upon CAD of the precursor ion under investigation, or (b) the generation and characterization of the ion's neutral counterpart, accessible by charge-exchange reduction, which can provide additional structural and mechanistic information.



Collisionally activated $GlyH^+$ dissociates by several competitive pathways, giving rise to the CAD spectrum of Figure 1a. The most prominent decomposition yields the $H_2N^+{=}CH_2$ ion (*m/z* 30) by consecutive losses of H_2O and CO. The alternative pathway, i.e., direct cleavage of $:C(OH)_2$ (or HCOOH) is ruled out from the absence of a sizable amount of these molecules among the coproduced neutral fragments. Other primary CAD fragments include $H_3NCHCOOH^+$ (*m/z* 75), $CH_2C(OH)_2^+$ (60), H_2NCHCO^+ (57), $H_2N^+{=}CH_2$ OH_2 (48), ^+COOH (45), and $H_3NCH_2^+$ (31). Either of the functional groups in glycine can bind the added proton. The CAD data point out that the ionic products commence from both the N- and the O-protonated species. Examination of the neutralized form of $GlyH^+$ shows that both isomers are present at the moment of neutralization. Since glycine neutrals should prefer direct dissociation over rearrangement, the initial protonation process most probably occurs at both the amino and the carboxyl functionality.

When subjected to dissociating collisions, $GlyNa^+$ and $GlyCu^+$ produce mainly the metal ion Na^+ and Cu^+, respectively (viz. Figure 1b and 1c). The majority of additional fragments has organometallic character. The glycine-sodium adduct eliminates H, H_3N, H_2O, H_2NCH_2, CH_5N, COOH to give Na^+-containing ions at *m/z* 97, 81, 80, 68, 67, and 53, $GlyCu^+$ produces ions at *m/z* 120 (H_2O loss), 108 ($-H_2NCH_2$), 92 ($-CH_2O_2$), and 90 ($-CH_4O_2$). Both complexes generate the immonium ion $H_2N^+CH_2$. The other

significant organic product ion arising from $GlyNa^+$, namely ^+COOH (*m/z* 45), is not reproduced in the $GlyCu^+$ spectrum, which displays an abundant $CH_2O_2^+$ at *m/z* 46, instead.

In summary, despite their small size, glycine-cation adducts exhibit rather complex dissociation characteristics. Combining tandem mass spectrometry techniques provides a valuable means to investigate the unimolecular chemistry and binding sites of such species.

MULTIPLY CHARGED COMPLEXES BETWEEN PEPTIDES AND TRANSITION METAL IONS: ESI MS-MS AND MS-MS-MS USING B/E VS MIKES SCANS

M. Cameron Sullards and Jeanette Adams, Department of Chemistry and the Emory University Mass Spectrometry Center, Emory University, Atlanta, GA 30322

Experiments were conducted to determine if product ions from $(M + Me)^{2+}$ complexes of angiotensin II, in which $Me^{2+} = Co^{2+}$, Ni^{2+}, Cu^{2+}, and Zn^{2+} are are discriminated against in B/E scans. MS^2 and MS^3 experiments were performed using electrospray ionization (ESI) and a JEOL JMS-SX102/SX102A/E five-sector, tandem mass spectrometer.

MS^2 B/E spectra of the $(M + Me)^{2+}$ precursors reveals abundant doubly charged product ions (Figure 1a). Singly charged product ions are either weakly abundant or not observed. MS^2 MIKES scans, however, reveal the presence of singly charged product ions of higher *m/z* than the precursor (Figure 1b). The low-mass complementary ions are significantly less abundant than their high-mass counterparts.

Narrow signal-averaged MIKES scans show that the complementary ion pairs exhibit a large kinetic energy release. Virtually identical kinetic energy release distributions (KERDs) indicate that the ions are indeed complementary. Increased dishing and decreased detectability occurs for the low-mass ions.

MS^3 B/E spectra of the first-generation product ions that arise from $(M + Me)^{2+}$ precursors reveal abundant doubly charged second-generation product ions (Figure 2a). Singly charged product ions are either weakly abundant or not detected. MS^3 MIKES scans, however, show a greater abundance of singly charged product ions (Figure 2b). The low-mass complementary ions are not observed.

Metastable ion and collision-induced dissociations (CID) are traditionally used for structure determination of singly charged gas-phase complexes between peptides and metal(II) ions [1,2]. Singly charged product ions that arise from doubly charged precursors must be formed via charge separation reactions. These reactions are characterized by a large kinetic energy release (KER). Sector instruments discriminate against ions that have a large KER, and this discrimination is proportionately greater for low-mass ions. This discrimination is caused by the finite heights and widths of slits, and the limited kinetic energy bandpass of the magnet and ESA.

Consequently, double-focusing B/E scans give misleading relative ion abundances for product ions formed by charge-separation reactions. MIKES experiments can be used to either detect or to estimate relative ion abundances. Furthermore, accurate mass calibration is vital for correct *m/z* determination and product ion assignment in B/E scans.

ELECTROSPRAY MASS SPECTROMETRY OF ALKALI-METAL ION COMPLEXES OF PROTEINS AND PEPTIDES

Jianyao Wang, Fu Ke, Roger Guevremont and K.W. Michael Siu, Institute for Environmental Research and Technology, National Research Council of Canada, Ottawa, Ontario, Canada, K1A 0R6; J.C. Yves Le Blanc, SCIEX, 71 Four Valley Drive, Concord, Ontario, Canada, L4V 4V8.

Gas-phase alkali-metal ion complexes of proteins and peptides that contain one to tens of metal ions can readily be produced in electrospray mass spectrometry from peptide/protein solutions containing the appropriate alkali metal hydroxides. For tripeptides, the $[M-H+2X]^+$ and the $[M-2H+3X]^+$ ions (where X is the alkali metal ion) are the most intense species observed in the positive ion detection mode {1}, while the $[M-H]^-$, the $[M-2H+X]^-$ and the $[M-3H+2X]^-$ ions are those observed in the negative ion detection mode. Collision-induced dissociations of these adduct ions showed that the alkali metal ions attach to one or several of the following moieties, the C-terminal carboxylate anion, the amide nitrogen atom, the amide carbonyl oxygen, and the N-terminal nitrogen atom {1}. The above adduct ions may be expressed in the general form $[M+nH+mX]^{(n+m)}$; e.g. the $[M-2H+3X]^+$ ion is a $[M+nH+mX]^{(n+m)}$ ion where n = -2 and m = 3. $[M+nH+mX]^{(n+m)}$ ions in which n and m are relatively large are observable from longer peptides and proteins. Figure 1 shows the electrospray mass spectrum of a 20 μM bradykinin (RPPGFSPFR) solution in 50/50 water/methanol adjusted to pH 12 with potassium hydroxide. The most abundant cluster is doubly charged, (n+m) = 2, with n = 1 to -7 and m = 1 to 9. Similar results for ubiquitin are displayed in Figure 2. For the 8+ cluster, cluster ions with n = -5 to -10 and m = 13 to 18 are evident.

$[M+nH+mX]^{(n+m)}$ ions, especially those of oligopeptides, are revealing in that they show "substitution" of peptide protons that are not conventionally considered acidic by alkali-metal ions. These protons are likely to be the amide protons on the peptide backbone. We have argued that a gas-phase ion-ion reaction to form the positively charged $[M+nH+mX]^{(n+m)}$ ions is unlikely as non-complexed peptides are anionic in a pH 12 solution, and anions are not expected to desorb when the electric field is directed outward from the air/solution interface {1}. As a result, we speculated that the $[M+nH+mX]^{(n+m)}$ ions or their "precursor" ions must exist in solution and desorb into the gas phase during the electrospray experiment. The precursor ions that desorb are transformed into the $[M+nH+mX]^{(n+m)}$ ions in the front end of the mass spectrometer and measured {1}. The mechanistic limitations on the formation of the $[M+nH+mX]^{(n+m)}$ ions are identical for the scenarios in which desorption takes place from a droplet formed from solvent evaporation and Rayleigh fission and in which desorption takes place from the surface of the Taylor cone.

INFLUENCE OF SECONDARY STRUCTURE ON PEPTIDE ION DISSOCIATION IN A TANDEM TOFMS

Mary Gimon Kinsel, Damon C. Barbacci, and David H. Russell, Laboratory for Biological Mass Spectrometry, Department of Chemistry, Texas A&M University, College Station, Texas 77843

The non-covalent interactions experienced by biomolecule ions in the gas-phase may or may not be similar to those which determine their solution-phase conformations. It has been suggested that these interactions have an effect on ion dissociation. A series of peptides, Bradykinin and fragments containing amino acid residues 1-5, 1-6, 1-7, 1-8, and 2-9, has been studied in a TOF/ ReTOF mass spectrometer. Fragment ions are produced by metastable decay of the cationized peptide $[M+H]^+$ ion ($[M+Na]^+$ ion) or by 193-nm photodissociation of the cationized peptide ion. We have evaluated the information content of these spectra in terms of (i) sight of cationization, (ii) stability of fragment ion as well as neutral fragment lost, and (iii) relationship, if any, to the known solution phase structure of bradykinin determined by circular dichroism (CD)[1].

The metastable decay product ion spectra for bradykinin is shown in Figure 1. All spectra were recorded using the MALDI matrix α-cyano-4-hydroxycinnamic acid, 337-nm output of a nitrogen laser, 15.0 kV acceleration voltage, and -2.35 kV detector voltage. The $[B_8 + H_2O]^+$ product ion is the dominant fragment. Less abundant signals arise from a-type, b-type, and internal cleavages To investigate the nature of the effect ion structure, we examined the dissociation of 5 commercially available fragments of bradykinin: Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg (fragment 2-9); Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe (fragment 1-8); Arg-Pro-Pro-Gly-Phe-Ser-Pro (fragment 1-7); Arg-Pro-Pro-Gly-Phe-Ser (fragment 1-6); and Arg-Pro-Pro-Gly-Phe (fragment 1-5)

Compositional effects have an influence on the relative abundances of internal fragment ions in metastable decay spectra. The relative abundances of these product ions are shown in Figure 2. The competition between formation of the various product ions is a function of the stabilities of the product ions formed and the neutral(s) lost. Photodissociation of bradykinin $[M+H]^+$ ions yields an increase in the abundance of N-terminus containing product ions. However, the most dramatic increase is in the abundance of internal fragment ions (see Figure 3). This result is not unexpected because the internal energy of

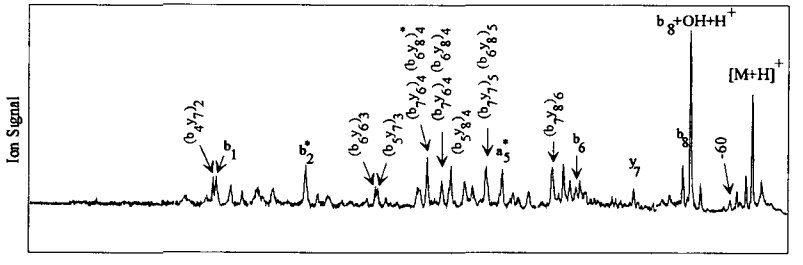

Figure 1: Metastable decay mass spectrum obtained for bradykinin using the α-cyano-4-OH-cinnamic acid matrix. An '*' following a sequence ion indicates loss of 17 mass units.

ions excited by absorption of a 193-nm (6.42eV) is high and the formation of internal fragments requires that two bonds break. Loss of the N-terminal Arg, Arg-Pro, and Arg-Pro-Pro appear to be common dissociation pathways. Metastable decay and photodissociation of the bradykinin and related fragment $[M+H]^+$ ions and $[M+Na]^+$ ions (results not shown) suggests that the sequence Pro-Gly-Phe (and/or Pro-Gly) has a high cation affinity.

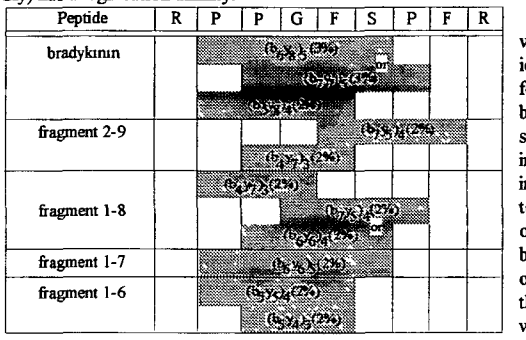

Figure 2: Relative abundances of internal fragment ions observed from the metastable decay of MALDI generated peptides.

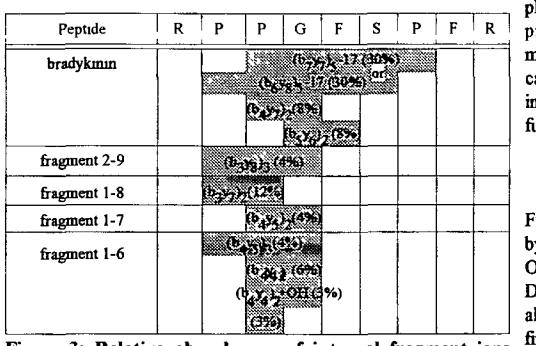

Figure 3: Relative abundances of internal fragment ions resulting from the 193-nm photodissociation of MALDI generated peptide ions.

From the results of this study, we find no indication that the gas-phase ion retains the secondary structural features (*i.e.*, intramolecular H-bonding) observed in solution-phase studies. We are currently investigating in detail the mechanism of dissociation, in particular, the role played by the N-terminal Arg. For example, the effect of exchanging Arg[1] for Lys[1] in bradykinin. If the mechanism for loss of the N-terminal residues depends on the length of the quananine side chain, we expect to see less efficient production of product ions by this mechanism. The identity of the neutral(s) lost can be further investigated by isolation followed by photoionization of the neutral products We are also exploring in more detail the use of semiempirical calculations as a tool to aid the interpretation of fragmentation as a function of peptide structure.

Intra-ionic Acid/Base Interactions in the CID of Protonated Peptides

[1]K.A. Cox, [2]A. Whiting, [3]M. Morris, [1]S.J. Gaskell

There has been a strong driving force to understand the factors which determine low energy dissociation processes of peptides.[1,2] The poor fragmentation efficiencies observed in the low energy CID of peptides containing strongly basic residues[3] is of particular interest because of widespread analyses involving tryptic peptides which contain C-terminal basic residues.

The nature of product ions derived from the dissociation of a precursor peptide ion is highly dependent on the primary structure of the peptide, particularly on the number and location of the basic amino acid residues.[4] In the presence of a highly basic amino acid residue, a precursor ion population is generated in which the ionizing proton is localized on this residue in a high proportion of the ions. The presence of the strongly localized charge is a detriment to the low energy CID of these peptides, and suppresses efficient and varied backbone cleavages.

The work described here represents a systematic investigation of the effects of charge heterogeneity in the precursor ion population of model peptides in low energy CID experiments. The nature and extent of low energy decompositions of peptides which contain highly basic arginine residues are compared to dissociations of analogous peptides in which acidic groups have been incorporated to balance the protonated arginines, allowing further protonation at less basic sites. In addition, molecular modelling has been utilized to determine preferred low energy conformational states of these gas-phase peptide ions.

Figure 1 shows the product ion spectra of doubly protonated RLCIFSCFR and RLC*IFSC*FR (where C* indicates cysteic acid) under identical conditions. In the first case, both ionizing protons reside on the highly basic arginine side chains, creating a precursor ion population which is homogeneous with respect to charge site; thus suppressing low energy fragmentation, which occurs primarily via charge directed mechanisms. Incorporation of the cysteic acid residues allows the generation of a heterogeneous charge population; these residues remain negatively charged upon ionization and effectively balance the positive charges incorporated on the arginines. The ionizing protons locate along the amide bonds of the peptide backbone and efficient low energy fragmentation is observed.

Molecular modelling was incorporated to provide insight into broad structural features of these peptides. In the case of RLCIFSCFR, the energy minimized structure is highly compact, with the hydrophobic backbone on the inside of the structure and the hydrophillic side chains on the outside. In contrast, the incorporation of cysteic acids results in a more open structure in which the negatively charged cysteic acid groups adopt a position proximal to the positively charged guanidino groups, giving clear evidence of electrostatic interactions.

RLCIFSCF can also produce a doubly charged precursor ion population which is heterogeneous with respect to charge site. Here, one proton remains on the N-terminal arginine, but the other site of protonation is variable. A predominant series of b-type ions is observed due to the charge retention on the arginine. In contrast, CID of tryptic peptides, where a strongly basic amino acid residue is at the C-terminus, generally yields more abundant y-type ions.[5] The present data suggest that the stability of the product ion is not solely due to its type (y or b), but to whether it retains its charge on the side chain of the basic residue, remote from the peptide backbone, making it resistant to further charge proximal dissociations.

In an effort to investigate the specificity of the electrostatic interactions and their influence on observed fragmentation patterns, we analyzed the peptides RLAIFSCFR and RLCIFSAFR which differ only in the relative positions of the amino acids at position 3 and 7. CID of the $(M+2H)^{2+}$ ions resulted in virtually identical fragmentation spectra. However, CID of the oxidized forms of these species resulted in strikingly different product ion spectra, apparently due to the specificity of the electrostatic interactions. This was substantiated by molecular modelling, which indicated distinct structural conformations for these species.

A MULTISTEP PATHWAY LEADING TO PEPTIDE w_n IONS CONFIRMED BY MS^3 AND MS^4

Kevin D. Ballard, Ralph S. Orkiszewski and Simon J. Gaskell[1]
Center for Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030
[1]Centre for Mass Spectrometry, UMIST, Manchester, M60 1QD UK

Fragment ions of the d_n, w_n, and v_n types from peptide $[M+H]^+$ ions represent concomitant side-chain and peptide backbone cleavages. Such ions are often observed during tandem mass spectrometric analyses of peptides under high energy collisionally activated decomposition (CAD) conditions. These types of ions facilitate amino acid sequencing of peptides, particularly the distinguishing of isobaric amino acid residues such as leucine and isoleucine. The formation of each these types of ions necessarily requires the cleavage of at least two covalent bonds, and thus involves at least one reaction intermediate in each of the fragmentation pathways leading to the formation of these ions. Previous studies from these and other[1] laboratories have shown that the activation energy requirement for the formation of w_n ions may be substantially lower than the corresponding requirements for the formation of the d_n and v_n species. Based on some elegant modelling studies, Wysocki and co-workers[1] suggested that one possible pathway for the formation of w_n ions from $[M+H]^+$ species involves the initial formation of an x_n+1 ion, which then decomposes to form a z_n+1 ion, which then further fragments to form the w_n species (Figure 1). The present studies were undertaken to test this hypothesis experimentally.

Results. Previous studies from these laboratories using reaction intermediate scanning demonstrated that z_n+1 species are involved as intermediates in w_n ion formation. The z_n+1 ions are not the only intermediates involved, however. Figure 1 presents a reaction intermediate scan representing the $[M+H]^+ \rightarrow$ intermediates $\rightarrow w_6$ reaction sequence for the peptide SIGSLAK. The first stage of decomposition occurred under high energy CAD conditions, with low energy CAD conditions for the second stage. It is clear from the spectrum that other intermediates, in addition to the z_6+1, are involved in the formation of the w_6 ion, including the $[M+H-H_2O]^+$ ion. The observation that an $[M+H-H_2O]^+$ intermediate, subjected to low energy CAD, can give rise to a w_n species again suggests that the energy requirements for w_n ion formation may be comparatively low. A reaction intermediate scan obtained under strict unimolecular decomposition conditions for the $[M+H]^+ \rightarrow$ intermediates $\rightarrow w_3$ reaction sequence for neurotensin (1-6) showed that the z_3+1 ion from this peptide can derive through unimolecular decomposition of the $[M+H]^+$, then subsequently decompose unimolecularly to form the w_3 ion *m/z*-deconvoluted MIKES analysis of the peptide VHLTPVEK representing the $[M+H]^+ \rightarrow w_6$ fragmentation (by all possible pathways) occurring in FFR2 under unimolecular decomposition conditions gave similar findings. These data thus demonstrate unequivocally that w_n ions can be formed unimolecularly from FAB desorbed peptide $[M+H]^+$ ions.

In order for the proposed multistep pathway for the formation of w_n ions to occur, it must be possible for z_n+1 ions to derive through the initial formation of x_n+1 intermediates. Reaction intermediate and sequential product ion scans with several peptides demonstrated that z_n+1 ions can be formed through x_n+1 intermediates. The third generation product ion spectrum (MS^4) depicted in Figure 2 explicitly demonstrates the occurrence of the $[M+H]^+ \rightarrow x_6+1 \rightarrow z_6+1 \rightarrow w_6$ reaction sequence for the peptide VHLTPVEK. The first two stages of decomposition occurred in the absence of added collision gas, with low energy CAD conditions employed for the third stage. The signal detected was very weak but was nevertheless reproducible The multistep mechanistic pathway for the formation of w_n ions, delineated as $[M+H]^+ \rightarrow x_n+1 \rightarrow z_n+1 \rightarrow w_n$, which was proposed by Wysocki and co-workers[1] based upon modelling studies, has thus been experimentally demonstrated to occur. As a serendipitous finding, new internal cleavage fragmentations, representing concomitant w-type and either B-type or A-type cleavage, have been identified during MS^3 analyses of FAB desorbed peptide $[M+H]^+$ ions.

WHY ARE B IONS STABLE SPECIES IN PEPTIDE SPECTRA?

T. Yalcin, I.G. Csizmadia, M.R. Peterson and A.G. Harrison
Department of Chemistry
University of Toronto
Toronto, Canada

Protonated amino acids and derivatives do not form stable acylium ions on fragmentation, rather the incipient acylium ion exothermically eliminates CO to form the immonium ion

$$RCH(NH_2)C(=O)X.H^+ \longrightarrow [RCH(NH_2)CO^+] \longrightarrow RCH{=}NH_2^+$$

On the metastable ion time scale the overall reaction occurs with substantial release of kinetic energy ($T_{1/2} \approx 0.2$-0.4 eV).

By contrast, protonated peptides and derivatives frequently show abundant B_n ($n \geq 2$) ions, which nominally are acylium ions, in their FAB and CID mass spectra. The present work addresses the question of why these B_n ions (nominally acylium) are stable when the acylium ions derived from protonated amino acid derivatives are unstable. We have used metastable ion studies, CID studies and *ab initio* molecular orbital calculations in these investigations.

We have observed that protonated dipeptide derivatives $H_2NCH(R')C(=O)NHCH(R)C(=O)X.H^+$ and protonated N-acyl amino acid derivatives $R'C(=O)NHCH(R)C(=O)X.H^+$ show a very similar behaviour in that HX is lost to form stable B_2 ions. These B_2 ions fragment metastably, in part, by loss of CO with substantial release of kinetic energy

$$B_2 \longrightarrow A_2 + CO \quad T_{1/2} = 0.3 - 0.5 \text{ eV}$$

In the same way, the B_3 and B_4 ions observed in the FAB mass spectra of larger peptides fragment unimolecularly, in part, by elimination of CO with a similar release of kinetic energy.

These results indicate that there exist stable configurations (S) of the B_n ions which fragment by way of reacting configurations (RC) which are higher in energy than the fragmentation products A_n + CO. Some of the exothermicity of the final fragmentation step is partitioned into kinetic energy of the separating fragments leading to the large $T_{1/2}$ values.

Both experimental results and theoretical calculations indicate that the stable structures (S) are protonated oxazolones formed by interaction of the next-adjacent carbonyl oxygen with the developing charge as HX is eliminated from the protonated species.[1] Experimentally we observed that the B_2 ion, nominally $C_6H_5C(=O)NHCH_2CO^+$, derived by loss of neutral glycine from protonated hippurylglycine shows the same metastable ion and CID behaviour as protonated 2-phenyl-5-oxazolone (Figure 1).

Theoretical calculations (3-21G and 6-31G**) for the simplest B ions nominally

$HC(=O)NHCH_2CO^+$	B_2
$HC(=O)NHCH_2C(=O)NHCH_2CO^+$	B_3
$HC(=O)NHCH_2C(=O)NHCH_2C(=O)NHCH_2CO^+$	B_4

show, in each case, that the global energy minima correspond to protonated oxazolone structures. Those for B_2 and B_3 are shown in Figure 2. Calculations for the acyclic acylium form of the B_2 ion showed one imaginary frequency indicating that the structure corresponded to a

saddle point or transition state on the potential energy hypersurface. These calculations showed that the acyclic structure (the reacting configuration, RC) was 1.5 eV higher in energy than the stable cyclic structure (S) and 0.9 eV higher in energy than the fragmentation products $HC(=O)NHCH_2^+$ + CO, consistent with the measured kinetic energy releases.

For the B_3 and B_4 ions the calculated structures indicate that there is a strong interaction of the next-adjacent carbonyl oxygen with the site of the positive charge in the oxazolone ring. Thus, a concerted electron shift can readily lead (Scheme) to the fragmentation reaction $B_n \longrightarrow B_{n-1}$ as is observed experimentally for B_3 and higher B ions.

This work will be published (hopefully) in J. Am. Soc. Mass Spectrom.

Bombesin is a tetradecapeptide with thermoregulatory and gastric effects in mammals. There are 39 other biologically active peptides closely related to bombesin[1], alytesin being one such example and so the importance of understanding how these compounds breakdown or form adducts is significant. The creation of a peptide/gas adduct was first proposed by Neumann et al[2] who said that under the correct collision conditions the system would have the maximum internal energy.

The peptides were analysed on a Kratos Concept IIHH four sector tandem mass spectrometer with EBEB type geometry. Ions were generated using static probe liquid secondary ion mass spectrometry (LSIMS) and were detected after MS2 by a scanning array detector.
The ions produced at the source were accelerated to 7.9kV (V_{acc}) and passed through MS1. The collision cell was floated to a potential (V_{cell})in order to create the desired laboratory frame energy (E_{LAB}) such that:

$$E_{LAB} = (V_{acc} + V_{cell})e \qquad (1)$$

Ions now travelling with an energy of (E_{LAB}) entered the second electric sector whose potential had been manually reduced to account for the centre-of-mass collision energy (E_{COM}).

$$V_{ESA\ potential\ used} = V_{full\ ESA\ potential} - E_{COM} \qquad (2)$$

$$E_{COM} = E_{LAB} \times m_{gas}/(m_{ion}+m_{gas}) \qquad (3)$$

Equation 3 gives the centre-of-mass collision energy (E_{COM}) provided the entire gas molecule joins the peptide. If fragmentation of the adduct occurs, the electric sector potential will be greater depending on the mass of the fragment.

The second magnet was scanned in order to produce a spectrum.

The target gas was allowed into the collision cell at such a pressure that the adduct could be seen. This value reduced the parent peak to about 80-90% its original size.

When the alytesin parent ion is collided with CH_4 an adduct appears at a +14Da mass shift from the molecule-ion, CD_4 produces a +17Da mass shift and $C^{13}H_4$ produces a +15Da mass shift. Results for CH_4 and CD_4 reactions are consistent with work done on renin substrate by Fenselau et al[3]. The +15Da mass shift obtained using $C^{13}H_4$ confirms that one proton (or in the case of CD_4, one deuterium) is lost from the target gas and one proton is lost from the parent molecule-ion, thus producing $(CH_3M)^+$, $(CD_3M)^+$, $(C^{13}H_3M)^+$ species as shown in figure 1

Correlation of Energy Losses from CID with Observed Peptide Fragments

Richard W. Vachet, Andrew D. Winders, and Gary L. Glish
Department of Chemistry, University of North Carolina, Chapel Hill 27599-3290

Introduction: Collision- induced dissociation (CID) has been used quite extensively in mass spectrometry to bring about the dissociation of ions and allow for the elucidation of analyte structure. In CID, some of an ion's kinetic energy is converted into internal energy upon collision with a neutral target. It is known that the kinetic energy lost upon collision(s) is proportional to mass.[1] The kinetic energy lost is also related to the amount of internal energy taken up by any individual ion. To see dissociations of different critical energies on the same time scale, different amounts of internal energy need to be deposited into the parent ion. This should be evident in the kinetic energy lost by the parent ion in the formation of different product ions.

Thus we postulate that measuring the energy losses in the formation of product ions may provide a means for identifying product ion types in complex spectra. Also, the magnitude of the energy loss may provide some insight into the mechanism of the fragmentation pathway and intramolecular interactions.

Experimental: Experiments were performed using a Finnigan MAT 900 instrument which has the normal (EB) geometry. Ions were generated by FAB using an 8 keV Argon beam and glycerol as the liquid matrix. Various peptide were used including leucine enkephalin and analogues, bradykinin, des- Arg[1]- bradykinin, and Substance P. Data was obtained using a B^2/E linked scan which provided the desired energy information of a parent ion when a particular product ion was selected. Helium was used as a collision gas and enough was added to attenuate the beam 60-70%. To determine the energy loss during CID, two experiments were performed. Observing the metastable decomposition of the parent ion to a particular product ion served as the reference to compare the energy lost by a parent during CID. Mass values reported by the data system were converted to energies and energy losses were calculated.

Results and Discussion: The rate of dissociation of an ion is a function of a number of parameters:

$$k=\nu\left(\frac{\epsilon-\epsilon_o}{\epsilon}\right)^{N-1}$$

where ν is a frequency factor, ε is the internal energy of the ion, ε_o is the critical energy of a particular decomposition, and N is the number of degrees of freedom of the ion. In our experiments the time scale is fixed, and for a given ion, N is fixed. Since product ions of a particular type presumably have the same mechanism for formation and thus similar critical energies, they should show similar energy losses. This is indeed evident for a number of peptides. For example the $\mathbf{y_2}$, $\mathbf{y_3}$, and $\mathbf{y_4}$ ions of leucine enkephalin (YGGFL) show energy losses of 4.59, 3.57, and 3.74 eV respectively. A general trend that is also seen is that **a**- and **b**- type ions have greater energy losses than do **y**- type ions. Likewise, **a**- type ions show greater energy losses than **b**- type ions. These results make sense in view of the accepted mechanism for the formation of these type ions. Also note that the energy losses for a particular fragment type increase with increasing mass (Figure 1).

An ion that shows a particularly interesting result is the $\mathbf{b_8}$+ OH ion of bradykinin (RPPGFSPFR). Previous studies have shown that this ion results from the loss of the C-terminal arginine and not the N- terminal arginine which would give the isomeric $\mathbf{y_8}$ ion.[2] The formation of this ion involves a rearrangement, and ion decompositions that involve rearrangements generally have lower critical energies than simple cleavages. This seems evident in the energy loss measurement for this ion, since the value is substantially lower than for other values for bradykinin.

Another general trend in the energy losses can be noticed in the peptides that contain arginine

(R). Product ions that correspond to fragmentations on the amino acid adjacent to the arginine tend to show surprisingly large energy losses. The trend can be noticed for the $\mathbf{b_8}$ ion of bradykinin and the $\mathbf{y_4}$ and $\mathbf{a_4}$ ions of YGRFL and can possibly be attributed to the side chain of the arginine interacting with the carbonyl oxygen on the adjacent amino acids and forming some type of second order structure. More energy is needed to disrupt this interaction and cause the resulting dissociation. Efforts to use computer modeling to verify this are underway.

Conclusions: The amount of energy loss by a particular ion during CID is related to the type of fragmentation that occurs. These variations in energy losses are attributed to the differences in critical energy and mechanisms of the fragment types. The size of the energy loss may help elucidate mechanisms in the formation of various product ions. Furthermore, the energy loss of a parent ion in the formation of a particular product ion may serve as a means of classifying fragment types. This should facilitate the interpretation of the MS/MS spectra of peptides and thus simplify the sequencing of peptides by mass spectrometry.

Peptide Sequencing by MS/MS Using a Hybrid Magnetic Sector-Orthogonal Acceleration Time-of-Flight Mass Spectrometer

Yiping Sun, Mark D. Bauer, Martin P. Lacey and Thomas Keough, The Procter and Gamble Company, Miami Valley Laboratories, P. O. Box 538707, Cincinnati, OH 45253-8707

Introduction MS/MS sequencing using a triple quadrupole mass spectrometer has proven to be a powerful technique for the structural characterization of peptides. However, because of the low-energy collision process, it generates very few side-chain fragments (d, w, and v ions). High-energy collision-induced dissociation (CID) using four-sector mass spectrometers provides side-chain fragmentation, unit mass selection of precursor ions and accurate mass measurement of product ions. However, these instruments are very expensive and relatively difficult to operate. A novel combination of a magnetic sector and orthogonal acceleration time-of-flight (oa-TOF) mass spectrometer is an alternative approach offering several advantages: high sensitivity, high mass accuracy and both low- and high-energy CID (1, 2). In this study, peptide sequencing using the VG Zabspec instrument is demonstrated. Data obtained from both fast atom bombardment and electrospray ion sources is presented.

Experimental oa-TOF MS/MS experiments were performed on a VG ZabSpec instrument. Peptides were ionized with either fast atom bombardment (FAB) or electrospray ionization (ESI). For FAB ionization, the instrument was operated at 8 kV acceleration voltage and 800 V collision energy. The TOF detector was set at 2350 V. The collision gas used was xenon, helium or methane. The product ions from CsI cluster ions were used for calibrating the instrument. For electrospray ionization, ions were decelerated from initial energies (4000 V) to 400 V for singly, 200 V for doubly, and 133 V for triply charged ions.

Results and Discussion Detailed evaluations on optimal collision gas pressure, sensitivity, mass accuracy, peptide size, and peptide type (e.g. linear, cyclized, difulfide-bonded, and phosphorylated), were performed. Good spectra were obtained with as little as 10 picomoles of material using FAB. Oxidized bovine insulin B chain (MH^+=3496.9) was fragmented extensively (Figure 1), while bovine insulin (MH_2^{2+}=2867.6) showed only two major fragment ions corresponding to both A chain and B chain, with Xe as the collision gas (Figure 2). Using renin tetradecapeptide (MH^+=1758.7) as a model peptide, the optimum collision gas pressure was 6.5-8.5x10^{-7} mbar for xenon, 4-5x10^{-7} mbar for helium, and 1-2x10^{-6} for methane. In addition, a variety of peptides were tested. Data indicated that oa-TOF MS/MS can be used to sequence phosphorylated peptides (e.g. $PP^{60C\text{-}SRC}$ carboxyl-terminal phosphoregulatory peptide) and cyclic peptides (e.g. gramicidin-S and cyclosporin-A). For intramolecular disulfide-bonded peptides like oxytocin, MS/MS of the (MH^+) peak showed weak fragmentation. MS/MS of the $(MH+2)^+$, the reduced form generated during FAB analysis, showed good fragmentation. Intermolecular disulfide-bonded peptides like glutathione (oxidized form) can be also sequenced. Figure 3 is a plot of the ratio of relative intensity of d11/a11 of renin tetradecapeptide as a fuction of the collision energy in FAB mode. This plot is similar to high energy CID data from four sector type MS/MS systems (3). Figure 4 is the ESI-oa-TOF MS/MS spectrum of the doubly charged ion (MH_2^{2+}=769.0) of fibrinopeptide A. The side-chain fragment ion W8 indicates the amino acid residue at position 9 is Leu, not Ile. Because of much lower ion transmission for multiply charged ions, a few hundred picomoles of peptides were needed to obtain a good spectrum in the electrospray mode.

Conclusions The combination of a sector instrument and an oa-TOF mass analyzer for peptide sequencing provides: 1. good mass accuracy for product ions, better than ± 0.3Da; 2. high sensitivity at low picomole levels for both FAB and ESI; 3. both high- and low-energy CID; 4. choice of different collision gases; 5. good mass selection of precursor ions; 6. good product ion resolution, 1000-1500 (FWHM); 6. sequencing peptides up to 4000 Da; and 7. easy to use.

Peptide Fragment Mass Spectra: Comparison of PSD and CID

Wade Hines, John Peltier, Frank Hsieh and Stephen A. Martin
PerSeptive Biosystems Inc., 500 Old Connecticut Path, Framingham, MA 01701

Protein sequence determination is essential to a broad range of disciplines including a critical role in linking cellular phenomena to their genetic origins. We are pursuing strategies which integrate sample purification, enzymatic digestion, chemical derivatization and sequence ladder creation with mass spectrometric based detection to enable rapid and reliable sequence identification of peptides and proteins Matrix-assisted laser desorption (MALDI) post-source decay (PSD) analysis of peptides is one key feature of this program. PSD allows for peptide sequence determination from the mass analysis of gas-phase fragment ions in a manner very similar to collision induced dissociation (CID) commonly done with triple quadrupole, multisector or hybrid tandem mass spectrometers. In analysis of peptides by MALDI, PSD fragmentation occurs spontaneously within the time frame of a reflector time-of-flight (TOF) mass spectrometry experiment. The fragmentation pathways observed in PSD analysis are familiar from both high and low energy CID of peptides but the mix of immonium ions, internal sequence fragments, and other sequence ions requires new strategies in order to capitalize on this route to discover sequence information.

Using commercially available peptides and peptides from mixtures produced by enzymatic digestion, we acquired the PSD spectra by MALDI and in some cases compare this to that obtained by low-energy CID on a triple quadrupole with electrospray ionization. PSD spectra included those obtained with timed ion selection from peptide mixtures.

PSD spectra provided extensive sequence data from a wide mass range of peptides including the oxidized B chain of bovine insulin (Ave. MH^+ 3496.9) and the hemoglobin tryptic peptide representing the sickle cell mutation (monoisotopic MH+ 922.54). The insulin B chain spectrum obtained from sinnapinnic acid as a matrix includes an extensive y ion series from y9 to 28 (Figure 1). It further includes b ions with both complementary and additional sequence information. Somewhat suprizingly, PSD spectra obtained from alpha cyano as a matrix yielded less overall sequence information but it did yield more extensive immonium and lower mass fragments. The insulin B chain sequence data was complete for internal regions of sequence but lacking near the termini. This is common among the larger peptides studied. The difficulty with terminal regions is inherent in the technic because even when sequence ions are present, internal fragment ions can offer false sequence trails near low mass region. The tendency to detect strong b2 and bn+18 ions may in part compensate for this difficulty. In all cases, additional sequence information, perhaps from ladder sequencing techniques is expected to prove useful to assist and extend sequence interpretation (Patterson et al. ASMS 95). Suppresion of the sample ion signal can also be a problem in MALDI resulting in poor signal to noise and little or no PSD information, eg. the unmodified peptide ALILTLVS yield no signal. When this peptide was derivitized with a quartenary ammonium functionality (reagent a gift from Darrel Pappin) a strong molecular ion and extensive PSD was obtained (Figure 2).

In general, PSD spectra were found to include much more internal sequence fragments and more immonium ions. The extent of immonium ion data for PSD appears to be between that found in high and low energy CID. Strong signals, for example His at 110, are common in PSD and document some of the amino acids present in a peptide but the lack of an immonium ion for an amino acid does not appear to be a reliable indication that a given amino acid is absent. This is especially true for competing cases. While Phe normally yields a peak at 120, this signal is absent in the peptide DRVYIHPFHLLVYS. Finally, precharged derivatives can offer a method to enhance the primary ion yield and PSD information.

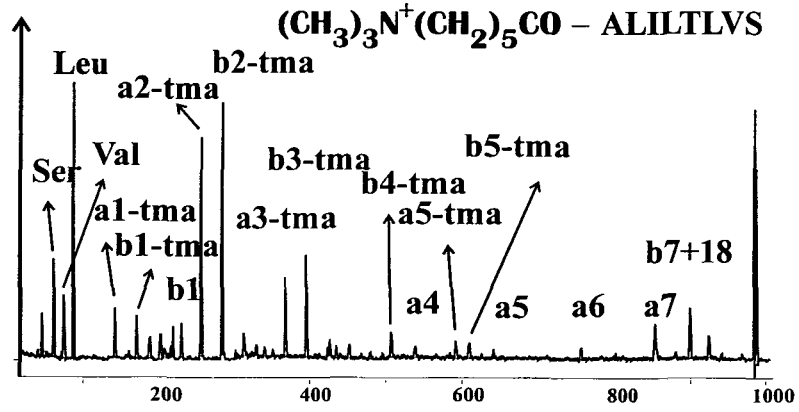

Figure 2. PSD MALDI-TOF mass spectrum of ALILTLVS derivitized with a quartenary ammonium functionality (reagent a gift from Darrel Pappin) exhibiting a strong molecular ion and extensive sequence specific fragment ions.

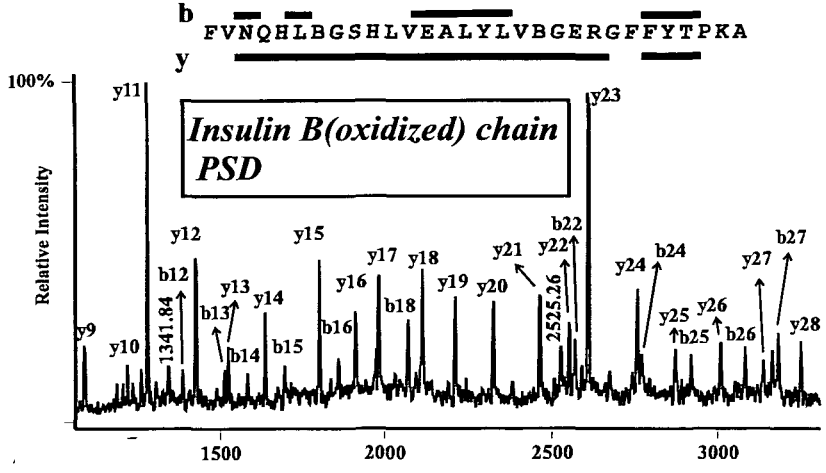

Figure 1. PSD MALDI-TOF mass spectrum of oxidized B chain of bovine insulin (Ave. MH^+ 3496.9) obtained from sinnapinnic acid as a matrix showing an extensive y ion series from y9 to 28.

COLLISONALLY ACTIVATED DISSOCIATION AND PHOTODISSOCIATION STUDIES OF MULTIPLY CHARGED IONS

Clifford H. Watson, Petia Shipkova, Richard D. Burton, Alan R. Katritzky, and John R. Eyler, Department of Chemistry, University of Florida, Gainesville, FL 32611-7200

In principle, multiply charged ions should be less stable than their singly charged analogs due to the inter-molecular strain resulting from columbic repulsions associated with two or more charged sites on an individual molecule. Prior to the emergence of electrospray ionization (ESI), detection of intact multiply charged ions was difficult because: (i) the intrinsic instability of such ions often leads to fragmentation; (ii) doubly charged ions often cluster with a counter-ion; and (iii) the loss or gain of a single electron is often favored[1]. Techniques used previously to study selected multiply charged organic halide and diquaternary ammonium salts have included FDMS[2], SIMS[3], LDMS[4], PDMS[5], and FAB[6] We report our initial results on the generation and dissociation of multiply charged organic cations using ESI coupled with Fourier transform ion cyclotron resonance (FTICR) mass spectrometry.

Previously, we have reported the production of singly charged cations using LD/FTICR and determined the CAD dissociation thresholds and infrared multiphoton dissociation pathways for a number of substituted alkyl pyridinium cations. These results are being extended using ESI to produce a series of doubly charged substituted alkyl pyridinium di-cations for study in the gas phase.

The di-cations are generated using an external ESI source, transferred to the FTICR analyzer cell using electrostatic ion optics, and trapped in the analyzer cell where they can be allowed to react with neutral molecules or fragmented using either collisional activation or laser-induced infrared multiphoton dissociation. In addition, we are also interested in studying multiply charged peptide molecules in a similar fashion.

The organic di-cation salts were dissolved in 50:50 (v:v) water/methanol solution at a concentration of 10^{-3} to 10^{-5} M and infused into the ESI source at a rate of 1 µl/min The relative intensity of the doubly charged cations for these organic salts was found to be concentration dependent. Lower concentrations tended to form a higher relative abundance of the doubly charged species while higher concentrations tended to favor production of "cluster" ions. Cluster ions consisted of one or more cations (CAT^{++}) associated with one or more anions (AN^-).

Shown in Figure 1 are portions of a typical ESI/FTICR mass spectrum of N-benzyl-2,4-diphenyl-6-[(N-methyl)-3-pyridinium] pyridinium di-perchlorate. When analyzed by ESI this compound tends to form two "cluster" ions $[2(CAT^{++})3(AN^-)]^+$ at m/z 1127 and $[(CAT^{++})(AN^-)]^+$ at m/z 513, a singly charged cation at m/z 413, and the doubly charged cation at m/z 207 as shown in Scheme 1 The doubly charged cation at m/z 207 undergoes dissociation via loss of $C_7H_7^+$ to produce the singly charged ions at m/z 91 and m/z 323 Similar dissociation patterns, i.e. loss of a singly charged alkyl cation and formation of a singly charged pyridinium cation, were observed for the other doubly charged pyridinium cations.

Impulsive Excitation of Ions During Surface-Induced Dissociation

John A. Burroughs, Samuel B. Wainhaus, and Luke Hanley
University of Illinois at Chicago
Department of Chemistry, m/c 111
Chicago, IL 60607-7061

While surface-induced dissociation (SID) has been demonstrated for a variety of ion-surface collision partners, little is known about its mechanism of excitation and fragmentation. The large assortment of ions which are amenable to fragmentation analysis via SID suggests that there exists a general mechanism which applies to the majority of ion-surface pairs. These experiments describe a three step model of SID which was previously applied to the dissociation of $Cr(CO)_6^+$ scattered off organic multilayers [1].

These experiments used a tandem mass spectrometer coupled to an ultrahigh vacuum surface analysis chamber [2]. The detecting quadrupole was used to measure the scattered ion kinetic energies.

These experiments scattered 20 to 90 eV $FeCp_2^+$ (Cp = cyclopentadiene) and $SiMe_3^+$ ions off multilayers of propylene (C_3H_6), hexafluoropropylene (C_3F_6), and tetrachloroethylene (C_2Cl_4) adsorbed on Ni(111). The ion internal energies following the surface collisions of the different multilayers were estimated from the relative fragment ion intensities and are shown in Figures 1 and 2 (discrete data points). The kinetic to internal energy transfer efficiencies varied as follows: C_2Cl_4 (~15%) ≥ C_3F_6 (~14%) > C_3H_6 (~10%). The scattered ion kinetic energies were less than 10% of the incident ion energy and did not depend upon the incident ion energy or angles, but did depend upon the chemical identity of the multilayer.

The experimental data was analyzed in terms of a three step model of SID consisting of impulsive excitation, inelastic scattering and unimolecular dissociation. The impulsive collision model predicts the average internal energy, <Q>, imparted to a polyatomic ion during a surface collision to be

$$\langle Q\rangle = E \cdot [2M_aM_s/(M_s + M_a)^2] \cdot [M_s(M_{ion}-M_a)/(M_{ion})^2]$$

where E is the ion kinetic energy, M_a is the mass of the atom/functional group in the ion impulsively excited during the collision (Me or Cp), M_s is the effective mass of the surface (one adsorbate molecule), and M_{ion} is the mass of the entire ion [1]. The predictions of the impulsive model for the internal energies imparted to each ion are shown in Figures 1 and 2 (solid lines). Impulsive excitation was estimated to occur within 10 - 35 fs of the ion impact.

Inelastic scattering and unimolecular dissociation were the latter steps of this model. Both $FeCp_2^+$ and $SiMe_3^+$ underwent inelastic scattering, with the surface dissipating ~70% of the incident ion kinetic energy. Unlike the unimolecular dissociation observed for $Cr(CO)_6^+$ scattering off organic monolayers [1], the inelastic scattering and dissociation were separate here. Both $FeCp_2^+$ and $SiMe_3^+$ must have dissociated at the surface within 3 ps of the initial impact since all fragments from a given parent had similar kinetic energies.

Electrospray Mass Spectra of Simple Aliphatic Diamines and Their Methosalts.

Xiaokui K. Zhang and Henry M. Fales

Laboratory of Biophysical Chemistry, National Heart, Lung, and Blood Institute, Bethesda, MD 20892-1676

For many years mass spectrometrists have been interested in charge repulsion in dicationized ions. Such ions, difficult to prepare in aliphatic systems using electron impact, are easily formed in electrospray mass spectrometry. Gross et al. (J. Phys. Chem. (1995) 99 4034) have recently reported the detection of doubly protonated α,ω-diamines $H_2N(CH_2)nNH_2$ when $n \geq 7$, and discussed their properties as studied by FTMS. Using a Finnigan TSQ-700 we have examined the corresponding permethylated diamines $(CH_3)_2N(CH_2)_nN(CH_3)_2$ where n=1-12 and their methiodides, also with a view toward examining the effects of charge repulsion on their subsequent decomposition by collisional processes.

In general, we find that the spectra of both the diamines and their methiodides are very dependent on the presence of auxiliary gas, concentration, and high tube (skimmer) voltage. All of these tend to reduce the intensity of the ions, especially those which are doubly charged (see Fig. 1). The free amines or their dihydrochlorides provide low intensity $(M+H)^+$ ions. When examined by MS/MS, these ions show as their main fragmentation pathway loss of dimethylamine, likely by a cyclic process involving participation by the uncharged amino group on the opposite end. Shorter chains, where $n \leq 4$ fail to show any doubly protonated ions. However, in contrast to the results of Gross et al. when $n \geq 5$ doubly protonated ions were indeed observed, probably due to their increased basicity due to methylation. These doubly charged ions also were examined by MS/MS and were found to cleave to singly charged ions by loss of dimethylammonium ion instead of dimethylamine. The very stable $(CH_3)_2N{=}CH_2^+$ and simple $C_nH_{2n-1}^+$ ions were also observed.

Spectra of the dimethiodides are considerably more complex. These show two series of ions. One is singly charged, deriving from adduction of an iodide ion and its relative intensity is augmented as expected by the addition of NH_4I. The other is the doubly charged ion itself and it is the base peak as long as auxiliary air is not used and the concentration kept low (Fig. 1). The iodide- adducted ion undergoes attack on either the methyl or methylene group adjacent to the positively charged nitrogen losing either methyl iodide or trimethylamine, respectively. The ion losing methyl iodide then undergoes loss of trimethylamine from the opposite end forming a cyclic ammonium salt. The other iodine-containing ion (resulting from attack on the methylene group) can split to form either a cyclic iodonium ion (if n=3 or 4) or undergo homolysis producing the radical cation of trimethylamine. The doubly charged diquaternary cation undergoes proton rearrangement losing trimethylammonium ion and $(CH_3)_2N{=}CH_2^+$ or simple homolysis to form the two radical cations m/z $59^{+\bullet}$ and $M\text{-}59^{+\bullet}$. Of considerable interest is the offset voltage applied to the collision cell that is required to cause this process to occur to the extent that these two ions are equal in intensity (Fig. 2). As can be seen, it is very nearly linear with respect to the chain length and does not reflect simple Coulombic repulsion.

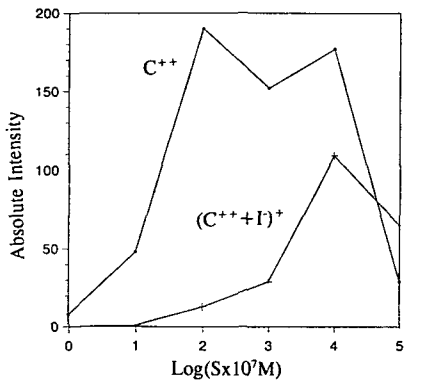

Fig.1 Effect of N,N,N',N'-tetramethyl nonanediamine 2MeI concentration (S) on the intensities of C^{++} $(C^{++}{:}(CH_3)_3N^+\text{-}(CH_2)_9\text{-}N^+(CH_3)_3$ and $(C^{++}+I^-)^+$.

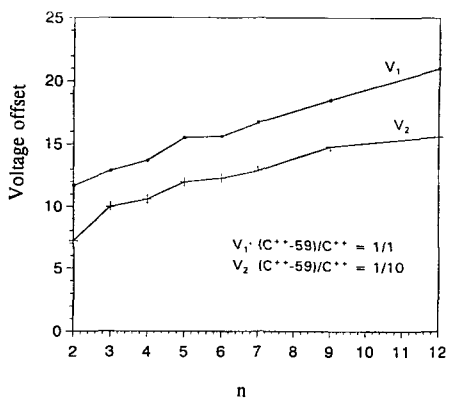

Fig.2 Variation of voltage offsets applied on collision cell for the cleavage of C^{++} to $[C^{++}\text{-}N^+(CH_3)_3]^+$ $(C^{++}\text{-}59)$ with n=1-7,9,12 for $(CH_3)_2N\text{-}(CH_2)_n\text{-}N(CH_3)_2$

Thermal radiative dissociation of covalent weakly-bound cations

Chuan-Yuan Lin and Robert C. Dunbar*
Chemistry Department, Case Western Reserve University, Cleveland, OH 44106
D. Scott Tonner and Terrance B. McMahon*
Chemistry Department, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada

Radiatively activated thermal dissociation (ZTRID) has been demonstrated to be a promising technique to study weakly-bound ions, with dissociation energies in the range 0 5-1.0 eV Under extremely low pressure conditions, the dissociation can be activated radiatively by absorption of IR photons from surrounding A thermal dissociation theory has been described recently by Dunbar[1] which uses a steady-state truncated Boltzmann distribution and a simplified Tolman equation to extract the dissociation thermochemistry The main interest of the present work is carrying out the ZTRID experiment on some well behaved systems and extracting their thermochemical information using the thermal dissociation theory Here, the bond dissociation energies and corresponding thermochemical information of $Si(CH_3)_4^+$ (TMS) and $Si(C_2H_5)_4^+$ (TES) are reported.

Experiments were performed on an ion cyclotron (ICR) mass spectrometer The loss of the first ligand, L (L= CH_3^- or C_2H_5) from the parent ions gave the daughter ions, SiL_3^+ Both parent ions also react with a water molecule to give another product ions, $SiL_3(H_2O)^+$ The reaction scheme is:

$$SiL_4^+ \xrightarrow{k_r} SiL_3^+ + L \qquad (1)$$

$$SiL_4^+ + H_2O \xrightarrow{k_w} SiL_3(H_2O)^+ + L \qquad (2)$$

Fig 1 shows the time plots along with kinetic fits using this scheme. The nonzero intercept in the rate-pressure plots (Fig 2) indicates that the dissociation processes were activated radiatively. Using different buffer gases, CH_4 and C_4H_{10}, the y-intercept was the same (Fig. 2a) The activation energy (E_a) of eqn.1 can be derived from the Arrhenius plots (Fig. 3) which give 0 45 and 0 43eV for TMS and TES respectively To obtain the dissociation threshold energy, E_t, one can use either the Tolman equation or master equation modeling. From the result of the Tolman equation, E_t is estimated to be 0.56 and 0 70eV respectively. Master equation modeling gives E_t of 0.56 and 0.71eV respectively The dissociation threshold energies obtained from these two analyses are surprisingly consistent The heats of formation of the ion species, SiL_3^+, were derived from the E_t values and are shown in Table 1 As seen in the Table 1, the heat of formation of $Si(CH_3)_3^+$ is in excellent agreement with Baer's results The discrepancy of previous literature values of $\Delta H_f^0(Si(C_2H_5)_3^+)$ makes it difficult to compare the present value However, based on the sucess in estimating $\Delta H_f^0(Si(CH_3)_3^+)$ using ZTRID, the value of $\Delta H_f^0(Si(C_2H_5)_3^+)$ derived in this work is considered to be more reliable than the previous results From this quantitative study, it appears that ZTRID is a useful technique to measure the dissociation thermochemistry of weakly covalent bound ions

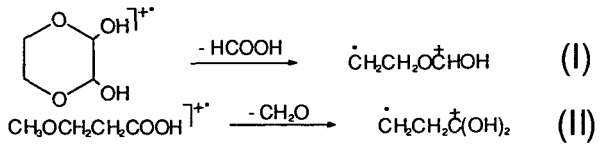
Some more $C_3H_6O_2^{+\cdot}$ distonic ions

Yan An & John L. Holmes
University of Ottawa, Ottawa, Ontario

The experimental results presented here describe the direct production and characterization of the distonic radical cations $\dot{C}H_2CH_2{-}O{-}\overset{+}{C}HOH$ and $\dot{C}H_2CH_2\overset{+}{C}(OH)_2$.

Formation of $\dot{C}H_2CH_2O\overset{+}{C}HOH$ and $\dot{C}H_2CH_2\overset{+}{C}(OH)_2$



Characterization of $\dot{C}H_2CH_2O\overset{+}{C}HOH$ (I)

The MI mass spectrum of ion **I** (Table 1) shows that this distonic ion is distinguishable from its conventional isomer $[HCOOCH_2CH_3]^{+\cdot}$ by the intense fragment $C_2H_4^{+\cdot}$ and minor presence of $C_2H_5O^+$.

The doubly charged ion peak in the CID mass spectrum of **I** (Table 2) further confirms that this ion is more stable than $[HCOOCH_2CH_3]^{+\cdot}$. Indeed the $\Delta_f H^\circ$ value of **I** has been determined by an appearance energy measurement to be 137 ± 4 kcalmol^{-1}, which is 16 kcalmol^{-1} lower in energy than $HCOOCH_2CH_3^{+\cdot}$.

Characterization of $\dot{C}H_2CH_2\overset{+}{C}(OH)_2$ (II)

The MI mass spectrum of ion **II** is identical to that of $[CH_3CH_2COOH]^{+\cdot}$ (Table 1), however, the distonic structure of ion **II** is confirmed by $:CH_2$ loss in its CID mass spectrum (Table 2).

$$\dot{C}H_2CH_2\overset{+}{C}(OH)_2\ (II) \rightarrow CH_2C(OH)_2^{+\cdot} + :CH_2$$

Table 1. *MI mass spectra of $C_3H_6O_2^{+\cdot}$ isomers*[1]

Fragments	I	EF	II	PA

II: $^\cdot CH_2CH_2C^+(OH)_2$ **PA:** $CH_3CH_2COOH^{+\cdot}$

Table 2. **CID mass spectra of $C_3H_6O_2^{+\cdot}$ isomers**[1]

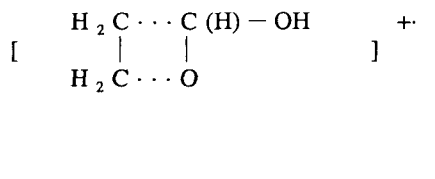
Fragments	I	EF	II	PA
$C_3H_5O_2^+ + H^\cdot$	16	100	100	100
$C_2H_4O_2^{+\cdot}+CH_2$	-	-	3	-
$C_3H_4O^{+\cdot}+H_2O$	16	100	51	47
$CH_2O_2^+$, $C_2H_6O^{+\cdot}$	3	6	17	14
CHO_2^+, $C_2H_5O^+$	8	10	60	44
$C_3H_6O_2^{2+}$	1	-	3	3
$C_2H_6^{+\cdot}+CO_2$	5	18	28	22
$C_2H_4^{+\cdot}+HCOOH$	100	99	41	38

1. Relative intensities (%).

I: $^\cdot CH_2CH_2OC^+HOH$ **EF:** $HCOOCH_2CH_3^{+\cdot}$
II: $^\cdot CH_2CH_2C^+(OH)_2$ **PA:** $CH_3CH_2COOH^{+\cdot}$

I dissociates to $C_2H_4^{+\cdot}$ by HCOOH loss. The process is a direct bond cleavage, and thus sensitive towards collisional activation. In contrast, the H_2O loss, which is dominant in the MI dissociation of **I**, is inactive towards collisional activation. Therefore, the process involves other intermediate(s).

Since the daughter ion has been identified as $[CH_2CH_2CO]^{+\cdot}$, the dissociation process involves an O—C bond cleavage and a C—C bond formation. This is proposed to be a concerted process, and a possible intermediate is:



The Fragmentation of Geometric Isomers, Ionized Maleic and Fumaric Acids

Hongwen Chen and J.L. Holmes, University of Ottawa, Canada

The earliest example of geometrical isomerism dates back to the very beginning of three-dimensional chemistry, namely the Z,E isomerism of ethene-1,2-dicarboxylic acid (maleic and fumaric acids) first discussed by Van't Hoff in 1871 The influence of stereochemistry on the mass spectrometry of chemical compounds has long been recognized and the accumulated knowledge in this area has proved worthy of a recent monograph

The mass spectra of maleic and fumaric acids were first described in detail some twenty five years ago In brief, the EI mass spectra of the isomers differ significantly in that ionized maleic acid loses $^{\bullet}OH$, H_2O, CO and CO_2 while its E-isomer loses only $^{\bullet}OH$, H_2O and CO. The loss of CO_2 was proposed to be related to carboxyl-carboxyl interaction and furthermore it was argued that ionized fumaric acid was unable to undergo rotation about the formal C-C double bond - otherwise it too should lose CO_2.

In the present study the full range of tandem mass spectrometry experiments together with Ionization Energy (I.E.) and Appearance Energy (A.E) measurements have been used to extend our understanding of this pair of simple geometric isomers and to correct or modify the earlier speculative proposals.

Typically, geometric isomers have closely similar IEs, this is illustrated in Table 1. However, where the two carboxyl groups are rigidly held in the Z- configuration, o-benzene dicarboxylic acid and maleic acid, the ionization energies are conspicuously lower than those of their isomers This effect must result from carboxyl-carboxyl interaction.

Table 1 Thermochemical data. The experimental results from this work are in bold characters

molecule	IE (eV)	$\Delta_f H^\circ$ neutral (kJ mol^{-1})	$\Delta_f H^\circ$ ion (kJ mol^{-1})
Z-2-butenoic acid	10 08	(- 346)	627
E-2-butenoic acid	9 9	(- 350)	606
m-benzene dicarboxylic acid	9 98	- 696 ± 2	267
p-benzene dicarboxylic acid	9 86	- 718 ± 3	233
o-benzene dicarboxylic acid	**9.4 ± 0.1**	- 675 ± 1	**240 ± 10**
maleic acid (Z)	**10.0 ± 0.1**	- 679 ± 3	**287 ± 13**
fumaric acid (E)	10 7 **10.6 ± 0.1**	- 676 ± 6 (- 704)	355 (319)

In the metastable time frame, the molecular ions of maleic and fumaric acids display two common fragmentation channels, i.e H_2O and CO losses, note that the relative intensities of the MI peaks as well as their kinetic energy releases ($T_{0.5}$ values, in meV) are the same, shown in Table 2 below. Deuterium labelling experiments showed that H atoms did not completely lose their positional identity prior to loss of H_2O.

Molecular Ion	Fragment Ion, m/z						
	100 ($T_{0.5}$)	**99** ($T_{0.5}$)	**98** ($T_{0.5}$)	**90** ($T_{0.5}$)	**88** ($T_{0.5}$)	**74** ($T_{0.5}$)	**72** ($T_{0.5}$)
maleic acid	-	-	**22** (24)	-	**100** (164)	-	**200** (85)
maleic acid-2,3-d_2	**31** (24)	**38** (25)	-	**100** (173)	-	**108** (88)	-

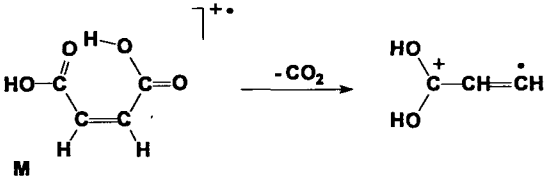
43rd ASMS Conference on Mass Spectrometry and Allied Topics

These fragment ions along with those generated in the ion source were examined by CID. It was found that the characteristics of the corresponding ions from both acids are the same. The following reaction schemes, different from the original, are proposed. The structures of fragment ions were confirmed by independently generateing them for comparison with those from maleic and fumaric acids.

Maleic acid (M) has a unique reaction channel:



Both maleic (**M**) and fumaric acid (**F1**) rearranged to a common intermediate, **F2**, prior to dissociation.

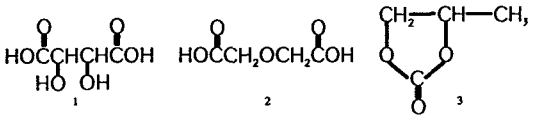
CHARACTERIZATION OF SMALL HIGHLY OXYGENATED IONS.

C. Aubry and J.L. Holmes,
Chemistry Department, University of Ottawa, Canada.

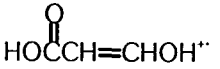
Producing gas phase ions which have a high oxygen content is not always straightforward due to the tendency of the larger ionized precursor molecules to easily dissociate by losses of H_2O, CO and/or CO_2, thus eliminating some oxygen atoms. Examples of highly oxygenated species are $C_2O_2^+$, $C_3O_2^+$ (1) and $C_3HO_2^+$(2).

The mass spectrometry of different ions of general formula $C_3H_nO_3$ (n = 3 and 4), generated by electron impact of larger precursor molecules is presented here and structural information concerning these ions is described below. The precursor molecules were tartaric 1 and diglycolic 2 acids as well as propylene carbonate 3.

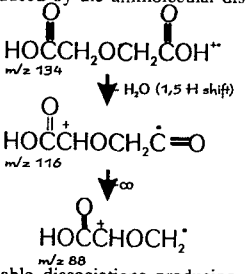


$C_3H_4O_3^{+\cdot}$ ions, m/z 88

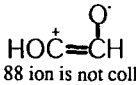
Maleic, fumaric(3) and tartaric acids all show in their normal mass spectra the presence of a m/z 88 ion. MI and CA characteristics of these ions are identical. The proposed structure (3) for this ion is:



A distinct isomer can be produced by the unimolecular dissociation of diglycolic acid:



This ion shows three metastable dissociations producing ions at m/z 60 (loss of CO, $T_{0.5}$ = 41meV), m/z 58 (loss of H_2CO, $T_{0.5}$ = 22meV) and m/z 42 (loss of H_2CO_2, $T_{0.5}$ = 13meV). The H_2CO loss being the favoured dissociation channel. The identities of the m/z 60 and m/z 42 are not, as yet, firmly established. Preliminary results on source generated ions suggest that m/z 42 is not ketene, hydroxyacetylene or oxirene. As for the m/z 58 ion, the following distonic ion is in keeping with the CA results:



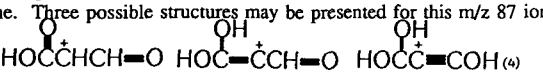
The dissociation of metastable m/z 88 ion is not collision sensitive and no NRMS recovery signal

is obtained when Xe and O_2 are used as neutralization and reionization gases respectively This may indicate that m/z 88 is not a covalently bonded ion, but better represented by an electrostatically bound complex of possible structure $[H_2CO...HCO_2H]^{+\cdot}$.

$C_3H_3O_3^+$ ions, m/z 87

Two distinct $C_3H_3O_3^+$ isomers have been produced from the unimolecular dissociations of tartaric acid and propylene carbonate.

The m/z 87 from tartaric acid shows three metastable process leading to the formation of m/z 69 (loss of H_2O), m/z 59 (loss of CO) and m/z 43 (loss of CO_2), m/z 69 being the predominant one. Three possible structures may be presented for this m/z 87 ion:



Daughter ion characteristics are needed in order to determine the correct structure for the m/z 87 ion. Dissociation characteristics of source generated m/z 43 indicates that it is not acetyl but most likely CH_2C^+OH ion. The kinetic energy released by this dissociation (114meV) suggests the presence of a large reverse activation barrier which could be associated with a major rearrangement of the precursor species before fragmentation. The CA characteristics of metastably generated m/z 69 from m/z 87 indicates that it is most likely to be $OCCHCO^+$ (2) ion.

The available data indicate that isomers a and b are satisfactory representations of the m/z 87 ion, but more information is needed to decide which particular structure is involved.

The m/z 87 ion from propylene carbonate shows two metastable dissociation processes producing m/z 59 (loss of CO) and m/z 43 (loss of CO_2) daughter ions, the latter being most intense. Characterization of the metastably generated m/z 43 indicates that it is the acetyl cation. Due to the small kinetic energy released by the dissociation of m/z 87 ion into the acetyl cation (1.7meV), the involvement of an ion-neutral complex, $[CH_3CO^+ ..CO_2]$, cannot be neglected That the CA mass spectrum does not indicate that new dissociation channels are opened and that no NRMS recovery signal is observed support proposal.

It has been shown that tartaric and diglycolic acids as well as propylene carbonate could be used as precursor molecules for generating highly oxygenated ions. These ions have structure dependent dissociations. As is often the case, the involvement of electrostatically bound complexes seem to the part of their dissociation.

It is evident that more work is needed to confirm the structures proposed. This will involve labelling compounds with deuterium atoms to provide the mechanistic and structural information needed.

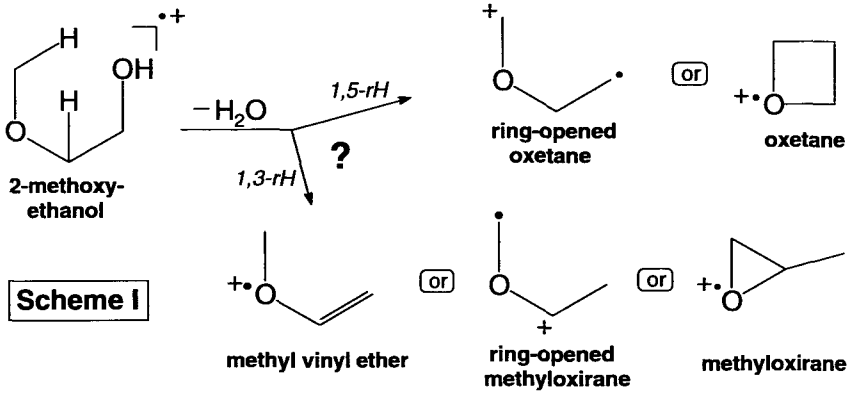
THE IDENTIFICATION OF $C_3H_6O^+$ FROM 2-METHOXYETHANOL

Michael J. Polce and Chrys Wesdemiotis

Chemistry Department, The University of Akron, Akron, OH 44325

The product formed upon water elimination from ionized 2-methoxyethanol was originally classified, more than 20 years ago, as a mixture of ionized oxetane and methyl vinyl ether.[1] More recently, the C_3H_6O ion produced by H_2O loss from 2-methoxyethanol ions was shown to be a mixture of ionized oxetane and methyloxirane,[2] or oxetane radical cation,[3] or oxetane molecular ion and/or eventually its ring-opened isomer $CH_2CH_2OCH_2^{+\cdot}$.[4] This study[5] presents results which identify the m/z 58 $C_3H_6O^+$ obtained from 2-methoxyethanol and resolve the question outlined in Scheme I.



Scheme I

All experiments were performed with a modified VG Autospec instrument of E_1BE_2 geometry.[6] *The structure of source generated or metastably formed $C_3H_6O^+$ product from 2-*methoxyethanol was determined by comparison of its collisionally activated dissociation (CAD) and neutralization-reionization (NR) spectra with reference spectra produced from the above ions listed in Scheme I. Electron ionization of oxetane, methyl vinyl ether, and methyloxirane were used to provide their corresponding molecular ions, while dissociative EI of 1,4-dioxane and 2-methyl-1,3-dioxolane furnished ring-opened oxetane and ring-opened methyloxirane ions, respectively.

The CAD spectrum of m/z 58 from 2-methoxyethanol most closely resembles that of ring-opened oxetane. Both of these spectra include formation of $C_3H_6O^{++}$ dications (m/z 29), indicative of distonic ions; a prominent product of m/z 44 (CH_2 elimination), which is diagnostic for the $CH_2CH_2OCH_2^+$ connectivity;[7] m/z 57 as the most abundant CAD fragment; and a similar m/z 56:55 ratio. In sharp contrast, the oxetane ion shows an increased amount of $C_3H_{0-3}^+$ (m/z 36-39), characteristic of a structure with three carbons in a row; an absence of 58^{++}; and a sizeable m/z 55 fragment. The CAD spectra of the $C_3H_6O^+$ from 2-methoxyethanol and that of ring-opened oxetane are not identical. For example, the former contains more abundant m/z 15 and 42-43 peaks, suggesting that 2-methoxyethanol must coproduce other $C_3H_6O^+$ isomer(s). CAD of reference ions of methyl vinyl ether, ring-opened methyloxirane, and methyloxirane yield substantially more m/z 15 and 42-43. Based on the m/z 42:43 ratio observed for the 58^+ from 2-methoxyethanol, methyl vinyl ether is the best match.

The NR Xe/O_2 spectrum of $C_3H_6O^{+\cdot}$ from 2-methoxyethanol is most like that of ring-opened oxetane with a striking similarity of peak shapes and relative abundances observed for m/z 24-30. Neutralization of ring-opened oxetane ions yield the weakly-bound diradical $CH_2CH_2OCH_2$ that decomposes extensively and with large kinetic energy release to $CH_2{=}CH_2$ (28 u) and $O{=}CH_2$ (30 u).[7] As a result, substantial peak broadening is observed after reionization for m/z 24-30. Only a small fraction of the diradical survives intact based on the intensity of the survivor ion (m/z 58). Compared to ring-opened oxetane, the NR spectrum of m/z 58 from 2-methoxyethanol contains more abundant fragments above m/z 30 and a larger survivor ion. Evidence that at least one more $C_3H_6O^+$ isomer is formed. Based on NR survivor ion yields,[8] the m/z 58:57 ratio, and the relative abundances of m/z 42-43 vs. 58; only methyl vinyl ether can account for the additional component (<14% based upon survivor ion yields).

Metastable 2-methoxyethanol ions, which possess lower internal energies than 2-methoxyethanol ions dissociating in the source, produce a different $C_3H_6O^+$ mixture. The C_3H_6O ions formed in the metastable window yield less m/z 42-43 upon CAD and less ions above m/z 30 upon NR. Hence, 2-methoxyethanol ions of low internal excitation generate a larger proportion of $CH_2CH_2OCH_2^+$ and a smaller amount of methyl vinyl ether. Specifically, based on the absolute intensity of the survivor ion (m/z 58) in the NR spectrum of metastably generated 2-methoxyethanol, <2% of methyl vinyl ether ions are coproduced.

In summary, MS/MS experiments conclusively identify the m/z 58 C_3H_6O ions obtained from 2-methoxyethanol as a mixture chiefly comprised of the distonic radical cation $CH_2CH_2OCH_2^+$ (ionized ring-opened oxetane). These results also strongly indicate that the other minor component is ionized methyl vinyl ether. Methyl vinyl ether ions are thermodynamically more stable but their formation must require a higher critical energy since they are produced with a lower yield from metastable 2-methoxyethanol ions. We find no evidence for the generation of ionized oxetane, methyloxirane, or ring-opened methyloxirane.

Oxygen Rearrangement in N-Substituted Benzizothiazolinones on Electron Impact

József Langó
Department of Structure Research
Institute for Drug Research Ltd.
P.O. Box 82, Budapest, Hungary, H-1325

During the mass spectral studies on N-substituted benzizothiazolinone-1,1-dioxides and N-substituted benzizothiazolinones an oxygen atom rearrangement from the carbonyl group to the sulfur atom leading to loss of SO_3 and SO has been observed. A similar observation of an SO_3 loss has been reported earlier, but it was not confirmed [1].

EXPERIMENTAL

Materials: compounds studied were prepared in the **Institute for Drug Research** by known methods[2].
Mass spectrometric conditions: EI low resolution and MS/MS spectra were taken with a **VG Quattro** tandem mass spectrometer, electron energy of 70eV, trap current 200 μA, source temperature of 150 °C. CID MS/MS conditions: *collision* gas N_2, pressure: 1-6x10^{-4} torr, energy: 120-180 eV, scanning speed: 0.1 sec/decade. The peak intensities reported are the averages from 20-60 consecutive spectra. The HR measurements were made by peak matching method relative to PFK on an **Finnigan MAT 8430** double focusing mass spectrometer. HR conditions: electron energy: 70 eV, trap current: 500 μA, acceleration voltage: 3 kV, source temperature: 250 °C, resolution: 12500 (10 % valley definition).

RESULTS AND DISCUSSION

Fig.(I) contains the compounds studied. Fig.(II) shows (from up to down) the straight *EI⁺ spectrum* of **Ia**, the *product spectrum* of $M^{+\bullet}$ of **Ia** (*m/z*259, $C_{13}H_9NO_3S$, Δ=3.3 ppm) the *precursor spectrum* of ion *a* (*m/z*195, $C_{13}H_9NO$, Δ=2.7 ppm) and ion *b* (*m/z*179, $C_{13}H_9N$, Δ=0.6 ppm). Most of the ions that appear in the EI^+ spectrum of **Ia** are easy to explain by direct decompositions except for the relatively abundant ion *b*. The *product spectrum* of molecular ion of **Ia** is very similar to the EI^+ spectrum the differences are in the ion intensities only. *Precursor spectrum* of ion *a* and ion *b* show that the loss of SO_2 and SO_3 are **one-step processes**, *i.e.* there is an experimantal evidence that ion *b* results from a real rearrangement. Fig.(III) shows the most probable transition structure capable of SO_3 loss, where bonds of the 5-membered ring have been *rearranged*. Driving force of this process may be an interaction of the oxygen lone pair with the low energy unoccupied ***d*** orbitals of sulfur. Similar processes have been observed in the case of the compounds **Ib-c**. Data in Tab.(I) show the intensities of product ions of interest. Comparing these data of **I** type compounds the changes in the column can be explained by the increasing electronaffinities of substituents of **R**. Fig.(IV) shows (from up to down) the EI^+*spectrum* of compound **IIa**, the *product spectrum* of $M^{+\bullet}$ (m/z227, $C_{13}H_9NOS$, Δ=1.5 ppm), the *precursor spectrum* of ion *a* (m/z195, $C_{13}H_9NO$, Δ=1.7 ppm) and ion *b* (m/z 179, $C_{13}H_9N$ Δ=2.4 ppm). The *b* type of ion *has appeared* too, but with low intensity. The transition structure capable of an SO loss, similar to that for **I** type compounds. Same ions have also been observed in the case of **IIb-f**. Comparing the data in Tab.(I) a significant decrease in the intensities of ion *a* and *b* can be observed in the case of **II** type compounds. The difference is due to that in the-*heats of formation of neutral fragments* (SO_2 *v.* S, SO_3 *v.* SO) because of the ionic fragments are the same.

CONCLUSION

Experimental evidences show that loss of SO_3 and SO are one step decompositions of the title compounds. They assume bond rearrangement of the 5-membered ring probably promoted by the ***d*** orbitals of sulfur.

The Unimolecular Dissociation of Acetophenone Ions by Thermal Radiation

Marcelo Sena and José M. Riveros
Institute of Chemistry, University of São Paulo, Caixa Postal 26077, São Paulo, Brazil, CEP 05599-970

Weakly bound ions have been reported to undergo slow unimolecular dissociation in ICR cells through processes which exhibit weak pressure dependence.[1] Molecular ions with low energy fragmentation pathways (~ 10 kcal/mol) have also been shown to undergo such dissociation.[2] The case of acetophenone is particularly attractive case since its has been extensively characterized by mass spectrometry.

$$C_6H_5COCH_3^{+\cdot} \rightarrow C_6H_5CO^+ + \cdot CH_3 \quad \Delta E_{298K} = 8.2 \text{ kcal/mol}$$

A typical graph of the kinetics of dissociation observed for the molecular ion of acetophenone, $C_6H_5COCH_3^+$ in the cubic cell of our FT-ICR spectrometer is shown in Figure 1. The data were obtained at a nominal electron energy 9.5 eV, an acetophenone pressure of 4.9 x 10^{-8} Torr and cell temperature of 357 K. At this ionizing energy, the relative intensity of the unresolved *m/z* 121 ion, a mixture of $(C_6H_5COCH_3)H^+$ and $^{13}CC_7H_8O^+$, remains essentially constant indicating the ion/molecule reaction leading to protonated acetophenone is slow compared to the dissociation of the molecular ion. The kinetics of dissociation of molecular ions isolated 500 ms after ion formation yield the same rate constant within experimental error. A similar behavior is observed when the molecular ion is formed via a charge exchange reaction.

The analysis of the pressure and temperature dependence of the dissociation observed in these experiments yields a valuable clue as to the mechanism responsible for the dissociation. Rate constants for the dissociation of $C_6H_5COCH_3^{+\cdot}$ are shown in Figure 2 as a function of acetophenone pressure at different temperatures controlled essentially by the filament current. There is a very mild increase of the rate constant with pressure but a dramatic temperature effect. In all cases, extrapolation to zero pressure reveals that *the most significant contribution to the dissociation rate of the molecular ion of acetophenone is of a non-collisional nature*. A similar behavior was observed with SF_6 as a static bath gas, up to pressures of 6x10^{-6} Torr, or by raising the pressure progressively with longer gas pulses from the pulsed valve.

Similar experiments with $C_6H_5COCD_3^+$ yield the same behavior but the extrapolated zero pressure dissociation rates are 40 to 80% *slower* than for the normal acetophenone ion depending on the temperature.

The data on the collisionless dissociation of these molecular ions is consistent with the view that these processes are driven by the thermal radiation of the surroundings.[3] A model has been deveoped to simulate this phenomenon based on the assumption that the initial internal energy of the ions can be represented by a vibrational Boltzmann distribution truncated near the dissociation limit. A random walk in energy was then simulated by considering absorption of blackbody radiation, spontaneous and induced emission and dissociation when the interanl energy exceeds the critical energy for dissociation. The dissociation rate was determined by doing a large number of ion energy random walks simulations (~ 3000) from which the dissociation time of each ion can be obtained. The actual calculation involves the following steps: a) The initial internal energy and vibrational configuration were chosen using the truncated Boltzmann distribution as a weight function; b) Each harmonic oscilator can increase, decrease or not change its occuptation level. The probability of these events is related to the Einstein coefficients which were derived from the vibrational intensities obtained from an AM1 calculation on $C_6H_5COCH_3^{+\cdot}$ and $C_6H_5COCD_3^+$. Vibrational frequencies were also obtained from these calculations; c) If the total vibrational energy after each step exceeds the dissociation threshold, the elapsed time was recorded and a new simulation begins. Otherwise, the internal energy is redistributed (IVR) and a new step simulation is made.

The energy random walk simulation reveals a single exponential decay in time. The dissociation rate constant for $C_6H_5COCH_3^+$ is calculated to be 0.29 s^{-1} compared with the experimental value of 0.5 s^{-1}. The simulation and the semi-emprical calculation on the molecular ions also agree with the experimental finding that $C_6H_5COCD_3^+$ dissociates at a slower rate than $C_6H_5COCH_3^+$.

HYPERTHERMAL SURFACE IONIZATION OF ORGANIC MOLECULES : ALKYL ALCOHOLS

HIROSHI KISHI (OYAMA NATIONAL COLLEGE OF TECH. ; OYAMA, TOCHIGI, JAPAN)
TOSHIHIRO FUJII (NATIONAL INSTITUTE FOR ENVIRONMENTAL STUDIES ; TSUKUBA, IBARAKI, JAPAN)

INTRODUCTION

Hyperthermal Surface Ionization Mass Spectra (HSIMS) for alkyl alcohols ($C_1 \sim C_5$) were obtained using ReO_2 as solid surface, and were compared with 70 eV EIMS. HSIMS exhibited completely different pattern from those of EIMS. Important ions observed in HSIMS were even electron ions(EE^+), such as $(M-H)^+$, $(M-3H)^+$, $(M-R)^+$, $(M-OH)^+$, $(M-H-H_2O)^+$, R^+, whereas characteristic odd electron ions ($OE^{+\cdot}$) are observed generally in EIMS. In addition to these abundant even electron ions, radical cations $(M-2H)^{+\cdot}$ were observed for some cases. Fragmentation patterns in HSIMS were strongly dependent on the kinetic energies of the molecules, whereas the surface temperature did not affect the patterns so much.

EXPERIMENTAL

The experimental setup for HSIMS has been reported in detail elsewhere[1]. The supersonic nozzle used was made of alumina with a pinhole of 100 μ m-ϕ, and was heated electrically to $\sim$ 1000 ℃ at its end of 1.5 cm by an external winding of tungsten wire, and its temperature T_N was measured by a Chromel-Alumel thermocouple. The dead volume of its heated part is 3×10^{-3} cm^3, flow rate of carrier gas $\sim$ 2 cm^3 /sec, and the residence time of the gas is few msec, therefore thermal dissociation of the organic molecules behind the nozzle is negligible.

RESULTS AND DISCUSSIONS

MASS SPECTRA HSIMS of methanol and *n*-propanol are shown in Fig. 1. The parent is missing and $(M-H)^+$, $(M-2H)^+$, $(M-3H)^+$, $(M-OH)^+$, $(M-H-H_2O)^+$, CH_3^+, H_2O^+ are observed These ions are produced on account of thermal dissociation in the surface collision The appearance of Na^+ and K^+ ions come from impurity atoms in the surface.
HSIMS for the other alkyl alcohol ($C_1 \sim C_4$) are tabulated in Table 1, as m/z (% Intensity).

EFFECT OF KINETIC ENERGY The ion yield of m/z 29, 30, 31, and m/z 23 for methanol is shown in Fig 2, as a function of incidint kinetic energy (E_K) at surface temperature of 600 ℃. At lower E_K, SI yields are enhanced with increase in E_K, the slope for m/z 31 the steepest
At higher E_K, the intensity of m/z 31 goes down, while those of the other ions increase steeper. In ethanol, similar kinetic energy dependence was observed for $(M-H)^+$, $(M-2H)^+$, $(M-3H)^+$, and alkali ion. These behaviors might be the consequence of some competitive surface reactions, including the energy transfer of molecular kinetic energy to the solid surface.

EVEN ELECTRON IONS HSIMS and 70 eV EIMS of 1-pentanol are shown in Table 2 Characteristic odd electron ions are observed in EIMS at m/z 70 $(M-H_2O)^{+\cdot}$ (37%) and m/z 42 $(M-H_2O-C_2H_2)^{+\cdot}$ (100%, McLafferty peak), whereas no $OE^{+\cdot}$ ion is observed for HSIMS at any combination of (E_K,T_S), and the m/z 69 peak constitutes the base peak. This suggests that radical species are first generated on the surface, followed by ionization of these species.

MASS SPECTRA OF ISOMERS No similarity exists between EI spectra of 1- and 2-propanol, and they exhibit low intensity for parent and quasi molecular $(M-H)^+$ ions In HSIMS, quasi molecular ions are abundant and some other signals can be reasonably assigned as $C_3H_7^+$ (43), $C_3H_5^+$ (41), CH_2OH^+ (31), $C_2H_5^+$ (29). HSIMS of butanol show each characteristic peaks for 4 isomers. 1-butanol : m/z43($C_3H_7^+$), 2-butanol m/z73$(M-H)^+$, iso-butanol : m/z58$(M-CH3)^+$, tert-butanol : m/z57$(M-OH)^+$. In this respect, the HSIMS contain structural information, hence the HSI results are very useful for diagonostic analysis.

Unimolecular Decomposition of Energy Selected 2,5-Dihydrofuran

Bibi Teklehaimanot, Gang Ma, and Gerry G. Meisels
Department of Chemistry, University of South Florida
Tampa, FL 33620

The unimolecular dissociation of energy selected 2,5-dihydrofuran ions has been studied using threshold photoelectron photoion coincidence (TPEPICO) time of flight (TOF) mass spectrometry The ion chemistry of the molecule is elucidated from measurements of breakdown curves, appearance energies (AP) and kinetic energy releases (KER). A detailed breakdown graph (BDG) obtained in the energy range 9.20 - 14.52 eV is shown in Fig. 1. The breakdown curve of m/z 69 shows considerable variation with two maxima at photon energies of 11.64 and 12.74 eV, corresponding to the third and fourth photoelectron bands respectively in the He-I PES of 2,5-dihydrofuran. This is contrary to what can be expected on the basis of simple statistical theories where fragmentation directly from a parent ion is predicted to result in a monotonic and smooth change of breakdown curves unless a new dissociation channel begins to open. Therefore the variation in the breakdown curve suggests that the process leading to m/z 69 involves more than one state or isomers at photon energies above 11 60 eV.

The average KER accompanying the formation of m/z 42 directly from the parent ion is found to be consistent with that computed on the basis of RRKM-QET (Fig. 2). However in the case of m/z 41 the experimental and theoretical average KERs agree only up to 11 5 eV.(Fig 3) The slope of experimental KER implies that there is an almost zero kinetic energy release at the threshold. This result suggests that the observed KER arises mainly from the excess internal energy of the activated complex and that there is negligible reverse activation energy.

Table 1. AEs and heat of formation of product ions form 2,5-dihydrofuran

Product Ion	[a]AE, eV	ΔH_f Kcal mol^{-1} This work	Literature[b]
$[C_4H_6O]^+$	9.10 ± 0.01	194 ± 1	195
$[C_4H_5O]^+$	10.15 ± 0.01	166 ± 1	165[c]
$[C_4H_4O]^+$	9 16 ± 0 01	195 ± 1	195[c]
$[C_2H_3O]^+$	10.25 ± 0.09	157 ± 3	157 ± 3.6[d]
$[C_3H_6]^+$	10.11 ± 0.10	243 ± 3	240
$[C_3H_5]^+$	10.94 ± 0.10	226 ± 3	226

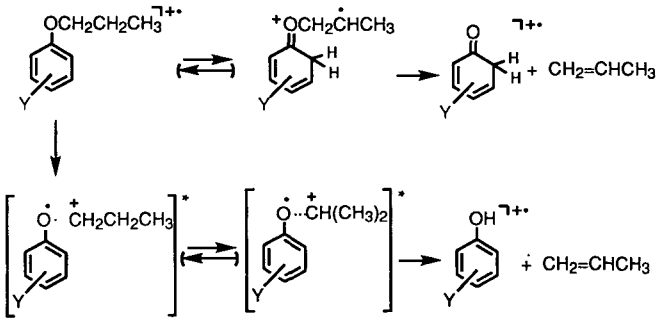
Influence of Substituents on Propene Loss from n-Propyl Aryl Ether Ions

Henri E.K. Matimba, Steen Ingemann and Nico M.M. Nibbering
Institute of Mass Spectrometry, University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

The loss of a propene molecule is the main unimolecular reaction of a series of ionized 3- and 4-substituted aryl n-propyl ethers ($YC_6H_4OCH_2CH_2CH_3$, Y = CH_3, CF_3, NO_2, OCH_3 and SCH_3) in the ion source as well as in the field free regions of a double-focussing quadrupole hybrid mass spectrometer. This reaction can proceed through two distinct pathways: i) a 1,5-H shift from the β-position of the propyl group to the ortho position of the ring (Eq. 1) and ii) intermediate formation of an ion-neutral complex consisting of a $YC_6H_4O^{\cdot}$ radical and a $^{+}CH(CH_3)_2$ cation (Eq. 2). The latter complex reacts further by proton transfer prior to dissociation.



The occurrence of these pathways becomes visible by deuterium labelling of the propyl group at the β-position. If the 1,5-H shift initiated loss of propene is the only process occurring, C_3H_5D will be lost exclusively. By contrast, the process involving an ion-neutral complex is predicted to lead to a ratio of 5 to 1 between the losses of $C_3H_4D_2$ and C_3H_5D provided that only one deuteride shift occurs prior to the proton/deuteron transfer (isotope effect neglected). If all the hydrogen and deuterium atoms become equivalent through rapid hydride/deuteride shifts in the propyl carbenium ion this ratio is estimated to become 5 : 2.

Table. Relative importance of H- and D-transfer in the propene loss from the molecular ions of the labelled n-propyl aryl ethers, $ArOCH_2CD_2CH_3$.

Substituent	H-transfer : D-transfer		
	Ion-source react.ions		Metastable Ions
	70 eV	10 eV	
H	81:19	82:18	84:16
4-NO_2	85:15	85:15	84:16
4-CF_3	85:15	86:14	88:12
4-CH_3	80:20	83:17	81:19
4-CH_3O	76:24	76:24	74:26
4-CH_3S	75:25	76:24	72:28
3-NO_2	84:16	84:16	85:15
3-CF_3	74:26	84:16	88:12
3-CH_3	81:19	81:19	72:28
3-CH_3O	70:30	38:62	10:90
3-CH_3S	76:24	-	36:64

The experimentally obtained ratio's for the abundances of the products of $C_3H_4D_2$ and C_3H_5D loss are for most of the ethers close to that anticipated for both the ion-neutral complex mediated processes, as can be seen from the results in the Table. An exceptional result is obtained for the molecular ions with a CH_3O-group substituted at the 3-position (Table). For these molecular ions propene loss proceeds with a marked preference for transfer of a hydrogen atom from the β-position of the propyl group. This preference is even more pronounced for the metastable ions, which eliminate propene by a nearly selective β-hydrogen atom transfer. Furthermore, the initial 1,5-H shift for these ions is a reversible process, resulting in the retention of both deuterium atoms in a small fraction of the product ions. In addition, tandem mass spectrometric experiments support the inferred formation of substituted cyclohexadienone ions by the 1,5-H shift, whereas phenolic ions are formed by the pathway involving an ion-neutral complex.

Competing Kinematic Models for Describing Energy Transfer in Low-Energy CID of CS_2^+

Ronald E. Tosh, Anil K. Shukla and Jean H. Futrell
Department of Chemistry and Biochemistry
University of Delaware, Newark, DE 19716

Collision-induced dissociation (CID) of CS_2^+ ions to form CS^+ or S^+ has attracted attention in recent years because several earlier experiments suggested that excited electronic surfaces participate in the reaction dynamics. Small polyatomic ions like this are intermediate between diatomics, which typically either dissociate from repulsive curves in a single vibration or rapidly predissociate, and more complex polyatomics, in which dissociation occurs after electronic energy is redistributed among internal modes. Accordingly, a precise specification of the role of electronic excitation in the present system is expected to be helpful in developing a model for CID of small polyatomics that interpolates between exact quantum dynamics and quasi-equilibrium theory (QET). Moreover, the relative simplicity of this system makes it a good candidate for testing theoretical models of translational-electronic energy transfer in low- to intermediate-energy collisions, which has been found to be of some importance in CID of more complex cations.[1,2]

We report here the results of recent crossed-beam experiments on both the non-dissociative scattering and CID of CS_2^+ (to form S^+ or CS^+) in collisions with Ar atoms at 17.8 eV (CM). The crossed-beam technique, which permits simultaneous angle and energy measurements of reactants and products, is well suited to resolving state-to-state electronic excitation when the energy levels of the parent molecule are well-separated, as is the case with CS_2^+. All of our measurements clearly show that translational-electronic energy transfer is involved in distinct ways in each of the three processes, and the angular scattering patterns reveal that this is related to the existence of distinct underlying mechanisms for momentum transfer: one involving a simple two-body collision between the target neutral and parent ion, while the other involves an impulsive scattering event in which only part of the parent ion participates in the collision (the other part is a spectator).

The simple two-body scattering mechanism is clearly evident in the recoil spectra for $CS_2^{+(*)}$ that result from collisions with Ar at 8.9 and 17.8 eV (CM). In the latter case, the velocity contour plot shows that purely elastic scattering dominates at all scattering angles and that the relative probability for vibrational or electronic excitation appears to be negligible. The contour plot for 8.9 eV collisions is similar; however, in this case we carried out a more thorough search for backward scattered CS_2^+. As a result, we found peaks at recoil velocities consistent with simple two-body inelastic scattering that results in electronic excitation of CS_2^+ to the *A* and *B* states. This is a few percent of the corresponding forward-scattered signal at the same laboratory angle and may have been overlooked in the run at 17.8 eV. This will be reinvestigated in the future after some improvements are made to the energy analyzer.

Our initial measurements of the recoil spectra for the fragment ions S^+ and CS^+, performed on the Delaware "tandem" instrument, did not reveal any deviations from the two-body kinematic scheme that characterizes the non-dissociative scattering described above. Consequently, we used the conventional excitation/delayed-dissociation model to interpret the measured velocity contour plots in our recent publication.[3] However, more recent studies done with the Delaware "crossed-beam" instrument have shown scattering of both fragment ions outside of the elastic circle with a discernible symmetry about a point other than the reactant CM: for the S^+ data this point is the Ar/S CM; it is the Ar/CS CM for the CS^+ data. Such scattering is indicative of an impulsive mechanism like that described above (the neutral CID fragment in each case comprises the collision spectator) followed by a prompt dissociation, and thus constitutes a departure from the two-step model that is commonly used for interpreting CID data.

The "knock-out" model for CID presented here was recently developed to explain the angular scattering of S^+ resulting from CS_2^++Ar collisions at 17.8 eV (CM).[4] The model enables us to calculate the reaction Q (inelasticity) from the S^+ recoil circle, and the result we obtain, 4.5±0.8 eV, is very close to the minimum 4.8 eV necessary to break the S^+--CS bond. A slightly better fit to the scattering data results if the model is modified to allow for electronic excitation of the molecule by the amount Q as the reactants approach. The modification also presents us with a very satisfactory explanation for how the collision between Ar and S^+ can occur without momentum transfer to CS, since excitation of CS_2^+ by about 4.5 eV is sufficient to populate a non-bonding state for S^+ and CS.

Similar symmetry in part of the velocity contour plot for CS^+ implies that a complementary pathway exists for this reaction. The reaction Q determined from the velocity contour plot is 6.3±.8 eV , which is just above the minimum 5.7 eV necessary to break the CS^+--S bond. As with S^+, refinements of the model permit a slightly better fit to the data, suggesting that an electronic transition within the CS_2^+ ion occurs before the CS^+ moiety is knocked out. This explanation pertains to the ridge in the contour plot that is most discernible at large scattering angles; however, the large, highly inelastic peak in the forward direction extends over a large range of scattering angles but exhibits no symmetry about either the Ar/CS CM or the reactant CM. We are currently evaluating other kinematical models in an effort to understand it.

Tandem Crosed-Beam Collision-Induced Dissociation of CO_2^+

Rahul Chawla, M. Krishnamurthy, A. K. Shukla and J. H. Futrell
Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

Angle and energy resolved CID provides valuable information about energy transfer, reaction mechanisms and role of excited states in activation and dissociation steps. Recent studies from our laboratory have demonstrated that electronic excitation is a prominent mechanism in low and moderate collision energy CID of certain molecules (acetone, nitromethane) but others (enol acetone, methane, propane, methyl nitrite) dissociate predominantly on the ground state hypersurface.

A current focus of our research is angle and energy resoved CID studies of triatomic cations whose potential surfaces are relatively well described. They are a logical bridge between diatomics (which dissociate in a single vibration) and more complex polyatomics (which generally follow RRKM/QET delayed dissociation mechanisms). In the accompanying poster we develop a prompt dissociation kinematics model and demonstrate that CID of CS_2^+ is well described by this model. Although the structure and energetics of CO_2^+ are similar to CS_2^+, we find rather different dissociation dynamics for the analogous O^+ and CO^+ products.

The hybrid tandem mass spectrometer used by us in these studies has several features which make it ideal for studying angle-and-energy-resolved CID of ions:

1. A series of tube and rectangular lenses capable of slowing a beam of several kV energy to a variable range between 1 eV to a few hundred eV while maintaining a well defined ion beam, monoatomic to within +/- 1 eV.

2. A supersonic neutral beam which overlaps the slit image of the ion beam. This provides us with higher gas densities and narrower velocity distribution than collision chamber experiments.

3. A hemispherical energy analyzer to provide high energy resolution and high ion transmission.

4. A rotating detector assembly consisting of hemispherical energy analyzer, quadrupole mass filter and detector.

CID of CO_2^+ with Ar to give CO^+ at 47.6 eV CM collision energy (Figure 1) shows that intensity maxima of CID peaks at different angles are all confined within the ESC and follow a circle whose center corresponds to Ar/CO_2^+ center-of-mass. It is a forward scattered peak with an endothermic energy transfer of 7 eV. At 8.7 eV with He , the peak is side scattered, again with an energy transfer of 7 eV. The threshold for this process is 5.7 eV, however, dissociation of CO_2^+ to CO^+ from C state takes place

through the $a^4\Pi_u$ state. Therefore, for the dissociation to take place, excess energy is transferred into CO_2^+ ions.

CID of CO_2^+ to form O^+ at 49 eV CM energy (Figure 2) shows a forward scattered peak just outside the elastic scattering circle. This suggests that O^+ is formed from a long lived excited state present in the reactant ion beam. Profile of distribution traces along the O^+/Ar scattering circle. At 15.2 eV CM and 8.6 eV CM collision energies, the peak maximum is clearly outside the ESC. The profile of the peak intensity as a function of scattering angle also circumscribes the O^+/Ar center of mass.

This demonstrates that the ions are already activated prior to collision, no energy transfer into internal modes for this dissociation process is observed even though this process is endothermic by at least 5.3 eV. Further, The contours have a ridge of intensity that is outside the ESC and follows a circle corresponding to the recoil velocity of O^+ from O^+/Ar collisions instead of CO_2^+/Ar CM. This is very similar to CID of CS_2^+ to S^+ ions except that the S^+ ions were inside the ESC at smaller scattering angles. The data are consistent with the hypothesis that our CO_2^+ beam includes a population of vibrationally excited $C_2\Sigma_g^+$ which require only a small perturbation to break the O-CO bond.

1. CID of CO_2^+ to give CO^+ and O^+ follow different kinematics. CO^+ ions are scattered within the elastic circle described by CO_2^+/Neutral and closely follows the traditional two-step kinematic model conventionally used to describe CID with this result. O^+ follows a spectator knockout model in which O^+ is scattered along the O^+/Neutral scattering circle.

2. The CO_2^+ ion beam formed by 70 eV electron impact consists of both ground state CO_2^+ ions which after collision preferentially give CO^+, and a smaller population of excited CO_2^+ ions which preferentially dissociate to O^+ ions.

Investigation of *Trans* Influence in the Fragmentation of Dinuclear Platinum Complexes by Electrospray Ionization Surface-Induced Dissociation Tandem Mass Spectrometry

Thomas G. Schaaff, Yun Qu, Nicholas Farrell, Vicki H. Wysocki
Department of Chemistry, Virginia Commonwealth University
Richmond, Virginia, 23284, USA

Dinuclear platinum complexes of formula $[\{Pt(NH_3)_2Cl\}_2\mu\text{-}NH_2(CH_2)_nNH_2]^{2+}$ are novel antitumor agents of clinical interest.[1,2] In contrast to the pair of mononuclear cis/trans-$[Pt(NH_3)_2Cl_2]$ isomers, both cis and trans isomers in this dinuclear series display antitumor activity, but with different abilities to overcome cellular resistance to the "parent" cis-$[Pt(NH_3)_2Cl_2]$. [*Cis*-$\{Pt(NH_3)_2Cl\}_2(NH_2(CH_2)_nNH_2)](NO_3)_2$ (1,1/c,c) and [*trans*-$\{Pt(NH_3)_2Cl\}_2(NH_2(CH_2)_nNH_2)](NO_3)_2$ (1,1/t,t), where the diamine was 1,4-butanediamine (n=4) and 1,6-hexanediamine (n=6), were studied using electrospray ionization surface-induced dissociation[3] (ESI/SID) tandem mass spectrometry. The same fragment ions were observed for both the *cis* and *trans* isomers of a given diamine length, but the relative intensities were dependent on the isomer studied (Figure 1a and 1b). Capillary/skimmer CID, combined with SID, allowed for the determination of the two step fragmentation processes. The dinuclear complex was fragmented by increasing the potential difference between the capillary and skimmer in the source, then the fragment ions of interest were selected and fragmented by SID. For all of the complexes studied the first step in the fragmentation pathway was the dissociation of one of the Pt-N(diamine) bonds, forming the $[Pt(NH_3)_2(diamine)Cl]^+$ ion (m/z 380). The difference in the isomers was found in the second step. In the second step, two pathways were possible for the complexes: (i) dissociation of the other Pt-N(diamine) bonds in a two step process, producing the $[Pt(NH_3)_2Cl]^+$ (m/z 264) and the free diamine (m/z 117) fragment ions, and (ii) retention of the other Pt-N(diamine) bond. The first and second pathways produced principally the $[Pt(NH_3)_2Cl]^+$ (pathway i) and $[Pt(diamine\text{-}H^+)]^+$ (pathway ii) fragment ions; both ions fragmented further. It is proposed that in the second pathway the diamine binds to the platinum through the other NH_2, after the initial fragmenting collision. The ESI/SID data and energy resolved mass spectra (Figure 2a-2d) show that the position of the chloride plays a significant role in the fragmentation of these ions. The 1,1/t,t isomers fragmented to yield a larger abundance of $[Pt(NH_3)_2Cl]^+$, which corresponds to pathway (i) (i.e. cleaving the bonds *trans* to the chloride). In contrast, the 1,1/c,c complexes fragmented (at lower collision energies) to yield a larger abundance of $[Pt(diamine - H)]^+$; pathway (ii). A critical energy was reached for both the 1,1/c,c n=4 and n=6 complexes, at which the abundant fragment ion produced changed to the $[Pt(NH_3)_2Cl]^+$ ion.

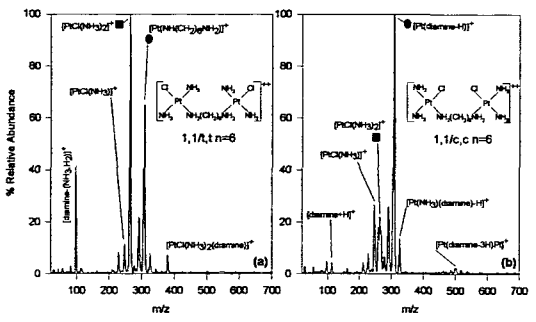

Figure 1:

50 eV ESI/SID spectrum for the 1,1/t,t n=6 (a) and 1,1/c,c n=6(b) complexes Note the difference in the ions corresponding to the two mechanisms, (i, ■) and (ii; ●)

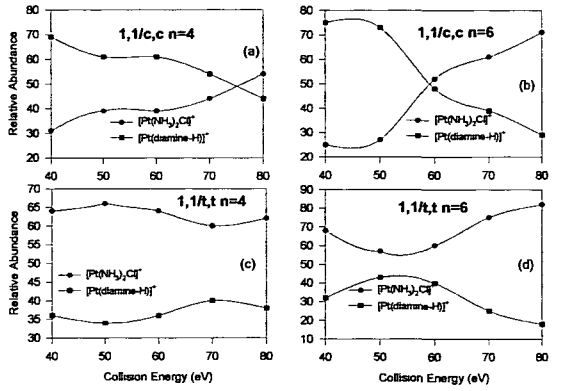

Figure 2:

Energy resolved mass spectra for the 1,1/c,c n=4,6 (a and b) and 1,1/t,t n=4,6 (c and d)

In solution phase, the trans influence allows for the prediction of reaction pathways of transition metal complexes. The thermodynamic property of the trans influence in platinum complexes holds that a Pt-N bond trans to a chloride donor is more labile than a corresponding Pt-N bond trans to a nitrogen donor. The differences in the ESI/SID spectra between the *cis* and *trans* isomers can be explained by the *trans* influence. By fragmenting the platinum complexes at varying collision energies, it was determined that the trans influence can be applied to the fragmentation pathways of platinum complexes in the gas phase. The cleavage of the Pt-N bond *trans* to chloride was the most favorable pathway for both isomers of the complexes in the ion-surface collision at lower collision energies. At higher collision energies, the steric effects of the molecule outweigh the thermodynamic stabilization due to the trans influence.

NI FAB and DCI-MS of Sulfonylurea Herbicides: CAD Spectra of $(M-H)^-$ Ions

Witold Winnik,*♥ Leon Betowski, William Brumley
United States Environmental Protection Agency, National Exposure Research Laboratory, Characterization Research Division, Las Vegas, Nevada 89193
♥ National Research Council Associate at the U.S. EPA, Las Vegas, Nevada.

A major goal of the analytical chemistry research program at the U. S. Environmental Protection Agency (Las Vegas) is to ensure that advances in mass spectrometry become incorporated into the tools available for routine environmental monitoring. Soft ionization techniques, such as fast atom bombardment (FAB), and selective ionization techniques, such as electron capture negative-ion mass spetrometry (ECNI MS) and proton-abstraction negative ion chemical ionization mass spectrometry, are underutilized in environmental analysis. An example of the application of these techniques to sulfonylurea herbicides is presented.

Negative-ion desorption mass spectra (DCI-MS) of sulfonylureas were obtained using a Finnigan-MAT TSQ 700 mass spectrometer employing methane, ammonia, deuterium oxide vapor, or a mixture of approximately 10% nitrous oxide in methane. A Finnigan direct exposure probe (DEP) was used as a desorption probe. Sulfonylurea herbicide standards were obtained from ChemService. Typically 100-1000 ng of solid was deposited on the tungsten wire of the DEP probe. NI/FAB/MS and NI/FAB linked-scan B/E experiments (Xe gas, 1mA, 8kV) were performed using a VG 7070EQ mass spectrometer. Glycerol, triethylenetetraamine (TETA), and 3-nitrobenzyl alcohol (NBA) were investigated as FAB matrices.

Background-subtracted negative ion FAB-MS spectra of the herbicides exhibit $[M-1]^-$ peaks and their fragmentation products. Of the three matrices used, TETA and NBA gave best results. Generally, enhanced fragmentation was observed with the TETA matrix. In contrast, in the NBA FAB spectra, high-abundance $[M-1]^-$ peaks and fewer fragment peaks were typically noted.

A similar fragmentation pattern of the precursor $[M-1]^-$ ions was observed in the DCI-MS/MS (TSQ-700) and FAB-B/E linked-scan (VG) experiments. The DCI-MS/MS experiments, however, demonstrated better sensitivity than the FAB-B/E experiments. The fragmentation pattern was supported by the MS/MS spectra of the *in situ* deuterated sulfonylureas and also by the spectra of the independently acquired compounds. For example, identity of the m/z 182 ion that was present in the MS and MS/MS spectra of several compounds (Fig. 1) was confirmed by the CAD experiments involving the ion obtained independently by deprotonation of saccharin. Similarly, the CAD spectrum of the sulfometuron methyl $[M-1]^-$ product ion (m/z 214) matched the spectrum of the ion derived from methyl-2-(aminosulfonyl)benzoate (Fig. 1).

Early in the desorption profile of the DCI-MS experiments, rather weak ions corresponding to M^- and $[M-H]^-$ were observed as well as some fragment ions. Spectra obtained in the later stages of desorption exhibited abundant peaks corresponding to thermal decomposition products.

Notice: The U.S. Environmental Protection Agency (EPA), through its Office of Research and Development (ORD), prepared this abstract for a poster presentation. It does not necessarily reflect the views of the EPA or ORD.

DEP/CI-MS/MS Characterization of Sulfonylurea Herbicides

Jodie V. Johnson and Richard A. Yost.
Chemistry Department, P.O. Box 117200, University of Florida, Gainesville, FL 32611-7200

Introduction. Sulfonylurea herbicides (SUs) are very potent herbicides, which have relatively short half-lives once applied in the field due to their thermal lability and ease with which they undergo chemical hydrolysis, as well as biological degradation[1]. This susceptibility to rapid degradation also contributes to the difficulty in analyzing these compounds. Although GC/MS has been used to characterize SUs via their stable derivatives or their thermal degradation products, more commonly they are analyzed via LC/MS[2,3] or LC/MS/MS[4] using one of the amenable ionization techniques. In this work, sulfonylurea herbicides are characterized by direct exposure probe/chemical ionization/tandem mass spectrometry (DEP/CI-MS/MS) utilizing methane and ammonia as reagent gases.

Experimental. All data were acquired on a Finnigan MAT (San Jose, CA) TSQ45 triple quadrupole tandem mass spectrometer operated in the CI mode with an ionization energy of 100 eV and an ion source temperature of 150 °C. The reagent gas pressures were adjusted to yield maximum intensity of the reagent ions: CH_5^+ and H_3O^+ for methane at 0.12 torr (indicated) and NH_4^+ for ammonia at 0.2 torr (indicated). Normal mass spectra were taken in the Q1MS mode with ion lense tuning performed to optimize transmission of m/z 414 of FC43 under CH_4 CI conditions. MS/MS daughter spectra were acquired with a collision energy of 20 eV and collision gas pressure of approximately 1.6-1.9 mtorr argon (ion lenses were tuned to yield maximum conversion of m/z 414 to m/z 69 of FC43). SUs were obtained from Chem Service (West Chester, PA) with certified purities > 98%. Approximately 1-2 μL of an SU solution (1-5 mg SU/mL CH_2Cl_2) were placed on the DEP filament, allowed to air dry, and then introduced into the ion source. Vaporization of the SU occurred via resistively heating the DEP filament from ambient to approximately 450 °C @ 5 °C/s.

Normal Mass Spectrometry. With the introduction/vaporization of SUs via a conventional out-of-source solids probe, thermal degradation predominated over vaporization with little or no evidence of molecular-type ions. However, with the introduction/vaporization of SUs via an in-source direct exposure probe, $(M+H)^+$ and $(M-H)^-$ ions were readily observable. The major PCI- and NCI-MS ions were due to cleavages along the sulfonylurea bridge with and without hydrogen rearrangement and were very indicative of the SU structure[2,3]. NH_3 PCI-MS resulted in reduced fragmentation compared to CH_4 PCI due to the higher proton affinity of NH_3 resulting in less internal energy in the formed $(M+H)^+$ ion. NH_3 NCI-MS resulted in increased numbers and intensities of fragment ions. This was due to the abundant NH_2^- reagent ions generated by NH_3 in contrast to the relatively low abundance of OH^- ions generated in CH_4 NCI. NH_3 adduct ions (e.g. m/z 123) were observed in the NH_3 NCI; no adduct ions were readily observed with CH_4 NCI.

Tandem Mass Spectrometry. The (M+H)+ and (M-H)- ions underwent collision-induced dissociation (CID) very easily and with high efficiency under relatively mild CID conditions (20 eV, 1 mtorr argon). The resulting daughter ions were indicative of the two portions of the SU (i.e. the sulfonamide and the heterocycle) and thus were highly characteristic of the individual SUs (Figures 1 and 2). The daughter spectra of the $(M+H)^+$ ions matched well with those obtained under CE/ESI-MS/MS conditions[4]. The daughter spectra of the $(M+H)^+$ and $(M-H)^-$ ions were essentially identical regardless of whether the parent ion was produced under CH_4 or NH_3 CI. The daughter spectra of common sulfonamide and heterocycle structural ions were identical. For example, Thifensulfuron (Harmony), Metsulfuron Methyl (Ally), and Chlorsulfuron (Glean) all contain the same heterocycle; CAD of its protonated ion (m/z 141) yielded the same spectra for all three SUs. Thus, it should be possible to utilize CI-MS/MS of the molecular-type ions and fragment ions of unknown SUs or SU degradation products to elucidate their structure.

DETERMINATION OF PROTON AFFINITIES OF PHOSPHONATES BY USING THE KINETIC APPROACH

A. Leroy[1], F.Fournier[1], J.C. Tabet[1]*, J. Dissard[2], I. Daoust-Maleval[2], and A. Tambuté[2].

[1]*Laboratoire Chimie Organique Structurale, EP 103, UPMC, Paris cédex 05, FRANCE,* [2]*Laboratoire Chimie Recherche Analyse, Centre d'études du BOUCHET, B.P. 3, 91710 Vert-le-Petit, FRANCE*

Organophosphorus compounds are widely used as pesticides, fertilisers or detergents in different fields like industry and agriculture They can be very efficient and are generally not persistent However, some of these compounds (or their corresponding degradation products) can be highly toxic and can affect irreversibly the environment[1]. Consequently, trace detections and identifications of such compounds required the use of an efficient analytical method such as mass spectrometry Moreover, tandem mass spectrometer coupled to gas chromatography can yield enhancement of the selectivity and specificity allowing to reach more structural informations[3], which is the case from decompositions of the selected $M^{+\circ}$ ions The studied $(RO)(R'O)P(CH_3)=O$ compounds are ·

1a R=R'=CH_3, 1b R = CH3, R'=C2H5 , 1d R=R'=C_2H_5, 1e R=CH_3, R'=iC_3H_7, 1g R=R'=nC_3H_7, 1f R=C_2H_5, R'=iC_3H_7, 1m R=R'=nC_4H_9, 1i R=CH_3, R'=C_6H_{11}, 1p R=R'=$CH(CH_3)C(CH_3)_3$, 1j R=CH_3 R'=$CH(CH_3)C(CH_3)_3$, 1r. R=R'=iC_4H_9, 1k R'=C_2H_5, R'=C_6H_{11} 1n R=C_2H_5, R'= $CH(CH_3)C(CH_3)_3$

Unfortunately, in EI, these compounds yield extensively fragment ions without detection of $M^{+\circ}$ Actually, formation of MH^+ ions is favored even at low pressure source Recently, mechanism of the MH^+ preparation has been investigated in ion trap instrument, and has been shown to proceed according to an ion-molecule reaction induced by the phosphonate $M^{+\circ}$ ion after ion isomerisation (Equation 1a) into an enolic form Alternatively, under CI-NH_3 conditions, they give rise to formation, as expected, of MH^+ and MNH_4^+ (in weak abundances) This trend reflects that proton transfer from NH_4^+ is exothermic meaning that PAs of phosphonates (noted as $PA_{(Pi)}$) are larger than $PA_{(NH_3)}$. In the present study, in order to obtain more informations on the phosphonate basicity, proton affinities of more than ten organophosphonate compounds have been estimated by using gas chromatography tandem triple quadrupole mass spectrometer according to the kinetic method developped some years ago by Cooks and col[3] from competitive decompositions of proton bounded mixted dimers according to the following relations obtained from RRKM theory

$$\mathbf{Ln\ k_1/k_2 = Ln(Q^*_1/Q^*_2)-[AP_2-AP_1]/RT \quad and \quad Ln\ k_1/k_2 \# -[AP_2-AP_1]/RT}$$

From trimethyl and triethylphosphate esters used as reference, metastable decompositions of the protonated phosphate/phosphonate dimers provide the first PA scale of phosphonates By using different measurements allowing the AP overlap, it appears that the obtained PA scale was self consistent over ± 2 (or less) kJ/mol in spite of the use of two references only In order to appreciate of the PA order of phosphonates as well as their corresponding values through the PA scale, a second approach based upon an indirect determination of $PA_{(Pi)}$ by using the PA scale (reported by Lias and modified by Harrison) of amines accurately known has been applied according to the modified kinetic treatment proposed by Fenselau *et al*[4] · $\mathbf{Ln\ k_{RNH2}/k_{Pi}=[Ln(Q^*_{RNH2}/Q^*_{Pi})-PA_{Pi}]+(AP_{RNH2}/RT)}$ in which each organo-

phosphorus can be compared to those of the appropriate amine serie Studied of the heterogeneous chemical mixed dimer provided a phosphonate PA scale very close to that obtained from TMP and TEP and furthermore PA_{TEP} determined by this latter was yield comparable results as proposed from Lias scale The choice of the proton affinity scales as reference (Lias or Harisson) does not modified strongly the relative PA values determined from both scales

Table 1. Comparison of the proton affinities of phosphonates determined by using PAs values of TMP and TEP, and the published values from the PA scales of Lias[8] and Harrison.

Organo-phosphorus	PA (kJ/mol) (*)	PA (kJ/mol) *Lias scale*	PA (kJ/mol) *Revised scale*
TEP	(907 1)&	908 5 ± 0 8	907 4
MiPrMP	903 2	905 3 ± 1.0	904 6
DEMP	904 6	904 2 ± 1 5	902 9
MCMP	910.2	908 9 ± 1 2	907.7
MPiMP	910 8	911 0 ± 0 6	908 9
DnPMP	911 3	913 2 ± 1 0	910 6
EiPrMP	911 4	911 3 ± 2 1	910 0
DBMP	911 5	910 5 ± 0 8	908 8
ECMP	917 9	916 1 ± 1 1	914 7
EPiMP	$	917 2 ± 1.0	916 9
DiPrMP	$	918 7 ± 0 8	916 2
DPiMP	919 4	918 3 ± 1 0	916 6

Ester substituants influence significantly the PA values Indeed, the change of CH_3OP into C_2H_5OP leads to a strong PA variation by 20 $kJ.mol^{-1}$, for relatively small phosphonate esters, and by 9 $kJ\ mol^{-1}$ for larger esters A ramification of the side chain ester leads to a slight increase of basicity by about 1kJ mol^{-1} The last point in the PA rises with increasing of the alkyl chain length which is due to a coiling effect providing a charge stabilization (i e polarisability effect). Both PA method of determinations seem to be consistent since similar PA values are obtained Furthermore, the PA scale from the second method seems to be less extended than the first one wich is shifted towards higher PA values by 10 kJ mol^{-1} Note that the PA value obtained for TEP from the second method is very close to that which was reported in litterature[4]. VERY LIKELY, AMINES ARE SUITABLE REFERENCES TO STUDY BASICITY OF PHOSPHATES AND PHOSPHONATE ESTERS Alternatively, these results indicate that the protonated dimers generated from phosphonate and phosphate esters as well as phosphonates and amines are characterized by a common structure very likely as proton bounded dimers rather than formation of covalent bounded complex

CID STUDIES OF INORGANIC SPECIES RELEASED DURING BIOMASS COMBUSTION

David C. Dayton and Dingneng Wang
National Renewable Energy Laboratory
1617 Cole Boulevard
Golden, CO 80401-3393 USA

A limiting factor in using solid biomass fuels for electricity production is the accelerated fouling and slagging caused by alkali metal released during biomass combustion. A detailed understanding of alkali release mechanisms during biomass combustion as well as identification of these alkali metal species will provide insights as to how these vapors enhance deposit formation in power generating facilities A molecular beam sampling triple quadrupole mass spectrometer (MBMS) system, in conjunction with a variable-temperature quartz tube reactor, was used to directly sample the hot gases liberated from the combustion of small (20-60-mg) biomass samples The MBMS system is a three stage differentially pumped vacuum system. High temperature, ambient pressure gases underwent a freejet expansion as they were introduced into stage one through a 200μm diameter sampling orifice The expanded gases were skimmed at the entrance of stage two with a conical skimmer to form a molecular beam which was directed into the ionization region of the triple quadrupole mass spectrometer[1] in stage three.

Direct, real-time measurements of sampled gases during combustion of selected feedstocks have been used to identify gas phase alkali metal containing species as a function of feedstock composition[2,3] During these investigations, species with m/z = 81 and m/z = 120 were detected during combustion of alfalfa stems and almond hulls. Collision induced dissociation (CID) experiments were initiated to unambiguously identify these species released during the combustion of these high potassium and nitrogen containing feedstocks Both parent and daughter ion experiments were performed during the combustion of alfalfa stems and almond hulls at 1100°C in 20% O_2 in helium

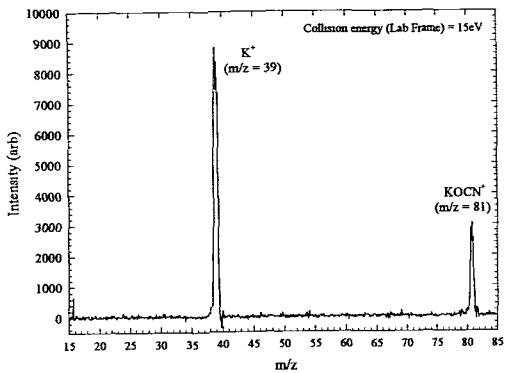

FIGURE 1: CID daughter spectrum of m/z = 81 recorded during the combustion of alfalfa stems at 1100°C in 20% O_2 in helium.

The only fragment daughter ion detected during the CID experiments on m/z = 81 measured during alfalfa stems combustion was K^+ at m/z = 39 as shown in Figure 1 This confirmed that the species with m/z = 81 released during combustion of alfalfa stems contained a potassium atom. Daughter ion spectra of m/z = 81 were also recorded during almond hulls combustion with identical results. Because this species definitely contains a potassium atom, the other fragment must have a mass of 42 amu. The only combination of atoms that is reasonable for this fragment is NCO and the identity of the species with m/z = 81 is $KOCN^+$ This signifies a new mechanism for alkali metal released during the combustion of high potassium and nitrogen containing feedstocks, like alfalfa stems and almond hulls, based on the vaporization of potassium cyanate.

After identifying the species with m/z = 81 as $KOCN^+$, the species with m/z = 120 could be identified as K_2OCN^+, the fragment ion of KOCN dimer OCN behaves like a pseudo-halogen based on the fragmentation characteristics and dimer formation of KOCN. This assignment was confirmed by recording CID daughter spectra of m/z = 120 during alfalfa stems combustion at 1100°C in 20% O_2 in helium where the only daughter fragment ion observed was K^+ at m/z = 39

During the combustion of high alkali containing feedstocks, most of the parent potassium containing species could be identified from the parent ions in the mass spectra. These species, however, undergo substantial fragmentation in the ionizer yielding an intense peak at m/z = 39, the K^+ fragment. Parent ion spectra of m/z = 39 were recorded during alfalfa stems and almond hulls combustion at 1100°C in 20% O_2 in helium to confirm the identity of all the parent potassium containing species which fragment to produce K^+

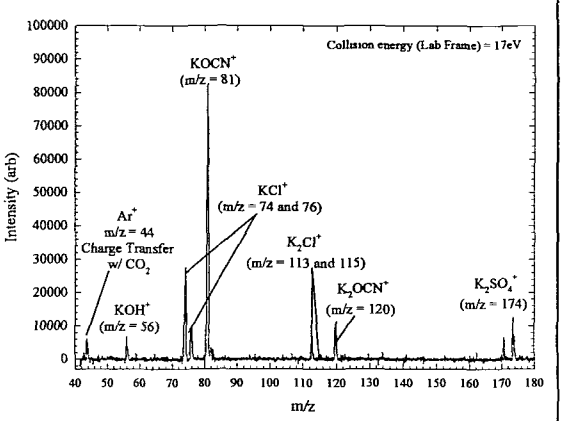

FIGURE 2: CID parent spectrum of m/z = 39 recorded during alfalfa stems combustion at 1100°C in 20% O_2 in helium

Peaks at m/z = 56 (KOH^+), m/z = 74(KCl^+), m/z = 76 (KCl^+), m/z = 81 ($KOCN^+$), m/z = 113 (K_2Cl^+), m/z = 115 (K_2Cl^+), m/z = 120 (K_2OCN^+), and m/z = 174 ($K_2SO_4^+$) were identified in the CID parent spectra of m/z = 39 recorded during alfalfa stems combustion as shown in Figure 2 Most of these parent ions were observed in the standard spectra recorded during alfalfa stems combustion, with the exception of the potassium sulfate parent ion. Similar spectra were recorded during almond hulls combustion Potassium hydroxide, potassium cyanate, and potassium sulfate are observed in the CID parent spectra of m/z = 39 recorded during almond hulls combustion. These experiments suggest that there are four different pathways for potassium release to the gas phase during alfalfa stems combustion: 1) via potassium hydroxide, 2) via potassium chloride, 3) via potassium cyanate, and 4) via potassium sulfate

Photodissociation of Electrosprayed Ions in the Quadrupole Ion Trap

*Stephen M. Boue', James L. Stephenson, and Richard A. Yost

Traditionally, collision-induced dissociation (CID) has been the method of choice for the activation of polyatomic ions in quadrupole ion trap tandem (MS/MS) experiments. More recently, however, photo-induced dissociation (PID) has developed into an important alternative to CID for the structural elucidation of biologically important molecules. Recently, our group has constructed an electrospray-ion trap instrument utilizing a multi-pass optical arrangement for PID studies.[1] An RF-only octopole ion guide efficiently transmits ions from the high pressure source region to the lower pressure region of the analyzer. In this presentation we report the development of the ESI/QITMS system and the first results on the photodissociation of four classes of biologically important molecules (oligosaccharides, antibiotics, peptides, and oligonucleotides).

The ESI/QITMS instrument used in our experiments was designed and built at the University of Florida. A simplified schematic drawing of the instrument including the ESI source, differentially pumped vacuum chamber, RF-only octopole, and ion trap analyzer is seen in **Figure 1**. The RF-only octopole was constructed from 2.0 mm diameter, 30 cm long, stainless steel rods. The ratio of the rod diameter to the field radius was 0.33 and the optimum RF frequency was 1.659 MHz.[2]

For ion injection, two of the more important instrument parameters of our system were the electrospray gate lens and the octopole offset voltage. As shown in **Figure 2** for the electrospray gate lens, the maximum peak intensity for the individual charge states of the peptide Ubiquitin varied over a 20V range. The trend observed showed lower charge states (higher m/z values) required higher gate lens voltages for optimal transmission to the octopole. This mass dependency can also be seen when varying the octopole offset voltage. Although this mass discrimination can be problematic, when compared to traditional DC lens systems for ion injection, the amount of mass discrimination observed was significantly reduced

PID is an excellent tool for obtaining oligosaccharide sequencing information due to the ease in cleaving the **C-O-C** ether (glycosidic) linkage. The PID spectra of the ammonium adduct of stachyose (m/z 684) is shown in **Figure 3**. Complete fragmentation of the tetrasaccharide was obtained with two laser pulses. The peaks observed included $(M+NH_4-179)^+$ at m/z 505, $(M+NH_4-NH_3-179)^+$ at m/z 488, $(M+NH_4-NH_3-179-162)^+$ at 326, and $(M+NH_4-NH_3-179-162-162)^+$ at m/z 164. The loss of 179 corresponds to the loss of either the non-reducing or reducing end of the molecule, while the loss of 162 occurs due to internal cleavages. In addition to the complete fragmentation of oligosaccharides, PID is also useful for cleaving sugar moieties from the aglycone unit of antibiotics. Currently, work is being done with the antibiotics vancomycin and erythromycin.

The ability to cleave amide linkages has enabled PID to be useful in peptide (and protein) sequencing. **Figure 4** shows the PID spectrum of the $(M+3H)^{+3}$ ion of Angiotensin I using a cw IR laser. Typical fragments observed were mid-range singly charged b ions (b_5, b_6, and b_9) derived from β-cleavage and charge migration along the peptide backbone. Also observed were the y ions (y_2, and y_4, y_8^{+2}) originating from hydrogen ion migration(s) from the amino end of the peptide. Also, current experiments with oligonucleotides are being conducted to examine the utility of PID for DNA/RNA sequencing.

For the structural elucidation of biomolecules, photo-induced dissociation is an effective alternative to collision-induced dissociation of electrosprayed ions inside the quadrupole ion trap. In this study, four classes of biologically important molecules were examined. These compounds were chosen to demonstrate the capabilities of a new ESI/ion trap instrument designed and recently constructed for PID studies at the University of Florida. Currently, more complex biomolecules, including larger DNA

fragments and glycopeptides, are being characterized in our laboratory. The high level of control over energy added and higher fragmentation efficiency of PID enable this technique to provide invaluable structural information to the analytical biochemist.

PULSED PRESSURE QUADRUPOLE ION TRAP FOR TANDEM MS OF PEPTIDES

Vladimir M. Doroshenko and Robert J. Cotter
The Johns Hopkins University School of Medicine, Baltimore, MD 21205

Collision-induced dissociation technique is widely used in tandem mass spectrometers including quadrupole ion traps (QIT). The main feature of QIT is the presence of helium buffer gas at relatively high pressure of ~ 1 mTorr. Collisions with helium atoms are commonly used also for fragmentation after additional excitation of parent ions. One of the problems which is specific for QIT, on the way of practical use of CID technique for elucidation of peptide in QIT is due to its ability to trap ions within limited range of m/z. Energy deposition in CID process is also limited due to the large mass difference between colliding partners. The effect of adding of heavy target gases on the CID efficiency and overall performance of QIT was extensively investigated. Higher activation energy reactions were observed in collisions with heavy gases. However, the trapping efficiency for introduced ions dropped with increase of content of heavy gas in buffer gas mixture. The buffer gas pressure also effects on the fragmentation pattern. In this work a pulse gas valve technique was used for studying the influence of heavy gases at separate experimental stages of QIT operation.

Experiments were carried out on a modified Finnigan MAT ion trap detector. These modifications include additional hardware for interfacing of ITD with laser and external control of the instrument, and developed in-house *TrapWare* software (see *Rapid Commun. Mass Spectrom.* **1994**, *8*, 766). A Quatech (Akron, OH) WSB-100/WSB-A12M waveform

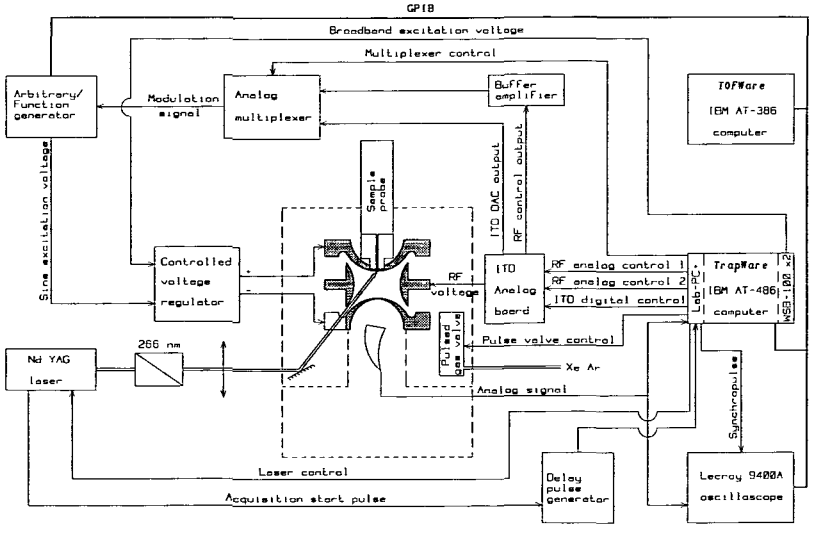

Fig. 1. Block diagram of the modified ITD instrument.

synthesizer plug-in board connected to an IBM computer was used for SWIFT waveform generation (see ASMS'95 poster ThPC 083 for details). The instrument scan functions and SWIFT pulses were designed by TrapWare software. For the pulsed gas introduction experiments the ion trap assembly was mounted on a new holder inside a two-section coffin vacuum chamber. The characteristic pumping time of the ion trap section was ~7.6 ms that allowed us to limit the influence of injected gas on a chosen stage only. A General Valve (Fairfield, NJ) Series 9 pulse valve with a bullet style body and 0.1 mm diameter exit orifice was placed inside vacuum chamber near the ion trap assembly.

The introduction of different gases was studied at different stages of ion trap operation. A significant improvement in QIT operation was observed only during the injection of heavy gases at the CID stage while the gas introduction during the ion trapping, ion isolation and analytical scan stages had negative effect. The effect of the sort of injected gases on the CID process at different q_z was studied using the protonated α-Casein Fragment 90-96 ions as a sample molecule. The CID efficiency was smaller for smaller q_z values and increased with the increase of the mass of collisional counterpartner which changed from 4 for He to 131 Da for Xe. No difference was observed for CID fragmentation pattern for partners without and with internal structure (such as NH_3 and air). In the case of ammonium this means that no chemically reactive collisions were observed. The most probable explanation is that in the case of α-Casein Fragment 90-96 the protonation does not occur at the amide bond. The increase of pressure of the injected gas in the limits studied in this work (up to 5 mTorr) resulted in the improvement of fragmentation. The exemplary CID mass spectrum of α-Casein is shown in Fig. 2. CID was performed using xenon as collision gas at q_z= 0.05 which allows the trapping of low mass product ions. The mass spectrum in Fig.2 contains long a and b fragment ion series that allows full recovering of amino acid sequence.

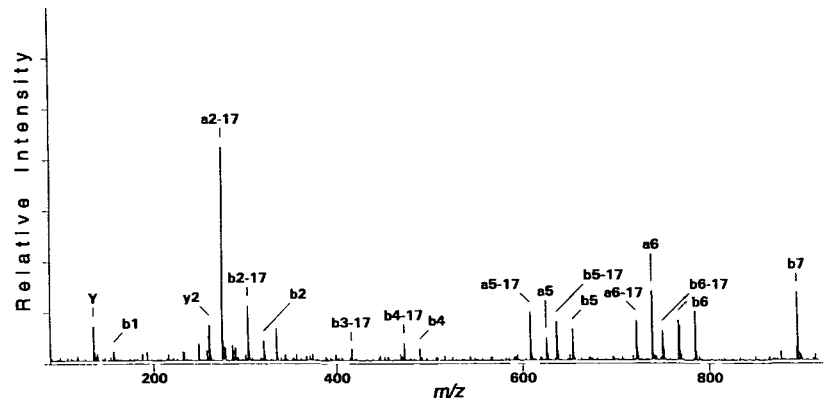

Fig.2. Monoisotopic tandem mass spectrum of protonated ions of α-Casein Fragment 90-96 (MW=913 Da) obtained with the use of a pulsed introduction of xenon at the pressure of ~2.5 mTorr for CID at q_z= 0.05.

Thermal Activation of Stored Ions in a Quadrupole Ion Trap

William J. Herron, Douglas E. Goeringer, and Scott A. McLuckey
Oak Ridge National Laboratory

Trapped ion techniques offer a unique opportunity to probe the nature of isolated ions in the gas phase. We have expanded our experimental capabilities by adapting an electrospray/atmospheric glow discharge quadrupole ion trap combination to allow for a heated vacuum system. (1) By increasing the temperature and the average collisional energy, we are studying changes in the dissociation behavior and the ion-molecule reactivity of ions as a function of temperature. The temperature plays a role in both the activation of unimolecular fragmentation and desolvation phenomena. This set-up has allowed us to acquire ESI mass spectra of multiply-charged Horse Heart Myoglobin and to explore its dissociation behavior as a function of bath gas temperature. Thermal activation which raises the internal energy of the ion, also affects intermolecular interactions such as the solvation of a multiply-charged ion by a large number of neutral species. Raising the temperature of multiply-charged species will "heat" them above the binding energy of the weakly bound neutral species, thus desolvating the ion. We have observed this process during the the thermal activation of multiply-charged Horse Heart Myoglobin.

We are particularly interested in relating collisional activation data acquired at room temperature with data acquired from thermal activation. Quantifying the effects of thermal activation on ion internal temperature requires an ion whose thermochemistry is well defined. We have resorted to the use of heavily-studied "thermometer" ions such n-butylbenzene to model ion activation. The basic assumption of thermal activation is that ions are in thermal equilibrium with the bath gas. This assumption is compromised by the ion isolation technique used to remove all other ions except the ions of interest in the quadrupole ion trap. The ion isolation is accomplished by ramping the primary RF trapping voltage amplitude applied to the ring electrode, while applying a small amplitude axial modulation frequency to the endcaps. This isolation step will kinetically heat the parent ions. To compensate, a cooling phase is added to the scan function which allows the parent ion populations to be collisionally cooled back to the ambient helium bath gas temperature (Figure 1). The extent of ion heating during the isolation step is inversely proportionally to the amount of helium, while the time required to regain equilibrium is proportional to the amount of helium. By judiciously selecting an excessive cooling period (20 ms, 1 mtorr He) the thermal activation of well characterized ions can be monitored. Within the temperature range accessible to our experimental set-up (25-100 °C), we did not observe the dissociation of the n-butylbenzene radical cation by thermal activation alone. However, we were able to increase the extent of collision induced dissociation by thermal activation (Figure 2).

Figure 1. The effect of the addition of a cooling phase after the isolation step. The isolated n-butylbenzene radical cation is (a) stored and kinetically excited by a small axial modulation amplitude for 25 ms, and (b) is collisionally cooled by the helium bath gas for 20 ms before being kinetically excited by a small axial modulation amplitude for 25 ms.

Figure 2. The effect of thermal activation of stored ions. The isolated n-butylbenzene radical cation is stored, collisionally cooled, (20 ms, 1 mtorr He) and kinetically excited by a small axial modulation amplitude for 25 ms (a) at 26 °C, and (b) and at 90 °C.

The Analytical Utility of Photodissociation in Tandem Mass Spectrometry

D. J. BEUSSMAN[1,2], T. A. ERICKSON[1], C. G. ENKE[1,2]
[1]Department of Chemistry, University of New Mexico, Albuquerque, NM 87131
[2]Department of Chemistry, Michigan State University, East Lansing, MI 48824

Photodissociation (PID) is an established method of fragmenting ions. Fundamental studies have been performed on a few select chemical systems, but no broad study has been undertaken to demonstrate the analytical utility of PID in mass spectrometry relative to the widely accepted approach of collisional-induced dissociation (CID).

CID is a well-established method of creating product ions in tandem mass spectrometers. CID is a nearly universal fragmentation method, at least for ions below a few thousand mass units, which contributes to its usefulness. However, CID does suffer from two drawbacks. As the molecular weight of a precursor increases, the energy imparted to it decreases, making CID less attractive as a fragmentation method for high-mass ions. Also, in time-of-flight applications, the product-ion spectrum generation rate is limited by the duration of the CID gas pulse and the time required to pump the gas away. For tandem mass spectrometry on the GC time scale this spectral generation rate is too slow.

The energy imparted to an ion with PID is not dependent on the molecular weight of the ion, but only on the wavelength of the light used. The spectral generation rate utilizing PID as the fragmentation method is limited to the repetition rate of the laser used. Laser repetition rates greater than 200 Hz are possible, which would allow multiple product spectra to be obtained during the elution time of a GC peak. For these reasons, PID appears to be an attractive alternative to CID for product ion creation.

The PID product spectra for a broad range of compounds with various functional groups, have been determined. Using 193 nm photons, all organic ions studied have been fragmented, including alkanes. Table 1 shows the % depletion for several ions using a laser pulse energy of 200 mJ. The effect of laser pulse energy on the PID process has been studied and the results used to calculate the PID cross-sections. For the ions studied at 193 nm, there is less than an order of magnitude difference in PID cross-sections, indicating that all ions are efficiently fragmented and that varying the functional groups does not significantly change the PID process at 193 nm. The linear relationship between the depletion of the precursor ion and the laser pulse energy indicates that all processes studied are single photon events.

In order to establish the general analytical utility of PID as a fragmentation method, the resulting product spectra have been compared to those obtained with CID on a triple quadrupole mass spectrometer. This indicates whether PID and CID provide comparable structural information. For all ions studied so far, the major product ions are the same for both CID and PID. PID does, however, yield fragment ions that are not present in the low-energy CID product spectrum. The results of these studies indicate that PID spectra for 193 nm photons may more closely resemble the high-energy CID product spectra.

Since all ions studied have been efficiently fragmented, including alkanes (Figure 1), PID using 193 nm photons appears to be a general fragmentation method for organic ions,

regardless of the functional groups present in the ions. Also, the high efficiency demonstrates that analytically useful product spectra can be obtained with every laser shot.

SMIKES: A New Scan to Determine Artefact Peaks in MIKE Spectra.

Yves Mouget and M.J. Bertrand,
Regional Center for Mass Spectrometry, Dept. of Chemistry,
University of Montreal, Montreal, Canada, H3C 3J7.

A common origin for artefacts in Mass Analyzed Kinetic Energy Spectra (MIKES) performed with instrument of reverse configuration is the decomposition of higher mass ions in the field free region before the magnet, such that the apparent mass ($m^*=m_2^2/m_1$) of the fragment corresponds to the mass selected during the scan. When MIKE scans are performed using EBE geometry instruments, artefacts are not necessarily eliminated but their intensity can be substantially reduced [1]. However, instruments of this latter geometry offer a scanning method that allows these artefacts to be identified. By linking and scanning the 1st and 2nd ESAs such that $E_1=E_2$, with the magnet set to the mass of interest, the spectrum shows only peaks that correspond to artefacts. This scan is labelled a Selected Mass analyzed Ion Kinetic Energy (SMIKE) scan. Experiments were performed with an EBEqQ geometry instrument, featuring an "experiment design" function, which allows analyzers to be linked and scanned by means of user-specified mathematical relationships. The SMIKE scan could also be performed by hard-wiring the two ESAs together.

Several artefacts appear in the MIKE spectrum of the protonated dimer of the dipeptide Lys-Lys, $[(Lys\text{-}Lys)_2H]^+$, of m/z 549.4 [2]. Intense peaks are observed at relative energies of 0.942, 0.939, and 0.936. They were found to result from the loss of an HCl entity from the higher mass ions $[(Lys\text{-}Lys)_2(HCl)_2H]^+$, at m/z 623, before the magnet. Using a recently proposed graphical method [1], the previous rationalization describing the presence of an artefact is represented in Figure 1. This approach uses a cube to reflect the effect of the three analyzers in an E_1BE_2 geometry instrument ($\rho1$ for E_1, $\rho2$ for E_2, and B for the magnetic sector). The decomposition of higher mass ions would be represented by a diagonal line (a-b) drawn from the mass of the precursor (m/z 623) on the B axis (at $\rho1=1$ and $\rho2=1$) to the origin. Artefacts in MIKE scans obtained using instruments of E_1BE_2 geometry correspond to fragmentations occurring between the first ESA and the magnet. This is reflected in Figure 1, where the diagonal line representing fragmentations of the precursor at m/z 623.4 has been projected on the (B, $\rho2$) plane at $\rho1=1$, and now intersects the MIKE scan line (c-d), which is also projected onto the (B, $\rho2$) plane. The intercept coordinates of the diagonal with the scan line correspond to the energy at which the fragment will be transmitted, and appear as an artefact in the MIKE spectrum.

Alternatively, if a line were drawn through the cube at a constant value of B, such that it reflects a variation in both E_1 and E_2 such that $E_1=E_2$, this line would intersect all the diagonal lines describing the decomposition of higher mass precursor ions. This line can be related to a real scan, a scan of the two ESAs, which will result in a spectrum containing only the artefact peaks that can be present in a MIKE spectrum. Such a scan is represented by the line d-e in Figure 1. It samples fragments formed in FF1, with ions reaching the detector only if their apparent mass of m* corresponds to the magnet mass. Figure 2 is a spectrum resulting from this SMIKE scan at $E_1=E_2$, with B set to 549.5. The result is two clusters of peaks, at relative energies of ~0.939 and ~0.998. The precursor and fragment ions determined for the resulting mass losses, by taking into account the energy at which each peak is transmitted with respect to the energy of the main beam, correspond to those previously suggested for the artefacts. For example, the peak which appears at 7508 Volts is the result of $[(Lys\text{-}Lys)_2(H^{35}Cl)(H^{37}Cl)H]^+$, of m/z 623.4, losing $[H^{37}Cl]$ to form the fragment $[(Lys\text{-}Lys)_2(H^{35}Cl)H]^+$ of m/z 585.4. The masses for the different fragment ions were confirmed by scanning the quadrupole located after E_2.

Vitamin K is another compound that may produce artefacts in a MIKE spectrum. When a MIKE scan of the fragment ion of m/z 198 is performed on an EBE geometry instrument, two narrow peaks at m/z 185 and m/z 186 are visible (Figure 3), corresponding to relative energies of 0.9342 and 0.9389, respectively. When the SMIKE scan of the fragment ion of mass 198 is performed, two peaks appear among several others at 0.9384 and 0.9340 of E_0, which is close to the energy at which the peaks appeared in the MIKE spectrum (Figure 4). It would therefore seem that these peaks could indeed be artefact peaks, corresponding to the decomposition of m/z 225-->211, and m/z 227-->212. When considering the structure of the two fragment ions of mass 225, the first loss could more easily occur from the $C_{16}H_{33}$ fragment ion, than from the $C_{15}O_2H_{13}$ fragment ion, both of which have a mass of 225. Such structure elucidation represents another advantage of this scan. The SMIKE scan is an example of an MS/MS scan developed by picturing the desired scan within the 3D visualization approach, and then defining the corresponding scan equation by means of an interpretation program. The resulting spectrum shows peaks that would correspond to artefact peaks in a MIKES, and the structural information obtained should therefore be considered complimentary to that obtained from the MIKE scan.

Mapping Metastable Decays in a Time-of-Flight Mass Spectrometer with a Single-stage Ion Mirror

G. Brinkmalm, P. Håkansson, B.U.R. Sundqvist and D F. Barofsky[†]
Division of Ion Physics, Department of Radiation Sciences, Uppsala University, Box 535, S-751 21 Uppsala, Sweden
[†]*Department of Agricultural Chemistry, Oregon State University, ALS 1007, OR 97331-7301, USA*

We have developed a procedure to map unimolecular metastable decompositions in a time-of-flight mass spectrometer with a single-stage ion mirror. The procedure includes correlation of fragment ions to their precursor as well as extraction of the fragment masses.

Correlation is possible since the instrument is equipped with two stop detectors, a 0°-detector situated at the rear end of the mirror and a 180°-detector for the reflected ions. By comparing a normal 0°-mode spectrum (recorded with the mirror inactive) to a 180°-mode spectrum (with the mirror active and the instrument tuned for optimal resolution) the metastable ion peaks can be located. Reversed correlation on each metastable peak of interest (in the 180°-mode spectrum) is performed in order to determine the precursor ion undergoing decomposition. Normal correlation on each precursor of interest is performed, revealing any multiple decay paths.

Unimolecular metastable decompositions have been mapped for different precursor ions originating from thin film samples of valine, behenic acid and tri-alanine bombarded by 72 MeV $^{127}I^{13+}$ ions and 20 keV $^{69}Ga^{+}$ ions.

The masses of the fragment ions corresponding to these peaks can be approximately estimated using a simple relationship [1] between masses and true flight times in the 180°-mode spectrum

$$m_{fragment} = m_{precursor}\left(2\frac{t_{fragment}}{t_{precursor}} - 1\right). \quad (1)$$

Two ways to obtain more accurate mass assignment were investigated. One is to establish a correction curve to Eq. (1). The correction curve is established by plotting the deviation of $m_{fragment}/m_{precursor}$ from its theoretical value, $\Delta(m_{fragment}/m_{precursor})$, versus $m_{fragment}/m_{precursor}$ (see Fig. 1). Both linear and quadratic fits were attempted and the improvements are substantial in both cases.

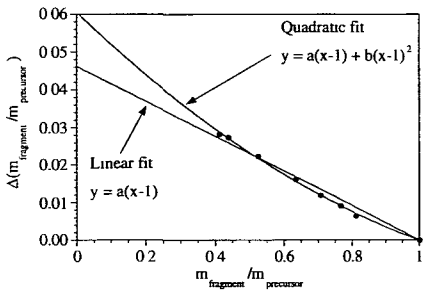

Figure 1. Generation of correction curves for more accurate mass assignment.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Another way is to match a fragment ion's flight time with that of its precursor [2]. This is accomplished by lowering the mirror voltage so that the fragment ion's flight time will be identical to the precursor's in the normal 180°-mode. When this condition is met, the ratio of the mirror voltages is exactly equal to the ratio of the masses of the respective precursor and fragment ions, and thus the fragment ion's mass can be accurately determined. The ultimate accuracy of this method is only limited by the mean and the degree to which the flight time can be matched.

The two methods are compared in Fig. 2 for the case of 72 MeV $^{127}I^{13+}$ primary ions. With our present apparatus, the quadratic correction and the path matching method yield comparable mass accuracy: better than 0.6% for keV primaries and better than 0.2% for MeV primaries (0.2% and 0.1% on average for the respective cases). With the path matching method, it is in principle possible to determine a fragment ion's mass to within an accuracy of 0.01% (the mass accuracy the instrument has for stable ions). This requires voltage supplies and meters with an accuracy better than 0.005% under operating conditions.

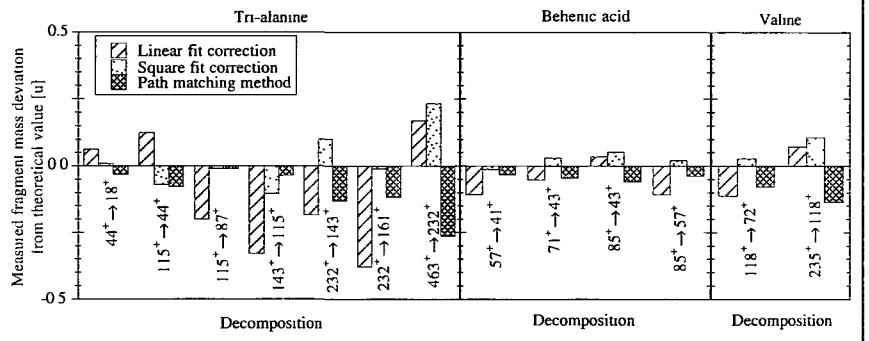

Figure 2. Comparison of the mass accuracy for the correction curve method and the path matching method for the case of 72 MeV $^{127}I^{13+}$ ions.

TANDEM MASS SPECTROMETRY UTILIZING THE ADVANTAGES OF BOTH MALDI AND FTMS

John A. Castoro*, Sanford Shew, Howard Stout, Brian Winger and Joseph Campana
Extrel FTMS, Inc., 6416 Schroeder Rd., Madison WI, 53711-2424

Matrix-assisted laser desorption/ionization (MALDI) is known to have several advantages over other ionization methods. For example, very large molecules (>200,000 Da) can be effectively ionized, and suppression effects from the presence of salts are less than other ionization techniques. MALDI is generally accepted as a "soft" ionization technique resulting in little or no fragmentation. However, metastable decay resulting in extensive fragmentation can be observed with sufficient laser power density and by increasing the time after desorption prior to detection. This decay process has been reported to take place with a half-life of several milliseconds[1] to approximately 10 ms for bovine insulin and melittin.[2] These results are consistent with RRKM theory, which generally predicts lower rates of unimolecular decomposition as the size and the number of degrees of freedom of a molecule increases.

Here we show how the variable ion trapping duration, tandem MS, high-resolution and accurate mass measurement capabilities of Fourier transform mass spectrometry (FT/MS), have been used to obtain sequence-specific information resulting from the metastable decay of MALDI-generated peptide ions. A standard Extrel FTMS Model 2001 mass spectrometer equipped with and a nitrogen laser (337 nm) was used for these studies.

The laser power density is a factor that can affect the extent of fragmentation. By maintaining the laser output energy, and varying the spot size, the extent of fragmentation as a function of power density was measured. In agreement with published literature, we have observed that the extent of fragmentation is directly proportional to the laser power density. Previously published data have indicated that the type of matrix or co-matrix used is another parameter that can effect the extent of fragmentation.

As an example of the amount of sequence information that can be obtained, MALDI activation was applied to the peptide bradykinin. A total of 270 femtomoles of the peptide was loaded onto a sample disk with an excess of 2,5-dihydroxybenzoic acid matrix. By increasing the time delay after ion trapping and prior to excitation and detection from 1 ms to 1000 ms, the extent of fragmentation with respect to time is observed. After a one second delay, the extent of fragmentation is such that the molecular ion is no longer the base peak, and nearly the entire sequence of the peptide is obtained. The y- and b- series ions are observed, which is in agreement with ion-trap/reflectron time-of-flight mass spectrometer measurements.[3] The average measured mass error for the 8 fragments detected (y_1'', b_2, y_2'', y_3'', y_4, b_5, b_7 and b_8) is less than 5 ppm for the all ^{12}C isotopes. These high mass accuracy results were obtained in the source cell of a dual cell system by using an external calibrant.

Structural information is typically obtained by tandem mass spectrometry performed by collision-induced dissociation (CID) of an isolated parent ion with a neutral inert collision gas. The efficiency and resulting fragmentation of on-resonance excitation, sustained off-resonance irradiation (SORI) and multiple excitation collisional activation (MECA) were compared by dissociating the $[M+H]^+$ species of the decapeptide pGlu-Leu-Trp-Pro-Arg-Pro-Gln-Ile-Pro-Pro, *m/z* 1214.67. The extent of fragmentation and efficiency of SORI (1 second, 500 Hz lower frequency) and MECA (1 ms excite, 50 ms collision delay, repeated 20 times) were similar, for a range of translational energies, with up to 70% fragmentation efficiency at 20 eV (using peak areas, and a 15% standard deviation of the control measurement). As expected, higher translational energies were required to obtain similar fragmentation for the on-resonance excitation measurements (1 ms excite, 1 second collisional delay) with less efficiency, up to 15%. Argon was used as a collision gas in all measurements (pulsed to ~10^{-6} torr)

The fragments produced by MALDI activation can be used for a second stage of mass spectrometry.

The MALDI-generated sequence ions b_8 and y_1'' of the peptide bradykinin, were isolated by stored waveform inverse Fourier transformation (SWIFT) for SORI-CID (Figure 1). The tandem mass spectrum of the y_1'' ion produced predominately y_3'' and y_4 ions while fragmentation of the b_8 ion produced b_5 and b_7 ions, in addition to the b_6 ion, which was not detected in the metastable decay measurement. The fragments detected from the tandem MS measurement, in addition to the metastable decay measurement produced complete sequence information.

As the size of the molecular ion increases, it becomes increasingly difficult to deposit sufficient energy into the ion to promote fragmentation by using standard tandem mass spectrometry. Depending on the MALDI conditions, the extent of metastable decomposition can be somewhat controlled and used as a method of obtaining analytically useful sequence information for peptides. The ion storage capabilities of a FT/MS ion trap can be used to perform a tandem MS measurement of the MALDI activated fragments produced for additional structural information.

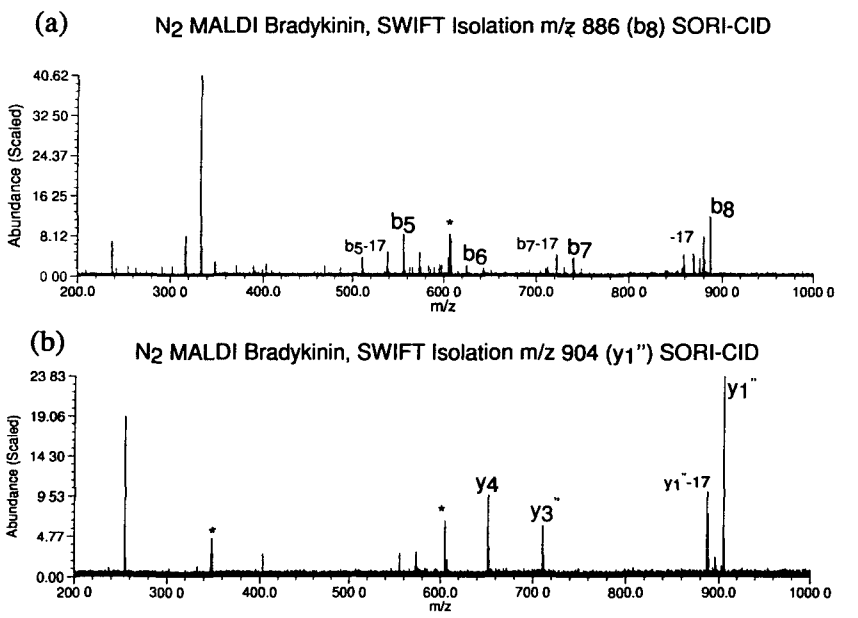

Figure 1: MALDI-FT mass spectrum of 270 femtomoles of bradykinin deposited onto a sample disk with a 1 second delay after desorption, SWIFT isolation for SORI-CID of MALDI-generated fragment (a) b_8 (15 eV, 25 laser shots) and (b) y_1'' (10 eV, 20 laser shots). * indicates a noise peak.

MSMS STUDIES USING A HYBRID MAGNETIC SECTOR-ORTHOGONAL ACCELERATION TIME-OF-FLIGHT MASS SPECTROMETER; Thomas Keough, Martin P. Lacey, Mark D. Bauer and Yiping Sun; The Procter and Gamble Company, Miami Valley Laboratories, P.O. Box 398707, Cincinnati, OH 45239-8707.

A hybrid magnetic sector oaTOF mass spectrometer was recently developed for high sensitivity MSMS studies (1,2). It offers high resolution precursor ion selection, unit product ion selection and both low- and high-energy collisionally activated dissociation (CAD). The purpose of this study was to characterize the performance of this new instrument. Two configurations were evaluated: A = a 2 cm collision cell and a 4 in diffusion pump on the oaTOF housing; B = a 5 cm cell and 6 in diffusion pump. We assessed ion transmission into the oaTOF as a function of deceleration energy, CAD efficiencies and ion losses as a function of collision gas pressure, and the internal energy content of the fragmenting parent ions. The performance of the system was illustrated with both continuous (EI, static FAB and electrospray (see abstract by Yiping Sun and coworkers)) and pulsed (MALDI) ionization techniques.

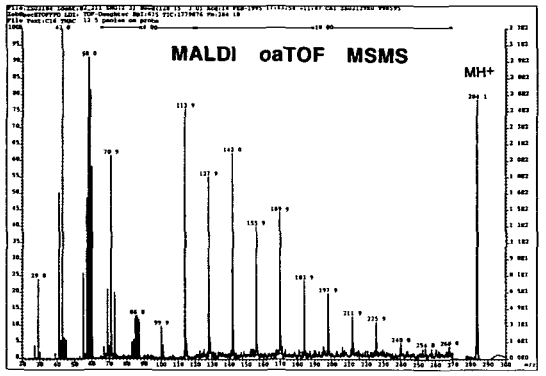
Ion transmission losses occur in the deceleration region as mass selected precursor ions are decelerated from their initial energies of 8000 V to 800 V or less. This deceleration step is needed to improve oaTOF sampling, and it occurs prior to collisional activation. The MSMS experiments that we are concerned with here involve collisions of 800 V (or less) parent ions with neutral collision gases like He or Xe. Parent ion transmission varies from 45% (800 V precursors) to about 4% (50 V). Transmission losses were identical, within experimental error, for both configurations, and the losses appeared to be mass independent.

We've studied in detail the MSMS spectra obtained from a CsI cluster ion (m/z 1691.7) as a function of collision gas pressure (all experiments at 800 V collision energy). Both Xe and He were used in these experiments. With Xe as the collision gas using configuration A, the observed efficiency for fragment ion production (CAD efficiency) was 24%, and 45% of the non-attenuated parent ion beam was "lost" due to scattering and ion neutralization. CAD efficiency increased to 33%, and losses were reduced to 39%, with configuration B. With He, losses accounted for only 22%, and CAD efficiency was over 50% using configuration A. CAD efficiency increased to 94%, and losses were eliminated using configuration B. We believe that scattering of low mass fragment ions out of the acceptance angle of the oaTOF accounts for much of the observed ion loss. Therefore, we compared the transmission/detection of two low mass fragment ions (m/z 133 from the CsI cluster ion at m/z 1691.7 and m/z 70 from the bradykinin molecular ion) with previously published results from four sector MSMS instruments. The oaTOF equipment appears to perform as well as four sector instruments in this regard.

The fragmentation of the molecular ion of n-butylbenzene, a well-known "thermometer" molecule (3), was studied as a function of collision energy at a fixed pressure (He and Xe). The maximum average precursor ion internal energies sampled in these experiments, 7.0 eV (He) and 4.6 eV (Xe), were obtained with the 5 cm collision cell. MSMS of tungsten hexacarbonyl (4) was also carried out to assess the internal energy distributions of the fragmenting precursor ions. The distribution calculated from the MSMS spectrum obtained following 800 V collisions (He) shows an average energy of about 6 eV and a high energy "tail" that extends beyond 12 eV. This internal energy distribution is very similar to those previously reported from higher energy collision experiments (4). With 50 V collisions, the internal energy distribution shifts to much lower values. The observed average energy is 2.6 eV (He) and the high energy tail does not extend beyond 6 eV. These results confirm that MSMS spectra from the oaTOF instrument should be "tunable" over a wide range of precursor ion internal energies and that there is

sufficient energy to produce high-energy fragments like side-chain cleavage in peptides (2) or remote-site fragmentation for various classes of ionic surfactants (sulfonates, sulfates, quaternary ammonium salts).

The operation of the oaTOF instrument was evaluated for both continuous and pulsed ion sources. Excellent quality static FAB MSMS spectra of small peptides are typically obtained with 100 pmole of material. Usable quality FAB MSMS spectra of substance P have been obtained after loading as little as 3.8 pmoles of material onto the probe. The MSMS spectrum of the C16-trimethylammonium cation, generated by MALDI, is shown in the Figure. A total of 12.5 pmoles



of material were loaded onto the solids probe for this experiment (in alpha-cyano-4-hydroxycinnamic acid matrix). Only about 20% of the sample was actually interrogated with the N_2 laser beam. MSMS spectra of singly, doubly and triply charged precursor ions have been successfully obtained with the oaTOF (electrospray ionization). The fragment ion mass range is up to 6000 Da, and fragment ion mass resolution is typically 1500 (FWHM), except at low mass. Product ion mass measurement accuracy of ±0.3 Da is routine. Collision energies spanning the range of 800 to 50V have been used, and the resulting spectra confirm that there is enough energy to produce both low- and various high-energy products.

Acknowledgments - We gratefully acknowledge the many contributions that R.H. Bateman, M.R. Green and R.G. Vickers (VG Fisons) made to this work. They designed, built and installed the oaTOF mass analyzer and the time-delay circuitry needed to perform the MALDI MSMS measurements. They offered many helpful suggestions on data acquisition. We also thank Kenny Morand (Procter & Gamble) for helpful discussions concerning the ion internal energy distribution measurements.

Surface Induced Dissociation of Biomolecules by MALDI-FTMS

Salvador J. Pastor, Jie Yao, and Charles L. Wilkins
Department of Chemistry, University of California, Riverside, CA 92521

Introduction:

Surface-induced dissociation (SID) continues to be a viable alternative to the more popular techniques of collision-induced dissociation (CID) and photodissociation (PD). SID has several significant advantages over the other two techniques. SID is a universal ion activation technique because it is better candidate for high mass analysis as compared with CID, does not require a chromophore (necessary for photodissociation), and is better suited for the low-pressure conditions of an FTMS experiment. Some criticisms stem from the fact that dissociation efficiencies tend to be low, and, in the case of a trapped ion cell, frequent neutralization of the ion species occurs when an electrode is contacted. Despite these drawbacks, significant results have been achieved in a Fourier transform mass spectrometer[1,2] and, recently, by the McLafferty group using multiply charged ions introduced through an electrospray interface where they reported efficiencies up to 36%, and the high mass dissociation of carbonic anhydrase (29 kDa).[3]

This paper describes the analysis of singly charged biomolecules generated by MALDI undergoing surface induced dissociation in a standard cubic trap FTMS. The method is similar to the grazing incidence angle experiment demonstrated by Ijames and Wilkins.[4] Here we apply quadrupolar excitation in the presence of argon collision gas to effect a broadband axialization of the off-axis fragment ions to improve the trapping efficiency

Method:

All MALDI experiments were performed using an Extrel FTMS-2000 Fourier Transform Mass Spectrometer operating at 6 tesla and equipped with a differentially pumped dual cell and automatic solids probe. Samples were prepared by dissolving 0.5 mg of sample with 2,5-dihydroxybenzoic acid and d-fructose in the molar ratio 1:4000:2000 into 5 ml of methanol. Approximately 0.5 ml was aerosprayed onto a rotating stainless steel probe tip to create a uniform sample surface Ionization occurred via an excimer laser operating at 308 nm. Laser energies varied from 12 mJ/pulse - 28 mJ/pulse (power density of ~10^7 W/cm^2) and were measured at the laser.

The experiment described here is designed for a single cell experiment. Following MALDI, ions were trapped using a gated deceleration protocol. After a short delay, a SWIFT ejection was used to remove ions of lower mass [5] The parent ion was given an on-resonance 1 cm SWIFT excitation to raise its internal energy and place it off axis for the SID event. A carefully timed push potential from a prototype extended trapping module (Waters-Extrel, Madison, WI) was applied to the source trapping plate to accelerate the selected ion into the solid stainless steel conductance limit that was biased at a negative potential in a "quench-like" fashion Broadband quadrupolar excitation was applied to the cell through the use of a switching box to configure the cell for either a dipolar or a quadrupolar excitation. Argon collision gas was controlled by a combination electropneumatic gate valve/leak valve assembly. For bradykinin, broadband axialization of the SID product ions was demonstrated using a 1.75 volt SWIFT file from 450-1050 m/z and lasted approx. 5 msec. A delay of equal duration (5 msec) was added, and the broadband sequence was repeated for 500 cycles at a pressure of 5 x 10^{-6} torr to give an overall axialization time period of 5 seconds. Following the broadband axialization of the product ions, the cell was switched back to dipolar mode, and a 5 second delay was imposed to allow the background pressure to reach 5 x 10^{-8} torr before detection. A general excitation was applied from 50 - 200 kHz All detection was done in direct mode using a bandwidth of 400 kHz and 16k data points. Poly(ethylene glycol) 1000 served as the external calibrant, and standard Odyssey 3 0 calibration software was used (Waters-Extrel, Madison, WI).

Discussion:

Bradykinin was used as a test model for MALDI analysis. The objective was to apply quadrupolar axialization to the off-axis fragment ions to improve collection efficiency. This would afford a great reduction in the number of scans required to produce adequate S/N ratios. The figure is the spectrum resulting from an optimized SID/axialization experiment showing the co-addition of only 9 spectra. Fragment ions include sequential loss of amino acids from both terminal ends of the peptide. As with CID, major fragments are the m/z 886 and m/z and m/z 887 peaks which correspond to loss of -OH from the C-terminus and loss of arginine from either end. The peaks at m/z 1000 and m/z 983 (loss of 17) are due to impurities from the acetate salt buffer.

By applying the broadband axialization to the fragment species, the experimental dissociation and collection efficiency was increased to 39.0%. This is compared against an optimized SID experiment without axialization, which gave a dissociation efficiency of 7.0%, typical of previous efforts by many groups. These calculations were based on a more strict definition that uses the sum of the product ion abundances divided by the starting ion abundance of the molecular ion following an ejection event of the lower mass species. A spectrum of the same experimental sequence with the SID push event turned into a time delay showed no significant fragmentation or decay caused by *post-SID collisional activation. When the product ion abundances are referenced against each other,* the efficiency jumps to 95.5%! This seems to indicate that SID can be a very efficient process, and better collection schemes such as floating the cell[3] should show great improvements.

It appears that electrospray ionization might have a slight advantage for SID analysis due to the multiple charging, which promotes coulomb repulsion, lowers the m/z range, and increases an ion's chances of not being effectively neutralized. Both MALDI and ESI-FTMS have shown that in a trapped ion cell, it is essential to have timing such that the ions are allowed only one encounter with the dissociating surface. Last, it will be particularly interesting to see if the many motional modes of high masses can be overcome to produce desired fragmentation patterns for singly charged MALDI generated species.

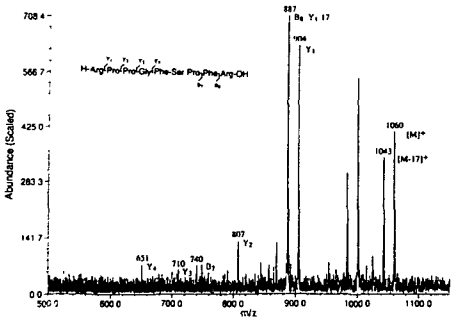
Bradykinin - SID with Axialization (9 Shots)



Identifying Possible Sources of Ion Neutralization During Low Energy Collisions at Self-Assembled Monolayer Surfaces

*Vince Angelico, Tom Kane, Hair Nair, Arpod Somogy, Vicki H. Wysocki
Department of Chemistry, Virginia Commonwealth University
Richmond, Virginia, 23284, USA

Low energy collisions (>100 eV) of polyatomic ions with a surface promote extensive, structurally characteristic fragmentation of the selected ion in an experiment referred to as surface-induced dissociation (SID)[1,2] Neutralization of the projectile ion at the surface is a major contributor to the loss of ion signal in the instrument. Alkanethiolates $^{-}S(CH_2)_nH$ (n=18,12,8,4)and $^{-}S(CH_2)_2(CF_2)_8F$ chemisorbed on gold substrates have been shown to act as electron transfer inhibitors when used as collisional targets, thereby reducing the amount of ion neutralization observed compared to bare metal surfaces [2]. Of particular interest here is to identify the possible mechanisms responsible for the amount of ion neutralization observed with SAM surfaces Because the ion neutralization process involves the transfer of electrons, a prediction would be that the measured scattered ion efficiency would increase with decreased I.E. of the incident ion, as well as the increased I.E. of the surface material (Table 1).

Table 1.

Monolayer		Film Thickness (Å) [a]	I.E.
Au-$S(CH_2)_{18}H$	(C18)	22.0	~9.5[b]
Au-$S(CH_2)_{12}H$	(C12)	15.3	~9.5[b]
Au-$S(CH_2)_8H$	(C8)	10.8	~9.5[b]
Au-$S(CH_2)_4H$	(C4)	6 38	9.14[3]
Au-$S(CH_2)_2(CF_2)_8F$	(PF)	14.4	~11.5[b]

a. calculated from atomic radii
b. extrapolated from experimental I.E. data of C_nX_{2n+2} X = H,F

Benzene and three benzene derivatives with varying ionization energies are employed as probes to investigate neutralization processes.
The amount of ion neutralization at the surface is measured using two separate methods [2].
Method I: A finite efficiency value is calculated for each monolayer surface from the ratio of the total ion current of a collision spectrum to the total ion current of the transmission spectrum (0 eV, no collision) at the same multiplier setting (Table 2).

Table 2. % Efficiency at 30eV collision energy (I_{col}/I_0 X 100)

Ion	I.E. (eV) [4]	%E (C18)	%E (PF)
Nitrobenzene	10.4	0.328	53.5
Benzene	9.25	13.2	62.6
$Cr(CO)_6$	8.24	14.9	66.4
NNDMA	7.12	37.4	75.6

Method II: The relative surface efficiencies are presented as a total ion current (TIC) plot measured at the detector with units of signal versus time. A multiple surface holder allows several monolayer surfaces to be present in the instrument at a given time. While the signal intensity/spectral data is continually obtained for a given energy ion collision, each surface is positioned in the ion optical path for a period of time. This method guarantees the same instrument tuning parameters and similar environment (e g , chamber pressure, temperature, etc.) for all of the surfaces investigated. Gold surfaces modified with n-alkanethiolates contain a small percentage of defect sites and regions of incomplete monolayer formation. In order to ascertain

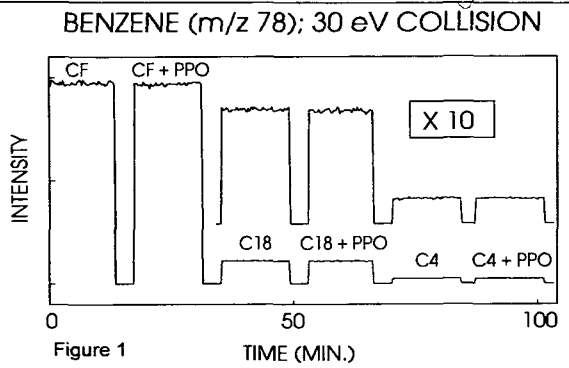


Figure 1

whether the ion neutralization is favored at the monolayer pinholes, a series of monolayer films are electrochemically passivated according to the procedure described by Finklea et al.[4], and the scattered ion efficiency is compared to that obtained with unpassivated monolayers. Any change in the scattered ion efficiency between surfaces of the same chain length will be associated with the presence of the pinholes in the monolayer films (Figure 1). Using data obtained from both methods the following conclusions were formulated.

- The efficiency of the hydrocarbon monolayer series indicates a decrease in ion neutralization with increasing alkanethiolate chain length (Figure 1).
- The fluorinated monolayer surface consistently yields the greatest scattered ion signal and the least amount of ion neutralization for all of the ion probes employed (Figure 1, Table 2).
- For these surfaces, the amount of ion neutralization increases with increasing ionization energy of the (neutral) projectile ion, and decreasing monolayer ionization energy (Table 2).
- The absence of any appreciable change in the TIC intensities between the electrochemically passivated and unpassivated monolayer surfaces suggests the pinholes present within the monolayer surface have a negligible role in the ion neutralization process (Figure 1).

Two separate but related electron transfer processes are supported by the data presented. The decrease in ion neutralization with increasing monolayer chain length, while maintaining similar chemical properties of the monolayer surface (e.g., surface I E , chemical composition, etc) suggests a remote transfer process from the underlying gold substrate to the incident ion (electron tunneling) [5]. In this mechanism, the monolayer acts merely as an insulating partition between the active donor-acceptor pair. Observing that the tunneling-monolayer thickness argument is not supported when comparing the highest % efficiency measured for the fluorinated surface for each incident ion. The thickness of the fluorinated surface is calculated to be 14.4Å, however greater neutralization is observed for the longer C18 surface (22 Å) The data in Table 2 indicates a correlation to the energy difference between the I.E. of the incident ion (neutral) and the surface. This suggests a second electron transfer mechanism where the electron originates from the monolayer material itself. Both processes are believed to occur simultaneously, however the differences in the % efficiencies of the C4 and C18 monolayer surface (representing the extreme short and long hydrocarbon chains) is considerably smaller in magnitude as compared to the fluorinated surface. This suggests the monolayer ionization mechanism is the dominant process

HYDROGEN-ADDITION REACTIVITY OF IONS ON ODD VS. EVEN CHAIN ALKANETHIOLATE SELF-ASSEMBLED MONOLAYER FILMS

Rebecca L. Franklin, Wenqing Zhong, Árpád Somogyi, and Vicki H. Wysocki
Department of Chemistry, Virginia Commonwealth University
Richmond, Virginia 23284

Several methods such as wettability, ellipsometry, IR, Raman spectroscopy, electrochemistry and XPS have been used to describe the surface characteristics of various alkanethiolate self-assembled monolayer films (SAMs).[1] Studies by several groups indicate that the orientation of the terminal groups in an alkanethiolate SAM is different if the chain length of the thiolate is odd or even.[2] On gold, when the chain length is even, the terminal methyl group is oriented so that all of the hydrogens are equivalently exposed. For an odd chain length on gold, the terminal methyl group is oriented parallel to the surface so that one of the hydrogens is pointing out of the monolayer. This orientation is reversed when the assembly is on silver because the bond angle between the metal-S-C changes from roughly parallel (Au) to roughly perpendicular (Ag).[2a]

Recently, SAMs have been used extensively in surface-induced dissociation (SID) studies.[3-6] Correlations were found between the hydrogen-addition reactivity of alkanethiolate films toward simple organic projectile ions such as benzene and DMSO-d_6 and the chain length and chemical composition of the films.[4-6] It has been shown that peaks corresponding to the hydrogen-addition for low energy collisions (20-30eV) of various projectile ions on SAMs exhibit a drastic decrease for alkanethiolate chain lengths greater than 8 carbon units long.[7]

Experimental The instrument used consists of two Extrel quadrupoles positioned at 90° whose ion optical path is bisected by a metal surface.[8] Self-assembled monolayers were prepared by spontaneous assembly of thiols on vapor deposited gold or silver foil surfaces. The gold surfaces are first UV cleaned (Ag surfaces are mechanically polished with various mesh sizes of Al_2O_3) and placed in a solution of thiol in ethanol prior to use. Mixed monolayer SAMs were prepared so as to give a 1:1 ratio of each thiol on the surface after 12 hours.[9] Alkanethiolate SAMs ($n \geq 9$) on Au and Ag were prepared from 1 mM solutions of thiol in ethanol and were in solution for 75 (for $n \leq 8$, solutions were prepared in hexanes and were in solution for 1 hour) hours prior to use. The SAMs used in this study include $CH_3(CH_2)_{n-1}SH$ (n=2-18,22) and $HO(CH_2)_{11}SH$.

Results and Conclusions - Alkanethiolates on Au and Ag

The hydrogen-addition reactivity of benzene and DMSO-d_6 as low energy projectiles on alkanethiolate surfaces is enhanced for odd chain lengths (i.e. n=11,15,17) for monolayers prepared on gold surfaces. For monolayers prepared on silver foil the even chain lengths showed enhanced reactivity (see Figure 1).

Results and Conclusions - Mixed monolayers

Mixed monolayers prepared from a hydroxy-terminated alkanethiolate and alkanethiolates (n=22) showed hydrogen-addition reactivity intermediate to that of pure hydroxy and pure alkanethiolate surfaces. SAMs prepared from hydroxyl-terminated alkanethiolates are more reactive than alkanethiolate surfaces (see Figure 2).

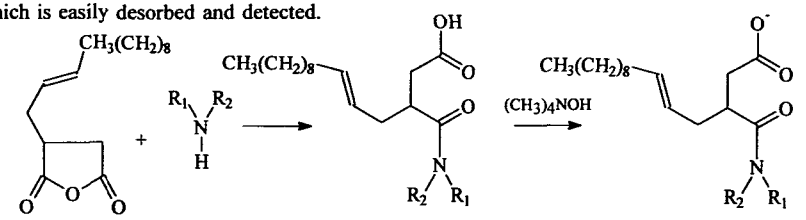
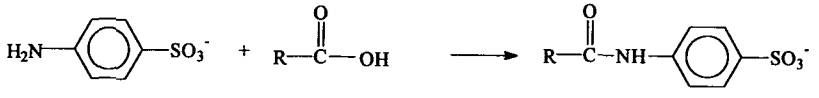
DERIVATIZATION REACTIONS FOR FAB, LSIMS AND ELECTROSPRAY IONIZATION

Richard E. Carlson and Kenneth L. Busch
School of Chemistry and Biochemistry
Georgia Institute of Technology, Atlanta GA 30332-0400

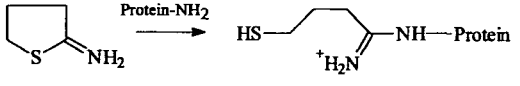
Derivatization reactions in mass spectrometry represent several creative examples of problem solving. Many of the same derivatization reactions developed for FAB and LSIMS can be used in electrospray ionization mass spectrometry. In FAB and LSIMS, these reactions were developed to increase the sensitivity of the analysis, or to provide a mass shift characteristic in the mass spectrum for easy recognition. Although the issue of sensitivity enhancement is unclear in electrospray, the characteristic mass shifts can be useful in interpretation of the ES mass spectrum and determination of the charge state of the ions. Most reactions target hydroxy, carboxylic, or amine functionalities in the analyte molecule. Some examples of the types of derivatization reactions for mass spectrometry are shown below. For FAB/LSIMS, the reaction of 2-dodecen-1-yl succinic anhydride with primary and secondary amines, as reported by Ligon and Dorn[1]. This derivatization scheme results in the formation of an amic acid (see below), which is easily desorbed and detected.



Griffiths and co-workers have reported the use of 4-aminobenzensulphonic acid[2a] to incorporate a stable charged end group on fatty acids as shown in the reaction below. Following CID, these derivatization products undergo charge-remote fragmentation. Aminoethanesulphonic acid derivatized bile acids have been reported[2b] to fragment similarly.



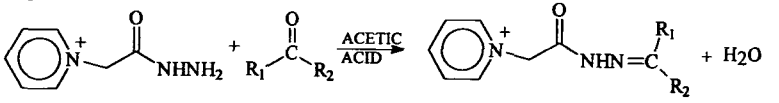
Bartlett and Busch[3a], and Cohen and Chait[3b] have both reported the use of 2-iminothiolane to derivatize the N-terminal amine group of small peptides.



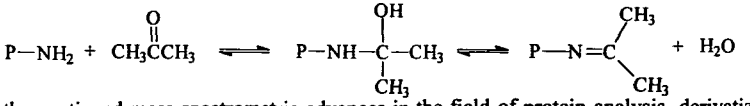
Charge-transfer reactions, which have proven to be valuable derivatization methods in FAB/LSMIS and SIMS for several years[4a], have also found application in ESI[4b,c]. These reactions are based on electron donor/acceptor chemistry and several derivatization analytes are available.

$$\text{DONOR} + \text{ACCEPTOR} \rightleftharpoons (\text{DA}) \longrightarrow D^{+\cdot} + A^{-\cdot}$$

Girard's P and T reagents have proven useful for the derivatization of carbonyl groups, as reported by Ross *et al.*[5]. These reactions result in the formation of a precharged cation, which is readily detected following desorption ionization techniques. A general reaction scheme for Girard's P is shown below:



Interestingly, Laude and co-workers[6] have reported essentially the reverse of the above reaction, using acetone to derivatize N-terminal amines and amines on lysine residues in proteins. The authors report the utility of acetone derivatization to determine the charge state of the ions in low resolution ESI experiments. P represents a protein in the following scheme.



With the continued mass spectrometric advances in the field of protein analysis, derivatization chemistry may prove to be an invaluable link in providing additional mass spectrometric information.

EFFECT OF A MATRIX ON LIQUID-SIMS-INDUCED FRAGMENTATION OF THE PHOSPHATE ESTER BOND

CHHABIL DASS
THE UNIVERSITY OF MEMPHIS, DEPARTMENT OF CHEMISTRY, MEMPHIS, TN 38152, USA

INTRODUCTION: Liquid-SIMS has become a standard analytical technique for the analysis of biomolecules such as peptides. The success of liquid-SIMS, however, depends upon the use of a proper liquid matrix. The use of the matrix has the advantage that it acts as a medium to dissolve the sample molecules, facilitates the formation of the protonated and deprotonated molecule ions, and helps in maintaining persistent emission of the analyte ion current. Although a number of matrices are available for liquid-SIMS analysis, a careful selection of the matrix is needed to optimize the spectral appearance and the solute ion current. Glycerol, α-thioglycerol, a cocktail of dithiothreitol and dithioerythritol (5:1), and 3-nitrobenzyl alcohol are the common matrices used for the analysis of peptides. A unique advantage of a liquid matrix is that it can absorb the impact of the bombarding beam. In spite of this feature, analyte molecules are formed with excess energy over their ground state, resulting in the formation of compound-specific fragment ions. It was reported by us earlier (1) that the extent of fragmentation of peptides is dependent upon the type of matrix used, with glycerol leading to extensive fragmentation and α-thioglycerol and dithiothreitol producing least fragmentation. The spectra of other classes of compounds also differed from matrix to matrix.

OBJECTIVE: The loss of the phospho group (80 Da) is frequently observed from the protonated molecule of phosphopeptides, resulting in an ion that corresponds to the mass of the protonated molecule of the unmodified analogs. This aspect may render simultaneously detection of the phospho and nonphospho forms of a peptide difficult when they are present together. Therefore, it is important to search for a matrix that leads to the least amount of the loss of 80 Da. In this preliminary report, we discuss the effect of a few common liquid matrices (glycerol, α-thioglycerol, and dithiothreitol) on the loss of the phosphate moieties from the protonated molecules of phospho amino acids and peptides.

EXPERIMENTAL: All data were acquired by using VG AutoSpecQ mass spectrometer outfitted with the Digital VAX station-based Opus software. Ionization used a beam of 30 keV Cs^+ ions. A fixed amount of phosphopeptides (3.8 nmol) and amino acids (25 nmol) was dissolved in 1.40 μmol of the matrix and the spectra were obtained in the narrow mass range to encompass the molecular ion and the ions formed by the loss of the phosphate moieties and at a scan speed of 10 s/decade. All spectra are the sum of 10 (amino acids) or 20 (phosphopeptides) scans, all acquired within 40s of introducing the probe in the source. This way, the loss of matrices due to their differential evaporation rates was held to a bare minimum.

DISCUSSION: The phospho-Tyr usually exhibit the loss of HPO_3 and HPO_4 moieties, whereas, the phospho-Thr and -Ser residues undergo primarily the loss of H_3PO_4 molecule (2). The preliminary data presented here show that the extent of the loss of phosphate moieties from phospho-compounds when bombarded with Cs^+ ion beam is influenced by the liquid matrix used. Although no clear trend is observed, the data is consistent with our earlier observation (1). It is noted that the loss of HPO_3 from phospho-Tyr and H_3PO_4 from phospho-Thr is more pronounced when dithiothreitol is used as the matrix. On the other hand, the loss of HPO_3 and HPO_4 is greater from phospho-enkephalins dissolved in glycerol. It is evident that the $[M + H]^+$ ions are formed with different amount of internal energy. The sputtered $[M + H]^+$ ions are usually associated with the matrix molecule, the desolvation of which produces the $[M + H]^+$ ions with different amount of internal energy. It is obvious that the number of the solvent molecules associated with the ion-molecule complex and the strength of the solute-solvent and solvent-solvent bonds will have strong bearing upon the internal energy of the $[M + H]^+$ ions.

THE LOSS OF THE PHOSPHATE MOIETIES FROM PHOSPHO-AMINO ACIDS

peptide	group lost	glycerol	thioglycerol	dithiothreitol
Phospho-tyrosine	HPO_3	11 5	6.3	40 2
	HPO_4	6 7	3.3	6.9
Phospho-threonine	H_3PO_4	26.2	103.0	143.0

Values given are relative to the $[M + H]^+$ as the base peak

THE LOSS OF THE PHOSPHATE MOIETIES FROM PHOSPHOPEPTIDES

peptide	group lost	glycerol	thioglycerol	dithiothreitol
Phospho-leucine enkephalin	HPO_3	12.8	10.3	8 3
	HPO_4	6.9	3.5	2 9
Phospho-methionine enkephalin	HPO_3	11.7	10.3	10.6
	HPO_4	8.2	5.5	5 4

Values given are relative to the $[M + H]^+$ as the base peak

PARENT RESOLUTION IN FFR1 MS/MS: REVELATIONS FROM ION INTENSITY PLOTS

Kevin D. Ballard, Richard W. Vachet[1], Ralph S. Orkiszewski, Gary L. Glish[1], J. James Vrbanac[2], and Simon J. Gaskell[3]. Center For Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030; [1]Department of Chemistry, University of North Carolina, Chapel Hill, NC 27599; [2]The Upjohn Company, Drug Metabolism Research, Kalamazoo, MI 49001; [3]Centre for Mass Spectrometry, UMIST, Manchester, M60 1QD, U.K.

Product ion scanning and constant neutral loss scanning experiments on double focusing instruments are frequently employed for studying parent-product ion relationships for first field-free region (FFR1) decompositions Previous studies from these laboratories have shown that the effective resolution of the parent ion varies during the course of such scans, and that the poor parent resolution and the variation therein are attributable to the occurrence of kinetic energy release during fragmentation. Lacey-Macdonald ion intensity diagrams[1] accurately reflect the decomposition events occurring in various regions of sector mass spectrometers. The application of such diagrams to the parent ion resolution issue has led to new means of defining and calculating the effective parent resolution for both product ion scans and constant neutral loss scans on double focusing instruments. The new approach incorporates the effects of kinetic energy release and fully accounts for the observed variation in parent resolution during the course of the scans.

Results. In ion intensity diagrams, fragmentation reactions can be plotted as elliptical regions of ion intensity, using the coordinate system $\rho=M_d/M_p$, $M^*=M_d^2/M_p$, where M_p and M_d are the masses of the parent and product, respectively. The size of the ellipses depends primarily upon the kinetic energy release involved in the fragmentations. Various scan functions, such as for product ions of a particular parent, are readily incorporated into these diagrams. Such plots reveal that, at higher proportional product ion mass, product ion ellipses derived from a given parent are relatively well resolved from neighboring scan functions, and thus the effective parent resolution is comparatively high. At progressively lower proportional product mass, however, neighboring scan functions begin to cross the elliptical regions, leading to progressively poorer effective parent resolution as proportional product mass decreases. Based on these diagrams, the scan function from a neighboring parent can be considered just resolved if it passes through one of the end-points of the major axis of a given ellipse. Parent resolution for product ion scans calculated in this fashion generates curves such as those shown in Figure 1 (where T=kinetic energy release). The curves in Figure 1 demonstrate that even a small amount of kinetic energy release exerts a profoundly detrimental effect on parent resolution. A method has been devised for predicting the relative contributions of interfering peaks in FFR1 product ion scans. The method assumes that the relative abundances of the parent species and the kinetic energy releases involved in the fragmentations are known. The method takes into account the gaussian, three-dimensional nature of the ion intensity regions, and involves integration over the area transected as the product ion scan function passes through the elliptical ion intensity region. This method has been applied to a few examples, and the predicted values are within ~10 % of the experimental observations. Constant neutral loss scans involving isotopomers on two-sector instruments can be especially deceptive regarding the effective resolution of the parents, because signals due to interfering parent-product relationships can precisely overlap with the intended signal. Rubidium bromide gives rise to isotopomeric clusters such as $[Rb_3Br_2]^+$ due to natural abundance ^{85}Rb, ^{87}Rb, ^{79}Br, and ^{81}Br. Various members of the isotopomeric cluster can lose either 165.8 or 167.8, but none can lose 169.8 as a neutral fragment. Nevertheless, when rubidium bromide is analyzed by constant neutral loss scanning with the neutral loss mass set to 169.8, four signals corresponding to members of the isotopomeric $[Rb_3Br_2]^+$ cluster are detected (Figure 2). This can again be explained through kinetic energy release considerations and ion intensity diagrams. The relative intensities of these peaks can again be predicted mathematically, with excellent agreement between theoretical and experimental results.

Identification of fullerenes in natural flames by APCI/LCMS

Koli Taghizadeh, William J. Grieco, Arthur L. Lafleur, and Jack B Howard
Center for Environmental Health Sciences and Department of Chemical Engineering
Massachusetts Institute of Technology,
77 Massachusetts Avenue, Cambridge , MA 02139

The recent discovery of fullerenes in mineral deposits [1] strongly suggests a natural means of fullerene formation Previous work in our laboratories showed that fullerenes were relatively abundant in benzene/oxygen flames [2] but not at ambient conditions Reports of the detection of fullerenes in soots from free-burning toluene and common candle flames under ambient conditions [3] led us to explore fullerene formation in natural flames.

In this paper we are reporting the detection of fullerenes from six soot samples collected from laboratory small open-flames The first four soot samples in Table 1 were collected from common candle flames and pine wood flames with and without an argon jet penetrating the flames. The soots were deposited in a water-cooled copper cup. Deposits were removed either by washing the collector with toluene or scraping off the soot and extracting with toluene. The last two wood soots were collected from burning pine woods diluted with nitrogen gas A water-cooled copper probe was inserted directly into the diffusion flame, and airflow through the probe was provided by a vacuum cleaner, an in-line glass wool plug was inserted between the probe and vacuum to trap solid materials The sample was collected by retaining the glass wool in toluene and cleaning the inside of the copper probe with toluene-soaked paper wipes Both the glass wool and wipes were sonicated, filtered and concentrated in a rotary evaporator.

In order to detect the small amount of fullerenes in these samples, preparative HPLC was necessary to remove polycyclic aromatic hydrocarbons (PAH) The majority of the PAHs were separated from fullerenes using a Beckman prep HPLC system with a two-wavelength detector and a 500 ul injection loop. Two Jordi Gel DVB (Divinyl Benzene) columns were used, each 500 mm in length, with IDs of 10 mm, packed with 5u particle size, and a 500 A pore size. The mobile phase was dichloromethane with a flow rate of 1.5 ml/min. Fractions of fullerenes were collected between 62 to 80 min. Depending upon the sample size, this step required two to four injections. The fractions from each sample were collected in a vial and concentrated almost to dryness, then re-dissolved in 50 to 100 ul of toluene of which a 20 ul solution was injected into APCI/LCMS system. The Beckman HPLC system consisted of dual pumps, a diode array detector, and a small Jordi Gel column (100 mm x 10 mm) Dichloromethane.benzene (98·2) was used as a mobile phase with a flow rate of 500 ul/min. This HPLC system was interfaced through a heated pneumatic nebulizer to PE/SCIEX APCI/MS. The conditions of the heated nebulizer and APCI/MS were as follows: nebulizer gas (air zero 1 0) 80 psi, auxiliary gas (air zero 1.0) 1 l/min, with the nebulizer temp set at 550 C, the curtain gas (nitrogen 5.0) at .8 l/min, the orifice at 35 volts, and an interface temp of 60 C. The mass spectrometer was scanned from 716 to 725 u , with steps of 0 1u, and a dwell time of 10 msec. for C60 for 0-25 min., and then from 836 to 845 u for C70 for 25.1-33.0 min.

The results of this study are summarized in Table 1. The total ion chromatogram of pine dowel and the extracted ion chromatograms for C60 and C70 are shown in Figure 1 The mass spectra for C60 and C70 are shown in Figure 2.

All six samples revealed the presence of C60 and the candle soots and last two wood samples showed the presence of C70, confirming other reports of fullerenes in common flames . In conclusion, these results suggest that wildfires could be a natural source of fullerenes.

Effect of Mobile Phase Buffer Components on Sensitivity in Negative Atmospheric Pressure Chemical Ionization LC/MS

William H. Schaefer and Frank Dixon Jr., Drug Analysis Department, Drug Metabolism and Pharmacokinetics, SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

Atmospheric pressure chemical ionization (APCI) is used routinely for high throughput and high sensitivity quantitative LC/MS assays. Negative ion APCI is particularly useful for analytes which contain acidic protons. Ionization by APCI is dependent on proton affinity of the chemical ionization reagent(s) relative to that of the analyte of interest. This consideration becomes very important since most reverse phase HPLC is done at pH <7 using mobile phases that contain acidic components. These acidic buffer components can inhibit the ionization of analytes which have a higher proton affinity. We have investigated the effect of several common buffers on the ionization of a series of model compounds which are amenable to negative APCI to determine the extent of ionization quenching which can occur. In addition, we have compared the sensitivity using these standard mobile phases to a mobile phase which does not contain an acidic buffer component, but rather a base (N-methyl morpholine). A better understanding of the interaction of solvent components with ionization of analytes should facilitate more rational development of chromatography conditions which are amenable to highly sensitive analyses.

Compound selection strategy Compounds were selected which contained functional groups commonly encountered in pharmaceuticals, including carboxylic acids, phenols, and hydroxamic acids, which could be analyzed in negative ion mode. The carboxylic and hydroxamic acids which were selected ranged from aliphatic to aromatic in order to cover a range of acidic strengths. One group of compounds was selected which contained only one protic functional group in order to avoid any additive or interfering effects of additional protic functional gorups. Additional compounds were analyzed which had multiple functional groups in order to compare their response relative to those with only one acidic functional group.

Solvent selection strategy The mobile phases buffers used to test ionization efficiency (or signal intensity) included 10 mM and 100 mM ammonium acetate (natural pH) which were selected to investigate the effect of acetic acid at low and high concentrations. Formic acid (10 mM) was used to test the effect of a stronger acid in negative APCI. An N-methylmorpholine mobile phase, which lacked an acidic modifier, was also used. N-methylmorpholine was a volatile, non-nucleophilic base which also provided good column retention perhaps by ion pairing with acidic analytes.

Instrument Optimization Instrument parameters including orifice potential, heated nebulizer temperature, and gas flows were optimized for each analyte in each mobile phase. Only orifice potential varied dramatically between compounds. Analytes which contained a phenylacetic acid moiety tended to eliminate CO_2 readily even at moderate orifice potentials (>60-70 V).

Sample Introduction and Mass Spectrometry In order to evaluate ionization efficiency, analytes were loop injected into the APCI source at a flow of 1 ml/min and the $[M-H]^-$ was detected using single ion monitoring (Q1 SIM). A mobile phase composed of acetonitrile/aqueous buffer (1:1) was used and analytes were dissolved in the appropriate mobile phase prior to analysis. Six sequential injections of 2 pmol/5 ul/injection were made for each analyte (as well as blank injections) in each mobile phase. The area of each peak (above background noise) was determined using the Sciex MacQuan software.

Chromatography The chromatographic behavior of several compounds was demonstrated under gradient conditions using a 10 mM N-methylmorpholine:acetonitrile mobile phase with a 4.6 x 150 mm EM Science Aluspher C8 column. N-methylmorpholine provided better retention of acidic analytes than either triethylamine or ammonium hydroxide, perhaps through better ion pairing. The stability of the analytes under basic these conditions must be evaluated when considering the use of these alkaline mobile phases.

A portion of the results are summarized in Table 1.

Table 1. Comparison of the Ionization of Model Compounds by Negative APCI in the Presence of Various Buffers (Mixed with Acetonitrile 1:1)

- Peak area values are expressed as a percent ratio relative to areas observed using N-methylmorpholine. The actual peak area values are shown in parentheses (area).

Carboxylic Acid Compounds	$[M-H]^-$	N-Methyl morpholine 10 mM	Ammonium acetate 10 mM	Ammonium acetate 100 mM	Formic Acid 10 mM
2-Norbornane acetic acid	153	100% (586550)	14% (84884)	2% (9574)	3% (15442)
3-(4-Methoxyphenyl) propionic acid	179	100% (425758)	47% (198069)	5% (22821)	2% (6434)
Ibuprofen	205	100% (339635)	96% (325740)	10% (32747)	3% (9661)
Acetylsalicylic acid	179	100% (268290)	28% (76061)	42% (113220)	14% (37641)

Phenolic Compounds	$[M-H]^-$	N-Methyl morpholine 10 mM	Ammonium acetate 10 mM	Ammonium acetate 100 mM	Formic Acid 10 mM
β-Estradiol	271	100% (97551)	6% (5787)	1% (1203)	1% (912)
Isoeugenol	163	100% (155067)	8% (11734)	3% (4974)	<1%

The N-methylmorpholine mobile phase, which lacked acidic components, generally provided the highest sensitivity for acidic compounds in negative APCI. For analytes possessing a single protic functional group, those which were stronger acids (in solution) were less severely effected by the more acidic buffer components. Formic acid, which was the most acidic modifier tested, tended to show the most pronounced inhibition of ionization. For analytes which were more weakly acidic, the 100 mM ammonium acetate showed more inhibition of ionization than the 10 mM ammonium acetate. Interestingly, ionization of some compounds which contained multiple functional groups was quite good in all of the mobile phases tested.

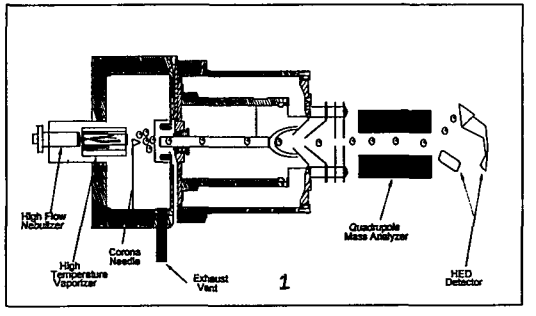
Conclusions

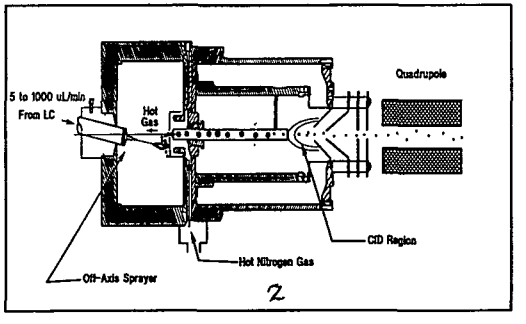
- Moderate orifice potentials can induce significant elimination of CO_2 from some carboxylic acids in negative APCI.
- The buffer components used in the HPLC mobile phase can have a dramatic effect on sensitivity using negative APCI and can even quench ionization completely.
- Formic acid (relatively strong acid) can be very detrimental to formation of negative ions.
- The mobile phase which contained an amine modifier (N-methylmorpholine), and lacked acidic components, generally provided the highest sensitivity for acidic compounds in negative APCI.
- For analytes which ionize poorly by positive APCI or electrospray (as a protonated or ammoniated adduct) or negative electrospray, the use of a volatile amine mobile phase (such as N-methylmorpholine) and an HPLC column which is stable at pH >9 may provide a useful analytical system.

ANALYSIS OF SELECTED PHARMACEUTICALS USING LIQUID CHROMATOGRAPHY COUPLED TO DIFFERENT ATMOSPHERIC PRESSURE IONIZATION MASS SPECTROMETRY TECHNIQUES

Paul C. Goodley and Steven Fischer, Bay Analytical Operations,
Hewlett-Packard Co., 1601 California Ave., Palo Alto, CA 94304

Liquid chromatography combined with mass spectrometry (LC/MS) has become one of the most powerful analytical techniques for specific identification of nearly all types of organic compounds. Atmospheric pressure ionization techniques such as atmospheric pressure chemical ionization(APCI and atmospheric pressure electrospray ionization (API-ES) provide a rapid and simple way to generate ions from compounds which were here-to-fore difficult or impossible to obtain for MS analysis. As a result of these ionization techniques, analytical chemical analysis of pharmaceuticals and most drugs can be analyzed with a high level of confidence and certainty. **Figures 1** and **2** provides a technical diagrams of the Hewlett-Packard APCI and the API-ES respectively.





Figures 1 and 2. APCI and API-ES ion sources

Additional results using the APCI ion source is shown in Figures 3 and 4. Figure 3 shows the signal-to-noise measurement of 50 picograms of reserpine injected in the flow injection mode (FIA) while monitoring ion m/z=609.3. Figure 4 shows the signal-to-noise measurement of 20 nanograms injected using FIA while scanning the mass range, 100-650 using the APCI ion source. The peal-to-peak measurements were at 52 for the SIM measurement and 720 for the scan measurement of S/N respectively. The API techniques are indeed very powerful and sensitive with good linear response for reserpine, cortisol, and many other pharmaceuticals.

Oscillating Capillary Nebulizer Interfacing with Mass Spectrometers

Z Stacy Ho, Barry Drew and Richard F. Browner
School of Chemistry and Biochemistry
Georgia Institute of Technology, Atlanta, GA 30332-0400

Aerosol introduction is an important stage in the coupling of liquid chromatography with mass spectrometry and the performance of the nebulizer is a major determining factor in the quantity of the analysis. The ideal nebulizer should be simple and robust, and the performance of the nebulizer should be independent of the flow rate and mobile phase. A new nebulizer, the oscillating capillary nebulizer (OCN) shows great promise as a very versatile sample introduction system.

The OCN nebulizer consists of two concentric capillary fused silica tubes. Liquid flows through the inner capillary, while gas passes though the annular gap between the two concentric capillaries. Characteristics of the OCN include a smaller mean drop size and narrower drop size distribution than nebulizers available currently The OCN has been developed exclusively for inorganic analysis using an ICP LC/MS system The OCN can handle a wide liquid flow range and solutions containing a high salt content

Experiments have shown that the OCN can be coupled with a Hewlett-Packard particle beam interface, an Extrel ThermaBeam interface, and a Perkin-Elmer Sciex atmospheric pressure chemical ionization interface

Optimization and characterization of the OCN was carried out on a Hewlett-Packard particle beam interface. The relative positions of inner and outer capillary tubes are important to signal optimization A plot of signal vs the relative position of the capillaries shows there are multiple maxima and minima Plots of signal vs relative position of the capillaries and vs the flow rate show that at the optima, the slopes of the signal changes are very sharp However, at other

capillary positions, the performance of the OCN may be almost independent of tube position Best general operating conditions are with the liquid capillary tube sightly inside the outer capillary, and with a helium flow rate between 1.5 L/min and 2 5 L/min.

Measuring the OCN signal vs flow rate in the particle beam interface shows that best signal response is at a flow rate of about 10 ul/min. At flow rates between 0 05 ml/min and 0 2 ml/min, the signal becomes largely independent of the flow rate for both water and methanol as mobile phase. At above 0.2 ml/min, the signal degrades quickly

The performance of the OCN is quite stable Flow injection of caffeine with water as mobile phase shows a standard deviation of about 12% over a period of one hour At flow rates as high as 0.2 ml/min with 100% water as mobile phase, no water deposit is detected in the momentum separator after more than one hour of continuous pumping.

It has proved possible to interface the OCN at different water flow rates with both Hewlett-Packard and Extrel quadrupole instruments, and with a Perkin-Elmer Sciex triple quadrupole instrument

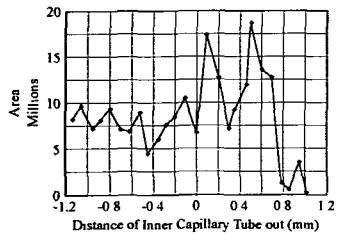

Fig. 1 OCN signals vs two capillary tubes relative positions. The experiments were done using caffeine as sample with methanol as mobile phase at flow rate of 0 2 ml/min.

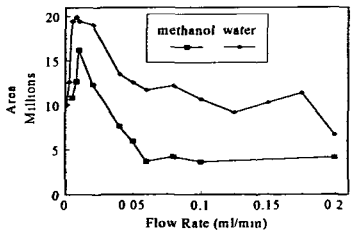

Fig. 2 OCN signals vs liquid flow rates with methanol or water as mobile phase The sample is caffeine

Evaluation and Application of Negative Ion Attachment LC/MS

Daniel L. Norwood, Dixie L. Fisher, and James O. Mullis
Glaxo Research Institute, 5 Moore Drive, Research Triangle Park, NC 27709

Introduction

Negative ion attachment LC/MS was evaluated as a technique for on-line molecular weight recognition, either as a complement to positive ion techniques or when applied to molecules that perform poorly as positive ions. Thermospray (TSP), electrospray (ESI), and atmospheric pressure chemical ionization (APCI) LC/MS interface/ionization processes were investigated. Initial evaluations were accomplished with a series of model compounds derived from pharmaceutical applications, including substituted phenylboronic acids, quaternary ammonium compounds, and phosphorus compounds. The phenylboronic acids, many of which produce poor positive ion spectra, were examined by ESI to study substituent effects on negative ion attachment. Trifluoroacetic acid (TFAA), a typical mobile phase modifier, was studied with all model compounds and LC/MS techniques Other potential attaching species (acetate, *p*-toluenesulfonic acid, chloride, bromide) were also investigated using ESI and APCI. Additional experiments included sensitivity assessment, optimization of source potentials (ESI and APCI), and optimization of probe temperature (APCI).

Experimental

TSP experiments were accomplished on a VG Trio-II quadrupole mass spectrometer, with ESI and APCI experiments accomplished on a VG Quattro triple quadrupole instrument. The HPLC mobile phase was typically acetonitrile/water at various ratios, with 0.05-0.1% modifier (TFAA, acetate, *p*-toluenesulfonic acid, chloroacetonitrile, bromoacetonitrile). Flows were 1 mL/min for TSP and APCI and 10 µL/min for ESI.

Discussion

Molecular specific confirmation using negative ion attachment was demonstrated with all model compounds and LC/MS techniques. As examples, Figures 1 and 2 show respectively the TSP- TFAA attachment spectrum of 3-nitrophenylboronic acid and the APCI- TFAA attachment for methylbenzethonium chloride. The technique was demonstrated to have good sensitivity when compared to detection of the [M-H]- ion from *p*-toluenesulfonic acid (Figure 3, a good negative ion performer). Instrument parameters (ESI and APCI) were shown to affect the attachment spectra in a compound dependent manner. ESI- TFAA attachment experiments with a series of variously phenyl substituted boronic acids clearly indicated that attachment was related to the net positive charge on the boron (a nucleophilic attachment process). An APCI- LC/MS experiment with 4 pairs of quaternary ammonium compounds and matched neutral controls (M_Q^+ and [M+H]+ isobaric) clearly demonstrated that quaternary ammonium compounds could be

unambiguously distinguished with a combination of positive ion and negative ion TFAA attachment experiments.

Analysis of Ceftiofur in Milk by LC/API-MS

Jeffrey Keever[1] Robert D. Voyksner[1] and Krystyna L. Tyczkowska[2]

[1] Analytical and Chemical Sciences, Research Triangle Institute, P. O. Box 12194, Research Triangle Park, North Carolina 27709
[2] Dept. of Anatomy, Physiology Sciences and Radiology, College of Veterinary Medicine, North Carolina State University, 4700 Hillsborough St., Raleigh, NC 27606

Introduction

A number of veterinary drugs which are frequently used to prevent infections, can contaminate meat and milk products destined for human consumption. Ceftiofur is a cephalosporin β-lactam antibiotic which is finding widely increased use to treat bacterial infections. While residues of ceftiofur and its metabolites have been reported in bovine milk and serum MS methodology has not been developed for the confirmation of this antibiotic. This paper presents the research into developing a screening procedure at the tolerance level of 50 ppb and developing a quantitative confirmation methodology based on liquid chromatography/electrospray-mass spectrometry (LC/ES-MS).

Results and Discussion

The development of the method took into account the need to handle large numbers of samples. For this reason the simple and rapid procedure of ultrafiltration using a 10 K molecular weight cutoff filter was chosen for sample cleanup. A 100 µL aliquot of the filtrate was concentrated on column (C_{18} 4.6 x 75 mm) followed by a gradient elution (5-60% acetonitrile in water containing 25 mM heptafluorobutyric acid (HFBA) in nine minutes, with a hold at initial conditions for 0.5 min at a flow rate of 1 mL/min. A 8:1 post column split and the post column addition of 75:25 propionic acid:isopropanol at 75 µL/min was used to achieve optimal electrospray operation, overcoming problems from suppression from the HFBA or 1 mL/min flow rate. Using the conditions ceftiofur eluted at a retention time of 8.6 min and the internal standard (cephapirin) at 6.3 min.

Furthermore, the use of an Rf ion guide (Analytica of Branford) on the electrospray interface improved the S/N ratio by 7.5 for the $[M+H]^+$ ion at m/z 524 for ceftiofur compared to the conventional lens stack. The ion guide also resulted in slightly better precision with a 7% RSD (n=5) compared to a 12% RSD (n=5) for the conventional lens stack. The sensitivity gains from on-column concentration, addition of propionic acid post column and the Rf ion guide permitted the detection of ultrafiltrate samples down to about 10 ppb for ceftiofur. A five point calibration curve from 0-200 ppb for the $[M+H]^+$ of ceftiofur (m/z 524) (using cephapirin $[M+H]^+$ at m/z 424 as an internal standard spiked into each sample at 100 ppb) was linear with a correlative coefficient of 0.993 (n=19). The ion chromatograms for the $[M+H]^+$ ion of ceftiofur at the 50 ppb level (ceftiofur tolerance in milk) and blank are shown in Figure 1A and 1B. The method was tested on milk samples collected from bovine milk following dosage with ceftiofur. The ion

chromatogram for ceftiofur determination in one of these samples is shown in Figure 1C and was measured to be present at 71 ppb. The other milk samples were measured to contain 27, 54, 66, 24 and 31 ppb.

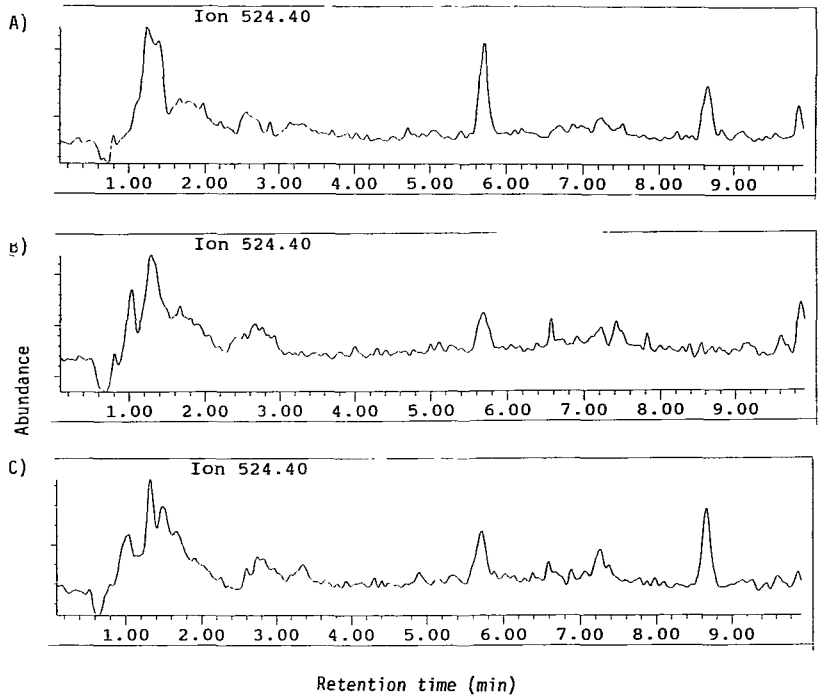

Figure 1. Ion chromatogram for the $[M+H]^+$ ion of ceftiofur (m/z 524), at a retention time of 8.6 minutes, from the LC/electrospray-MS determination for (A) 50 ppb of ceftiofur spiked into milk, (B) Blank milk and (C) milk sample which was above the 50 ppb tolerance for ceftiofur (measured level of ceftiofur was 71 ppb).

Electrospray Liquid Chromatography/Mass Spectrometry of Ginsenosides

Richard B. van Breemen, Chao-Ran Huang, Zhi-Zhen Lu, Agnes Rimando, Harry H. S. Fong, and John F. Fitzloff
Department of Medicinal Chemistry and Pharmacognosy, University of Illinois at Chicago (m/c 781), 833 South Wood Street, Chicago, IL 60612-7231

This investigation reports the first LC/MS analysis of ginsenosides and ginseng extracts. This study is also the first application of electrospray to ionize this class of compounds. In addition, unusual ginsenoside adduct ions, $[M+138]^+$, are described for the first time, and their origin as artifacts arising from the aminopropyl silica HPLC stationary phase is described.

EXPERIMENTAL SECTION

Panax quinquefolius and *Panax ginseng* are commonly known as "American ginseng" and "Korean ginseng", respectively. Ginseng (American or Korean) root powder was extracted with 80% methanol. An Extrelut QE extraction column (EM Industries, Inc.) was used for partial purification of the ginsenosides.

Electrospray mass spectra were obtained using a Hewlett-Packard (Palo Alto, CA) 5989B MS Engine quadrupole mass spectrometer coupled to a Hewlett-Packard 1090L gradient HPLC system by a pneumatic nebulizer-assisted electrospray LC/MS interface. HPLC separations were carried out using a Waters Associates (Milford, MA) Carbohydrate Analysis column (10 μm aminopropyl silica; 125Å pore size, 3.9 x 300 mm) at a flow rate of 1.0 ml/min. The mobile phase consisted of isocratic water/acetonitrile (17:83; v/v) for 8 min followed by a linear gradient from 17:83 (v/v) to 30:70 (v/v) over the next 22 min. During LC/MS, the flow was split 1:50 so that 21 μl/min entered the electrospray ionization source of the mass spectrometer. Ginsenoside standards (approximately 100 ng/μl in water/methanol/acetic acid, 50.50 0.05, v/v/v) were infused into the electrospray ionization source at 10 μl/min using a Harvard Apparatus (South Natick, MA) Model 22 syringe pump.

RESULTS AND DISCUSSION

Ginsenoside standards were analyzed by infusing solutions directly into the electrospray ion source. Positive ion electrospray produced abundant cationized ginsenoside ions, $[M+Na]^+$, but no protonated molecules. For example, an $[M+Na]^+$ ion of ginsenoside R_e (M. W. = 947) was detected at m/z 970 with no detectable fragmentation (Figure 1A) However, addition of sodium to the mobile phase (100 μM NaCl) did not significantly enhance the abundance of $[M+Na]^+$ ions. Initial experiments using negative ion electrospray mass spectrometry produced no sample ions. Acidification of the carrier solution with acetic acid was investigated as a means to enhance the formation of protonated molecules, but still no $[M+H]^+$ ions were observed. Therefore, post-column addition of acid was determined to be unnecessary.

Next, ginsenoside standards were injected onto an aminopropylsilica HPLC column and then detected upon elution using a photodiode array absorbance detector followed on-line by positive ion electrospray mass spectrometry. The positive ion electrospray mass spectrum of ginsenoside R_e, which eluted from the HPLC column at 11.6 min, is shown in Figure 1B. In addition to the expected sodium adduct detected at m/z 970, an unexpected adduct ion, $[M+138]^+$, was detected at m/z 1085, and an ion corresponding to loss of water from this unusual adduct was detected at m/z 1067. During LC/MS analysis of an extract of American Ginseng, ginsenoside R_e was detected with a retention time of 11.6 min as the adduct, $[M+138]^+$, m/z 1085, but no sodium adduct was observed (See mass spectrum in Figure 1C). Ions corresponding to the loss of one or two molecules of water from the ion of m/z 1085 were detected at m/z 1067 and 1049, respectively. Although sodium adducts and $[M+138]^+$ ions were observed together in the

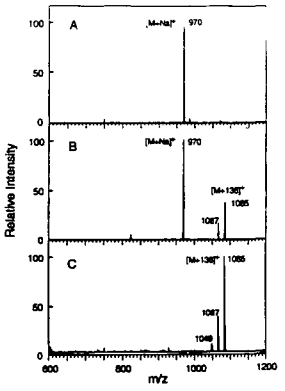

Figure 1

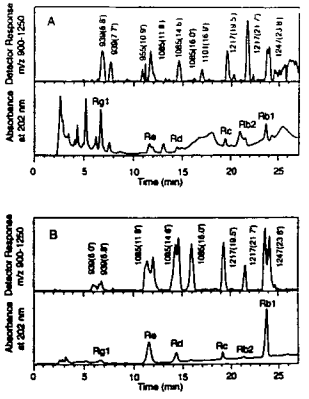

Figure 2

electrospray mass spectra of all ginsenoside standards obtained during LC/MS analysis, ginsenosides contained in ginseng extracts were detected only as $[M+138]^+$ ions, probably because the standards contained more sodium cations than did the ginseng extracts.

Positive ion electrospray LC/MS analyses of Korean and American ginseng extracts are shown in Figure 2. Ginsenosides were identified based on comparison to standards with respect to retention times, and m/z values (detected as $[M+138]^+$ ions). In all cases, ginsenosides eluted from the aminopropyl silica column in order of increasing molecular weight Although most ginsenosides were identified in both extracts, the relative proportions of each were different.

Because adducts ions, $[M+138]^+$, were only observed during LC/MS and not during infusion of standards, the origin of this unusual set of ions was determined to be the stationary phase. 3-Aminopropyltrialkoxysilanes may be used in the synthesis of 3-aminopropyl stationary phases and for end-capping active sites in HPLC columns. Consequently, 3-aminopropyltrihydroxysilane (molecular weight 137) would be a hydrolysis product that might strongly adsorb to the column and bleed off over a long period of time The column manufacturer confirms that this molecule might be present on the aminopropylsilica column used in this investigation. An alternative source of 3-aminopropyltrihydroxysilane might be degradation of the aminopropylsilica stationary phase. Therefore, the most likely identity of the cation weighting 138 is protonated 3-aminopropyltrihydroxysilane, $^+NH_3(CH_2)_3Si(OH)_3$. In support of the identification of the unusual cation as protonated 3-aminopropyltrihydroxysilane, ions were observed at m/z 138 in all the positive ion electrospray LC/MS spectra obtained using aminopropylsilica columns, and $[M+138]^+$ ions were more abundant than $[M+Na]^+$ adducts in LC/MS spectra of ginsenoside standards when a new aminopropylsilica column was used. Because elimination of a neutral molecule of water from ginsenoside adducts, $[M+138]^+$, was much more abundant than loss of water from $[M+Na]^+$ ions, the probable source of the eliminated water molecule was the less stable silanol moiety instead of a ginsenoside hydroxyl group.

ACKNOWLEDGEMENT

Use of the electrospray mass spectrometer was generously provided by the Hewlett-Packard Company. Support from the American Botanical Council (Austin, TX) is gratefully acknowledged.

ELECTROSPRAY LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY OF CAROTENOIDS

Richard B. van Breemen, Department of Medicinal Chemistry & Pharmacognosy, College of Pharmacy, University of Illinois at Chicago, 833 S. Wood Street, Chicago, IL 60612-7231

More than 600 carotenoids have been isolated and identified from natural sources. Carotenoids in the human diet function as metabolic precursors to vitamin A, antioxidants, immunoenhancers, and potential cancer chemopreventative agents. High performance liquid chromatography (HPLC) with photodiode array absorbance detection is the preferred method for the separation, identification and quantitation of carotenoids from biological tissues.[1] However, in addition to HPLC uv/vis detection, mass spectrometric and tandem mass spectrometric analyses[2], which provide molecular weight and characteristic fragmentation patterns, may then provide final confirmation of individual carotenoid identities.

Previous reports exploring the application of LC/MS to carotenoid analysis used 1) a heated moving belt interface with EI ionization,[1] 2) particle beam interface with negative ion CI and a heated ion source,[3] or 3) continuous-flow FAB.[4] Among these methods, only continuous-flow FAB does not require the use of gas-phase ionization or a heated ion source, which might lead to carotenoid pyrolysis. However, the flow rate of continuous-flow FAB is limited to <10 µl/min. In the present investigation, the development of an electrospray LC/MS method is reported that is compatible with analytical scale HPLC column flow rates of 1.0 ml/min. This new electrospray LC/MS method will be demonstrated to be compatible with the C_{30} reversed-phase HPLC stationary phase recently engineered by Sander, *et al.*,[5] for the separation of carotenoids and their *cis/trans* isomers.

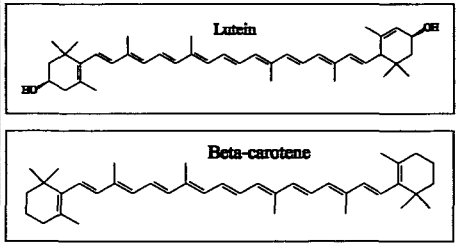

Figure 1.

METHODS

Mass spectra were obtained using a Hewlett-Packard (Palo Alto, CA) 5989B MS engine quadrupole mass spectrometry equipped with a pneumatic nebulizer-assisted electrospray LC/MS interface, and 1090L gradient HPLC system equipped with a photodiode array UV/vis absorbance detector. Unit resolution was used for all measurements; the quadrupole analyzer was maintained at 120°C; nitrogen pressure at 80 psi was used for nebulization; and the nitrogen bath gas was 350°C at a flow rate of 50 ml/min. The electrospray needle was maintained at ground potential, while the counter-electrode was at -5100 V. The range m/z 200-610 was scanned over approximately 2 s during LC/MS.

HPLC separations were carried out using a reversed-phase column, 4.6 x 125 mm, containing a C_{30} silica stationary phase.[5] The solvent system consisted of a 60 min gradient from 85:15 to 10:90 methanol/methyl-*t*-butyl ether containing 1.0 mM ammonium acetate at a flow rate of 1.0 ml/min Absorbance spectra were recorded from 250-600 nm using a photodiode array detector located in-line between the HPLC column and electrospray LC/MS interface. Based on the method of Van Berkel and Zhou,[6] carotenoids were oxidized in solution by postcolumn addition of a halogenated oxidant (i.e., 2% v/v 2,2,3,3,4,4,4-heptafluoro-1-butanol) at a flow rate of 50 µl/min. Optimization experiments were carried out in which different halogenated compounds at various concentrations were evaluated.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

RESULTS

Positive ion electrospray mass spectrometry produced molecular ions, $M^{+\cdot}$, without any fragmentation for both polar xanthophylls (i.e., lutein) and nonpolar carotenes (i.e., β-carotene). A comparison of different halogenated solvents for solution-phase oxidation including heptafluorobutanol, hexafluoropropanol, heptafluorobutanoic acid, trifluoroacetic acid, and chloroform showed that postcolumn addition of heptafluorobutanol and hexafluoropropanol produced the most abundant molecular ions. The limits of detection of lutein and β-carotene were determined to be approximately 1-2 pmol during flow-injection analysis. Unlike the results of Van Berkel and Zhou,[6] who detected doubly-charged molecular ions and deprotonated, singly-charged ions for β-carotene during electrospray mass spectrometry with solution-phase oxidation, only singly-charged molecular ions were observed.

Electrospray LC/MS analysis of a mixture of α- and β-carotene is shown in Figure 2. Both *cis*- and *trans* isomers were separated by the C_{30} column and then detected by electrospray mass spectrometry. Because of the its lower sensitivity, only the more abundant *all trans*-carotenoids were detected by the UV/vis photodiode array detector (Figure 2B).

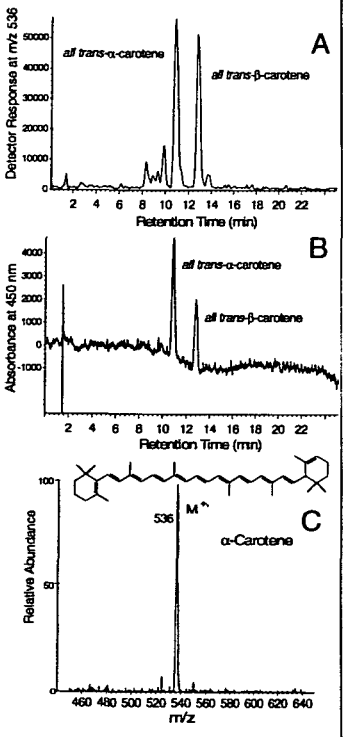

Figure 2. Positive ion electrospray LC/MS analysis of a mixture of α-carotene and β-carotene (20 ng each) using a C_{30} reversed phase HPLC column with postcolumn addition of heptafluorobutanol as oxidant. (A) reconstructed mass chromatogram of the molecular ions of m/z 536. (B) Absorbance chromatogram at 450 nm recorded on-line. (C) Electrospray mass spectrum of α-carotene at a retention time of 10.8 min.

ACKNOWLEDGEMENTS

Alexander Schilling and Steven Fischer provided fruitful discussions and technical assistance with mass spectrometry. Use of the electrospray mass spectrometer was generously provided by the Hewlett-Packard Co. The C_{30} HPLC column was a gift from Lane Sander of the NIST.

Multi-Residue Method for ß-Agonists By Immunoaffinity Extraction-LC/LC/MS/MS

Jianyi Cai and Jack Henion
Analytical Toxicology, Diagnostic Laboratory, Cornell University, 927 Warren Dr., Ithaca, NY 14850

Introduction

ß-agonists have been used as bronchodilators in human and veterinary medicine as therapeutic drugs for the treatment of pulmonary diseases. Recently, there has been evidence that the illegal and potentially poisonous drug, clenbuterol, is being used on calves as a growth-promoting agent within Europe and the United States. The widespread use of clenbuterol in European veal production has claimed at least five deaths. In addition to the most frequently used ß-agonist, clenbuterol, several other analogs have emerged over the past few years and have been found to be illegally used for improving meat production efficiency in livestock.

Since the use of such drugs has great risk to consumers of food products from treated animals, a good analytical method, preferably a multi-residue method, is essential. On-line immunoaffinity extraction (IAE) and coupled-column liquid chromatography-tandem mass spectrometry using an automated column-switching system and electrospray mass spectrometry has recently been evaluated in our laboratory. This presentation describes the implementation of this system for multi-residue analysis of several ß-agonists in spiked bovine urine without conventional sample pretreatment.

Experimental

The mass spectrometer used was a Sciex API-300 triple quadrupole mass spectrometer (Thornhill, Ontario). An automated column-switching system (INTEGRAL micro analytical workstation, PerSeptive Biosystems) was used for on-line sample clean-up and enrichment. Three columns were involved including a protein G immunoaffinity column (2.1 x 3.3 mm, 30 µm, ChromatoChem, Missoula, MT), a trapping column (C-18 packed-capillary column, 0.5 x 15 mm, 5 µm, LC Packings, Amsterdam, the Netherlands), and an analytical column (C-18 packed-capillary column, 0.3 x 150 mm, 3 µm particles, LC Packings).

The automated column-switching system was programmed to perform the complete process of on-line sample pretreatment, which includes priming the protein G antibody column, loading PBS-diluted urine sample onto the antibody column washing with PBS, desorbing bound analytes from the antibody column and trapping onto trapping column, and finally eluting the trapped analytes from the trapping column into the analytical column and to mass spectrometer for separation and identification.

Results and Discussion

To evaluate the performance of the automated on-line immunoaffinity extraction coupled column capillary HPLC and tandem mass spectrometry system, a synthetic mixture of five ß-agonists including clenbuterol, bitolterol, mabuterol, methyl-clenbuterol, and tulobuterol was prepared and analyzed using an antibody specific to clenbuterol. Figure 1 shows the results obtained with the synthetic mixture of ß-agonists. The system was also used for the analysis of bovine urine spiked with the ß-agonists. Figure 2 shows the SRM ion current chromatogram obtained with a 1 part per billion (ppb) levels of ß-agonists in spiked bovine urine by SRM/IAE/LC/LC/MS using the automated system.

Acknowledgments

Partial financial support from Advanced Bioanalytical Services, Inc. is greatly appreciated. We acknowledge PE Sciex for the loan of the API-300 triple quadrupole mass spectrometer, and PerSeptive Biosystems for the loan of the INTEGRAL micro analytical workstation. We thank LC Packings for the packed capillary columns, ChromatoChem for the protein G column, Dr. M.-P. Montrade of Ministere de l-Agriculture, France and Dr. L. Leyssens of Dr. L. Willems-Instituue, Belgium for supplying several ß-agonist standards. Special thanks also goes to Dr. T. Wachs for his technical support.

AN LC/MS METHOD FOR USING NON-VOLATILE MOBILE PHASE ADDITIVES WITH IONSPRAY MASS SPECTROMETRY

Larry M. Mallis and John R. B. Slayback

Bristol-Myers Squibb Pharmaceutical Research Institute
1 Squibb Dr., Building 90, New Brunswick, NJ 08903

To obtain satisfactory HPLC behavior during the analysis of multi-functional acidic compounds, it is often necessary to keep the charge sites protonated rendering the compound neutral. For this reason, the HPLC methods that are developed for purity assessment of in-process reactions typically employ a potassium phosphate buffered mobile phase adjusted to pH 3.0 using phosphoric acid. In addition, ion-pairing reagents such as hexanesulfonic acid are often used when analyzing basic compounds.

For impurity profiling applications using mass spectrometry (MS), an ammonium acetate buffered HPLC method is preferred since it is compatible with LC/ionspray mass spectrometry (LC/ISP-MS). Chromatographic resolution and peak shape considerations often prohibit the use of this volatile mobile phase buffer. Therefore, a modified LC/ISP-MS method was developed which uses a post-column HPLC pump for dilution (using acetonitrile/water as diluent) of the non-volatile mobile phase additive (e.g., potassium phosphate, hexanesulfonic acid, etc.). A schematic diagram depicting the LC/MS method is presented in Figure 1.

In the gas phase using ISP/MS, acidic compounds are preferentially ionized and detected in the negative ion mode as the $[M-H]^-$ specie. However, at a mobile phase pH of 3.0 most acidic compounds exist primarily in a non-charged state. The method presented herein also allows for post-column adjustment of the mobile phase pH. The higher pH and greater flow rate of the post-column diluent (acetonitrile/water) acts to raise the mobile phase pH, to approximately 4.2, above the first pKa of the acid. This enables the $[M-H]^-$ ion to be formed in high abundance for improved detection and sensitivity when analyzing in the negative ion mode.

Figure 2 shows the total ion chromatograms for the analyses (positive and negative ion modes) of several key intermediates in the formation of a triacid compound currently under development. Although a dilution of 4:1 occurs during the analysis, little or no loss of resolution or sensitivity is observed. In addition, this method has been used for as much as seven days running 10 hours per day. A wash of acetonitrile:water:methanol is used to flush the system of potassium phosphate. In an attempt to extend the utility of this new method, other non-volatile mobile phase buffers (i.e., sodium acetate, sodium phosphate, etc.) have been used.

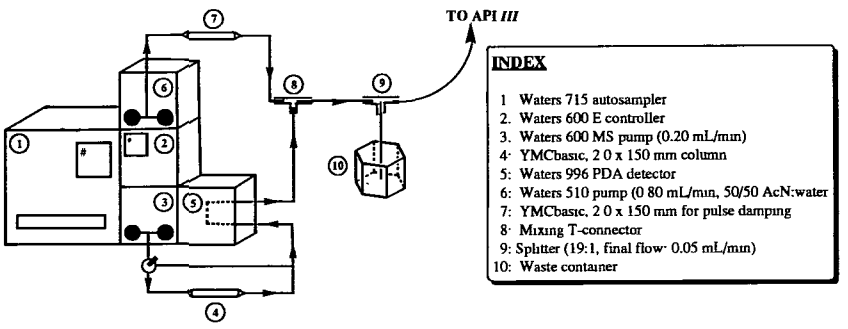

Figure 1. Schematic diagram of the instrumental setup used for post-column modification of the potassium phosphate pH 3 HPLC mobile phase and mass spectrometry detection.

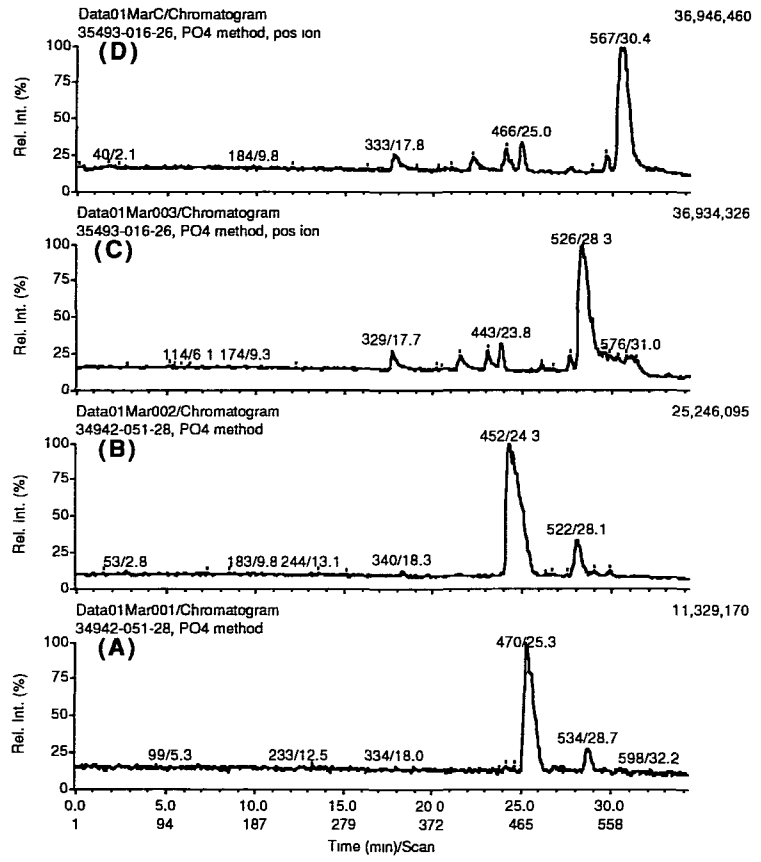

Figure 2. These four total ion chromatograms were acquired successively over a time span of 5 hours. Note that the overall sensitivity of the mass spectrometer has not degraded even though potassium phosphate is used in the HPLC mobile phase. Chromatograms A and B were acquired in the negative ion mode (A: 10 µL injection; B: 25 µL injection, respectively of BMS-188494) while chromatograms C and D were acquired in the positive ion mode (10 µL injection of BMS-192683.

A Rapid Universal LC/ESI-MS Method for Profiling Drug Metabolites

Susan C. Taylor, Anne M. Starrett, Gerald C. DiDonato, Mike S. Lee, Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton, NJ 08543-4000

Increasing demands on the pharmaceutical industry to quickly market drug candidates have challenged scientists to expedite the drug discovery process. In response, our laboratory sought a rapid and efficient LC/ESI-MS method that would profile the majority of drug metabolism samples that we receive. Presently, a liquid chromatographic method is developed for each metabolism sample prior to LC/ESI-MS analysis. These methods, whether isocratic or gradient, frequently extend to one hour and require the availability of a variety of columns. Automated analysis is difficult when manual column or solvent switching is required for each run. The development of a universal method for analyzing metabolites from both *in vitro* and *in vivo* sources eliminates the need for lengthy method development time and hardware conversion and reduces overall analysis time.

A Perkin Elmer Series 4 Chromatograph equipped with an Applied Biosystems 783A Variable Wavelength UV detector set at 210 nm was used for all preliminary LC/UV method development. Subsequent LC/MS experiments were performed on a Waters 600MS HPLC system equipped with a Waters 717 autosampler, directly interfaced with a Finnigan Electrospray TSQ 700 mass spectrometer.

Most separations were performed on a YMC-ODS AQ, 3 micron, 150 x 4.6 mm, HPLC column. One additional column, a Waters Symmetry C_{18}, 5 micron, 150 x 4.6 mm, column was investigated. Mobile phases consisted of either 0.05 % trifluoroacetic acid or 50 mM ammonium acetate (pH 5), for the separation of acidic or basic compounds, respectively. Acetonitrile was used as an organic modifier to which 0.05% TFA was added when acid mobile phase was used. Linear gradients were run from 5/95 organic/aqueous to 95/5 organic/aqueous in 15 minutes. Flow rate of 1 mL/min was used to eliminate the need for a split.

The application of this universal system is shown below(Fig.1) in the LC/UV and LC/MS profiles of metabolites from microsomal incubations of BMS-180291, a thromboxane receptor antagonist. Hydroxylated and dihydroxylated metabolites were separated with very good efficiency. This method has also been applied to metabolites derived from basic compounds with similar results. This method has been proven as a useful tool in the rapid identification of biotransformation products.

Electrospray LC/MS Profiling in Evolving Drug Development Paradigms

Edward H. Kerns[1], Kevin J. Volk[1], Steven E. Klohr[1], Robyn Rourick[1], William L. Thompson[3], Jeffrey L. Whitney[1], and Mike S. Lee[2]
Bristol-Myers Squibb Pharmaceutical Research Institute,
[1]Wallingford, CT 06492, [2]Princeton, NJ 08543-4000, [3]New Brunswick, NJ 08903-0191

The intensity of pharmaceutical research activities are expanding as a result of emerging technologies, economic forces, and competition. As a result, pharmaceutical scientists are forced to respond to the growing number of samples with new strategies for analysis. One strategy which we have found successful is the expanded role of LC/MS. Despite growing awareness of the technique, application of LC/MS is often reserved for "special" studies using unique methods developed for each project. This is due, in part, to the highly regulated nature of the pharmaceutical industry and common use of traditional experimental paradigms. The expanded role of LC/MS has been examined, as part of a "front-line" analytical methodology to accelerate drug development experimental paradigms.

This has been accomplished through the development of a standard protocol for profiling front-line research samples using electrospray LC/MS, which may be applied to a majority of pharmaceutical research and development projects. This standard protocol approach provides rapid "front-line" profiling of components in mixtures from sample types commonly encountered throughout pharmaceutical research and development. This standard profiling approach takes advantage of electrospray characteristics (i.e., high sensitivity, reliable molecular ion formation, amenability to LC/MS, front end for MS/MS) to accelerate the analysis of many samples from various areas of pharmaceutical research for which "traditional" experimental paradigms involving scale-up, isolation, and individual spectroscopic analysis are used. Our approach is useful for profiling impurities, metabolites, degradants, natural products, and synthetic products.

Our standard LC/MS profile protocol utilizes a tandem quadrupole mass spectrometer (PE-SCIEX API III), gradient HPLC with diode array UV detector (HP1090), and a C_{18} HPLC column (Zorbax, 2 mmX150 mmX 5 µM) gradient programmed from 10% ACN/90% Buffer (2 mM NH_4OAc) to 90% ACN/10% Buffer in 30 min. at 200 µL/min). This integrated on-line system provides the following analytical data:

1) LC/UV provides t_R and UV spectrum of components to construct a library of components and permit matching to a library of previously elucidated analogs
2) LC/MS provides MW of components and further library comparisons or cataloging
3) LC/MS/MS provides substructural detail for structure elucidation of novel compounds.

Traditional drug development experimental paradigms for metabolites, impurities, degradants and natural products can be very expensive for an organization and delay progress on projects. A generalized scheme for the elucidation of structures in these areas involves many of the following stages: synthesis of radiolabeled drug, sample acquisition (biological fluid/bulk drug/active culture), HPLC/UV profile, extraction, fraction collection, scintillation detection, scale up batch size, fractionation, and spectroscopic analysis of each component. In contrast, front line LC/MS profiling involves only: use of small quantities of standard drug or sample

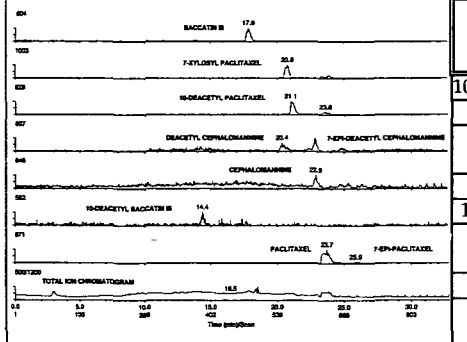
from biological fluid/bulk drug/active culture, LC/UV/MS, and LC/MS/MS. The advantages of this streamlined scheme can be illustrated by the following resource comparison:

	Traditional	LC/MS Profiling
Radiolabeled Drug	[1 month]	–
Biological Dosing	[4 hr]	[4 hr]
HPLC/UV Profile	[2 hr]	–
Extract/Prepare	[2 hr]	[0-2 hr]
Fraction Collection	[4 hr]	–
Scintillation Detection	[4 hr]	–
Scale Up	[24-40 hr]	–
Fractionate	[24 hr]	–
Analyze Each Compound	[6-24 hr]	[4-10 hr]
TOTAL TIME	[40-280 hr]	[8-14 hr]
COST	[$6,000-$35,000]	[$2,000]

The type of information obtained from this standard LC/MS protocol approach is illustrated in the results, in which impurities of paclitaxel (the active in TAXOL®) were rapidly profiled.

TAXOL® PROCESS SAMPLE

LC/MS PROFILE



PROFILE LIBRARY OF TAXOL® SAMPLE

Proposed Structure	Relative Retention Time	Molecular Weight
10-Deacetyl Baccatin III	0.61	544
Baccatin III	0.76	586
10-Deacetyl Cephalomannine	0.86	789
7-Xylosyl Paclitaxel	0.88	985
10-Deacetyl Paclitaxel	0.89	811
7-Epi-10-Deacetyl Cephalomannine	0.96	789
Cephalomannine	0.97	831
7-Epi-10-Deacetyl Paclitaxel	0.99	811
7-Epi-Xylosyl Paclitaxel	1.0	985
Paclitaxel	1.0	853
7-Epi-Paclitaxel	1.09	853

Standard LC/MS profiling can be used as a front-line method for a variety of samples. The LC/MS profiling paradigm saves 50% to 90% of cost and wait for analyses. A "library" of components is created and includes: hplc t_R, UV spectrum, molecular weight, substructures, and proposed structures of components. This "library" is transferable throughout drug development stages of discovery, development, and manufacturing. This method, cost/time savings, and transferable libraries provide support for the accelerated rate of drug development.

TITLE: EXAMINATION OF CHIRAL PURITY BY HPLC-MS

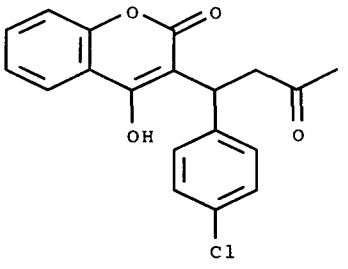
D. S. Richards, S. M. Davidson, R. M. Holt, F. S. Pullen
Pfizer Central Research, Sandwich, Kent, UK.

An increasing number of compounds of therapeutic interest are being developed as single enantiomers. Therefore the need to determine chiral purity is becoming more important within the pharmaceutical industry.

Confirmation of chiral purity is usually carried out via HPLC separation. However, the mobile phases required to effect good separation, using polar organic phase chromatography on cyclodextrin columns, present the chromatographer with a number of problems. The major problem is the HPLC detection of compounds which have UV chromophores absorbing below the UV cut-off wavelength of the mobile phase(~240nm). The use of refractive index detectors is possible, but they often lack the necessary sensitivity and specificity. We have investigated the use of LC-MS techniques to overcome this problem.

The mobile phase composition is a critical factor in maintaining the enantiomeric selectivity of cyclodextrin columns in the polar organic mode and cannot be compromised to suit the mass spectrometry; consequently, our options were somewhat restricted. However after exploring a number of different approaches, a robust and reliable, analytical, chiral LC-MS system has been developed.

Coumachlor (p-chlorowarfarin) has no known pharmaceutical value but is used as an internal standard in the analysis of the rodenticide warfarin, and it serves as a good example of the method described.



Coumachlor (p-chlorowarfarin)

The mobile phase required for separation (ref 1) is acetonitrile, acetic acid, triethylamine (998.25 : 1 : 0.75), which effectively prevents UV detection below 240nm. Unfortunately the λmax for Coumachlor is 207nm. However, this compound has a relative molecular mass (RMM) of 342 Da. and a distinctive isotope pattern.

In the presence of large quantities of triethylamine and acetic acid, particle-beam is an ineffective inlet system and soft ionisation techniques such as thermospray proved to be inefficient. It was found that plasmaspray mass spectrometry (PSP-MS), often considered as a fragmentation device for thermospray, is able to provide both the sensitivity and selectivity required for this work. Chromatograms for mass and UV detection are shown in figure 1

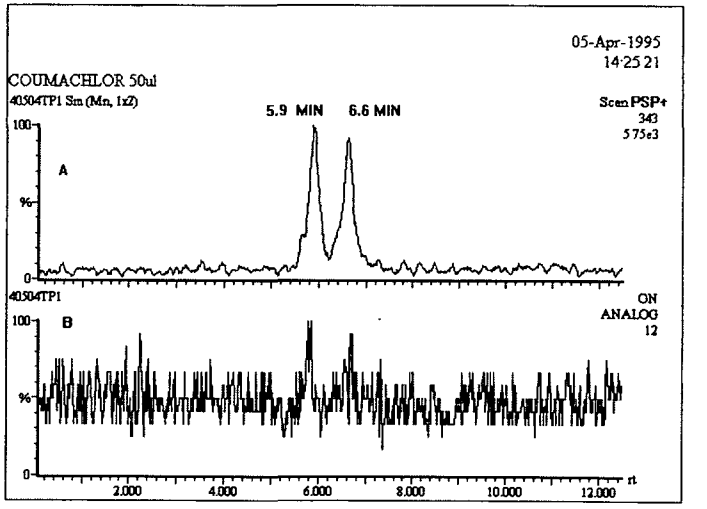


Figure 1: Chromatograms for A the $(M+H)^+$ ion at m/z = 343 and B the UV trace at 207nm.

The mass chromatogram above clearly shows a superiority in signal to noise ratio with respect to the UV chromatogram at the λmax for Coumachlor. Although setting up the system requires considerable expertise the method itself proved sufficiently robust that we were able to carry out the analyses and obtain the data presented using our 'open-access' LC-MS system (ref 2).

Quantitative Aspects of LC Peak Purity by Electrospray Ionisation/Mass Spectrometry (ESI/MS)

Duncan K. Bryant
SmithKline Beecham Pharmaceuticals, Old Powder Mills, Tonbridge, Kent TN11 9AN, United Kingdom.

When validating chromatographic methods and determining analyte purity, it is essential that the purity of the main chromatographic peak is established, particularly within the pharmaceutical environment. HPLC peak homogeneity can be determined by using multiple wavelength UV detection in conjunction with a number of chemometric manipulations such as principle component analysis (PCA) and factor analysis (FA). However, these methods require UV spectral differences between the main component and the coeluting impurity, a condition frequently not met for impurities closely related to the main component.

Mass spectrometry has been used to establish chromatographic peak homogeneity (1-3) and we have found IonSpray (nebulizer assisted electrospray) mass spectrometry to be particularly effective for analysis of HPLC peaks. Using our method, coeluting impurities can be observed down to a level of 0.01%. Clearly, it would be of great interest to be able to quantitate coeluting impurities observed by LC/MS. The objective of this study is therefore to see whether this can be achieved by comparing the responses for the coeluting impurity and the main component.

Mass spectrometry was performed on a Sciex API-III (Sciex, Toronto, Canada) triple quadrupole mass spectrometer using nebuliser assisted electrospray (IonSpray) as the ionisation technique. The structures of the two compounds used in this study are shown in the Scheme. The LC method was developed so that known impurites in ropinirole would coelute with ropinerole itself. The levels of SKF-96266-A in ropinirole were measured by comparing the mass spectral peak abundances for the two protonated molecules. The mass spectrometer was set up so that the low orifice voltage used (+50V) caused very little fragmentation to occur in the source and virtually all of the analyte ions that were detected were protonated molecules (3). A typical spectrum is shown in Figure 1 and was obtained by summing the spectra acquired across the main LC peak. The experiment was performed on solutions of 10^{-4}M ropinirole which contained SKF-96266-A at levels of 0.01, 0.02, 0.05, 0.1, 0.2, 0.5, and 1.0% w/w. The batch of ropinirole used was known to contain 0.01% w/w (by HPLC assay) of SKF-96266-A prior to spiking. Were the coeluting impurity to have an unknown structure it would be assumed that the relative response factor for the impurity is the same as the main component. A relative response factor of 1.0 has been used in this study for SKF-96266-A and ropinirole, and indeed the electrospray responses for ropinirole and SKF-96266-A are very similar. It is reasonable to assume that most impurities likely to coelute with the drug substance would have similar structures to the main component and that their mass spectral response would also be similar.

In order to observe the protonated molecule of the coeluting impurity at low levels, the protonated molecule of the main component had to be overloaded, thus preventing direct comparison of their responses. In many cases the carbon 13 peak of the major component was also overloaded to some degree, mainly due to the small dynamic range of the detector on the API-III. To overcome this, the reponses for the protonated molecule of the impurity and the $[M+3+H]^+$ ion (molecules containing three carbon 13 atoms) of the main component were compared in order to determine the levels of the impurity (Figure 1). It was assumed that the relative abundance of the $[M+3+H]^+$ peak of rropinirole was 0.133% that of the carbon 12 peak ($[M+H]^+$. Using this method, the responses for the protonated molecules of ropinirole and SKF-96266-A are shown graphically in Figure 2. It can be seen that a linear response is obtained with moderate precision (r^2=0.993) and good accuracy.

Data Dependent Automated MS/MS Switching Methods for Routine LC/MS/MS.

Iain Mylchreest, Clay Campbell, Kevin Wheeler and Michael Wakefield.
Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

Data dependent automated LC/MS/MS is a powerful analytical tool for the analysis of protein digests and other complex biological mixtures, providing amino acid sequences and other structural information with minimal analyst interaction with the experimental procedures. Data dependency can also be applied for the rapid screening of complex mixtures for target compound analysis using precursor and neutral loss scan modes.

Three methods to automatically switch between MS and MS/MS modes during a chromatographic run, and scan to scan are described. First, simple retention time windows can be used and multiple experiments can be performed across the eluting chromatographic peaks. For useful MS/MS spectra of peptides the optimal collision energy is not often known, therefore in a qualitative method the energy can be varied from scan to scan through three or more energies. The resultant spectrum gives an average energy fragmentation pattern which usually gives a more complete sequence than selecting a single energy across the whole peak. In the second method the mass spectrometer's data system can make decisions independent of retention times, based upon the appearance of an ion that meets a predefined intensity, signal to noise or peakwidth, comparing it with a list of ions that the analyst wishes to perform MS/MS experiments on. The instrument then decides which ion to perform the experiment on, turns on the CID gas and sets up the experiment based upon the data it has just acquired. The flow of this 'Data dependent method' is shown in figure 1. Figure 2 shows the RIC of a separation of five angiotensins in a data dependent MS/MS experiment The resultant individual collision energy CID spectra from -15, -20 and -25 eV for product ions of m/z 442 are shown in figure 3. The inverse of this experiment can also be performed, where MS/MS is carried out on all ions not in the main predefined list.

In the third method, described as 'monitor all ions', the data system can switch between scan modes based on the increase in ion signal when a peak elutes, checking for variables such as signal to noise in real time. This method requires no information about mass or retention time, but indiscriminately performs MS/MS on the base peak in a spectrum. An example of this is shown in Figure 4 for a tryptic digest of myoglobin. Each peak in the trace is a data dependent MS/MS experiment, demonstrating the potential for unattended peptide sequencing, and automated protein database searching.

The technique can also be used to screen for target compound classes and automatically collect full scan product ion spectra, when a predefined precursor ion is detected. This can be applied to the analysis of drug metabolites or post translational modifications, such as glycosylations. This method has been successfully applied to a neutral loss experiments, when screening for phosphorylations on peptides and drug metabolite functionality's in complex synthetic and natural product mixtures.

Comparison of Electrospray and Thermospray LC/MS for Analysis of Small, Chemical-Weapons-Related Molecules

William R. Creasy
EAI Corporation/AMC Treaty Laboratory Division
1308 Continental Drive, Suite J
Abingdon, MD 21009

The Chemical Weapons Convention, the treaty to ban chemical weapons, requires the detection of degradation products of chemical weapons agents in environmental samples for its verification. As part of the development of methods for this purpose, a comparison was done between electrospray and thermospray ionization for LC/MS analysis of some typical compounds in aqueous samples. The compounds include thiodiglycol (TDG) and thiodiglycol sulfoxide (TDGO), degradation products of mustard gas, and O-pinacolyl methylphosphonic acid (PMPA) and diisopropyl methylphosphonate (DIMP), related to nerve agents. These compounds have been found to be easily detected with thermospray ionization.

The thermospray equipment was the standard Hewlett-Packard system for the HP 5989A MS Engine. The electrospray system was sold by HP but manufactured by Analytica of Branford, Inc. The source was designed for high flow applications by using a nozzle that incorporated a drying gas flow coaxial to the liquid capillary, which assisted in the liquid nebulization. A 50 ppm PPG solution in 0.1 M ammonium acetate and 75/25 water/methanol was used for calibration and tuning of both sources The analyses were done on two separate MS Engines in the same lab

LC was done using a C_{18} (ODS Hypersil) column. The mobile phase was 100% 0.1 M ammonium acetate in water for TDG and TDGO. It was 60/40 water/methanol, 0.06 M ammonium acetate, for DIMP and PMPA. Flow rates were 0.2 ml/min with a 2.1 mm I.D. column for electrospray, and 1.0 ml/min with a 4.6 mm I.D. column for thermospray. The lower flow rates were used for electrospray to improve the performance, but no attempt was made to use smaller (1 mm or less) columns. No post-column addition of solvents was used.

The LC and MS source conditions were chosen to be appropriate for routine, general analysis of samples containing unknown compounds. As a result, the tuning of the source with a standard solution of the particular compounds of interest was not done. Instead, tuning was done using the PPG solution. This solution is recommended by Hewlett-Packard for tuning the thermospray source, and an autotune program is available for this purpose. It was also found to give good ion signal with electrospray. Since all PPG ions are singly charged, it is likely that the electrospray tuning conditions for PPG are more representative of the analytes of interest than a multiply-charged protein would be. Only the positive ion mode was used.

Results indicate that for these analytes and these conditions, thermospray is more sensitive, more stable, and has less compound-dependent sensitivity variation than electrospray. With thermospray, all four compounds could be detected at the 1 to 5 ppm level with the mass spectrometer in scan mode, and at sub-ppm levels in SIM mode. Sensitivity to TDG and TDGO was particularly good, with sensitivity in SIM mode to 50 ppb (S/N=10:1).

For electrospray, in contrast, sensitivity was adequate for 1-10 ppm detection levels only for DIMP. A comparison of the extracted ion LC chromatograms is shown in Figure 1. The mass spectrum base peak for thermospray ionization is m/z 181, but for electrospray it is the protonated dimer at m/z 361. PMPA had detection limits at the 10-100 ppm level in the scan

mode. The sensitivity to TDG and TDGO was even worse, since there was unacceptable signal to noise for even 100 ppm solutions. It is interesting that the least polar, least water-soluble compound, DIMP, provided the greatest sensitivity. This observation suggests that the factor that limits ionization in these cases is likely to be the solubility of the analyte in the sprayed droplets, rather than its affinity for charge.

Further improvements in the operating conditions or in the electrospray source design may improve the performance. Work is planned to compare the Analytica source to a Finnegan electrospray source.

This work was performed at and funded by the AMC Treaty Laboratory, ERDEC, Aberdeen Proving Ground, Edgewood Area, MD.

Enhanced Sensitivity LC/MS Using Low Resolution Quadrupole Mass Analysis

Dodsworth, D. W., Alexander, A. J., and Blackledge, J. A.
Bristol-Myers Squibb Co., Inc.
Pharmaceutical Research Institute
P.O. Box 4755
Syracuse, NY 13221-4755

LC/MS, using a quadrupole mass analyzer, is a well established technique in which the quadrupole mass analyzer is typically run at a resolution that maximizes sensitivity, yet provides adequate resolution of the isotope ions. This is in contrast to the low Q1 resolution used in the triple quadrupole experiment, where good parent ion sensitivity is essential. LC/MS analysis and identification of impurities and degradation products at less than 0.2% by area is frequently required for pharmaceutical products, and is a challenging analytical problem. Frequently, due to low ion intensities, only molecular weight information is obtained.

Using a Fisions Instruments VG Quattro triple stage quadrupole mass spectrometer, electrospray (ESI) LC/MS experiments were performed using Q1 resolutions of ca. 0.6 ("Unit Mass") to 5.0 ("Open") Da. half height peak width and data were acquired in continuum mode, thus allowing spectral averaging. The "Open" resolution condition resulted in ion signals that were minimally ca. 15 fold higher than those obtained by operation under "unit mass" resolution (Figure 1). This increase in ion abundance also resulted in qualitatively better spectra for the low level analytes, particularly when data was acquired using ESI in-source fragmentation. Mass accuracy problems (nominal mass rounding errors) are not evident until the mass of the analyte exceeded 1200 Da. or the elemental composition of the analyte differed greatly from that of the polyethylene glycol reference compound used for calibration (ie. In the case of CI containing compounds).

Figure 2 illustrates the theoretical peak shape change of an analyte ion as compared to a calibrant ion. The decrease in resolution results in a shift of the unresolved peak top to higher mass. The value of this positive mass shift is very similar for both the sample and calibrant. That is, any shift in the peak top of the analyte ion arising from the isotope contribution will be compensated by a corresponding shift in the calibration ion. This trend is also observed in analytes that contain one or two chlorine atoms. In this case, the shift to higher mass is greater, however if all mass defect values of 0.8 Da. or less are rounded down to nominal unit mass values, the mass assignment of the ion remains correct.

Figure 1: Comparison of "Open" vs. "Unit Mass" Resolution TIC's showing sensitivity enhancement.

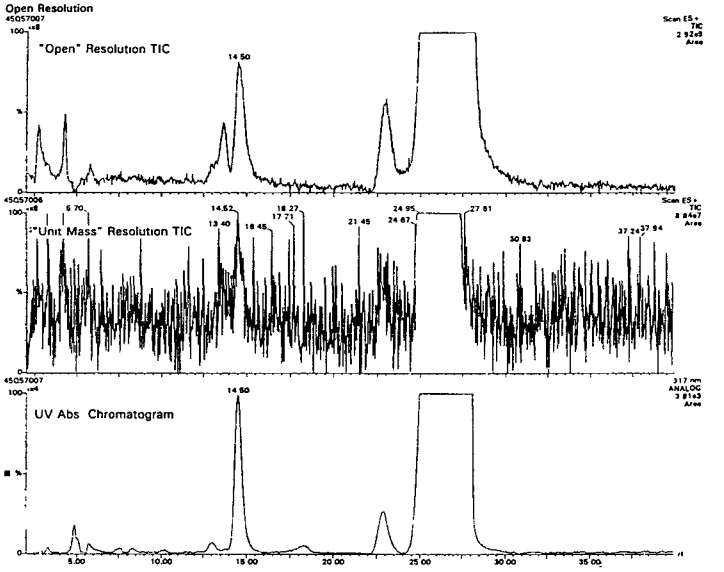

Figure 2: Effect of opening resolution on peak top assignment.

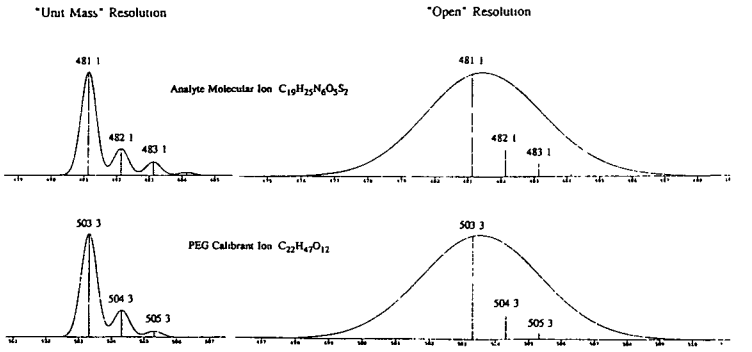

Electrospray Interface for Submicroliter LC/MS Analyses

Michael T. Davis, Douglas C. Stahl and Terry D. Lee
Beckman Research Institute of the City of Hope, Duarte, CA 91010

An ultra-low flow microcapillary HPLC system designed for the gradient elution of peptide and protein samples at nanoliter/minute flowrates has been coupled to a Finnigan TSQ 700 mass spectrometer via a simple sheathless electrospray interface. The coupled capillary HPLC - Microspray interface was optimized for column flowrates as low as 100 to 200 nanoliters/minute and UV detection of the column effluent was retained without loss of resolution in the mass spectrometer. True high performance LC was achieved using a packed 100 µm reverse-phase column coupled to a 100 µm on-column flowcell. Peak resolution was maintained throughout the system using 20 µm ID transfer lines from the column to the detector and from the detector to the microspray interface.

The microspray needle assembly utilized a flame drawn 150 µm ID x 350 µm OD FSC approximately 5 cm in length. Capillary drawing was performed manually using a vertically suspended section of FSC to which a small weight (HPLC Tee, ca 30g) had been attached. The capillary was slowly heated to melting using the smallest "blue" flame attainable from a Micronox torch (Alltech Associates, Deerfield, IL), which was then quickly withdrawn once the capillary began to draw. All tips were drawn to separation. Tip patency was confirmed by immersion of the tip into a vial of methanol followed by visual inspection for drawn solvent using a 8x ocular loop. A discontinuous 150 µm OD x 25 µm ID capillary was placed within the 150 µm ID needle to both minimize the deadvolume and retain a hydrophilic PVDF membrane filter. The final assembly was easiest to perform under a dissecting microscope. The needle was connected to the LC transfer line via a 1/32" stainless steel capillary union which served as a liquid-metal interface for application of the necessary potential (0.5 to 1 Kv) to the sample stream. The precise positioning of the microspray needle relative to the sampling capillary of the mass spectrometer was controlled using a XYZ multi-axis positioner and observed in real time using a micro borescope/video imaging system.

Ultra low flow LC/ESI/MS analyses of a standard peptide map were performed using a City of Hope built microscale HPLC system which is distinguished by its use of a preformed gradient for column development (1). A full presentation of the design and operational characteristics of the LC system is scheduled for publication in the June issue of JASMS . The general construction and packing of the microcolumn and the fabrication of the on-column flowcell was as previously described (2).

Mass spectral analyses were performed on a Finnigan TSQ 700 quadrupole mass spectrometer equipped with a Finnigan electrospray source with the voltage interlock locked in the closed position for use with the microspray interface. Automatic MS/MS analyses were performed using real time automated analysis programs developed in our laboratory (refer to poster WPB 026 for details).

Analyses performed at the sub ten femtomole level suggest limits of detection for proteins and peptide digest mixtures within the attomole range. The reduced spectral background facilitated the acquisition of MS/MS sequence information using automated real time analysis procedures. The benefits of on-line capillary LC - Microspray analysis over the conventional electrospray methodology is evident in reduced spectral background, decreased sample consumption and enhanced sensitivity.

Separation and Analysis of Human Lens α-Crystallins by LC-ESIMS

Peiping Lin, Jean B. Smith and David L. Smith
Department of Chemistry, University of Nebraska - Lincoln, Lincoln, NE 68588

Crystallins are the structural proteins in the eye lens. Post-translatonal modification of crystallins may disrupt the order of crystallin packing and/or lead to protein aggregation resulting in opacification of the lens. This condition is commonly known as cataract. A series of separation methods have been developed and applied to isolate the crystallins according to differences in size (size exclusive chromatogaphy), hydrophobicity (reversed phase HPLC) and charge state (ion exchange and 2D-PAGE). In this study, post-translationally modified human α-crystallins were isolated and identified by combining these separation techniques with HPLC-ESIMS and other mass spectrometry methods shown in Fig. 1.

Two different HPLC-ESIMS systems were used to meet the requirements of 1) multi-step and 2) high sensitivity experiments. System 1 consists of a microbore reversed phase column and a post-column splitter which diverts 10% of the effluent to the ESIMS for molecular weight determination, and the other 90% to a UV detector and fraction collector Collected fractions were stored for use in subsequent experiments. System 2 consists of a capillary column directly-coupled to the ESIMS, permitting analysis of samples with higher sensitivity. After determining the molecular weight of modified protein, we identified the modification site of protein and confirmed the structure of modification by enzymatic digestion (peptide mapping example shown in Fig. 2), exact mass measurement and MS/MS.

The lens was homogenized in buffer consisting of 0.5M NaCl, 0.05M Tris, 0.001M EDTA, pH 7.4 and centrifuged at 15,000 *g* for 1h The supernantant was fractionated by Sephadex G-200 size exclusive chromatography (SEC). The α-crystallins from SEC were fractionated into αA and αB by reversed phase HPLC (RPHPLC). Isolated proteins were further fractionated by anion exchange (IEX) on a Mono Q column using 6M urea, 0.01M Bis-tris, pH 6.2 for αA, and 6M urea, 0.01M Tris, pH 7.5 for αB as buffers A, respectively. The proteins were eluted with a linear gradient to 50% of buffer B (buffer A + 0.2M NaCl).

The HPLC-ESIMS analysis of desalted proteins was performed on a VG Fisons Platform quadropole MS. The HPLC system consisted of Gilson pumps, an Upchurch low volumn mixing tee and a Rheodyne 8125 injector. Microbore separations were achieved using a 50x1mm C8 column, 50μl/min flow rate, and a post-column flow splitter with ratio of 1 (MS) to 9 (UV detector). Capillary separations were accomplished using a 50x0.3mm C8 column at a flow rate of 5μl/min. A splitter located before the injector was used to split the flow rate of 50μl/min from pumps by clamp pressure on the waste side outlet. Exact mass and MS/MS analyses of the enzymatic fragments were performed using a VG Fisons Autospec high resolution mass spectrometer equipped with an orthogonal acceleration TOF mass analyzer.

HPLC-ESIMS offers a fast and sensitive method in microanalysis of minor components present in the lens crystallins. In addition, it also minimizes the sample loss and contamination by reducing the sample handling steps. The combination of a variety of chromatographic separation techniques, including SEC, RPHPLC, IEX and 2D-PAGE, together with MS techniques, involving HPLC-ESIMS, peptide mapping, exact mass and MS/MS, proves to be useful in the determination of the post-translational modifications in human lens proteins.

Preparative Applications of Microcapillary HPLC for Mass Spectrometry

*Murray Hackett[1], Ronald C. Hendrickson[1], Rocco Falchetto[1], Carthene B. Walker[1], Jeffrey Shabanowitz[1], Donald F. Hunt[1,2]

Departments of Chemistry[1] and Pathology[2], University of Virginia, Charlottesville, VA 22901

Methods for collecting 50 to 500 nanoliter volumes during preparative microcapillary HPLC fractionation of complex peptide mixtures are described, with reference to further analysis by mass spectrometry. For MALDI-TOF analysis, fractions were collected directly into unmodified disposable 1 μL polyethylene micropipet tips (Fisher Cat. Num. 21-199-9). For triple quadrupole electrospray ionization microcapillary LC/MS/MS, fractions were collected in short (less than 3 cm) lengths of teflon tubing with the i.d. (typically 180 μm) matched to the o.d. of the microcapillary column used on-line with the mass spectrometer. The fractions were loaded into the reversed-phase analytical capillary column using N_2 pressure. The point of the exercise was to scale down the multiple stages of HPLC such that the total sample consumed was less than 5 pmol. These methods were applied to the study of bacterial exotoxins, insect neuropeptides, alcohol dehydrogenase N-termini and other projects which required multi-stage separations with minimal sample consumption. This approach allows the scaling down and application of HPLC methods which may not be easily compatible with LC/MS, but which offer chromatographic selectivity and (or) enhanced resolution not found using our standard reversed-phase microcapillary HPLC conditions. *Preliminary results with known standards of angiotension 1 and acylated peptides derived* from adenylate cyclase toxin suggest that two stages of microcapillary HPLC can be performed on 100 fmol of peptide before S/N becomes too low to acquire an interpretable CAD spectrum, using the TSQ mass spectrometer.

At right: an off-line microcapillary HPLC fraction, about 100 nL, was collected in a 180 μm i.d. X 2 cm teflon capillary tube, and the sample loaded roughly 50 nL at a time directly on the analytical capillary column, using a bomb under N_2 pressure. This approach was used to generate the second dimension HPLC trace and main beam ESI mass spectrum (A), and the free acid CAD spectrum (B) of the doubly charged ion at *m/z* 614, confirming the sequence shown in panel B. Leu was distinguished from Ile based on the gene sequence, P. Glaser *et al., Mol. Microbio.* 1988, *2*, 19-30. LC/MS conditions used with the upgraded Finnigan TSQ 70 (Finnigan API-ESI interface) were routine reversed-phase binary gradient elution, using a packed column length of 12 cm (PLRP-S 4000, Polymer Labs, Amherst, MA), 190 μm o.d., 75 μm i.d., 12 min gradient from 0-80% B, solvent A, 1% acetic acid, solvent B, neat acetonitrile, 400:1 precolumn split (solvent only). The flow rate measured at the capillary column at 0% B was 0.5 μL/min.

Integrated Multidimensional LC-MS and LC-MS/MS Analysis for Protein Sequencing and Mapping

Frank Hsieh, HongQi Wang, Chris Elicone, George Tarr, Fred Regnier, and Stephen Martin
PerSeptive Biosystems Inc., 500 Old Connecticut Path, Framingham, MA 01701

Multiple manual manipulations of small amounts of samples characteristically give poor sample recovery, increase the probability of contamination, and make it more difficult to analyze large numbers of samples. In this study, manual transfers were eliminated; i.e. once the sample was introduced into the multi-dimensional LC-MS system it would be automatically carried through all steps of the analysis to identification. This approach shows a wide ranged applications in pharmaceutical and biotechnological industry.

A novel integrated tandem chromatography-tandem mass spectrometry system (5 LC -MS, Figure 1) is used for protein sequencing and mapping. The antigen protein (normal or sickle-cell hemoglobin) is sequentially i) purified from the human serum by immunoaffinity perfusion chromatography using the immobilized anti-hemoglobin antibody (ImmunoDetection Cartridge, PerSeptive Biosystems) , ii) Hemoglobins were eluted with 12 mM HCl and neutralized with 10mM NH_4OAc (pH 7.5) in the buffer exchange column, i.e., the mixed-bed perfusion anion and cation exchange column (PerSeptive), iii) antigens are flow through an immobilized trypsin bed column (Porozyme, PerSeptive) in 5 minutes, iv) captured and rapidly desalted in a dilute capture column (PerSeptive), v) the trypsin digest fractionated by reversed phase chromatography, and vi) the separated peptides are identified and sequenced by ion spray mass spectrometry and MS/MS.

Tandem chromatography using on-line immunoaffinity, ion exchange, immobilized enzyme, dilute capture, and reversed-phase columns were explored with mass spectrometry (LC/LC/LC/LC/LC-MS). The results show the 5 LC-MS of total ions between *m/z* 400 - 1500 of both Hb A0 and Hb S, respectively. The total ion chromatograms (TIC) of 5 LC-MS mapped well with the sequence of Hb A0 (Figure 2) and Hb S (Figure 3). In the comparison of the novel tandem LC-MS TIC, only one peak pair differs. The different tryptic peptides can be further sequenced by 5 LC-MS/MS. The tandem LC-tandem MS spectra between *m/z* 50 - 1000 show the peptide sequences are VHLTPEEK and VHLTPVEK for normal-cell Hb and sickle-cell Hb, respectively. The coupling of tandem chromatography and the tandem mass spectrometry has been shown to be a powerful combination technique to determine protein sequence rapidly, automatically, and accurately. This modern analytical technique will provide a unique and excellent tool for biochemical and biomedical studies.

The multi-dimensional LC-MS may be formatted into a capillary size resulting in significant enhancement in sensitivity with much less sample required. The results from capillary multi-dimensional LC-MS (proteins are flowed through capillary trypsin column in 2 minutes, eluted into the capillary RP column, and then identified by MS, m/z 500-1500) using gradient elution (100% 0.1% TFA to 50% 0.1% TFA+80% ACN) at 2 µL/min show the detection may down to 5 pMole hemoglobin.

The integration of multi-dimensional LC with the orthogonal electrospray time-of-flight MS (LC-ESI TOF MS) may be an alternative bioanalytical technique for biological study (Figure 4). ESI-TOF MS provides very fast data acquisition and good resolution simultaneously compared to a quadrupole MS which requires compromises between scan step size, dwell time, and mass range to be made.

The Effect of Column Diameter on Sensitivity for the Analysis of Peptide Mixtures by LC-ESI/MS

B. L. Ackermann, S. M. Fields, B. T. Regg, and T. A. Dourdeville*
Marion Merrell Dow Research Institute, Cincinnati, OH 45215
*Waters Chromatography, Milford, MA 01757

The concentration dependence of ESI has several implications for LC/MS operation. Of primary importance is the increase in sensitivity gained through the use of smaller bore columns, which due to operation at reduced flow rates, present more concentrated bands to the mass spectrometer for ESI/MS analysis. In this study, the sensitivity of four C18 columns was compared for the analysis of peptide mixtures in both the MS and MS/MS modes of operation. The four columns types examined were analytical bore (4.6 mm), narrow bore (2.1 mm), microbore (1.0 mm) and packed capillary (0.32 mm). Because concentration enrichment varies as the inverse of the square of the column diameter, the relative response for the four columns should be 1 : 5 : 21 : 207, respectively. In practice, the observed ESI signal intensity reflects several factors including the efficiency of the particular ESI interface used. As one would not expect the efficiency to remain constant over a wide range of flow rate (i.e., 1 to 1000 µL/min), an investigation of sensitivity vs. column diameter allows for a practical understanding of the performance for a given ESI interface. This work represents a study undertaken to evaluate an ESI interface based on a "heated capillary" design employing nebulization assistance.

The instrument used in this study was a Finnigan MAT TSQ 700 triple quadrupole equipped with a Finnigan ESI interface. Two peptide mixtures were examined: a test mixture of 7 synthetic peptides and the tryptic digest of horse apomyoglobin. Except for the packed capillary column, gradients were formed using a Waters 625 LC system. A Waters R&D prototype µLC system, operated at 5 µL/min, was used for packed capillary work.

Figure 1 compares the observed vs. predicted sensitivity enhancement obtained for the synthetic peptide mix at the 250 pmol level. For each column the data are expressed as a ratio relative to the performance of the analytical bore column operated at 1 mL/min. In each case, the overall enhancement factor represents an average of the individual factors determined for the 7 peptides. The trend displayed in Figure 1 was corroborated by a similar comparison of the 4 columns using 100 pmol of the tryptic digest of horse apomyoglobin. In this investigation, 5 representative tryptic fragments were considered and the results obtained were almost identical to the data in Figure 1 (results not shown). Although superior sensitivity was obtained by the use of smaller bore columns, the data in Figures 1 reveal that, the full measure of enhancement was not realized for the microbore (1.0 mm) or the packed capillary column (0.32 mm). A probable explanation for this outcome is the expected variation in interface performance at the different chromatographic flow rates used. To investigate this phenomenon, a post-column flow splitting experiment was performed to vary the flow introduced to the ESI interface while keeping the concentration fixed. The data from this experiment are plotted in Figure 2. Essentially, no change in performance was observed up to a split ratio of 5:1; however, as the flow to the MS was lowered to 50 µL/min or less, a significant degradation in response was observed. The observation that response at 10

µL/min could be improved through the co-introduction of 2-methoxyethanol suggests that the spray conditions at low flow rates are less than optimal.

These and other data acquired in this study enable recommendations to be made concerning column selection for the analysis of peptide mixtures: (1) analytical bore columns should only be used when high capacity needed, (2) for the interface used, a post-column effluent split of up to 5:1 can be implemented without a decrease in sensitivity (allows majority of sample to be recovered), (3) packed capillary LC is recommended for all sample limited situations (< 100 pmol), (4) microbore LC (1.0 mm) is not recommended since the gain in sensitivity does not offset the need to use a modified HPLC system, (5) a liquid sheath is advised when performing packed capillary LC with the interface used in this study.

Enhancing API-MS Performance through Chromatography: Determination of Growth Hormone in Milk

Robert D. Voyksner* and Jeffrey Keever, Analytical and Chemical Sciences, Research Triangle Institute, P. O. Box 12194, Research Triangle Park, North Carolina 27709.

Introduction

Bioengineered human or bovine growth hormone (hGH or bGH) is now available from several sources. hGH has been approved by FDA for the treatment of hypopituitary dwarfism while bGH has been approved to increase milk production for cows. To better understand GH excretion and residue from metabolism as well as cases related to GH abuse or GH product labeling for food stuffs; fast, sensitive, and specific analytical methodology must be in place, namely LC/MS. Electrospray or Ion Spray MS [1-3] has been demonstrated to detect intact GH (molecule weight ~22,000) as well as various hydrolysis products at the sub-pmole level. In an effort to increase the resolution of the separation and decrease analysis time (often 30-60 minutes for LC) we propose to evaluate capillary perfusion LC/electrospray-MS for the determination of GH.

Results and Discussion

The development of an extraction and analysis method for hGH took into account the potential need for numerous analyses. Therefore, the simplicity and analysis time were parameters that required careful consideration, resulting in the proposed methodology of ultrafiltration clean-up and perfusion LC/electrospray-MS. The ultrafiltration approach employing a single stage filter provided >80% yield of hGH in milk. The addition of acetonitrile (1:1) to the sample was necessary to achieve these high yields. The evaluation of a 30K and 100K MWCO filter showed that hGH was partially retained on the 30K filter (18% yield) while the 100K filter resulted in a 89% yield. The separation of hGH on a perfusion column was developed using a gradient of 10-100% acetonitrile in water containing 0.1% TFA in 7 min., which resulted in a retention time of hGH of about 6.4 min. The electrospray mass spectrum of hGH peak exhibited a multiple ion cluster ranged from 13 to 20 charges on the protein. Deconvolution of this multiple charged cluster resulted in a measured molecular weight of 22,126.4, less than 0.006% error from the literature value of 22125.

To achieve the best sensitivity both selected ion monitoring for the MS and on-column concentrations were employed. The MS was set to monitor the three most intense ions for GH (+18, +17, +16 ions), each for 100 ms. Secondly due to the hydrophobic nature of GH, injection of 50-100 µL could be made on the 0.32 mm i.d. perfusion column in the initial mobile phase of the gradient (90% water), without significant peak broadening. Using these approaches the linearity and detection limits of GH spiked in milk was evaluated. The linear correlation coefficient for the six point GH calibration ranging from 0.1 -100 pmoles/mL was 0.9987. The detection limits for the LC/MS method is presented in Figure 1 for GH in milk. A 0.05 pmole/mL sample (55 µL injected) could be detected, with no interferences from the milk matrix.

This methodology is capable of detecting ppb levels of hGH in milk, demonstrating the potential of performing LC/electrospray-MS for monitoring food products employing GH or for monitoring hGH levels. The speed, sensitivity, and specificity of the method is well suited for the potential numerous determinations at trace levels in a matrix.

Effect of Salts and Trifluoroacetic Acid on Aerosol MALDI Ion Signal

Michelle D. Beeson, Xiaona Wei, and David H. Russell,

Laboratory for Biological Mass Spectrometry, Department of Chemistry

Texas A&M University, College Station, TX 77843

There is much interest in combining mass spectrometry with liquid separation techniques such as liquid chromatography and capillary electrophoresis. These techniques routinely use mobile phase modifiers, such as salts and acids, to yield a more efficient separation of analytes. Thus coupling the effluent of liquid chromatography or capillary electrophoresis with mass spectrometry brings these salts and acids into the mass spectrometer. Salts and acids in the chromatographic effluent interfere in the FAB and ESI ionization of analyte.[1] Alternatively, MALDI is reportedly tolerant of contaminants, including salts.[2] However, the typical MALDI experiment can not be easily coupled with liquid separation techniques for on-line analysis. We have developed an aerosol liquid introduction system combined with MALDI ionization[3] and have demonstrated its use in combination with HPLC.[4]

Using the aerosol MALDI technique, the matrix solution is delivered using a syringe pump to a mixing tee where it is mixed with the HPLC effluent and sprayed into the mass spectrometer as an aerosol. The aerosol first passes through a heated drying tube at 500 C to remove solvent and then ionization is performed at 355 nm using a frequency tripled Nd:YAG pulsed laser. The ions are orthogonally accelerated at 10 kV, mass separated in a 1.1 m flight tube, and are detected with a microchannel plate particle multiplier. Each laser pulse generates a mass spectrum of the HPLC effluent. The mass spectra are collected by a digital oscilloscope and downloaded to a microcomputer for analysis.[3,4]

The size of the aerosol particles created by aerosol MALDI is influenced by the solvent surface tension, viscosity, and density. Small aerosol particles are formed from solvents with low surface tension, low viscosity, and high density. These parameters also promote particle break-up: the same characteristics that yield small aerosol particles also promote particle break-up. During aerosol particle break-up, smaller particles are formed from the surface and large particles are formed from the interior of the initial aerosol particle. Because of hydrophobic interactions with the air, the hydrophobic species in the aerosol particles reside along the surface and the hydrophilic species remain in the interior of the aerosol particles. Thus the smaller particles are enriched in the *more* hydrophobic species and the larger particles contain the *less* hydrophobic species. If the solvent hydrophobicity is much less than that of the matrix and analyte, *or* if the matrix and analyte hydrophobicities are similar, the matrix and analyte are both forced to the surface of the aerosol particle. Matrix/analyte interactions can also be influenced by other species in the solution. For example, when trifluoroacetic acid (TFA) is present, the matrix/analyte interactions are increased, either by the TFA providing a hydrogen-bonding bridge between the matrix and analyte or through hydrophobic interactions[5] between the TFA/matrix/analyte, forcing the matrix and analyte to the surface of the aerosol particle. As a result, the small aerosol particles formed during break-up contain matrix and analyte, and yield increased ion signal. A decrease in ion signal is observed when the matrix and analyte are separated as a result of dissimilar hydrophobicities or because of an interference in matrix/analyte interactions. Decreased aerosol MALDI ion signal is observed at ammonium acetate,

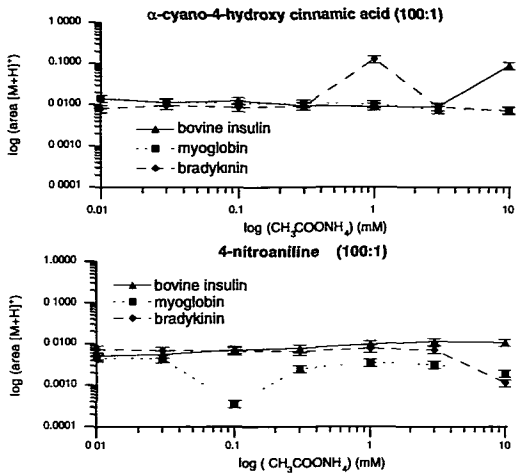

Figure 1. Log/log plots of the area of the $[M+H]^+$ ion signal as a function of the ammonium acetate concentration using the matrices a) α-cyano-4-hydroxy cinnamic acid and b) 4-nitroaniline. The laser energy was 13 mJ/pulse (160 MW/cm^2).

potassium dihydrogen phosphate, and sodium bicarbonate concentrations above 3 mM. Because solvent evaporation from the aerosol particles occurs rapidly,[3] the salt is forced into contact with either the matrix or analyte, separating the matrix and analyte. As more salt is added, more crystals of salt with matrix or analyte forms, further decreasing the ion signal. At concentrations below 3 mM, salts do not significantly affect the formation, redistribution, evaporation, or break-up of the aerosol particles.

The above model suggests that the salts typically used in chromatographic and electrophoretic separations do not interfere with aerosol MALDI ion formation at concentrations below 3 mM. This may be a result of the hydrophobicities of the analyte and matrix being different from that of salts, promoting the segregation of salt from the matrix and analyte. Using TFA in chromatographic and electrophoretic separations will promote the aerosol MALDI ion signal. Further work determining the effect of other organic acids is underway.

Application of LC/IT/reTOF MS to Peptide Mapping and Drug Analysis

Mark G Qian, Li Liang, Ling He, and David M. Lubman

Department of Chemistry, The University of Michigan
Ann Arbor, MI 48109-1055

Introduction. The combination of liquid chromatography with mass spectrometry as a hyphenated technique (LC/MS) provides the possibility of taking advantage of both chromatography as a separation method and mass spectrometry as a highly selective and universal identification method In this presentation, the application of a new LC/MS system based upon an ion trap/reflectron time-of-flight mass spectrometer (IT/reTOF) is reported for fast peptide mapping and drug analysis. A unique data presentation method, which is based upon a 3-D topographic mapping of the mass spectra versus the chromatographic elution time, was successfully employed to exhibit the advantages of using the IT/reTOF mass spectrometer combined with liquid chromatography for both peptide mapping and for the analysis of small-molecular-weight drugs

Methods. A Star 9012 solvent delivery system (Varian Associates, Inc) was operated at a fixed flow rate of 200 µL/min for microbore HPLC separations. A prime/purge valve located immediately before the injection valve was used to split the mobile phase flow with a ratio of 3.1 Microbore separations were accomplished with a 1.0 mm x 15 mm C_{18} column (5 µm, 300 Å) at a flow rate of 50 µL/min Effluents exiting the columns were monitored by a Star 9050 (Varian Associates Inc.) variable wavelength UV detector at 214 nm. All separations were carried out with 0 1% TFA in water as solvent A and 0 09% TFA in 90/10 acetonitrile/water as solvent B A linear gradient was employed for the LC/MS separations beginning with 100% of A followed by ramping the B content to 80% in a period of 60 minutes The flow exiting the UV detector entered the ion spray source through a 50 cm length of 75 µm i d. x 175 µm o.d. fused silica capillary.

The quadrupole ion trap storage device used in this experiment was operated at a preset rf voltage and ions whose mass-to-charge ratios exceed a minimum cutoff value are trapped. The extraction of ions from the ion trap for TOF analysis is performed by turning off the rf voltage and applying a dc pulse on the exit endcap. This dc pulse is phase synchronized with the rf source The TOF of the extracted ion packets was measured on a high-speed transient recorder (Model 9845, Precision Instruments Inc) embedded in a Pentium PC compatible computer A user-written driving program was used to control the board and data processing. All the measurements were performed at a repetition rate of 2 Hz with a sampling time window width of 150 µs, which corresponds to a mass range from 0 to ~1500 amu. Each spectrum is an average of 4 transients and thus results in a sampling rate of 2 s/acquisition.

Results. Figure 1 shows the application of the IT/reTOF mass spectrometer for peptide mapping of 20 pmol β-lactoglobulin B tryptic digest In Figure 1a and b are shown the UV trace at 214 nm and the total ion chromatogram, respectively The full chromatographic separation can be displayed as a 3-D topographic map, in which each mass spectrum was plotted versus the chromatographic elution time where the difference of the intensity of mass peaks was indicated by different shades of color

Because of the extended trapping period, the solvent cluster ions are significantly reduced, which results in significant enhancement of sensitivity. In addition, the IT/reTOF is also useful for the detection of small-molecular-weight substances, like drugs Figure 2 shows the separation and sensitive detection of a mixture of 2 ng each of four quaternary ammonium drugs. Since the UV detection of such compounds may be not sensitive, the mass detector is better suited in this case Figure 2 is the total ion chromatogram of the separation which shows four peaks and which could be identified by their SICs. As shown in Figure 2b, the peak eluted at ~17 min and has a mass of 284, which is related to one of the mixture components, ipratropium bromide. Its mass spectrum is given in Figure 2c

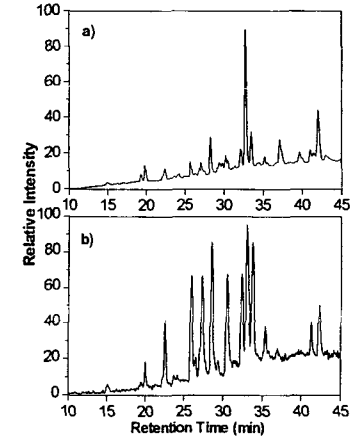

Figure 1

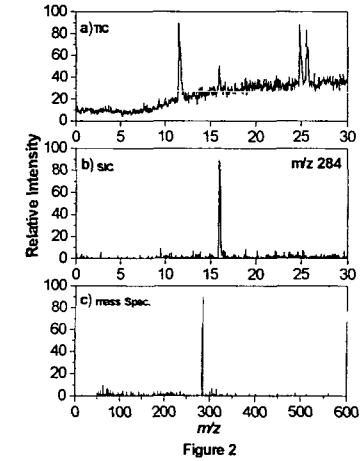

Figure 2

Conclusions. The ion trap storage/time-of-flight mass spectrometer serves as a rapid method of detecting the eluent of a liquid chromatographic separation over a broad mass range with a high duty cycle The SIC mode provides further enhancement of the S/N ratio, so that subpicomole detection can be obtained for each component. Using this methodology, peptide mapping and drug separation and detection could be carried out with excellent sensitivity in a relatively simple and inexpensive device

Continuous Flow MALDI MS in an Ion Trap/reTOF Mass Spectrometer

Li Liang, Ling He, Benjamin Chien and David Lubman
Department of Chemistry
The University of Michigan
Ann Arbor, MI 48109

A LC/MS interface for the analysis of peptides and proteins has been developed by coupling a continuous flow probe with an ion trap/reflectron time-of-flight (IT/reTOF) mass spectrometer. The sample probe was directly inserted into the ion trap, and matrix-assisted laser desorption ionization (MALDI) method was used to ionize the peptides and proteins. The advantages of the ion trap include the ability to operate efficiently at the elevated pressure which is required for direct liquid introduction into the trap. Resonance ejection method can be used with the ion trap to selectively eject unwanted solvent and matrix ions from the ion trap by applying low voltage auxiliary field to the endcaps of the ion trap, providing enhanced signal to noise ratio and improved resolution for target peptide ions. It is demonstrated that picomole level sensitivity was routinely achieved by using this methodology. The upper detectable mass range for this system is greater than 12,327 Da. Absolute quantitative measurements using MALDI are difficult since the signal level is strongly dependent on laser fluence, laser beam homogeneity, sample homogeneity and probe surface conditions. Internal calibration with molecules having similar chemical properties was used in this work to obtain quantitative measurements. The response was shown to be linear for 3 orders of magnitude.

An important factor involved in obtaining reproducible continuous flow MALDI results is achieving stable operation of the continuous flow probe. The stable operation of the probe can be achieved when the rate of evaporation of the solvent from the probe surface and the pumping speed of the mass spectrometer are in balance. The evaporation rate can be adjusted by changing either the flow rate of liquid to the probe tip or the

amount of heat applied to the tip. Insufficient heat leads to freezing within the capillary tip and results in unsteady ion signals. When too much heat is applied to the probe tip, ion signals disappear due to the rapid evaporation of the matrix (3-NBA). A flow rate that is too high results in arcing inside the ion trap and space charge problems. The optimum temperature for the system was around 60°C. The optimum flow rate was 1.0-5.0 μl/min.

Structures of Biopolymers; A Combined MALDI - Ion Chromatography Approach

Thomas Wyttenbach, Gert von Helden, Seonghoon Lee and Michael T. Bowers
Department of Chemistry, University of California, Santa Barbara, CA 93106

The application of mass spectrometry to the analysis of large molecules has undergone explosive growth in the past decade. For the most part, this work has been carried out simply for mass determination and sample identification. In this paper we will present results of conformational studies applying a new method, which has recently been described.[1] An essential feature of this method is a new instrument that couples a MALDI source with our previously developed ion chromatography (IC) device. Another aspect is the significant amount of theoretical analysis that we apply in an effort to identify the conformation of the species in question. Here we will focus on Bradykinin (Bk).[2]

Experiment. The experimental setup has previously been described.[1] Briefly, ions are formed in a MALDI source using a pulsed N_2-laser. The ion pulse thus obtained is mass selected in a double focusing, reverse geometry, mass spectrometer and injected into the ion chromatography cell, which is filled with ~3 torr of He. The ion packet drifts through the cell under the influence of a weak electric field. Ions exiting the cell are collected on a multi channel scaler with 2 μs time resolution yielding an ion arrival time distribution. The drift time, and hence the mobility, of an ion depends strongly on its geometric shape, its conformation. While the mobility cannot directly yield the structure of the ion, theoretically determined structures can be converted to mobilities for comparison with experiment.

Calculations. For the calculation of structures we chose molecular dynamics methods. Since the site of protonation in Bk [2] is not *a priori* obvious, three isomers have been assembled.[3] For each of them 100 low energy conformations were located using a combination of 100 sequential molecular dynamics and energy minimization runs with the AMBER suite of programs. One cycle consists of a 30 ps dynamics simulation at 800 K to move across conformational space, a 10 ps dynamics run while temperature is dropped from 800 K to 200 K and finally an energy minimization to obtain the 0 K structure. Nine of the lowest energy conformations have been selected as input structures for semi-empirical calculations to obtain heats of formation. For all these structures orientation-averaged cross sections, or mobilities, are calculated using the Monte Carlo algorithm described previously.[4]

Results and discussion. The arrival time distribution of protonated Bk [2] shows only the presence of one single narrow peak, which agrees perfectly with a theoretical transport model fit of a single species. We can therefore conclude that either only one isomer in one conformation is present or, if there are multiple isomers and conformations, they have essentially identical collision cross sections of 242±5 Å^2 at 300 K, or the change from one conformation to another is fast on an experimental time scale. The value of 242 Å^2 is slightly higher than the cross sections determined for conformations of the AMBER calculations. It is interesting that all of the AMBER structures have common features. The protonated site is solvated by several groups with excess electron density, such as the neutral guanidine in arginine, the back bone acyl (>C=O) groups and the phenyl rings of the phenylalanines. This multiple coordination gives the ions fairly spherical shapes. Fig. *1a* shows cross section distributions of two 1 ns AMBER dynamic runs at

300 K, one for Bk protonated at the C-terminus arginine and one for the zwitter ionic structure.[3] The mean values of 232 and 225 Å^2 are indicated by vertical lines. Nine representatives of the 0 K AMBER structures, shown in fig. *1b* as a function of relative energy, have been used as input structures for semi-empirical AM1 (fig. *1c*) and PM3 (fig. *1d*) calculations. It can be seen that the semi-empirical structures thus obtained have larger cross sections than those predicted by AMBER and agree better with experiment. On the vertical axis of fig. *1c* and *1d* the heat of formation of the corresponding structure is given. It can be seen that all three isomers [3] have similar heats of formation. The AM1 calculations seem to indicate that the zwitter ionic isomer is the most stable one. PM3 calculations are known to underestimate the proton affinity of arginine by more than 10 kcal/mol.[5] Therefore the PM3 heats of formation for zwitter ionic Bk conformations might be underestimated by the same amount.

It is not *a priori* clear whether purely empirical (AMBER) or semi-empirical (AM1, PM3) methods are more accurate for calculating conformations of large molecules such as Bk. Both methods have advantages and drawbacks. The AMBER force field is highly optimized for peptides and this appears to be appropriate for our applications. However, AMBER has never been optimized for gas phase studies and thus may not be suitable in its present form. Semi-empirical methods, on the other hand, are pushed to the limit when applied to systems with 150 atoms. Furthermore, parametrisation was optimized for neutral molecules. However, we can conclude that structures obtained by semi-empirical methods yield cross sections which agree better with experiment than structures obtained by AMBER.

CITP ESI-FTICR for the Study of X-Irradiation Damaged Tetranucleotides

*Steven A. Hofstadler[1], Zhongxi (Zack) Zhao[1], Richard D. Smith[1], Ed Budzinski[2], Jean Dawidski[2], Jason Gobey[2], and Harold Box[2]

[1]Pacific Northwest Laboratory, Richland WA 99352

A unique advantage of capillary isotachophoresis (CITP) is the ability to pre-concentrate low-level analytes and subsequently perform high resolution separations starting with relatively large (and dilute) sample volumes. The inherent isoelectric focusing and purification common to CITP make it well suited for trace analysis. The coupling of this technique to a high performance mass spectrometric detection scheme provides an unprecedented opportunity to obtain molecular weight and structural information from analytes which are present in a concentration limited regime. We have recently combined CITP with electrospray ionization (ESI) Fourier transform ion cyclotron resonance (FTICR) mass spectrometry in order to analyze and identify low level DNA damage products which result from the X-irradiation of oligomeric DNA in N_2-saturated aqueous solutions.

Damage to DNA is a critical event in mutagenesis, as well as for the initiation and possibly the promotion of carcinogenesis. The necessity of degrading polymeric DNA to the monomer level in order to carry out analyses has invariably complicated the study of DNA damage. Using short oligodeoxynucleotides of specific length and sequence, it is possible to isolate modified oligomers bearing specific lesions and to carry out analysis on the intact modified oligomers.

In this study, we are undertaking the analysis of radiation damage in the tetranucleotide triphosphate d(CpGpTpA). This oligomer provides a unique opportunity to study the relative susceptibility of the primary purine and pyrimidine DNA bases toward radiation damage. An N_2-saturated aqueous solution of d(CpGpTpA) was X-irradiated at a dose of 240 Gy. The resulting damaged (and undamaged) tetranucleotides were separated by HPLC (using an Ultremex 3 µm C_{18} 25 cm x 10 mm column; (Phenomenex)) and a 2 hour elution with a 0-10% acetonitrile gradient in 0.1 M ammonium acetate. A representative HPLC chromatogram is shown in a). Fractions were collected and further separated/concentrated using on-line reversed anionic capillary isotachophoresis utilizing a 50 µm uncoated capillary with 7 mM HCl/13 mM β alanine as the leading buffer and 10 mM caprioic acid as the trailing buffer. A series of FTICR spectra acquired at ≈3 second intervals is shown in b).

The FTICR detection scheme provides high resolution (i.e. > 25,000 FWHM) mass spectra with low ppm measurement error. Additionally, the application of MS/MS methods including collisional induced dissociation (CID) and thermal dissociation in the ESI source provide insight into the location and type of trace level nucleotide damage. The CID spectrum shown in figure c) (acquired on a triple quadrupole instrument) demonstrates fragmentation consistent with the conversion of thymine to hydroxyhydrothymine.

We are presently applying tandem FTICR mass spectrometry techniques, utilizing both sustained off-resonance irradiation and quadrupolar axialization, to probe the structure of several unidentified damage products.

Pacific Northwest Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy, through contract DE-AC06-76-RLO 1830.

Complex Mixture Analysis by using Liquid Chromatography Coupled with Fourier Transform Mass Spectrometry

Brian E. Winger and John A. Castoro, Extrel FTMS, Waters, 6416 Schroeder Rd., Madison, WI 53711-2424.

High performance liquid chromatography (HPLC) in combination with electrospray ionization Fourier transform mass spectrometry (ESI-FT/MS) was used for the analysis of a drug mixture. By using stored waveform inverse Fourier transform, or SWIFT, to continuously eject the protonated drug molecule during the LC-MS analysis, trace impurities that co-eluted with the major component during the chromatographic separation, were detected. Additionally, other trace impurities that eluted after the main drug component were easily detected. Figure 1 shows a comparison of the TIC data obtained a) without the use of SWIFT and b) with continuous SWIFT ejection of the protonated drug molecule. The TIC data in Figure 1a shows only one peak, while the TIC data corresponding to SWIFT ejection of the protonated drug molecule shows several other components. The mass spectrum shown in Figure 2a corresponds to the TIC peak in Figure 1a. Along with the protonated drug molecule, only the proton-bound dimer of the drug and low-abundance fragment ions were observed. By using SWIFT to eject the protonated drug molecule, in addition to the two major fragment ions, peaks were observed between *m/z* 200 and 350 (Figure 2b) for the TIC peak #4. The chemical nature of these components have yet to be identified.

Figure 3 shows the LC-ESI-FT/MS spectra for two of the trace constituents detected by using SWIFT ejection during the analysis (Figure 1b). Figure 3a shows the mass spectrum for TIC peak #6 while the mass spectrum corresponding to peak #8 is illustrated in Figure 3b. Comparing the measured mass of the component in Figure 3a to the calculated mass resulted in a mass error of 0.5 ppm while the mass accuracy for the component in Figure 3b was 2.6 ppm. These data demonstrate that accurate mass analysis can be obtained for trace components in a mixture by using LC-ESI-FT/MS.

An alternative approach to analyzing complex mixtures by LC-MS is direct-infusion ESI-FT/MS in combination with SWIFT ejection of the most abundant species. Figure 4 shows the direct-infusion ESI-FT/MS spectrum acquired with SWIFT ejection of all species below *m/z* 275. The peaks designated with an asterisk (*) indicate trace components expected to be in the mixture. These were the same components that were detected by using LC-ESI-FT/MS. This data indicates that direct-infusion ESI-FT/MS in combination with SWIFT ejection is a viable methodology for the direct analysis of complex mixtures.

MALDI- TOF -MS of Organometallic Species: Comparison to FAB and ESI

Deborah A. Grimm[1], Aaron I. Baba[2], Liang Yongwu[2], Jerald Simon[2], and Russell H. Schmehl[2]
[1]Coordinated Instrumentation Facility and [2]Department of Chemistry
Tulane University, New Orleans, LA 70118

The purpose of this study is to qualitatively compare the MALDI, FAB and ESI spectra of a series of Ru-, Re- and dimetallic compounds. Organometallic species are often characterized by FAB-MS. The FAB technique is hindered by secondary processes and becomes less effective with higher mass and higher charge state. In recent years, ESI-MS has been used to analyze organometallic species. Such compounds have also been analyzed by laser desorption (LD) techniques. The recent development of MALDI-TOF-MS has found most of its application in the biochemical arena, we have had success analyzing organometallic species with this technique.

Organometallic species were synthesized. Their structures are outlined in Table 1. MALDI-TOF-MS were collected on a Finnigan LaserMat 2000. Analytes were mixed in 80% ACN at 1mg/100-500uL. Matrix was a-cyano-3-hydroxy cinnamic acid. About 0.5uL each of analyte, matrix and Sub P (as internal mass calibrant) were co-deposited on the target. 5-20 laser shots were averaged. FAB-MS and ESI-MS were reported at ASMS 1993.

——For comparison, Figs. 1 and 2 show FAB, ESI and MALDI for **I**. **A** has a +1 charge state and shows $(M\text{-}PF_6)^+$ by all techniques. The +2 compounds, **D**,**E**,**I** and **K**, also show $(M\text{-}PF_6)^+$ by all techniques. By FAB and to a greater extent by MALDI, they show loss of $2PF_6^-$'s with reduction. This reduction is not observed in ESI. The corresponding doubly charged ions are observed in FAB and to a greater extent by ESI. The +3 compounds, **B**,**C**, and **F**, show $(M\text{-}PF_6)^+$ by all techniques. The base peaks in both MALDI and FAB correspond to loss of $2PF_6^-$'s with reduction. The doubly charged ions are observed by FAB. ESI on these compounds does not show any reduction, only loss of successive PF_6^-'s. The +4 compounds, **H** and **J**, do not really give any information by FAB or MALDI. ESI appears to be more successful, but some reduction is observed with loss of 3-4 PF_6^-'s. A +8 compound, **L**, was attempted by FAB and MALDI, but no structural information was obtained. Fragmentation is observed in both MALDI and FAB. For example, **I** shows loss of the bpy ligand. (Figs. 1-2)

CONCLUSIONS

1. All techniques give information on organometallic species.
2. Based on the relative intensities of $-2PF_6^+/-2PF_6^{2+}$ the extent of reduction is: MALDI > FAB >> ESI.
3. Both FAB and MALDI appear to lose their effectiveness at higher mass and higher charge state.
4. ESI is much less hindered by higher mass and charge.
5. Both FAB and MALDI produce informative fragmentation.
6. ESI does not produce informative fragmentation.
7. MALDI-TOF-MS spectra are more difficult to interpret because of the lower mass resolution.

ATMOSPHERIC PRESSURE CHEMICAL IONIZATION FOR CE/MS

Yasuaki Takada, Minoru Sakairi and Hideaki Koizumi

(Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo 185, Japan)

Capillary electrophoresis/mass spectrometry (CE/MS) is a promising technique for analyzing mixtures. Two types of interfaces, electrospray and fast atom bombardment, are currently used for CE/MS. However, present ionization techniques can not ionize all of the samples separated by the CE, and the buffer compositions that are available for electrospray are so limited that the extraordinary separation potential of CE has not been sufficiently utilized for CE/MS analysis. Therefore, new CE/MS interfaces based on different ionization methods are required for a wide range of applications.

We previously developed an atmospheric pressure chemical ionization (APCI) interface for CE/MS.[1] The on-line combination of micellar electrokinetic chromatography (MEKC) and MS has been examined using this APCI interface.[2]

The APCI interface consists of an electrospray-type nebulizer,[3] a vaporizer, and an APCI ion source (Fig. 1). We call this interface an "ES-CI interface".[2] One end of the capillary column (50-μm i.d., 150-μm o.d., and 50-cm long) was inserted into the electrospray probe (0.25-mm i.d. and 0.40-mm o.d. stainless steel). The probe was maintained at 3 kV. The sheath flow was pure methanol and the flow rate was 5 μL/min. The vaporizer consists of a stainless steel block, with a 5-mm i d., 60-mm long opening, that was uniformly heated to about 350°C by cartridge heaters. A 3 kV was applied to the needle electrode located between the vaporizer and a first aperture to produce a corona discharge. The vaporized samples and solvent molecules were ionized by the corona discharge, resulting in ion/molecule reactions. The separation mediums used were 25-mM phosphate buffers (pH 6.6) with and without 50-mM sodium dodecyl sulfate (SDS). A net voltage of 5 kV was applied to the capillary. The sample concentration was 1 mg/mL for each component.

When the CE buffers include high concentrations of nonvolatile salts, the APCI method is expected to be more useful than the conventional electrospray method because the APCI process is not heavily affected by these salts.[1] By using the ES-CI interface, we were able to conduct MEKC/MS analysis. Figure 2 show the ion electropherograms of alkaloids obtained by (a) ordinary CE/MS analysis and (b) MEKC/MS analysis. The alkaloids could not be separated by the CE mode, but were separated by the MEKC mode due to the interaction between the sample molecules and the SDS micelles, although the protonated molecular ions of the samples were clearly observed for each mode.

In conclusion, this CE/APCI-MS is a very promising technique because the APCI process is not heavily affected by the salts in CE buffers, allowing the use of a variety of CE buffers that include high concentrations of nonvolatile salts for CE/MS analysis.

Acknowledgment We are grateful to Professor Shigeru Terabe of the Himeji Institute of Technology and Mr. Hiroto Ozaki of Kaneka Techno Research Co. Ltd. for their helpful discussions about the MEKC separation.

Determination of Amino Acids by On-line Capillary Electrophoresis-Electrospray Ionization Mass Spectrometry

Wenzhe Lu, George Yang, and Richard B. Cole*
Department of Chemistry, University of New Orleans
Lakefront Campus, New Orleans, LA 70148 (USA)

Amino acids and peptides are the basic building blocks of proteins and they are important in many scientific and medical areas. The main difficulty to be solved in the CE analysis of amino acids is the problem of detection. Since the majority of natural amino acids exhibit low absorbance characteristics in the UV-visible wavelength range, direct UV detection is rarely used for amino acid analysis. Alternative means of detection include chemical derivatization fluorescence, electrochemical detection, and indirect modes.

Compared to the optical methods of CE detection, mass spectrometry (MS) provides some unique advantages. In particular, much additional structural information can be obtained regarding ionic forms of the molecules separated by CE. The identities of unknown analytes can be deduced from mass spectral information in combination with migration times of the analytes, rather than solely from the migration times. This is particularly important for CE analyses since the reproducibility of migration times in CE is not always easy to control.

In this report, on-line capillary electrophoresis-electrospray ionization mass spectrometry (CE-ESMS) has been used for the separation and detection of amino acid and peptide mixtures. Four natural amino acids, histidine, tryptophan, phenylalanine, aspartic acid, and a tripeptide, glutathione, were separated and determined. Acetic acid electrolyte solutions have been used to separate and detect the amino acid mixtures using CE-ESMS. Elevated buffer concentrations which may offer improved CE separation are often incompatible with ESMS due to high conductance in the CE capillary. A high conductance may impede the ability to maintain a constant voltage, hence, a stable electrospray at the ES needle. Furthermore, high levels of background electrolyte can severely suppress analyte signals in ESMS. Many natural amino acids and peptides have relatively low pI values, hence, these compounds require low pH environments to become positively charged. In this study, relatively high concentrations of acetic acid (operating electrolyte) were used to provide environments sufficiently low in pH to enable protonation of analyte amino acids.

Parameters which have been examined and optimized include capillary diameter (50 to 100 μm internal diameter), applied separation voltage (20 to 30 kV), and electrolyte concentration (10% to 60% acetic acid). Stable working conditions were maintained when the CE currents were less than 18 μA. Protonated molecules were detected in the CE-ESMS mode with detection limits of about one pmol. Because background electrolytes are known to suppress analyte signals, the use of electrolyte solutions such as those described in this report instead of true buffers should offer advantages of reduced signal suppression, as well as increased signal stability.

Capillary Electrophoresis-Ionspray/MS Analyses of Protein Digests Using A Benchtop Single Quadrupole MS

Joseph F. Anacleto, Mark Allen and **Ron Bonner**, SCIEX, 71 Four Valley Drive, Concord, Ontario, Canada, L4K 4V8

Mass spectrometric detection of proteins and peptides separated by capillary electrophoresis offers several advantages over other detection systems. Analytes can be differentiated not only by their migration times but also by their molecular weights and characteristic fragmentation patterns. Mass spectrometry is anticipated to become one of the most powerful and popular detection methods for CE because of its universality, sensitivity, selectivity and structural elucidation capability.

This study illustrates the use of a novel benchtop single quadrupole mass spectrometer (the PE SCIEX API 100) as the detector for CE separations of protein tryptic digests. The API 100 system offers the ability to run a variety of scan modes simultaneously (called mixed-mode experiments). These types of experiments can be used to identify the sites of glycosylation and phosphorylation in glycoproteins and phosphoproteins, respectively, or determine the entire protein sequence in a single analysis by using collisionally induced dissociation (CID) and data base searching.

Glycosylation of proteins is an important feature of protein structure and function. The site of glycosylation and structure of the glycan are currently the focus of much investigation especially for glycoproteins used as therapeutics in humans. Methods have been developed to facilitate the location of glycopeptides in the LC-MS (1) and CE-MS (2) analysis of tryptic digests of glycoproteins by monitoring glycan marker ions at m/z 204 ($HexNAc^+$) and m/z 366 ($Hex\text{-}HexNAc^+$) produced by high energy CID reactions in the ion sampling region of the MS. This technique was used for the CE-MS analysis of a fetuin digest but with a mixed-mode acquisition of both full scan data (at a normal declustering potential in the orifice-skimmer region of the MS) and single ion monitoring (SIM) data of the fragment ion at m/z 204 (at a high declustering potential) in a single analysis. The full scan data provides molecular weight information while the SIM data indicates where the glycopeptides migrate.

Similar methods have been developed to identify phosphopeptides in the LC-MS analysis of tryptic digests of phosphoproteins by monitoring the PO_3^- (m/z 79) fragment ion produced by high energy CID reactions in negative ion mode (3). This technique was also used for the CE-MS analysis of ß-casein and α-casein (Figure 1) tryptic digests with a mixed-mode acquisition of both full scan data (at a normal declustering potential in positive ion mode) and single ion monitoring data of the fragment ion at m/z 79 (at a high declustering potential in negative ion mode) in single analyses. The polarity switching is important in these analyses since peptide molecular ions are usually much more abundant in positive ion mode while the marker ion can only be observed in negative ion mode.

Protein digests were also analyzed by CE-MS using a mixed-mode experiment where full scan data under both low and high energy CID conditions was acquired. The low energy spectra exhibit primarily molecular ions ($[M+2H]^{2+}$ and $[M+H]^+$) while the high energy spectra show prominent fragment ions above the mass of the doubly charged ion (the Y″ ion series). Examining the mass differences between prominent Y″ ions can reveal amino acid sequence information which can be used as a "sequence tag" (4). When the weight of the tryptic peptide along with the sequence tag are entered into the PE SCIEX PeptideScan™ protein database search routine, a list of known proteins containing the peptide is produced.

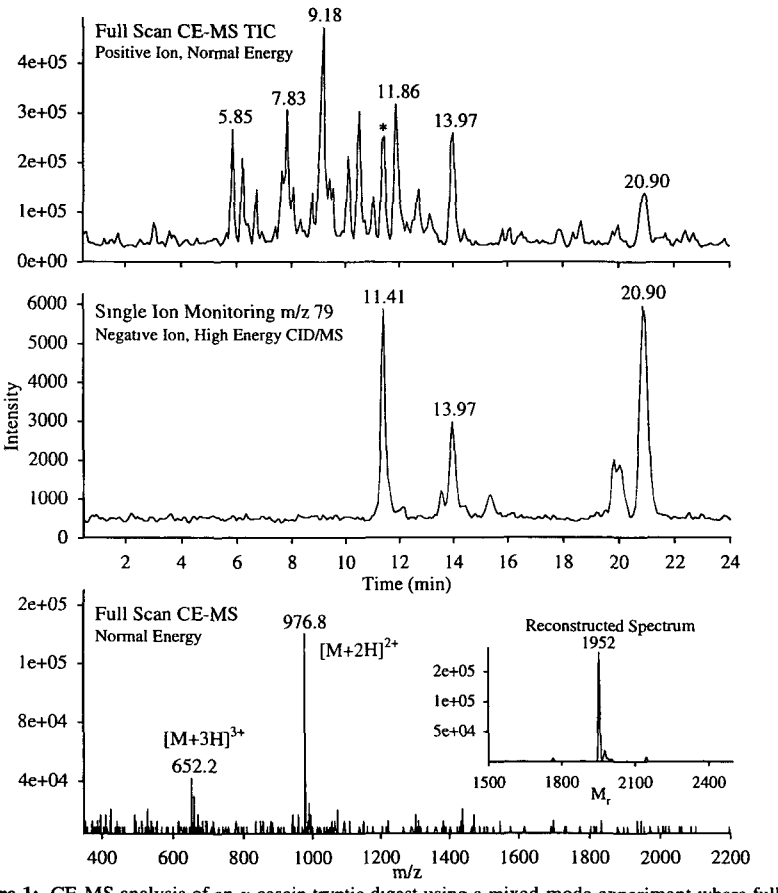

Figure 1: CE-MS analysis of an α-casein tryptic digest using a mixed-mode experiment where full scan data (at a normal declustering potential, 40 V, in positive ion mode) and single ion monitoring data (at a high declustering potential, -200 V, in negative ion mode) are acquired in a single analysis. The CE separation was performed with untreated fused silica (50 µm ID x 180 µm OD x 90 cm) and a 10 mM ammonium acetate, 1% formic acid, pH 2.4 buffer.

CE/ES/MS OF PEPTIDES AND PROTEINS USING A NEW SHEATH-FLOW PROBE

J. Fred Banks and Craig M. Whitehouse
Analytica of Branford, Inc. 29 Business Park Drive., Branford, CT 06405

While ES/MS has rapidly matured into a useful detector for LC, the practical application of CE with ES/MS has lagged behind. This is largely due to the additional challenges associated with CE operation and can be summarized here: (1) CE buffers generally contain no organic phase and therefore cannot be elctrosprayed (2) CE buffers are high in conductivity due to the presence of salts and therefore cannot be electrosprayed (3) CE flow rates are usually well below 1 µl/min and therefore cannot be electrosprayed (4) the CE column body is itself non-conductive so the CE buffer solution must be grounded at the column outlet while it is being electrosprayed.

To overcome these difficulties, we have designed a CE probe based on the sheath-flow concept developed by Smith et al. This arrangement allows for the use of many column chemistries and diameters without further modification and is thus convenient. Various critical parameters including sheath-flow flow rate and composition have been examined to determine optimum performance.

Figure 1 shows the effect that methanol added to the CE buffer phase (0.10 M acetic acid in water) has on the TIC of a separation of peptides (peaks: 1=Arg-Gly-Asp, 2=morphiceptin, 3=Val-Pro-Leu, 4=leucine enkephalin, 5=methionine enkephalin. In general, this shows a trend of increasing peak width and migration time of the analytes. The separation is adversely effected.

Figure 2 shows the effect of sheath flow rate (pure methanol) on the signal of leucine enkephalin analyses. Although the signal decreases, it only does so by about a factor of two over this range.

Figure 3 shows the linear dynamic range and detection limit for leucine enkephalin analyses in SIM and full scan (100-1000 m/z) modes. The detection limits here are 1.5 and 100 fmol, respectively.

Figure 4 shows the average of scans under one the leucine enkephalin peaks as in Figure 1.

Analysis of Peptides and Proteins Using CE/ESI/MS

Mehdi Moini, Ping Cao, Kenneth L. Ray, Anthony W. Holbert

Department of Chemistry and Biochemistry, University of Texas at Austin, TX 78712

Electrospray is a soft ionization technique for analyzing nonvolatile and thermally labile compounds. This ionization technique is especially useful for mass analysis of high molecular weight biopolymers such as proteins and oligonucleotides. Capillary electrophoresis (CE) allows separation of large biomolecules under conditions that favor retention of biological activity. CE/MS is thus a technique of great interest and promise in the field of analytical biochemistry.

Our CE/ESI/MS interface consists of a P/ACE 2100 capillary electrophoresis instrument (Beckman Instruments), CE/ESI interface, and ESI/MS interface. The P/ACE 2100 CE is modified for CE/ESI/MS. In addition, the CE cartridge holder is modified to permit easy exchange between different CE cartridges. The end of the CE capillary is inserted inside a double layer coaxial tubing for sheath liquid and scavenger gas introduction. The ions formed in the electrospray are introduced into the mass spectrometer via an in-house-fabricated ESI interface [1] which consists of a heated capillary tube and then two stages of mechanical pumping in addition to the pumping capability of the Finnigan-MAT TSQ 70 mass spectrometer and the VG TS 250E MS.

Capillary Tip

Several kinds of capillary tips have been examined· HF etched with no gold coating; HF etched and chromium/gold coated; sanded tip; and treated gold coated tip. The latter two capillaries showed similar sensitivity and both showed higher sensitivity than the non-gold coated capillaries; however, the sanded-treated gold capillary was more durable than the HF-etched gold coated tip. Minimum peak width was observed when the gold coated capillary was used.

Capillary Position in the CE/ESI interface

The position of the CE capillary inside the sheath flow tubing plays an important role in peak shape of CE/MS electropherograms. Minimum peak tailing was observed when the end of the CE capillary was approximately 0.3 to 0.7 mm outside the sheath liquid capillary. This is shown in Figure 1. Strong peak tailing for gramicidin S was observed when the CE column was between 0.1 to 1 mm inside the sheath flow capillary, as shown in Figure 1b. In addition, lower sensitivity was observed when the CE capillary was inside the sheath flow capillary. However, the electrospray was more stable than when the CE capillary was outside.

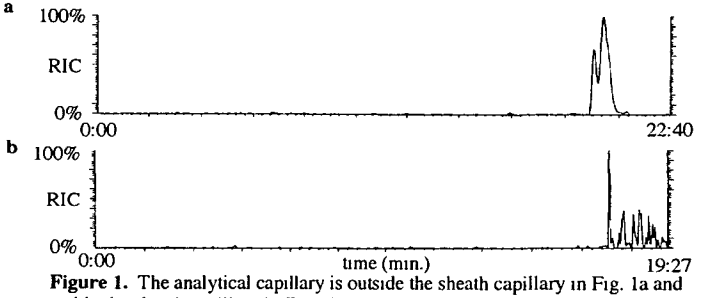

Figure 1. The analytical capillary is outside the sheath capillary in Fig. 1a and inside the sheath capillary in Fig. 1b.

Ethylchloroformate as a New Derivatizing Reagent for CE Capillaries

Successful separation of proteins by CE involves efficient suppression of adsorption to the fused silica wall. Basically there are two approaches to prevent protein adsorption: modifying the fused silica surface by dynamic or static coating or performing the analysis under the conditions that minimize adsorption. The most popular derivatization technique that has been used for CE/ESI/MS is that described by Bruin et al. [2] in which 3-aminopropyltrimethoxysilane (APTMS) is used as derivatizing agent. While this derivatization method has been successfully applied to analysis of proteins and peptides, this derivatization technique tends to clog the CE column. We have used ethylchloroformate (ECF) as a new derivatizing agent for CE capillaries. The ECF does not clog the column and gives separations similar to those of APTMS.

Figure 2 compares CE/ESI/MS of derivatized vs. non-derivatized column for a mixture of lysozyme, cytochrome C, and gramicidin S. As is shown, lysozyme is barely visible in the electropherogram of the non-derivatized column, and the peak for cytochrome c is very wide. With the derivatized CE column, however, peaks are only approximately 4 seconds wide. In addition, the reproducibility of the derivatized column is superior with respect to the non-derivatized column.

Conclusion

Coating the tips of the capillaries with gold increases the sensitivity of the CE/MS apparatus by preventing the dilution of the sample by the sheath flow of liquid. However, the capillary has a greater tendency to plug due to the absence of the cooling effects of the sheath flow liquid. Additionally, the gold coating can be vaporized by both heating due to the capillary current and electrical discharge between the CE and the MS. Further research on techniques to ameliorate these problems is in progress

Derivatization of the CE capillary with ECF decreases the adsorption of proteins on the CE column, enhancing the resolution and, therefore, the sensitivity of detection.

On-line Characterization of Peroxidation Intermediates of NAD+ by CE-ESI-MS

Zhongxi (Zack) Zhao, Harold R. Udseth and Richard D. Smith
Chemical Methods and Separations Group, Chemical Sciences Department,
Pacific Northwest Laboratory, Richland, WA 99352, USA

Equine liver alcohol dehydrogenase (LADH) is one of the NAD-dependent enzymes with various physiological functions. LADH also exhibits several alternative catalytic activities. Among them, the most unusual one is the LADH-catalyzed degradation of NAD^+ in the presence of hydrogen peroxide (H_2O_2). A two-step reaction mechanism has been proposed for this enzymatic peroxidation. In the first (fast) step, NAD^+ catalyzed by LADH is converted to a (so far) unidentified intermediate: "compound I". The following slower step is enzyme independent and consists of at least two distinct processes; one of them leads to another unknown substance: "compound Y" which is the product of further reaction of "compound I" with excess H_2O_2; another process converts "compound I" to adenosine(5')-diphospho(5)-ß-D-ribose-NHCH=C(CHO)$CONH_2$ (NADX) if catalase is added to destroy excess H_2O_2 soon after the end of the faster enzymatic step.

One of the advantages of capillary electrophoresis (CE) is its fast operation cycle, which could be utilized to monitor relatively slow reaction processes. Capillary electrophoresis-mass spectrometry (CE-MS) has the capability of high resolution separations coupled with highly sensitive and selective detection providing crucial molecular weight and structural information.

In this presentation, reversed anionic capillary isotachophoresis (CITP)-electrospray ionization mass spectrometry (ESI-MS) has been demonstrated to separate the reaction mixture and to monitor the reaction process. Also, real-time CITP-tandem MS was utilized to provide both molecular weight and structural information of the interaction intermediates. For reversed anionic CITP, 7 mM HCl/13 mM ß-alanine was used as the leading electrolyte and 10 mM caproic acid as the trailing electrolyte.[1,2] A coaxial sheath liquid interface was used. The sheath liquid was composed of 0.1% formic acid, 24.9% water, and 75% methanol. The mass spectra of the reaction intermediates provided support for the reaction mechanism previously proposed. The results also indicate that a different reaction intermediate ("compound II") could possibly be involved in the interaction, which may provide a clue to further define the reaction mechanism. Figure 1 shows the proposed structural information and CITP-tandem mass spectrum of "compound I".

Electrospray LC/MS With An Ion Trap Mass Spectrometer

Catherine Stacey, Annette Hauser Fang, Frank Laukien, Bruker Instruments, Inc, Billerica, MA
Michael Schubert, Bruker Franzen Analytik, GMBH, Bremen

A new commercial mass spectrometer, the ESQUIRE, has been developed. The instrument uses QUISTOR technology and is supplied with an external ionization source for electrospray, MALDI or LSIMS. MS/MS and MS/MS/MS experiments are easy to perform on a QUISTOR. Collisionally induced dissociation of an isolated ion is easy to perform. Product ions are retained with high efficiency in the trap, to produce high sensitivity CID spectra. Resolution at a standard scan rate of 2000 a.m.u./s is 0.4u at any mass. Thus, resolution sufficient to resolve the charge state of most peptides is possible from on-line separation techniques. A slower scan rate is also available for higher resolution of up to 0.1u.

Further sensitivity enhancements are possible by switching from standard electrospray to low-flow electrospray methods as described below.The use of a new small-scale "micro electrospray" or "NanoSPRAY" needle[1] with a standard electrospray source allows for analysis of 1 µl or less of solution at a flow rate of 25nl/min.The long running time from this low flow rate allows for the analysis of complex mixtures, including the isolation and MS/MS of individual components on less than 5 pmol of sample An added advantage is that the "micro electrospray" is a much more efficient ion source. Concentration sensitivity is improved by the production of smaller droplets which leads to more efficient ion evaporation. The high field strength at the small needle tip allows for onset of the electrospray at low voltages so that aqueous, organic or high salt solutions can be sprayed without arcing.

Examples of proteins using the NanoSPRAY needles show good sensitivity in the low femtomole range Total sample applied to the needles was in the low picomoles and most of the sample could be recovered for other analyses. Analysis of a crude protein digest is possible directly with the NanoSPRAY needles. Since this method is tolerant of a wide range of solvent compositions and buffer and salt concentrations, no sample clean up is needed prior to analysis. Only 1-2µl of sample is used, most of which can be recovered for other techniques.The electrospray spectrum of a tryptic digest of myoglobin shows several prominent ions. Peptide masses were calculated assuming doubly charged ions in each case, and all masses were entered in the search.The search results are shown below. Only equine myoglobin matched to four of the peptides.

An ion from a Lys-C cytochrome c digest was isolated and fragmented by CID in the ion trap. The ion at *m/z* 780 produced an MS/MS spectrum from which the sequences [312]AFIM and [519]IK could be assumed. Searching for the first resulted in matches to cytochrome c in 36 species, all contained the sequence MIFAGIK, the second in 38 matches, including 2 non-cytochromes. A second peptide was isolated for MS/MS. The ion at *m/z* 647 was a double charged ion (M = 1292). Fragmentation produced a series of singly charged fragment ions from which the sequences GFIGHI and IHGIFG could be deduced (The assumption was made that this was the same internal sequence running from C- and N- terminal directions). This peptide was confirmed as TGPNLHGLFGRK, a peptide present in the cytochrome c of 37 species.

Total sample consumption for the series of MS and MS/MS spectra, which were generated in about 10 mins, was 600fmol. More sample remained in the needle should further experiments be required. No sample preparation was involved, and most of the available sample was left for LC/MS methods.

[1] M.Wilm and M.Mann, 42nd ASMS Conference on Mass Spectrometry, Chicago IL, June 1994.

The ESQUIRE™ is an ideal instrument for on-line detection of time-resolved components. Ion accumulation time in the trap can be set so that good sensitivity is possible without compromising the efficient duty cycle of the instrument. A fixed scan rate of 2000 a.m.u./s is available. Most synthetic or enzymatic peptides have an *m/z* range from 300-1000. For tryptic peptides, where cleavage is adjacent to a basic amino acid, fragments will have at least 2 basic sites, the N-terminus and the basic side chain. Thus 2+ions (or 3+ ions if the peptide contains His) are the most prevalent. The separation of a tryptic digest of myoglobin was carried out at a 50pmol, 5pmol and 1pmol level. Previous experiments showed that all significant ions had an *m/z* value > 500u. Each LC/MS run shows a number of peaks from which expected peptides can be confirmed.

[2]Dept. of Chemistry, The Pennsylvania State University, University Park, PA 16802

Direct chemical analysis of living cells has received considerable attention in recent years; the single cell approach provides a major step towards answering important questions in the field of cellular biochemistry. In this work we present preliminary results which demonstrate the feasibility of using the CE-ESI-FTICR combination as a high performance detection scheme for the analysis of cellular proteins acquired directly from small populations of intact living cells. The human erythrocyte (red blood cell) was chosen as a model system owing to its availability, relatively homogeneous composition, and thorough documentation of contents by previous researchers. The contents of the erythrocyte are unusually homogeneous; nearly the entire volume of the cell is filled with hemoglobin, approximately 450 amol per cell, a challenging but attainable level for mass spectrometric detection with current instrumentation. In this work we demonstrate the on-line acquisition of high resolution mass spectra (average resolution ≥ 45,000 FWHM) of the α and β hemoglobin chains acquired from the injection of as few as 10 human erythrocytes† (this corresponds to ≈ 4.5 fmol of hemoglobin). Additionally, when used in conjunction with quadrupolar axialization and sustained off-resonance irradiation, it is possible to directly obtain partial sequence information of selected cellular components obviating the need for additional isolation/purification steps. Given the extremely small volume of the human erythrocyte (typically ≈ 87 fL/cell), we are optimistic that the techniques implemented here will be adaptable to the study of many larger mammalian cell systems.

Shown in Figure (a) is a total ion current (TIC) trace from the injection of 20 erythrocytes derived from the detection of the electrospray ion current signal from the ion beam impinging on the front shutter of the FTICR instrument. The initial peak observed in the TIC trace is attributed to buffer ions from the cell injection procedure. Approximately one minute after the buffer peak elutes, a broad peak due to the major cell contents is observed from which mass spectra of the α and/or β chains of hemoglobin are acquired. The noncovalent tetrameric hemoglobin complex consisting of two α chains and two β chains ($\alpha_2\beta_2$) is dissociated due to the low pH of the 10 mM HOAc CE running buffer. In general, the eluting peaks are broad and poorly resolved due to variations in cell lysing and injection times. The initial spatial distribution of the cell population combined with variable cell lysing times adversely affects the resolution of the separation. These effects are substantially reduced when fewer cells are injected.

The mass spectrum of the α chain in (b) was acquired from the injection of only 10 erythrocytes and demonstrates a nearly complete separation of the α and β chains. The MS/MS spectrum in (c) was acquired from the selective ion accumulation (using single frequency quadrupolar axialization) of the 18+ charge state of the α chain (≈ 75 erythrocytes) followed by sustained off-resonance irradiation (SORI) at -1000 Hz relative to the 18+ α chain. Extensive dissociation producing predominantly y and b fragments is observed.

Efforts are presently underway to improve sensitivity in order to facilitate the analysis of single cells. We believe there are still orders of magnitude improvement in sensitivity to be achieved with the incorporation of more efficient ion generation and ion accumulation methods.

Capillary Electrophoresis/Ion Trap Mass Spectrometry: Achieving Ultra-low Detection Limits

R S Ramsey, D.E. Goeringer, G.J. Van Berkel, and S.A. McLuckey
Chemical and Analytical Sciences Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

Sensitivity remains an important issue in the on-line coupling of CE with MS. The small sample volumes typically analyzed by CE (less than 1-2% of the total column volume) result in high concentration detection limits and the various approaches, including assorted on-line preconcentration strategies, that have been taken to improve LODs often compromise either separation or MS performance. We have interfaced CE with a quadrupole ion trap to exploit its inherent advantages in duty cycle and MS/MS efficiency for high sensitivity analysis. Our previous investigations using a conventional sheath flow electrospray source and 50 µm i.d. columns showed that full scan detection limits for peptides were at the 10 fmole level (1). In view of the advantages that have been cited for small diameter columns in on-line analysis (2,3), we have evaluated sheathless electrospray sources using small diameter gold-tipped capillaries. By optimizing ionization efficiency and enhancing trapping efficiency significant improvements in sensitivity have been obtained.

All analyses were conducted on a Finnigan MAT ITMS (San Jose, CA) modified for ESI. The trap was operated using up to 4 mtorr of helium pressure where an approximate 3 to 8 fold improvement in signal levels for various molecular ions was obtained relative to operation at 1mtorr pressure. The CE columns were tapered at the cathode end to ca. 40 µm o d and 3-5 µm i d. using a laser-based micropipette puller. Sheathless ES interfaces were prepared by coating these tips with a thin film of chromium followed by a 250 nm layer of gold using a magnetron sputtering system. Some continuous infusion experiments to compare capillaries of different i.d. were also performed using gold coated emitters prepared as previously described (4). CE analyses were typically conducted at 20 kV using acetic acid buffers and samples were injected electrokinetically.

Figure 1 shows the sensitivity which has been obtained on-line for our sheathless electrospray CE interface/ITMS combination using columns of moderate i.d. (20µm). A S/N ratio of 6:1 for the lowest injection level of leucine enkephalin indicates that midattomole detection limits in total ion electropherograms may be obtained. MS/MS data could also be acquired on-line from low femtomole injections as shown in Figure 2. In comparing different sources, the sheathless interface was found to provide only modest improvements in signal (factors of 3 to 4) relative to coaxial liquid sources using capillaries of the same diameter. The greatest gains in sensitivity were derived from the use of small diameter columns at low flow rates (e.g., a factor of 60 observed for a 100 vs. 25 µm i.d. emitter). The sheathless interface, however, eliminates solvent effects which may confound detection if the sheath solvent induces changes in charge state distribution which the analyzer is not "tuned" to detect.

A New Setup For On-Line CE-MS

Michael X. Li, Jingtao Wu, Hongwei Li, David M. Lubman
Department of Chemistry, The University of Michigan
Ann Arbor, MI 48109

The combination of capillary electrophoresis(CE) with electrospray ionization mass spectrometry(ESI/MS) has become a powerful analytical tool in biological field. In particular, the high separation efficiency and resolution of CE, combined with the abundant information acquired in the MS in terms of the molecular weight and structure, has made the on-line CE-MS a promising technique in various areas. However, scanning speed and detection mass range are often comprised to obtain sufficient MS signal-to-noise ratio from high efficiency separations. In other words, the sensitivity, scanning speed, and instrument duty cycle would sometimes be critical issues for the identification and characterization of unusually narrow peaks that result from the CE separation.

In this work, the capillary zone electrophoresis(CZE) system has been coupled to an electrospray interface with a quadrupole ion trap (IT)/ reflectron time-of-flight (reTOF) mass spectrometer Since TOF is a nonscanning mass analyzer possessing extremely high sensitivity, the duty cycle can be enhanced enormously, which is essential when it is employed with a CZE system The ion trap acts as a unique tool for the storage of ions over a wide mass range with excellent detection limits and removing unwanted background ions. After a period of storage, the ions are ejected into the TOF tube for mass analysis by applying a DC voltage to the ion trap end cap. Through this storage, both of the resolution and sensitivity were improved greatly

The coupling between the CZE and the electrospray interface utilized a common coaxial sheath flow, where the capillary cathodic end was directly inserted into the electrospray needle and the added sheath liquid flows through the space between them. The flow rate was around 5-10 μm/min, in order to meet the optimum condition for electrospray. The sample was directed into the capillary by electrokinetic method from the ~10^{-4}M sample solution. Separation and detection of peptide mixtures and biological samples have been performed so as to demonstrate the capability of applying this CZE-ESI-IT/re TOF setup in different situations.

Figure 1 shows the total ion electropherogram of three peptide mixture: Angiotensin I, Angiotensin II, and Angiotensin III The injection sample amounts were around high femtomoles. As noticed, when either the sample loading time or the applied injection voltage was increased, the electropherogram peaks became broader and more tailed. Figure 2 shows the separation and identification of two peptides: Substance P and Neurotensin, with FWMH around 20s. The sample consumption of Substance P was at low femtomole range. Figure 3 is the separation of two small peptide mixture· Leu-Gly, Met-Enke-Arg, and TBAH. It was observed that the signal can be optimized by appropriate tuning of the storage time, buffer gas pressure, and the RF voltage applied to the IT ring electrode. While both sample and buffer compositions are possible reasons for

the peak broadening, another important point is the fact that the fused silica capillaries were employed without any coating.

These preliminary results show the promising future of this combination to achieve the success in maintaining the CE resolution and catching up the concentration detection limits, given the potential of Ion Trap and TOF would be fully developed and tuned up in the coupling. As sensitivity around femtomole for most sample components was often achievable and the reconstructed total ion electropherograms with peak widths between 10 to 20s were routinely obtained, it is quite clear that the advantages of the combination that couples the CZE and the IT/reTOF could be really applied to many different application arenas. Nevertheless, in order to utilize this design more broadly, it is necessary to further narrow down the electropherogram peaks, and improve its detection limit so that it can be employed to the extremely diluted mixtures. To do this, several methods are available, e.g. optimize the CZE operating condition and coat the fused silica capillaries.

OFF-LINE COUPLING OF CAPILLARY ELECTROPHORESIS AND MALDI-TOF MS

Kathleen L. Walker,* Rick W. Chiu, Curtis A. Monnig and Charles L. Wilkins,
Department of Chemistry, University of California, Riverside, CA 92521-0403

Capillary electrophoresis (CE) is an efficient tool for the separation of mixtures of ionized molecules. When compared with liquid chromatography, CE usually requires similar analyte concentrations (nanomolar and above) but smaller sample volumes (nanoliters). As a consequence, the quantity of analyte available for detection is extremely limited. The characterization of unknown molecules isolated by CE requires a sensitive detector which can provide detailed chemical information about the analyte. MALDI mass spectrometry is an analytical technique capable of providing the requisite sensitivity and chemical information, but it does not routinely lend itself to the analysis of complex mixtures. However, when mass spectrometry is coupled with CE the resulting instrument provides a very effective means for characterizing difficult samples.

The utility of capillary electrophoresis with mass spectrometric detection has long been recognized, but is difficult to implement. Most often these instruments have been coupled through on-line electrospray ionization sources. While electrospray MS is capable of monitoring a diverse range of chemical species, it can be adversely effected by ionic species such as buffer salts commonly used in CE separation buffers (NaH_2PO_4, NaH_2BO_3, etc). Previous efforts have been made to off-line couple CE and MALDI MS, however most did not demostrate tolerance of diverse CE analysis conditions.[1-4] A more useful coupling of these instruments would tolerate non-volatile and ionic electrolytes, and so not require that the separations be tailored to the shortcomings of the mass spectrometry.

The interface used in these studies contains an on-column ultraviolet absorbance detector to allow isolated zones to be observed prior to passing from the capillary A computer monitors the absorbance signal in real time and positions a laser-target probe tip under the capillary outlet so that zone is collected individually. A conductive polymer coated capillary or a co-axial flow capillary configuration allows electrical contact to be maintained during sample deposition and can allow simultaneous deposition of the sample and the matrix on the probe surface. After the samples have dried, the probes are manually transferred to a MALDI time-of-flight mass spectrometer for subsequent analysis.

The off-line interface is successfully applied to couple CE and MALDI TOF under a variety of separation conditions which are realistic for separation of biological macromolecules. Bonded coatings (Ucon, APTES) and chemisorbed (polyarginine) capillary coatings are used in conjunction with a variety of buffers ranging from 30 mM amine-acetate to high ionic strength (100 mM) sodium phosphate. Samples are collected directly on the laser target probe. The practicality of this instrument for complex mixture analysis is demonstrated by separation and analysis of peptides from a tryptic digest of cytochrome *c* and of synthetic mixtures of proteins. By decreasing the pH of the MALDI matrix solutions, spectral resolution and signal to noise are enhanced through the formation of increased amounts of protonated molecular ions in the presence of the buffer salts.

Sample quantities as large as a few picomoles can be separated and analyzed, however the separation quality is less than optimal under these conditions. Miniaturization of the interface and use of a capillary coated with a conducting polymer allow acquisition of high quality MALDI spectra from sample quantities as low as 150 fmol. Under these conditions the efficiency of capillary electrophoresis is optimal and separation of more complex mixtures is realistic.

Mass data from synthetic protein mixture separated by CE and analyzed by MALDI MS, 150 fmol of each analyte

PROTEIN	EXPECTED MASS#	MEASURED MASS	MASS ACCURACY, ppm	RESOLUTION
Myoglobin	16,951.7	16,949.7	118	142
Ribonuclease A	13,683	13,683.5	37	131
Cytochrome *c*	12,361.5	12,363.1	129	180
Lysosyme	14,307	14,306.7	21	157

LC/Thermospray-mass spectrometry has been extensively applied for the identification and determination of carbamate pesticides in various environmental samples, in our laboratories [1-3]. In these studies the influences of many parameters were investigated and optimized. For some carbamates significant differences between their mass spectra were observed, when using various interface types. Although it has never systematically been investigated, we thought that the ion source geometry might play a role in the ion formation of various types of compounds. In this presentation the results of a comparison study among three thermospray interfaces and their standard ion source (a Hewlett Packard 5988A, and a Finnigan MAT TSQ 700 with their respective standard TSP interfaces and a Vestec 700 TSP interface on a Finnigan SSQ 4600) are presented using 16 carbamate pesticides (*N*-methylcarbamates, *N*-phenylcarbamates, Methyl ester substituted carbamic acid and a *N*-dimethylcarbamate) [4].

Table 1. The main ions formed, and their relative abundances, of sixteen carbamates with a Vestec (A), a HP (B) and a Finnigan (C) type of thermospray interface, using filament assisted ionization with an 50:50 mixture of methanol-water and 100 mM ammonium acetate adjusted at pH 6.

	Compound	200 °C			250 °C			300°C		
m/z	ion structure	A	B	C	A	B	C	A	B	C
	Aldicarb									
249	$[M+59]^+$	3	8	10	2	11	14	1	7	16
222	$[M+32]^+$	23	13	2	20	13	5	21	29	17
208	$[M+NH_4]^+$	100	100	100	100	100	100	100	100	45
191	$[M+H]^+$	7	7	5	8	12	14	10	15	15
148	$[M+H-MeNHCOOH+MeOH]^+$	7	6	15	14	24	59	30	60	100
	Carbofuran									
280	$[M+59]^+$	3	11	9	2	10	4	1	3	2
239	$[M+NH_4]^+$	100	100	26	63	71	5	30	10	
222	$[M+H]^+$	72	30	100	100	100	100	100	100	100
	Promecarb									
266	$[M+59]^+$	2	12		1	7	2	1	8	2
225	$[M+NH_4]^+$	100	100	100	100	100	100	100	100	22
208	$[M+H]^+$	15	10	10	20	17	53	40	75	100

In Table 1 the results are listed for some representative carbamates. For 12 of the 16 investigated carbamates nearly identical results are obtained if the different thermospray interfaces are operated under comparable conditions and at an ion source temperature of 200 °C. The differences in the mass spectra of the other four compounds are related either to their thermal instability (asulam, thiodicarb and thiofanox) or to a strong heat and pressure dependence of the equilibrium between the protonated molecule and the ammonium adduct ion (carbofuran). Increasing the ion source temperature to 250 and 300 °C diminishes the formation of ammonium adduct ions and promotes fragmentation. This source temperature effect is largest for the Finnigan interface and consequently causes a divergence in the thermospray mass spectra obtained with the various TSP interfaces. It was found that an ion source temperature of 250-260°C results in the highest signal to noise ratio for all compounds and interfaces (Figure 1). Furthermore, for some carbamates at all ion source temperatures a [M+32]+ ion was observed, which is probably due to thermally-assisted hydrolysis of the carbamate group in the vaporizer probe prior to ionization.

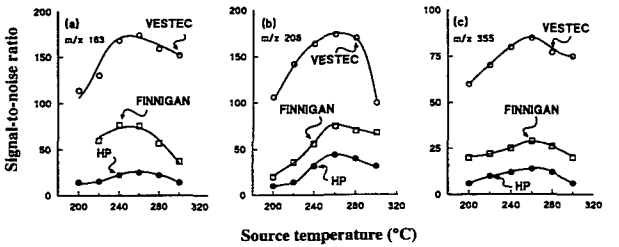

Figure 1. The signal-to-noise (S/N) ratios for the protonated molecules, $[M+H]^+$, of methomyl (A), promecarb (B), and thiodicarb (C), at m/z 163, 208 and 355, respectively, as a function of the ion source temperature

Determination of Anabolic Steroids by HPLC UV-VIS/Particle Beam Mass Spectrometry

Mantai Z. Mesmer and R. Duane Satzger, USFDA, Forensic Chemistry Center,
1141 Central Parkway Cincinnati, OH 45202

In February of 1991 Congress designated 27 steroids and their esters, salts and isomers as Schedule III Controlled Substances. This action expanded the analyses of steroids from toxicological to forensic areas (seized exhibits). Commercially available anabolic steroids are synthetic derivatives of testosterone and include many closely related ring structures as well as their esters. Products seen in the illegal market are mostly oil based injectables, water suspensions, dietary supplements and herbal drugs marketed as capsules or tablets, which often do not contain the ingredients declared on the label.

The analysis of steroids is complicated by the sheer number of known steroids (over 7000), the close structural similarities common to the entire class, their poor volatility, thermal lability and low UV extinction coefficients. We have developed a general screening method for the determination of anabolic steroids in oil based injectables and other pharmaceutical preparations. The compounds are extracted into methanol and separated on a reversed phase column with an acetonitrile/water gradient and detected by using a uv-vis detector and mass spectrometer sequentially. Identification is based on retention time, uv spectra and mass spectra. Mass spectral confirmation is accomplished by matching with a standard when available, and/or by comparison with in-house generated or commercially available library of EI mass spectra

The mass spectrometer used is a Hewlett-Packard 5989A equipped with a particle beam interface. Mass spec parameters were set as follows: ion source temperature: 250° C, quadrupole at 100° C, EM voltage 2072V, mass range monitored 56-460. The HPLC is a Hewlett-Packard model 1090L equipped with a photodiode detector.

The EI mass spectra of 36 steroid standards were generated by FI introduction of 200-1000ng amounts into the mass spectrometer and stored in a unique library. This library is used frequently in our laboratory for confirmation of the presence of anabolic steroids in forensic samples. We have found acetonitrile to be a better mobile phase than methanol because, as the percent methanol goes above 90 there is a drastic increase in the baseline of the total ion chromatogram, while increasing percentage of acetonitrile has little effect on the baseline. In addition, acetonitrile shows less overall background and a lower UV cutoff. There is no significant difference in sensitivity when using either solvent.

Under the gradient conditions used (from 60% acetonitrile to 90% acetonitrile in 20 minutes) one can separate at least 21 of the anabolic steroids used in this study. The tandem nature of the analysis provides quantitative as well as qualitative information in a single experiment. Figure 1 is the total ion chromatogram of a herbal medicine claimed to cure a host of ailments. Only methyltestosterone and sugars were detected in the sample. Figure 2 is a total ion chromatogram of a veterinary drug sample suspected of containing four steroids in cottonseed oil. All four steroids were confirmed in the sample using the in-house generated library of EI spectra. The percent recovery for three representative steroids spiked in sesame oil is better than 96%. We have applied this method in the analysis of oil based steroid containing vet drugs, food supplements and herbal drugs.

LC Particle Beam MS with Massive Cluster Impact

T.-C.L. Wang, L.J. Cornio and S.P. Markey
Section on Analytical Biochemistry, National Institute of Mental Health, Bethesda, MD 20892

Introduction

Massive cluster impact (MCI) uses very large, highly charged clusters of glycerol as a primary desorption beam. The primary beam is formed by electrohydrodynamic emission of an electrolyte-glycerol solution in a vacuum(1). One advantage of this technique compared to FAB/SIMS is the formation of singly and multiply charged molecular ions similar to electrospray ionization(2). Secondly, liquid matrices are not required for the successful desorption of biomolecules by MCI ionization. MCI produces spectra from dissolved samples in commonly used FAB/SIMS liquid matrices and from dry solid samples(3).

Particle beam LC/MS with FAB has been reported(4). Interfacing particle beam LC with MCI mass spectrometry allows transport of desolvated molecules to the probe target and desorption and ionization of the solid samples. The feasibility of LC particle beam with MCI was demonstrated by repetitive flow injections of acetylcholine and gramicidin S.

Experimental

All the experiments were performed on Finnigan-Mat TSQ-70 mass spectrometer equipped with a Phrasor Scientific (Duarte, CA) MCI ion gun. The MCI gun was positioned on a 0.5" thick Lucite window in line with the EI electron entrance hole. The solution used for cluster generation was 1.5 M ammonium acetate in glycerol. The flight tube for the cluster beam was approximately 1.5" away from the probe. Typical MCI gun operating voltages were 17 kV on the emitter, 15 kV on the focus element, and 2 to 5 kV on the extractor. The optimal signal stability was obtained when cluster current monitor indicated between 4 to 10 μA.

A Hewlett-Packard (HP) particle beam interface delivered essentially solvent-free analyte molecules through a side port directly into an EI ion source at room temperature (Figure 1). The EI ion source was inverted from its normal orientation and the filament block was removed. The LC (HP-1050) flow rate was 0.4 mL/min and the solvent was 1:1 water and methanol. For gramicidin S experiments, 0, 15, or 50 ppm of glycerol was added to the water.

A 45° polished copper probe tip similar to the Finnigan standard FAB/SIMS copper tip but four times larger surface area was positioned ~45° to the incidence of the cluster primary beam and ~45° to the incoming particle beam.

Results and Discussion

The feasibility of LC particle beam with MCI was first demonstrated by repetitive injections of 20, 50, 100 and 200 ng of acetylcholine. The ion chromatogram contains peaks 30sec wide with consistent height as detected by selected ion monitoring (SIM). This result indicates that dried molecules were transported by the particle beam and desorbed completely from the target surface by the massive cluster beam in a relatively short period of time. The background was monitored by characteristic debris ions from MCI (e.g., m/z 110, 202, etc.). They remain constant. LC particle beam MS with MCI was further tested with a larger molecule, gramicidin S. Full scan spectra of gramicidin with 10 to 1 S/N can be obtained by repetitive injections of 440 picomoles of gramicidin S. Clearly, molecules as large as gramicidin S were able to be transported by the particle beam, desorbed, and mass analyzed. It was found that mixing glycerol in the mobile phase improved the stability and sensitivity of detection. The sensitivity of the present instrument configuration was shown by repetitive injections of 44 picomoles of gramicidin S detected by SIM of the +2 charge state, $[M+2H]^{2+}$, of the molecule (m/z 571, Figure 2). In this experiment 25 ppm of glycerol was added to the mobile phase.

From our initial results, the LC particle beam MS with MCI shows great applicability and sensitivity for polar organic compounds and has potential of becoming a routine LC/MS device.

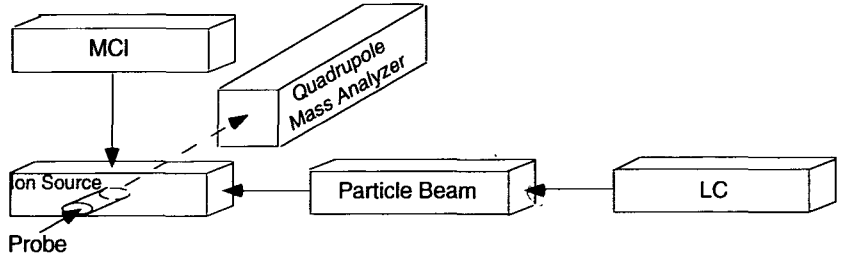

Figure 1. Block diagram of LC particle beam with MCI.

Particle Beam LC/MS using a Glow Discharge Ionization Source

Patrick A. DePalma, Jr., Jianzhang You, and R. Kenneth Marcus

Clemson University, Department of Chemistry, Howard L. Hunter Laboratories, Clemson, SC 29634-1905

Ross C. Willoughby and Edward W. Sheehan

Chem-Space Associates, 75 Chapel Ridge Place, Pittsburgh, PA 15238

The coupling of liquid chromatography with mass spectrometry has proven to be a powerful tool for the analysis of involatile organic compounds which heretofore have required substantial chemical processing for GC/MS analysis. Less common has been the use of LC separation of elemental (inorganic) species prior to mass spectrometric analysis. Unfortunately, ion sources which are applicable to one type of analysis (organic/inorganic) are not applicable for the other. For example, chemical ionization is not a viable option for elemental analysis. A "universal" ion source which could be applied to both sample types could be very valuable. The glow discharge is one such device.

For this presentation, we describe the interfacing of liquid chromatography to a hollow cathode ion source via a particle beam interface. Specifically, a hollow cathode discharge has been adapted to a particle beam LC/MS instrument (benchmark™, Extrel). The combination of a thermoconcentric nebulizer, particle beam interface, and the hollow cathode discharge allows the efficient introduction of low volatility mobile phases (e.g., water) at flow rates of up to 1.5 mL/min. Data will be presented illustrating the utility of this combination of sample introduction and ionization in the analysis of organic, organometallic, and elemental species. The role of discharge conditions on the fragmentation of organic species and intensities of atomic ions will be presented as a point of comparison to existing methodologies. Figure 1 contains the stacked electron impact (EI), chemical ionization (CI), and representative glow discharge (GD) spectra of brucine.

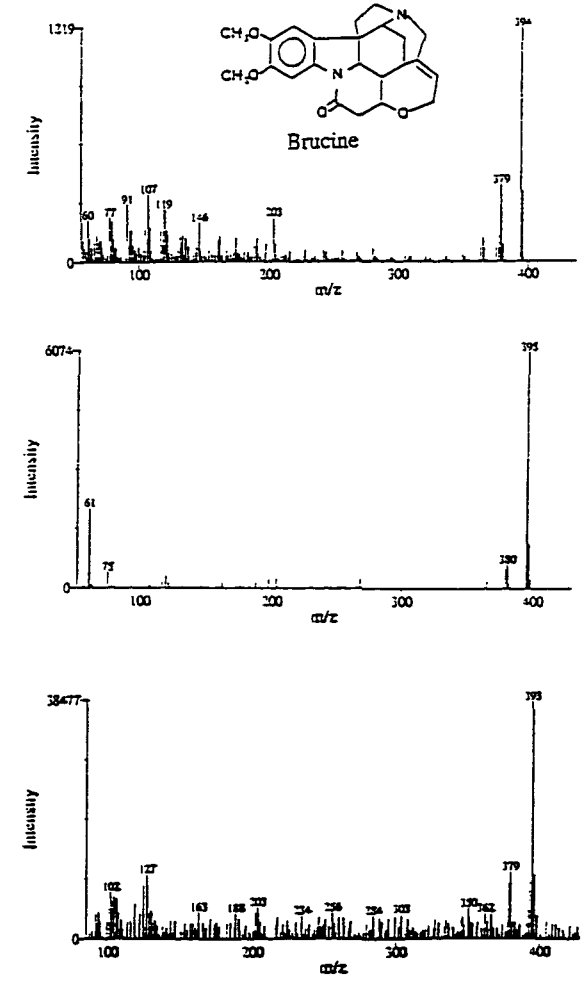

Figure 1. Electron impact (EI), chemical ionization (CI), and glow discharge (GD) mass spectra of brucine, respectively.

Application of LC/Particle Beam/MS for the Identification of N-Nitrosamines in Cosmetic Skin Products and Their Raw Materials

Stanley M. Billedeau, Jon G. Wilkes, David L. Vollmer, and Harold C. Thompson, Jr. FDA, NCTR, Jefferson, AR 72079

INTRODUCTION: For many years the occurence of volatile N-nitrosamines, known carcinogens (e.g.: R_2N-N=O), in various consumer products (bacon, latex rubber infant pacifiers, beer, and nitrite preserved hams packaged in latex rubber netting) has been monitored and regulated.To reduce or eliminate these hazardous contaminants and hence, lower the risk of cancer posed by human consumption or use of such products. Recently, a reversed phase LC/particle beam (PB) interfaced to a TEA or LC/PB/TEA method[1] for detection of low volatility N-nitrosamine contamination in cosmetic skin creams has been introduced using a parallel confirmation by LC/PB/MS employing EI/MS and (+) ion, methane CI/MS[2]. N-Nitrosodiethanolamine (NDELA) and N-nitrosomethyl-p-amino-2-ethylhexylbenzoate (NMPABAO) are two low volatility nitrosamines reported as contaminants in skin care cosmetic products.[1,3] In this study, a forced nitrosation reaction (1 M $NaNO_2$ at pH 2.5 and/or Bronopol addition) was performed on several cosmetic raw materials used in formulations of skin creams or moisturizers. The objective was to determine the possibility of formation of N-nitrosamines in the raw materials under similar conditions present in off-the-shelf cosmetic products.

EXPERIMENTAL INSTRUMENTATION: The LC/PB/TEA consisted of a Spectra Physics 8800 LC pump with a Universal Interface UIB (Vestec, Houston, TX) with a single stage momentum separator for particle beam and a TEA model 502 (Thermo Electron, Waltham, MA). The PB/MS used a UIB with a dual stage momentum separator interfaced to a Vestec LC/MS model 201 (Vestec, Houston, TX). The LC/Electrospray was performed on a Finnigan MAT TSQ7000 (San Jose, CA). The LC column used for LC/PB/TEA and EI/MS was a MetaChem C-8, 250 x 4.6 mm, pumped isocratically at 1 ml/min of 80:20 ACN/water (0.025 M NH_4 Acetate). The ESI/MS was performed on a Microbondapak C-18, 300 x 3.9 mm column at 1 ml/min of 85:15 ACN/water using a 1:4.5 split (or 222 μl/min into the MS).

NITROSATION PROCEDURE : A 20-50 mg sample of the raw material was weighed into a 10 ml tube. A 1 ml aliquot of $NaNO_2$ (1 M in 2.5 pH glacial acetic acid) solution was added to the tube and vortexed for 1 min to mix. The reaction was carried out for 1 hr at room temperature in the dark. The nitrosation is stopped by addition of 2 ml of sat. Na_2CO_3 (pH=10). The resulting solution is extracted with 5 ml of hexane (3 + 2 ml). The combined organic (top) phase was evaporated to dryness (in low light conditions). The raw material extract is made up in exactly 2 ml ACN. Ten microliter aliquots of the final 2 ml extract was analyzed by LC/PB/TEA and EI/MS and 20 ul of a 1:10 dilution was analyzed by LC/ESI/MS. The same extraction procedure was used on the non-nitrosated raw materials (with no $NaNO_2$ present) and a blank (1 ml of pH 2.5 glacial acetic).

RESULTS AND DISCUSSION:

LC/PB/TEA The TEA analysis of the nitrosated Padimate O recorded peaks at 6.3, 7.0, 7.7 and 8.5 min. The 7.0 min peak was the N-nitroso Padimate O (NMPABAO) which has also been confirmed by particle beam EI and (+) methane CI/MS in a cosmetic cream formulation.[2] The NMPABAO peak was an order of magnitude greater than in the parent material due to the forced nitrosation. Both allantoin and imidazolidinyl urea were subjected to the nitrosation procedure. No other TEA response was shown past the 2.3 min peak near the void volume (i.e. indicates no nitrosation occurred and little chance of problems from nitrosamine contamination in skin cream products).

LC/PB/EIMS Although the retention times were slightly shorter, the LC/PB/MS chromatogram (Fig. 1) indicated that following nitrosation of the Padimate O, the parent material is the major peak at 7.3 min exhibiting a strong EI spectrum with 277, 278, and 165 ions (M, M+1, and 100% peak, resp.) and four other peaks at 5.2, 5.5, 6.1, and 6.5 min. The 5.5 and 6.1 min peaks are the free amine, MPABAO, a very minor peak, and the N-nitrosamine of MPABAO (NMPABAO), respectively. These two peaks were previously identified by EI and (+) methane CI/MS in a nitrosated cosmetic sample containing Padimate O.

LC/ESI/MS To obtain molecular weight data, the nitrosated Padimate O extract was subjected to electrospray ionization (ESI). The RIC and several ion chromatograms are shown in Figure 2. Although retention times were not comparable with EI/MS chromatograms, the 6.1 min major peak was confirmed to be the parent material exhibiting M+H and M+H+ACN (or M+41 m/z) ions at 278 and 319 m/z. Although an NMPABAO peak was not detected, a 5.1 min peak with ions at 305 and 346 m/z was indicated which was also detected by EI/MS.

CONCLUSIONS: Two of the three raw materials, allantoin and imidazolidinyl urea, indicated no sign of N-nitrosamine formation following nitrosation. However, as in similar experiments on a cosmetic cream containing Padimate O, the nitrosation of the raw material produced the N-nitrosamine, NMPABAO, and several other possible compounds which need to be identified. The use of UV degradation studies using LC/PB/TEA and EI/MS may be useful in helping to identify the unknown peaks as UV labile N-nitroso compounds. Also, experiments using UV photolysis prior to ESI/MS will be used to further examine the nitrosated raw material as well. We feel that the combination of LC/PB/TEA, LC/PB/EIMS and LC/ESI/MS will be a powerful tool for helping to answer some if not all of the questions presented by environmental nitrosation of amine raw materials in cosmetic skin products. Although there are hundreds of primary, secondary, and tertiary amine raw materials used in formulating skin care cosmetic products, it is possible that utilizing analytical techniques such as these will make the job of determining which raw materials do not undergo nitrosation in real world cosmetic formulations a little easier for the FDA chemist.

SFC/MS: DEVELOPMENT AND PROBLEM SOLVING

J. David Pinkston, Rosemary T. Hentschel, Claudia A. Smith, Timothy R. Baker, and Donald J. Bowling, The Procter & Gamble Company, Miami Valley Laboratories, P.O. Box 538707, Cincinnati, Ohio 45253-8707 U.S.A.

This presentation (1) illustrates the power of supercritical fluid chromatography/mass spectrometry (SFC/MS) for solving industrial problems with representative examples, and (2) describes the design of and early results from a modified electrospray ionization (ESI) interface for open-tubular SFC/MS. SFC/MS is a powerful technique for solving problems in a variety of industrial areas. The utility of SFC/MS is ultimately drawn from the unique combination of properties inherent in a supercritical fluid mobile phase: as compared to a liquid, supercritical fluids offer greater efficiency and/or greater speed of analysis; as compared to a gas, supercritical fluids provide greater molecular weight range. In addition, SFC/MS with a traditional ion source allows full access to electron and chemical ionization techniques for nonvolatile analytes. These ionization methods can be powerful tools in solving problems, and are not always available with modern liquid chromatography/MS methods. Applications of SFC/MS involve mixtures which range from nonpolar (polysiloxanes), to moderately polar (surfactants), to ionic (polyacrylates). Low molecular weight polysiloxanes and polysiloxane-containing polymers are important components in many industrial and consumer products. The detection and identification of low levels of polysiloxanes, especially functionalized polysiloxanes, can provide valuable clues in deciphering the structure of a polymer. Figure 1 shows an example of this type of work. The left trace shows the reconstructed-ion-current chromatogram of a functionalized polysiloxane. The NH_3 CI spectrum of one of the components, the oligomer containing 16 dimethylsiloxane units, is shown on the right. We postulate that this oligomer is capped with a phenyl group on one end, and an alkyl chain bearing a hydroxyl group on the other. Other examples of mixtures which we have characterized using SFC/MS include surfactants and emulsifiers, "active" (i.e., tend to adsorb on components of a chromatographic system) pharmaceutical agents, and polyacrylates.

Most open-tubular SFC/MS is performed with pure CO_2 as mobile phase, pressure/density programming, a fixed flow restrictor, and the direct-fluid-introduction interface coupled to an EI/CI ion source. The flow of CO_2 from the column to the ion source thus increases over the course of a separation. This usually has little effect, but can cause a change in the ionization mechanism and/or the ion transmission efficiency under some conditions. Atmospheric pressure ionization should avoid this potential source of problems. The groups of Henion (1) and Markides (2) have used the "heated nebulizer" and atmospheric pressure chemical ionization. Sadoun et al. have used ESI for SFC/MS (3). However, adding an organic modifier to the mobile phase was required for ionization. We've designed a "sheath-flow" interface for SFC/ESI-MS. Addition of modifier to the mobile phase prior to the separation is not required. Figure 2, an example of our early results, shows the SFC/ESI-MS chromatogram and spectrum for didodecylamine. As expected, the spectrum is dominated by the ammonium adduct ion. The [M+44+1] is an adduct with CO_2 which may be formed in the ion source or in the chromatographic column.

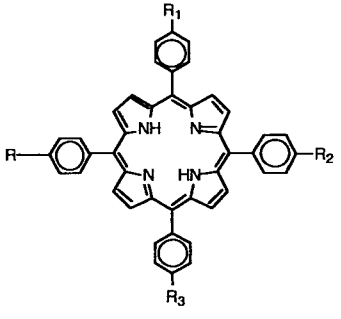
Separation and Identification of *meso* substituted tetraphenylphorphyrins

M. R.Marques Domingues, M. A. Faustino, M. G. O. Santana Marques, and A. J. Ferrer Correia

Department of Chemistry - Mass Spec. Lab., University of Aveiro - Portugal

Porphyrins and related tetrapyrrolic analogues are a large and important group of natural and synthetic compounds. They play a significant role in life biochemistry, chemistry, chemical industry, geology and medicine Some of their more recent applications are as oxidising catalysts, in the conversion of light energy in chemical energy, as diagnosis agents and in photodynamic therapy[1]. Mass spectrometry has been widely used for the characterisation of this compounds specially after the development of desorption ionisation methods.

In this work HPLC with Vis and MS detection was used to analyse a synthetic mixture of *meso*-substituted tetraphenylporphyrins that were not amenable to separation. The mixture was obtained by condensation of pyrrole with 4-methoxybenzaldehyde and 4-nitrobenzaldehyde by using a published method[2]. The presence of a mixture sample was confirmed by FAB-MS although it was not possible to identify, positively, all the constituent porphyrins. The porphyrins that we expected to be in the mixture are shown in Figure 1.



Porphyrins	
1	R=R1=R2=R3=OCH3
2	R=R1=R2=OCH3 ; R3=NO2
3	R=R1=OCH3 ; R2 =R3=NO2
4	R=R2=OCH ; R 1=R3=NO2
5	R=OCH3 , R1=R2=R3=NO2
6	R=R1=R2=R3=NO2

Figure 1

We were unable to separate this porphyrins by the usual methods, although several attempts were made using normal phase and reverse phase HPLC. Only when carbonated methanol was used as eluent in reverse phase HPLC the separation was possible.

HPLC separations were carried out using a reverse phase HPLC system (307 Gilson) and Vis absorbance detector (SFA 103, Kratos, Schoeffel Instruments) monitored at 410 nm. The eluent consisted of carbonated methanol prepared by addition of 1.4% ammonium carbonate to methanol HPLC grade. The flow rate was 0.5 ml/min. Samples were injected in the column (5μl) in chloroform solution.

FAB and Coaxial Continuous Flow-FAB mass spectra were obtained using a VG Autospec EBE-Q mass spectrometer equipped with a OPUS2.1c data system. A focused Cs ion gun with a primary ion of 20 keV energy and ion current about 3 μA was used. For FAB -MS 3-nitrobenzylalcohol was used as FAB matrix and for Coaxial Continuous Flow / FAB the matrix solution was methanol / 3-NBA / TFA 3% (87/10/3).

In the HPLC analysis of the mixture six peaks were separated. The FAB mass spectra of the mixture show some major peaks that we can identify as the $[M+H]^+$ ions of the porphyrins which were expected to be in the mixture. The correspondent molecular ion $M^{+\cdot}$ are also present but with less abundances, in agreement with other published FAB - MS studies of porphyrins[3]. The same HPLC system was also directly interfaced with a Coaxial Continuous Flow / FAB probe. The Selected $[M+H]^+$ Ions Chromatograms of porphyrin 1 and porphyrin 2 are shown in figure 2. The five porphyrins were identified by their $[M+H]^+$ ions.

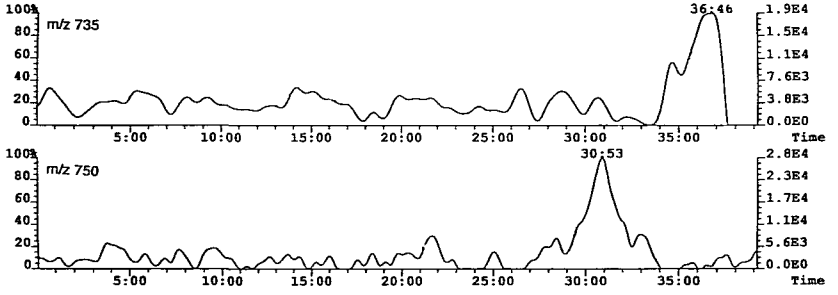


Figure 2-Selected $[M+H]^+$ Ions Chromatograms of porphyrin 1 (m/z 735) and porphyrin 2 (m/z 750)

The presence of six compounds is confirmed by HPLC and five of them are identified as the *meso*-substituted tetraphenylporphyrins 1-5, by HPLC/MS from their $[M+H]^+$ ions.

HPLC directly interfaced with a Coaxial CF-FAB is an important and rapid method for the analysis of mixtures such as the porphyrin mixtures obtained either during the process of organic synthesis or in the extraction from natural compounds.

Quantitative Analysis of Abscisic Acid in Plant Embryogenic Tissue Using Liquid Chromatography/Continuous Flow Secondary-ion Mass Spectrometry with Reaction Monitoring: a Comparision with the ELISA Assay

L.R. Hogge, S.R. Abrams, G.D. Abrams, C.A. Bock, D.I. Dunstan , D.J. Olson and A.C. Shaw

Plant Biotechnology Research Institute, National Research Council of Canada
110 Gymnasium Place, Saskatoon, Saskatchewan, S7N 0W9, CANADA

Introduction:

The plant hormone (+)-abscisic acid (ABA) is known to regulate many processes in higher plants. We are interested in how (+) and (-) ABA stimulate spruce somatic embryo maturation, in order to develop procedures that will be applicable to a broad range of genotypes. As part of this approach it was necessary to determine the uptake and fate of exogenous ABA by the plant tissue during the maturation process. An ABA-enzyme-linked immunosorbent assay (ELISA) system provides a relatively accessible and sensitive method for quantifying natural ABA. In addition to the ELISA system, we have used packed capillary liquid chromatography /liquid secondary ion tandem mass spectrometry (LC/LSIMS/MS) to achieve two objectives: a) to develop methodology for quantifying ABA extracted from spruce embryogenic tissue, and b) to discriminate between ABA of exogenous and endogenous origins. This report describes the MS methodology developed as well as the results obtained from the analysis of Picea glauca x engelmannii somatic embryogenic tissue extracts.

Experimental:

ABA extraction from tissues:

Internal standards [8',8',8',9',9',9'] (+) d_6 ABA and [7',8',9'] (±) $^{13}C_3$ ABA were synthesized at this institute using a procedure that will be published elsewhere. Two hundred ng of the d_6 ABA was added to 10 mg of lyophilized plant tissue and the mixture extracted with .05% acetic acid in MeOH overnight. The samples were centrifuged, filtered using 2 µm filters and evaporated using a SpeedVac. The extracts were re-dissolved in MeOH and eluted through an acidified LC-SCX column, the filter washed with MeOH and the eluates evaporated to dryness. The extracts were re-dissolved in 50% MeOH:water, filtered through a Centricon-3 filter using a centrifuge, divided into two aliquots (one for ELISA and one for LC/MS/MS) and evaporated to dryness. Finally the aliquots for LC/MS were dissolved in 25% acetonitrile in water at a concentration of 10 ng/ul of the d_6 ABA internal standard (calculated from the original amount of standard added).

ELISA:

An indirect ELISA for (+)-ABA was used, following the method of Walker-Simmons, 1987.

LC/MS and LC/MS/MS analyses:

All analyses were done using an Applied Biosystems Model 140A Solvent Delivery Syringe Pump System. Samples were injected through a Rheodyne Model 7520 injector (1 µL loop) on to a Spherisorb 3 micron C18 ODS2 (0.32 mm ID by 200 mm) packed capillary column prepared in this laboratory.

The mobile phase used for the LC analyses consisted of the following: solvent A, 0.1 % TFA and 2% glycerol in 95 % acetonitrile; solvent B, 0.1% TFA in 2 % glycerol. The gradient elution program was as follows: 90% solvent B to 30 % in 10 min, held for 2 min, then to 0% in 3 min and then held for 10 min.

The LC system was interfaced to a VG Analytical 70-250 SEQ hybrid mass spectrometer equipped for continuous flow SIMS analysis. Reaction monitoring experiments were carried out by monitoring the loss of water from the protonated molecular ions for d_6 ABA (m/z 271.1 to 253), $^{13}C_3$ ABA (m/z 268.1 to 250 .1) and ABA (m/z 265.1 to 247.1).

Results and Discussion:

The spruce cultures were grown on medium containing 40 µM (±) ABA. The ABA taken up by the cultures was measured using LC/MS/MS and the ELISA system.The LC/MS/MS results and a comparision of these data with the ELISA data are shown here.

It is important to note that in order to obtain useful LC/MS data with the packed fused silica columns, it was necessary to elute the extracts through a high molecular weight filter and an LC-SCX ion exchange column prior to analysis. Without these additional cleanup steps, we have observed a serious degradation in both the chromatographic separation and the intensity of the ion current.

The two internal standards, d_6 ABA and $^{13}C_3$ ABA were used for reaction monitoring (loss of water transition) MS quantitative analyses with several calibration curves generated. This was done by analysing a known amount of the d_6 and $^{13}C_3$ standards relative to varying amounts of natural ABA respectively as well as a known amount of d_6 relative to varying amounts of $^{13}C_3$ ABA. **Figure 1** shows the plot of the natural ABA ion count/ d_6 ABA ion count ratio against the amount of ABA injected. The plot is linear over at least the range of 500 pg to 13 ng of ABA injected.

For the MS analysis, the known amount of d_6 ABA was added to the lyophilized tissue before extraction in order to ensure accurate quantitative data. Using this method, an extract of tissue that had been fed racemic ABA and harvested after Day 1, was found to have taken up 615 ng ABA

Endogenous ABA can be distinguished from exogenous by feeding $^{13}C_3$ ABA and using d_6 ABA as the internal standard as described above. *Results from an experiment where* $^{13}C_3$ ABA had been added to the medium used to grow spruce embryogenic tissue showed that the tissue incorporated a significant amount of the labeled ABA. **Figure 2** shows a plot of comparison of the amount of $^{13}C_3$ ABA incorporated in the tissue over the time course (42 days) of the experiment determined by LC/MS/MS and the ELISA system. As an example, an extract obtained from 21-day-old tissue was found to contain 677 ng of $^{13}C_3$ ABA by MS and 358 ng of ABA using the ELISA.

The ELISA assay is specific for (+)-ABA, the naturally-occurring enantiomer, and will not detect (-)-ABA or either enantiomer of 2-trans ABA. In contrast, under the conditions reported here, the mass spectrometer detects both enantiomers of ABA as well as any 2-trans ABA that may be present.

No endogenous ABA was found in any of the tissue extracts harvested during the time course of this experiment. As the detection level for ABA using this method is about 250 pg, it can be calculated that if there is endogenous ABA produced under these conditions, the level is less than 450 pg per mg of tissue.

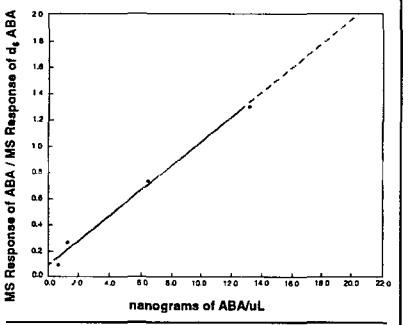

Figure 2

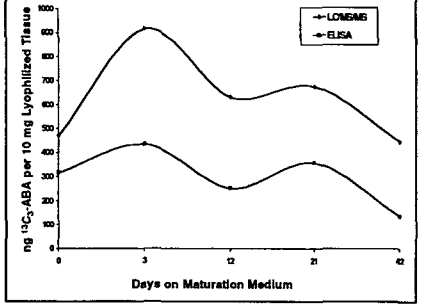


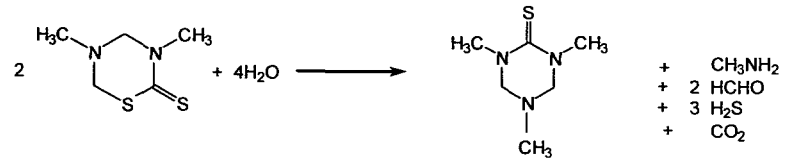
Evaluation of GCMS and FABMS for Analysis of Fungicidal DTTT Degradation

Lynn Teesch[†], Peter. S. Thorne and P. Subramanian[*]. Department of Preventive Medicine and Environmental Health and [†]High Resolution Mass Spectrometry Facility, University of Iowa, Iowa City, IA 52242

Introduction: DTTT (3,5-dimethyl-tetrahydro-2H-1,3,5-thiadiazine-2-thione) is a dithiocarbamic acid incorporated heterocyclic compound It is used as an agricultural fungicide, nematocide and herbicide and an industrial slimicide Hydrolysis of DTTT to the formation of primary intermediate (MeNH-C(=S)-S-CH_2-NHMe) has been hypothesized previously[1]. This intermediate is suggested to undergo further decomposition to formaldehyde and methylisothiocyanate (MeNCS) in aqueous media Decomposition of DTTT and the mechanistic pathways against the solution pH is not well understood[2] We have followed the degradation kinetics of DTTT in aqueous solutions and monitored the formation of intermediates and final products using UV-VIS and HPLC. We have carried out time-dependent FABMS analysis for the identification of primary intermediates from the hydrolysis reactions in FAB matrix from the partially hydrolyzed and aged DTTT solutions. We have also analyzed the hydrolytic degradation products of DTTT by GCMS and chemical derivatization methodologies. These techniques allowed the identification of several degradation products. Mass spectrometric results from these studies are discussed in this extended abstract.

Experimental: The sample preparation for GCMS analysis is as described· The product mixture resulted from the hydrolysis of DTTT in water ($5\ 0 \times 10^{-4}$ M or $1\ 0 \times 10^{-2}$ M) was freeze dried and extracted with 10mL CH_2Cl_2 and dried over anhydrous Na_2SO_4 Trimethylsilyl (TMS) derivatives were prepared by placing the freeze dried product mixture in reactivials with CH_3CN (200µL) and BSTFA (200µL) and stirring overnight or 7 days, at room temperature. 1µL of the extracts or their TMS derivatives in CH_3CN/ CH_2Cl_2 were injected for GCMS analysis GCMS analyses were carried out on a VG Trio-1 GCMS using DB-1 (DB-1, 15m; 0 32mm i d ; film thickness, 1µm) FABMS and collision induced decomposition (CID) experiments were performed on a VG ZAB-HF reverse geometry mass spectrometer The FAB matrices were thioglycerol, magic bullet, m-nitrobenzyl alcohol or triethanolamine Samples were bombarded with 8-keV Xe atoms and gun current of 1.5mA. Helium was used as the collision gas at analyzer pressures of 2×10^{-7} torr, as measured by the ion gauge in the second field-free region. Fragment ions formed by the unimolecular decomposition or by CID in the second field-free region were observed via MIKES The MIKES spectra are the results of averaging 8 to 10 scans

Results and Discussion: GCMS analysis allowed tentative identification of intermediates and products: 1,3-dimethyl-2-thiourea (**1**), N-methyl-dithiocarbamic-methyl ester (**2**), 2-methyl-5-dihydro-3H-4-thia-1,2-isooxazolidine-3-thione (**3**), 1,3,5-trimethyl-hexahydro-2H-1,3,5-triazine-2-thione (**4**), 4-methyl-5-methylimino-1,2,4-dithiazolidine-3-thione (**5**), 2,4-dimethyl-1,2,4-thiadiazolidine-3,5-dithione (**6**) Chemical derivatization with BSTFA allowed the characterization of -NH, -OH or -SH protons. Compound **4** (see below) had been previously synthesized[3] starting from methylamine, dimethylthiourea and formaldehyde. FABMS studies also allowed the identification of **4** and the structural confirmation was made by HR-FABMS and MIKES studies.



DTTT **4**

We have also analyzed CH_2Cl_2-extracts of MeNCS solutions by GCMS studies. Compounds **5** and **6** were observed as common products from MeNCS and DTTT solutions, with the same molecular formula and similar ions fragmentation pattern, but different GC retention times (t_r = 13.63min **5** 14 35min **6**) and relative abundance for m/z 105 and 137a.m.u. (Figure 1). Thorn had synthesized **5** and **6** by the oxidation of N,N'-dimethyldithiram disulfide[4]. N,N'-dimethyldithiram disulfide was synthesized by the mild oxidation of N-alkyldithiocarbamate. The CH_2Cl_2-extract containing products **1**, **4**, **5** and **6** were stable at 4°C for a period greater than 18 months.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

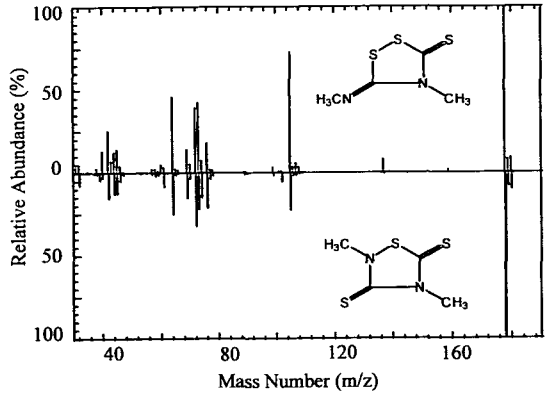


Figure 1 Mass spectra (EI) of products **5** and **6**

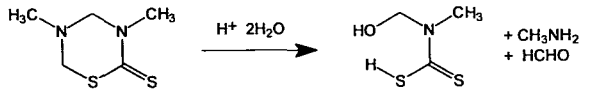
We were not successful in characterizing the putative intermediate(s) from the DTTT solution undergoing degradation in water or water-methanol solution. However, in strongly acidic solution (trifluoroacetic acid pH <2 0) and glycerol as the FAB matrix, mass ion having m/z 136a.m.u was observed When thioglycerol or magic bullet instead of glycerol was used as the FAB matrix, a new ion with m/z 140a.m u. was observed. We interpret that the compound having molecular weight 137 a.m.u undergoes a two electron reduction in thiol matrices as below

$$C_3H_7NOS_2 + 2RSH + H^+ \longrightarrow [C_3H_9NOS_2]H^+ + RSSR$$

Dithiocarbamates are also known to undergo easy oxidation and hence the formation of $[M-H]^+$ ion in glycerol matrix We tentatively assign the primary intermediate as N-methyl-N-hydroxymethyl-dithiocarbamic acid (**7**).



7

Time-dependent studies of DTTT decomposition using FABMS and GCMS techniques, GCMS provided most valuable information for the analysis and the identification of final products. Even though DTTT undergoes continuous decomposition in aqueous environment, GCMS is most useful technique for tracing the usage of DTTT by monitoring the most persistent triazine **4** which is efficiently extracted into CH_2Cl_2 We were unable to discern the ions corresponding to an intermediate following the addition of one mole equivalent water, possibly due to higher matrice background Currently, we are investigating HPLC-MS studies for the characterization of most polar intermediates and products from DTTT decomposition

Pentafluorobenzyl Chloroformate as a Derivatization Reagent for NCI/MS

J.T. Simpson, D.S. Torok and S.P. Markey
Section on Analytical Biochemistry, National Institute of Mental Health, Bethesda, MD 20892

Introduction

There have been several reports in the recent literature concerning the use of chloroformates for aqueous, rapid, room temperature one-step derivatization of amino acids (AA's) with analysis by GC or GC/MS [1,2].

We have investigated the use of pentafluorobenzyl chloroformate (PFBCF) as a reagent for this derivatization with analysis by GC/MS in negative chemical ionization mode [3]. In addition, PFBCF was used for the anhydrous derivatization of alcohols.

AA's were derivatized in aqueous solution, plasma and whole blood at room temperature. Phenethyl alcohol was derivatized under anhydrous conditions at 70°C.

Experimental

Preparation of pentafluorobenzyl chloroformate: The method of Lee and Norton [4] was used without significant modification. Briefly, PFBCF was formed by reaction of pentafluorobenzyl alcohol and phosgene, in the presence of dimethyl aniline. PFBCF was purified by distillation under vacuum (bp 116-117 °C, 20 mm). The chloroformate is stable when kept cold (-20°C), however, no special precautions were necessary for use at room temperature for derivatizations.

Standards: AA standards (AA-S-18 and individual) were obtained from Sigma Chemical Co. ^{13}C-ring labeled phenylalanine was obtained from Cambridge Isotopes. Phenethyl alcohol, dimethylaminopyridine (DMAP) and pentafluorobenzoyl chloride (PFBzCl) were obtained from Aldrich. All solvents were of HPLC grade.

Whole Blood and AA Standards Derivatization: Briefly, a 10 µL aliquot of an AA solution in 0.1M HCl, or 10 µL whole blood (with 10 µL 0 1M HCl added), was added to 100 µL of H_2O / ethanol / pyridine, 60/30/10, v/v/v, and vortexed. PFBCF (10 µL, neat) was then added and the solution vortexed for 30 sec. The reaction mixture was then extracted with 100 µL of toluene, frozen in dry ice, and an aliquot of the upper liquid phase transferred to an autosampler vial for GC/MS analysis. No prior extraction of the blood sample was performed.

Plasma: Samples of plasma (0.5 mL) from 4 human controls (3 male, 1 female) were purified by cation exchange chromatography as previously described [5]. The lyophilized residue was diluted to 1 mL with 0.1M HCl and 10 µL treated as described above.

Protein Hydrolysate: A sample (25.8 µg) of human apo A-I was subjected to HCl hydrolysis for 23 hrs at 105°C. A portion (6.4 µg) was dried and derivatized as described above.

Quantification of Phenylalanine in Human Plasma: A standard curve was constructed by PFBCF derivatization of duplicate samples of phenylalanine at 0 pg, 500 pg, 750 pg, 10 ng, 100 ng, 200 ng, 300 ng, 400 ng and 500 ng per tube. ^{13}C-ring-labeled phenylalanine (100 ng per tube) was used as the internal standard. Internal standard (100 ng) was added to duplicate 10 µL aliquots of the plasma and the samples derivatized.

Alcohol Derivatization: Phenethyl alcohol (PEA) was derivatized by adding 10 µL of PFBCF and 50 µL 1% pyridine (in CH_3CN) to 50 µL of a 26 ng/µL CH_3CN solution of PEA. The reaction mixture was heated at 70°C for 1 hr and analyzed by GC/MS. A duplicate sample of PEA was derivatized with 10 µL PFBzCl (1% in CH_2Cl_2) and 50 µL 1% pyridine (in CH_3CN). The solution was heated at 70°C for 1 hr and analyzed by GC/MS.

GC/MS Conditions: All data were collected on a HP-5989 mass spectrometer interfaced with a HP-5890 GC. The ion source temperature was 250°C and the transfer line 300°C. Full scan data was recorded from m/z 100 to 750. Methane was used as reagent gas for all chemical ionization experiments.

GC separations were performed on a DB-17, 15 m x 0.25 mm, 0.25 µm film thickness or a HP Ultra 2 (5% phenyl methyl silicone), 25 m x 0.2 mm capillary column, 0.33 µm film thickness. A typical oven ramp profile was 70°C to 150°C at 30°/min, 150°C to 250°C at 10°/min and 250°C to 300°C at 30°/min with a 3 min hold at 300°C. Injection was splitless at 300°C. All injections were 1 µL.

Results and Discussion

The N-pentafluorobenzyloxycarbonyl amino acid ethyl esters (*fø*-AA-OEt) formed readily at room temperature in seconds under aqueous conditions. The derivatives exhibited excellent GC properties and their NCI mass spectra were dominated by $[M-181]^-$. PFBCF derivatization was applied to AA's in protein hydrolysates, plasma and whole blood with no prior sample clean up necessary. Sensitivity and quantitative analysis were demonstrated by the analysis of phenylalanine in human plasma. Four subjects gave Phe concentrations ranging from 48-60 µmol/L. The yield for the reaction of PFBCF with phenylalanine was determined to be 97%.

The *fø*-AA-OEt derivatives have been stable over a period of months when kept at -20°C. Of the AA's tested, only arginine failed to elute from the GC column. Histidine and tyrosine gave two derivative peaks, as did tryptophan. *fø*-Ser-OEt had low sensitivity.

Phenethyl alcohol (PEA) was also derivatized with PFBCF. Alcohol derivatization required anhydrous conditions and heating at 70°C for 1 hr. Yields were 90%. The *fø*-PEA carbonate NCI mass spectrum was also dominated by the $[M-181]^-$ ion. Of technical note, an Alltech "CapSaver" GC injection port liner was used for splitless injection and gave dramatically better results than other liners used.

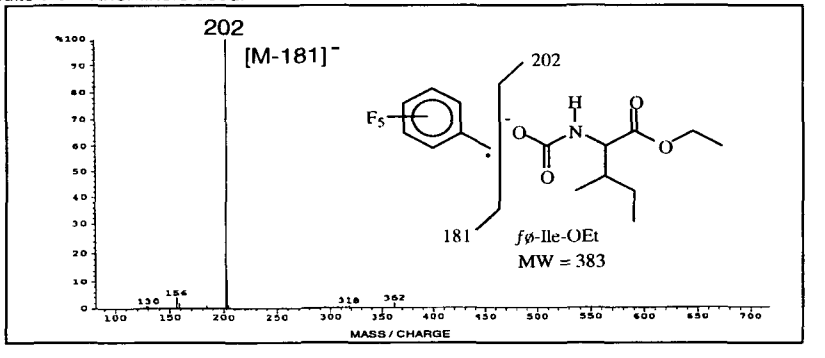

Figure 1: NCI mass spectrum of *fø*-Ile-OEt

THERMAL STUDY OF GLYCYRRHIZIC ACID BY ON-LINE THERMOGRAVIMETRY/ GAS CHROMATOGRAPHY/MASS SPECTROMETRY

Henry L. Chung*, John C. Aldridge, Gary M. Dull, and Chi-Kuen Shu

R. J. Reynolds Tobacco Company, Bowman Gray Technical Center, Winston-Salem, NC 27102

Thermal analysis has become an important analytical technique with the introduction of modern thermal analytical instruments. An on-line thermogravimetry/gas chromatography/mass spectrometry (TG/GC/MS) system (1) was used to study the stability, weight loss, and thermal degradation products of glycyrrhizic acid. The on-line TG/GC/MS system employed a Du Pont 951 thermogravimetric analyzer equipped with a 9000 thermal analysis system interfaced to a Hewlett-Packard 5890 GC/5970 MSD system. The TG/GC interface consisted of a heated transfer line, an adsorbent trap packed with Tenax and a six-way valve. Glycyrrhizic acid was heated and purged with air at a flow rate of 30 ml/min during the heating and purging process. The TG temperature was programed from 22°C to 900°C at 20°C/min. The volatile compounds generated in the TG were swept into an adsorbent trap. The purge gas, after passing through the trap, was vented to the atmosphere. After the heating and purging process, the trap was rapidly heated to 250°C and the volatile compounds in the trap were swept into the GC/MS system by helium at a flow rate of 35 ml/min. The volatile compounds were separated by GC. A 60 m X 0.25 mm ID DB-1701 (0.25 μ film thickness) fused silica capillary column was used for compound separation. The GC injection temperature was 250°C. The column head pressure was 25 psi. The column temperature was held at 35°C for 10 minutes, programmed to 220°C at 3°C/min and held for 48 minutes. An open-split GC/MS interface was used and the temperature was at 275°C. The mass spectrometer was operated at 70 eV in the EI mode. The ion source of the mass spectrometer was maintained at 250°C. The mass range scanned was from 29-500 amu. The volatile compounds were identified by mass spectra. The on-line

43rd ASMS Conference on Mass Spectrometry and Allied Topics

TG/GC/MS system permits evolution of thermal degradation products of glycyrrhizic acid by TG, separation of the volatile thermal degradation products by GC, and identification by MS. The thermogram of glycyrrhizic acid revealed that decomposition occurred in four steps. The first decomposition occurred over a temperature range of 39-131°C with a weight loss of 7%. The second decomposition was between 183-262°C with 14% weight loss. The third decomposition occurred over a temperature range of 262-350°C with 47% weight loss. The fourth decomposition was between 350-668°C, and involved a further 31% weight loss. Thus, a temperature and weight loss profile of glycyrrhizic acid was obtained. The total ion chromatogram showed that a number of thermally degraded compounds were generated from glycyrrihizic acid under the conditions studied. The volatile compounds were identified by mass spectra. The volatile degradation products were identified as ketones, esters, carboxylic acids, aldehydes, alcohols and hydrocarbons.

CHARACTERIZATION OF AROMATIZED BIOMARKERS BY GC/MS/MS WITH CHEMICAL IONIZATION

C. S. Hsu and G. J. Dechert
Exxon Research and Engineering Co., Annandale, NJ 08801
M. E. Schaps and G. B. Hieshima
Exxon Production Research Co., Houston, TX

Although present in trace amounts, biomarkers are extensively studied by geochemists to understand paleotransformation processes that convert ancient living organisms into petroleum components and to assess age, maturity and source input of the petroleum Most studied are saturated biomarkers that yield both molecular and characteristic fragment ions under high voltage (50-70 V) electron-impact ionization (HV/EI) conditions. Linking these molecular and fragment ions derived from saturated hydrocarbon compounds using GC/MS/MS resolves coeluting components and provides less ambiguous geochemical information than GC/MS.(1)

The same GC/MS/MS techniques cannot be applied to aromatized biomarkers because they yield trace or no molecular ions under HV/EI conditions. To overcome these difficulties, chemical ionization (CI) has been studied for producing ionic species more representative of molecules. Among the reagent gases evaluated isobutane yields predominantly protonated molecular ions while methane and ammonia yield more than one type of pseudomolecular ions. Thus, isobutane is the gas of choice for the aromatic biomarkers using GC/MS/MS with CI. This analytical technique is particularly useful for resolving overlapping monoaromatic steranes (MAS). Characterization of aromatic biomarkers more accurately would help us to understand better the maturation mechanism of petroleum molecules under thermal stress.

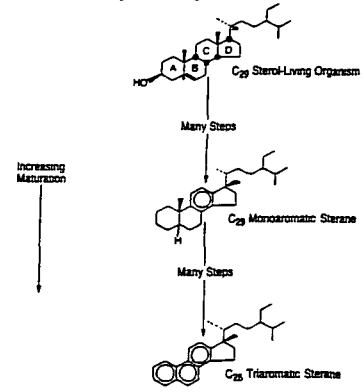
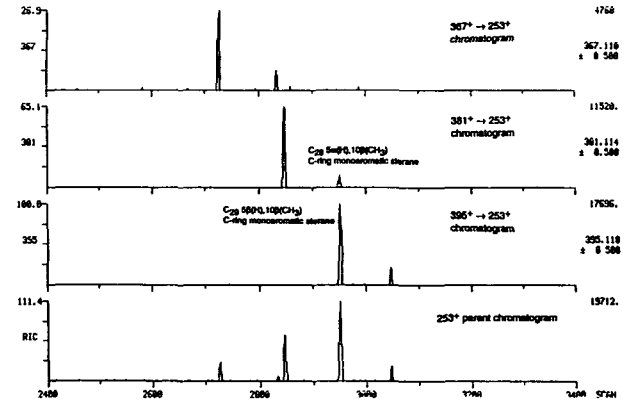
STERANE AROMATIZATION

Beginning during diagenesis and continuing throughout catagenesis, hydrogen is progressively removed from the steroidal hydrocarbon skeleton, resulting in increasing aromatization.



The degree of sterane aromatization can be used as an indicator of maturity in oils and source rocks.

COELUTION OF C_{28} AND C_{29} MONOAROM. STERANES CAN BE READILY DETECTED BY GC/MS/MS WITH CI



Structure Elucidation of Trace Components in Pharmaceuticals Using GC/MS^n

Steve Schachterle, Varian Chromatography Systems, Walnut Creek, CA

Introduction

Tandem mass spectrometry (MS/MS) is widely used to provide structural information for the identification of compounds in pharmaceutical products. Coupling gas chromatography to product ion MS/MS and MS/MS/MS (MS^3) can provide sufficient information to deduce the structure of minor components in the presence of the active compound and tablet compounding agents. An over-the-counter antihistamine tablet was analyzed using GC/MS/MS and GC/MS^3 and the fragmentation pathway and a possible structure were proposed for an impurity.

Experimental

A Saturn GC/MS with 4D MS/MS was used for all experiments.
The Toolkit® was used to build Ion Preparation Methods to perform MS^3 and automated methods development (AMD) MS/MS. Ions were produced from the sample by either EI, or by CI using the vapor from liquid acetonitrile as the CI reagent.

	Active Ingredient				Impurity			
Ion	P_1	V_{CID}	P_2	V_{CID}	P_1	V_{CID}	P_2	V_{CID}
$[M+H]^+$	275^+	42 V	230^+	72 V	241^+	42 V	196^+	72 V
$[(M+H)-45]^+$	230^+	72 V	167^+	92 V	196^+	72 V	167^+	92 V

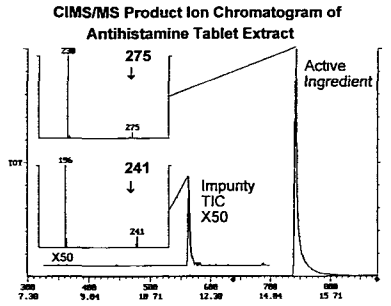
Where P_1 = First Generation Parent Ion
P_2 = Second Generation Parent Ion

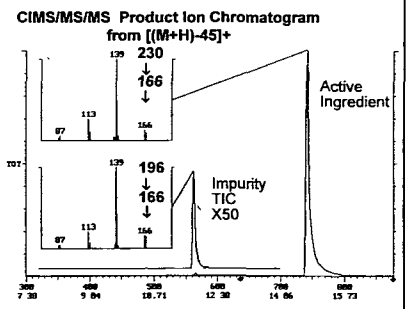
Sample: Generic chlorpheniramine maleate antihistamine tablets, purchased at local drug stores.
Sample preparation: Crush a tablet. Place 5-10 mg into a 2 ml vial. Add 0.9 ml water. Adjust to pH11 using 1.0*N* NaOH. Shake well. Add 1 ml methylene chloride. Shake again. Remove the methylene chloride layer. Inject 1µl

Results and Discussion

The structure of the active ingredient is shown in figure 3. Several common spectral features can be seen between the active ingredient and the impurity:

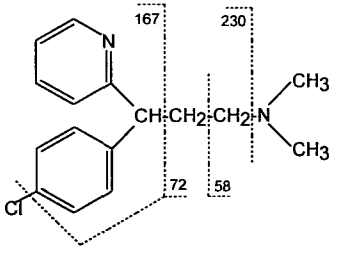
Analysis Type	Spectral Features
EIMS	Both spectra show 58^+, 72^+ ions. Neither spectrum shows M^+
CIMS	Both spectra show $[M+H]^+$ and $[(M+H)-45]^+$, with a difference of 34 between $[M+H]^+$ for the active ingredient and for the impurity.
CIMS/MS	Both spectra show $[(M+H)-45]^+$ as the major ion.
CIMS^3 of $[M+H]^+$	Both spectra show 167^+ as a major ion after MS^3.
CIMS^3 of $[(M+H)-45]^+$	The product ion spectra are virtually identical, implying that any difference in structure has been lost by this point.



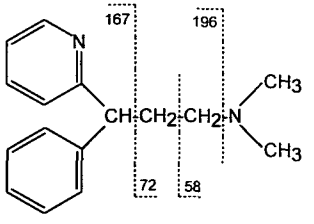


Mapping these features onto the structure of chlorpheniramine leads to the conclusion that the compounds are the same except for a chlorine atom which has been replaced by a hydrogen atom on the impurity. This compound, pheniramine, is also used as an antihistamine.

Chlorpheniramine, MW 274



Pheniramine, MW 240



Conclusions

MS/MS allows the CID energy to be tuned to explore different fragmentation patterns. MS^3 provides an easy way to determine fragmentation pathways through a selected ion. In this example, an impurity was identified in an over-the-counter antihistamine tablet. Common ions in the various mass spectrometric modes were interpreted as common structure between the active ingredient and an impurity and allowed a structure for the impurity to be proposed.

Isotopically Labeled Internal Standards Analysis Using Ion Trap GC/MS/MS

Barbara A. Bolton, Steve Schachterle and Greg Wells

Varian Chromatography Systems
2700 Mitchell Drive
Walnut Creek, CA 94598

The ability to sequentially change ion trap scan functions from scan to scan allowed trap parameters to be varied numerous times during the elution of a sample peak from a gas chromatograph. The chromatogram could be divided into as many as 200 time segments; one for each compound. In each segment 10 different scan groups could be sequentially acquired. Each scan group could isolate and dissociate a different parent ion. The scan groups are sequentially repeated throughout the particular time segment, producing a spectrum for each group. In this work scan Group 0 was used to produce product ion spectra from phencyclidine (PCP) and scan Group 1 was used to produce product ion spectra from deuterated phencyclidine (D-5 PCP) as shown in Figure 1

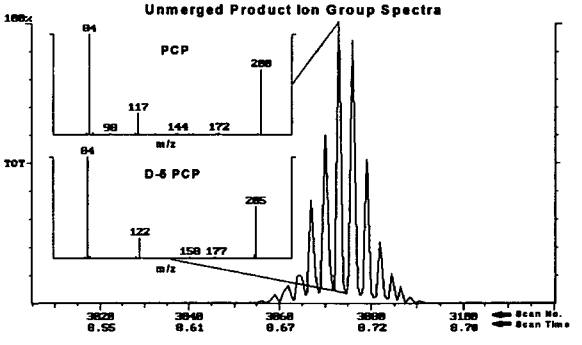


Figure 1

The set of individual group spectra could be directly merged to form a composite spectra (Figure 2); or specific ions could be extracted from the individual group spectra first and then merged to form the composite spectrum (Figure 3).

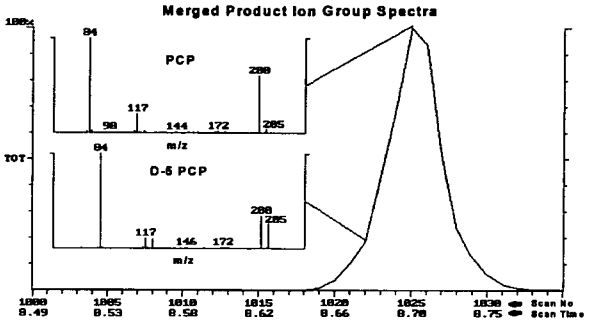

Figure 2

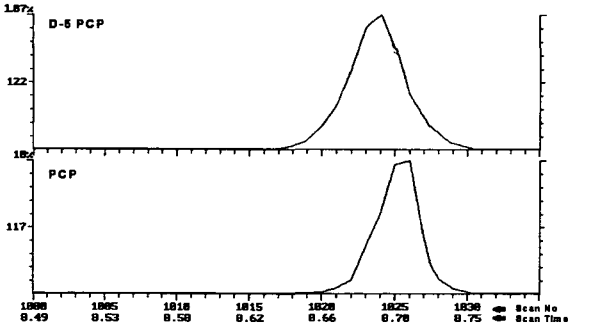

Figure 3

Reproducibility Study of GC/MS/MS with Ion Trap Mass Spectrometer

Barbara A. Bolton and Steve Schachterle
Varian Chromatography Systems ,Walnut Creek, CA, USA

Introduction

The utility of MS/MS for quantitative analysis depends explicitly on the *reproducibility* of the parent ion isolation and CID process for product ion formation The MS/MS experiment should produce an identical fragmentation pattern each time the same sample is analyzed Comparison of current MS/MS spectral data to MS/MS spectral data stored in a library maybe used for routine identification or confirmation of target compounds Any uncharacterized or uncontrolled changes in MS/MS spectral patterns compromise the integrity of that comparison

Recently, new methods of parent ion isolation and collision-induced dissociation (CID) have provided a reliable method for routine GC/MS/MS analysis with an ion trap (1-2). This method has the option of using either a non-resonant or resonant technique for the CID process. Using a standard mixture of semiviolatile organics, MS/MS method reliability was evaluated in terms of long-term reproducibility of sample response, linearity and relative ion ratios.

Methods

This study used a **Varian Saturn 4D** ion trap mass spectrometer. The four compounds, 2-methylnapthalene, acenaphthene, chlorpyrifos and chlordane, were dissolved in hexane to give six concentrations between 10 pg/µL and 1900 pg/µL Table 1 shows the EI/MS/MS method used for each compound A multisegment MS acquisition method was created to apply the appropriate MS/MS method to each analyte as it eluted from the GC column. The method was not altered over the course of this three month study Weekly routine checks of electron multiplier voltage, mass calibration and trap function calibration were the only potential causes of instrument paramter changes.

Results and Discussion

Ion Ratio Comparison

The relative abundance of ions in a mass spectrum or MS/MS spectrum are often used as a basis to distinguish isomeric compounds Relative product ion abundances have also been used as a measure of internal energy of the parent ions(3) Three scan average spectra (apex + adjacent scans) were analyzed for reproducibility of product ion intensity relative to base peak. The variation of the relative intensities are reported as %RSD in Table 2 Variation of product ion ratio data was greatest at the lowest concentration (~10 pg). The %RSD for relative ion abundance was much lower at concentrations of > 50 pg.

Library Search Comparison

MS/MS spectral interpretation relies on a comparison of current data with that obtained from previous samples or standards Saturn software provides for the generation of a MS/MS library based on mass spectra generated by the user, and uses the same search routines as used for the regular mass spectral library The Library search algorithm is sensitive to matches by mass and intensity The **Purity Search** measures the similarity between the sample mass spectrum and the library mass spectrum. A purity of 1000 implies that the library and sample mass spectra are identical with respect to both the presence and intensities of mass peaks. A Purity Search analysis of the compounds at the beginning, mid point and last week of the study is shown in Table 3.

Quantitation

External standard calibration curves generated for the four compounds for the first and last week of this study. The response was either linear or quadratic with excellent correlation coefficients The %RSD results for sample response (sample area/sample conc.) are shown in Table 4. Generally, the greatest variation in sample response was observed at the ~ 10 pg concentration level

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Conclusions

- o A new method of isolation and excitation has provided a GC-MS/MS method that is reliable and reproducible Four compounds were examined for reproducibility of relative ion abundances, quantitation and library identification The MS/MS spectra gave good linearity with correlation coefficients > 998, and high fit when library searched
- o The CID method has provided controlled energy desposition and uniform fragmentation. Spectral integrity (relative ion ratios) was maintained over the concentration range (10 to 2000 pg) and was stable for several months The high reproducibility of ion ratios is comparable to that obtained with the electron ionization mode of analysis
- o Reproducibility of product ion spectra over time and concentration suggests that a useful data library for a wide range of compounds is feasible Preliminary examination of product spectra from different instruments using the same MS/MS method showed that small changes (several volts for non-resonant) in the excitation voltage may be required to obtain similar product ion spectra

High Speed Method Optimization For Routine GC/MS/MS In An Ion Trap

Greg Wells and Chuck Huston

Varian Chromatography Systems
2700 Mitchell Drive
Walnut Creek, CA 94598

The ability to sequentially change ion trap scan functions from scan to scan allows trap parameters to be varied numerous times during the elution of a sample peak from a gas chromatograph. The chromatogram can be divided into as many as 200 time segments; one for each compound. In each segment 10 different scan groups can be sequentially acquired. Each scan group can have a different value of a selected parameter (such as CAD voltage). The scan groups are sequentially repeated throughout the particular chromatographic time segment, producing a spectrum for each group An MS/MS method of five pesticides (Figures 1 and 2) was optimized and calibrated with only three sample injections.

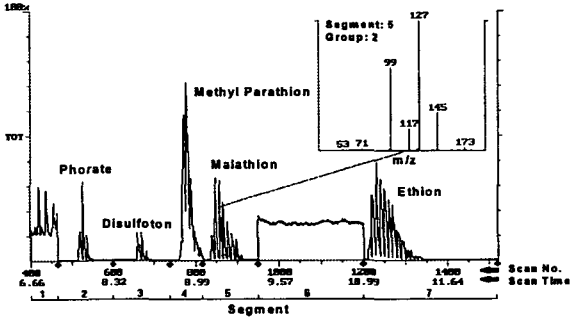

Figure 1

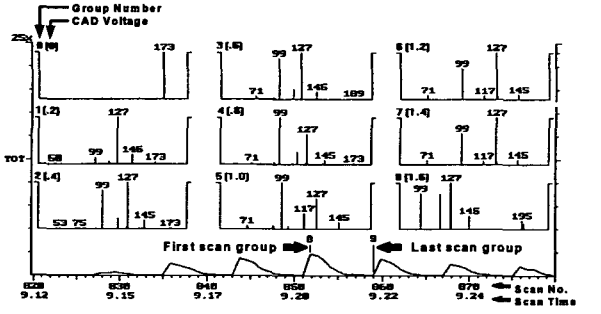

Figure 2

The spectra that resulted were inspected and the optimum CAD spectra were selected for each compound based on the operator's criteria. The value of the parameter associated with the scan group for each selected spectra was then entered into the final MS/MS method (Figure 3).

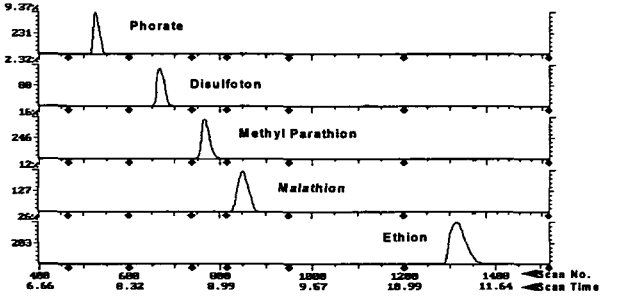

Figure 3

Dual Oven Multidimensional Fast Gas Chromatography with Spectral Detection

Tania A. Sasaki and Charles L. Wilkins
Department of Chemistry, University of California–Riverside, Riverside, CA 92521–0403

Multidimensional gas chromatography (MDGC) with spectral detection has been well established as a powerful tool for analysis of complex mixtures. The ability to acquire both mass and infrared spectra is desired because the complementary information that can be obtained leads to a more accurate identification of unknown components. In our research, a fast secondary separation is used to reduce the analysis time of this stage by at least an order of magnitude. We have also implemented a dual oven configuration so that heartcuts can be trapped and reinjected onto the fast column "on the fly." This configuration further reduces analysis time by allowing analysis of more than one heartcut per injection, which is analogous to using parallel traps. Although we succeeded in decreasing the analysis time, the fast separation creates some challenges for most spectral detectors. Because of the small retention time differences between compounds and the low column capacities of the fast columns, detection limits and chromatographic resolution become concerns when coupling fast GC to spectral detectors.

We have previously demonstrated the feasibility of fast GC with off–line matrix isolation FTIR detection. By using a programmable speed rotating cryogenic disk to trap the GC effluent, the chromatographic resolution is maintained by increasing the rotation rate. Signal averaging is used to improve the detection limits.

Although detection limits are not a problem for mass spectrometers, as they are inherently quite sensitive, maintaining the chromatographic resolution can be very difficult. This is especially true for scanning instruments such as the quadrupole mass spectrometer. In order to maintain good chromatographic resolution, the mass range scanned must be quite small. Most fast GC peaks are on the order of 250-350 ms (FWHH) so the scan rate must be at least 20 scans/second. Although the reduced mass range makes unambiguous identification using mass spectral information difficult at best, it can be used for target analysis of various compounds. This aspect of the fast MDGC/FTIR/MS system is be the focus of this paper.

The fast MDGC/FTIR/MS system utilized in this study consists of two gas chromatographs connected by a cryogenic trap housed in an external oven. For evaluation, a standard polynuclear aromatic hydrocarbon (PAH) sample was injected onto the pre-column and then directed to either a vent line or the cryogenic trap. Using rapid resistive heating, the sample was reinjected from the trap onto the fast column. Detection from the fast column utilized a flame ionization detector (FID), matrix isolation FTIR spectrometer, and quadrupole mass spectrometer. To obtain a selected ion chromatogram (SIC) and mass spectra of the target analytes, the mass range of the quadrupole was set to scan from 150 to 160 amu. The target analytes were acenaphthylene and acenaphthene, which correspond to peaks 2 and 3 in **Figure 1**, which shows the total ion chromatogram (TIC) of the sample. **Figures 2a** and **2b** show the SIC and FID chromatogram of the fast separation. The mass spectrum of peak 2 is shown in **Figure 3a**. **Figure 3b** shows the corresponding portion of the spectrum of peak 3 of Figure 1. The agreement between the two spectra demonstrate the feasibility of this method for the identification of target analytes. Infrared spectra, which were obtained in conjunction with the mass spectra, can be used to confirm the identification.

Table 1: Identifications of PAH standard mixture components

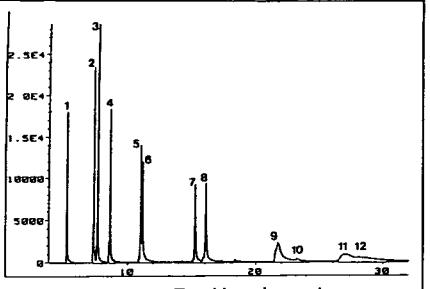

Figure 1: Total ion chromatogram of PAH standard separated on a DB–5 column.

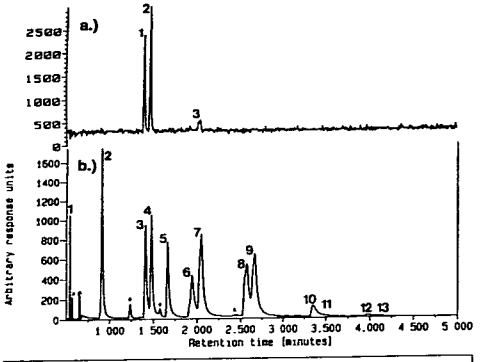

Figure 2: Chromatogram of fast separation of PAH standard, a.) selected ion chromatogram (SIC) and b.) FID chromatogram.

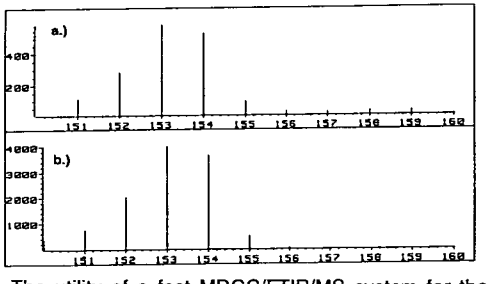

Figure 3: Mass spectrum of acenaphthene. a.) Selected ion mass spectrum of peak 2 in Figure 2a; b.) 150-160 amu section of spectrum from peak 3 in Figure 1.

The utility of a fast MDGC/FTIR/MS system for the target analysis of mixtures has been demonstrated. By selecting an appropriate, small mass range for the compounds of interest, the quadrupole mass spectrometer was able to both maintain the chromatographic resolution of the fast GC separation and collect spectra of the analytes of interest. The IR spectra which were simultaneously obtained were used for a more positive identification of the compound.

High-Speed GC/MS Using a Quadrupole Mass Filter

Casey C. Grimm & Steven W. Lloyd
USDA, Agricultural Research Service, SRRC
New Orleans, LA 70122

Linda Muchausen
Deptarment of Chemistry and Physics, Southeastern Louisiana University
Hammond, LA 70402

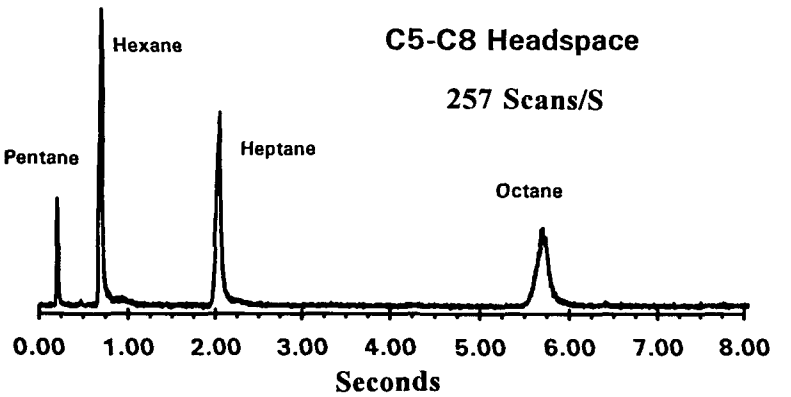
Gas chromatographic separations utilizing short narrow bore capillary columns (I.D. < 0.1 mm), can be performed with run times ranging from a few minutes down to a few seconds. The short columns and the high flow rates enable separations to be performed at lower oven temperatures. Sample capacities are limited to a few nanograms of each analyte, but the narrow peak widths result in an increase in the signal to noise ratio. GC peak-widths are on the order of 0.1 s and require high data acquisition rates which are problematic for scanning mass spectrometers.

Quadrupole mass spectrometers have proven to be relatively inexpensive, reliable and rugged. The major limitation to scanning a quadrupole mass filter is in the flight time required for a given molecule to pass through the filter. The flight time is determined by the quadrupole length, mass, and potential difference between the source and the quadrupole which is normally around 5 V. Table 1 shows the intensity of the m/z 69 ion from PFTBA as a function of source potential and sampling time after stepping the mass filter across 1 amu. The signal is at a maximum at 15 µs.

Intensity for m/z 69 as a Function of Sampling Time and Acclerating Potential

m/z 69	5 us	15 us	25 us	35 us	45 us	55 us	65 us	75 us
0 V	22	110	112	91	116	102	104	101
5 V	39	3380	2656	1645	878	845	796	814
10 V	135	3395	2238	1577	1018	1043	1080	1072
15 V	486	3395	2062	1592	1184	1130	1216	1196
20 V	1017	3473	2006	1514	1284	1237	1301	1298
25 V	1598	3724	2020	1663	1541	1364	1458	1436
30 V	1907	3564	2092	1602	1533	1357	1430	1404

A data acquisition and control program has been developed to exceed the physical limitations of a quadrupole mass spectrometer. By reducing the scan range, increasing the acceleration voltage, and reducing total sampling, scan rates exceeding 250 Hz over a 100 amu range have been achieved, resulting in scan speeds in excess of 25,000 amu/sec. The mass spectra are sufficient to identify the compounds. This system can be used for rapid analysis or on-line quality control. Figure 1 shows a total ion chromatogram produced by injecting 1µl of headspace above a mixture of pentane, hexane, heptane and octane. The GC head pressure was at 40 psi of H_2, and the capillary column was 1 m with a DB-5 stationary phase and a 50 µm I.D. A split injection of approximately 10:1 was used. The quadrupole mass spectrometer was scanned from 40 to 140 amu at 257 scans/S. The fast scan resulted in an increased M+1 peak due to the decreased mass resolution. However, the mass spectra were sufficient for unambiguous identification. Quantitation was not possible, partly due to the injection techniques and partly due to the accelerated scan rates.



HIGH-SPEED GC/MS WITH A FAST DOUBLE-FOCUSSING MASS SPECTROMETER

Peter G. Van Ysacker, Jeff Brown*, Andy Phillips*, Hans-Gerd Janssen and Piet A. Leclercq
Laboratory of Instrumental Analysis, Department of Chemical Engineering
Eindhoven University of Technology, P.O. Box 513, 5600 MB, Eindhoven, The Netherlands
**VG Analytical, Floats Rd., Wythenshawe, Manchester M23 9LE, England*

Modern magnetic sector mass spectrometers have several advantages over quadrupole instruments and appear highly promising for on-line coupling to high-speed narrow-bore GC columns. Double-focussing instruments are capable of better sensitivity, higher resolution and selectivity than quadrupoles. In magnetic instruments ions of higher energy are used, and hence higher scan speeds than with quadrupoles can theoretically be obtained. With conventional sector instruments scan speeds are limited in practice to a few spectra per second. The state-of-the-art VG MassSpec, however, allows higher scan speeds because this EBE instrument has a small, fast, fully laminated low inductance magnet.

The performance of the MasSpec in combination with narrow-bore (50 μm I.D.) GC columns has been evaluated. The detection limits in the full scan mode are in the low pg range. In the SIM mode, detection limits as low as five to 50 fg are observed, depending on the resolving power of the mass spectrometer and on sample complexity. With complex mixtures, detection limits for a given compound are limited by interferences from other compounds. By increasing the mass spectral resolution in the SIM mode, interferences from ions of the same nominal m/z value are significantly reduced, thus enhancing the signal-to-noise ratio. Furthermore it was found that the mass spectrometer exhibits perfectly linear behavior over the entire dynamic range from the detection limits up to a few ng where overloading of the GC column starts to occur.

The maximum achievable scan speed in the full magnetic scan mode varied from three to ten scans over one decade per second, again depending on the spectral resolving power (2000 and 300, respectively). Over a smaller mass range (40 to 200 Dalton), up to 20 scans/s could be acquired at a mass resolution of 300. Scanning the electrostatic analyzer is not useful because the applicable mass range in this mode is too small to preserve good sensitvity.

In the SIM mode, more than 50 m/z values could be monitored per second when the electrostatic analyzer was used. However, the abundance of only 25 different ions per second could be obtained by changing the magmetic field strength.

The overall performance of this high-speed GC/MS system is illustrated by analyses of samples from industrial and environmental origin. An example is given in Figure 1.

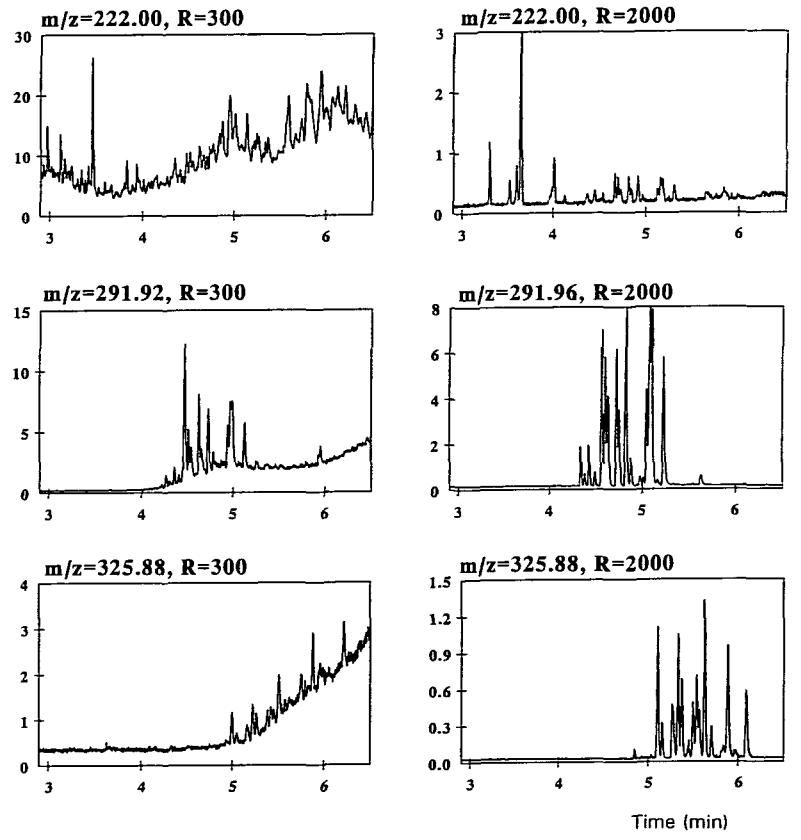


Figure 1. Fast separation of a waste oil spiked with PCB's (arochlor 1242). Ion current profiles of m/z 222.00, 291.92 and 325.88 are shown at mass resolving power of 300 (left) and 2000 (right). GC conditions: 5 m x 50 μm I.D. DB-1 column (0.17 μm film thickness), ballistically heated from 50°C to 280°C; helium inlet pressure 11 bar.

FAST, VERY FAST AND ULTRA FAST GC-MS IN SUPERSONIC MOLECULAR BEAMS

Aviv Amirav and Shai Dagan
School of Chemistry, Tel Aviv University, Tel Aviv 69978, Israel, Fax: 972-6409293

Supersonic molecular beams (SMB) are characterized by several unique features that make SMB an ideal sample introduction method, enable a unique fast GC inlet, and result in important implications to ionization processes.

A 50 cm long capillary column that connects the atmospheric pressure open inlet to a supersonic nozzle, serves as an ultra fast GC short column. Alternatively, a coupled conventional GC can serve as a fast or a very fast GC, with no restrictions on the column diameter, length or flow rate. With this GC, the two columns are simultaneously connected for increased flexibility.

GC-MS in SMB provides improved solutions to all the fast GC-MS requirements. A broad range of molecules, including relatively thermolabile and nonvolatile, are amenable for fast GC-MS. The directional kinetic energy is used to filter out vacuum background ions, thus tail free chromatograms are obtained, regardless of the molecular volatility. These chromatograms are combined with the electron impact mass spectra of the vibrationally cold supersonic beam molecules, that exhibit enhanced molecular weight peak and controlled degree of ion dissociation. Sufficient overall GC-MS resolving power is achieved by the use of Hyperthermal Surface Ionization (HSI) as a tunable selective ion source, and due to the enhancement of M^+ peak in electron impact. On the other hand, the fast GC peak widths usually exceed 0.5 seconds, being compatible with conventional quadrupole MS. These peak widths are achieved through the use of a high flow rate short megabore columns. The extreme sensitivity of HSI (400 attograms MDA), simplifies sample preparation requirements. Fast splitless injections are achieved through the very high gas flow rate prevailing, that further contributes to lower minimum detected concentration.

The GC-MS analysis time is defined in terms of speed enhancement factor (SEF), which is the multiplicity of the column length reduction by the gas linear velocity increase, in comparison with a conventional 30 meter long narrow bore capillary column, having 1 ml/min flow rate. Fast, very fast and ultra fast GC-MS have an SEF of 5-30, 30-400, 400-4000, respectively. The use of SMB enables a free choice of SEF with the trade off of handling thermally labile compounds, GC resolution, sensitivity and analysis time.

In figure 1 we show fast, very fast and ultra fast GC-MS analysis of different mixtures of

underivatized steroids that demonstrate this trade off between the SEF and the degree of decomposition observed. Note that corticosterone is effectively analyzed with very fast GC-MS, while with ultra fast GC-MS, even cortisone that is our most thermally labile compound, is analyzed. In figure 2 we demonstrate the application of fast GC-SMB-MS for the screening of drugs in urine. 0.3 mL of untreated urine were injected and the clean RSIM traces demonstrate low ppb range minimum detected concentration.

Non-Peptide Libraries: Structure Determination by LC/MS/MS.

Issakova, Olga; Ma, Nina; Kocis, Petr; Sepetov, Nikolai.
Selectide Corporation, 1580 E. Hanley Blvd, Tucson, Az 85737.

Synthetic combinatorial libraries are becoming an important tool of the pharmaceutical industry for the discovery of new drug candidates. Structure determination of hits, found after screening a large number of compounds (library) against a biological target, is a key element of the application of library technology for drug discovery. The sequencing of compounds from peptide libraries is well developed and can be done by either classical Edman degradation, ladder sequencing, or, because fragmentation characteristics of peptides are well known, by tandem mass spectrometry (MS/MS). However, direct structure determination of compounds from non-peptide libraries is analytically challenging.

Here we describe an example of direct structure identification by LS/MS/MS of compounds from a non-peptide library based on Kemp's triacid scaffold (Fig.1). The library was synthesized on solid phase in accordance with standard split-and-combine technology [1]. Synthesis was initiated with the coupling of Gly to the resin (TG-OH, 130 µm beads) via an ester bond, followed with the sequential coupling of β-Ala, Gly and β-Ala, forming a linker between the resin and first position for randomization. Thirty amino acids were used in the first randomization. Two of the three carboxyls of the Kemp's triacid were modified by ethylenediamine and served as two other positions for randomization (identical sets of fifty carboxylic acids were used for randomization at these positions). Thus, the library contained 75,000 different compounds. Compounds found as a result of screening against different biological targets, using on-bead binding procedures [1], were cleaved from the resin by alkaline hydrolysis. Releasates were analyzed by LC/MS/MS, using a micro HPLC (Michrom, BioResources Inc.) coupled on line with an API III triple qudrupole mass spectrometer (Perkin Elmer, Sciex Instruments, Thornill, Canada) equipped with a low energy collision cell. The analysis of a large variety of compounds showed that they fragmented at amide bonds, and that most of the daughter ions observed could be formally explained by cleavage of two or more amide bonds. Fig.2 presents a hypothesis for a fragmentation mechanism which we suppose is responsible for most of the observed fragmentation patterns. The proposed mechanism involves cleavage of an amide bond adjacent to the cyclic moiety with subsequent formation of a cyclic imide product (Fig.2a,b) and cleavage of another amide bond (Fig.2c). For example, in the daughter spectrum of a positive bead found after library screening (Fig.3, upper trace), all ions we were able to assign are marked with an *, and those whose origin we explain by the mechanism of cyclic imide intermediate formation, are marked with a circled *. Using the fragmentation patterns found, we developed computer software for automatic structure determination of compounds from this library, and used this software for structure identification of hits found after screening the library against biological targets. The accuracy of the analysis was confirmed by resynthesis.

In conclusion, this work demonstrates the successful practical

utilization of mass spectroscopy for direct structure elucidation of hits from non-peptide non-coded libraries.

OPTIMIZATION OF MALDI SEQUENCING OF SUPPORT-BOUND COMBINATORIAL LIBRARIES; R. Scott Youngquist, Gary R. Fuentes, Cathy M. Miller, Gregg M. Ridder, Martin P. Lacey and Thomas Keough; The Procter and Gamble Co., Miami Valley Laboratories, PO Box 538707, Cincinnati, OH 45253-8707.

Combinatorial libraries are a new approach to lead compound identification. Large mixtures of compounds are synthesized, and a selection strategy is applied to isolate the few compounds having the desired activity from the many compounds that don't. This approach has three main advantages relative to the classical method of screening extracts from bacteria, fungi or plants: First, all compounds are present at approximately equimolar concentration, which eliminates concentration effects in testing. Second, a chemist controls the synthesis, so it can be tailored for the required application. Third, isolation and screening of active compounds is fast and straightforward.

In this study we've optimized our previously reported (1,2) method for MALDI sequencing of biologically active molecules isolated from support-bound libraries. We optimized the synthesis and sample handling to facilitate the use of small resin beads (17 μm). We've automated the screening and sorting processes with flow cytometry, and extended the method to non-peptide chemistries including linear and cyclic carbamates (in collaboration with Dr. Charles Cho and Prof. Peter Schultz, UC Berkeley).

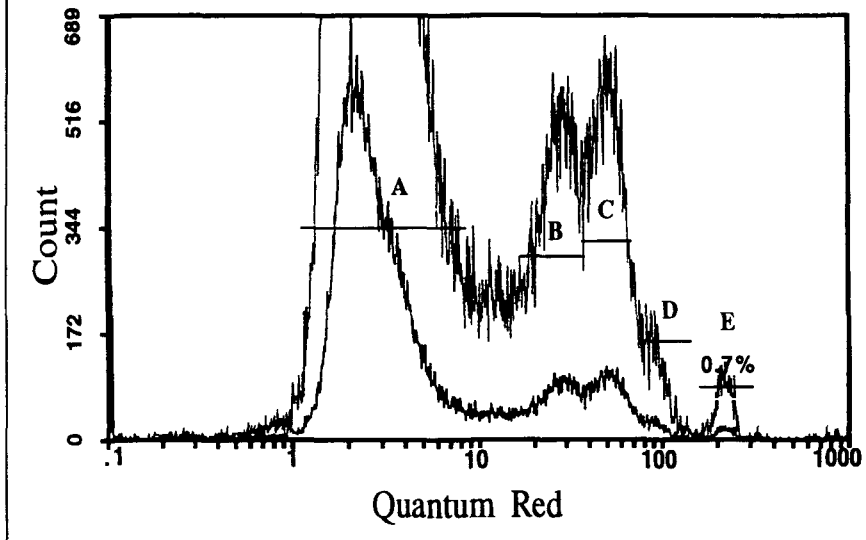
Initially, library screening and sorting was done manually, but there were several problems associated with that approach: First, the enzymes used for staining require specific conditions (pH = 9) that are different from our screening conditions, and this could affect target protein binding. Second, it is difficult to distinguish varying levels of staining. Third, manual isolation of the positive beads is slow and tedious.

To avoid these problems, we automated the screening and sorting process with flow cytometry. As an initial test, a small library containing multiple copies of only 128 distinct sequences (members) was analyzed to see if flow cytometry could successfully isolate the known high affinity ligand (Ac-HPQFx) to streptavidin. The flow cytometry screening and sorting results are given in the Figure, and several peaks (B,C,D and E) having varying Quantum Red fluorescence intensity are seen in the positive region. The beads associated with the highest fluorescence intensity, peak E, contained the expected recognition sequence. All 10 of the beads that were sequenced from peak E contained Ac-HPQFF. This sequence was not detected in any of the other peaks. The large peak associated with inactive peptides, peak A, showed random sequences having no homology. The observed intensity of peak E, 0.7%, agreed well with the calculated relative abundance of Ac-HPQFF in the small library (0.8%).

Larger libraries consisting of more than a few thousand members will have an extremely low percentage of actives. With these libraries, it is necessary to perform a two-pass sort. The first pass sort enriches the sample in positive beads while eliminating negatives. The sorted beads from each library are then run back through the flow cytometer and sorted a second time. The highest fluorescence beads from the target library sorts are then collected for subsequent sequencing with MALDI. With this approach, a library containing over 60,000 members was successfully screened against an anti-gp120 antibody, and the correct high affinity ligands were isolated. We are currently extending automated flow cytometry screening and sorting to libraries containing more than one million members.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Termination synthesis with MALDI sequencing is a very general method. Since it is not degradative, it is compatible with libraries of any compounds that can be prepared in a stepwise synthesis. For instance, it can be used with libraries of poly-N-substituted glycines, oligocarbamates, or nucleic acid analogs as well as libraries that combine several different monomers. Even monomers of identical mass, such as geometric or stereoisomers, can be easily distinguished (2). An example of non-peptide sequencing with termination synthesis/MALDI can be found in our previous study of methylphosphonate oligonucleotides (3). We are currently applying termination synthesis/MALDI sequencing to libraries of both linear and cyclic oligocarbamates. Synthetic procedures have been optimized, and excellent quality MALDI spectra have been obtained from the carbamate products isolated from single resin beads.



Acknowledgments: We gratefully acknowledge Dr. Charles Cho and Professor Peter Schultz (University of California at Berkeley), who synthesized all of the oligocarbamates sequenced in this study.

CHARACTERIZATION OF SMALL MOLECULES BY ESI AND APCI

Richard G. McKay, Charles N. McEwen, and Barbara S. Larsen
The DuPont Company, Central Research & Development
P.O. Box 80228, Wilmington, DE 19880-0228

Combinatorial libraries should prove useful in the discovery and optimization of new crop protection chemicals for the agricultural industry. A key advantage of the library approach is the rapid assembly of diverse, novel compounds by combining automation with synthesis on solid supports. Using a matrix synthesis approach, a chemist can quickly vary the type and nature of functional groups attached to selected organic scaffolds. One-hundred fold productivity increases the number of novel compounds synthesized for biological testing by these methods.

Rapid analytical support is critical for the chemist to develop the optimal synthetic processes and monitor the quantity of products produced. We report here our approach to rapidly analyze these samples by applying APCI.

We have upgraded our VG TRIO-2000 with APCI. The choice of APCI as an ionization technique is sound because it is robust, can be automated, and generates molecular ions for approximately 95% of the molecules synthesized. Shown in Figures 1 and 2 are a comparison of an electrospray and APCI spectra from a study, noting the observed fragmentation from the APCI spectrum. The system is configured using an HP1090 liquid chromatograph for direct injection of 10 µL of a 1.0 µg/µL solution. The diode array detector is used to check for the presence of the synthesized product monitoring an appropriate wavelength. The 1090 HPLC communicates to the MassLynx software allowing for a sample to be analyzed every 1.5 minutes (Figure 3). With this approach, 40 samples per hour can be analyzed with an averaged spectrum generated for each injection.

The volume of data from the mass spectrometer needs to be effectively managed. When a chemist begins with a new organic scaffold, we will work closely with them to assist in identifying the best conditions for library synthesis such as evaluating reactant and solvent concentrations. The mass spectrometer shows the chemist any side reactions or incomplete reactions. Once the synthetic route has been optimized, we provide only an excel spread sheet with an indication of whether the molecular ion was observed and the presence of other significant peaks. All spectra have been archived using a CD rom. Once a hit has been made using a whole plant screening approach all analytical data for that molecule can be retrieved.

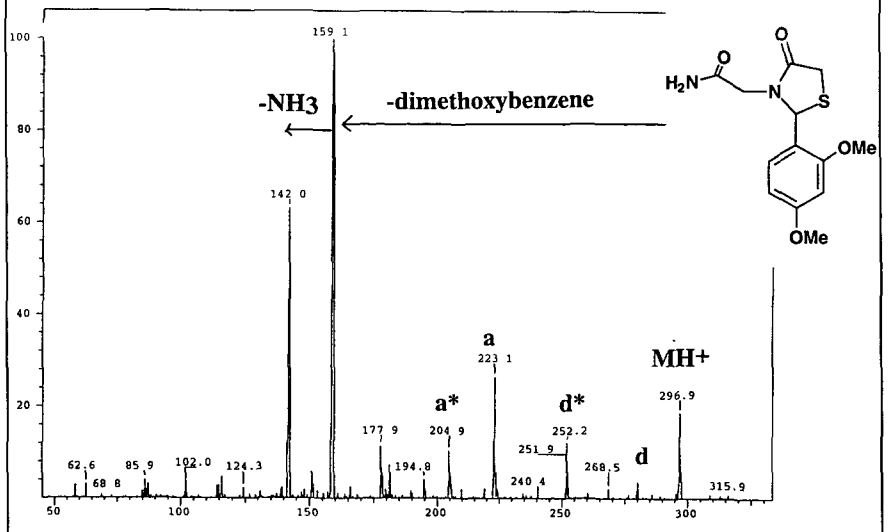
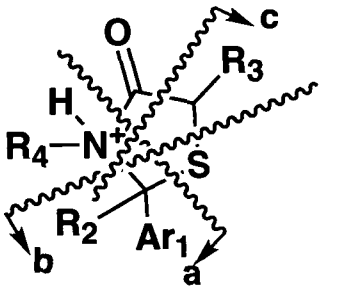
MS/MS of Thiazolidinones: Applications of MS in Combinatorial Chemistry

William L. Fitch, Nikhil Shah, Christopher P. Holmes and Gary C. Look
Affymax Research Institute, 3410 Central Expressway, Santa Clara, CA 95051.

Medicinal chemists are increasingly relying on robotic synthesis and solid phase combinatorial chemistry (SPCC) to leverage their drug discovery efforts. Affymax has been pioneering SPCC and we have been applying mass spectrometry to these efforts. In the rehearsal phase of SPCC, compounds are synthesized one at a time and their structures confirmed conventionally. In the library production phase of SPCC, using the "split and pool" method, compounds are made in mixture, one compound per bead. Mass spectrometry is the key method for quality control of these libraries. The pooled libraries can be bioassayed in the solid phase or after cleavage into microtiter plates. In either case, a decoding or deconvolution step is required to ascertain the structure of the active ligand. The MS behavior learned in the rehearsal phase is critical to the success of this sample limited step.

We illustrate these steps with pure compounds and libraries of thiazolidinones prepared by solution or solid phase condensation of amino acids, aldehydes and thioacetic acids. Mass spectra were recorded on a Finnigan TSQ7000 using ESI or APCI. APCI is more sensitive for these neutral molecules. Below is a typical MS/MS spectrum.





All of the compounds showed the a fragmentation pathway. Other dissociations were very dependent on the aromatic substituents and on the loss of neutrals from the R_2, R_3 and R_4 sidechains. The d and d* fragments in the opposing spectrum are due to loss of NH_3 and CO from the parent ion. The a* is due to loss of H_2O from a.

A 125 member library of thiazolidinones was prepared by SPCC and submitted blind to the MS lab. The APCIMS and APCIMS/MS of this compound are shown below. Of the 125 possible structures 5 had molecular weight 432. So the MS/MS experiment was necessary to complete the structure proof. All of the candidates had $CONH_2$ groups; the primary loses of NH_3 and CO were uninformative. But only the correct structure with an R_3=methyl would be expected to give the ion at m/z 300 due to a cleavage followed by loss of NH_3 and CO.

Characterization of Complex Chemical Libraries Using LC/MS/MS

Kerry Nugent and Sam Baldwin,Michrom BioResources, Auburn, CA
Adrian Land, Mark Bier, and Kevin Wheeler, Finnigan, San Jose, CA
Kerry Spear, Gianine Figliozzi and Ron Zuckerman,Chiron, Emeryville,CA

The synthesis of combinatorial libraries of chemical compounds is a powerful tool for screening vast numbers of diverse molecules for biological activity. These techniques were first used with synthetic peptides, but are now being used with peptoids (oligo N-substituted glycines) and other small molecules to produce libraries with dozens to thousands of components. These libraries can then be screened for components with desirable biological characteristics in a wide range of bioassays.

For this study, a 272 component proprietary synthetic peptoid mixture, produced by split resin methodologies was used as a model system for analytical characterization. Although only a few components of any mixture may be of biological interest, it is often important to fully characterize the entire combinatorial library to validate that the multiple synthesis reactions are producing the expected results, and to verify the exact makeup of the library in the event that it has to be produced more than once.

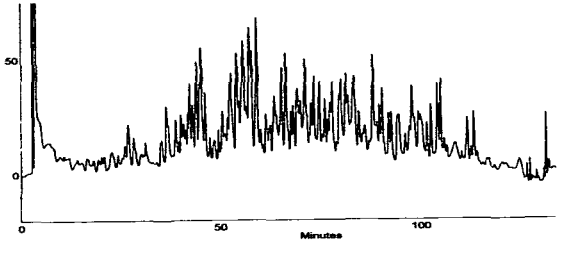
With very complex samples, it is generally advantageous to provide some degree of separation prior to mass spectral analysis to aid in the data interpretation. An initial 30 minute LC/ESI/MS run showed that all of the components in the mixture had masses between 300 - 700, and several components had the exact same mass. Although most of the components in this mixture could be identified using multiple short LC/MS/MS runs, it was found that by running a high resolution, 120 minute LC/MS/MS analysis, the entire mixture could be characterized in a few runs.

Figure 1

20 Picomoles
272 Peptoid Mix

1x150 3u 100A RC18
5-65% ACN / 120 min

1-3 Peptoids / Peak



A Michrom UMA microbore HPLC was coupled to either a Finnigan TSQ 7000 Triple Quad MS/MS or a Finnigan LCQ Benchtop MS/MS to screen the sample for parent ions. The initial LC/MS runs employed a rapid 20 minute gradient from 5 - 65% B, to screen a 20 picomole aliquot of the 272 component peptoid sample, giving a total analysis time of 30 minutes. Over 90 parent ions were easily identified during this rapid screening run, and an automated MS/MS experiment was then set up to fragment and help identify these specific compounds.

Figure 2 shows a portion of the output of the automated LC/MS/MS experiment run on the Finnigan LCQ Benchtop MS/MS, with each spike representing an individual MS/MS experiment. The upper trace shows the results of monitoring one specific MH+ ion (419.1), while the lower trace shows the base peak output. Two major components (Peak A and Peak B) were found at different elution times, but had the exact same molecular weight (419.1).

From the MS/MS Spectra in Figures 3 and 4, it is clear that these two isobaric components are indeed different molecules. The automated MS/MS experiments produced useful spectra for most of the other target ions identified in the fast LC/MS runs. Using the proprietary information about the starting materials, all of sample components were easily identified from their MS/MS spectra.

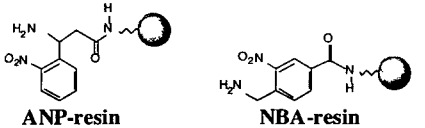
A Single Bead Decode Strategy using Electrospray Ionization Mass Spectrometry and a New Photolabile Linker: 3-Amino-3-(2-Nitrophenyl)Propionic Acid

*David S. Wagner, Bradley B. Brown, and H. Mario Geysen
Glaxo Research Institute, Diversity Sciences Department,

The advent of high throughput screens have increased the number of compounds screened per drug target, and augmented the need for large numbers of novel compounds. Combinatorial chemistry is a synthetic strategy that generates a huge number of chemical compounds and is designed to replace the expensive and time consuming process for individual synthesis. We are investigating procedures that allow for the partial cleavage of support-bound oligomers thereby extending the screening and analytical techniques available to identify active ligands.

A new polymer support that employs a photolabile 3-amino-3-(2nitrophenyl) propionyl functionality (ANP resin) has been developed.



ANP-resin **NBA-resin**

Photolabile resins offer some advantages over traditional resins including the ability to promote partial cleavage [assay versatility], stability in acidic and basic reaction conditions, and reduction of the number of side products from cleavage. Rich and Gurwara[1] showed that polystyrene based *o*-nitrobenzylamide resins (**NBA-resin**) can be cleaved to carboxamides but often suffer from difficult preparation procedures, extended $t_{1/2}$ times, and low photocleavage yields. To determine if the ANP group provides an effective solution to many of the problems commonly encountered by the NBA resins, the utility of the ANP-resin was investigated (analysis by ESI-MS, LDI-MS).

A diverse set of 20 amino acids were individually coupled to ANP-resin and photolyzed for 2 hours (hand held Mineralight 720 uW/cm^2). The MH^+ ions were observed by ESI-MS(Sciex API-III) for all compounds and all protecting groups survived these photolytic conditions. After 16 hours, 3 of the protecting groups were either oxidized or reduced. A pool containing equal amounts of the 20 amino acids was photolyzed for 12 hours. Seventeen of the twenty amino acids were observed as MH^+ ions, figure 1, (3 samples not observed were the unstable protecting groups).

We prepared Fmoc-Arg(Tos)-**NBA** for comparison to the ANP analog. The intensity of the MH^+ (by ESI) was correlated with irradiation time. A standard solution of Fmoc-Arg(Tos)-NH_2 was used to normalize the intensity of the MH^+ signals and determine percent cleavage from resin. The overall yield from the ANP-resin > NBA-resin. The faster ANP$t_{1/2}$ is beneficial considering analytical and assay needs.

A single bead of Fmoc-Asp-Arg(Tos)-Val-NH2 in 5 ul of H_2O was partially cleaved by irradiating for 1 hour. The 5 ul was removed and diluted to a final volume of 25 ul. ESI-MS of 5 ul showed and intense MH+ ion at 764.2 Da, in complete agreement with the calculated value. MS/MS was performed on the remaining 20 ul and allowed for full mass spectral characterization of the tripeptide, figure 2. The same bead was then re-suspended and

irradiated for 16 hours. As before, ESI-MS detected a strong MH^+ ion, and MS/MS allowed for complete sequencing. Verifying structure elucidation utilizing partial cleavage (controlled release) on a single bead and without encoding methods.

Laser desorption (VG TofSpec SE) was employed to determine the feasibility of direct desorption from the solid resin (Figure 3). Several dry beads of the Fmoc-Arg(Tos)-NH2 were loaded on the sample probe. LD produced a weak but distinct MH^+ signal. Matrix (α-cyano) was added on top of the beads, MALDI produced a stronger MH+ signal. The 20 carboxamides were analyzed. Matrix enhanced the signal from the beads. Most samples produced a characteristic signal in the mass spectrum. Approximately 30% of the carboxamides produced distinguishable MH+ ions.

The ANP-resin proved to be a versatile solid support for the synthesis of C-terminal carboxamides. The cleavage rate of ANP > then the commonly employed NBA-resin. The synthesis and controlled release of tripeptide from a single bead validates the ESI-MS strategy for decoding resin-bound peptide libraries. LDI has shown promise for direct cleavage form the ANP-resin. Currently, modified ANP-resins and alternative analytical techniques are being evaluated for their application with solid phase small-molecule libraries.

LC/MS Strategy for the Rapid Profiling of Solid Phase Synthetic Products

Robyn A. Rounck[1], Jeffrey L. Whitney[1], Steven E Klohr[1], Kevin J. Volk[1], Edward H Kerns[1] and Mike S. Lee[2], Bristol-Myers Squibb Company, [1]Wallingford, CT 06492, [2]Princeton, NJ 08543

Traditional synthetic chemistry methodologies used for the production of therapeutically relevant compounds often emphasize the "hand-crafting" of a single compound in milligram or greater amounts by a single chemist. Activity is assessed on each final product and is often used to determine the next relevant structural change to be made. A single chemist using the traditional approach produces, on average, less than 100 final compounds per year. Combinatorial chemistry methodologies facilitate the rapid systematic synthesis of molecularly diverse libraries using predetermined sequence variations on solid-phase supports[1-4]. These resulting libraries contain hundreds or even thousands of structurally similar compounds in sub-milligram amounts. The library or "matrix" of compounds produced can be tested for activity using high throughput screening techniques. Relevant targets often include membrane bound receptors, enzymes and metabolic intermediates. Many more compounds can be produced and tested with combinatorial techniques compared to traditional methods.

Libraries of compounds in solution or on solid support present numerous challenges when traditional proof of structure approaches are applied. Some analytical techniques, such as NMR, elemental analysis and infrared spectroscopy do not lend themselves to direct and rapid analysis of synthetic analogs at sub-microgram levels. The analytical methodologies we have developed over the past five years based on LC/MS and LC/MS/MS techniques have provided detailed structural information on trace impurities and degradants, metabolites from biological fluids, natural product extracts and crude reaction products[5,6].

Coupling solid phase synthesis with our profiling methodologies provides a rapid on-line approach for the identification of synthetic reaction products. Analytical strategies were developed utilizing solid phase chemistry and electrospray mass spectrometry for the rapid synthesis and profiling of reaction products. For this study, captopril (SQ 14,225) was the model compound chosen for the application of solid phase synthesis. Library design centered around the combination of five amino acid monomers and six acid R-groups; one combination producing Captopril. Standard peptide synthesis conditions were used involving a Wang-based resin, FMOC deprotection with piperidine, PyBOP coupling conditions, and resin release with TFA. Substructure screening methodologies were developed using LC/MS and LC/MS/MS techniques. Structurally related compounds were identified by screening for monomers contained in the compound matrix.

The released resin-bound compounds were initially characterized by flow injection analysis on an ESI equipped tandem mass spectrometer. The presence of Captoril was confirmed by observing the molecular ion and expected substructures. The negative product ion spectrum of m/z 217 indicated a major fragment at m/z 114, corresponding to the proline substructure. The negative precursor ion spectrum of m/z 114 indicated an ion at m/z 217, corresponding to the molecular ion of Captopril (fig. 1). The characterization and identification of compounds in the library mixture were performed using standard LC/MS and LC/MS/MS methodologies[5,6]. LC/UV data obtained on the mixture indicate the separation of several components with diverse retention times. Substructural screening methodologies were illustrated by the identification of three major components containing the proline substructure, using negative precursor LC/MS/MS on m/z 114 (fig 2). These components correspond to the addition of heptanoic, methyl valeric, and ethyl butyric R-group moieties.

MALDI-TOF-PSD-MS of Peptides off of Single Polymeric Beads

Patrick R. Griffin and Zenon D. Konteatis
Merck Research Laboratories, Rahway, NJ 07065

Previously, we have shown that structural information of a peptide/peptoid can be obtained from analysis of a single bead by MALDI-TOF-MS (1). Here we present a strategy for direct structural characterization of peptide and/or non-peptide combinatorial libraries utilizing MALDI-TOF-PSD-MS and Sequest© (2). The strategy involves the use of differential cleavage linkers, three cleavage strategies, and direct structural identification of active compounds by MALDI-TOF-PSD. Differential cleavage was used to allow multiple biological assays in solution and /or direct assaying of the solid support (3). Advantages of the proposed strategy are as follows: First, it is fast, sensitive, flexible and easy to perform. Second, the strategy should be compatible with various types of chemistries, peptide and non-peptide. Lastly, the method does not rely on encoding or capping strategies. Both the encoding and capping strategies may limit compatibility with various chemistries or types of subunits used. In addition, additional ligands that would be present in both strategies may interfere with the biological assay in which the libraries are used.

The steps involved in identifying active structures were as follows: First, differential release of peptide/non-peptide from resin was performed either by exposing resin to acetic acid or TFA. Second, biological assays performed in solution. Third, treatment of active beads with cyanogen bromide (CNBr). Lastly, released peptide/non-peptide was analyzed using a Finnigan MAT Vision 2000 reflectron MALDI-TOF mass spectrometer in two modes. In the first mode, the normal reflectron mode of the instrument, the molecular mass of the compound was determined. Figure 1 shows a normal reflectron spectrum obtained from analyzing peptide, Phe-Ile-Phe-hSer(lactone), [M+H]+ = 509.6, released from a singly polymeric bead that was treated with CNBr. Next, the precursor mass was selected and analyzed in the PSD mode of the instrument. The PSD mode permits the analysis of metastable fragment ions of a pre-selected precursor ion that are formed in the first field-free region. These fragments are structurally informative and can be used to identify the structure of compounds from combinatorial libraries. Figure 2 displays a MALDI-TOF-MS-PSD spectrum obtained from analyzing the peptide described above. The insert on Figure 2 highlights the sequence ions observed in the spectrum.

To aid in the interpretation of PSD spectra, the database matching program Sequest©, developed by John R. Yates, III and Jimmy K. Eng of the University of Washington, was used.

CHARACTERIZATION OF BENZODIAZEPINE COMBINATORIAL CHEMICAL LIBRARIES BY IAE/LC/LC/MS/MS

Michael Nedved, Bruce Ganem,* and Jack Henion
Cornell University, Analytical Toxicology, 927 Warren Dr., Ithaca, NY 14850
*Cornell University, Department of Chemistry, Ithaca, NY 14853

Recently developed combinatorial chemistry techniques allow the generation of large chemical libraries of potential drugs which must then be screened for pharmacological activity (1). Although individual components of combinatorial libraries have been characterized by the use of chemical or fluorescent tags (2), mass spectrometry provides a means for direct and more specific characterization. This has already been demonstrated using a MALDI-TOF mass spectrometer (3). We have demonstrated that a combination of immuno-affinity extraction (IAE) and reversed-phase chromatography followed by on-line, ion-spray mass spectrometry can be used to select and detect components of small benzodiazepine combinatorial chemical libraries using an antibody specific for benzodiazepines. From full-scan IAE/LC/LC/MS/MS data, it is shown that selected components can be characterized by their MS/MS spectra.

EXPERIMENTAL

Automated, on-line column switching was done using a PerSeptive Biosystem's Integral™ Micro-analytical Workstation. IAE was performed by loading a benzodiazepine monoclonal antibody onto a Protein G column (4.6 x 50 mm) which binds the antibody non-covalently. A buffer containing 10 mM NaH_2PO_4 pH 7.4, 0.15 M NaCl was used as the mobile phase at a flow rate of 1 mL/min. A mixture of benzodiazepines in this buffer was subsequently loaded onto the column with unbound components flushed to waste. Antibody and bound analytes were desorbed onto an SPS, C-18, internal-surface, reversed-phase column (0.3 x 10 mm) using 2% (v/v) acetic acid thereby separating the analyte from antibody which was flushed to waste. The trapped analytes were backflushed onto a third column (reversed-phase, C8 Betasil, 2 x 100 mm) at 200 µL/min using a mobile phase containing 40/60 CH_3CN/H_2O, 5 mM NH_4HCOO pH 3.5. Between runs, residual antibody was stripped from the Protein G column with 20% acetic acid (v/v). Full-scan, postive ion mass spectra were recorded using a Perkin-Elmer-Sciex API 300 tandem mass spectrometer by directing the effluent from the C8 column without splitting through an ion-spray interface at 4.1 kV. Full-scan MS/MS spectra were acquired using Argon as the collision gas. A known chemical library of 19 commercially available benzodiazepines, and an unknown, 20-component benzodiazepine chemical library were analyzed.

RESULTS

Figure 1 shows the full-scan LC/MS (A) and IAE/LC/LC/MS (B) chromatograms for a known, 19-component benzodiazepine chemical library. The monoclonal antibody is specific for benzodiazepines and thus does not display great selectivity towards any one component. One component, diazepam, was chosen, and in a subsequent experiment, a full-scan IAE/LC/LC/MS/MS chromatogram was acquired (Figure 2A). The MS/MS spectrum shown in Figure 2B is the average of 15 scans over the peak eluting at 11.44 minutes, and the fragment ions are characteristic of diazepam when compared to the MS/MS spectrum of a standard solution. The same approach is being used to characterize the unknown, 20-component benzodiazepine chemical library.

SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

INTRODUCTION The developing importance of parallel synthesis of large numbers of compounds either as combinatorial libraries (e.g., via the split synthesis method) or as discretely synthesized compounds on pins, on surfaces, or in 96-well plates puts increasing demands on the development of methods to identify the compounds synthesized. At certain stages during the development of a synthetic strategy, it may be important to analyze a number of the components of the library to verify that the synthesis is producing the desired compounds. However, analysis of every compound in a library that may contain over 10^6 compounds would be an onerous, if not impossible, task. Therefore, a reasonable strategy would be to provide a means to determine the structure of those compounds that are found to be active in biological assay systems. One approach is tagging, the encoding of the beads at each step of the synthesis with information about the chemical reaction at that step. The tag is then released from the bead and "read" using an high sensitivity analytical method appropriate to the tags employed. Tagging carries with it the burden of additional chemical reactions for each step of the combinatorial synthesis with the requirement that the tagging chemistry and the combinatorial chemistry be mutually compatible; also, the release chemistry for the tags and the library compounds must be mutually exclusive. Alternatively, direct mass spectral analysis of the active library compounds is an option. Such a strategy should include the ability to obtain both molecular weight information as well as fragmentation from the amount of compound that would remain on a bead after several rounds of partial compound release and biological assay. Good mass accuracy can help to reduce the MW redundancy that is typically observed in combinatorial mixtures, and reducing such redundancy may obviate the need for tags. Likewise, fragmentation can be used to further narrow the list of possible structures. Ideally, these methods should be amenable to high throughput modes of operation in order to efficiently deal with the large number of beads/compounds that would be generated through massive screenings of combinatorial libraries for biological activity.

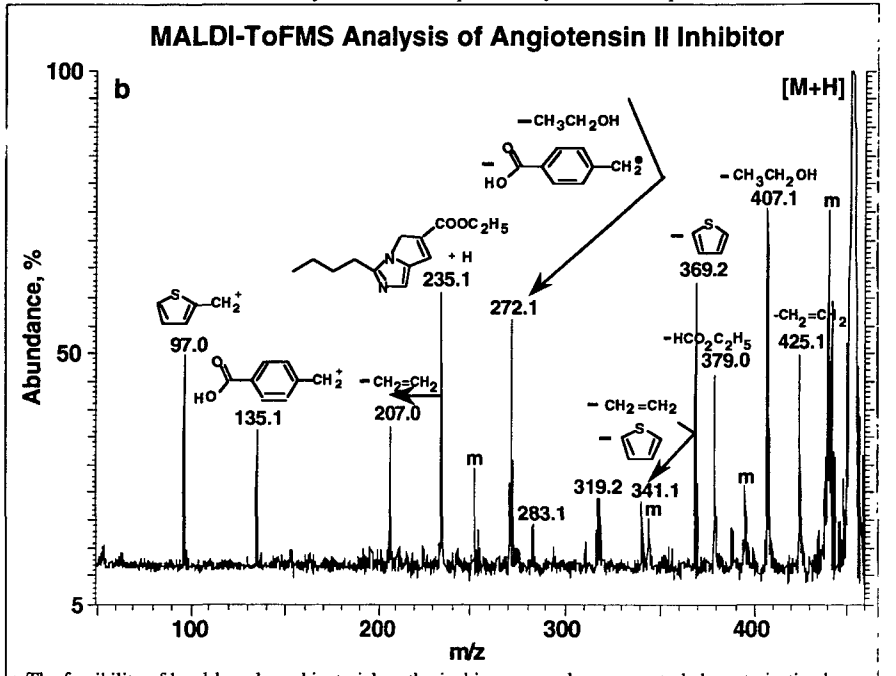
RESULTS

- All three methods produce analytically useful results from ≤ 100 pmol of material – both molecular ions and interpretable fragmentation.
- Fragmentation efficiency is comparable for all 3 techniques. However, PSD efficiency in MALDI appears to be matrix-dependent.
- Reduction processes for susceptible compounds in MALDI may reduce utility of isotope ratios for identification of halogenated compounds.
- Mass accuracy is in the order: MALDI-ToF < ESI-Q^3 << MALDI-FTMS

for fragment ions	MALDI-ToF	ESI-Q^3	MALDI-FTMS
avg. std. dev.	0.026	0.012	na
avg. error (Da)	0.039	0.013	0.001
avg. error (ppm)	161	85 (27)[a]	4.4

[a] Without outliers at m/z 97 (412 ppm) and m/z 107 (395 ppm).

- Sensitivity appears to be sufficient to allow identification of compounds after several sequential releases of material for bioassay. However, it is obvious that cleavage conditions need to be well-characterized in order to provide a reasonable amount of material (e.g., ca. 100 pmol) after the after n rounds of bioassay to allow for complete mass spectral analysis.



- The feasibility of bead-based combinatorial synthesis, bioassay, and mass spectral characterization has been demonstrated.

CONCLUSIONS We have found several methods that appear to be capable of producing the desired information at the desired sensitivity. We have demonstrated that both MALDI on a ToFMS (or FTMS) and ESI on a quadrupole mass analyzer are capable of providing MW information on the compound from a single bead with relatively high mass accuracy (<75 ppm); MALDI-FTMS provides ≤5 ppm mass accuracy. ESIMS/MS is capable of providing a useful fragment ion spectrum on another aliquot of material from the same bead. Taking advantage of post-source decay fragmentation in MALDI, we have been able to generate a comparable fragment ion spectrum. Taking advantage of the SORI technique in FTMS, we have been able to generate a comparable fragment ion spectrum with very good mass accuracy (≤10 ppm). We have also demonstrated the ability to analyze the compound remaining on a single bead after multiple successive cleavages and also from a single bead that was determined to be active in a angiotensin II receptor antagonist biological assay system tested with both active and inactive beads. This project demonstrates the feasibility of analysis of bead-bound combinatorial libraries by mass spectrometry and that, with libraries carefully designed to reduce mass redundancy, the need for a complete, systematic tagging scheme is obviated.

ACKNOWLEDGMENTS Special thanks to John Hoyes (VG Analytical) for obtaining preliminary MALDI-PSD data and to John Castoro (Extrel FTMS) for providing the MALDI-FTMS data.

DETERMINATION of the DIVERSITY of SMALL-MOLECULE LIBRARIES by CZE-ESI-MS

Yuriy M. Dunayevskiy[1], Paul Vouros[1], Thomas Carell[2], Edward A. Wintner[2], Julius Jr. Rebek[2]
1 Department of Chemistry and the Barnett Institute, Northeastern University, Boston, MA
2. Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA

Combinatorial chemistry is considered a powerful tool for the development of new therapeutic agents[1,2]. Instead of synthesizing individual compounds and evaluating their biological activity, promising lead candidates are efficiently selected from the vast mixtures through application of modern screening and isolation techniques. Nowadays the main interest lies in synthesizing the libraries in solution where a wide variety of efficient solution phase syntheses can be employed. However, chemistry in solution offers less control on the final mixture composition compared to synthesis on a solid support. Therefore, it is important to determine if all of the anticipated compounds are produced and if there are any side products that potentially can be responsible for the biological activity of the library We utilized electrospray mass spectrometry, both alone and coupled to capillary zone electrophoresis (CZE-MS), to evaluate the diversity of small-molecule libraries. Our approach allowed to investigate the "population density" of the "molecular landscape" generated by the compound variety

The synthetic procedure for the preparation of the molecular libraries is presented schematically in Figure 1 and has been described previously[3]. The libraries consisted of more than 65,000 compounds with different functional groups (19 amino acids) about a rigid xanthene core 1, which determined the overall shape of the molecules. The combinatorial libraries were subjected to a screening procedure to identify the bioactive component(s) to trypsin[3]. All experiments were performed on triple quadrupole mass spectrometers VG Quattro and TSQ-700.

In the view of the fact that complete characterization of the 65,341 component mixture was unrealistic, small representative sublibraries were synthesized based on the core molecule 2 which contained only two acid chloride groups in the position four and five. Molecule 2 provides a realistic test for the determination of building block combination not favored in the synthesis as positions two and five have the highest susceptibility to steric crowding Libraries containing theoretically 36, 45, 55, 78 and 120 compounds were obtained through reaction of 2 with mixtures of 8, 9, 10, 12 and 15 amino acids, respectively. First, we analyzed several single xanthene diamino acids and their simple mixtures in order to investigate the effect of different building blocks on the ionization efficiency of the molecules. The positive ion ESI mass spectra exhibited mainly the protonated molecules without fragmentation in the mass range of interest (m/z:500-900) under the experimental conditions employed. As expected, the derivatives of amino acids with positively charged side chain gave $(M+H)^+$ ions of higher intensity than the derivatives of non-charged and especially of negatively charged amino acids. However, the differences in response signals were not drastic, and there was no ion signal suppression. As the complexity of a mixture increases, one might observe a peak at virtually every nominal mass in the ESI spectrum Therefore, we examined mixtures with different relative concentrations of the components in order to determine when the molecules of lower ionization efficiency still constitute a signal distinguished from the background. As a result of these experiments the threshold of 10:1 S/N was set as a minimum acceptable signal for confirmation of the presence of any given compound in the mixture within the relative concentration range of ten. However, for the derivatives exhibiting peaks of a S/N ratio close to the threshold, additional evidence was deemed necessary to prove a "hit". For these purposes we used negative ion detection mode, which yielded well defined molecular ion data represented by the $(M-H)^-$ ion peaks and offered less background noise This complimentary information helped to verify the presence of the compounds obscured by basic analytes in positive ion mass spectra.

Even though we constructed the libraries to avoid the presence of isobaric compounds, some of the mixture components had the same molecular weights. MS/MS experiments were used as a third confirmatory step and revealed the occurrence of two major fragmentation pathways. The first one led to the formation of the fragment consistent with the core molecule and another one was determined by the structure of the attached amino acid. The CID results allowed us to detect and establish the structure of some side products with the related xanthene rigid core and differentiate between isobaric compounds. Thus, model libraries containing up to 55 components were analyzed and characterized by positive ion, negative ion and MS/MS detection modes. In order to reduce the number of

sub-libraries the analysis of larger mixtures was desirable. However, the increased number of compounds reduces peak capacity, since ions could be observed at every mass within the limited mass range. Accordingly, we explored the use of CZE-MS in order to introduce a fast and efficient further dimension to the analysis Electrophoretic conditions were chosen such that the complex mixture could be separated into several groups of compounds. Within each of the group only several peaks had the same masses and were distinguished by daughter ion spectra analysis An example of separation of isobaric compounds in a library of 120 entities (15 building blocks) is shown in Figure2, where asterisk represents an isotopic peak from Pro/X/Glu derivative (m/z 637) The investigation of the model sub-libraries revealed that most of the anticipated compounds were formed (approximately 85%) Only molecules containing one or more Trp^{Me} or multiple Gly^{Me} and Tyr^{Me} building blocks could be absent in the library based on core molecule 1

The combination of different mass spectrometric approaches allows the analysis of complex mixtures with closely related structure and determination of their composition and purity. The further introduction of a on-line separation method gives an opportunity to examine larger mixtures and, therefore, to reduce the number of tedious synthesis of representative sub-libraries. This provides for rapid screening of combinatorial libraries for their expected complexity and allow the optimization of the synthetic methodology in order to maximize the yield of library compounds.

Mapping Chemical-Space: Application and Prediction within LC/MS

Samuel Mitrovich, Jr.* and Ross C. Willoughby
Waters Corporation, Extrel Mass Spectrometry 575 Epsilon Drive, Pittsburgh, PA 15238

We have developed chemical mapping techniques that allow the visualization of the domain of organic compounds using only the empirical formula and basic physical properties. These Chemical-Space maps can be used to establish a relationship between an analyte, or analyte class, relative to other compounds within the domain of organic compounds. We have constructed 3-D maps of Chemical-Space by plotting molecular weight, frequency of occurrence and specific refractivity using the Wiley data base of mass spectral compounds. The surface created is a graphic representation of the domain of organic compounds. Since the position of any single compound in this domain is a function of its intermolecular interaction and intramolecular properties, the relative position of any analyte on the map is used to predict the applicability of a specific analytical technique. We have also constructed 2-D maps of randomly selected compounds from the Merck Index by plotting molecular weight against a calculated quantitative polarity index (QPI). The QPI includes a factor for the dielectric constant. By including the dielectric constant the maps reflect the boundaries of the strongest intermolecular interactions.

Specific Refractivity

Specific refractivity is derived from the equation for polarizability also known as the Lorentz-Lorenz relation.

$$\alpha = \frac{3}{4\pi N}\left(\frac{n^2-1}{n^2+2}\right)\frac{M}{\rho}$$

(N is Avogadro's number, n is the refractive index, M is the molar mass and r is the density.)

Polarizability is related to the ease with which an electric field can distort the molecule, size of charge fluctuations, melting and boiling points, volume of the molecule as well as London dispersion forces. Unfortunately it is difficult to calculate. Therefore, another version of the Lorentz-Lorenz relation called molar refractivity is used; it is given by the equation:

$$R_M = \left(\frac{n^2-1}{n^2+2}\right)\frac{M}{\rho} = \frac{4}{3}N_A\pi\alpha$$

Molar refractivity can be calculated from the values of the bond refractions that make up a molecule. These values are known and are additive(1). It is only necessary to know the molecular formula to do the calculation. From those values the specific refractivity is calculated. Specific refractivity is the molar refractivity divided by the molecular weight:

$$R_S = \frac{\left(\frac{n^2-1}{n^2+2}\right)\frac{M}{\rho}}{M}$$

Quantitative Polarity Index

The QPI was calculated using the equation for estimated dielectric constant:

$$\varepsilon_{est} = (\alpha_1\varepsilon_1+\alpha_2\varepsilon_2+...)\frac{\rho}{M}$$

The equation assumes that each atom and group make a specific contribution to the dielectric constant. The information needed to do the calculations is similar to that needed

for calculating molar refractivity. To avoid the need for density values, the partial dielectric constant (ε_p) was calculated:

$$\varepsilon_p = \frac{(\alpha_1\varepsilon_1+\alpha_2\varepsilon_2+...)}{M}$$

The ε_p represents the relative contribution of each constituent atom to the total dielectric constant. QPI is calculated as the product of molar refractivity and the partial dielectric constant:

$$QPI = R_M\varepsilon_p = \frac{1}{\rho}\left(\frac{n^2-1}{n^2+2}\right)(\alpha_1\varepsilon_1+\alpha_2\varepsilon_2+...)$$

The equation contains aspects of intramolecular structure and intermolecular interaction. $R_M\varepsilon_p$ is equivalent to the specific refractivity (R_S) times the specific contribution of each atom or functional group to the dielectric constant.

Alkylation of *E. coli* Thioredoxin by S-(2-chloroethyl)glutathione

John C. Erve[†‡], Elisabeth Barofsky[†], Douglas Barofsky[†], Max Deinzer[†], Don Reed[‡]
[†]Department of Agricultural Chemistry and [‡]Department of Biochemistry/Biophysics, Oregon State University, Corvallis OR, 97331

Introduction:

The tripeptide glutathione (GSH) is an important component of the cells defense mechanism due to its ability to combine with reactive electrophiles that can cause damage to biologically important macromolecules. It is now realized, however, that GSH conjugation may also lead to toxification reactions, such as occurs for the dihaloalkanes. 1,2-Dichloroethane (DCE) is a major organic chemical produced in the U.S. for use as a starting material for vinyl chloride synthesis. Following exposure to DCE, GSH conjugation can result in formation of S-(2-chloroethyl)glutathione (CEG). By a process of intramolecular cyclization, CEG can form a potent alkylating agent that can alkylate nucleophilic sites in DNA, such as the N^7 position of guanine. The focus of our research has been to better understand the protein alkylating ability of CEG, in order to elucidate the possible component of protein covalent binding in the mechanism of toxicity of DCE.

Materials and Methods:

E. coli thioredoxin was used as a model protein due to the presence of a reactive sulfhydryl group present at the active site of the enzyme. CEG, synthesized by the method of Reed and Foureman, was added in 5, 10 and 25 fold molar excess over reduced thioredoxin and allowed to react in an ammonium bicarbonate buffer at pH 7.4. Separation of the adducts utilized RP-HPLC with a C4 column. MALDI-MS was accomplished with a custom built TOF instrument and tandem mass spectrometry was accomplished with a Sciex III plus triple quadrupole.

Results:

The major thioredoxin alkylation product was a mono-adduct, which after collection off the HPLC column was pure, as judged by MALDI-MS (Figure 1). This adduct was digested with trypsin and analyzed by MALDI-MS. An alkylated tryptic peptide at *m/z* 2,370 corresponds to the tryptic peptide containing the two active site cysteines at positions 32 and 35 (Figure 2). This peptide was collected following separation of the tryptic digest peptides on a C18 column and analyzed by ionspray MS (Figure 3A). The doubly charged ion was fragmented to produce the product ion spectrum in Figure 3B. Ion y_5, seen at *m/z* 897, fragments to lose a glutamic acid residue to produce the peak observed at *m/z* 768. Examination of the fragment ions produced led to the conclusion that only one of the active site cysteines was alkylated by the episulfonium ion of CEG. The work presented here shows the power of mass spectrometry in identifying particular alkylation sites in proteins and should be useful in elucidating the role of protein covalent binding in the toxicity of certain toxic chemicals.

OPTIMIZATION OF EXPERIMENTAL PARAMETERS USED IN HRMS OF DNA ADDUCTS

Asoka Ranasinghe, Nova Scheller, Kuen Y. Wu, James A. Swenberg
Department of Environmental Sciences and Engineering, University of North Carolina, Chapel Hill, NC 27599-7400

The pursuit of more sensitive and specific methods for the detection and quantitation of DNA adducts has led to the application of high resolution mass spectrometry (HRMS), in combination with gas chromatography-electron capture negative chemical ionization (GC-ECNCI)[1]. In this work, we have investigated the effect of several experimental parameters, including mass resolving power, sample introduction and derivatizing reagent on the quantitation of N^2,3-ethenoguanine (EG), *a promutagenic adduct, using isotopic dilution mass spectrometry.*

The samples were analyzed using HP 5890 GC interfaced to a VG70-250SEQ mass spectrometer. Both on-column and direct injections were made on to a DB-5 fused silica capillary column (30m X 0.32 mm) with a He head pressure of 10 psi. Two reagents, pentafluorobenzyl bromide (PFBB) and 4-trifluoromethyl-2,3,4,5-tetrafluorobenzyl bromide (TTBB), were used for derivatization. ECNCI selected ion monitoring experiments were performed by monitoring the fragment ions, $(M\text{-}PFB)^-$ [m/z 354.0413, 358.0549 ($^{13}C_4$-labelled int. std.)] for PFB_2-EG and the ions, $(M\text{-}HFB)^-$ [m/z 404.0381, 408.0517 (IS)], for *diheptafluorobenzyl bromide*, HFB_2-EG. Perfluorokerosine (PFK) was used for tuning and for lock masses (m/z 354.9792 and 404.9760) during HRMS, and the dwell time was 50 ms per ion. The ion source temperature and the methane pressure were 250°C and $3X10^{-5}$ mbar respectively. The DNA assays were carried out according to previously published work.[2]

Although increased resolving power (RP) causes a decrease in intensity of the analyte signal, better detection limits than low resolution MS (LRMS) can still be obtained for biological samples because of the reduction in chemical noise obtained in the narrower mass window used at RP 10,000. For example, HRMS of a synthesized standard PFB_2-EG (190 amol) gives similar detection limits (S/N 9; Figure 1) to the reported[2] LRMS experiment. However, analyses of endogenous EG in human liver samples indicate S/N improvement when changing the RP from 1000 (Fig. 2a; S/N 44) to 10,000 (Fig. 2b; S/N 80). Derivatization using TTBB also seems to increase the method detection limit, perhaps due to greater electron affinity of HFB_2-EG (14 F atoms compared to 10 in PFB_2-EG). Electrophore-labelled biological samples are complex mixtures which can quickly degrade capillary columns when injected using on-column mode. Guard columns can extend the life of the analyte column but disrupt the system due to constant clipping at the injection port, and are prone to leaks each time they are handled. Direct injection (Fig. 2b; S/N 80) using a press-fit liner (uniliner #20355, Restek) has given better detection limits than on-column injection (Fig. 2c; S/N 45). These reusable liners allow as many as forty to fifty continuous injections with no increase of signal background and no need for column clipping.

Method calibration for ultra trace amounts of analyte (spiked EG)(Fig. 3) can only be done using HRMS because of the lower detection limit obtained. The HRMS for the lowest calibration point (25 fmol spiked; Figure 4) shows an excellent agreement with the expected RF (0.26 obs.; 0 18 calc.) while LRMS shows a much larger deviation (0.99 obs.). The method limit of detection for EG is 25 fmol/μmol G at a S/N of 5 inspite of limited sample recovery (12%) and injection of only 1 μl (500 amol) out of 50 μl final solution. These results demonstrate the strength of HRMS in the analysis of endogenous DNA adducts.

This work has been supported in part by a grant from the National Institute of Health (P42 ES05948).

Quantitative Analysis of DNA Adducts by Using HPLC/ESI-MS

Ten-Yang Yen, Nadia I. Christova-Gueorguieva, Nova Scheller, James A. Swenberg and M. Judith Charles
Department of Environmental Sciences and Engineering, University of North Carolina
Chapel Hill, NC 27599-7400

Introduction: The analytical methods needed for the determination of DNA adducts in human or laboratory animals must have the capability to detect 1 adduct in 10^6-10^{10} parent bases with a high degree of specificity. Recently, gas chromatography-electron capture negative chemical ionization-mass spectrometry (GC-ECNCI-MS) has provided the sensitivity and selectivity needed for the analysis of DNA adducts *in vivo*[1]. This method normally requires sample extraction and chemical derivatization followed by clean-up prior to analysis by GC-MS. Due to low yields or analytical interferences arising in the derivatization procedure, sample quantitation can be ambiguous. DNA adducts can be analyzed by high performance liquid chromatography-electrospray ionization mass spectrometry (HPLC-ESI-MS) without derivatization. In this study, we selected the DNA adduct, N^2,3-ethenoguanine (EG, biomarker of vinyl chloride exposure), to develop and optimize a quantitative HPLC-ESI-MS method.

Experimental: The ESI-MS mass spectra were acquired on a Finnigan 4000 quadrupole mass spectrometer retrofitted with a Analytica of Brandford, Inc. pneumatic electrospray source and a Teknivent Vector 2 data system. The HPLC was performed with a LC Packings LC-18 300 μm i.d. x 150 mm column. The mobile phase was delivered through the column at a flow rate of 4μL/min with a linear gradient of 100% water to 20% water/80% methanol in 18 minutes. *In vitro* samples were prepared from 25 mg (2.5 mg/mL) calf thymus DNA (CTDNA) incubated with 210 μmol chloroethylene oxide (CEO) for 20 minutes at 25 °C[2]. A series of samples containing 18-54 μg CEO-CTDNA were prepared for analysis. After spiking each sample with an isotopically labelled internal standard, $^{13}C_4$-EG, EG was isolated[1] and dissolved in 30 μL water, of which 0.5 μL was injected and analyzed by HPLC-ESI-MS. Using selected ion monitoring (SIM), EG was quantified by determining the ratio of the chromatographic areas of EG (m/z:176) to $^{13}C_4$-EG (m/z:180).

Results and Discussion: The HPLC-ESI-MS has provided the sensitivity required for quantifying the DNA adducts. The full scan (m/z: 20-400) mass spectrum obtained from 3.8 pmol of EG is shown in Figure 1. We found that the injection volume on the capillary LC column was optimized at ≤ 0.5 μL for obtaining the lowest detection limit. We were able to detect 5 fmol of EG on column at a S:N = 2:1 by SIM. A linear dynamic range from 25 fmol to 500 fmol of EG (Figure 2) demonstrates the capability

of HPLC-ESI-MS for quantitative analysis of purified DNA adducts.

Figure 1

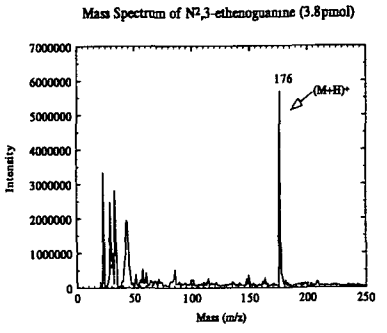

Figure 2

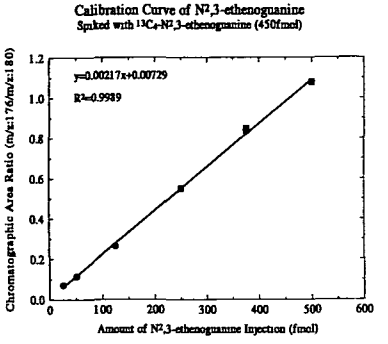

We were able to quantitate EG in 18-54 μg of CEO-CTDNA containing 45.7±5.0 pmol EG/μmol guanine from a set of 6 samples. We also tested the accuracy of the method by adding EG (4 pmol/sample) to the samples. Results of our analyses (2 samples before acid hydrolysis, and 2 samples after acid hydrolysis) showed a recovery of 3.33±0.21 pmol EG at an accuracy of 83.2±5.3 %. These data demonstrated that we can employ the HPLC-ESI-MS method to quantitate N^2,3-ethenoguanine in CEO treated CTDNA with a detection limit of 20 fmol/injection at a S:N = 5:1 (Figure 3).

Fragmentation of Thioether Conjugates using Electrospray Ionization and Low-Energy Collision Induced Dissociation

C.H. Oberth and A.D. Jones, Facility for Advanced Instrumentation, University of California, Davis, California, 95616

Thioether conjugation of reactive electrophiles is important as a biological mechanism of detoxification, but reactions with protein sulfhydryls have been shown to inactivate critical enzymes and are implicated in mechanisms of toxicity. Characterization of thioether conjugates of peptides and proteins is important for developing an improved understanding of the molecular basis of species- and tissue selective toxicity.

Many xenobiotic substances such as the alpha,beta-unsaturated aldehydes react with sulfhydryls via Michael addition, and our earlier work has shown that retro-Michael fragmentation complicates structural characterization of thioether conjugates of acrolein because the acrolein moiety is lost as a neutral fragment and CID spectra often contain little information about the site of modification.

The aim of this study has been to probe the mechanism of retro-Michael fragmentation by using a series of structurally related peptides that vary in the number of their basic functional groups.

N-Acetylcysteine-, glutathione-, and N-acetylglutathione-acrolein thioether conjugates and corresponding reduced S-(3-hydroxypropyl)- analogs, were used in this study. All of the mass spectrometry was performed on a Fisons/VGQuattro-BQ triple quadrupole mass spectrometer in positive ion mode.

The dynamics of competing fragmentation processes have been investigated by performing Energy Resolved Mass Spectrometry (ERMS) by varying the collision cell potential over the range of 0-50 V.

ERMS data from S-(3-oxopropyl)-N-acetyl-L-cysteine show that retro-Michael fragmentation predominates in spectra obtained at low collision cell potentials. Spectrum 1 shows the CID mass spectrum obtained at a collision cell potential of 0 V and these results suggest that retro-Michael fragmentation is a process with a low energy-of-activation barrier and that sulfur is the site of protonation (low-energy CID cleavages are principally charge-directed). The fragmentation process yielding the retro-Michael product is facilitated by the acrolein moiety undergoing a proposed keto-enol tautomerization.

Figure 1 is a plot of relative abundance's of five daughter ions as a function of increasing collision cell potential observed in ERMS spectra of S-(3-oxopropyl)-N-acetyl-L-cysteine. This plot shows the prevalence of retro-Michael fragmentation at low collision cell potentials but as higher potentials are reached, other higher energy fragmentation processes become accessible.

Reduction of the acrolein moiety is an effective measure to prevent this fragmentation process from occurring. In larger peptides the peptide backbone is more basic and sulfur no longer is a site of protonation. Therefore, retro-Michael fragmentation is not significant.

ESI-LC-MS ANALYSIS OF HETEROCYCLIC AROMATIC AMINES AND THEIR PHASE II CONJUGATES

W.G. Stillwell, J.S. Wishnok, L.R. Kidd, S.R. Tannenbaum, and R.J. Turesky[a]
Massachusetts Institute of Technology, Cambridge, MA 02139 and
[a]Nestle Research Centre, Nestec Ltd., Lausanne 26, Switzerland

The heterocyclic aromatic amines formed in cooked meat represent an important class of mutagenic/carcinogenic compounds with wide dietary impact. MeIQx (2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline), PhIP (2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine), and related food-borne compounds are biotransformed in animals to give a variety of metabolic products including amine-and ring-hydroxylated metabolites, as well as sulfamate, sulfate and glucuronide conjugates. Because of their polarity and thermal instability many of these compounds cannot be analyzed by conventional mass spectrometric techniques. In the current study we have analyzed urine of MeIQx-treated rats for the presence of polar conjugates and are carrying out analytical studies for the determination of these metabolites in human urine. In previous work it was shown that humans excrete nanogram amounts of phase II metabolites of MeIQx in urine after ingestion of cooked meats (1). These studies employed acid hydrolysis of urine samples and negative ion chemical ionization GC-MS methods for measurement of derivatized MeIQx. These procedures were used to measure MeIQx in human urine in a multi-ethnic study of population groups in Los Angeles County (2). In the present study PhIP analysis in human urine is being carried out by ESI-LC-MS.

A Hewlett-Packard model 5989B mass spectrometer equipped with an electrospray ionization source was used to obtain mass spectral data. The standard amine conjugates of MeIQx and urine from MeIQx-treated rats were analyzed using Vydac reverse-phase narrowbore HPLC columns with a flow rate of 200 ul/min. A gradient buffer composed of 40 uM aqueous ammonium acetate (pH 4.0) and methanol was employed for the HPLC separation. For the analysis of PhIP a reverse-phase microbore column was used with a flow rate of 50 ul/min. The mobile phase was the same as above.

The glucuronide and sulfamate conjugates of MeIQx in positive ion mode showed protonated molecular ions in high abundance (figure 1). Analysis of the amine conjugates by selected-ion monitoring procedures gave good sensitivity. 250 Picograms of the *N*1-glucuronide injected on-column were detected with a signal-to-noise ratio of 60. Similar results were obtained with the N^2-hydroxy-N^2-glucuronide conjugate. ESI-LC-MS of an aliquot of urine from MeIQx-treated rats confirmed the presence of polar phase II conjugates (figure 2).

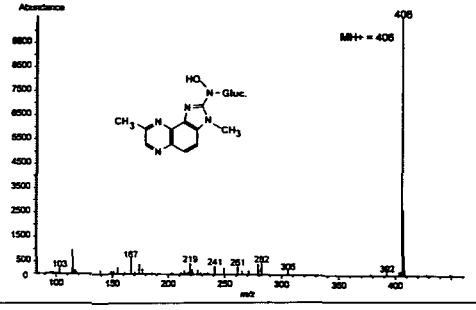

FIGURE 1

ESI mass spectrum of the N^2-hydroxy-N^2-glucuronide conjugate of MeIQx

43rd ASMS Conference on Mass Spectrometry and Allied Topics

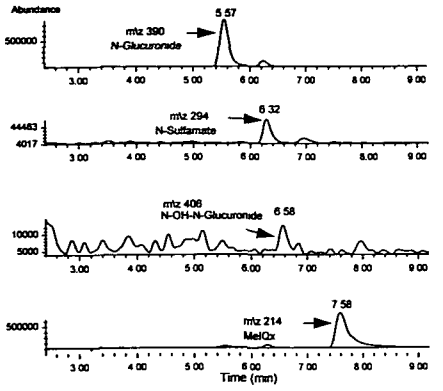

FIGURE 2

ESI-LC-MS analysis of urine from MeIQx-treated rat. A narrowbore column was used with a flow rate of 200 ul/min. The peaks identified by selected ion monitoring of the protonated molecular ions are the N^2-glucuronide (upper trace), the sulfamate conjugate (second trace), the N^2-hydroxy-N^2-glucuronide conjugate (third trace), and MeIQx (lower trace).

In our study of PhIP excretion, urine samples are hydrolyzed in 1 N HCl to cleave the *N*3-glucuronide conjugate of PhIP and liberate the parent amine. After extraction and purification by immunoaffinity chromatography the samples are run in positive ion mode and analyzed by selected ion monitoring of the protonated molecular ions of the amine and its deuterated (d_5-phenyl) internal standard. Good sensitivity has been obtained for the standard compound. 35 Picograms injected on column gave a signal-to-noise ratio of 26. The limit of detection for PhIP in urine is of the order of 10 pg/ml. Figure 3 shows a representative analysis of an extract from human urine.

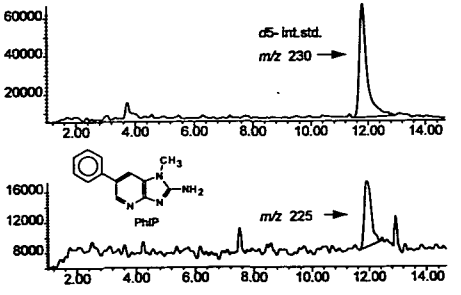

FIGURE 3

ESI-LC-MS analysis of PhIP in human urine. The selected ion chromatograms are of the d_5-deuterated internal standard (upper trace) and PhIP (lower trace). The concentration of PhIP in this urine sample was 29 pg/ml.

These results demonstrate that ESI-LC-MS can be utilized for the analysis of heterocyclic aromatic amines and their phase II conjugates in biological samples. The combination of immunoaffinity chromatography and microbore HPLC column separation provide sufficient specificity and sensitivity for the analysis of PhIP in human urine samples. Further work in sample clean-up and extraction is required for the direct analysis of MeIQx conjugates in human urine.

Characterization of Heterocyclic Amine Metabolites by Electrospray Mass Spectrometry

Donald M. Eades[1], Michael A. Malfatti[2], and James S. Felton[2]

[1]Chemistry and Materials Science, [2]Biology and Biotechnology
Lawrence Livermore National Laboratory, Livermore, CA 94551

Heterocyclic aromatic amines (HAA) are found in cooked meat products and are potential dietary health hazards [1]. HAAs, formed as pyrolysis products during high temperature cooking, have been found to be potent mutagens in the Ames/Salmonella assay as well as carcinogens in animal models [2]. Of the known HAAs, 2-amino-1-methyl-6-phenylimidazo[4,5,-b]pyridine (**PhIP**) exhibits moderate mutagenic activity, but often is present in very high amounts compared to the other HAAs.

Once in the body, PhIP undergoes two metabolic routes, bio-activation and detoxification, both of which are initiated primarily by the P450 microsomal mono oxygenases (e.g. P4501A2). The bio-activation route forms intermediates by hydroxylation, acetylation, and sulfonation at the N_2 position while the detoxification route forms hydroxylation, sulfonation, and glucuronidation at the 4' position as well as glucuronidation at the N_2 position. Here we report a µLC-ESI/MS method for the identification of urinary metabolic intermediates of the food mutagen, PhIP.

All experiments were performed on either a Finnigan MAT TSQ 700 or SSQ 7000. Both instruments were coupled to a Finnigan electrospray ionization (ESI) source operated with the capillary at 250° C and 45V. The needle was at 4500V, octopole at -3V, and the N_2 pressure set at 50 psi. All CID spectra were obtained via "source-CID" by increasing the ESI octopole offset voltage to ~25 eV. The ESI interface was coupled to a Michrom BioResources micro-LC system (µLC). The LC method employed a Reliasil C-18 BDS column (1 mm diam. X 15 cm), a flow rate of 50 µLs/min, a linear gradient from 10%B-90%B in 15 min (solvent A: 2% Acetonitrile/0.1% TFA; solvent B: 95% Acetonitrile, 0.1% TFA), and on-line UV detection at 315 nm.

The µLC-ESI/MS method was used to analyze a mixture of PhIP metabolites present in the urine of animal models. Full scan spectra were collected during the 15 minute LC analysis of ~75 pmoles of each metabolite (i.e. PhIP, 4'-OH PhIP, 4'-SO_4 PhIP, and N_2-OH PhIP glucuronide). "Source CID" spectra were acquired by flow injection analysis of the individual metabolites. The full scan spectra exhibited the expected $(M+H)^+$ ion for each metabolite and, except for 4'-SO_4 PhIP, all exhibited efficient ion production in the positive ESI mode. The CID spectra exhibited characteristic fragmentation via the direct loss of the metabolic substituent or from cleavage of the lone methyl group on the parent PhIP compound. Shown in **Figure 1** are the CID spectra of a) PhIP, b) N_2-OH PhIP glucuronide, c) 4'-OH PhIP, and d) the bio-activated metabolic intermediate, N_2-OH PhIP. Note that the two hydroxyl isomers can be differentiated with the CID spectra. The N_2-OH isomer (Fig 1d) exhibited cleavage of the hydroxyl group (i.e. [M+H-OH]+, m/z 224), while the 4'-OH isomer (Fig 1c) exhibited a loss corresponding to the cleavage of the lone methyl group (i.e. [M+H-CH3]+, m/z 226). The loss of the methyl group from the 4'-OH isomer is similar to that exhibited by the parent PhIP molecule. These characteristic fragments can be used to confirm the presence of specific metabolites found in the urine.

Shown in **Figure 2** are the mass chromatograms from the µLC-ESI/MS SIM analysis of a 20 µL injection of a 75 fmole/µL metabolic mixture (a total of 1.5 pmoles of each metabolite loaded on the column). With the exception of 4'-SO_4 PhIP, each metabolite demonstrated a signal-to-ratio above 10. With further method optimization and MS-MS techniques, the detection limit is expected to be in the mid to low fmole range. Additionally, selective extraction protocols currently under investigation also are expected to improve the detection limits. Our aim is to quantify the individual urinary metabolites in animal models, and apply the technique towards the identification and quantitation of urinary metabolites in humans. Based on previous studies [3], human exposure to PhIP in cooked meat generates parent compound urinary concentrations in the low fmole/µL range. Further optimization of this method should allow metabolic studies of humans following normal dietary exposure to HAAs.

Determination of Nitrosamines by ESI with On-line Photochemical Enhancement David Vollmer*, S. M. Billedeau, and J. O. Lay, USFDA, National Center for Toxicological Research, Jefferson, AR 72079

Introduction N-nitroso compounds have been found in a wide variety of foods and consumer products such as meat, beer, cosmetics, infant pacifiers, and drug formulations. The occurrence of N-nitroso compounds in these constituents is of great concern owing to the carcinogenic properties that many of them exhibit.

Goal The goal of this study is to utilize an on-line photolysis reactor in the LC-MS experiment (LC-uv-MS) as a means for detection and confirmation of N-nitrosodialkylamines. Parameters such as irradiation wavelength, irradiation time, mobile-phase pH, and different organic-acid modifiers are investigated to evaluate the potential of the LC-uv-MS system.

Results and Discussion In consecutive experiments, the wavelength of the irradiation source is changed, whereupon the relative abundance of protonated N-nitrosodimethylamine (NDMA) or protonated N-nitrosomorpholine (NMOR) decreases from no irradiation, to 366-nm irradiation, to 254-nm irradiation, in which no protonated species is detected. Conversely, the relative abundance of the dissociative photolysis products increases from no irradiation, to 366-nm irradiation, to 254-nm irradiation. These results can be directly correlated to the molar absorptivity (a_m) for N-nitrosodialkylamines at lower-wavelength irradiation (254 nm; $a_m \sim 5500$ for NDMA) compared to those at higher-wavelength irradiation (366 nm, $a_m \sim 110$ for NDMA. That is, a larger molar absorptivity yields a greater relative abundance of dissociative photolysis products.

To determine the optimum signals for the molecular ion and the photolysis products, the flowrate through the on-line photolysis reactor is varied, which correspondingly changes the irradiation residence time. Although the flowrate is restrictive owing to the chromatographic separation of the N-nitrosodialkylamines and the electrospray response, the length of the reactor can be changed to yield the optimum irradiation time for a given flowrate. Upon 366-nm irradiation, the relative abundance of the molecular ions of NDMA and NMOR decreases exponentially with time, while the dissociative photolysis products increase. A log plot of the data is linear (NDMA, 0.98; NMOR, 0.99) and is consistent with previous reports indicating that photolysis of nitrosamines follows first-order kinetics. The relative rate of the dissociative photolysis, however, is greater for NDMA (relative rate of dissociative photolysis, $k_{dp} \sim 89$) than for NMOR ($k_{dp} \sim 71$), and can be attributed NDMA's larger molar absorptivity at 366 nm.

N-nitrosodialkylamines readily undergo photolysis in the presence of acid solutions. In consecutive experiments, the relative abundance of both protonated NDMA or NMOR decreases as the pH increases (2.5 to 3.0). Conversely, the relative abundance of the dissociation products increases as a function of pH. Similar trends are observed when comparing acetic acid ($pK_a = 4.75$), formic acid ($pK_a = 3.75$), and trifluoroacetic acid ($pK_a = 0.2$). That is, the rate of photolysis decreases as the strength of the acid increases.

The overall effectiveness of on-line photolysis is estimated by comparing, in consecutive experiments, the type of information obtained from dissociative-photolysis processes to that of in-source collision-induced dissociation (CID). Both techniques offer a means for producing structurally significant ions. For on-line photolysis, the dissociative photolysis process is class-specific; that is, the primary mode of dissociation for N-nitrosodialkylamines is formation of alkylidenealkylamine and parent amines. For in-source CID, the fragmentation patterns are more complicated and they are not class-specific. For example, the CID spectra for NDMA gives three main peaks whereas the CID spectra for NMOR gives 4 main peaks. These differences can be attributed to a greater number of fragmentation possibilities for NMOR compared to those of NDMA. Moreover, the structure of the fragment ions is not always obvious. NDMA dissociates to produce an ion at *m/z* 43, which can correspond to $[CHNO]^+$ or $[C_2H_5N]^+$. NMOR fragments to give an ion at *m/z* 57, which can be $[CHN_2O]^+$ or $[C_3H_7N]^+$.

There are also distinct differences between on-line photolysis and in-source CID with respect to absolute abundance. To produce CID spectra needed for structure confirmation, the potential difference is increased to amounts where there is a 20-60 % loss in ion signal for NDMA, and a 10-70 % loss in ion signal for NMOR. For on-line photolysis, a 10-15 % loss in ion signal is observed for NDMA, whereas a 20-30% *gain* in ion signal is seen with NMOR. Presumably, the signal enhancement for irradiated NMOR is related to the greater ability of its photolysis products to form ions in solution.

To validate the LC-uv-MS method, the linearity and detection limits are measured for NDMA, N-nitrosdiethylamine (NDEA), N-nitrosoethylbutylamine (NEBA), NMOR, N-nitrosopiperdine (NPIP), and N-nitrospyrrolidine (NPYR). External standard calibration curves are determined by summation of the peak areas for the two primary dissociative photolysis products and the molecular ion from a full scan spectrum (from *m/z* 10-250). The calibration curves for the six N-nitrosodialkylamines are linear from approximately 5 ng to 800 ng. The signal-to-noise ratios at the lowest concentrations on the calibration curve are at least 3-to-1 for all the compounds. The full-scan limits of detection, as estimated by a signal-to-noise ratio of 3-to-1, are ~ 2-6 ng for the N-nitrosodialkylamines. The limit of detection for NDMA can be decreased to 100 pg by using selected-ion monitoring (SIM). These limits of detection compare favorably with LC-TEA which were estimated to be approximately 500 pg.

Experimental The eluents used in the chromatographic separation were delivered by a HPLC pump at a flow rate of 1 mL/min. For separation of the N-nitrosodialkylamine standards, a 3.9 mm x 300 mm μ-Bondapak C-18 with 5-μm particles was used. The acetonitrile:water eluent composition was linearly programmed from a 5:95 ratio held for 5 minutes to a 95:5 ratio over 10 minutes and then held for an additional 10 minutes at a 95:5 ratio. The column was connected directly to an injection valve equipped with a 10- or 20-μL loop. A 15-m knitted-open tubular reactor (Aura Industries, Staten Island, N. Y.) was connected after the column and was followed by a 1:4.5 split. Approximately 220 μL/min of sample and eluent were admitted into the electrospray source of a triple-quadrupole mass spectrometer. Typical operating conditions were as follows: capillary temperature, 240 °C; electrospray voltage, 4.5 kV; and sheath gas pressure, 3100 Torr.

Conclusion Although the ability to detect N-nitrosodialkylamines by LC-MS at the low-ng level is significant, the additional capacity to confirm their presence by utilizing an on-line photolysis reactor is also of importance. For the N-nitrosodialkylamines, the LC-uv-MS system produces three primary ions: protonated nitrosamine, protonated alkylidenealkylamines and protonated parent amines. The optimized parameters for separation, irradiation, and detection of N-nitrosodialkylamines are as follows: irradiation wavelength, 366 nm; irradiation time, 45-75 seconds and mobile-phase organic acid modifier, formic acid at pH 2.75. Under these conditions, the linearity and detection limits compare favorably with conventional HPLC techniques for detecting N-nitrosodialkylamines.

MS/MS Criteria for a Confirmatory Method - Sarafloxacin in Catfish Tissue

Steven Cepa, Stanley Menacherry and Lalit Bavda
Abbott Laboratories, Dept. 418, Bldg. R-13, North Chicago, IL 60064

A common screening technique used for drug residue analysis of food products intended for human consumption is liquid chromatography with UV detection. However this technique is not specific for a particular residue, and should the screening indicate some level of the residue, other techniques may be needed as a confirmation.

Mass spectrometry is frequently used as a confirmatory technique, especially in regulated applications[1,2]. To date, most of those methods have used GC/MS with electron impact ionization or chemical ionization. Some have been developed using LC/MS with a thermospray or particle beam interfaces and normal scanning experiments[3].

Here we describe a confirmatory method for the animal antibacterial drug, sarafloxacin (Figure 1), using an LC/MS/MS product ion scan. Attempts to analyze the drug by thermospray, particle beam with CI, and electrospray all exhibited good molecular ion information, but no significant fragmentation. Confirmatory methods should exhibit at least three, and possibly four, structurally significant ions in order to be rigorous[1,2]. In addition, the relative abundances of these ions should be within a specified tolerance of the same ions in the reference standard. In this case, we were required to have the relative abundances of each ion within an absolute +/- 10% of the standard's product ion spectrum[4].

Experimental

Samples were prepared by homogenization, extraction and isolation of the residue with an SPE column. The mass spectrometer was a Sciex API-III operated with an Ion-Spray™ interface. The data system was operated in MRM mode, monitoring each channel (ion) for 100 msec at unit resolution (see Figure 2 and Results below). A reverse phase LC system was employed at a column flow rate of 1 mL/min and split 50:1 into the mass spectrometer.

Results

Figure 2 is an example of the MRM chromatographic trace. The retention time was sufficient enough to allow chromatographic separation of sample-preparation salts and buffers from small organic compounds. One of the confirmation criterion was that the retention time be within +/- 20 seconds of the standard's retention time. The specificity of the product ion scan would allow sarafloxacin to be distinguished from any coeluting compounds. However, analysis of control tissue with no added sarafloxacin, indicated that the sample clean-up had eliminated any coeluting components.

Table 1 lists the ions monitored and statistical results from analysis of 5 controls (tissue blanks), 10 spiked tissue extracts (0.65 ppm and 1.3 ppm), plus 10 biologically incurred tissue extracts. Four ions were monitored and all were within the requisite +/- 10% relative ion abundance compared to the first standard run of the day.

Key factors in obtaining these results were the sample preparation and SPE step to remove interfering components, especially salts which inhibited the mass spectrometric signal; the use of MRM mode to maximize signal; and the need for a strong signal to achieve adequate ion statistics. During method development, it was observed that at sarafloxacin levels below 0.5 ppm we could not achieve the necessary +/- 10% window for relative ion abundances, even though the signal strength made the drug easily detectable.

Table 1: Product Ion Summary

Ion (m/z)	Mean (%)	Standard Deviation	Range (%)
386	54.44	2.7	48.00-59.32
368	100.0	n.a.	base ion
342	16.50	1 0	14.71-17.90
299	26.65	1.7	24.41-30.49

ANALYSIS OF BREVETOXINS IN "RED TIDE" ALGAE BY HIGH PERFORMANCE LIQUID CHROMATOGRAPHY WITH ON-LINE ELECTROSPRAY IONIZATION MASS SPECTROMETRY DETECTION

Yousheng Hua[1], Wenzhe Lu[1], Michael S. Henry[2], Richard H. Pierce[2], and Richard B. Cole[1*]

1. Department of Chemistry, University of New Orleans, Lakefront, New Orleans, LA 70148 USA
2. Mote Marine Laboratory, 1600 Thompson Pkwy, Sarasota, FL 34236 USA

Brevetoxins are a class of marine toxins found in "red tide" algae blooms. They are responsible for massive fish kills and they pose certain health risks to humans. So far, ten brevetoxins produced by the dinoflagellate *Gymnodinium breve* have been structurally characterized in red tide algae. We are reporting the development of an on-line high performance liquid chromatography-electrospray mass spectrometry (HPLC-ESMS) method which has been successfully applied to the separation and identification of brevetoxins in red tide algal extracts.

The HPLC-ESMS method employs reversed-phase microbore HPLC on a C-18 column with a mobile phase consisting of 85:15 (methanol : water), a flow rate of 8 µl/min, and a post-column split ratio of 1:3 (mass spectrometer : UV absorbance detector). Three known brevetoxins PbTx-1, PbTx-2, and PbTx-9 were tested as standards (separately and as a mixture) to examine the capability of this on-line LC-ESMS system for brevetoxin determinations. The mass spectra for each of these three brevetoxins show four related ions with overlapping elution profiles, corresponding to MH^+ (low abundance), $[M+Na]^+$ (base peak), $[3M+2Na]^{2+}$, and $[2M+Na]^+$. The brevetoxin molecules exhibited a high tendency to bind to alkali cations in positive ion ESMS. Detection limits and linear dynamic ranges were determined with the mass spectrometer scanning from m/z 850-950 to detect $[M+Na]^+$ forms of the various brevetoxins. The detection limits for PbTx-9, PbTx-2 and PbTx-1 were less than 600 fmol, 1 pmol, and 50 fmol, respectively (S/N = 3). Correlation coefficients of the signal response vs. concentration curves showed good linearity with r=0.989 (n=4), 0.988 (n=4), and 0.995 (n=6) for PbTx-9, PbTx-2, and PbTx-1, respectively. Linearity was maintained until the concentrations exceeded 20 µg/ml, where the column became overloaded.

A brevetoxin culture sample was found to contain at least six components (Figure 1) including two well-separated fractions of the brevetoxins PbTx-1 (sodium adduct, m/z 890) and PbTx-2 (sodium adduct, m/z 918), as well as four fractions of unknown components with molecular masses of 657, 959, 963, and 899 Da (sodium adduct ions appear at m/z 680, 982, 986, and 922, respectively). An unknown "U_a" with molecular mass of 899 Da has the same molecular mass as PbTx-9, although the two were well-separated on the column, suggesting that "U_a" is an isomer of PbTx-9. The unknown "U_d" with molecular mass of 657 is postulated to be a product of brevetoxin decomposition whose formation occurred in solution.

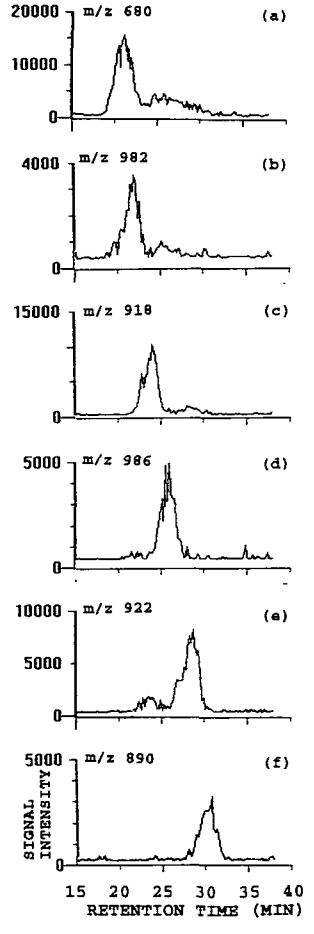

Figure 1. Reconstructed ion chromatograms for on-line HPLC-ESMS of a red tide extract "B" containing brevetoxins. Conditions: 100mm × 1mm ID C_{18} column, methanol:water (85:15,v/v) as mobile phase at 8 µl/min; post-column split to 2 µl/min into the mass spectrometer; injection volume 1 µl.

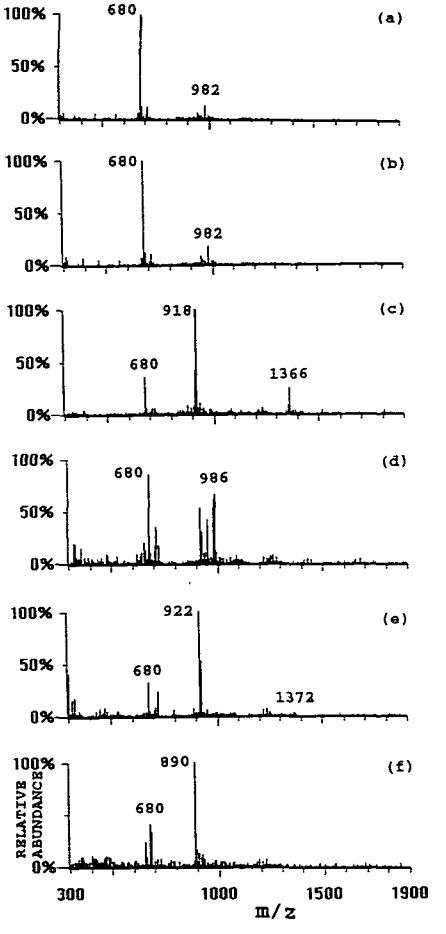

Figure 2. Electrospray ionization mass spectra obtained as an average of three scans at peak maximum from corresponding selected ion chromatograms (Figure 1) found immediately to the left of each spectrum.

DIFFERENTIATION OF PACIFIC AND CARIBBEAN CIGUATOXINS BY APCI/LC/MS

Steven M. Musser[1], H. Ray Granade[2] and Robert W. Dickey[2]

[1]Center for Food Safety and Applied Nutrition, Food and Drug Administration, Washington, DC 20204 and [2]Gulf Coast Seafood Laboratory,Food and Drug Administration, Dauphin Island, AL 36528

Introduction. Ciguatoxins are large cyclic polyether toxins produced by marine dinoflagellates and accumulated in the flesh of tropical reef dwelling fish. Human consumption of fish contaminated with small quantities (0.1 - 1 ng/g) of ciguatoxin results in unpleasant neurological and gastrointestinal symptoms (1). The presence of ciguatoxins in fish is usually verified by mouse bioassay. Although this method has sufficient sensitivity and is useful for screening purposes, it lacks accuracy and specificity. Because the structure of ciguatoxin varies according to its source (Caribbean or Pacific), a more definitive analytical method is needed to provide information regarding both the type and amount of toxin present in fish when cases of human poisoning have occurred. Electrospray (ES)/LC/MS has been used successfully to obtain the molecular weight of Pacific ciguatoxin (P-CTX1), as well as other toxins of similar structure (2). Consequently, we have evaluated ES and APCI as ionization methods, which combined with LC could be used to differentiate and quantitate cigautoxins in fish tissue.

Experimental. Approximately 50 grams of fish tissue known to cause human poisoning was first homogenized and extracted with acetone. The acetone extract was chilled to -20°C overnight. The chilled extract was filtered and evaporated, leaving an aqueous suspension. Methanol was added to completely dissolve the suspension. The resulting solution was defatted by extraction with hexane. The methanol/water fraction was then evaporated to an aqueous suspension. The aqueous suspension was extracted with chloroform and the aqueous fraction was disguarded. The chloroform fraction was applied to a Varian Mega Bond Elut silica column which was first washed with chloroform, followed by elution of the ciguatoxin fraction with 9:1 chloroform:methanol. The eluate was evaporated under nitrogen to yield a dry film of 5-10 mg.

A Hewlett-Packard (Palo Alto, CA) Model 1050 HPLC pump was used to provide linear gradients and a constant flow rate of 200 ul/min. All chromatography was performed on a YMC Inc. C-8 Basic HPLC column (2 x 250 mm). Chromatography conditions started with 50 % ACN followed by a linear gradient to 90 % ACN in 30 minutes. Formic acid, at a concentration of 0.1 %, was used to maintain a mobile phase pH of 3. A Finnigan Model TSQ-7000 triple-quadrupole mass spectrometer with the standard Finnigan ES or APCI ion source was used. Nitrogen was used as a nebulizing gas and the capillary temperature was 250°C for ESP and 150 °C for APCI. A vaporizer temperature of 450 °C was used for APCI experiments. The instrument was scanned over the range of 700-1300 amu at 1.5 sec/scan.

Results and Discussion. Electrospray LC/MS analysis of toxin contaminated fish extracts produced an [MH]+ ion for Caribbean ciguatoxin with little or no fragmentation. Although electrospray provided sufficient sensitivity at physiologically relevant levels, the lack of fragmentation diminished its usefulness as a regulatory technique. Attempts to increase the fragmentation by using CID in the high pressure region of the ion source resulted in increased noise levels and higher detection limits. Analysis of fish extracts (figure 1) for ciguatoxin using APCI yielded a 5-fold increase in sensitivity over that obtained with electrospray, in addition to producing structurally significant fragmentation

without increasing the overall noise level. Fragmentation of both Caribbean and Pacific ciguatoxins using APCI was limited to 3-4 consecutive losses of water from the molecular ion species. The ratio of the fragment ions to the parent ion, in addition to differences in parent ion mass (P-CTX1 = 1111.6, C-CTX1 = 1123.6) and LC retention time, allowed unambiguous identification of the geographical origin of the ciguatoxin.

Characterization of 3,4-Dichloro-1-butene Rat Metabolism by LC-MS-MS

Frank Brach, Zamas Lam, Steve Carpenter, and Doulgas Keller
The DuPont Company, Haskell Laboratory for Toxiciology and Industrial Medicine, P.O. Box 50, Elkton Rd, Newark, DE 19714

3,4-Dichloro-1-butene (3,4-DCB) is an intermediate in the manufacture of elastomers. 3,4-DCB is known to be a poor alkylator but is mutagenic in bacterial systems with activation. A study was undertaken to investigate the metabolism of 3,4-DCB as a key to understanding the lack of reactivity. The 3,4-dichloro- moiety of 3,4-DCB is a potential site for conjugation with glutathione (GSH). It is known that GSH conjugation at vicinal dichlorides can give rise to reactive episulfonium ions. The research described in this presentation was conducted to investigate the pathways of metabolism of 3,4-DCB.

RESULTS and DISCUSSIONS

In vitro experiments

No reaction of 3,4-DCB with GSH was detected, with or without added glutathione-*S*-transferase.

No reaction of 3,4-DCB with 4-nitrobenzylpyridine (4-NBP) was detected. By contrast, other DCB isomers and butadiene diepoxide reacted readily with 4-NBP.

In vivo experiments

HPLC analysis of bile from rats treated with 3,4-DCB revealed several peaks that were not present in control bile (m/z 412/414, m/z 414/416, m/z 283/285, m/z 285,287, and m/z 226/228). These peaks generally increased in size from 2 to 4 hrs post dosing, then declined in size over the next 20 hr. The urine of treated rats contained one major peak (m/z 268) that was not present in control urine.

MS analysis of the bile peaks showed that the peak eluting at approximately 22 min. contained one Cl as well as the addition of an O atom and GSH (m/z 412/414) . The peak eluting at approximately 18 min. contained the ring-open (hydroxylated) metabolite of the epoxide metabolite at retention time 22 min (m/z 414/416). The daughter ion (m/z 412) spectrum of the 22 min. peak revealed the structure of this species to be the GSH conjugate of an epoxide metabolite of 3,4-DCB, in which the epoxide has migrated from the 1,2 position to the 2,3 position, releasing one Cl.

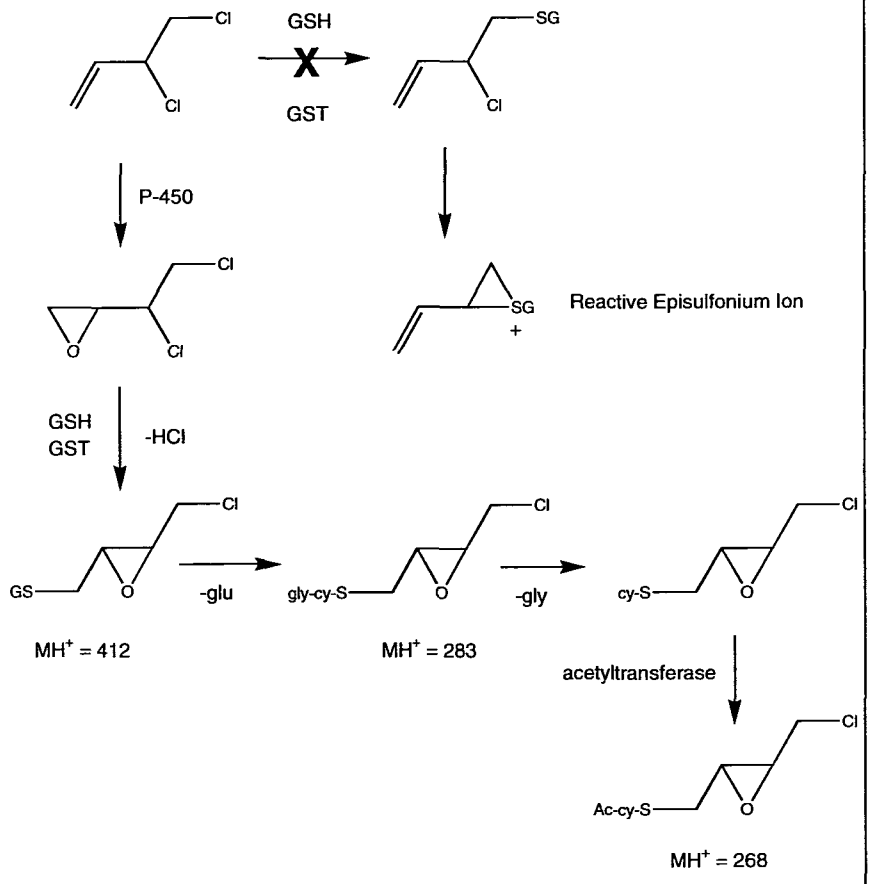
The downstream conjugates of the parent conjugate, with the *glu* and *gly* residues removed, were detected with retention times of 18 and 15 min., with protonated molecular ion at m/z 283/285 and m/z 226/228, respectively. These structures were also confimed by MS/MS.

The Cl-containing peak detected in the urine was identified as the mercapturic acid of the bile conjugate with with protonated molecular ion at m/z 268.

CONCLUSIONS

* The major pathway of metabolism of 3,4-DCB determined from our experiments is shown in below. Metabolites derived from the primary pathway expected prior to the experiments, conjugation with GSH at a chlorine, were not detected in bile or urine. The mass of a GSH conjugate directly displacing a Cl would be 396, which was not detected.
* The primary pathway of metabolism of 3,4-DCB in the rat appears to be *via* epoxidation of the double bond, followed by GSH conjugation with the epoxide, with migration of the epoxide to the 2,3 position releasing Cl. The pathway leading to the highly reactive episulfonium ion was not detected.
* Epoxidation of 3,4-DCB as the initial step in metabolism may explain the lack of direct alkylation activity and the mutagenicity of 3,4-DCB after activation.

Postulated Pathway of 3,4-DCB metabolism in Rats.



Preliminary Screen for the Biodegradation of Xenobiotics

Sean E Ottinger, M. Neal Guentzel, & Stephan B. H Bach
Division of Life Sciences & Division of Earth and Physical Sciences
The University of Texas at San Antonio, San Antonio, Texas 78249-0662

Introduction: Currently there a myriad of sites contaminated with an infinite number of combinations of chemicals or xenobiotics. Bioremediation is one method which poses strong potential for cost effective remediation of contaminated sites. However, the expediency and effectiveness by which biological organisms can remediate a site posses some problems. Inherent in bioremediation is the somewhat unpredictable nature of the microorganisms and their performance at a given site. By customizing the microbes used to afford the best match for a contaminated site both in terms of microbe survive-ability and efficacy, the unpredictability in performance can be elevated. Determining the efficacy a microbe will have for various contaminants can be done by GC/MS. Through the use of a preliminary screen coupled with GC/MS confirmation and quantitation, it is possible to determine the potential of a microorganism's ability to remediate the contaminants at a site in a quick and cost effective method.

The preliminary screen used is a mineral salts broth, metabolic indicator, and a xenobiotic as the sole carbon/energy source.[1] If the enzyme's produced by the microbe are able to utilize the chemical as an energy source then the breakdown products will react with the indicator and produce a color change. Confirmation of the microbial degradation is then done by GC/MS. In addition, GC/MS allows for identification of the metabolites produced. It is important to make sure that any metabolites generated were not more hazardous than the original starting product. However, if such a case were to arise it would still be possible to utilize another microbe to get degrade the toxic metabolite which was generated.

Methods: *Materials & Preparation:*

- VWR disposable culture tubes (16 X 125mm) were rinsed with 5mL of methanol
- Tubes were then baked for at least 12 hours in a hot air oven @ 180°C to both sterilize and remove any remaining methanol
- After the tubes cooled, the caps were then tightened completely down
- The mineral salts broth solution was then prepared and heated
- The mineral salts solution was then autoclaved for 21 minutes @ 250°C and 25psi
- The indicator was then dissolved in dH_2O to a concentration of .0005g/mL and filter-sterilized using a .22μm membrane filter
- Once the salt solution had cooled the indicator solution was added at a conc. of .001g/Liter of mineral salts broth
- 10mL of the salts solution was then asceptically dispensed into the sterilized tubes using a pre-sterilized Cornwall pipette
- 10μL of the xenobiotic was then added to the tube
- The pure microbial isolate was next added to a saline solution until a visual density equivalent to a Macfarland 1 was reached (roughly 10^8 CFU/mL)
- The microbial solution was then diluted to about 10^4 CFU/mL
- One drop of the diluted microbial solution was added to the tube
- For each tube of microbe and chemical tube there are two corresponding control tubes of chemical only and microbe only

Analyses.

- Microbial testing was done by removing 10μL of the test solution and using a four quadrant streak method to estimate the microorganisms or Colony Forming Units (CFU)/mL
- Tubes not containing microbes were sampled randomly to insure no microbial contamination occurred
- The pH of the solution was checked using test strips to simply estimate; pH testing was done the same time microbial analysis was done
- The chemical analysis was done by removing 25μL of the test solution and placing it into an autosampler vial containing 1475μL of methanol
- The GC/MS was tuned according to EPA method 624/8260[2]; *This was done both to quantitate the amount of chemical present and to allow for utilization of EPA MS library to identify the metabolites produced*
- The tune was then verified by injection of BFB
- Quantitation was done as specified by EPA method 624/8260[2], using a single characteristic ion

Results: In all cases the xenobiotics dissipated within several days. However, microbial counts revealed no substantial increase which would be associated with microbial enzymatic degradation. In addition, there was no drop or change in pH. A drop in pH and a color change in the solution would both occur if the microbes were utilizing the chemicals as carbon/energy sources. Neither pH nor the color changed. All microbes tested in all the repetitions produced almost identical results with complete dissipation of the chemical over a three week period.

Conclusions: Although the xenobiotics dissipated over time, we can not say that the microbes were the causative agent of the dissipation for two reasons. One, the volatilization controls also had dissipation occur at an identical rate. Two, no metabolites were detectable in any of the incubations containing microbe and chemical together. The results are primarily due to error in that the caps on the all the tubes were left loose instead of sealed The chemical concentration of .1% may have also lead to the rapid volatilization. Increasing the amount of chemical used would also be helpful, but it would be important that the concentration is not enough to become toxic to the microbes. In previous tests where caps were tightened down, there was some degradation and metabolite formation. In the past study using only TCE (plus an inducer) and different organisms, there was a small amount of degradation, but the metabolites formed were in such small concentration as to be extremely uncertain in regards to a possible identification of the metabolites In subsequent studies, it would be more advantageous to utilize a purge and trap as opposed to an autosampler. The inherent concentration of a purge and trap will allow for greater sensitivity in detection of any metabolites produced. Unfortunately from this study it can not be ascertained whether the mineral salts broth would be useful in a rapid cost-effective prescreen of a microorganism's degradative potential. However, coupling the mineral salts screen with GC/MS should provide a good piece of the puzzle in selecting which microbes to use on a given contaminated site and thus make bioremediation a much more viable choice in the removal of organic wastes from contaminated sites.

Identification of Tamoxifen Metabolites in Patients on Long-term Therapy for Breast Cancer

G.K. Poon[1], P.E. Lønning[2], D.H. Phillips[1] and M. Jarman[1]
[1]*CRC Centre for Cancer Therapeutics, Institute of Cancer Research, Surrey, UK.*
[2]*Department of Oncology, University Hospital of Bergen, Haukeland Hospital, Bergen, Norway.*

Introduction

Tamoxifen is an antiestrogen widely and chronically used for the treatment of hormone-dependent breast cancer in postmenopausal women. Recently, it has also been a controversial antiestrogen drug undergoing clinical trial as a prophylactic for women who have a high risk of breast cancer [1]. This is because tamoxifen has been shown to be hepatocarcinogenic to female rats and human MCL-5 cells by forming DNA adducts [2,3]. The precise mechanism of formation of these DNA adducts has not been established. It has been proposed that tamoxifen give rise to DNA adducts in the livers of rats through metabolic activation involving α-hydroxylation of the ethyl group [4].

Previous studies of the metabolism and pharmacokinetics of tamoxifen in patients and animals have shown that the drug is extensively metabolized after oral administration. In human, the major metabolite is *N*-desmethyltamoxifen (metabolite **I**), whereas 4-hydroxytamoxifen (metabolite **II**) and tamoxifen *N*-oxide (metabolite **III**) are present in minor concentrations. Metabolite **II** and 4-hydroxy *N*-desmethyltamoxifen (metabolite **IV**) have been isolated as their glucuronides in human bile. This report demonstrates the utilization of liquid chromatography - electrospray ionization - mass spectrometry (LC-ESI-MS) methodology, it is possible to determine the minor and /or polar metabolites of tamoxifen.

Conclusion

In addition to several established human metabolites of tamoxifen modified by *N*-demethylation, 4-hydroxylation or *N*-oxidation, we have for the first time detected α-hydroxy (**VI** and **VII**) and monohydroxy-*N*-oxide (**X**) metabolites in plasma samples of patients receiving tamoxifen treatment as summarized in Figure 1. This result is an important finding, given the supposition that α-hydroxylation can lead to formation of DNA adducts and possible carcinogenicity. Whether these metabolites have any significance to formation of the DNA adducts is currently being investigated. When Phillips et al. [5] examined the genotoxicity of tamoxifen-d_5 in rat and human cells, they noticed a 2- to 3- fold decrease of DNA adduct formation compared with tamoxifen as a substrate. Oxidation at the ethyl side chain was at a slower rate due to an isotope effect. Thus, α-hydroxylation is a possible metabolic pathway for DNA adducts formation.

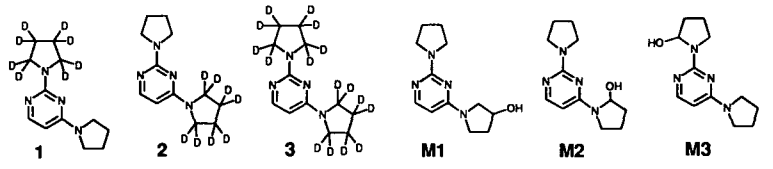
In Vitro Metabolic Transformations of 2,4-Dipyrrolidinylpyrimidine: A Chemical Probe for P-450 Mediated Oxidation of Tirilazad Mesylate. Robert T. Streeper[§†], Paul G. Pearson[§], Zhiyang Zhao[§], Stephen A. Mizsak[#] and J. James Vrbanac[§*] — [§]Drug Metabolism Research and [#]Physical and Analytical Chemistry, The Upjohn Company, Kalamazoo, MI 49001.

Tirilazad (**T**, FREEDOX®), which is currently under clinical development for the treatment for subarachnoid hemorrhage and head injury, contains as part of its structure a 2,4-di(pyrrolidin-1-yl)pyrimidine (**2,4-DPP**) moiety. The identification of the oxidized metabolites of **T** is of considerable interest as this provides insights into the mechanisms of action and metabolic clearance of **T**. In the present investigation, we have employed **2,4-DPP** as a chemical probe to further characterize P-450 mediated oxidation of the heterocyclic domain of **T**. In pursuit of this objective, deuterium labelled analogs of **2,4-DPP** have been prepared and employed as metabolic probes (**1**, **2**, and **3**; below) in conjunction with LC-MS techniques to characterize *in vitro* biological transformations of **2,4-DPP** in male rat liver microsomes. We have determined that **2,4-DPP** undergoes three characteristic hydroxylations *in vitro*. We determined that the oxidations occurring in male rat liver microsomes were not aryl hydroxylations or formations of *N*-oxides by observing that all three observed metabolites had lost one deuterium when **3** was used as substrate. When **1** was incubated in male rat liver microsomes, **M1** and **M2** had not lost deuterium and **M3** had lost deuterium. When **2** was incubated with rat liver microsomes **M1** and **M2** were observed to have lost one deuterium while **M3** did not. Synthetically prepared 4-(3-hydroxypyrrolidinyl)-2-pyrrolidinylpyrimidine was observed to elute at the same time as **M1**, Tr = 20.0 minutes. Synthetically prepared 2-(3-hydroxypyrrolidinyl)-4-pyrrolidinylpyrimidine did not elute at the same time as any of the three hydroxylated metabolites. These data, obtained by particle beam-liquid chromatography-mass spectrometry, have characterize the three metabolites as: 4-(3-hydroxypyrrolidinyl)-2-pyrrolidinylpyrimidine (**M1**), 4-(2-hydroxypyrrolidinyl)-2-pyrrolidinylpyrimidine (**M2**) and 2-(2-hydroxypyrrolidinyl)-4-pyrrolidinylpyrimidine (**M3**).



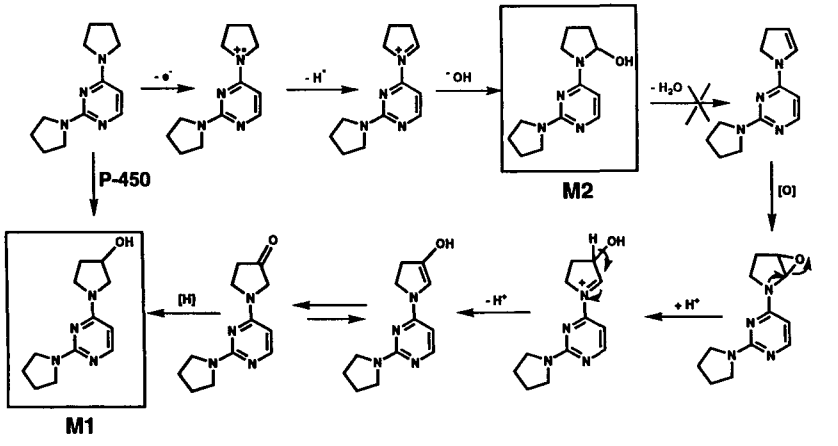
Manipulations which did not influence the formation of metabolites or result in the formation of other oxidation products included addition of 3% hydrogen peroxide, addition of superoxide dismutase and catalase individually and together and heating the microsomes to 55 °C for 90 seconds prior to incubation. Manipulations which decreased or eliminated the formation of the metabolites included addition of 1-aminobenzotriazole, carbon monoxide, *N*-octylamine and absence of microsomal protein, or a viable NADPH generating system. Collectively, these findings indicate an exclusive role for cytochrome

43rd ASMS Conference on Mass Spectrometry and Allied Topics

P-450 in the oxidation of **2,4-DPP** to **M1**, **M2** and **M3**. We observed that in microsomal incubations carried out in the presence of cyanide, a single 2-pyrrolidinyl cyanide adduct is formed implicating an iminium ion intermediate in the oxidation of the 2-pyrrolidine ring. **1**, **2**, and **3** were used to characterize the adduct.

As an initial experiment to elucidate the mechanisms of hydroxylation of **2,4-DPP** by cytochrome P450's, we performed an intermolecular deuterium isotope effect experiment by co-incubating **2,4-DPP** and [$^{16}H_2$]**2,4-DPP** (**3**) in equimolar concentrations. The observed isotope effects reported as the mean of five measurements for the three metabolites are: **M1**, $k_H/k_D = 14.55 \pm 0.54$; **M2**, $k_H/k_D = 6.01, \pm 0.65$; **M3**, $k_H/k_D = 5.35 \pm 1.18$. We interpret these data as suggesting that **M2** and **M3** are formed by the same mechanism, probably including the formation of an iminium ion, and that **M1** is formed by direct hydrogen abstraction.

We propose that the hydroxylation of the 2-position of the 2-pyrrolidine ring of **2,4-DPP** proceeds *via* a pathway(s) that includes formation of an iminium ion, evidence provided from studies with selectively deuterated analogs and cyanide trapping. Our observation of the large intermolecular isotope effect in the formation of **M1** seems to preclude a mechanism involving initial *N* electron abstraction with subsequent iminium ion formation in the formation of **M1**. Besides the large isotope effect, the loss of only one deuterium precludes the formation of **M1** ***via*** the mechanism detailed on the right below.



ANALYSIS OF PAHS IN HUMAN SERUM USING CLOUD POINT EXTRACTION AND LC/MS

Sarath R. Sirimanne, Li. Ma, Cheryl McClure, John Barr and Donald G. Patterson. Jr.
Centers for Disease Control and Prevention, National Center for Health, Environmental Health and Laboratory Sciences. Atlanta, GA 30341-3724.

Polycyclic aromatic hydrocarbons which are known to be mutagenic, carcinogenic and toxic to humans even at trace levels, are ubiquitous environmental pollutants resulting from emissions from sources such as automobile exhaust and industrial combustion of fossil fuels. Methods for quantifying these mixtures at trace levels generally involve solvent extraction and extensive sample cleanup procedure prior to the analysis. The extent of a cleanup depends on the complexity of the sample matrix. These solvent extraction methods utilize a considerable amount of organic solvents during sample cleanup generating a large quantities of solvent waste.

Aqueous solutions of many nonionic surfactants above their critical micellar concentration form turbids above a certain temperature also known as cloud point temperature. During the cloud point precipitation process, these micellar vesicles aggregate into a surfactant rich phase and any bound nonpolar species concentrate in the surfactant-rich phase. The analyte/surfactant-rich phase also permits analysis and quantification of the analytes by techniques such as reversed-phase HPLC without further sample cleanup.

In the recent past, cloud point extraction (CPE) attracted analytical chemists because of
(a) the ability to concentrate a variety of analytes with high concentration factors;
(b) safety and cost benefits. (It is an excellent alternative to conventional sample concentration methods which use large amounts of toxic and flammable organic solvents);
(c) easy disposal of the surfactant;
(d) the enhancement of the detection due to concentration;
(e) the compatibility of the surfactant rich phase with liquid chromatographic techniques;
(f) the preclusion of analyte losses during the evaporation of solvents used in traditional liquid-liquid extraction techniques;
(g) the inhibition of adsorption of nonpolar analytes to glass surfaces by the surfactants used.

In our laboratories, we assess human exposure to environmental toxicants by quantifying the levels of target toxicants in serum of exposed individuals. The levels of our target analytes are often in trace levels and hence preconcentration and cleanup are prerequisites to the analysis of these trace toxicants. We have identified cloud point extraction as an impressive alternative to conventional solvent extraction due its beneficial properties and the greater extraction efficiencies. We report for the first time, extraction of PAHs from human serum using cloud point technology and analysis by HPLC.

The quantification of PAHs in serum normally requires a series of steps consisting of extraction, concentration, and removal of detrimental impurities from the final analytical samples. In the recent past, there have been a number of applications of cloud point extraction to analytical sample preparation implicating its potential use as an alternative to solvent extractions. Since micellar serum samples failed to undergo CPE similar to water samples, we utilized sodium chloride to induce phase separation. Serum samples ranging from 0.5-5 mL can be easily worked up by the cloud point extraction. The initial analyses were carried out using HPLC/UV detection. The analysis of cloud point extracts using LC/Electrospray MS is also being explored. The optimum recoveries of individual PAHs were found to be quantitative at 8% Triton X-100, 5 M NaCl and at 60 °C and are summarized in the Table.

When extractions were performed at 60 °C, average recovery from the extractions of PAHs reaches a 100% maximum at 5.0 M NaCl and 8% Triton X-100 concentration. When the incubation

temperature was increased from 25°C to 50°C, the average recoveries tripled and the extraction recoveries were not significantly improved at temperatures above 60°C. The recovery of PAHs also increases as the sodium chloride concentration increases between 3.0 - 5.5 M. The concentrations above 5.5 M, NaCl remains undissolved indicating the serum/surfactant solution is saturated. The concentration of Triton X-100 has the greatest effect on the recovery of PAHs from serum. The recovery of PAHs increased from 50-100% as the Triton X-100 concentration was increased from 0.5-8% w/v.

The results presented in this paper indicate that the proper combination of temperature, salt concentration, and surfactant concentration can effect extraction PAHs from human serum with excellent recoveries. The simplicity and the advantages of the cloud point methodology prove that it is an excellent sample preparation technique for complex aqueous matrices such as serum.

LC-APCI-MS/MS for the Analysis of PAP Biotransformation Products

L.M. Benson[1], A.N. Mayeno[2], G.J. Gleich[2], S. Naylor[1]
[1]Biomedical Mass Spectrometry Facility and Department of Biochemistry and Molecular Biology,
[2] Department of Immunology; Mayo Clinic, Rochester, MN. 55905, USA

During late 1989, the eosinophilia-myalgia syndrome (EMS) developed as an epidemic in the United States, with numerous additional cases reported in several other countries worldwide. Eight years earlier, a closely-related disease, the toxic oil syndrome (TOS) occurred in Spain as a massive foodborne epidemic. Although EMS was linked to the ingestion of tainted L-tryptophan, and TOS to aniline-denatured rapeseed oil, the etiologic agent(s) responsible for both diseases remains undetermined. Contaminants in these foodstuffs are believed to have triggered the diseases. Aniline contaminants, including 3-phenylamino-1,2-propanediol (PAP), have been reported in oil used by patients who developed TOS. A related aniline derivative, 3-(phenylamino)-L-alanine (PAA), was recently isolated from L-tryptophan associated with the onset of EMS. The presence of these two structurally similar aniline derivatives, PAP and PAA, suggests a possible related etiology. To investigate possible links between TOS and EMS, the biotransformation of PAP has been studied in rat hepatocytes and human liver tissue. On-line LC-APCI-MS/MS was used to identify and structurally characterize the resulting products. The initial studies to investigate the possible metabolic interconversion of PAP into PAA *in vitro* were accomplished using [^{14}C] PAP incubated with isolated rat hepatocytes or human liver tissue. The supernatants were analyzed by HPLC using on-line UV and ^{14}C-radioisotope detectors. One of these ^{14}C-labelled metabolites eluted with the same retention time as synthetic PAA and displayed an identical UV spectrum suggesting the conversion of PAP to PAA.

To unequivocally confirm the formation of PAA from PAP, LC-MS and LC-MS/MS analyses were performed on the incubation mixtures. HPLC was performed on an Ultrafast Microprotein Analyzer System using a Phenomenex Primesphere C18 column (3.2 x 250 mm) at a flow rate of 400 ul/min. A slow gradient of NH_4OAc and MeOH was used to separate the different components of the mixtures. MS and MS/MS analyses were performed on a Finnigan MAT 95Q mass spectrometer of BEQ_1Q_2 configuration. A Finnigan MAT APCI source was used in positive mode throughout with capillary and vaporizer temperatures at 200°C and 475°C, respectively, and the corona spray needle energy at 2.5 kV. Protonated molecular weight ions (MH^+) were subjected to collision-induced dissociation in the octapole collision cell utilizing an argon gas pressure of ~6 x 10^{-5} mbar with collision energies of 20-30 eV. The product ions were analyzed in Q_2 with spectra collected over a mass range of 40-200 with 10 to 20 scans acquired and averaged to afford a composite product ion spectrum.

LC-MS analysis of rat and human incubations are found in Figures 1 and 2, respectively. The extracted total ion chromatograms (m/z 104-300) demonstrate numerous peaks present in the mixtures. The extracted ion chromatograms at m/z 181 demonstrate a peak with the same retention time as standard PAA. For more conclusive evidence, LC-MS/MS analysis was done to obtain structural information. LC-MS/MS spectra of m/z 181 ions from the rat and human incubates (Figure 4A and 4B) proved to be identical to the standard PAA product ion spectrum (Figure 3).

In this study, we have demonstrated the *in vitro* biotransformation of PAP to PAA, linking related diseases TOS and EMS to a common chemical substance. PAA represents the first and only reported direct chemical link between TOS and EMS. The identification and characterization of PAA could readily be confirmed using LC-APCI-MS and LC-APCI-MS/MS. These powerful techniques continue to play an increasing role in the study and diagnosis of disease states.

GC-MS Analysis of Hydroxytestosterones to Measure Cytochrome P-450 Activity

M.P. Purdon, L.D. Lehman-McKeeman, and D. Caudill
Procter & Gamble Company, Miami Valley Laboratories
P.O. Box 538707, Cincinnati OH, 45253

Introduction

Steroid hormones are natural substrates for microsomal cytochrome P-450 enzyme systems. Specific P-450 isozymes catalyze the regio- and stereospecific hydroxylation of the steroid ring structure. Given this, hydroxylation of testosterone has historically been used to profile specific P-450 activity.

Current HPLC-UV Method

Currently RP-HPLC with UV detection is used to identify hydroxytestosterones (HT) via chromatographic retention (Arch. Biochem. Biophys. 255:27 1987).This is a challenging separation involving the resolution of 17 isomers and 7 epimer pairs. The separation is further complicated because the testosterone can be oxidized to androstenedione, which then also generates hydroxy metabolites that elute along with the HT. As a result, the samples may need to be run under differing chromatographic conditions to identify the peaks with certainty. These technical challenges, along with the expense and lack of availability of the standards, limits general application of this potentially powerful technique.

Proposed GC-MS Method

Here a gas chromatographic separation is presented which can easily separate the testosterone metabolites as their TMS derivatives. In addition, by coupling with mass spectrometry the isomers can be identified by their EI-MS spectra. The separation was performed on a Hewlett Packard 5890 GC and 5971A MS (EI mode) using a J&W DB1701 column (25m x 0.25mm). The temperature program was 220°C to 300°C at 2°C/min. Full scan EI spectra could easily be generated injecting 2ng of each component (the same amount needed for the HPLC procedure). The derivatization must be done under gentle conditions so that the enol form of the 3-keto group is not silylated. Reaction with Sigma SIL A at room temperature for 1hr was found to derivatize all but the partially hindered 11β without significant enol silylation. The 11β was typically used as the internal standard for the HPLC procedure because it is not formed in this system. 19 hydroxytestosterone can be substituted as the internal standard for the GC procedure.

Advantages

The GC-MS procedure gives a more robust separation of the hydroxytestosterones and does not depend on retention to identify the specific metabolites. Quantification can be performed by splitting the column effluent to both an FID and MS. Since unity response should be expected for all isomers (by FID) the need for the expensive and rare standards is virtually eliminated.

DETERMINATION OF CLENBUTEROL IN RETINAL TISSUE BY ELECTROSPRAY LC/MS/MS

John A. Tomlinson, Rick A. Flurer and R. Duane Satzger
Forensic Chemistry Center, U.S. Food and Drug Administration
1141 Central Parkway Cincinnati, OH 45202

Introduction

Clenbuterol is an illegal veterinary drug. The FDA is particularly concerned about its use in food producing animals such as cattle, lamb and swine. Clenbuterol is considered a toxic substance. Some deaths caused by clenbuterol tainted bovine liver have been reported in Europe.

The FCC has received numerous samples of ocular tissue suspected of containing clenbuterol. Because of the large sample load, there was a need to develop a method that would permit handle a high sample throughput. The approach currently used by many laboratories is GC/MS with a methaneboronic acid derivitization.[1] Although the GC/MS method is adequate, sample preparation requires time to derivatize and the detection limit of approximately 4 ng/g is not always sufficient. The approach that was selected for development was LC/ESI/MS/MS. This technique was chosen for the selectivity, the sensitivity and the ability to obtain a high sample throughput.

The electrospray method allows for direct comparison of the concentration of clenbuterol in a sample to a clenbuterol standard. The percent recoveries of published methods for the determination of clenbuterol in retinal tissue are usually corrected with an internal standard carried through the method. The absolute recovery of clenbuterol through the sample preparation method is not addressed. In this work, methods are presented and evaluated on the basis of absolute percent recovery of a clenbuterol standard added to retinal tissue prior to sample workup. The goal is to develop a selective, sensitive and legally defensible method which permits quantitation of clenbuterol residues in retinal tissue.

Experimental

Two methods were developed for the determination of clenbuterol in retinal tissue:

Method #1:

Place a weighed amount of minced retinal tissue into a 20 mL glass vial and then add 5 mL of 0.1 M KH_2PO_4/ 0.1 M NaH_2PO_4 buffer solution. Sonicate preparation for 15 minutes, then centrifuge for 10 minutes at 5000 rpm. After centrifugation, decant the supernatant into a separate 20 mL glass vial. Add 2 mL of 2 M Na_2CO_3 to the supernatant to make the solution basic (pH ~ 12). Mix the Na_2CO_3 with the supernatant. Add 5 mL of ethyl acetate to the basic solution and then shake gently for 5 minutes. Centrifuge for 10 minutes at 5000 rpm. Decant upper ethyl acetate layer into a 4 mL vial and then reduce ethyl acetate to dryness at 80° C under nitrogen. Add an additional 5 mL of ethyl acetate to the aqueous layer and shake gently for 5 minutes. Centrifuge for 10 minutes at 5000 rpm and then decant upper ethyl acetate layer into the 4 mL vial which contains the first extraction residue. Dry the ethyl acetate as before. After residue has been completely dried reconstitute with 0.5 mL of 1% formic acid in H_2O.

Method #2:

Weigh out an amount of minced retinal tissue and place into a 20 mL glass vial. Add 5 mL of tris buffer (0.2 M tris HCl containing 0.1 M $CaCl_2 \cdot H_2O$ pH to 8 with 0.1 M HCl) and 5 mL of H_2O. Add 150,000 units of hyaluronidase to the buffered solution and heat vial at 37° C for 45 hours. At the end of the 45 hours add 250 µL of a 200 mg/mL solution of pronase E to the vial. Heat vial again at 37° C for 3 hours. At the end of the three hours quantitatively transfer the contents of the glass vial to a plastic vial and then centrifuge the vial at 7500 rpm for 10 minutes. Decant the supernatant to another plastic vial and then add 120 µL of 10 M NaOH(pH ~ 12). Shake vial for 10 seconds then add 5 mL of ethyl ether to the basic solution and shake for 5 minutes. After shaking, centrifuge the vial at 7500 rpm for 5 minutes and decant the ether layer into a 4 mL glass vial and reduce the ether to dryness at 80° C under nitrogen. Add another 5 mL of ethyl ether to the aqueous layer and again shake for 5 minutes, centrifuge for 5 minutes and decant the ether layer combining the residue and the ether layer. Reduce the ether to dryness at 80° C under nitrogen. Reconstitute the combined residues with 0.5 mL of 1 % formic acid in H_2O.

Results

Method #1 did confirm all positive and negative results of the immunoassay method, however the recovery of clenbuterol was 25% to 35%. The clenbuterol limit of detection for Method #1 is approximately 1 pg/µL with a signal to noise ratio of 3:1. No quantitation of clenbuterol was performed using this method because of the low recoveries; only an estimate of concentration could be given.

After exhausting all efforts to increase the recovery of Method #1, it was believed that the clenbuterol was being bound in the retinal tissue. References indicate that clenbuterol is also retained in synovial fluid for long periods of time after the cessation of administration. The mechanism for the binding of clenbuterol in the synovial fluid is electrostatic binding to acid mucopolysaccharides.[2] One of the polysaccharides that binds clenbuterol is hyaluronic acid. Hyaluronic acid is found in the vitreous humor and in the first few layers of the retina. From this information Method #2 was developed using two enzymatic digestions. The first digestion involves hyaluronidase to cleave the bond between clenbuterol and the hyaluronic acid. This digestion requires approximately 150,000 units of hyaluronidase and 45 hours digestion time at 37° C. The second enzymatic digestion employs pronase E to destroy the protein in the retinal tissue solution so the clenbuterol does not bind to the protein after it is cleaved from the hyaluronic acid. The protease digestion requires three hours at 37° C.

Method #2 was developed in the attempt to increase the percent recovery of clenbuterol from retinal tissue. The recovery of a clenbuterol spike increased significantly with the use of Method #2. The mean recovery was 101 7%*. Recoveries have been determined using retinal preparations spiked at 25 ng/g clenbuterol. Based on the response for the 25 ng/g clenbuterol spike it is estimated that detection of clenbuterol could be accomplished at a level of 500 pg/g in the retina. Although this method has not been optimized, results to date are promising and further experiments will be performed to determine this method's ruggedness and reproducibility.

High Energy CID Spectra of Chlorambucil- or Melphalan-modified Peptides

Joseph Zaia and Catherine Fenselau, University of Maryland Baltimore County
5401 Wilkens Ave., Baltimore, MD 21228

Introduction. Metallothionein is a metal binding protein whose function has been linked to cancer drug resistance[1,2]. CID MS studies have determined the covalent binding sites for the nitrogen mustard drugs chlorambucil (CLB)[3] and melphalan (MEL)[4] on metallothionein. This work was made challenging by the unusually high cysteine content of MT, *i.e.* 20 of its 61 residues are cysteine. Specifically, MT proteolytic peptides ionize very poorly by FAB, and fragment poorly during CID. The fragmentation effect is compounded when either a CLB or a MEL molecule is attached to the MT peptide *via* a cysteine side chain.

The purpose of this work is to improve the CID fragmentation pattern produced from drug-modified MT peptides.

Methods. The dimethyloctylammoniumacetyl (DMOAA) derivatives were prepared using a published method[5]. CLB-modified MT peptides were isolated as has been described[3]. All CID spectra were acquired using 6 keV collision energy with a JEOL Ltd. (Akeshima, Japan) HX110/HX110 tandem mass spectrometer operating in the FAB ionization mode.

Results. Peptides modified at cysteine by CLB are characterized by abundant ions produced from fragmentation of the drug moiety and by peptide sequence fragment ions in low abundance. Scheme 1 describes the fragmentation that is specific to the modifying group. The second mustard group on the CLB moiety has been observed to undergo a variety of reactions involving substitution or elimination of the mustard chlorine atom. Therefore, the *m/z* of the ions produced will vary according to the reaction that has taken place. In all cases, an abundant ion is produced at low mass (*m/z* 254.6 for the ion with an intact second mustard group). Ions at high mass are also observed, and these result from loss of part or all of the CLB moiety as a neutral fragment. Generally, the ions noted as 2*, 4*, and 5* are observed for peptides that have at least one basic group. The 1* and 3* ions are produced only for those peptides containing multiple cysteines.

Model peptides, modified at cysteine with CLB, were used to study several means of affecting the appearance of CID spectra. Decreasing the collision energy from 6 keV to 0.5 keV reduced the relative abundances of peptide sequence fragment ions. N-acetylation increased the abundances of a few peptide sequence fragment ions, but the overall pattern was not conducive to interpretation. Substitution of the CLB chlorine atom with trimethylamine produced a fixed charge ion, the CID spectrum of which was also not readily interpretable for an unknown peptide. Attachment of a fixed positive charge to the N-terminus of the modified peptide was the only measure found to produce a spectrum coherent enough to render it interpretable in a reasonably straight-forward manner. The same conclusion was reached using MEL-modified peptides.

In order that both the fragmentation pattern and the ionization efficiency be improved, the DMOAA derivative was used for MT-peptides. An example spectrum is shown in Figure 1. The fragmentation pattern is consistent with MT 45-52 (CAQGCICK), modified at Cys-49 with a CLB group. The ions denoted $a_n+1\text{-}CH_3$ and $a_6+1\text{-CLB}$ are produced from loss of the CH_3 or CLB from the corresponding a_n+1 ion, respectively[6]. The *m/z* values of the ions produced from fragmentation of the drug moiety are consistent with substitution of an OH group for the mustard chlorine (see Scheme 1). The spectrum represents a significant improvement over that acquired without a charged derivative.

Conclusions. Attachment of a charged derivative to the N-terminus of a CLB-modified peptide was the most potent of the means investigated for producing an interpretable CID spectrum. The same conclusion has been reached for MEL-modified peptides, although space does not allow these spectra to be shown.

FAB-MS AND MS-MS STUDIES OF EXTRACTS FROM *PINUS PONDEROSA*

Lynn M. Teesch†, Diane J. Lamb†, John P. N. Rosazza, and Mohsen S. Al-Mahmoud
Division of Medicinal and Natural Products Chemistry, College of Pharmacy, and †High Resolution Mass Spectrometry Facility, The University of Iowa, Iowa City, IA 52242

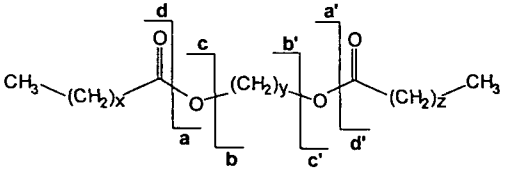
Needles from the *Pinus ponderosa*, or western yellow pine, cause abortions in cattle if they are consumed late in gestation. Components in the pine needles are thought to cause premature parturition by decreasing uterine blood flow to the fetus. Numerous natural products have been isolated from the pine needles such as various types of terpenes and wax alcohols and acids. Several have been implicated as the causative agent, but no definite biological association has been determined, yet. The focus of this study is the characterization of components from the needle's cuticular membrane. The cuticular membrane is composed of cutin which is a complex mixture of lipids.

Pine needles are first subjected to soxhlet extract with diethyl ether, methylene chloride, and finally, methanol. Each extract was then tested for biological activity via a placentome bioassay (1). The methylene chloride extract, **F7**, showed the most activity. Further purification of **F7** by flash column chromatography resulted in four fractions. The first fraction, **M1**, gave very good results in placentome bioassays and was analyzed via NMR, IR, and GC-MS. Fast atom bombardment mass spectrometry (FAB-MS) was used to determine the mass of the isolated compound in **M1**. The sample was mixed with 3-nitrobenzyl alcohol on the probe. **M1** is in fact a mixture of four components that are separated by 28 u or 2 methylene groups. The $(M + H)^+$ ions in the FAB mass spectrum include *m/z* 568, 596, 624, and 652. All the data so far suggests that the isolated material in **M1** consists of ω-hydroxy-fatty acids, fatty acids, alkanols, and alkandiols esterified to produce diesters. This is similar to structures proposed for cutin waxes, but the intact molecules have never been identified (2).

There are structurally important low mass fragment ions in the FAB mass spectrum of **M1** Because the isolated material is a mixture, we are unable to assign the low mass ions to a particular precursor ion. By using tandem mass spectrometry (MS-MS), the fragmentation pattern of each $(M + H)^+$ can be obtained. Several synthetic standards, such as 1,14-tetradecanedioyl-dilaurate (12:14:12) or 1,12-dodecanedioyl-1-laurate-12-myristate (12:12:14), are also available for MS-MS analysis (3). Thus, by comparing the **M1** results with that of the standards, we can identify possible structures.

MIKES experiments are used to acquire the metastable ion spectra of the four components in **M1** and standards. The $(M + H)^+$ ions are allowed to unimolecularly decompose in the second field free region of a VG ZAB-HF reversed geometry mass spectrometer. The observed fragmentations involve cleavages at the ester linkages, Scheme 1. Two of the metastable ion decompositions involve a hydrogen

Scheme 1
(x and z can be either10 or 12; y can be either 12 or 14)



rearrangement to produce an ω-hydroxy-fatty acid ester (**a** and **a'**) which can then lose H_2O (**b** and **b'**). The another set of decompositions involve cleavage to yield fatty acids (**c** and **c'**), which can also then lose H_2O (**d** and **d'**).

Figure 1 includes the metastable ion spectra of the $(M + H)^+$ ions of two components in **M1** and their corresponding standards. The standard compounds include 12:12:14 and 12:14:12 for the ion of *m/z* 596 (Figure 2A and 2B), and 14:14:12 and 14:12:14 for the ion of *m/z* 624 (Figure 2D and 2E). The fragmentation pattern of the unknown ion of *m/z* 596 (Figure 2C) and 624 (Figure 2F) correspond to 12:14:12 and 14:14:12, respectively. The most likely structure for the lowest mass $(M + H)^+$ ions (*m/z* 568) is 12:12:12. The identification of the highest mass ion of *m/z* 652 is more difficult, because its metastable ion spectra is more complex. However, after comparing the theoretically calculated fragmentations for 12:14:16, 12:16:14, and 14:12:16, the unimolecular decompositions of 14:14:14 and the unknown, the ion of *m/z* 652 is probably a mixture of 14:14:14, 12:14:16 and 12:16:14.

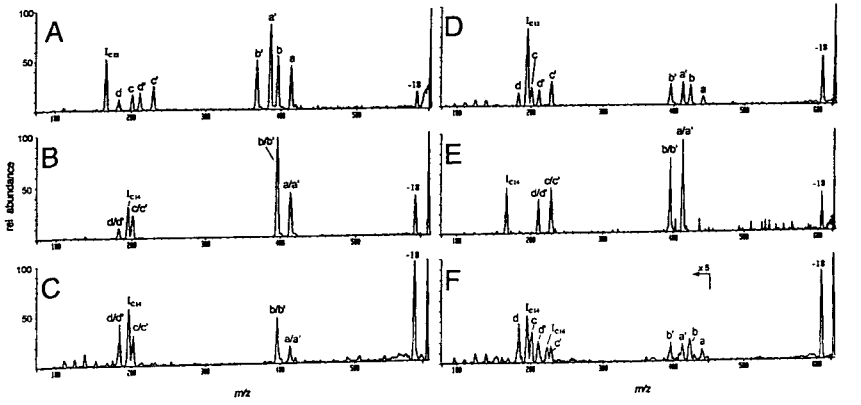


Figure 1. Metastable Ion Spectra of $(M + H)^+$ ions of *m/z* 596 standards, 12 12 14 (A) and 12:14:12 (B), and **M1** (C), and of *m/z* 624 standards, 14:14:12 (D) and 14:12:14 (E), and **M1** (F).

Collision-induced decompositions (CID) of $(M + Li)^+$ ions are also structurally informative and include charge-remote fragmentations analogous to those previosly observed for $(M + Li)^+$ions of fatty acid methyl esters.[4] We studied these complexes, because the dramatic effect these compounds have on the potassium sensitive channels during the placentome bioassays.

A Multi-Dimensional Approach to the Characterization of Environmental Contaminants: Yeast, DNA and Liquid Chromatography-Mass Spectrometry (LC/MS).

JOSE SERRANO and DOUGLAS KUEHL
U.S. Environmental Protection Agency
Environmental Research Laboratory-Duluth
Duluth, MN 55804 (218)720-5559

Mutagenicity assays using budding yeast *Saccharomyces cerevisiae* are important tools for the detection of genetically active chemicals, especially when combined with complementary microbial screening techniques such as the Ames test. We have developed a new analytical, multi-endpoint approach for the assessment of the mutagenic potential of environmental chemical contaminants, including those in complex mixtures. The method integrates for the first time, the principles of yeast genetics and LC/MS. The objective of the yeast assay is to measure the mutation frequency of a yeast/*E. coli* shuttle plasmid DNA (pDNA) that has been previously modified *in vitro* with selected contaminants (with or without fish liver microsomes). A portion of the pDNA is analyzed by LC/MS and LC/MS/MS to characterize the type (reaction sites) and amount (frequency of alkylation) of adducts formed, as well as the electrophilic characteristics of the toxicant (N vs O bonding). The *in vivo* bioassay of a second portion of the sample included the fast transformation of pDNA into various yeast strains (mutant and wild type cells) via electroporation, and the cloning of chemically-induced mutant plasmids (at the URA3 gene) by selection for 5-fluoroorotic acid (5-FOA) resistance. Mutation frequency is defined as mutants/transformants/µg pDNA. A series of allylhalides with different chemical reactivity (chloride, bromide, isothiocyanate) and benzo[a]pyrene (B[a]P), were used as model compounds for direct-acting toxicants and those requiring metabolic activation, respectively. A mixture of PAHs (B[a]P, pyrene and benzo[e]pyrene), was used to test the effectiveness of the method to estimate the mutagenic potential of model complex mixtures. It was demonstrated that a linear dose-response ocurred between mutation frequency and the toxicant dose measured by LC/MS for low doses of allylbromide and B[a]P (Figures 1 and 2). Mutation frequency was also found to be proportional to the relative reactivity of the allylhalides (Figure 3). Further, B[a]P/DNA adduct formation as well as mutation frequency were altered by the PAH co-contaminants present in the model complex mixture (Table 1). LC/MS results correlated well with those previously observed for the *in vitro* reactions of calf thymus and fish liver DNA with the same contaminants.

MONITORING ACID- AND BASE-INDUCED 'LIPID A' DEGRADATION BY ELECTROSPRAY IONIZATION MASS SPECTROMETRY

Richard B. Cole* and Yan Wang

Department of Chemistry, University of New Orleans, Lakefront, New Orleans, LA 70148

Lipopolysaccharides (LPS) are endotoxins produced by all gram-negative bacteria. They elicit a variety of biological, medical and immunological activities such as induction of fever, change in the white blood cell count, diarrhea, or even shock and lethal toxicity [1,2]. Because of these important properties, the study of the relationship between LPS structure and its toxicity has been an area of intensive investigation. Contained within lipopolysaccharides is a "lipid A" portion which constitutes the outer cell wall of gram-negative bacteria. Lipid A often takes the form of a β-1,6 linked D-glucosamine disaccharide; it is believed to be responsible for the toxicity exhibited by lipopolysaccharides. Approaches to detoxification of lipopolysaccharides include chemical degradation via acid and base hydrolysis.

A particular LPS that we have been investigating [3,4] is that produced by *Enterobacter agglomerans*, a gram-negative bacterium commonly found in field cotton. LPS in cotton dust has been found to be the cause of respiratory diseases such as byssinosis. Negative ion electrospray mass spectrometry was used to characterize structural changes to lipid A from *Enterobacter agglomerans* incurred after acid and base treatment. Shown in Figure 1 (a-d) are the negative ion electrospray mass spectra of lipid A from *Enterobacter agglomerans* obtained after 0, 30, 60, and 120 min of acid treatment (1% acetic acid, 100 °C). These mass spectra provide direct evidence of the substantial degree of hydrolysis of ester-linked fatty acyl chains resulting from acid treatment. The acid hydrolysis process with the fastest rate constant corresponded to removal of the palmitoyl group from the hepta-acyl form of lipid A. In the presence of excess acid, this reaction conformed to pseudo-first order kinetics with a rate constant of 3.3×10^{-3} min^{-1}. An approximate order of lability of acyl side chains on the lipid A molecule to acid hydrolysis was also deduced: R'_4 (palmitoyl) > R'_1 (myristoyl or hydroxymyristoyl) > R_3 (hydroxymyristoyl at position 3) > R_1 (oxymyristoyl group at position 3') > R'_2 (lauroyl). The negative ion electrospray mass spectra of the products of 0, 15, 30, and 60 min base treatment (0.05 N NaOH in 95% EtOH, 65 °C) are shown in Figures 2a, b, c, and d, respectively. Base hydrolysis under the employed conditions was observed to be even more effective than acid treatment at hydrolyzing ester-linked fatty acyl chains. Both approaches have been shown to be effective at lowering the endotoxin level as measured by the *Limulus* amebocyte lysate (LAL) assay. Mass spectral evidence also suggested that breakage of the glucosidic linkage may be occurring during base hydrolysis. The latter process could be responsible for the toxicity reduction known to accompany base treatment.

HPLC/IonSpray/MS/MS Analysis of Common and Illicit Drugs in Case Samples

Pierre Picotte, Direction des expertises judiciaires, Ministére de la Sécurité publiquè, Gourverment du Québec, Montréal, P. Q. H2L 4K6; Gabriel Sanchez, Bori Shushan and Takeo Sakuma*, PE-SCIEX Instruments, Concord, Ont. L4K 4V8

Among standard techniques utilized in forensic toxicology, immunoassays, GC/FID/ECD/NPD and GC/MS/MS are considered suitable. However, certain compounds are thermally labile or too polar to be GC-compatible without appropriate sample derivatization. These current methods lack sensitivity for some important drugs, and it is a limiting factor in pursuing forensic analyses. The IonSpray technique does not involve heat and offers gentle ionization of polar and thermally labile compounds. This method has been in use for the analysis of polar and thermally labile compounds for the last few years. In order to evaluate various aspects of HPLC/IonSpray/MS/MS techniques, standards and case extracts were prepared and analyzed for the presence of tetrahydrocannabinol(THC), Δ^9 - THC-OH, Δ^9 - THC-COOH, clonazepam, lorazepam, nitrazepam, procyclidine, salbutamol, temazepam, heroin, morphine, 6-acetylmorphine, cocaine and benzoylecgoine.

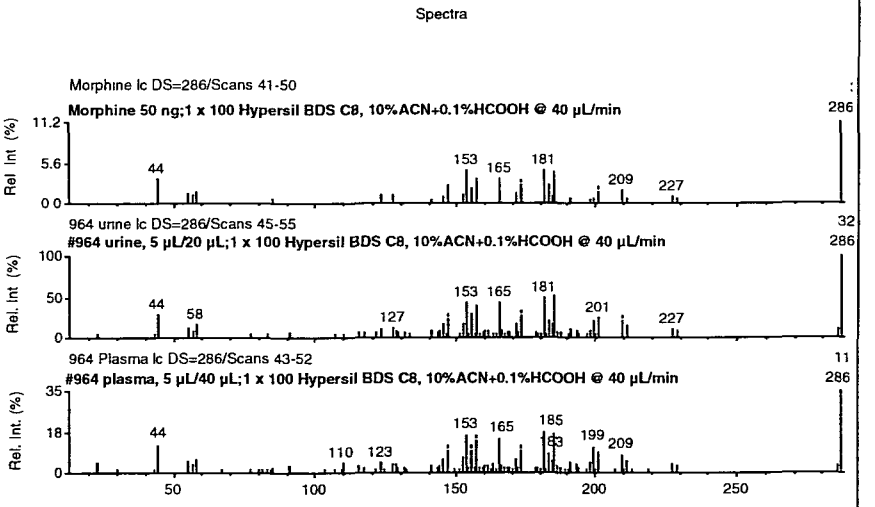
A 5-mL urine specimen for cocaine, morphine and 6-actylmorphine was added to a Cleanscreen solid phase extraction cartridge. A 0.1 M phosphate buffer (2 mL) was added to this cartridge. The eluent was centrifuged and filtered with a 20 µm frit. The cartridge was conditioned successively with 3 mL methanol, 3 mL water and 1 mL phosphate buffer (0.1M, pH 6). The filtered sample was passed at a rate of 1 - 2 mL/min through the conditioned cartridge under reduced pressure. This cartridge was washed with 2 mL water, 2 mL acetate buffer(0.1 M, pH 4.5) and 3 mL methanol. The cartridge was dried for 10 min. at 254 mm Hg. The analytes were eluted from the cartridge with 3 x 1 mL of a freshly prepared mixture of 70% methylene chloride, 20% isopropanol, 2% ammonia and 18% water. The combined eluent was evaporated with a nitrogen jet, and reconstituted with ethanol.

A blood specimen (5 mL) for clonazepam was mixed with 20 mL saturated saline solution, vortexed and centrifuged. The supernatant was filtered with a 20 µm frit. A Waters C18 solid extraction cartridge was conditioned with 5 mL methanol followed by 5 mL saline solution. The filtered sample was passed thorough the cartridge under reduced pressure. The cartridge was washed with 2 x 5 mL saline and 2 x 5 mL pentane, and dried under vacuum for 15 min. The analyte was eluted with 4 x 1 mL of a mixture of 50% methanol and 50% chloroform. The combined eluents were evaporated with a nitrogen jet, and reconstituted with ethanol.

A 5-mL urine sample for THC carboxylic acid was hydrolyzed with 500 µL of a 60% KOH solution for 30 min. at 60°C. The mixture was allowed to cool down, and its pH was adjusted to 1 - 2 with 500 µL of a 12 N HCl solution. The mixture was transferred to a 50 mL separatory funnel. To this a 25-mL mixture of 65% hexane and 35% ethyl acetate was added, and mixed well. After settling, the organic layer was filtered over a Whatman No. 1 filter paper. The filtrate was evaporated with a nitrogen jet, and reconstituted in ethanol.

HPLC separation was made using base-deactivated 100 x 1 mm or 150(or 100) x 2.1 mm Hypersil BDS C18 or NovaPak C18 columns. Acetonitrile, water and 0.1% formic acid were used either under isocratic or linear gradient conditions to give 2-5 minute elution time.

A PE-SCIEX API III plus LC/MS/MS system equipped with a TurboIonSpray inlet was used for the acquisition of basic data for commonly encountered drugs of abuse and their metabolites by flow injection analysis. The predominant ions were either MH^+ for basic compounds or $[M - H]^-$ for acidic compounds without any obvious fragmentation. Unique product ions were selected for rapid screening (2 - 6 elution time) of blood and urine extracts in the multiple reaction monitoring mode with a detection limit of 0.1 - 0.5 ng/mL. Calibration curves were prepared in the concentration range of 0.2 ng/mL to 2 µg/mL using a 1 x 100 mm or 2.1 x 100(or 150)mm base deactivated column. Excellent linearities (r2 ≥ 0.99) were obtained. The confirmation of these substances was done by LC-Product Ion spectral acquisition. The product ion spectra obtained from several case samples were almost identical to those obtained from chemical standards. The following compares product ion spectra obtained from morphine standard, urine and plasma extracts obtained from the same subject.



It has been shown that the use of fast chromatography combined with excellent specificity of the tandem quadrupole mass spectrometer and high sensitivity of the IonSpray technique to polar and thermally labile substances greatly improve the accuracy and speed of processing case samples for forensic chemists.

The authors wish to thank Ms. Carole Péclet and Ginette Rosato, toxicologists from the Direction des Expertises Judiciaires for their assistance in case selection and sample preparation.

IN VIVO METABOLISM OF PEPTIDE E, A LEU- AND MET-ENKEPHALIN PEPTIDE PRECURSOR, IN RAT BRAIN STUDIED BY MICRODIALYSIS/MICRO-ELECTROSPRAY MASS SPECTROMETRY

Per E. Andrén, Mark R. Emmett and Richard M. Caprioli
Analytical Chemistry Center and Dept. of Biochemistry and Molecular Biology, University of Texas Medical School, 6431 Fannin, Houston TX 77030

INTRODUCTION

Peptide E (YGGFMRRVGRPEWWMDYQKRYGGFL) is a mu-selective opioid peptide derived from proenkephalin A (263 amino acids). Peptide E and its known metabolites have been identified in brain and gastrointestinal tissue. Peptide E is unusual in that it contains two biological active peptides that could contribute to opioid actions, i.e. the [Met]^5-enkephalin sequence at the amino-terminus and [Leu]^5-enkephalin sequence at the carboxyl-terminus. In the present work we have studied the *in vivo* metabolism of peptide E in rat brain by using microdialysis/micro-electrospray mass spectrometry (micro-ES/MS).

In addition, we have utilized the highly sensitive micro-ES/MS-technique in order to detect endogenuous [Met]^5-enkephalin at attomole levels from brain microdialysis perfusates of freely-moving rats.

MATERIALS AND METHODS

In Vivo Metabolism of Peptide E

The microdialysis probe (CMA/10, 4 mm) was implanted in the striatum (AP+2.4, ML±3.0, DV-6.8) or the globus pallidus/ventral pallidum (GP/vP) (AP+1.0, ML±2.8, DV-4.3) of anesthetized rats. Peptide E was dissolved in artificial CSF (10 pmol/µL) and perfused at a flow-rate of 300 nL/min through the microdialysis probe. The probe was used to both deliver the peptide into the brain and to collect the degradation products. Samples were taken every 30 min.

Endogenous release of [Met]^5-enkephalin

A microdialysis guide cannula (CMA/10 Microdialysis AB, Sweden) was stereotaxically implanted under pentobarbital anesthesia (45 mg/kg) such that the microdialysis probe (CMA/10, 4 mm) would fully extend from the bottom of the cannulae and be positioned in the GP/vP. Three to five days after the surgery the microdialysis probe was inserted into the GP/vP through the guide cannula of the freely moving animal. The microdialysis probe was perfused with artificial CSF (5 mM KCl, 120 mM NaCl, 1.2 mM $MgCl_2$, 1.8 mM $CaCl_2$, 0.15% phosphate buffer pH 7.4) at a flow rate of 436 nL/min.

Capillary-liquid chromatography/micro-electrospray mass spectrometry

Mass spectra were obtained with a TSQ70 triplequadrupole mass spectrometer (Finnigan MAT, San Jose, CA) equipped with a micro-ES source. A capillary-LC/C18-packed column (50 µm i.d., 40 nL bed volume) was used for the concentration and desalting of the neuropeptides. The peptide samples were loaded with 2% MeOH/ 0.25% acetic acid on to a 10 µL loop on a 10-port valve (Valco Corp., Houston TX). The needle voltage was set to 3.5 kV, nozzle voltage 250 V, and repeller voltage to 10 V. Samples were eluted with 50% MeOH/0.25% acetic acid.

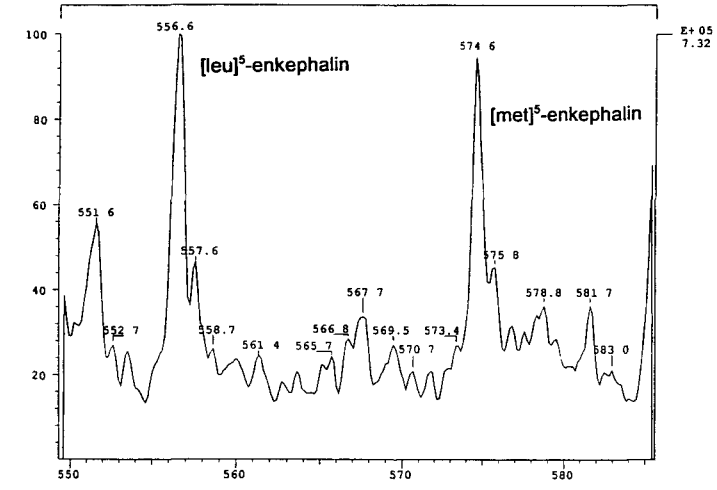
CONCLUSIONS

The present results showed that peptide E was metabolized *in vivo* to [Met]^5-enkephalin and [Leu]^5-enkephalin in the rat GP/vP. Larger fragments found were both N-terminal and C-terminal fragments, as well as internal fragments.

The structure-specific molecular detection of the endogenous neuropeptide [Met]^5-enkephalin released *in vivo* in rat brain has been accomplished using microdialysis and tandem mass spectrometry. The sensitivity of the technique for [Met]^5-enkephalin was in the attomole/µL range.

Measurements of the amounts of [Met]^5-enkephalin in the microdialysates obtained from studies of stimulated release showed that [Met]^5-enkephalin was present at a level of approx. 4-6 femtomoles per 10 µL dialysate, and that the baseline level was at approx. 1 femtomole per 10 µL dialysate.

The present study indicate that the methods and instrumentation described are suitable for detailed studies of neuropeptides in living animals, and this technique can be extended to studies of neuropeptide formation from precursors and their subsequent metabolism.



A microdialysis probe was used to both introduce peptide E into the brain and to collect metabolic products. Peptide E was metabolized to [Leu]^5-enkephalin (m/z 556.6), the C-terminus of peptide E, and [Met]^5-enkephalin (m/z 574.6), the N-terminus of peptide E, *in vivo* in the rat brain (GP/vP).

Characterization of Metabolites of a CCK Ligand on a LC/ESI/(MS)^n Ion Trap Mass Spectrometer, Arthur Moseley*[1], Tim Tippin[1], John Walsh[1], Jae Schwartz[2], Adrian Land[2], and Ian Jardine[2], [1]Department of Drug Metabolism, Glaxo Wellcome Research Institute, RTP, NC, [2]Finnigan MAT, San Jose, CA

GG772 is a novel 1,5-benzodiazepine derivative under study as a ligand of cholecystokinin (CCK). Biliary excretion in the guinea pig after iv administration of GG772 has been studied by LC/fluorescence and LC/MS. Prior to LC/MS, the bile sample was concentrated and cleaned up using a solid phase extraction procedure. The concentrated sample and corresponding predose bile were analyzed using microbore LC/ESI/(MS)^n on a Finnigan LCQ ion trap.

Prior to the analysis of the bile sample, reference (MS)^n spectra were acquired using a constant infusion of GG772. Each (MS)^n reference spectrum was obtained from approximately 6 ng of GG772. Reference spectra with high signal-to-noise ratios were acquired from n=1 (MS) to n=5 (MS/MS/MS/MS/MS). It was found that (MS)^3 was sufficient for the qualitative identification of the expected metabolites.

In order to evaluate the on-column levels of GG772 required to give useful LC/ESI/(MS)^3 spectra, an injection of 5 µL of 78 pg/µL of GG772 was made onto a 1 x 50 mm Hypersil BDS-C18 LC column. From this one injection of 390 picograms, LC/MS, LC/(MS)^2 and LC/(MS)^3 reference spectra were acquired.

A 2µL aliquot of the bile sample was analyzed using gradient elution from a 1 x 250 mm YMC AQ-C18 LC column. The gradient was 50% to 80% (10 minutes) of acetonitrile/2mM ammonium acetate (pH 4.5), with a mobile phase flow rate of 50 µL/minute. This analysis revealed a demethylated metabolite, a demethylated + sulfate metabolite, two major and three minor monooxidated metabolites, as well as parent GG772. The LCQ ion trap was able to acquire LC/MS, LC/(MS)^2, LC/(MS)^3, and LC/(MS)^4 spectra from the demethylated+sulfate metabolite, and LC/MS, LC/(MS)^2, and LC/(MS)^3 spectra from the demethylated metabolite, the two major monooxidated metabolites, and parent GG772. These spectra gave abundant structural information about these metabolites. For example, Figure 1 compares the LC/ESI/(MS)^3 spectrum obtained from 390 pg of GG772 with the LC/ESI/(MS)^3 spectrum of one of the monooxidated metabolites, indicated that the oxygen was located on the F2 portion of the molecule.

The ion trap's low full scan detection limits, coupled with its ability to perform LC/(MS)^n data acquisition, cause it to be very useful for the qualitative identification of drug metabolites from a "real world" samples.

Investigation of the Interactions Between Bicyclomycin and Rho Protein

[1] K.A. Cox, [1]S.J. Gaskell, [2]H.-S. Moon, [2]H.-G. Park, [2]W.R. Widger, [2]H. Kohn
[1] The Michael Barber Centre for Mass Spectrometry; UMIST; Manchester M60 1QD, U.K.
[2] Department of Chemistry; University of Houston, Houston, TX 77004

Bicyclomycin (MW 302) is a structurally unique antibiotic which possesses a broad spectrum of antimicrobial activity against a variety of Gram-negative bacteria (1). Its broad utility combined with a novel method of activation and bonding to nucleophiles at near neutral pH values (2) make it particularly interesting in the development of new antibiotics. In *E.coli,* the primary site for drug binding is rho transcription termination factor (3), a cellular protein necessary for antibacterial growth. This protein is comprised of six identical 47 kDa subunits which recognize and bind to discrete regions within the newly synthesized RNA chains. Rho then extends its interaction toward the 3' end of the RNA polymerase elongation process, destabilizing the complex and releasing RNA from the transcription bubble (4). Bicyclomycin (BCM) binds to rho protein, affecting bacterial protein synthesis. The interaction of bicyclomycin with rho protein is not yet fully understood, but model studies suggest bonding of the protein by Michael addition to the exocyclic methylene group of bicyclomycin (2). The aim of the work shown here was to use electrospray ionization mass spectrometry to investigate the nature of BCM bonding to rho protein under a variety of incubation conditions. The reaction of BCM with several model peptides was also studied using tandem mass spectrometry.

BCM Incubated with Rho Protein

The m/z spectrum of native rho protein is shown in Figure 1a. Rho protein has an expected molecular mass of 47,006 Da. The mass spectrum of rho protein (Figure 1b) was processed by MaxEnt, an iterative algorithm which uses the method of maximum entropy to produce a mass spectrum from a multiply charged electrospray spectrum. When rho protein was incubated with BCM for only 30 minutes, apparent incorporation of one molar equivalent of BCM was observed (Figure 2). However, the mass spectrum gave no indication of the site of BCM incorporation. When rho protein was incubated with BCM for 8 hours, a prominent cleavage product was observed at 14,378 Da. No unmodified rho was detected, and although the large number of peaks observed in the m/z spectrum suggested a mixture of a number of products, no series could be identified. Partial proteolysis studies have indicated that rho contains a trypsin sensitive site at or near residue 130 (4). Cleavage at the arginine residue (128) would result in a fragment with a mass of 14,374 Da. Further studes indicated the presence of a proteolytic contaminant in the BCM preparation obtained from the supplier.

BCM Incubated with Model Peptides

In an effort to understand further the interaction of BCM with proteins, BCM was incubated with a series of model peptides of the form Ac-YGFXGF-NH_2, where X= Lys, Arg, His and Cys. In the case of the basic residues, Lys and Arg, complete cleavage was observed, as would be seen upon incubation with trypsin. When BCM was incubated with the His and Cys-containing peptides, clear signs of adduction were observed.

Ac-YGFHGF-NH_2 + BCM: The HPLC fraction of this incubation revealed a peak at m/z 1070, as expected for the addition of BCM to the peptide, and a peak at m/z 1071 of a relative abundance greater than that expected from isotopic contributions, suggesting the presence of two species. This could also be due to conversion of the C-terminal amide to a carboxylic acid independent of BCM adduction. In addition, a peak at m/z 687.6 was observed, corresponding to the addition of 2 BCM moieties to this peptide. Product ion spectra of these species clearly identified the histidine residue as the site of BCM adduction.

Ac-YGFCGF-NH_2 + BCM: HPLC purification of this incubation mixture revealed two fractions, producing virtually identical mass spectra. The mass spectra showed a series of peaks from m/z 1036 to 1039; the expected mass for the proposed adduct is 1036 Da. Another species was observed at m/z 1019, corresponding in mass to the addition of BCM to the peptide with loss of 17 Da. Previous studies examining the incubation of BCM with cysteine derivatives gave a piperidinedione product (R+BCM-NH_3) at neutral pH and two structurally distinct (R+BCM) products at higher pH (5). The CID spectra of m/z 1036 and m/z 1019 show cysteine as the site of BCM modification. The CID spectra of the m/z 1019 species show the same fragments as in the dissociation of m/z 1036, with corresponding NH_3 losses observed only from the fragment ions which incorporate the BCM moiety, consistent with the existence of the piperidinedione structure. However, no ions were observed corresponding to cleavage of the BCM moiety, precluding further conclusions about its structure.

Introduction

d-Limonene (*p*-metha-1,8-diene) is a monoterpene with broad cellular anitproliferative activity and potent chemopreventive/chemotherapeutic activity in carcinogen-induced animal tumor models. Transforming activity of $p21^{Ras}$ and related 21-26 kDa GTP-binding proteins is dependent on post-translational isoprenylation but constitutively mutated, oncogenic forms of *ras* proteins have been associated with a broad spectrum of human malignancies including 90% of pancreatic and 50% of colorectal adenocarcinomas [1]. Farnesyl-protein transferase (FPTase) is the enzyme that catalyzes protein prenylation, and inhibitors of this enzyme may be potential antitumor agents. Limonene inhibits the post translational isoprenylation of $p21^{ras}$ and other small G proteins and has been demonstrated to have antitumor activity against *N*-methyl-*N*-nitrosourea (NMU) and 7,12-dimethyl benz-(a)anthracene (DMBA) induced tumors in the rat. It is the first FPTase currently undergoing phase I clinical trial in patients with advanced cancer.

Limonene is extensively metabolized *in vivo* to active metabolites and the parent compound is only a minor component. Quantitation and characterization of these metabolites are critical because they have greater pharmacological potency than limonene in the inhibition of small G protein isoprenylation. This report describes the direct analyses of limonene and its metabolites presence in the plasma and urine samples of patients by liquid chromatography - mass spectrometry, utilizing the atmospheric pressure chemical ionization (APCI) for the phase I metabolites and the electrospray ionization (ESI) interface for the phase II metabolites.

Conclusion

Four major metabolites were observed in the plasma samples, namely perillic acid, dihydroperillic acid, limonene-1,2-diol and limonene-8,9-diol. Together with limonene-10-ol, all these metabolites were also present in the urine samples as their corresponding glucuronides. All of these compounds are 5-10 times more potent than limonene *in vitro* in the inhibition of protein isoprenylation and cellular proliferation [2]. The rapid biotransformatin of limonene to these metabolites constituting the predominant terpene component in plasma, each substantially more potent than the parent compound strongly suggests that the biological activity of limonene is mediated by these plasma metabolites.

Metabolic Pathway of limonene after oral administration in human

An Electrospray Mass Spectrometric Study of the Gold Drug Myochrysine.

Richard W Smith, Daren J LeBlanc, Colin J.L. Lock and Helen E.Howard-Lock
Department of Chemistry, McMaster University, 1280 Main St W, Hamilton, ON, L8S 4M1, CANADA.

Although the gold (I) drug myochrysine (sodium gold-thiomalate) has been used for the treatment of rheumatoid arthritis for more than 60 years, its characterization by conventional methods such as NMR, X-ray crystallography and mass spectrometry has proven unsuccessful (1)

This drug, marketed as a mixture of several components (including excess di-Na thiomalate, glycerol and ethanol) has a number of toxic side-effects, some of which may be related to one or more of the Au containing minor components The characterization of the Au species may lead to improvements in the synthesis and purification of the unidentified active compound which is thought to be a Au(I)/thiomalic acid (L= $HO_2CCH_2CH(SH)CO_2H$) oligomer for which open and closed chain structures including pentamers, hexamers, and octamers have been postulated (1,2,3). Two classes of L Au complexes are thought to exist (1) in these samples, (i) closed ring oligomers with bridging S between two Au atoms with a L:Au ratio of 1·1, considered to be neutral apart from the ionizable carboxyl groups and (ii) open chain oligomers with both bridging and terminal S atoms, with a higher than 1.1 L:Au ratio (eg. the 2 1 and 3·2) and, in addition to the ionizable carboxyl groups, an overall negative charge due to the terminal thiol group(s)

Pneumatically assisted electrospray experiments were performed with 50/50 CH_3CN/H_2O as the mobile phase at a flow rate of 15µl/min employing a Brownlee Microgradient syringe pump Samples were introduced by flow injection at a concentration of 0.01M + 0.001M of NH_4OH for both the +ESI and -ESI experiments Full scan ESI experiments were performed with a Fisons Platform quadrupole instrument and the MS/MS data were generated with a Fisons Quattro II triple quadrupole instrument. Collisional activation (CA) MS/MS was performed with Ar as the collision gas at a main beam attenuation of 25% and a collision energy of 35eV All data was acquired in MCA mode (10 scans) A cone voltage (CV) of 35V was employed in all ESI experiments (unless otherwise stated) All samples employed in this study were used as supplied by the manufacturer or synthesized by conventional methods.

Analysis of the sodium and ammonium salts of gold-thiomalate by electrospray mass spectrometry indicated that the primary species is a molecular weight 1384 tetramer (Au_4L_4). In the case of the Na salt, the +ESI and -ESI mass spectra were very complex due to extensive Na^+/H^+ exchange, however, the ions corresponding to those observed from the NH_4^+ salt were present. Consequently, discussion of the results will be restricted to the NH_4^+ salt of myochrysine. In the negative ion mode, the ammonium salt exhibited intense singly, doubly and triply charged ions at m/z 1383, 691 and 460 respectively whereas in the positive ion mode the protonated and ammoniated ions dominated at m/z 1385 and 1402 (Figure 1) In addition, ions were observed at m/z 1267, 1151, 633 and 575 in -ESI which may correspond to the singly and doubly charged ions originating from species such as Au_4L_3SH and $Au_4L_2(SH)_2$ as well as an ion at m/z 495 which may correspond to the Au_1L_2 species Ions corresponding to the $Au_4L_{y=4-2}(SH)_{z=0-2}$ species were not observed in +ESI perhaps indicating that the -ESI species were fragment ions originating from the $[M-H]^-$ / $[M-2H]^{2-}$ ions In order to further clarify these observations CA MS/MS was performed. The $[M-2H]^{2-}$ ion yielded the same singly and doubly charged ions observed from myochrysine that is, the $Au_4L_{y=4-2}(SH)_{z=0-2}$ species The facile cleavage of the C-S bonds in the -Au-S-C- system has been reported previously (4) consequently, the observation of these fragment ions might be expected However, if the $Au_4L_{y=4-2}(SH)_{z=0-2}$ species are formed by "in source" fragmentation of the Au_4L_4 tetramer, then varying the cone voltage may further elucidate whether the ions observed are in fact derived from components of myochrysine

In +ESI (CV=25V) only the $[M+NH_4]^+$ and $[M+H]^+$ ions were observed while at a CV of 55V, the consecutive loss of 4 H_2O molecules was seen. In addition, the ion corresponding to the protonated Au_4L_3SH

species was observed at a CV of 80V In -ESI (CV=20-50V), the ions corresponding to the $Au_4L_{y=4-2}(SH)_{z=0-2}$ and Au_1L_2 species were observed Higher CV's (>60V) caused extensive dissociation of the Au_4L_4 species which produced intense ions such as m/z 495 (Au_1L_2) These results indicate that the Au_4L_4 tetramer is the major component of myochrysine. However, the presence of $Au_4L_{y=4-2}(SH)_{z=0-2}$ and Au_1L_2 in myochrysine still has to be determined due to the ambiguous nature of the results described here.

Identification of Diphenhydramine Metabolites Using Deuterated Ammonia DCI MS

T.M. Heinze, E.B. Hansen, Jr., J. Deck and C.E. Cerniglia
Food and Drug Administration, NCTR, Jefferson, AR 72079

INTRODUCTION The aim of this investigation was to isolate diphenhydramine metabolites formed from the fungal metabolism of diphenhydramine (DPH) and to identify them by using mass spectrometry and proton nuclear magnetic resonance spectroscopy. Deuterated ammonia (ND_3) desorption chemical ionization (DCI) mass spectrometry (MS) was used for the differentiation between possible isobaric diphenhydramine metabolites and for probing the mechanisms of ion formation under ammonia (NH_3) DCI conditions.

METHODS *Biotransformation and Semi-Prep HPLC Isolation of Metabolites:* DPH was metabolized by *C.elegans* in suspension culture for 168 hours. A methylene chloride extract of culture supernatant pooled with aqueous and methanolic cell washes was evaporated in vacuo. The residue was dissolved in HPLC mobile phase, 60% buffer (10 mM PO_4, 20 mM TMA, pH 7 with KOH) / 40% ACN. The metabolite isolation was on semi-prep HPLC columns (10 mm X 250 mm 5 μ, Cyano-propyl and SCD-100) at 5 ml/min. Peaks 1A, 1B, 2, 3, and 4 were isolated. *Proton Nuclear Magnetic Resonance (^{1}H-NMR):* Identities were confirmed by ^{1}H-NMR spectroscopy at 500MHz (Bruker Instruments) in methylene chloride-d_2. *Mass Spectrometry:* Experiments were performed by using a single quadrupole mass spectrometer (Finnigan MAT) model 4023 with PPINICI that was upgraded to a 4500. Sample introduction was via a direct exposure probe (DEP) with a rhenium wire and DEP programmer (Finnigan MAT) ramped at 5 mA /sec from 0 to 0.65 A. NH_3 DCI MS: positive ion, 50 to 650 daltons/1sec cycle, ionizer temp set at 120 and electron energy at 120 V. Reagent gas was a mixture of 10% NH_3 / 90% N_2 which was introduced until the analyzer pressure was 3.5 X 10^{-5} Torr with the probe inserted. Similar reagent gas mixture and conditions were used for ND_3 DCI MS.

RESULTS HPLC Peaks 1B, 2, 3 and 4 were identified as N-acetyl-DPH, DPH-N-oxide, N-desmethyl-DPH and recovered DPH, respectively. DEI MS, NH_3 DCI MS and ^{1}H-NMR spectroscopy confirmed the assignments. DEI and NH_3 DCI mass spectra indicated Peak 1A could be one of two isobaric metabolites, N-formyl-DPH or N-acetyl-N-desmethyl-DPH. The mass spectra of peak 1A were very similar to those of N-formyl-DPH standard, formylated Peak 3. ND_3 DCI mass

spectral analysis of peak 1A (Figure1a) solved the problem. Peak 1A had to be N-acetyl-N-desmethyl-DPH based on an extra exchangeable proton.

Acquisition of ND_3 DCI mass spectra for HPLC peaks 1B, 2, 3 and 4 completed the data set. The ion at *m/z* 167 common to all NH_3 and ND_3 DCI mass spectra of DPH and its metabolites was probably related to the ion at *m/z* 182 in the FAB mass spectra of doxylamine and its metabolites (1). Reaction of DPH-N-oxide with ammonia could yield the parent DPH and N-desmethyl-DPH resulting in a ND_3 DCI mass spectrum (Figure 1b) that looked like a composite of $[M+D]^+$ for the DPH-N-oxide and ions from N-desmethyl-DPH and DPH.

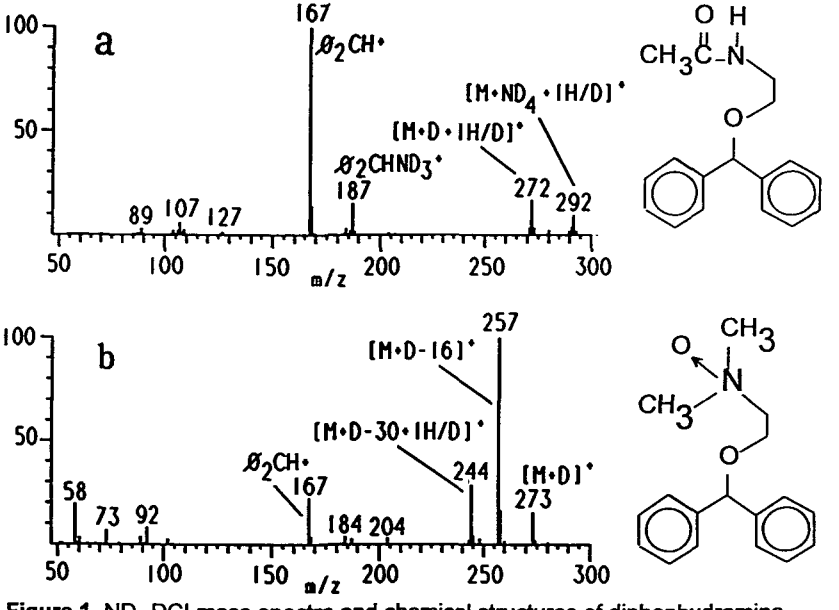

Figure 1. ND_3 DCI mass spectra and chemical structures of diphenhydramine metabolites found in Peak 1A (a) N-acetyl-N-desmethyl-DPH and Peak 2 (b) DPH-N-oxide.

LC/MS/MS Detection of the GSH-glucuronide Conjugate of (E)-2,4-Diene VPA in Rats

Wei Tang and Frank S. Abbott
Division of Pharmaceutical Chemistry, Faculty of Pharmaceutical Sciences,
University of British Columbia, Vancouver, BC, CANADA, V6T 1Z3

The hepatotoxicity of the anticonvulsant drug valproic acid (VPA) is thought to be related to the formation of toxic metabolites, namely 4-ene VPA and (E)-2,4-diene VPA (1,2). Previous work in this laboratory has shown that (E)-2,4-diene VPA, a product of 4-ene VPA metabolism in mitochondria, could react with the residing GSH and therefore deplete the mitochondrial GSH pool (2). In our continuing effort to explore the mechanism of VPA-associated hepatotoxicity, we report herein a LC/MS/MS characterization of new GSH-related conjugates of (E)-2,4-diene VPA. Bile samples collected from male Sprague-Dawley rats dosed i.p. with (E)-2,4-diene VPA (100 mg/kg) were injected onto a HP Hypersil ODS column (100 x 2.1 mm, 5 μm) interfaced to a Fisons VG Quattro LC/MS/MS instrument using electrospray ionization. Collision-induced dissociation (CID) involved argon as the target gas at a pressure of 3.0 x 10^{-4} mbar. The core voltage was 29 V with skimmer offset by 5 V, collision energy 50 eV and source temperature 80°C. LC mobile phase consisted of methanol/water (0.05% TFA) at a flow rate of 50 μL/min: 75% water for 2 min, a decrease to 50% water during 2-5 min, a hold at 50% water to 12 min, a decrease to 15% water during 12-16 min, a hold at 15% water to 30 min. Initial Q1 parent ion scanning indicated that the daughter ion *m/z* 162, a major fragment associated with the GSH conjugate of (E)-2,4-diene VPA, could also be derived from the ion at *m/z* 624. Subsequent MS/MS CID on the parent ion at *m/z* 624 revealed a neutral loss of 176 Da which is characteristic of glucuronides (Fig. 1). A similar neutral loss of 176 Da was observed in the daughter ion spectrum of a biliary metabolite arising from [$^2H_7$]-4-ene VPA dosed i.p. to rats, where the ion fragments containing the VPA portion were 7 amu higher than that seen in the bile of rats treated with unlabelled drug (Fig. 1). The daughter ion spectrum of the peak of interest also gave ion fragments characteristic for GSH conjugates, such as the loss of glycine (MH^+ - 176 - 75) and glutamate (MH^+ - 176 - 129) moieties (Fig. 1). Taken together, the evidence indicated the presence of a di-conjugated metabolite which was assigned initially as 5-GS-3-ene VPA-glucuronide by comparing its mass spectrum with the corresponding mono-GSH conjugate formed from (E)-2,4-diene VPA (3). Further proof of structural identity was obtained from ^1H NMR of the HPLC purified metabolite. The *N*-acetylcysteine-glucuronide di-conjugate of (E)-2,4-diene VPA was similarly characterized by LC/MS/MS as a biliary and urinary metabolite in rats treated with (E)-2,4-diene VPA. Because extensive glucuronidation of (E)-2,4-diene VPA occurs in rats, the GSH-glucuronide di-conjugate is most likely formed through the reaction of GSH with (E)-2,4-diene VPA-glucuronide. In support of this hypothesis, 2,4-diene VPA-glucuronide isolated from rat bile was incubated with GSH in the presence or absence of GST enzyme and the resultant 5-GS-3-ene VPA-glucuronide was readily detected by LC/MS/MS (Fig. 2). To our knowledge, this is the first recorded instance in which a drug is activated by glucuronidation to further conjugate with GSH *via* a Michael addition reaction.

Characterization of a Novel Metabolic Reaction Observed in the Metabolism of LY315535

Todd A. Gillespie, R. Mike Goodwin, John T. Catlow, and Steve P. Swanson
Department of Drug Metabolism and Disposition, Lilly Research Laboratories, Indianapolis, IN 46285

LY315535 (Figure 1), 1,2,3,4-tetrahydro-8-(5-isoxazolyl)-N,N-dipropyl-2-naphthalenamine, is a potent serotonin (5HT-1a) agonist with muscarinic antagonist activity and is under development for the treatment of irritable bowel syndrome (IBS). The objectives of these studies were to characterize the major and minor metabolites of LY315535 by on-line LC/ES/MS/MS to subsequently determine the preliminary metabolic profile in rats, dogs, and monkeys (*in vivo*). In addition, to determine the *in vitro* metabolism using microsomal incubates to help in the selection of an appropriate species for toxicological studies.

Sample Preparation: Rats were administered an oral dose of either 25 mg/kg/day over 5 days or 75 mg/kg of LY315535 (free base) for urine collection and plasma collection at 1 hr, respectively. Dogs and Monkeys were both administered an oral dose of 10 mg/kg of LY315535 for plasma collection at 1 hr. The urine was diluted 2:1 with 50 mM NH_4OAc (200 µL/100 µL) and plasma was diluted 1:1 with ACN (500 µL/500 µL). In addition, microsomal incubates were prepared appropriately and diluted with (50/50) ACN/50 mM NH_4OAc.

LC/ES/MS/MS: Samples were injected (50 µL or 100 µL) onto an Inertsil C8 (15cm x 3.0mm) column. Potential metabolites were then separated with a gradient consisting of 80% 50 mM NH_4OAc/20% ACN linearly ramped to 100% ACN over 20 minutes at a flow rate of 0.7 mL/min. Mass spectrometry analysis was performed on a Finnigan MAT TSQ700 equipped with a Finnigan API source and electrospray interface. Positive ion detection was achieved with a spray voltage of +4500 V, capillary heater temperature of 275°C, sheath gas of 70 psi (N_2), and an auxiliary gas flow of 20 mL/min (N_2). The CAD analysis utilized a collision offset energy of -30 eV and a collision gas pressure of 1.5 mTorr (argon).

Results and Discussion: A number of LY315535 metabolites have been identified both *in vitro* and *in vivo* by LC/ES/MS/MS. The main sites of metabolism appear to be the isoxazole ring and the propyl moieties. Comparison of the major metabolites observed between species showed no significant differences. However, differences were observed in the minor metabolites within the various species. The despropyl metabolite has been identified as a major metabolite in all analyzed species. In addition, oxidation (hydroxyl) on the propyl function has been observed as a minor metabolite in all of these except for the cynomolgus monkey. Interestingly, a novel metabolic reaction involving the opening of the isoxazole ring and subsequent loss of CN to yield the methyl ketone metabolites has been identified. Additionally, both despropyl and hydroxyl metabolites of the methyl ketone have been observed. Further experiments have identified both the carboxylic acid (Figure 2) and cyano (Figure 3) metabolites to be present. Consequently, the carboxylic acid has been postulated as a precursor to the formation of the more prominent methyl ketone metabolites. In addition, the cyano metabolite has been observed *in vitro* in all analyzed species.

API III-MS of Natural Products: Structural Elucidation of Bisbenzylisoquinoline Alkaloids by Ionspray-MS and MS/MS

*Wu-Nan Wu and Michael D. Moyer, Department of Drug Metabolism, The R. W. Johnson Pharmaceutical Research Institute, Spring House, Pa 19477, U.S.A.

INTRODUCTION

Natural products are an important source of novel therapeutic agents in a drug discovery program. For example, bisbenzylisoquinoline alkaloids exert hypotensive, antimicrobial, analgesic, muscle relaxant and antitumor activities (1-8). Previously, structural characterization of these natural products have relied mainly on EI-MS, CI-MS and FABMS; however, these techniques need >10 ug of material (1-8). Early EI-MS and CI-MS studies displayed low abundance molecular/adduct molecular ions and fragment ions (3-8). The objective of this study is to elucidate the structures of bisbenzylisoquinoline alkaloids isolated and identified previously from *Thalictrum* sp. (*Ranunculacea*) (3-8) using Ionspray-MS and Tandem mass spectrometric techniques.

METHODS

- 20 Bisbenzylisoquinoline alkaloids (17 diether, 3 monoether linkages, Fig&Tab) (2-8) were prepared at 20-50 ng/uL in acetonitrile/water (50/50, v/v) with 5 mM ammonium acetate (pH 4).
- Alkaloids were analyzed using PE/Sciex API-III, a triple quadrupole mass spectrometer interfaced to a Hitachi solvent delivery system (L-6200 A Intelligent Pump) via an Ionsprayer/Heated Nebulizer.
- Solvent system - methanol/water (1:1, v/v) at 100 uL/min (Ionsprayer) or 1 mL/min (Heated Nebulizer) flow rate into a 20 uL injection loop.

RESULTS AND CONCLUSIONS

- 20 Bisbenzylisoquinoline alkaloids were analyzed using PE/Sciex API-III-MS and MS/MS.
- Structures, summarized MS and MS/MS data for each alkaloid, and representative mass spectra (Q1 Scan, MS/MS) for 9 alkaloids are presented.
- Ionspray-MS exhibited intense protonated molecular/molecular ions for the alkaloids and intense doubly charged ions for the diether-linkage alkaloids.
- MS/MS analysis of the protonated molecular/molecular ion for each alkaloid revealed an apparent parent ion along with prominent as well as diagnostic daughter ions for the important isoquinoline moities which provided structural information for the alkaloid.
- Ionsprayer and Heated Nebulizer - similar MS data.
- Detection of protonated molecular ions - ng quantities.

Metabolism of the Antipsychotic Agent, Mazapertine Succinate: Structural Elucidation of Human Urinary Metabolites of Mazapertine Using LC/Ionspray-MS and MS/MS

*Wu-Nan Wu, Lee G. Gisclon and Linda A. McKown, Department of Drug Metabolism, The R. W. Johnson Pharmaceutical Research Institute, Spring House, PA 19477, U.S.A.

INTRODUCTION

Mazapertine (RWJ-37796) succinate, 1-[3-[[4-[2(1-methylethoxy)phenyl]-1-piperazinyl]methyl]benzoyl]piperidine succinate, is a new antipsychotic agent. The metabolism of mazapertine in dogs and rats (1, 2) and the effect of food on the bioavailability of mazapertine in humans (3) were reported recently. The objectives of this study were to investigate the metabolism of mazapertine and to characterize and elucidate the structures of mazapertine metabolites in humans using LC/Ionspray-MS and MS/MS techniques

METHODS

- 2 Healthy male volunteers.
- Mazapertine succinate (40 mg/kg as free base, oral).
- Urine collection - 0-48 h after dosing.
- Urine sample pooled (0-24 h) - Amberlite XAD-2 adsorption and methanol extraction for untreated and Glusulase-treated urine pools, and HPLC (C8) separation.
- Unchanged mazapertine and its metabolites were characterized and identified using PE/Sciex API-III Ionspray-MS and MS/MS, and by comparison to synthetic samples (mazapertine, M1, M2, M4, M6, M7, M8, M10).

RESULTS AND CONCLUSIONS

- Unchanged mazapertine plus 10 metabolites (M1-M10) were characterized, and tentatively identified from the urine samples.
- Structures, representative mass spectra for unchanged mazapertine and metabolites are presented.
- Ionspray-MS and tandem mass spectrometric analyses of mazapertine and the metabolites revealed apparent protonated parent ions and informative as well as prominent daughter ions for the structural elucidation of metabolites.
- Sites for the formation of mazapertine metabolites and the proposed metabolic pathways for mazapertine in humans are presented.

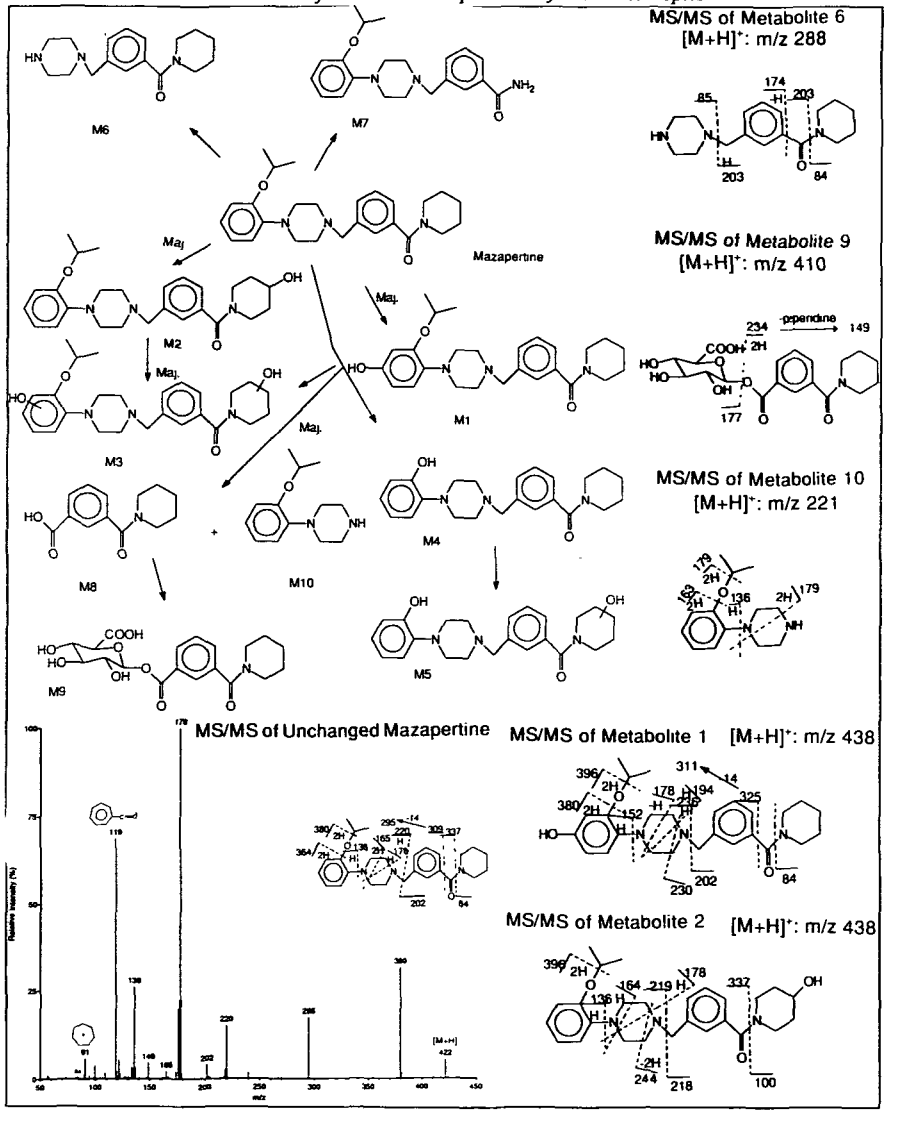
Metabolism of Mazapertine (RWJ-37796) in Humans :



Analysis of Tamoxifen and Its Metabolites by On-line Capillary Electrophoresis-Electrospray Ionization Mass Spectrometry Employing Nonaqueous Solvent

Wenzhe Lu[1], Grace K. Poon[2], and Richard B. Cole[1*]

1. Department of Chemistry, University of New Orleans, New Orleans, LA 70148, USA
2. CRC Center for Cancer Therapeutics, The Institute of Cancer Research, Surrey, UK

Tamoxifen [trans-1-[4-(2-dimethylamino)ethoxy]phenyl-1,2-diphenylbut-1-ene] is an antiestrogen drug that is routinely used for the treatment of breast cancer [1]. Tamoxifen is thought to act mainly by blocking the estrogen receptor in tumor tissue, thus inhibiting tumor growth. Alternative mechanisms of action have also been suggested. Isolation and structural characterization of the products of tamoxifen metabolites are necessary steps to understanding the mechanism responsible for drug activity.

HPLC-MS has been applied to the determination of tamoxifen metabolites in breast cancer patients [2]. Compared to HPLC separation methods, capillary electrophoresis (CE) offers the potential for higher resolution and faster analysis of many pharmaceutical compounds. Another advantage for sample limited studies is that very small sample quantities (e.g., fmol) can be analyzed.

We report the analysis of tamoxifen and its metabolites using on-line capillary electrophoresis-electrospray ionization mass spectrometry (CE-ESMS). Tamoxifen and its analogs, *N*-desmethyltamoxifen, 4-hydroxytamoxifen, 4-hydroxy-*N*-desmethyltamoxifen, tamoxifen-*N*-oxide, 4-hydroxytamoxifen-*N*-oxide, and tamoxifen epoxide, were separated and determined using nonaqueous solvent (methanol) as the CE electrolyte. This CE medium provided better resolution and detection sensitivity compared to aqueous systems or highly aqueous water/methanol electrolyte mixtures. Improved stability of electrospray ionization conditions are achievable when methanol electrolyte is employed as compared to highly aqueous systems because the lower surface tension permits droplet breakup at lower applied voltages while decreasing the tendency to produce unwanted electric discharges. The relative ease of methanol solvent evaporation may contribute to an improved yield of protonated analytes as compared to highly aqueous solutions. The enhanced CE resolution can be at least partially attributed to the better solubility of analytes in this solvent. Higher solubility implies less aggregation of hydrophobic analytes and thus improved homogeneity in solution.

Surfactants have been employed as buffer additives in CE-ESMS although their presence may cause severe suppression of analyte ion signals in ESMS [3]. The effect of sodium dodecyl sulfate (SDS) on ESMS sensitivity was examined, and the detection limit for *N*-desmethyltamoxifen was determined to be about 7 ug/mL when the SDS concentration was 7 mM. When this rather low concentration (below CMC) of surfactant SDS was added to the methanol electrolyte, the resolution was augmented relative to the unadulterated methanol electrolyte. The metabolites α-hydroxytamoxifen and 4-hydroxytamoxifen, which could not be resolved in methanol electrolyte, were completely separated upon addition of 7 mM SDS. The methanol-surfactant electrolyte system has been successfully used to determine tamoxifen and its metabolites formed after incubation of tamoxifen with mouse hepatocytes.

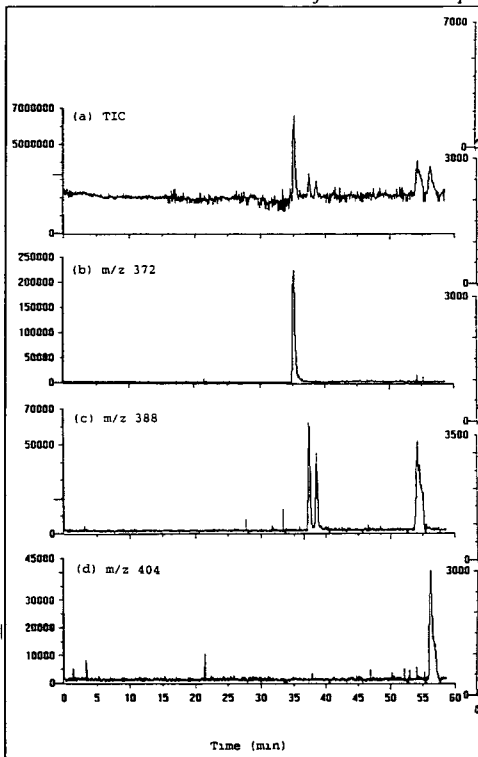

Figure 1. Selected-ion electropherogram showing raw data from on-line CE-ESMS analysis of tamoxifen and 4 analog standards, (a) total ion current of 5 components (b) tamoxifen (MH^+, m/z 372), (c) isomers: α-hydroxytamoxifen and 4-hydroxytamoxifen, and tamoxifen-*N*-oxide (in elution order, MH^+, m/z 388), and (e) 4-hydroxytamoxifen-*N*-oxide (MH^+, m/z 404). Experimental conditions: sample concentration: each component 300 ng/μL, CE voltage: 25 kV; capillary: 100 μm x 100 cm; electrolyte: 7 mM SDS, 2.5 mM NH_4OAc and 50 mM acetic acid in methanol; gravity injection: 15 cm for 2 s; ES voltage: 2.48 kV; MS scan rate: 3 s/scan.

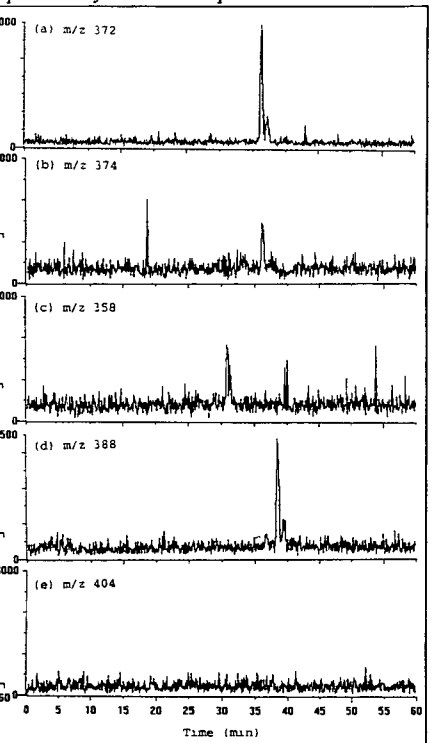

Figure 2. Selected-ion electropherograms from on-line CE-ESMS analysis of an extract from incubation of tamoxifen with mouse hepatocytes, (a) tamoxifen (MH^+, m/z 372), (b) 4-hydroxy-*N*-desmethyltamoxifen (MH^+, m/z 374) (c) *N*-desmethyltamoxifen (MH^+, m/z 358), , and (d) an unknown, α-hydroxytamoxifen and 4-hydroxytamoxifen (MH^+, m/z 388) (e) 4-hydroxytamoxifen-*N*-oxide (MH^+, m/z 404). Experimental conditions are same as Figure 1.

IDENTIFICATION OF LORATADINE METABOLITES FROM HUMAN LIVER MICROSOMES.

T.D. Cyr, B. Dawson, J. Ethier, M Jurima-Romet, A. Menzies and L. Whitehouse. Bureau of Drug Research, Drugs Directorate, Health Canada, Banting Research Centre, 2201A, Ottawa, K1A OL2, Canada

INTRODUCTION Loratadine, Claritin®, is a widely used, non-prescription, non-sedating antihistamine. The main metabolite is descarboethoxy-loratadine (Roman et al, Clin. Rev. Allergy, **11** 89-110, 1993) ; additional metabolites were detected as part of an ongoing study of drug-drug interactions. We have undertaken the structure determination of these metabolites by HPLC purification followed by electrospray/MS, GC/MS and NMR spectroscopy.

The human liver tissue was obtained from the Human Liver Bank, Dept. of Pharmacol., University of Toronto. Loratadine and descarboethoxy-loratadine were obtained from the Schering-Plough Research Institute, Lafayette, NJ.

Sample Preparation: The metabolites were produced by incubation of loratadine with human liver microsomes, at 37°C, with NADPH in phosphate buffer (2 mL incubation volume). The reaction was stopped by adding methanol (2 mL) or by adding methanol and HCl (0.1 mL). The samples were centrifuged, basified with 4 mL of 0.5 M Na_2HPO_4, loaded onto a 3 mL C-18 solid phase extraction column (conditioned with acetate buffer at pH 4). The column was washed with water, then the compounds of interest were eluted with methanol. The mixtures were chromatographed on an Inertsil ODS-2 HPLC column using an CH_3CN versus 0.1% $(ET)_3N$/ NH_4PO_4 buffer gradient.

RESULTS HPLC Analysis: Figure 1. shows the distribution of loratadine and its metabolites from human liver microsomes. In general, the main metabolite is descarboethoxyloratadine and the effects on the metabolite distribution of adding HCl/methanol versus methanol alone to stop the system. The products labelled 62 B, 61 A, 63 B, Fraction 9, and Fraction 10 were collected by preparative HPLC then analyzed by ES/MS, GC/MS, and NMR.

Mass Spectral Analysis: {ES/MS}: EI/MS: Unless indicated otherwise, all peaks have a Cl^{37} isotope peak.

Loratadine, m/z: {445 (adduct?, 405(adduct?),383(M^+), 337, 295, 282, 268}; 382 (100%), 292, 280 (no Cl), 266, 244 (no Cl)

Descarboethoxyloratadine, m/z: 310 (83%), 280 (no Cl), 266, 244 (no Cl), 216

62 -B, mixture, m/z.{ 460 (adduct?),399(M^+), 381, 335, 293, 281, 265} ; 398 (100%), 381, 308, 296 (no Cl), 282, 278

61 A, mixture, m/z {397(M^+), 381, 367, 293}, 396 (100), 395, 367, 323, 295, 242, 154 (no Cl)

63 B, single compound: m/z:{461, 399 (M^+); 398, 369 (100), 282 (no Cl), 268, 260 (no Cl), 254

Fraction 9, mixture of 3 (isomers?), m/z:{443 (adduct?),381(M^+), 353, 335, 310, 293, 281, 258, 246, 244, 228}; 380 (100%), 379 (85), 351, 307, 279 (no Cl)

Fraction 10, single compound, m/z {443 (adduct?), 389, 387, 371, 293, 281, 267, 258, 246, 228}, 380 (93%), 379 (69), 351, 307, 279 (100, no Cl)

ES/MS: Figure 2 shows the effect of varying the cone voltage on the degree of fragmentation as well as agglomeration for the parent drug, loratadine In general, data were collected for a few scans at a cone voltage of 55% to obtain good molecular ion information, then cone voltage was increased to 85% to obtain fragmentation information.

IDENTIFICATION The distribution of metabolites is sensitive to the pH of the workup medium. The new metabolites are hydroxylated on the aromatic and on the aliphatic rings, and there is indirect evidence for an N-oxide. We did not find major amounts of the metabolites of descarboethoxyloratadine.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

BIOMARKERS OF OH RADICAL FORMATION IN RAT BRAIN BY MICRODIALYSIS WITH MPP^+.

L. Ste-Marie, L. Vachon, D. Boismenu and J. Montgomery. Research Centre, Notre-Dame Hospital, Montréal, Québec, Canada.

In rat striatum, the neurotoxin, 1-methyl-4-phenylpyridinium ion (MPP^+), elicits dopamine (DA) release with a concomitant increase in hydroxyl radical ($^{\bullet}OH$) formation. We investigated $^{\bullet}OH$ formation by administering MPP^+ to the anterodorsal striatum. $^{\bullet}OH$ radicals were trapped with either 2-hydroxybenzoate (2HBZ) or 4-hydroxybenzoate (4HBZ) which are converted to 2,3- and 2,5-dihydroxybenzoate and 3,4-dihydroxybenzoate (34DHBZ) respectively. In our study, microdialysis probes were implanted bilaterally in the striatum and infused with artificial CSF (1μl/min). After 75 min equilibration, 4HBZ (300 mg/kg) was injected intraperitoneally (IP). At 90 min, MPP^+ was infused unilaterally (5 mM; 20 min), followed by a 90 min period where MPP^+ was replaced by CSF. A second series of microdialyses was performed to determine the effect of a monoamine oxidase B inhibitor, deprenyl, on $^{\bullet}OH$ production. The rats were injected IP with deprenyl just prior to starting the experiment. Microdialysate samples were analysed for DA, dihydroxyphenylacetate, norepinephrine and homovanillate by HPLC with electrochemical detection (EC) and 34DHBZ (formed by 4HBZ hydroxylation) was assayed by HPLC-EC or by GC-MS. Microdialysis samples plus [α,α-$^2H_2$]-phenylacetic acid added as internal standard were extracted and the residues were converted to TBDMS derivatives which were analyzed under electron impact conditions using a Varian Saturn II ion trap GC-MS.

Results show that MPP^+infusion alone did not augment the production of 34DHBZ compared to controls (Figure 1, Group 1). However, 34DHBZ normalized to 4HBZ release to account for individual regional differences in 4HBZ cerebral concentration, indicated that the MPP^+ side had a higher ratio of 34DHBZ/4HBZ (Figure 2, Group 1). Deprenyl caused a decrease in 34DHBZ production both with and without MPP^+ but its effect was more pronounced without MPP^+ (Figure 1, Group 2). Again, the ratio 34DHBZ/4HBZ indicated a greater proportion of 34DHBZ with MPP^+ treatment (Figure 2, Group 2). However, deprenyl treatment resulted in a lower ratio, 1/10th that observed in the series of microdialyses without deprenyl. Our results confirm that MPP^+ exerts some of its neurotoxic effect via a free radical mechanism.

In preliminary experiments using a microdialysis protocol where the HBZ trapping agent was infused via the microdialysis probe, we were hampered by an apparent "contaminant" in analyzing DHBZs by HPLC-EC. Using GC-MS and HPLC-EC we demonstrated the non-tissue derived production of $^{\bullet}OH$ radicals induced by contact with metal surfaces. When HBZ added to artificial CSF was infused through a microdialysis system (without a rat), we measured unacceptably high non-specific production of $^{\bullet}OH$ radicals. In addition, the effect of re-using a microdialysis probe in a subsequent experiment was demonstrated using a dual probe protocol, where one probe had been used before and the other was new. No MPP^+ was infused and the artificial CSF contained 4HBZ (1 mM). Microdialysis of rat striatum resulted in increasing production of 34DHBZ with time in both probes, with the used probe producing up to 9 pmol/15 min and the new probe less than 2 pmol/15 min.

Considerable technical difficulties were encountered due to the non-tissue derived production of $^{\bullet}OH$ radicals as measured by 34DHBZ production from 4HBZ. The combined use of GC-MS and HPLC-EC allowed positive identification of these products. This difficulty of non-specific $^{\bullet}OH$ radical production was circumvented by constructing an infusion system that minimizes contact with metal surfaces (1). Using this system in the experiments described above, we demonstrated 34DHBZ production comparable to that reported for DHBZ production from salicylate in a similar system (2).

2K3MVA IS NOT AN OBLIGATE INTERMEDIATE BETWEEN ISOLEUCINE & ALLOISOLEUCINE

O.A. Mamer, MS Unit, McGill University, 1130 Pine W, Montréal Qué Canada H3A1A3
F.L. Lépine, Institut Armand-Frappier, 531 boul des Prairies Laval Qué Canada H7N 4Z3

Introduction

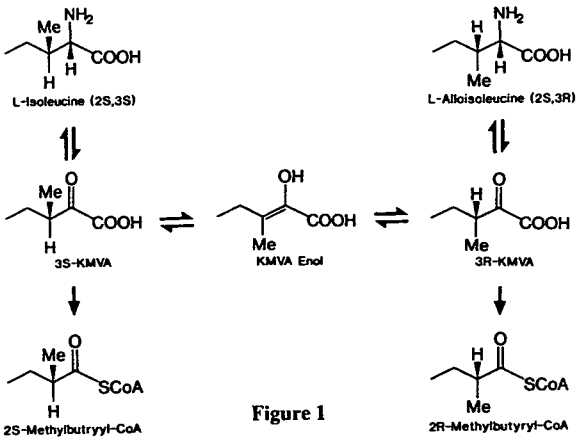

Figure 1

L-Isoleucine and L-allo-isoleucine have long been known to be interconvertible *in vivo*, and for the last half-century, the intermediate has been thought (without firm proof) to be an enol of the corresponding keto acid, 2-keto-3-methyl-valeric acid (KMVA), Figure 1. Here we present experiments that show that alloisoleucine is made from isoleucine *with retention* of the amino nitrogen, denying the possibility of the intermediacy of KMVA, and confirming an earlier proposal (1).

Experimental

Two rats (200 g) were given oral 20 mg loads of unlabelled and $^{15}N,^{13}C_6$-L-isoleucine. Urine samples were collected for 6 h following the loads and their amino acids were isolated and analyzed as their TBDMS derivatives in EI by SIM - GC/MS (HP-5988). Ions monitored were the $[M - t\text{-butyl}]^+$ and $[M - COOTBDMS]^+$ ions (m/z 302 and 200 respectively for the unlabelled derivatives of isoleucine and alloisoleucine).

Results

Figure 2 shows the SIM chromatograms for the urine collected following the loading with labelled isoleucine. The major peaks appearing in the unlabelled m/z 200 and 302 chromatograms are leucine (before 7.2 min RT), and alloisoleucine and isoleucine (in that order, after 7.2 min RT). It is clear that the majority of the alloisoleucine excreted is labelled with ^{15}N (m/z 206 and 309). The much smaller response at m/z 205 for alloisoleucine is due mostly to isotopic impurity (both ^{15}N and ^{13}C) in the original labelled isoleucine (determined by similar analysis). These observations are inconsistent with KMVA as the intermediate between the amino acids but support the mechanism of Figure 3 (PE = pyridoxal phosphate - transaminase complex) which represents a modification of the mechanism for the transamination of alanine proposed by Babu and Johnston (2). The existence of an enamine intermediate in that mechanism analogous to D was proven by NMR techniques (3). Isoleucine (**A**) and alloisoleucine (**A'**) form Schiff base aldimines (**B** and **B'**) with the pyridoxal aldehyde group which enzymatically isomerize to ketimines **C** and **C'**. The latter are much more enolizable than the keto acids **E** and **E'** (the imino N is more easily protonated than the keto O), and form the enol-like enamine **D**, thereby racemizing the chiral 3-carbon.

A large fraction of the excreted isoleucine derived from the load had lost its ^{15}N label (m/z 205 and 308), presumably by reverse reamination of $^{13}C_6$-KMVA, **E**. Part of the exchanged $^{14}N,^{13}C_6$-alloisoleucine could have been formed through **D** from the large amount of $^{14}N,^{13}C_6$-isoleucine produced by reamination of **E**. The formation of alloisoleucine is then an unavoidable consequence of the catabolism of isoleucine. It would appear from the relative amounts of N-exchanged isoleucine and fully labelled alloisoleucine that enolization of **C** to form **D** is much slower than the equilibration of **C** with **E** or **B**. The effects produced by this relationship have been well known from studies of metabolic errors affecting subsequent KMVA catabolism, even though the underlying mechanism was not known.

Characterization of reactive drug intermediates by ESI mass spectrometry

H.K. Lim, J.H. Bhasav, K. Chan and S. Sisenwine
Wyeth-Ayerst Research, Princeton Corporation Plaza
9 Deer Park Drive, Suite 100, Building 3, Monmouth Junction, NJ 08852

The cytochrome P-450 family of enzymes is considered to be responsible for the oxidation of a variety of drugs with diverse structures to reactive electrophiles. An equally important family of enzymes known to catalyze both one and two-electron oxidation of drugs to reactive intermediates is the peroxidases such as prostaglandin synthase and human leucocyte peroxidase (also known as myeloperoxidase). In peroxidase-rich organs such as kidney, bone marrow, etc., this family of enzymes plays an important role in the organ-specific toxicity of drugs. The direct detection of reactive intermediates presents a challenge because of their extremely short half-lives. Fortunately, a defense mechanism based on conjugation with nucleophilic glutathione exists for neutralizing these reactive electrophiles and the more stable glutathione conjugates can be used to characterize these intermediates. The recent reports on the high accuracy (<0.01%) of molecular weight determination of proteins (< 133,000 Da) by electrospray mass spectrometry provides a new way for rapid determination of covalently bound proteins with reactive intermediates. Proteins often contain a variety of nucleophilic sites that can undergo reactions with electrophiles, and they are not subjected to repair like DNA. Therefore, protein adducts are excellent surrogates for detection of genotoxic reactive intermediates.

The current work focused on the characterization of reactive intermediates as glutathione conjugates and covalently modified hemoglobin by electrospray LC/MS. The drug used in the study is an antimalarial drug, amodiaquine, a known myelotoxin and hepatotoxin in man. This drug has been of clinical concern recently because of its association with ocassionally fatal agranulocytosis (1) and liver damage ranging from mild hepatitis (2) to sub-massive necrosis (1). The objective is to investigate the mechanism of myelotoxicity of amodiaquine.

Initial efforts were directed to establish whether amodiaquine can be metabolized by myeloperoxidase to reactive intermediates. Total ion chromatogram (top panel) shows that amodiaquine was metabolized by myeloperoxidase via one and two-electron oxidation to semiquinone imine and quinone imine as suggested by the detection of mono and di-glutathione conjugates of amodiaquine. In addition, a tri-glutathione conjugate of an amodiaquine metabolite was also formed. All of these conjugates were formed in larger quantities by horseradish peroxidase catalyzed oxidation of amodiaquine (data not shown) and consequently, this enzymatic system was used to generate the glutathione conjugates for characterization by ESI LC/MS and LC/MS/MS. In addition to reaction with glutathione, these reactive intermediates also reacted with α and β-chains of human hemoglobin as indicated by their corresponding mass shift from native α and β-chains. This is illustrated by a mass spectrum showing covalent binding of amodiaquine to α-chain of hemoglobin (bottom panel). Interestingly, there were 3 partially resolved chromatographic peaks that show covalent binding of amodiaquine to α-chain. This observation suggested that in addition to covalent binding to the sulphydryl group of the only cysteine residue in the α-chain, oxidative intermediates of amodiaquine also bound to 2 other distinct nucleophilic sites.

The detection of several glutathione conjugates of amodiaquine and the covalently bound amodiaquine to relevant biomacromolecules like hemoglobin is suggestive that reactive intermediates may play a role in the myelotoxicity of amodiaquine.

CAPILLARY HPLC / CF-LSIMS CHARACTERIZATION OF LTD$_4$ ANTAGONIST METABOLITES, *J. A. Yergey, D. Nicoll-Griffith, N. Chauret, L. Trimble, Merck Frosst Centre for Therapeutic Research, P. O. Box 1005, Pointe Claire - Dorval, Quebec, Canada H9R 4P8

INTRODUCTION: Peptidoleukotrienes are postulated to play a critical role in the pathophysiology of human asthma. Antagonists directed against the leukotriene-D$_4$ (LTD$_4$) receptor, which is believed to be particularly important in mediating the asthmatic response, have, therefore, become key therapeutic targets. MK-0476 is currently in clinical trials as a treatment for asthma.

Studying the metabolic fate of compounds early in the discovery process has allowed for more immediate and meaningful feedback to the medicinal chemistry efforts. In particular, *in vitro* incubation of compounds with liver microsomes and hepatocytes has provided a straightforward means of generating relatively clean mixtures of metabolites. The *in vitro* metabolic profiles of MK-0476 and related analogs would be expected to include several metabolites analogous to those previously described for verlukast (MK-0679), including sulfoxidation, quinoline epoxidation under certain conditions, and acid glucuronidation.

Although isolation of individual metabolites remains necessary for NMR characterization and definitive identification of sites of metabolism, capillary HPLC with continuous-flow liquid secondary ion mass spectrometric detection (HPLC / CF-LSIMS) has provided a powerful means to examine the incubation mixtures directly. This poster details the oxidative biotransformations of MK-0476, with emphasis on the effective utilization of CF-LSIMS as a characterization tool.

EXPERIMENTAL: Liver Microsome Incubations: Incubations of 200 µM MK-0476 in 0.5 mL were made with 1 mg microsomal protein (species include rat, ß-naphthaflavone treated rat, ßNF-mouse, Rhesus monkey and human). Oxidation co-factors included 2 mM $MgCl_2$, 2 mM NADP, 20 mM glucose-6-phosphate, in a 100 mM PO_4 buffer, pH 7.4 plus 2 units of glucose-6-phosphate dehydrogenase. One hour reactions at 37°C were quenched with 0.5 mL of CH_3CN.

Capillary HPLC / CF-LSIMS Conditions: A Waters 600MS HPLC pump supplied 1 mL/min of mobile phase consisting of CH_3OH:20 mM NH_4OAc, pH 5 (1.5 % glycerol in each). The main flow was split prior to the injection valve using ~ 5 cm of 50 µm fused silica on a Valco ZDV tee. The split flow of 3 µL/min passed through a 10 µL injection loop on 6-port electrically actuated Valco valve, then through the KAPPA BDS-Hypersil ODS-2 0.3 x 100 mm capillary column (Keystone Scientific) and into the JEOL HX-110A CF-LSIMS mass spectrometer ion source. Injections were of 10 µL of a 10-fold dilution of incubation mixture. CF-LSIMS spectra were acquired from 0-1000 Da every 4 sec.

SUMMARY OF RESULTS: While capillary HPLC / CF-LSIMS total-ion chromatograms, which include glycerol adduct ions, often contain little chromatographic information regarding minor metabolites, reconstructed-ion chromatograms corresponding to likely metabolites or mass ranges, which exclude glycerol oligomers, provide noise-free and sentive information (Figure 1). Full-scan CF-LSI mass spectra contain extensive but useful fragmentation as well as pseudo-molecular ions (Figure 2,3). Glycerol background is substantially less than for probe samples, and can be effectively subtracted. Fragmentation in the primary mass spectrum usually allows the metabolized substructure to be pinpointed (Figure 3), although NMR is still required for precise positional information. Furthermore, full-scan CF-LSI mass spectra, including useful fragmentation, can be readily obtained at levels of 1-5 pmol. The capability of CF-LSIMS to provide both excellent sensitivity and structural information in the primary LC/MS mass spectrum make it an ideal tool for rapid characterization of metabolic profiles of drug candidates, as summarized below for MK-0476.

TP 168. CE-ES-MS ANALYSIS OF DRUG METABOLITES IN URINE.

Alison E. Ashcroft[1], Hilary J. Major[1], Stephen Lowes[1], Ian D. Wilson[2],
1. Fisons Instruments VG Organic, Altrincham, Cheshire, WA14 5RZ, UK.
2. Zeneca Pharmaceuticals, Alderley Park, Macclesfield, Cheshire, SK10 4TG, UK.

Introduction.

CE-ES has emerged as a viable on-line technique. The aim of these studies was to couple the sensitivity and specificity of ES-MS with the high resolution of CE to produce a practical method of analyzing and identifying small quantities of drug metabolites in urine while minimizing work-up procedures.

The drugs chosen were ibuprofen, flurbiprofen, aspirin and paracetamol, all of which produce metabolites of particularly high polarity. The results from ibuprofen are discussed in this abstract

Method.

Urine work-up After a therapeutic oral dose of one of the drugs, human urine from a healthy male volunteer (2mL) was passed through a solid phase extraction cartridge, evaporated to dryness and reconstituted in methanol (200µL).

CE-ES-MS CE was performed using a Beckman P/ACE system 2000 (Beckman Instruments Inc., Palo Alto, CA) with in-line UV (λ 200nm) detection. A 10 second pressure injection (30nL injection) was followed by a 20kV, 20mM aq ammonium acetate pH 9 buffer separation using a 100 cm capillary column

The CE capillary was interfaced directly through a CE-ES probe to a VG Quattro II (Fisons Instruments VG Organic, Altrincham, Cheshire, UK) tandem quadrupole mass spectrometer A make-up flow of 80:20 (v/v) water:propan-2-ol (8µL/minute) was teed co-axially into the probe.

Standard negative ionization ES conditions were set with the probe tip held at 4kV. To obtain molecular mass information i e. to optimize the $(M-H)^-$ ions, a low cone voltage was set For cone voltage fragmentation (CVF) this value was raised.

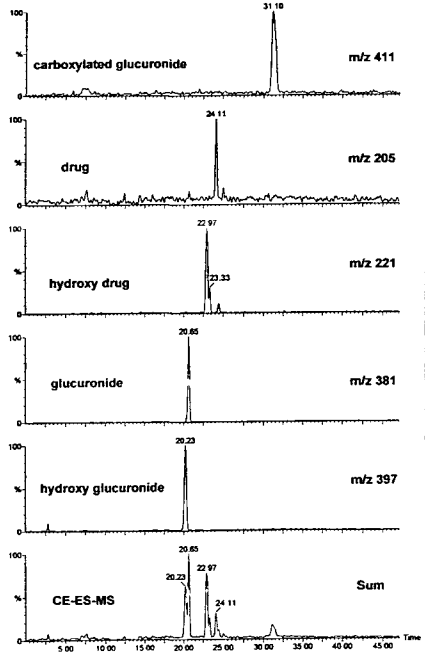

Figure 1. CE-ES-MS of Ibuprofen.

MS-MS fragmentation was achieved by introducing argon collision gas into the collision cell between the first and second analyzers.

Ibuprofen.

CE-ES-MS with a low cone voltage provided the molecular masses of several of the components including ibuprofen, hydroxylated ibuprofen, the glucuronide metabolites of both of these, and the carboxylated glucuronide metabolite, (Figure 1).

The experiment was repeated using CVF and also by MS-MS monitoring the product ions from the major components. The CVF spectra and product ion spectra show similarities indicating the potential of CVF on a single quadrupole mass spectrometer in producing interpretable fragmentation. All three of the glucuronide metabolites gave rise to a common fragment ion at m/z 175, representing the sugar moiety, and a complementary loss of 176 amu from the $(M-H)^-$ to leave the $(M-H)^-$ of the aglycones i e. m/z 205, 221, and 235.

A further MS-MS experiment monitoring the precursor ions of m/z 175 (Figure 2) readily highlighted the major glucuronides of ibuprofen.

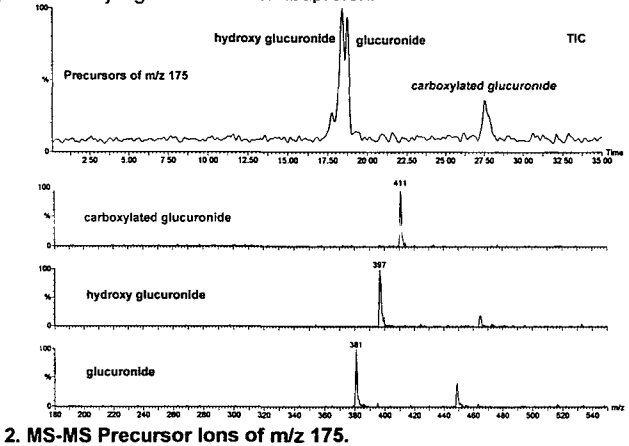

Figure 2. MS-MS Precursor Ions of m/z 175.

Summary.

Capillary electrophoresis has been coupled to negative ion ES-MS for the analysis of drug metabolites in human urine. Molecular masses were generated and in addition structurally useful fragmentation was produced by in-source CVF and also by low energy MS-MS. Selective screening for the presence of glucuronide metabolites was readily achieved by on-line CE-ES-MS-MS recording the precursor ions of the characteristic dehydrated glucuronic acid unit

The system used is robust and was operated for several days without any maintenance due to the fact that CE requires only minimum amounts of dirty matrices to be injected An environmental advantage of this technique over LC-MS methods is that solvent consumption is minimized

Analysis of β-Agonists Using Solid Phase Extraction and LC/APcI/MS/MS

Steve Preece[1] and Géry van Vyncht[2]
[1]VG Organic, Tudor Road, Altrincham, Cheshire, UK, WA14 5RZ and [2]University of Liège, Mass Spectrometry Center, B6, Sart Tilman, 4000 Liège, Belgium

β-Agonists are used in human medicine and veterinary science for the treatment of pulmonary disorders. When the dosage is increased to levels greater than ten times those used for therapeutic purposes, these compounds have a secondary effect of repartitioning metabolism to encourage the accretion of muscle tissue at the expense of fat deposition [1] This has led to the illegal use of β-agonists in cattle farming where, by increasing the ratio of muscle tissue (meat) to fat, the value of an animal is increased. At the higher levels used to produce repartitioning, there are concerns about the harmful effects to humans through eating contaminated meat and in 1990 there were recorded cases of food poisoning in Europe from the consumption of clenbuterol contaminated liver from veal calves[2] Thus the use of β-agonists for this purpose is prohibited in both the European Community and North America and screening is undertaken. This paper looks at the analysis of β-agonists in bovine urine and liver Urine analysis is necessary to allow the monitoring of cattle on farms for β-agonist abuse and liver analysis is necessary to monitor meat for human consumption In addition, as the liver is the centre of metabolic activity in the body, it often contains higher levels of residues Due to the high potency of β-agonists and the subsequently low dosages and because of the complexity of the matrices which are analysed, the analytical method for these compounds is required to be both sensitive and specific The use of LC/MS with atmospheric pressure chemical ionisation (APcI) as the ionisation method is already documented [3] Using APcI/MS provides the sensitivity and specificity required for the analysis and the use of liquid chromatography allows the analysis of β-agonists without the need for a derivatisation step which is required prior to analysis by gas chromatography. Thus the time required for analysis is reduced An improved method of solid phase extraction has been developed which, when coupled with analysis by LC/APcI/MS, allows the detection of five selected β-agonists down to and below the UK regulatory level of 0.5ppb in urine and liver

Experimental

Solid Phase Extraction - For urine analysis, 5mL were centrifuged prior to extraction. For liver analysis, 5g were homogenised and hydrolysis of any β-agonist conjugates was carried out by the use of β-glucoronidase prior to extraction. The extraction of the β-agonists was accomplished using a SCX solid phase (Varian) This phase contains benzene sulphonic acid groups allowing the extraction of β-agonists by ion exchange The eluted volume containing the β-agonists was evaporated to dryness and redissolved in 1mL of methanol.

Liquid Chromatography - The chromatography was carried out using a HP1050 quaternary solvent delivery system and a 3 x 250 mm (5μm) α-Chrom column (Upchurch) with the following conditions: injection volume : 50 μL, flow rate 0 5 mL/min. Mobile phase : A- 77% acetonitrile, 12% 10mM NH_4OAc (pH 7 0), 11% water and B- 65% acetonitrile, 35% 25mM NH_4OAc (pH 3.5) with a gradient of 0 - 5 5min - 100% A stepped to 100% B for 5 6 - 15min

Mass Spectrometry - A VG Quattro II tandem quadrupole mass spectrometer was used for detection. The instrument was equipped with an atmospheric pressure ionisation source operating in positive ion mode with a nebuliser temperature of 550°C and a cone voltage of 20 or 25V. Data was acquired in MS/MS mode using multiple reaction monitoring (MRM) with a collision cell argon pressure of $2x10^{-3}$ mbar and a collision energy of 15eV. In each case the selected parent ion was the protonated molecule and the most intense product ion was chosen for detection Terbutaline 226 → 152, Cimaterol 220 → 160, Salbutamol 240 → 148, Clenbuterol 277 → 203 and Mabuterol 311 → 237

Samples - Urine samples were spiked with the 5 ß-agonists in the range 0.5 to 25 ppb prior to extraction Liver samples were spiked in the range 2.5 to 25 ppb. Samples taken from animals treated with clenbuterol and salbutamol were also analysed These were spiked with d_6-clenbuterol as an internal standard prior to extraction

Results

The five β-agonists selected for this study were cimaterol, terbutaline, salbutamol, clenbuterol and mabuterol. These were chosen as they are commonly used, with clenbuterol and salbutamol known to be most frequently abused due to their high potency Extraction recoveries for clenbuterol and salbutamol were determined by using tritiated standards and radio-immunoassay. For clenbuterol the recoveries were 82% in urine and 45% in liver and for salbutamol, 60% in urine and 55% in liver. For the urine analyses, all five compounds could easily be detected down to the required level of 0 5ppb with signal to noise ratios for the MRM chromatograms in the region of 20 1. It was recognised that by dissolving the residues obtained from the SPE step in a smaller volume, there was a potential to reduce the detection levels further. Redissolving the residues in 100μL of methanol (instead of 1mL) resulted in improved detection of all of the compounds except for terbutaline where the chromatographic resolution was impaired, probably due to the effect of increased matrix concentration For the liver analyses the results are similar to those found for urine, except for terbutaline which has poor chromatographic peak shape This is likely to be due to effects from the more complex liver matrix It may be possible to improve the chromatography of terbutaline by redissolving the liver extract in a solvent other than methanol, but this has not been tested Analysis of the samples taken from animals treated with clenbuterol and salbutamol (with d_6-clenbuterol internal standard) showed that the method is suitable for detecting these compounds when they have been administered in a real life situation.

Conclusions

The combination of an improved solid phase extraction method and LC/APcI/MS/MS has been shown to provide a system suitable for the analysis of β-agonists. The efficiency of extraction and the sensitivity and selectivity of APcI/MS/MS allow the detection of these compounds down to, and below, the UK regulatory level of 0.5ppb The use of LC also negates the need for the derivatisation of β-agonists which is required prior to GC/MS analysis

Analysis of Cytochrome P-450 Metabolites of Arachidonic Acid using LC MS/MS.

*Carlos O. Garner[1], Frank J. Belas[2], and Ian A. Blair[1,2]. Department of Chemistry[1], Vanderbilt University and Department of Pharmacology[2], Vanderbilt University School of Medicine, Nashville, TN 37232.

The cytochrome P-450 (CYP-450) metabolism of arachidonic acid (AA) produces a number of structurally distinct eicosanoids with overlapping biological activities. It is becoming increasingly evident that this activity can be mediated by other enzymes involved in eicosanoid metabolism such as cyclooxygenase (COX) and lipoxygenase (LOX). Biotransformation of cyclooxygenase and lipoxygenase metabolites of arachidonic acid by CYP-450 has long been recognized. However, it is has been only recently that attention has become focused on the possible bioactivation of CYP-450 metabolites by COX and LOX. There is compelling evidence that COX plays a key role in the biological activity of several of the CYP-450 metabolites, including the four regioisomers of epoxyeicosatrienoic acid (EET). The physiological roles of these metabolites are only partially understood. Nonetheless, in studies to examine the effects of 8,9-EET on human platelet aggregation extensive COX metabolism of the EET was observed.[1] These metabolic products were identified as 11-and 15-hydroxy-EET (HEET). We propose that the formation of these HEETs is due to transcellular metabolism of CYP-450 AA metabolites by COX and that this process is important in determining the observed biological activities of these eicosanoids. In order to fully understand the suggested transcellular mechanism of CYP-450 metabolites to COX derived HEETs, it is necessary to have a convenient method of analysis for both of these metabolites. This method describes the development of a LC MS/MS assay for the quantitative determination of these metabolites.

Racemic EETs were purified and separated from the internal standard, 14,15-epoxyeicosaenoic acid, by reverse phase chromatography prior to ESI MS/MS analysis. Liquid Chromatography was conducted using a Hewlett-Packard 1090 series II liquid chromatograph equipped with a Zorbax Rx C-8 column (2.1 mm x 150 mm, 5 µm). A 0.2 µm pre-column filter was also used to prolong column life. Solvent A was 5 mM aqueous ammonium acetate and solvent B was 5 mM ammonium acetate in methanol:water (9:1). The flow rate was 200 µL/min. A linear gradient was employed over the first 2 minutes after injection at which the initial solvent composition was 20% A : 80% B, and the final composition was 10% A : 90% B. This solvent composition was maintained for the next 11 minutes, after which the solvent composition was returned to the initial conditions during a 2 minute period. A 5 minute post time was employed to allow the column to equilibrate at these conditions. EETs and HEETs were dissolved in a 1:1 mixture of methanol:water and injected onto the HPLC column.

Mass spectrometry studies were conducted using a Finnigan TSQ 7000 triple quadrapole mass spectrometer equipped with an electrospray (ES) ion source operating in the negative ion mode with a needle voltage of 4.5 kV. Nitrogen was used as the sheath gas (70 psi) and the auxiliary gas (25 psi) to assist with nebulization. The capillary was heated to 200 °C to provide optimal desolvation, and the electrospray interface and mass spectrometer parameters were optimized to obtain maximum sensitivity without sacrificing unit resolution. Flow injections of each EET isomer and HEET were conducted to determine the isomer-specific fragmentation of precursor ions (Figure 1). Selected reaction monitoring (SRM) experiments were then conducted with each regioisomer and internal standard to observe its characteristic transition. For each EET and EEA, the M-1 precursor ion was chosen and inherent transitions were monitored. For 8,9-EET the *m/z* 319→156 transition was monitored. Similarly, for 14,15-EEA the *m/z* 323.5→305.5 transition was monitored (Figure 2). Likewise, MS/MS experiments will be carried out to characterize and monitor a non-specific transition for the COX I

43rd ASMS Conference on Mass Spectrometry and Allied Topics

metabolites of 8,9-EET, 11- and 15-HEET.

Once methodology for the analysis of CYP-450 metabolites of AA and their subsequent COX derived metabolites is well defined, studies to elucidate the pathophysiological roles of these compounds will be undertaken. This research will not only expand our understanding of the physiological conditions associated with these eicosanoids but will also provide new methodologies for the study of a wide range of metabolic processes.

GC/MS/MS Characterization of Acylcarnitines

Shannan M. Carlson, Ulrich R. Bernier, Jodie V. Johnson, Peggy R. Borum† and Richard A. Yost
Departments of Chemistry and Food Science† University of Florida, Gainesville, FL 32611

Carnitine, an important metabolite, transports fatty acyl groups across mitochondrial membranes. Regular monitoring of carnitine concentrations is of clinical importance in the care of preterm infants and dialysis patients. Inherited disorders of metabolism (e.g. organic acidurias and Reye's Syndrome) are often associated with abnormally high ratios of acyl to free carnitine in the blood and urine.[1]

The standard method for the determination of carnitine concentrations is by radioenzymatic assay; however, only free and total carnitine can be determined using this method. Differentiation among the various acylcarnitines is necessary to determine the mechanism of carnitine metabolism and to assess the potential therapeutic role of carnitine supplementation. A number of methods for the determination of specific acylcarnitines have been developed, with mass spectrometric methods showing the most promise. While a continuous flow FAB/MS/MS procedure is the most complete method reported to date,[2] it has limited utility for unknown acylcarnitines or mixtures. Although HPLC methods also exist, the analyses are not specific and are labor-intensive. Recently, Gage and co-workers used a two-step derivatization to form N-demethylated propyl esters of free carnitine and acylcarnitines (**FIGURE 1**) followed by GC/MS on a double-focusing mass spectrometer.[3] Utilizing the Gage derivatization procedure to form N-demethylcarnitine t-butyldimethylsilyl esters, this work focuses on the use of several modes of GC/MS/MS on a triple quadrupole mass spectrometer. MS/MS analyses provide increased selectivity over single stage analyses.

All experiments were performed on a Finnigan MAT TSQ70 triple quadrupole mass spectrometer equipped with an octopolar collision cell in place of the second quadrupole. Sample introduction was from a Varian 3400 gas chromatograph (GC). The column employed for this study was a 30m, 0.25 mm i.d. open tubular DB5-MS temperature programmed from 140C (one minute hold time) to 290C at 20C/min. Unless otherwise noted, MS/MS experiments were performed with 1.0-1.2 mTorr argon at a collision energy of 10 eV The mass spectrometer was calibrated using perfluorotributylamine (PFTBA).

All samples were prepared by the Department of Food Science at the University of Florida. Standard acylcarnitine stock solutions (3 mM) were prepared in 1:1 methanol/chloroform. Red blood cells were hypotonically lysed prior to extraction. Plasma and red blood cell samples were extracted with methanol and chloroform, then filtered through a 0.2 µm nylon membrane via centrifugation to remove proteins. A 100 µL aliquot of the supernatant was allowed to evaporate to dryness overnight. Aliquots of standard acylcarnitines were dried in an analogous fashion. The dried samples were derivatized by silylation with MTBSTFA, DMP, TMP, and TMIS in methylene chloride. Samples were stored at -20C until the time of analysis.

Ten acylcarnitine standards were analyzed by GC/MS using methane chemical ionization (CI) to determine retention times and identify the $[M+H]^+$ ion characteristic to each. GC/MS/MS daughter spectra of the $[M+H]^+$ ion of the individual standards (**FIGURE 2**) were acquired to provide the basis for the identification of metabolites. The remarkable similarity of the daughter spectra of the $[M+H]^+$ ions of the different acylcarnitines provided an excellent foundation for monitoring carnitine concentrations. Identification of unknown acylcarnitines was possible using parent spectra of the common daughter ion at m/z 244. At a collision energy of 10 eV, the base peak was the $[M+H]^+$ parent ion with characteristic daughter ions observed at m/z 262, 244, 202, 199, 115, 112, 84, and 73 for all of the acylcarnitines. Parent and daughter spectra were taken of all characteristic ions to determine the fragmentation pattern.

After characterization of the fragmentation patterns of the acylcarnitines, standard mixtures were analyzed by GC/MS/MS. To maximize selectivity, selected reaction monitoring (SRM) was employed for the analysis of standard mixtures, plasma and red blood cell extracts. An instrument control language (ICL) routine was written to vary the selected parent ion during the GC run. External standard calibration curves were linear for eight different acylcarnitine standards over the 1-40 ng range with a coefficient of determination (r^2) of 0.98 or better.

While the radioenzymatic assay is used to indicate the ratio of free to total carnitine, the GC/SRM method allowed the elucidation of acylcarnitine profiles (e.g. identification of individual acylcarnitines) in plasma and red blood cells (**FIGURE 3**). The plasma data were in agreement with the radioenzymatic assay which generally indicates approximately 85-90 percent of carnitine in the plasma of healthy individuals is free carnitine. Comparison of plasma and red blood cell acylcarnitine profiles showed a variation in partitioning of acylcarnitines between the plasma and red blood cell compartments Free carnitine was observed as the most abundant of the carnitines detected in the plasma sample, while the red blood cell profile showed decreased free carnitine and increased acylcarnitines (**FIGURE 4**). Since this is one of the first reported comparisons of acylcarnitine profiles of plasma and red blood cells, the dramatic difference between the two metabolic compartments reveals many opportunities for enhancing the understanding of carnitine metabolism. Although red blood cell carnitine concentrations have not been studied extensively, the red blood cell compartment is a significant contributor in carnitine metabolism. Whole blood analyses may limit the diagnostic capabilities due to the variations between plasma and red blood cell carnitine concentrations. The full impact of these data is yet to be realized. Improvement in the quantitation of this method will be achieved when an appropriate internal standard is obtained.

Identification of in-vitro and in-vivo metabolites of Bosentan by LC-MS/MS

G. Hopfgartner, B. Lausecker, M. Zell, C. Husser, A. Viger-Chougnet and R. Haas
F. Hoffmann-La Roche, Pharma Division, Department of Drug Metabolism & Kinetics, CH-4002 Basel

Introduction

Endothelin is a bicyclic-21-amino acid peptide and a very potent long lasting vasoconstrictor. It is also a growth factor for vascular smooth muscle, mesangial and cancer cells and a potent bronchoconstrictor. Bosentan® (Ro 47-0203) an endothelin receptor antagonist is potentially useful in the treatment of diseases associated with abnormal vasoconstriction, such as subarachnoid hemorrhage (SAH), Raynaud's syndrome, migraine, NSAID-induced gastric ulcers and hypertension.

In a first step, the metabolism of the endothelin receptor antagonist has been studied in vitro using different liver preparations (liver homogenate S9 supernatant, microsomes, hepatocytes) of different species. The structures of the metabolites of the radio-labeled parent drug were characterised by liquid chromatography - ion spray tandem mass spectrometry in positive and in negative mode and NMR for the main metabolite.

In a further step the metabolites were analysed in biological fluids such as rat and dog bile. A semi-quantitative screening of the metabolites identified from in vitro experiments was performed in human plasma and urine using LC-MS/MS and LC-UV detection.

Experimental

MS detection was performed on an API III and an API III^{plus} (PE Sciex, Thornhill) with the ion spray interface in positive (4-6 kV) and in negative mode (3-4 kV) and no post-column splitting.
The declustering potential (OR) was in the range of ± 50-70 eV.
For tandem MS experiments (SRM, Neutral Loss, Precursor Ion Scan or Product Ion Scan) argon, was used as collision gas. An UV detector (equipped with a micro cell 2.4 µl, 8 mm length) was placed in serial prior MS detection. A Merck Hitachi L-6200A pump was used, equipped with a low pressure gradient module.

1) Kromasil 100, C18, 5 µm, 125 x 2 mm, Solvent A: MeOH / 5 mM CH_3COONH_4 30 / 70 (v/v), Solvent B: MeOH / 5 mM CH_3COONH_4 80 / 20 (v/v), Flow Rate = 200 µl/ml ; Gradient T_1 = 0 min 90 % A, T_2 = 10 min 10 % A, T_3 = 16 min 10% A.
2) Superspher RP-18, 5 µm, 125 x 2 mm, Solvent A: CH_3CN/ 2 mM CH_3COONH_4 with 1% HCOOH,30 / 70 (v/v), Solvent B: CH_3CN/ 2 mM CH_3COONH_4 with 1% HCOOH, 80 / 20 (v/v), Flow Rate : 200 µl/min, Gradient T_1 = 0 min 100 % A, T_2 = 10 min 20 % A, T_3 = 20 min 20% A.

The metabolism has been studied in vitro using different liver preparations (liver homogenate S9 supernatant, microsomes, hepatocytes) of different species (rat, dog, rabbit, marmoset, man).

0.5 ml of the urine or plasma samples were extracted with chloroform/isopropanol (4:1) at pH 8. The aqueous phase was removed and the sample was evaporated to

dryness under nitrogen. Prior injection the reconstitued sample was filtered over a 0.45 µm filter.

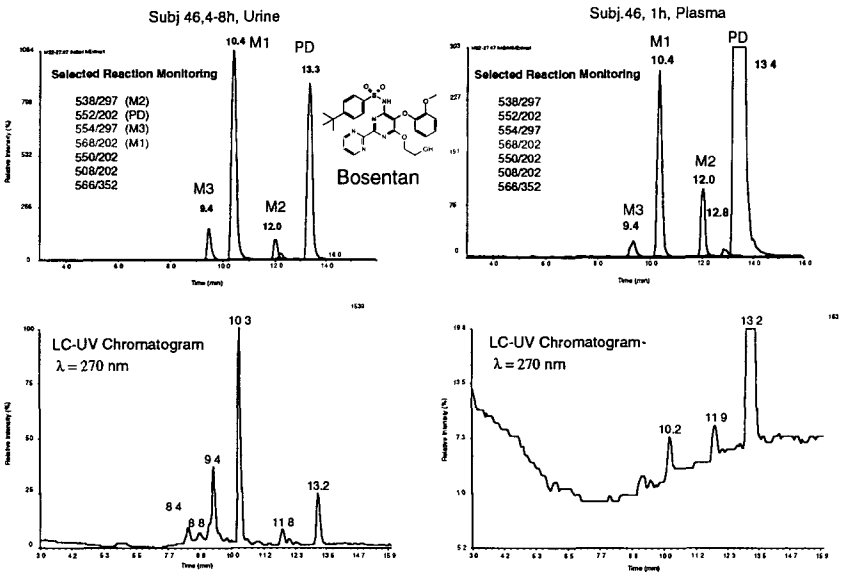
Results

In all conditions studied in vitro, the formation of the same major metabolite (M1) was observed corresponding to an hydroxylation of the parent drug occurring at the tert-butyl moiety. This was confirmed later on by synthesis and NMR. Other less important metabolites were also characterised by LC-MS/MS, which correspond to demethylation (M2) and and hydroxylation (M3) processes.

During the metabolic investigations the fragmentation process of Bosentan was extensively studied with a series of analogs and resulted in the observation of an unexpected case of a radical fragmentation of an even-electron-ion.

Using LC-MS/MS, it was possible to confirm the presence of the main metabolite (M1) in rat and dog bile by direct injection without prior purification.

Tandem LC-MS in combination with UV detection allowed the screening and the semi-quantitative determination of the major metabolites present in human plasma and urine without radio-labeled parent drug.

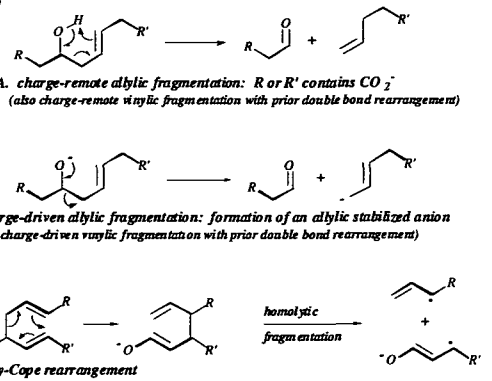


Mechanisms of Leukotriene B_4 Metabolism: Negative ion ESI MS/MS analysis

Pat Wheelan and Robert C. Murphy
National Jewish Center for Immunology and Respiratory Medicine,Denver, CO

Leukotriene B_4 (LTB_4) is a potent chemotactic lipid produced by activated cells involved in the immune response and is rapidly inactivated by numerous cell types. Extraction from biological samples and purification by HPLC followed by derivatization and GC/MS analysis has resulted in the identification of over 25 metabolites of LTB_4. In the present work, fragment ions observed in the negative ion electrospray ionization MS/MS spectra of LTB_4 metabolites were shown to arise principally *via* mechanisms previously described for the low energy decompositions of monohydroxy unsaturated fatty acids (**Figure 1**).[1]

Figure 1



The presence of the conjugated triene system in LTB_4 and in many of its metabolites requires a double bond rearrangement not previously observed in simple monohydroxy compounds. This rearrangement likely involves formation of a cyclohexadiene structure and results in prominent ions at m/z 195 and m/z 129 in the MS/MS spectra of LTB_4 (**Figures 2 and 3**). Deuterium exchange of labile protons and ^{18}O exchange of carboxylate oxygens were used to verify ion structures.

Metabolites were analyzed by negative ion electrospray ionization MS using a Sciex API III+ mass spectrometer with flow injection (1-5 ng of metabolite in methanol:water) using methanol:water (1:1) as the mobile phase at a flow rate of 20 µL/min. CID of the carboxylate anions were obtained using a collisional offset energy of 20 eV and a pressure of argon that resulted in a 40-80% reduction in the carboxylate anion. Deuterium exchange of labile protons was accomplished by dissolving the sample in MeOD followed by evaporation (X2) and reconstituting the sample in MeOD:D_2O (1:1) for negative ion ESI analysis using MeOD:D_2O (1:1) as the mobile phase. Exchange of carboxylate oxygens with ^{18}O was accomplished using porcine liver esterase in $^{18}OH_2$ as previously described.[2]

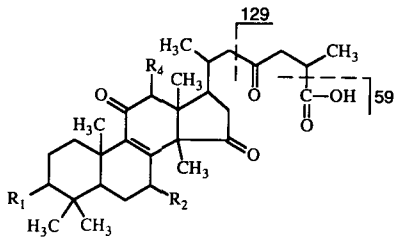
CHARACTERIZATION OF ACIDIC TRITERPENES BY HPLC/ESI/MS

Susan T. Weintraub, Robert T. Streeper, Neera Satsangi and William B. Stavinoha
Departments of Biochemistry and Pharmacology
The University of Texas Health Science Center at San Antonio

G. lucidum and its preparations have a long history of use throughout the East as traditional medicines in the treatment of a broad range of disorders. More recently it has been found that this mushroom contains a number of pharmacologically active molecules. Amelioration of the pain and inflammation associated with arthritis has historically been attributed to preparations of *G. lucidum* . We have determined that extracts rich in ganoderic and lucidenic acids prepared from various portions of the mushroom possess potent systemic and topical anti-inflammatory properties. The general structure for a ganoderic acid is shown below. Since the treatment of arthritis by chronic use of aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) is complicated by serious side effects, the identification of an agent that has potent anti-inflammatory properties but lacks the negative side effects of NSAIDs is of considerable importance. In this report, we present some of our initial observations on the biological activity of *Ganoderma lucidum* extracts as well as the results of preliminary chromatographic and mass spectrometric analyses of several of the ganoderic acids.



In view of the tremendous structural heterogeneity of the acidic triterpenes produced by *G. lucidum* and the effort required to separate sufficient quantities of pure ganoderic acids for controlled testing of *in vivo* activity, for our preliminary investigation we assessed the anti-inflammatory efficacy of crude water and ethyl acetate extracts of the mushroom. For our *in vivo* assay, mice were treated both orally and topically with water and ethyl acetate extracts of *G. lucidum*. The ability of these extracts to alleviate the swelling produced by the irritant croton oil was compared to the efficacy of one of the most commonly used topical anti-inflammatory drugs available, hydrocortisone. We found that topical application of the ethyl acetate extract of *G. lucidum* results in significant anti-inflammatory activity that compares favorably with the activity of hydrocortisone. The water extract, on the other hand, has little or no topical effect. After oral administration of the extracts, both the ethyl acetate and the water extracts have significant anti-inflammatory activity that extends for a longer time than hydrocortisone.

Mass Spectrometry - In preparation for structural elucidation of the acidic triterpenes in *G. lucidum*, we analyzed three reference ganoderic acids by ESI-MS and EI-MS. The ESI mass spectra obtained by infusion of ganoderic acids B, C2 and H in 70% aqueous acetonitrile/0.5% acetic acid solution at a flow rate of 1 µl/min were characterized by $[MH]^+$ of modest intensity. Although we could not quantitatively assess the relative proportions of the components on the basis of the ESI-MS data alone, it was immediately apparent that the ganoderic acid B and C2 samples were not pure. Moreover, ganoderic acid B appears to show a propensity to lose water under our analysis conditions while C2 and H do not.

Analysis of methylated ganoderic acids B, C2 and H by EI-MS reveals that a number of characteristic fragments are generated along with several obvious differences. In agreement with the ESI-MS data, there are additional components in the ganoderic acid B and C2 samples whereas H appears to be significantly more pure. The molecular ions for methylated B and C2 are substantially more intense than for methylated H while the cross-ring cleavage indicative of hydroxylation pattern (producing the ions at m/z 304 and m/z 306) is greater in H than in B and C2. Many of the differences in the fragmentation patterns are due to the presence of the C-12 acetate on ganoderic acid H.

HPLC Fractionation - Analysis of the ganoderic acids of *G. lucidum* is complicated by the exceedingly large number of ganoderic and lucidenic acids produced by the mushroom. Standard separation techniques relying on C18 reversed-phase fractionation are not equal to the task of resolving the hundreds of structural variants that are present. However, if semi-preparative C18 chromatography is followed by sub-fractionation using Supelco's new mixed function ABZ+ column, it is possible to separate, to a significant degree, a large number of the ganoderic acids. For example, when the 37-min fraction from semi-preparative C18 HPLC of the ethyl acetate extract of *G. lucidum* was analyzed by ESI-MS, it was clear that multiple species were present. When this fraction was treated with ethereal diazomethane and the product analyzed by EI-MS, the presence of intense ions at m/z 129 and m/z 59 indicate the predominance of ganoderic acids in the sample. Moreover, the observation of both m/z 304 and m/z 306 indicate that at least two different patterns of hydroxylation are present in these molecules. Evidence for a mixture of species is further borne out by the diversity of ions in the mass range anticipated for molecular ions of methylated ganoderic acids.

After methylation of the combined 31- and 32-min fractions from the ABZ+ column, the EI mass spectrum was in agreement with the results obtained by ESI-MS, showing that this fraction appears to be highly enriched in a single species. Although the mass spectrum is nearly the same as that of ganoderic acid H, the retention times of these substances are not identical on the ABZ+ column. Since we are not able to determine the isomeric variations in these compounds from the EI mass spectra, it will be necessary to utilize NMR to obtain more definitive structural information.

In conclusion, our data show that extracts of *G. lucidum* possess significant anti-inflammatory activity. While it is premature in this investigation to assign a rank order of potency to all of the members of this complex mixture of ganoderic and lucidenic acids, our preliminary studies have suggested that relatively minor structural differences among the components leads to measurable differences in anti-inflammatory potency. As we improve our abilities to isolate and characterize individual ganoderic acids, we expect to be able to deduce comprehensive structure-activity relationships for these molecules. This effort will be important not only for elucidating the mechanism of action of these molecules but also for future analog drug development.

Acknowledgements - The authors wish to convey their appreciation to Lone Star Growers (San Antonio, Texas) for providing the mushrooms used in this work and to the Il Yang Pharm. Co., Ltd. (Seoul, Korea) for their support of the *in vivo* work. We are also grateful to Tracy Ascah and Supelco Incorporated for generously donating one of their new Supelcosil ABZ+ HPLC columns, which has been of considerable help in resolving the tremendously complex mixtures of ganoderic acids.

Microbore HPLC/MS/MS of CP-166,572 Metabolites in the Rat

M. Avery, W. Ballinger, W. Zembrowski, P. Inskeep, L. Mylari and H. Fouda. Central Research Division, Pfizer INC Groton CT, 06340

CP-166,572 is a sorbitol dehydrogenase inhibitor with potential utility for the management of diabetic complications. , Following oral administration. CP-166,572 is extensively metabolized in the rat. Urinary metabolites were identified by on line HPLC/tandem atmospheric pressure ionization mass spectrometry.

An atmospheric pressure SCIEX API III triple quadrupole mass spectrometer was used. Sample introduction was via HPLC using a 1.0 X 250mm BDS-Hypersil C18 column (Keystone Scientific, Bellefonte, PA). A dual piston syringe pump (Applied Biosystems model 140B, Foster City, CA) delivered the mobile phase to the column at the rate of 40 µL/min. A binary gradient of acetonitrile and water, each containing 0.1% trifluoroacetic acid (TFA) was used.

Five µL aliquots of urine were injected onto the HPLC column. The effluent from the column was connected to a UV detector set at 251 nm . The outlet of the UV detector was connected to the ionspray interface of the mass spectrometer with fused silica tubing. The interface was operated in the positive ion mode with a nebulizer gas setting of 60 psi and a sprayer voltage of 5200V. Collision induced dissociation (CID) studies were performed using argon gas at a collision gas thickness of 3.3 $x10^{14}$ atoms/cm^2 and a collision energy of 30 eV.

Under positive ion APIMS conditions, CP-166,572 forms MH^+ at m/z 302. If m/z 302 is subjected to collision induced dissociation, the product spectrum shown in Figure 1 is obtained.

Analysis of MS data obtained from a rat urine sample suggested thirteen possible metabolites. Prominent HPLC peaks were observed for parent drug at m/z 302 as well as responses for 478 (drug + 176 daltons), 316 (drug + 14 daltons), four components at 318 (drug +16 daltons), 288 (drug -14 daltons) and 274 (drug -28 daltons). CID data was obtained for each of these possible metabolites.

The rat urine sample was then run by HPLC/UV/MS/MS and full product spectra obtained on each possible metabolite.

Since both HPLC/UV and HPLC/MS/MS MRM data are acquired simultaneously, the relative abundance's of each metabolite can be determined from the UV responses. A summary of the identified metabolites is given in Table 1.

Table 1. Relative abundances of drug related material in urine of rat dosed with CP-166,572.

High Pressure Liquid Chromatography/Ionspray MS/MS for the Identification of *In Vitro* Metabolites of CP-118,954

Donghui Cui and Chandra Prakash
Department of Drug Metabolism, Central Research Division, Pfizer Inc., Groton, CT 06340

Introduction:

CP-118,954, 5,7-dihydro-3-[2-1-(phenylmethyl)ethyl]-6H-pyrrolo[4,5-f]1,2-benz-isoxazol-6-one, is a potent and selective antagonist of acetylcholinesterase (AChE) with low affinity for butyrylcholinesterase (BuChE), a property which accounts for potent central effects without confounding peripheral activity. The compound is being developed for the palliative treatment of the cognitive decline in Alzheimer's disease. Preliminary studies using hepatic microsomes indicate that CP-118,954 is extensively metabolized to several metabolites. The microsomal data exhibit species differences in the metabolism of CP-118,954. The objective of present study was to characterize the *in vitro* metabolites of CP-118,954 using hepatic microsomal preparation from rat, dog, monkey and human liver microsomes in order to predict the *in vivo* metabolism. Metabolite identification was carried out by ion spray LC/MS using a combination of parent, daughter, and multiple ion reaction monitoring techniques.

Experimental procedures:

The microsomal incubation of [^{14}C]-CP-118,954-11 (labeled at C-3 position of the benzisoxazole moiety) with rat, dog, monkey, and human liver microsomes were carried out in potassium phosphate buffer with a NADPH regenerating system. The mixture was incubated at 37 °C for an hour. The reaction was terminated by addition of 1 ml methanol and was evaporated to dryness on a Speed-Vac evaporator. The residue was reconstituted in 1 ml of HPLC mobile phase, sonicated, and centrifuged. The supernatant was separated and an aliquot (60 ul) was analyzed by HPLC. Chromatography was carried out on a YMC basic HPLC column (4.6 mm x 250 mm, 5 µm: YMC) with a binary mixture of methanol and ammonium acetate (pH 5.0). The separation of metabolites of CP-118,954 was obtained by using a gradient system. The flow rate was 1 ml/min and the eluate was monitored with a β-RAM using Ecolite(+) scintillation fluid at 4 ml/min.

The analysis of the metabolites was performed on a SCIEX API III HPLC/MS/MS system (Toronto, Canada) using ion spray. The effluent from the HPLC column was split and about 50 ul/min was introduced into the atmospheric ionization source via an ion spray interface. The remaining effluent was directed into the flow cell of the β-ram. The ion spray interface was operated at 5000 V and the mass spectrometer was operated in the positive mode. Collision activated dissociation (CAD) studies were performed using argon gas at an orifice voltage of 65 eV and a collision gas thickness of 2.5 x 10^{14} molecules/cm^2.

Results:

A total of ten radioactive metabolites were identified from the incubations with rat, dog, monkey, and human microsomes. The identified metabolites in each spieces accounted for more than 90% of the total radioactivity detected by β-ram. The CAD

product ion spectrum of the parent drug is shown in Figure 1. The proposed major metabolic routes of CP-118,954 in liver microsomes are summarized in Figure 2.

Conclusions:

- CP-118,954 was extensively metabolized by PB induced rat and monkey liver microsomes.
- The metabolism of CP-118,954 in monkey was similar to that of human.
- The major metabolite was the N-debenzylated CP-118,954 in all species.
- No qualitative differences were found in the metabolism of CP-118,954 among rat, dog, monkey, and human liver microsomes.
- Structural characterization of the metabolites revealed that the metabolism of CP-118,954 occurred by three pathways: 1) oxidative N-dealkylation of the benzyl side chain attached to the piperidine nitrogen, 2) scission of the isoxazole in the benzisoxazole ring system and 3) oxidative cleavage of piperidine ring.

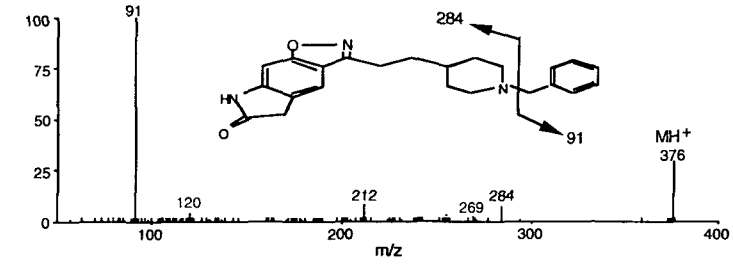

Figure 1. CAD daughter spectrum of CP118,954.

INHIBITION OF ALDEHYDE DEHYDROGENASE BY DISULFIRAM AND METABOLITES

K. A. Veverka[1,2], K. L. Johnson[1,3], D. C. Mays [2,5], J. J. Lipsky[2,4,5], and S. Naylor[1,2,3,5]
[1]Biomedical Mass Spectrometry Facility, [2]Department of Pharmacology, [3]Department of Biochemistry and Molecular Biology, [4]Department of Internal Medicine, [5]Clinical Pharmacology Unit, Gugg C009B, Mayo Clinic, Rochester MN 55905

Introduction: Disulfiram (DSF, trade name Antabuse, Fig. 1) is used clinically in the aversion therapy of recovering alcoholics. DSF acts by inhibiting the hepatic enzyme aldehyde dehydrogenase (ALDH) which leads to an accumulation of acetaldehyde in the blood upon subsequent ingestion of ethanol. DSF alone can inhibit ALDH *in vitro*, however, a variety of biotranformation products are thought more likely to be physiologically important, and many have greater inhibitory capacity than DSF itself. Two such compounds are methyldiethylthiocarbamoyl-sulfoxide and methyldiethylthiocarbamoyl-sulfone (MeDTC-SO and MeDTC-SO_2, respectively, Fig. 1). We report a systematic approach to study the mechanism of ALDH inhibition by DSF and metabolites which combines the direct analysis of protein and protein-drug interactions with bioassay.

Results: Yeast ALDH (yALDH), containing an ~ equimolar mix of the mitochondrial and cytoplasmic isozyme was used as a model, and the ESI-MS of the native enzymes is shown in Figure 2A (M_r=53962±5amu and 54099±5amu, respectively). Samples of purified yALDH protein were reacted with drug *in vitro* and the NAD activity of ALDH was assayed spectrophotometrically. Other samples of yALDH were treated with dithiothreitol to monitor the effects of a reductant on ALDH activity (both with and without inhibitor). After sample clean-up the reacted yALDH samples were further subjected to ESI-MS analysis.

ESI-MS analysis alone of DSF-treated yALDH establishes no recognizable difference in mass from native yALDH (Table 1). Bioassay provides the additional information that although no observed shift in mass is associated with DSF treatment of yALDH, activity is abolished. Moreover, if DTT is added to the sample as a reductant, activity is restored even though the mass remains unchanged.

yALDH that is likewise treated with MeDTC-SO or MeDTC-SO_2 affords a ~100 amu adduct or ~100 and ~200 amu adduct, respectively (Table 1). ESI-MS analysis of the intact protein reacted with MeDTC-SO is shown in Figure 2B. ALDH activity is inhibited in these samples and correlates with the observed protein adduct. If DTT is added to MeDTC-SO-inhibited yALDH as a reducing agent at pH 7.3, activity remains inhbitied (Table 1) and the protein remains adducted. This suggests that in the range of physiological pH the adduct is stable. High pH alone has no effect on destabilizing the sulfoxide-derived adduct, however, upon adding 1 mM DTT at increased pH (~pH 9), activity is fully restored (Table 1) and the mass of yALDH is lowered by ~100 amu (not shown).

Conclusions: Based on these results at least two mechanisms of inhibition of yALDH by DSF and related biotransformation products are now apparent. It seems conceivable that *in vitro* DSF acts directly on yALDH to oxidize proximal cysteines thought to occupy the active site, and thereby inhibits enzymic activity by forming an internal disulfide bond (not shown). Furthermore, our *in vitro* data supports the hypothesis that a nucleophile, perhaps cysteine 302 of the ALDH active site, attacks the electrophilic center of MeDTC-SO and/or MeDTC-SO_2 which forms a covalent adduct with the enzyme (Figure 3). The overall importance of this mechanism is that the covalent modification inactivates the ability of ALDH to metabolize acetaldehyde. Neither reduction or base hydrolysis is able to release the adduct and recover yALDH activity. Rather, DTT has sufficient nucleophilic character at high pH to attack the electrophilic center of the proposed thiocarbamoyl adduct and releases the adduct with a concomitant regaining of enzyme activity.

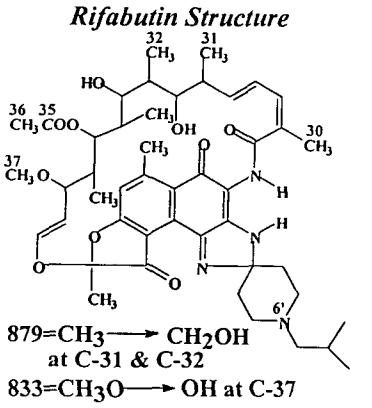
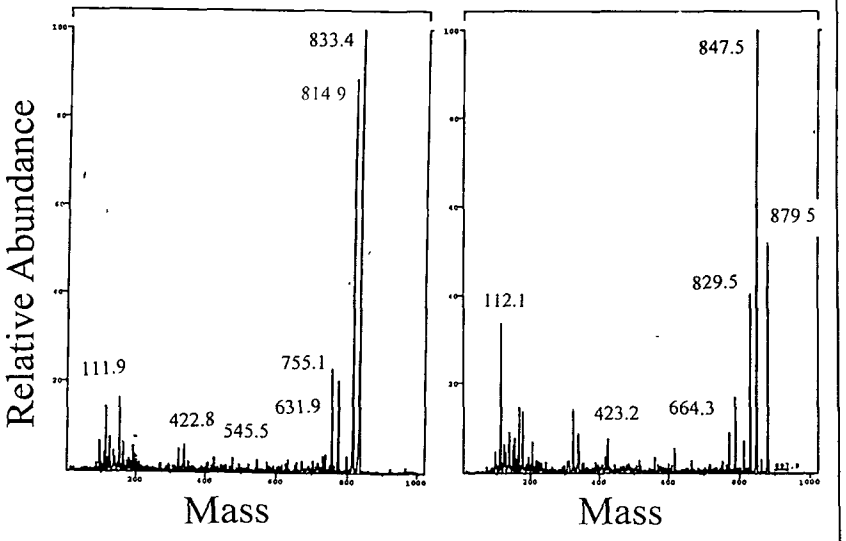
Rifabutin, a drug used as a prophylactic in treating patients with immun deficiencies for *Mycobacterium avium* complex (MAC) hasshown in vitro activity against *M. tuberculosis.* Most studies to date have been aimed at enhancement rifabutin's effectiveness by concurrently injecting metabolism inducing drugs. One of the metabolites, 25-O-deacetyl-rifabutin, is known to exhibit activity equal to rifabutin against MAC and is itself responsible for 10% of the overall drug activity. This activity exhibited by metabolite suggests that some of the other metabolites may also exhibit activity against MAC and *M. tuberculosis.* One author suggests that more than 20 metabolites my exist. Only six metabolites have been isolated and their structures identified. The major metabolic pathways appear to be oxidation of a methyl group or of the 6' N (forming an N-oxide), deacetylation and demethylation.

In our work, the origins of the various fragment ions were determined based on the mass value shifts observed in the spectra of the reference anaolgs This information assisted in ,the development of a library of pertinent fragment ion structures.

The metabolites were obtained from two sources—urine collected from rats injected with rifabutin, and liver microsome extracts. The microsomes were obtained by homogenizing excised livers and centrifuging the homogenate. Rifabutin and co-factor cytochrome P450 were then added and the metabolites extracted using a mixture of butyl chloride and sodium phosphate, pH 7 The metabolites were extracted from the urine with the same method The metabolites were then separated on a conventional HPLC column (C-18, 4.6 mm id, 15 cm long) with UV detection at 275 nm The buffers were B=acetonitrile and A=3%TEA, 0.3%TFA, H_3PO_4 to pH 2 in aqueous solution. The gradient was 27-45% B over 60 minutes. The fractions were collected and further purified by HPLC using the same buffers but substituting 1%TFA or 1% heptafluoro butyric acid for the 0 3%TFA. These purified fractions were analyzsed by electrospray ionization mass spectrometry to obtain molecular weight information. The samples were then analyzed by CID with collision gas (argon) at ~2mtorr and collision energy at -51eV All sample were infused into the mass spectrometer at 5μL/minute. The mass spectrometer was a Finnigan TSQ700 equipped with a Finnigan electrospray source.

The structures and CID spectra of three new metabolites, 27-O-deacetyl rifabutin and 31-OH-32-OH, are reproduced on the next page were shown. Several other metabolites have been analyzed by ESI/MS/MS and structures have tentatively been assigned to them. Several fragment ions are significan when analyzing these spectra. CID of rifabutin produces ions at *m/z* 112, 423, 545, 573, 632 When rifabutin is oxidized with two oxygens, some of these ions shift by 16u as dictated by the position of oxidation (i.e. *m/z* 112,423,561, 664). In the case of N-oxidation, the ion shifts are *m/z* 128, 439, 561, 589, 648





LC/IonSpray/MS/MS Analysis of Bile Acids

Guy LePage and Ibrahim Yousef, Hôpital Ste-Justine, Unversité de Montreal, 3175, Côte Ste-Catherine, Montréal(Québec) H3T 1C5, Canada; and Gabriel Sanchez, Bori Shushan and Takeo Sakuma, PE-SCIEX, 71 Four Valley Dr., Concord, Ontario L4K 4V8, Canada

There are 2 million Canadians suffering from hepatic disease. It is the 4th most common cause of death among Canadians between 35 and 55 years of age.

Accurate analysis of bile acids(BA) is essential in the bile research, as BA undergo complex biotransformation in both healthy and sick people. Mass Spectrometry(MS) has opened up the field of inborn errors of BA metabolism and greatly increased the understanding of the metabolism and biosynthesis of BA. The coupling of GC to MS is useful for the separation and identification of free BA. However, BA conjugates with taurine, glycine and ornithine must undergo time-consuming and labor intensive sample preparation procedures, i. e., extraction, hydrolysis, a second extraction, purification and derivatization prior to GC/MS analysis. B. M. Warrack and G.C. DiDonato(1) applied the microbore HPLC/IonSpray/MS technique to the analysis of bile acid components of monkey bile in the 40 - 100 fmole range using the selected ion monitoring mode.

In this paper we examined 17 BA standards, lithocholic acid(LC), glycolithocholic (GLC), taurolithocholic (TLC), beta-lithocholic (ß-LC), deoxycholic (DC), glycodeoxycholic (GDC), tauro-deoxycholic(TDC), chenodeoxycholic (CDC), glycochenodeoxycholic (GCDC), taurochenodeoxy-cholic (TCDC), cholic (C). glycocholic (GC), taurocholic (TC), ursodeoxycholic (UDC), glycourso-deoxycholic (GUDC), tauroursodeoxycholic (TUDC) and hyodeoxycholic acid (HDC).
Single MS mode spectra were obtained from these BA standards in the positive and negative ion modes. In the positive ion mode most BA produced strong MH^+ ions except for LC, ß-LC, UDC and HDC that underwent dehydration to give $[M-H_2O]H^+$ as base peak. As our LC method used trifluoroacetic acid, subsequent work was done in the positive ion mode.

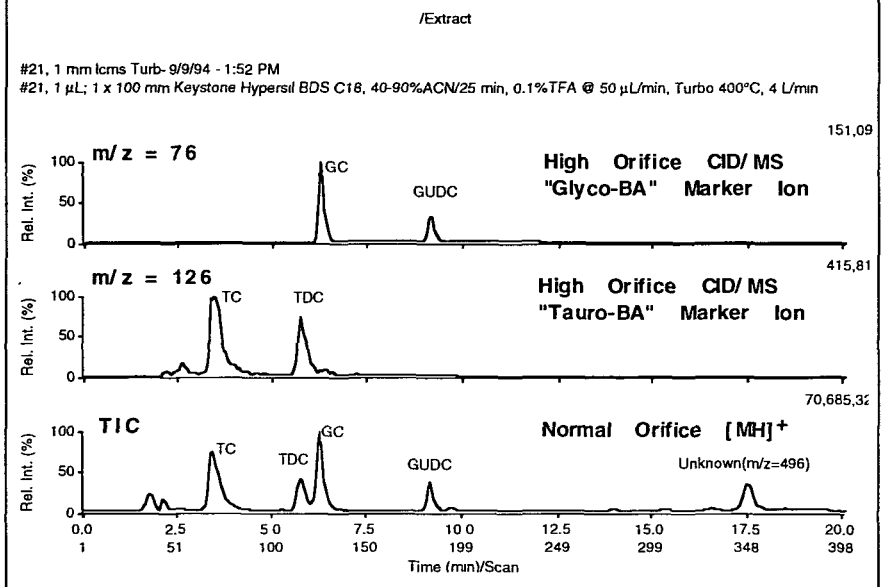
Product ion spectra were obtained from these BA. Common fragments observed were 323, 341 from LC, GLC, TLC and ß-LC; 321, 339 from DC, GDC, TDC, CDC, GCDC, TCDC, UDC, GUDC, TUDC and HDC; 319 and 337 from C, GC and TC.

We also discovered that N-(carboxymethyl)-amide containing "glyco-" BA produce strong 76 fragment ions, whereas N-(2-sulfoethyl)-amide containing "tauro-" BA form intense 126 product ions. These features were also observed from 2 crude human bile samples under the precursor ion and product ion scan modes. These spectra exhibited different fragmentation patterns and gave sufficient information for identification with the detection limits in the low picogram range.

The formation of Fragments 76 and 126 was also achieved by applying a high orifice potential of 100 - 150 V in the single MS mode followed by scanning from 340 - 600 amu using 60 V potential for the detection of parent ions. Figure 1 compares extracted ion chromatograms of 76, 126 and 340 - 600 amu. The top chromatogram shows "glyco-" BA, the middle chromatogram "tauro-" BA and the bottom the TIC.

1) B. M. Warrack and G. C. DiDonato, Biological Mass Spectrometry, 22, 101-111(1993)

Fig. 1 Extracted Ion Chromatograms from the LC/MS of Crude Bile Sample



Our results have proven that LC/MS/MS is the tool needed for research in the fate of BA in humans. Without MS/MS analysis of BA standards it would have been very difficult to discover the various marker ions indicative of certain BA compound classes. Subsequent analysis by LC/MS, under simultaneous high and low energy conditions, enables the acquisition of all the analytical information on the BA profiles including conjugate distribution and the characterization of unknown metabolites without any preparation of the biological samples.

Detection of Trypanothione Conjugates in Cell Cultures by ESI Tandem MS

Mark S. Bolgar and Simon J. Gaskell
The Michael Barber Centre for Mass Spectrometry, UMIST, Manchester, M60 1QD, U.K.

Kenneth T. Douglas, Amanda N. Wilton
Department of Pharmacy, University of Manchester, Manchester M13 9PL, U.K.

Trypanosomes are a group of flagellated protozoa responsible for African sleeping sickness and Chagas' disease. Trypanosomes differ from other organisms in their use of primarily trypanothione [N1, N8- bis (glutathionyl)spermidine] rather than glutathione to provide an intracellular reducing environment to protect against oxidative damage. By analogy with glutathione (GSH), it is anticipated that conjugation with trypanothione [$T(SH)_2$] may represent an important mechanism for the scavenging of xenobiotic-derived electrophilic compounds in these organisms. Since this pathway has not been definitively established we have investigated mass spectrometric procedures for the screening and identification of $T(SH)_2$ and GSH related conjugates from cell lysates. As a model system, the $T(SH)_2$ and GSH conjugates of 1-chloro-2,4-dinitrobenzene (CDNB) were prepared and examined by ESI MS and product ion scanning to determine common fragmentation pathways on which to base tandem-MS screening procedures. The GSH conjugate fragmented via loss of a neutral fragment 129 Da corresponding to the γ-glutamyl moiety. Scanning for a constant neutral loss of 129 Da has been previously demonstrated to be an effective method for the detection GSH conjugates (1-3). In addition to loss of a neutral γ-glutamyl moiety, its corresponding acylium ion was observed at m/z 130. The fragmentation pathways observed in the product ion spectra of the doubly protonated $T(SH)_2$ conjugate were similar to those of the GSH conjugate despite the difference in charge state of the precursor ions. The $T(SH)_2$ conjugate, like the GSH conjugate, fragmented by loss of a neutral γ-glutamyl moiety, but since the precursor ion had a charge state of 2^+, a neutral loss of 64.5 Da (129/2) was observed. Fragmentation via the consecutive losses of trypanothione's two γ-glutamyl residues resulted in a neutral loss of 129 Da. The γ-glutamyl moieties were also cleaved to form an acylium ion at m/z 130. Based on the observed fragmentation pathways, scanning for precursors of m/z 130 should detect GSH or $T(SH)_2$ conjugates regardless of their charge state. Scanning for a constant neutral loss of 129 Da should allow detection of singly charged GSH conjugates or doubly charged $T(SH)_2$ conjugates, while scanning for a neutral loss of 64.5 Da will be specific for doubly charged $T(SH)_2$ conjugates. The suitability of these tandem MS methods for the detection of conjugates in biological matrices was evaluated by analyzing 50 µL of a *Trypanosoma brucei brucei* lysate spiked with 25 pmol of the $T(SH)_2$ and GSH CDNB conjugates. After desalting, the lysate was analyzed by ESI MS and by precursor and neutral loss scanning (Fig 1) with 4 pmol of analyte consumed per experiment. Analysis of the spiked lysate by full scan ESI MS (Fig 1, top) did not allow reliable detection of the spiked conjugates due to chemical interference. Scanning for precursors of m/z 130 (Fig 4, upper middle) resulted in a large reduction in background interference and allowed detection of both the $T(SH)_2$ and GSH conjugates regardless of the charge state of the precursor ion. Scanning for a constant neutral loss of 64.5 Da (Fig 4 lower middle) resulted in the detection of only the doubly charged species of the $T(SH)_2$ conjugate, as expected since this loss corresponds to cleavage of a neutral γ-Glu residue from a doubly charged precursor. Scanning for a constant neutral loss of 129 Da (Fig 4 bottom) resulted in detection of primarily the GSH conjugate although the doubly protonated species from the $T(SH)_2$ conjugate was also detected.

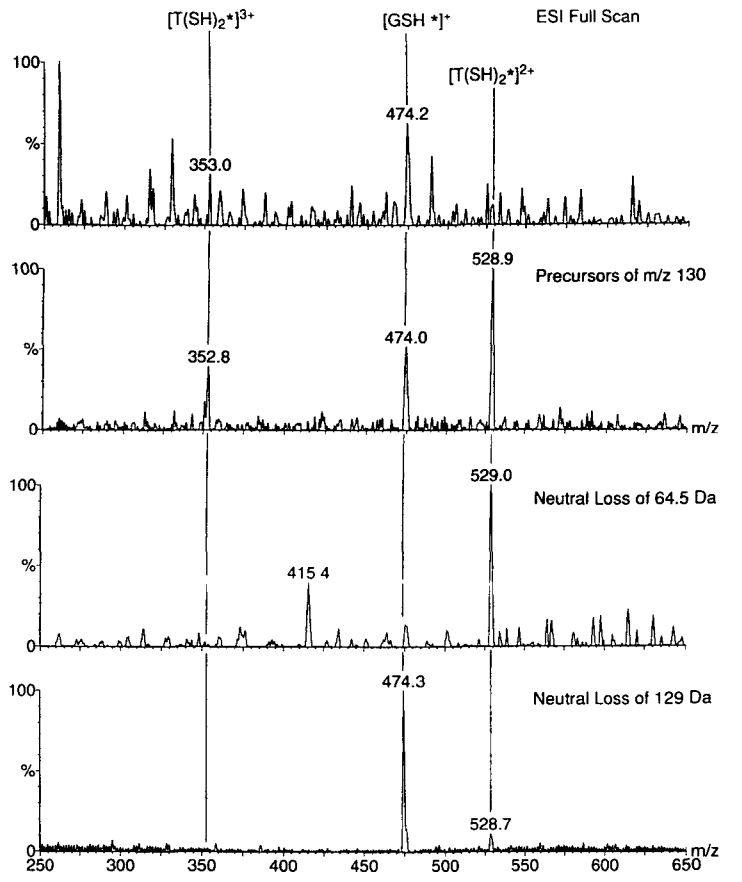


Figure 1. ESI MS and tandem-MS analyses of a *T. brucei brucei* lysate spiked with glutathione (GSH*) and trypanothione [$T(SH_2)$*] CDNB conjugates.

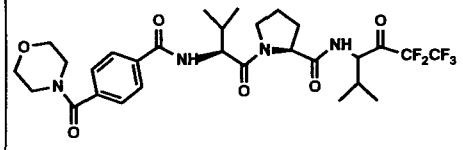
Characterization of Hemiketals of MDL 101146 by Normal Phase LC/ESI/MS

Paul W. Brown, W. Bart Emary and Nisar Akbari
Marion Merrell Dow, Kansas City, MO 64134

INTRODUCTION

MDL 101,146 is an orally active inhibitor of the enzyme elastase and has been approved as a clinical candidate for the treatment of chronic obstructive pulmonary disease. An unknown was detected after MDL 101,146 was dissolved in mobile phase for approximately two hours. Utilizing LC/UV, it was shown that the amount of unknown increased with time when MDL 101,146 was dissolved in mobile phase. This indicated that the detection of this compound was time dependent, and this property is not consistent with an impurity. The goal was to identify the unknown. The structure of MDL 101,146 is shown below:



MDL 101,146

After analysis by LC/UV, the sample which had been prepared in mobile phase was analyzed by LC/MS with electrospray ionization. MDL 101,146 was reacted with various solvents and the products were analyzed by LC/MS with electrospray ionization (ESI). The temperature of the heated capillary in the ESI source had a dramatic effect on the fragmentation of the unknown molecule.

Fragmentation Pathway of MDL 101,146 Hemiketal

Shown in Figure 1 is a scheme of the proposed thermally induced fragmentation pathway of MDL 101,146 hemiketals. This fragmentation pathway is unique to the hemiketals and is not observed in the ESI mass spectrum of MDL 101,146. The extent of fragmentation was correlated with three different capillary temperatures: 1) at 200°C very little fragmentation is observed compared to the natriated adduct, 2) at 225°C both the fragment ion and the natriated adduct are detected, and 3) at 250°C primarily the fragment ion is detected with minor contribution due to the natriated adduct. Thus the fragment ion which is produced from the unique and characteristic loss of 120 daltons (CF_2HCF_3) from the natriated adduct of the hemiketal is more abundant with increasing temperature.

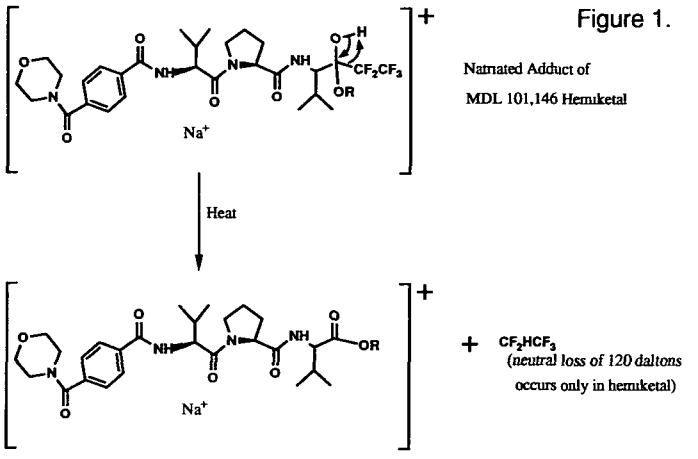


Figure 1.

Natriated Adduct of MDL 101,146 Hemiketal

where R=CH_3, CH_2CH_3 and $CH_2CH_2CH_3$

CONCLUSION

The unknown was determined to be MDL 101,146 methanol hemiketal.

The ketone moiety of MDL 101,146 also shows reactivity with water. When MDL 101,146 was dissolved in solution containing water, the hydrate (gem-diol) of MDL 101,146 was detected. The ketone moiety of MDL 101,146 will also undergo reversible nucleophillic addition reactions with water and straight chain aliphatic alcohols. Artifact (methanol hemiketal) formation can arise when compounds possessing a ketone moiety in close proximity of strong electronegative groups are prepared in solutions containing methanol, a common organic modifier. Hemiketals are thermally labile compounds which historically have been characterized by NMR and IR. Mass spectrometry has been used indirectly to characterize hemiketals because they can convert back to the ketone form upon volatilization in a GC inlet. Negligible molecular ion signal is usually observed because facile alpha cleavage results in a resonance stabilized ion (1).

Analysis of secondary plant metabolites in crude plant extracts by electrospray LC-MS

Jean-Luc Wolfender and Kurt Hostettmann, Institut de Pharmacognosie et Phytochimie, Université de Lausanne, BEP, CH-1015 Lausanne, Switzerland
Winfried Wagner-Redeker, Spectronex AG, Rotterdam-Strasse 21, CH-4002 Basle, Switzerland

The characterisation of natural products and their metabolites by mass spectrometry involves molecular weight determination as well as structural elucidation of a large variety of chemical compounds. As these substances are usually polar and thermally labile, often only soft ionisation methods are employed for their on-line LC-MS analysis. Much work has been done by thermospray (TSP) (1) and continuous flow FAB (CF-FAB), the former method giving molecular weight and structural information of small to medium sized metabolites (100 to 1000 u), while CF-FAB has been successfully applied for molecular weight determinations of metabolites ranging up to 3000 u. For rapid screening of plant extracts, routine coupling of mass spectrometry with liquid chromatography is of great importance; it permits, in conjunction with LC-UV, the early recognition of known constituents, thus avoiding their time-consuming isolation. In addition, an efficient localisation of interesting metabolites is possible (1).

Polyphenol and triterpene aglycones and glycosides have been studied by atmospheric pressure (API) LC-MS. The results were compared to previous TSP and CF-FAB measurements. API experiments were performed with a Finnigan MAT TSQ 700(0) and a prototype version of a Finnigan MAT LC-MS ion trap mass spectrometer. Electrospray (ES) and atmospheric pressure chemical ionisation (APCI) measurements were carried out in both positive and negative ion modes, with TFA and NH_4OAc buffer and with upfront CID on or off. The LC separation of the crude plant extracts was performed with a RP-18 column and H_2O/MeCN as gradient system.

For the LC-MS analyses of polyphenol aglycones and glycosides in crude plant extracts, TSP has been widely used (1). This technique however does not always give molecular weight information, especially for glycosides bearing more than 2 sugar units (2) or for compounds having a high degree of hydroxylation. In order to investigate the complementarity of different ionisation techniques, the crude MeOH extract of *Chironia krebsii*, a species of the Gentianaceae particularly rich in xanthones, has been analysed by ES, APCI, CF-FAB and TSP LC-MS. The TSP LC-MS (pos. ions) analysis of this extract showed a satisfactory response for all the peaks detected by UV at 254 nm. Generally $[M+H]^+$ ions were observed. In the case of glycosides, aglycone fragments $[A+H]^+$ were also formed. In ES and APCI, on the other hand, measurement with both ion polarities was necessary to give a general picture of the extract composition. Highly methoxylated xanthones or secoiridoids were only detected in the positive ion mode. Hydroxylated xanthones formed $[M-H]^-$ ions in the negative ion mode. The LC-MS spectra obtained for a xanthone monoglycoside clearly showed the dependence of ES on the solvent composition. In the negative ion mode with TFA or NH_4OAc, adducts of the respective anions $[M+TFAc]^-$ and $[M+Ac]^-$ were observed. The TFAc adducts were not fragmented by upfront CID while the Ac adducts

were easily cleaved, leading to $[M-H]^-$ ions and aglycone fragments $[A-H]^-$. ES and CF-FAB (pos. mode) only produced weak $[M+H]^+$ ions; TSP gave intense $[M+H]^+$ and $[A+H]^+$ ions.

In the case of triterpene glycosides (saponins), CF-FAB and TSP have already been used (3). Generally if more than 2 sugars were attached, TSP gave mainly aglycone information. CF-FAB, on the other hand, yielded both aglycone and sugar sequence information. ES was compared to these two latter techniques for the analysis of saponins bearing 2-5 sugars in the MeOH extract of *Swartzia madagascariensis* (Leguminosae) and *Phytolacca dodecandra* (Phytolaccaceae). By looking at the molecular weight ion traces of these different saponins, ES (neg. mode) was the method of choice (best sensitivity and peak shape). With NH_4OAc as buffer, some structural information was obtained by upfront CID, but the complete sugar sequence was not always observed. With TFA, only strong $[M+TFAc]^-$ were present and were not cleavable by upfront CID or MS/MS on the TSQ. In order to perform MS/MS on the strong TFA adducts produced in ES, a prototype of the new ion trap system LCQ from Finnigan MAT, equipped with an external API source, was used . CID of TFA adducts occurred at a very high yield in the ion trap. It was not possible to obtain all the sugar sequence information in one MS/MS measurement. Application of an MS^n experiment however yielded the complete sequence information. By adjusting the collision energy it was possible to cleave only one sugar at a time in a pentaglycosylated saponin, making the interpretation of the spectra very simple. The time requirement for switching between the different stages of the MS^n experiment was about 50 ms. Therefore three to four stages of the MS^n experiment could be readily performed during the time of a normal LC peak.

The comparison of techniques such as ES, APCI, TSP or CF-FAB has shown the complementarity of these various approaches. If API techniques are now easy to handle, they are also rather selective and are not always superior to the older techniques. Solution chemistry has always to be taken into account. Used in a suitable way, it provides an additional tool in LC-MS and can be used to increase sensitivity or to control the fragmentation of the ions formed. Looking at the different results makes it clear that ionisation of plant metabolites has to be investigated in more depth. There is still need to establish rules to predict the types of ions generated from the different classes of compounds in all these interfaces. For all techniques, MS/MS is an important additional feature. Comparison of MS/MS experiments of TSQ and ion trap shows that collision efficiencies are significantly higher in an ion trap than in the collision cell of a TSQ, probably due to the much higher residence time of ions in the trap. It has been shown that the MS^n experiments which can be carried out in ion traps represent a very powerful tool for on-line identification of plant metabolites.

Angiotensin II Receptor Antagonist Metabolite Identification by MS/MS

William DeMaio and George Morton
American Cyanamid Company*, Drug Metabolism Department
Pearl River, NY 10965
*** Current name is Wyeth-Ayerst Research**

CL 190,064 (cis-(+/-)-2-Butyl-6-(hexahydropyrrolo[1,2,-b]isoxazol-2-yl)-3-[[2'-(1H-tetrazol-5-yl)[1,1'-biphenyl]-4-yl]methyl]-4(3H)-quinazolinone) is an angiotensin II receptor antagonist with potential for use in the treatment of hypertension. The metabolism of CL 190,064 was investigated in rat liver preparations. Metabolites were purified from rat liver preparations prior to FAB-MS, MS/MS and NMR spectroscopic analyses. A Finnigan MAT TSQ 70 triple quadrupole mass spectrometer was used for FAB-MS and MS/MS analyses. Two metabolites of CL 190,064 isolated from rat liver preparations were analyzed to identify their structures. The Summary Figure contains the structures of CL 190,064 and two of its metabolites, A and B, which were identified as described below:

Comparison of the product ion mass spectra of CL 190,064 and its methyl substituted analog, CL 190,133 showed which product ions contained the "methyl label." CL 190,133 product ions 14 Da greater than corresponding CL 190,064 product ions indicated the presence of the carbon atom at position 5 of the isoxazole. Both CL 190,064 and CL 190,133 lose C_4H_6NO (85 Da) from the hexahydropyrrolo-isoxazole to give the *m/z* 463 and 477 product ions, respectively. For CL 190,064, the biphenyl-tetrazole system fragments from the quinazolinone to form the *m/z* 229 and 207 fragments. For CL 190,133 this process forms the *m/z* 243 and 207 fragments. The *m/z* 420 fragment of CL 190,064 and *m/z* 434 for CL 190,133 seemed to form directly from the molecular ion. The structure of these ions were assigned with less confidence than the other structures shown.

The molecular weight of A was 549, 2 Da higher than CL 190,064. The product ion spectrum of *m/z* 550 shows the same product ions as for CL 190,064. This means that the metabolism took place on the hexahydropyrrolo-isoxazole atoms which were lost to form the *m/z* 463 product ion. These data do not precisely indicate the specific site of metabolism to form A. For the NMR spectra of metabolite A vs. CL 190,064 in d6DMSO/TFA, H5' shifted upfield from 4.76δ to 3.0-3.7δ. H6' shifted upfield from 2.2-2.8δ to 1.8-2.4δ. H7' shifted upfield from 5.91δ to 4.93δ. The proposed structure for metabolite A was synthesized and found to have an HPLC retention time, molecular weight and product ion mass spectrum matching that for metabolite A.

Metabolite B is 16 Da larger than CL 190,064 and 14 Da larger than A and has a similar product ions spectrum as A. For the NMR spectra of metabolite B in CD_3OD and CL 190,064 in CD_3OD/NaOD, H2' was not present in metabolite B. H3' shifted from 1.78δ to 2.31δ. H6' shifted from 2.48δ to 1.95δ. H7' shifted from 5.25δ to ~4.9δ. Since H2' is missing and the mass spectrum indicates a net gain of 14 Da, the lactam structure is a good choice and this would be consistent with a conversion of metabolite A to metabolite B by addition of oxygen at C2'.From the exploratory metabolism study, we know that B most likely was formed from A. Therefore, B is formed by substitution of an oxygen atom for two hydrogen atoms of A.

IN VITRO HEPATIC METABOLISM OF TACROLIMUS (FK506) USING SIMS and MALDI MASS SPECTROMETRY

Arkady I GUSEV[1]; David C. Muddiman[1,3]; Andrew Proctor[1]; David M.Hercules[1,4]; Prasad Tata[2]; Raman Venkataramanan[2].

[1] Department of Chemistry, University of Pittsburgh, Pittsburgh PA 15260; [2] School of Pharmacy, University of Pittsburgh, Pittsburgh PA 15261; [3] present address: Chemical Methods and Separation group, Chemical Sciences, Department, Pacific Northwest Laboratory, Richland WA 99352;[4] present address: Department of Chemistry, Vanderbilt University, Nashville, TN 37235.

Tacrolimus is a recently approved immunosuppressive agent efficient in preventing the rejection of transplanted organs. However the chemical nature of its metabolites and their pharmacological activity and toxicity is not completely understood. *In vitro* results reported by other groups indicate that de-methylation and hydroxylation are the major metabolic pathways [1,2]. The objective of this work was application of matrix assisted laser desorption ionization (MALDI) time-of-flight (TOF) mass spectrometry and TOF secondary ion mass spectrometry (SIMS) for qualitative and quantitative analysis of the *in-vitro* hepatic metabolism of Tacrolimus.

Baboon microsomal preparations (2mg/mL) were incubated up to 60 min at 37°C with Tacrolimus in the presence of 20mM NADPH. 100-200μL of these incubates were mixed with Rapamycin and then extracted with ethyl ether. Ether was evaporated under a stream of nitrogen [3]. The residues were reconstituted in 150 μL of ethanol - water (1:1) before analysis. The MALDI matrix used in this study [2,5-dihydroxybenzoic acid (DHB) (20 mg/mL):fucose (2 mg/mL) dissolved in 1:9 ethanol-water] was mixed with each sample in a volume ratio of 1:1 [4]. A 2-μL aliquot of this mixture was deposited on polished stainless steel substrates and dried in high purity N_2. Sample preparation for SIMS analysis involved deposition of 1-μL of aliquots on previously etched silver substrates [8].

Several matrices i.e. sinapinic acid, ferulic acid, etc, have been evaluated for analysis of Tacrolimus (TAC). The best matrices were found to be DHB and DHB/fucose. The major limiting factor was the relatively large contamination resulting from the simple ether extraction from microsomal incubates. However, DHB and DHB/fucose provided consistent results for both methanol and ether extracts. The major peaks in MALDI were due to Na and K-cationization which led to some peak overlaps. SIMS spectra had the major peaks due to silver ($Ag^{107/109}$) cationization, hence, provided complementary results for metabolite identification. The difference between the major metabolite peaks and parent drug peak was found to be 14 Da, which indicates that these are mono and double de-methylated species i.e., (TAC-CH_3+H+Na, 812.5Da) and (TAC-$2CH_3$+2H,+Na, 898.5Da). Figure 1 presents the time course of *in-vitro* hepatic metabolism of Tacrolimus. Based on MALDI and SIMS results, 7 metabolites have been identified.

Quantification of the Tacrolimus was carried out using the MALDI instrumental protocol which is described elsewhere [4]. TOF SIMS application for quantitative analysis of immunosuppressive drug cyclosporin A is also described elsewhere [5]. Rapamycin was used as the internal standard for both SIMS and MALDI analysis. The relative standard deviation of the slope was 1.3-2.5% and the correlation coefficient (r_o) was 0.9980-0.9998. Using a proof of equal instrumental sensitivity for Tacrolimus and its major metabolite, Tacrolimus and de-methylated and double de-methylated metabolites have been quantified, Figure 2. SIMS and MALDI produced similar results. Thus successful application of MALDI and TOF SIMS for

qualitative and quantitative analysis of Tacrolimus hepatic metabolism has been demonstrated.

Identification of Levodopa and its Metabolites by HPLC-Ion Spray-MS

Mohammed R. Koupai-Abyazani, Barbara Esaw and Barbara Laviolette
Can Test Ltd., 1523 West 3rd Avenue, Vancouver, B.C., V6J 1J8, Canada

A combination of levodopa (*L*-3,4-dihydroxyphenylalanine) and a decarboxylase inhibitor such as carbidopa is used therapeutically in the treatment of Parkinson's disease. Levodopa is extensively metabolized in the human body mainly by decarboxylation to dopamine and also by methylation to 3-O-methyldopa. Other metabolites are 3,4-dihydroxyphenylacetic acid (DOPAC) and 3-methoxy-4-hydroxyphenylacetic acid (homovanillic acid, HVA).

HPLC with electrochemical detection is the most common technique used for the analysis of levodopa and its metabolites. This identification, however, is solely based on the comparison of the retention times of the compounds with those of the standard references. The application of a mass spectrometer as a detector for HPLC provides structural information which confirms the identification especially in complex matrices. This paper presents a liquid chromatographic-atmospheric pressure ionization mass spectrometric (API LC/MS) method for the analysis of levodopa and its metabolites in equine urine and serum. The method consisted of alumina extraction, isocratic separation of the compounds on a RP-18 column and detection using an API MS with ion spray interface.

Urine and serum samples (up to 24 h) collected from a standardbred mare after oral administration of 2 g levodopa and 500 mg carbidopa were analyzed. The HPLC analysis of levodopa and its metabolites requires the use of an ion-pair reagent such as 1-octanesulfonic acid in order to improve the retention and separation of these polar compounds on a reversed-phase column. The isocratic separation of these compounds demonstrated better reproducibility than the gradient elution.

The positive ion mass spectra of levodopa, its metabolites and carbidopa exhibited $[M+H]^+$ ion, with the exception of DOPAC and HVA which showed strong adduct ion $[M+NH_4]^+$ and weak $[M+H]^+$ ion. The $[M+H]^+$ ion was the base peak in the mass spectra of levodopa and 3-O-methyldopa while $[M+NH_4]^+$ ion was the base peak in the case of DOPAC. Other characteristic fragments in the mass spectra of some of the compounds were: $[M-NH_3+H]^+$ ion (M-16), $[M-COOH]^+$ ion (M-45) and $[M-HCCOOH]^+$ ion (M-58). The major ions observed in the positive mode mass spectra of these compounds are listed in Table 1. Figure 1 shows the positive ion mass spectrum of levodopa. The application of the method was demonstrated for the analysis of equine serum and urine.

Urine and serum samples were analyzed using the LC/MS method. The levodopa metabolites, dopamine, DOPAC and HVA were detected in all the administration urine samples collected. Figure 2 shows the extracted ion chromatograms of levodopa and its metabolites in a 12-14 h post-administration urine sample. The parent drug, however, was detected in the serum at the early collection times. Several administration samples were hydrolyzed in order to investigate the presence of conjugates of levodopa and its metabolites. The comparison of the chromatograms obtained for these samples before and after hydrolysis did not

exhibit the presence of any drug conjugates in the administration samples studied. The analysis of several pre-administration urine samples (blanks) did not show any naturally occurring levodopa and its metabolites under the conditions reported in this work.

Table 1. Major ions and relative abundances in positive ion mass spectra of levodopa, its metabolites and carbidopa.

Compound	MWt	Major ions (relative abundance)
Levodopa	197	198(100), 181(20), 152(74), 139(28)
Dopamine	153	154(54), 137(100), 119(25), 91(22)
3-O-methyldopa	211	212(100), 195(35), 166(60), 153(44)
HVA	182	200(71), 183(5), 137(7), 18(100)
DOPAC	168	186(100), 169(2), 123(4), 18(94)
Carbidopa	226	227(95), 195(9), 181(100), 139(19), 123(15)

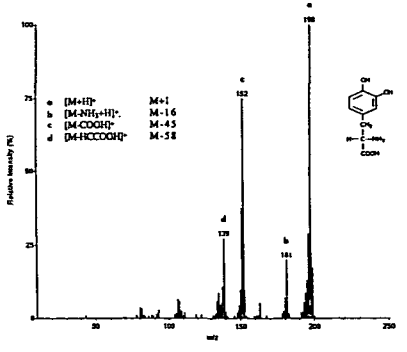

Figure 1. Positive ion mass spectrum of levodopa.

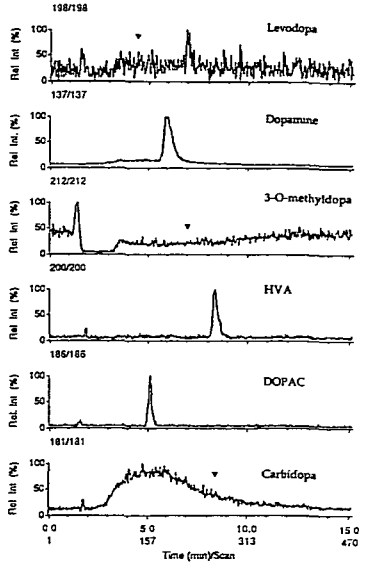

Figure 2. Extracted ion chromatograms of levodopa and its metabolites in a 12-14 h post-administration urine sample. The arrow shows the location of the peak in each chromatogram.

Identification of the urinary metabolites of Brivudin in the rat.

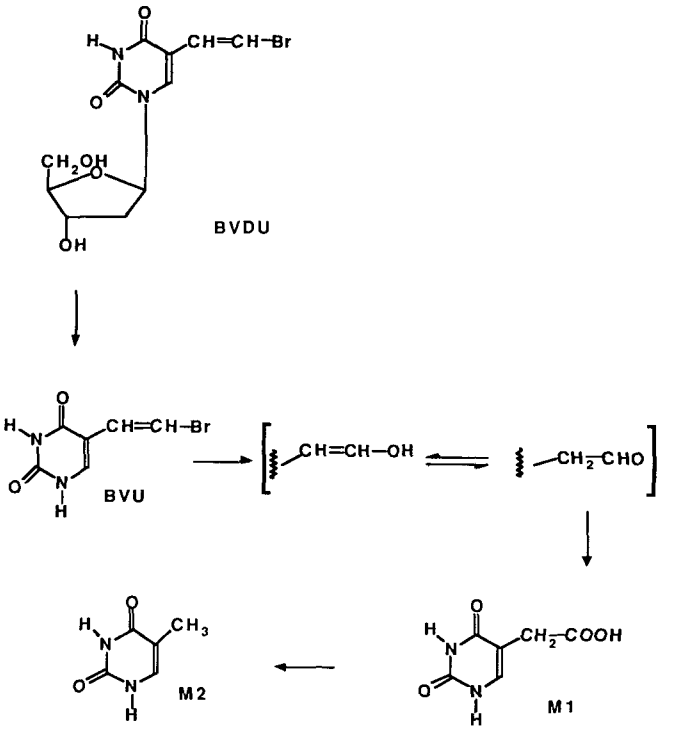
Brivudin (5-(2-Bromo-E-ethenyl)-2'-deoxyuridine, BVDU) is a modified deoxynucleoside characterized by potent anti-herpetic activity, expecially against herpes simplex virus type 1 (HSV-1) and varicella-zoster virus (VZV). Since its introduction in 1979, very few information about its biotransformation have been obtained. Early work by Y. Robinson et al., dated 1984, detected a prominent plasma metabolite in various animal species and in man, and identified it as the deglycosylated drug, that is 5-(2-bromo-E-ethenyl)uracil (BVU) [1]. Other in vivo and in vitro studies in the rat by C. Desgranges et al. [2] showed that BVU is not metabolized by the usual catabolic pathway of pyrimidines, and acts as an inhibitor of the metabolization of pyrimidines such as thymine and 5-fluorouracil. During the investigation of the metabolism of BVDU, two other metabolites besides BVU were detected by us after analysis by reverse-phase HPLC with radioactive detection in the urines of rats treated with the C2-radiolabeled compound. These metabolites, M1 and M2 respectively, were characterized by much higher polarity with respect to BVDU and BVU, as deduced by their HPLC retention times; their UV spectra, taken during an HPLC run by means of a diode-array UV detector, were different from that of the parent compound (showing two characteristic strong bands at 250 and 290 nm due to vinyl conjugation to the pyrimidine system), and quite similar to natural pyrimidine bases such as uracil (one band at about 260 nm).

Given the high polarity of M1 and M2, which caused their HPLC coelution with a great number of endogenous substances and rendered their detection by direct HPLC-MS urine analysis very troublesome, extraction and fractionation of pooled rat urine was undertaken: urine was extracted with ethyl acetate using an Extrelut® column, obtaining an extract containing M2, whereas M1 was eluted after washing with methanol. The extracts were furtherly purified by preparative HPLC

EI-MS and proton NMR analysis of the M2 fraction allowed easy identification of thymine, whereas M1 identification still could not be achieved, due to either difficulties in obtaining a satisfactorily pure fraction, or to difficulties in mass spectrometric investigation, which was performed unsuccessfully by a variety of ionization techniques (EI, DCI, FAB, Ion spray with

flow-injection analysis). Finally, a partially purified fraction of M1 was subjected to HPLC-tandem MS with Ion spray ionization, and the fragmentation pattern obtained from the collisionally-activated decomposition of the identified quasi-molecular ion (m/z 171), allowed identification of M1 as ((1H,3H)pyrimidine-2,4-dione-5-yl)acetic acid. The assignment was then confirmed by comparison with a sinthetic standard.

From the above data, the following metabolic scheme is proposed:



[1] Y. Robinson, N. Gerry, R. D. Brownsill, C. W. Vose, Biomed. Mass Spectrom. 11(4) 199 (1984).

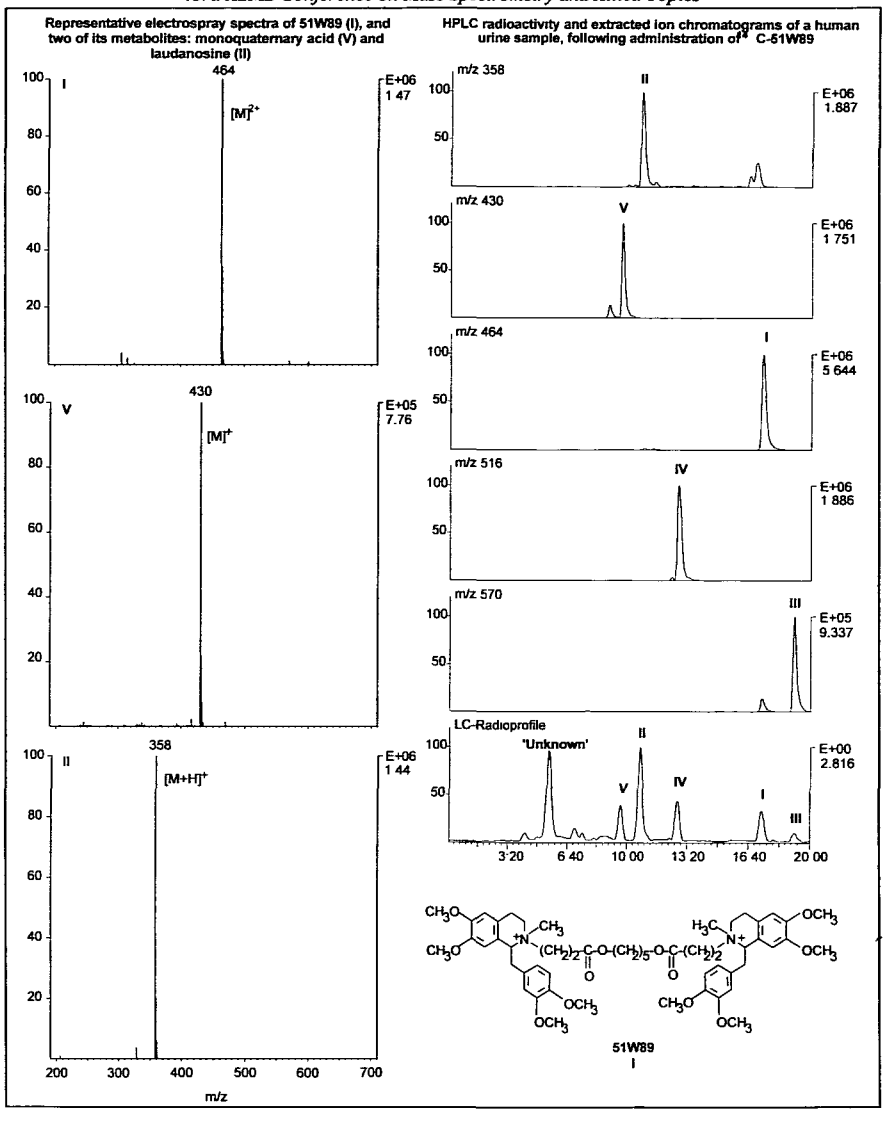
METABOLISM OF THE NEUROMUSCULAR BLOCKER CISATRACURIUM (51W89) BY LC-MS WITH SIMULTANEOUS RADIOACTIVITY MONITORING (LC-RAM-MS).

G.J. DEAR, A.E. JONES AND S. PLEASANCE
GLAXO-WELLCOME, Group Development Operations, Department of Bioanalysis and Drug Metabolism, Langley Court, Beckenham, Kent, BR3 3BS, U.K.

Cisatracurium, (1*R*, 1'*R*, 2*R*, 2'*R*)-2,2-(3, 11-Dioxo-4, 10-dioxatridecamethylene) bis (1, 2, 3, 4-tetrahydro-6, 7-dimethoxy-2-methyl-1-veratrylisoquinolinium) dibenzenesulphonate (51W89, see Figure), is an intermediate-acting neuromuscular blocking agent. 51W89 is one of ten isomers contained in TRACRIUM® (atracurium besylate) and represents approximately 15 percent of the atracurium mixture. Clinical studies have indicated that 51W89 is more potent and is significantly weaker as a histamine releaser than atracurium. *In vitro* studies in human plasma have shown that, like atracurium, 51W89 spontaneously degrades at physiological pH by Hofmann elimination to form laudanosine (**II**) and the quaternary monoacrylate (**III**). Subsequent ester hydrolysis of the monoacrylate generates the monoquaternary alcohol (**IV**). In rat plasma, 51W89 is also metabolised by non-specific carboxylesterases to the monoquaternary alcohol and the monoquaternary acid (**V**), the former being rapidly hydrolysed further to the more stable acid. It has been reported that laudanosine can be further metabolised via *N*-demethylation to yield tetrahydropapaverine (**VII**). The rate limiting step in the degradation of 51W89 in human plasma is Hofmann elimination, whilst in rat plasma, the action of non-specific carboxylesterases is rate limiting.

The disposition of ^{14}C-51W89 following a single intravenous bolus dose has been studied in various animal species and humans, and in the present work we describe the identification of 51W89 metabolites in urine and bile samples from these studies by high performance liquid chromatography mass spectrometry with simultaneous detection by a radioactivity monitor (LC-RAM-MS). All experiments were conducted on a Hewlett Packard Model 1090 liquid chromatograph coupled in series to a Bertold LB 507B radioactivity monitor and a Finnigan-MAT TSQ-700 mass spectrometer. The effluent from the RAM (1 ml/min) was directed to an electrospray interface without splitting and the ^{14}C radioactivity signal was connected to the TSQ-700 data system. Separations were achieved on a 250 x 4.6 mm i.d. Zorbax Rx-C8 column (Dupont) operated at 40°C, using gradient elution and a mobile phase consisting of 25mM aqueous NH_4 formate (pH 3.5) and acetonitrile.

Under electrospray ionisation, 51W89 is observed as its doubly-charged molecular species, $[M]^{2+}$, at m/z 464, by virtue of its two quaternary nitrogens (see Figure). The metabolites are observed as either singly charged molecular species, $[M]^+$, (**III, IV** and **V**) or protonated molecules, $[M+H]^+$, (**II** and **VII**). The extracted-ion chromatograms for 51W89 and its metabolites, **II-V**, from a human urine sample (0-8hr post-dose) compare very favourably with the simultaneously acquired radioprofile (see Figure). The ability to obtain molecular weight information directly from radioactive peaks enabled not only the confirmation of expected metabolites but also the detection of a number of urinary and biliary conjugated metabolites which co-chromatographed with an early eluting 'unknown' peak in the radioprofile (see Figure). Using a combination of enzyme hydroysis and tandem mass spectrometry these were identified as *O*-glucuronic acid conjugates of monodesmethyl laudanosine and monodesmethyl tetrahydropapaverine. A sulphate conjugate of monodesmethyl laudanosine was also identified in cat bile.



Development of A Sensitive LC/ESI/MS/MS Assay for the Antineoplastic Agents Cyclophosphamide and Ifosfamide. Charles A. Goldthwaite, Jr.[1], Frank J. Belas[1], Mark A. Phillips[1], Lowell Anthony[2], and Ian A. Blair[1,3]. Departments of [1]Pharmacology, [2]Oncology and [3]Chemistry, Vanderbilt University School of Medicine, Nashville, TN 37232.

Cyclophosphamide (2-bis(2-chloroethyl)amino tetrahydro-2H-1,3,2-oxazaphosphorine 2-oxide; CPA), a synthetic antineoplastic alkylating agent, is widely used in chemotherapy due to its capacity to undergo hepatic metabolic activation rather than alkylating cells directly. CPA is metabolized *in vivo* by cytochromes p450 into 4-hydroxy-CPA (4-OH-CPA) which exists in equilibrium with its acyclic tautomer, aldophosphamide (AP). AP spontaneously decomposes via a beta-elimination cleavage into stoichiometric amounts of the active cytotoxins acrolein and phosphoramide mustard (PM). Ifosfamide (3-(2-chloroethyl)-2-(2-chloroethylamino) tetrahydro-2H-1,3,2-oxazaphosphorine 2-oxide; IFOS) is a recently approved oxazaphosphorine alkylating agent used in cancer chemotherapy as an antitumor agent and immunosuppressant. A nitrogen mustard derivative and structural isomer of cyclophosphamide (CPA), IFOS has been successfully utilized in the treatment of non-Hodgkin lymphomas and solid malignomas such as bronchogenic carcinoma and certain sarcomas. Analogous to CPA, IFOS is a prodrug hepatically activated by a microsomal mixed-function oxygenase, although its metabolism may proceed through a different mechanism than CPA metabolism generating a different toxicity profile. Side-chain oxidation and subsequent liberation of the toxin chloroacetaldehyde comprises a competitive metabolic pathway to the ring oxidation at the C4 position (generating 4-OH-IFOS) observed with CPA. 4-OH-IFOS undergoes a subsequent spontaneous beta-cleavage to generate the active cytotoxins acrolein and IFOS-phosphoramide mustard (IFOS-PM). Consequently, serum concentrations of IFOS-PM are lower than those of the corresponding activated CPA mustard measured after administration of the same dose of parent compound, and IFOS is usually administered in greater dose than CPA.

Gas chromatography/mass spectrometry (GC/MS) and methodologies based upon high performance liquid chromatography (HPLC) with ultraviolet (UV), fluorescence and electrochemical detection have been developed to quantitate CPA and its metabolites in biological fluids. However, none of these techniques offers the sensitivity and rapid analysis time necessary for extensive clinical analyses. Consequently, we have developed an accurate, precise, rapid, and specific LC/MS assay for CPA and IFOS utilizing on-line coupling of an HP 1090 Series II LC with a Finnigan TSQ 7000 mass spectrometer. The chromatographic system consisted of a Zorbax C_8 reverse-phase column (2.1 x 150 mm; 5 μm) operated at 50 °C using a flow rate of 200 μL/min and a methanol/water solvent system containing 0.05% (v/v) acetic acid. Chromatographic conditions were as follows: A 65:35 H_2O:MeOH solution was held isocratically for thirteen min followed by a linear gradient to 80% MeOH in eight min. This condition was held isocratically for an additional five min prior to a ten min re-equilibration.

Mass spectrometric analysis was conducted using electrospray ionization (ESI) with a needle voltage of 4.5 kV. All operating parameters were optimized using CPA. Nitrogen was used as the sheath gas (65 psi) and the auxiliary gas (20 psi) to assist with nebulization. The capillary was heated to 200 °C to provide optimal desolvation, and the ES interface and mass spectrometer parameters were optimized to obtain maximum sensitivity without sacrificing unit resolution. Trofosfamide (N,N,3-Tris(2-chloroethyl)tetrahydro-2H-1,3,2-oxazaphosphorin-2-amine 2-oxide; TROFOS) was utilized as the internal standard, and selective reaction monitoring (SRM) experiments were conducted for each analyte. Figure 1 represents an LC/ES MS/MS analysis from an on-column injection of 800 pg each of CPA, IFOS and TROFOS displaying ion current chromatograms for *m/z* 323 → *m/z* 154 (TROFOS; top panel), *m/z* 261 → *m/z* 140 (CPA) and *m/z* 261 → *m/z* 154 (IFOS; middle panel) and the total ion current (bottom panel) for a gradient analysis. As seen in the Figure, IFOS and CPA were separated

to baseline resolution and eluted at 10.2 min and 11.4 min, respectively. TROFOS eluted at 24.1 min.

During SRM studies, a collision offset energy of -24.0 eV and a collision cell pressure of 2.48 mTorr were employed to induce fragmentation within the collision cell. Argon was used as the collision gas. The tube lens and the capillary were optimized for operation at 110.4 V and 20.0 V, respectively, and the electron multiplier was set at 1600 V. This technique allows for reproducible, specific, rapid and precise analysis of these compounds and will be validated for determination and quantitation of these antineoplastic agents in biological media.

This work was supported by NIH grant CA 68485-01.

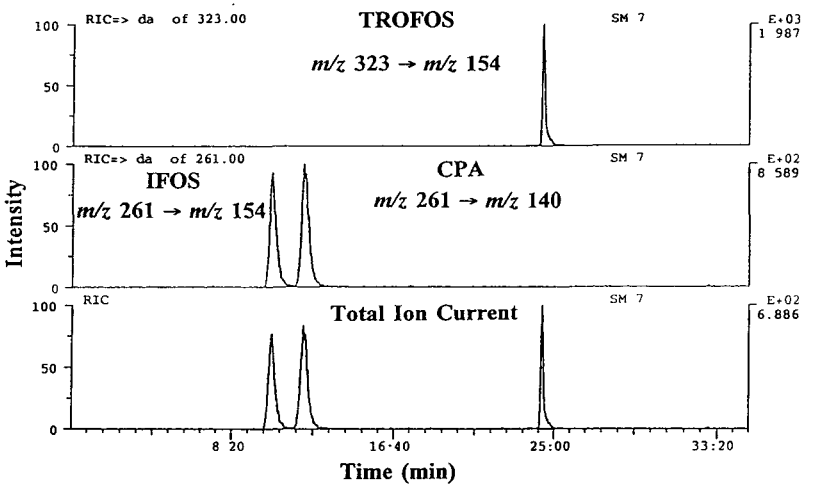


Figure 1. LC/ES MS/MS analysis from an on-column injection of 800 pg each of CPA, IFOS and TROFOS displaying ion current chromatograms for *m/z* 323 → *m/z* 154 (top panel), *m/z* 261 → *m/z* 140 and *m/z* 261 → *m/z* 154 (middle panel) and the total ion current (bottom panel) for a gradient analysis.

Determination of 2-Amino-5,6-dichloro-3,4-dihydroquinazoline, a Major Urinary Metabolite of Anagrelide, by Liquid Chromatography/Tandem Mass Spectrometry (LC/MS/MS)

Frank J. Belas[1], Suresh N. Yeola[1], Carlos O. Garner[3], Samir A. Saleh[1], Ajai K. Chaudhary[1,2], Bruce H. Migdalof[4], and Ian A. Blair[1,3]. Departments of Pharmacology[1], Biochemistry[2], and Chemistry[3], Vanderbilt University School of Medicine, Nashville, TN 37232 and Roberts Pharmaceutical Corporation[4], Meridian Center III, 6 Industrial Way West, Eatontown, New Jersey 07724

Anagrelide (6,7-dichloro-1H-2,3,4,5-tetrahydroimidazo-[2,1-b]-quinazolin-2-one monohydrochloride) is a potent inhibitor of agonist-induced platelet aggregation (Fleming and Buyniski, 1979), and its major urinary metabolite is 2-amino-5,6-dichloro-3,4 dihydroquinazoline (Figure 1). The present study was initiated in order to help delineate the fate of anagrelide after dosing human subjects. The assay is based upon liquid chromatography/tandem mass spectrometry (LC/MS/MS) using the monochloro-analog of anagrelide, 6-chloro-1,5-dihydroimidazo-[2,1-b]-quinazolin-2(3H)-one, as the internal standard (Figure 1).

Liquid chromatography was conducted using a Hewlett-Packard 1090 series II liquid chromatograph equipped with a Zorbax Rx C-8 column (2.1 mm x 150 mm, 5 μm) interfaced with a Finnigan TSQ 7000 triple quadrupole mass spectrometer operating with an electrospray ionization (ESI) source. Solvent A was 5 mM aqueous ammonium acetate containing 0.5 % (v/v) acetic acid and 0.02 % (v/v) trifluoroacetic acid, and solvent B was 5 mM ammonium acetate in acetonitrile:water (9:1) containing 0.5 % (v/v) acetic acid and 0.02 % (v/v) trifluoroacetic acid. The flow rate was 200 μL/min. The solvent composition was held at 85 % A:15 % B for 4 minutes after which a linear gradient to 20 % A:80 % B was employed over the following 8 minutes. The solvent composition was held at 20% A : 80% B for 1 minute and was then returned to the initial conditions during the next 3 minutes. Samples were dissolved in a total volume of 2 mL, and 50 μL of this solution was injected on column. The mean retention times for the metabolite and internal standard were 12.50 and 12.27 min, respectively.

Mass spectrometry studies were conducted using a Finnigan TSQ 7000 triple quadrupole mass spectrometer operating with an ESI needle voltage of 4.5 kV. Nitrogen was used as the sheath gas (70 psi) and the auxiliary gas (25 psi) to assist with nebulization. The capillary was heated to 240 °C to provide optimal desolvation, and the ESI interface and mass spectrometer parameters were optimized to obtain maximum sensitivity without sacrificing unit resolution. A selected reaction monitoring (SRM) experiment was conducted by monitoring the *m/z* 216 → *m/z* 199 transition of the metabolite. Similarly, for the internal standard, the *m/z* 222 → *m/z* 165 transition was monitored. An SRM ion current profile from urine (1 mL) containing metabolite (17.2 ng) and internal standard (20.0 ng) is shown as Figure 2. Calibration curves obtained by plotting the peak height ratio of metabolite to internal standard against the amount of metabolite added to the urine were linear in the range 1.7 ng/mL to 86.1 ng/mL using a weighted (1/concentration) least squares regression analysis. Correlation coefficients of 0.995 or better were obtained. The within-day precision of the method was determined from the relative standard deviation (RSD) of the mean for seven replicate analyses of the three control

pools on each of three days. The overall precision of the method was determined from the RSD of the mean of 21 analyses of the three control pools over 3 days. The within-day precision of the metabolite assay ranged from 3.7 % to 9.7 % RSD at the three control concentrations in human urine during the three days of the assay. The overall precision was 8.4 % for the lower quality control (LQC), 5.9 % for the middle quality control (MQC), and 6.5 % for the upper quality control (UQC), respectively. The accuracy of the urine metabolite assay was determined by comparing the means of the measured concentrations with the theoretical concentrations of metabolite in the urine controls. The overall mean values, at each level, did not exceed 8.8 % of their expected values. The lower limit of quantitation (LLQ) of the anagrelide urinary metabolite was 1.72 ng/mL. At this level, the RSD (n = 7) of the measured concentrations was 13.1 %. The deviation of the mean of the measured concentration from the theoretical concentration (DEV %) was -9.5 %.

The method presented for the determination of the urinary metabolite of anagrelide in human urine shows acceptable specificity, linearity, precision, and accuracy for the determination of metabolite concentration at a lower limit of quantitation of 1.7 ng/mL. The method is simple, robust, amenable to high sample throughput and further illustrates the utility of LC/MS/MS methodology for obtaining quantitative information from clinical studies.

STRATEGIES FOR THE QUANTITATIVE ANALYSIS OF OPIOID PEPTIDES IN PLASMA

Cristina Marquez and Philip C. Smith
The University of North Carolina at Chapel Hill

Robert T. Streeper and Susan T. Weintraub
The University of Texas Health Science Center at San Antonio

Structural elucidation and quantitative analysis of biologically active peptides are of considerable importance in understanding both the roles that these peptides play in normal and disease states as well as in the development of peptide-based pharmaceuticals. Neuroactive peptides are of particular interest due to the probability that disorders of neuropeptide processing are responsible for various pathological conditions. Essential to the study of neuropeptide pharmacology is the development of specific and sensitive analytical methods. Problems with many currently used assays for neuropeptides have led us to employ HPLC-ESI/MS/MS for the quantitative analysis of neuropeptides. The high degree of selectivity and sensitivity of this technique combined with the shortened analysis times and minimal requirements for sample preparation make LC-ESI/MS/MS ideal for analysis of samples of biological origin. This presentation describes the quantitative analysis of two opioid peptides, Met-enkephalin-Arg-Gly-Leu (Tyr-Gly-Gly-Phe-Met-Arg-Gly-Leu) and DSLET (Tyr-D-Ser-Gly-Phe-Leu-Thr) in plasma, using microbore-HPLC-ESI/MS/MS. Application of the analytical method to study the disposition of DSLET in rats is also described.

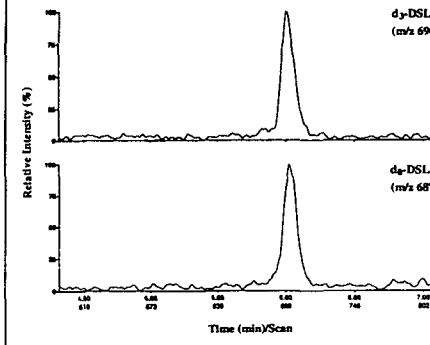
Peptide Stability - Stability studies were performed *in vitro* by incubation of each peptide at a concentration of 100 µg/ml in 25% plasma. Aliquots were removed at intervals between 0 and 30 min and the peptide quantified by HPLC with UV detection at 214 nm. The half-life of Met-enkephalin-Arg-Gly-Leu in 25% plasma was found to be 40 min while for DSLET $t_{1/2}$ was 480 min.

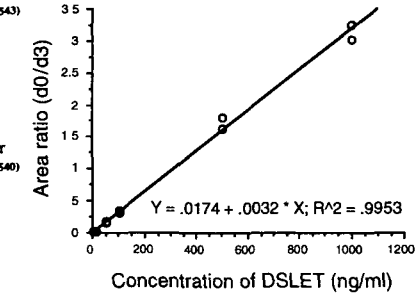
Sample Preparation - Standard samples were prepared by serial dilution and added to 0.5 ml of human plasma (0 - 1000 ng of peptide/ml of plasma). The corresponding deuterated internal standards were added to yield 50 ng/ml for Met-enkephalin-Arg-Leu-Gly-d_{10} (Tyr-Gly-Gly-Phe-Met-Arg-[$^2H_{10}$]Leu-Gly) and 10 ng/ml for DSLET-d_3 (Tyr-D-Ser-Gly-Phe-[$^2H_3$]Leu-Thr). The peptides were isolated from the plasma by solid-phase (C18) extraction. The peptide fractions were dried *in vacuo* and reconstituted in 25 µl of mobile phase prior to analysis by HPLC-ESI/MS/MS. Extraction recovery was assessed by radioactivity monitoring of [^{3}H]-DSLET and by HPLC with UV detection for Met-enkephalin-Arg-Gly-Leu and its deuterated analog. The overall recoveries were: Met-enkephalin-Arg-Gly-Leu, 65%; DSLET, 85%.

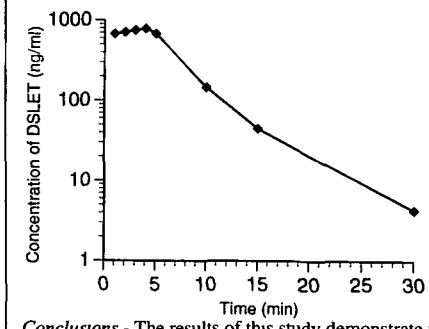
Mass Spectrometry - Electrospray ionization mass spectra were acquired on a Sciex API III mass spectrometer fitted with an ionspray interface. MS conditions were: ionspray voltage, 5500 V; orifice voltage, 60 V; collision gas, argon; collision energy, -20 V for Met-enkephalin-Arg-Gly-Leu and -25 V for DSLET; collision gas thickness, 131 for Met-enkephalin-Arg-Gly-Leu and 120 for DSLET. A polypropylene glycol mixture was utilized for instrument calibration.

HPLC - Chromatographic fractionation was accomplished by means of an Applied Biosystems model 140B solvent delivery system in conjunction with a Keystone Hypersil BDS C18 column (1.0 x 50 mm) fitted with a 20 mm guard column. The flow rate of the mobile phase was 50 µl/min. The binary solvent system consisted of: solvent A, 2 mM ammonium acetate, pH 4.4; solvent B, 60% aqueous acetonitrile. The gradient was produced by increasing the concentration of B from 20 to 80% over 10 min at which time the mobile phase was maintained at 80% B for an additional 2 min. A Valco switching valve that was connected to the mass spectrometer by a short length of fused silica capillary tubing was utilized to direct the effluent from the HPLC. The fractions eluting prior to 5 min were discarded. In order to ensure stability of the electrospray ion current, a 10-µl/min flow of 60% acetonitrile/2 mM ammonium acetate, pH 4.4 (1:1) was maintained through the interface during the initial 5-min period.

Quantitative Analysis - Quantification of peptides was accomplished by selected reaction monitoring of the following transitions: Met-enkephalin-Arg-Gly-Leu, m/z 450.5—>136.0 for d_0 and m/z 455.5—>136.0 for d_{10}; DSLET, m/z 687.0—>540.0 for d_0 and m/z 690.0—>543.0 for d_3. A representative selected ion retrieval chromatogram is shown below along with a typical standard curve for DSLET added to plasma. Linearity was routinely observed for both peptides over the range of 5 to 1000 ng/ml, with a limit of detection of 0.25 ng/ml for Met-enkephalin-Arg-Gly-Leu. A comparison of approaches to evaluate the standard curve data showed that a linear regression weighted by 1/x gave a better fit for the low mass range than when a non-weighted regression was employed.







DSLET Disposition in Rats - The disposition of DSLET was examined in rats administered an intravenous dose of 10 mg/kg of the peptide. Arterial blood samples (0.25 ml) were collected at intervals between 0 and 30 min after injection. After addition of 10 ng/ml DSLET-d_3, the peptide fraction was isolated as described above. A representative concentration-time profile is shown to the left.

In agreement with the results obtained by other methods, quantitative analysis by HPLC-ESI/MS/MS showed that DSLET has a short half-life and high clearance value.

Conclusions - The results of this study demonstrate that HPLC-ESI/MS/MS can be utilized for quantitative analysis of Met-enkephalin-Arg-Gly-Leu and DSLET in plasma. A 5-fold lower detection limit was observed for Met-enkephalin-Arg-Gly-Leu as compared to DSLET. However, DSLET exhibited a broader range of linearity than Met-enkephalin-Arg-Gly-Leu. In most instances, the coefficient of variation for replicate samples was less than 15%, although occasional lack of reproducibility was observed. Further experiments must be conducted to determine if this variability is related to sample preparation or is of instrumental origin.

Acknowledgements - We are grateful to Glaxo Inc. for the use of the Sciex API III mass spectrometer and to Dr. Arthur Moseley, Dr. Steve Unger and Kathy Halm in the Department of Drug Metabolism for their assistance with this project. Electrospray LC/MS and LC/MS/MS of Ecdysteroids

Russell P. Grant, Dai E. Games, M.S.R.U, Chemistry Department,
U.W. Swansea, Swansea, Wales, SA2 8PP
Ian D.Wilson, E. D. Morgan, Department of Chemistry,
Keele University, Keele, England, ST5 5BG

Introduction

Ecdysteroids are polyhydroxylated steroid compounds which participate in the regulation and development processes of invertebrates. Ecdysteroid concentrations in plant samples are very low, hence, highly sensitive and specific methods of analysis are required to identify them. Previous investigations have used GC, SFC, TLC and HPLC coupled with EI, CI, FAB and thermospray mass spectrometry. The requirement of pre-derivatization, however, precludes their use in trace analysis. The sensitivity potential of pneumatically assisted electrospray LC/MS combined with the specificity available via LC/MS/MS suggest that these techniques could be useful for the screening of plant samples.

Experimental

An HP1050 hplc system (Palo Alto, CA) with a C18 analytical column (200 x 4.6mm, 5 micron) (Shandon, Runcorn, UK) was employed using a flow rate of 1 ml/minute of Acetonitrile 23% : Water (TFA 0.1%) 77%. Mass spectrometry was performed using a Finnigan MAT TSQ 700 triple stage quadrupole via an electrospray interface (both Finnigan, MAT, San Jose, CA). Positive ions were detected in full scan mode (200-600 m/z, 2 seconds) with 200 ul/minute flow rate, 60 psi sheath N_2, 40 psi auxiliary N_2 and a capillary temperature of 240°C. A collision cell pressure of 1.5 mTorr of argon and a collision offset potential of -50eV were employed in the MS/MS studies.

Results and Discussion

The LC/MS analysis of a large number of ecdysteroids shows a variety of peaks corresponding to various ions being produced in the source. A typical spectrum is that shown for ecdysone (figure 1). The diagnostic spectra produced enable molecular mass elucidation, although with the number of analogs present within complex biological samples, these spectra cannot be considered specific. The detection limits for ecdysone and 20-hydroxyecdysone are 100ng and 50ng in full scan mode and 250pg and 150pg on-column in SIM respectively. These limits allow full scan screening of complex samples for ecdysteroids and a *Silene nutans* plant extract is shown (figure 2). The peaks were assigned using LC/MS/MS and a typical spectrum is shown (figure 3). The various ions seen originate from cleavages in the side chain (1-7) and also from losses of water molecules (8,9) from the parent ion (10) ($[M + H - H_2O]^+$, the base peak for ecdysone).

Conclusions

The use of LC/MS and LC/MS/MS via electrospray is shown to be very useful in the analysis of ecdysteroids. The detection limits available in full scan mode allow the screening of complex biological mixtures to be undertaken and the diagnostic LC/MS spectra combined with the highly specific LC/MS/MS spectra enable unambiguous assignment of ecdysteroid components.

High Performance Liquid Chromatography/Electrospray Ionization/Tandem Mass Spectrometry Studies on the Metabolic Fate of the Atherosclersis Combatant CP-230,821

E. W. Luther, M. J. Cole, S. Boyer

Drug Metabolism Department, Central Research Division, Pfizer Inc, Groton, CT 06340

CP-230,821 (Figure 1) is currently undergoing evaluation in our laboratories as a novel compound to combat atherosclerosis. Identification of metabolic pathways aids in the discovery and long-term development processes. HPLC with ESI and triple quadrupole mass spectrometry provide an effective means by which to elucidate these metabolic pathways.

Nine mono-oxidation products were identified in rat microsomal preparations. Individual HPLC precursor and CAD product ion scans were used to determine the presence and structures of the metabolites. The two major metabolites identified are hydroxylation on the 1,4 benzodioxane moiety, and represent oxidation of the cis and trans isomers of CP-230,821.

ABSTRACT:

CP-80,633 is a novel PDE4 inhibitor currently undergoing evaluation in our laboratories. Identification of metabolic pathways aids in the discovery and long-term devlopment processes. HPLC/on-line diode array detection combined with electrospray ionization and triple quadrupole mass spectrometry provide an effective means in which to elucidate these metabolic pathways.

Samples were analyzed from several different biological matrices, including rat plasma following I.V. and I.P. administration, human serum following oral administration, and rat urine following I.P. administration. Six drug-related compounds were identified in these matrices. A variety of mass spectrometric experiments, including precursor, neutral loss, full CID product ion, and conventional mass spectral scans provided a full metabolic profile. Metabolites identified were all Phase I-type species and included 2 species representing hydroxylation of the norbornyl moiety, 3 products corresponding to carbonyl formation on the norbornyl moiety, and one species representing O-demethylation. On-line diode array detection allowed relative quantitation of the metabolites. Norbornyl oxidation is the major route of metabolism for this molecule.

HPLC/ESI/MS/MS Studies on the Metabolic Fate of the LTB4 Receptor Antagonist CP-105,696 and Evidence of Intramolecular Acyl Migration of an Ester Glucuronide Conjugate

Mark J. Cole, Jeffrey W. Gauthier, Elbridge W. Luther, Hassan G. Fouda, Rosalina Destito, Theodore E. Liston

Drug Metabolism Department, Central Research Division, Pfizer Inc, Groton, CT 06340.

Plasma and bile metabolite profiles of the LTB_4 receptor antagonist CP-105,696 were generated to investigate the degree of metabolism in rat, dog, and monkey. High performance liquid chromatography, in conjunction with electrospray ionization tandem mass spectrometry, was used to identify eleven metabolites. The determination of these metabolites was based on a scheme of precursor and CAD product ion scans that identify drug-related components and provide structurally significant data, respectively. The CAD spectrum and structure of CP-105,696 are shown in Figure 1.

Three of the eleven metabolites were the result of glucuronidations. The chromatogram obtained from CAD scans of the expected glucuronide ion contains an early eluting peak and two closely-spaced later eluting peaks. The early eluting peak was identified as glucuronidation of the 4-hydroxy-chroman-7-yl moiety. The later two peaks represent ester glucuronides; the first represents the conventional ester glucuronide and the second results from an intramolecular acyl migration[1]. The structures of these latter two glucuronide conjugates were determined from their CAD spectra, as shown in Figure 2. The numerous peaks between m/z 622 and 411 in the CAD spectrum of the migration product provide evidence for the structure as drawn. The resistance of the migration product to B-glucuronidase provided further evidence for this assignment. Acidification of the sample during collection assured that this product was not formed as a result of sample handling.

HPLC/MS/MS Determination of CP-118,954 in Human Serum

M. Avery, S. Needham and H. Fouda
Central Research Division, Pfizer INC. Groton, CT 06340

CP-118,954 (Figure 1) is a cholinesterase inhibitor with utility for the management of Alzheimers disease. An analytical method for its determination in plasma was desired to support the investigation of its pharmacokinetics.

At clinically relevant doses, serum concentrations of 10 pg/mL were expected. GC/MS methods were not viable due to significant adsorption on capillary columns and attempts at derivatization failed. Standard HPLC methods were not successful due to insufficient sensitivity using UV detection. A successful assay was developed using a simple liquid-liquid extraction and detection by HPLC/APCIMS/MS. A stable isotope internal standard (I.S.) was used to correct for differences in extraction efficiency and to improve accuracy and precision.

The experimental procedure consisted of fortifying a 1 mL serum sample with the internal standard, adjusting the pH to 10 and extracting with 5 mL of n-butyl chloride. The organic layer was isolated after freezing the aqueous layer in dry ice/i-propanol and the solvent removed by evaporation. The reconstituted sample was chromatographed on a NovPak C18 column using a mobile phase of 72/25 MeOH/ 10 mM ammonium acetate. The entire HPLC column effluent was introduced into the APCI ion source of a SCIEX API III+ mass spectrometer where positive molecular ions were generated by a Corona discharge. MH^+ ions at m/z 376 were dissociated by collision with Argon and the major product ion at m/z 91 was monitored. This Multiple Reaction Monitoring (MRM) experiment produced high sensitivity and selectivity (Figure 2). Since the internal standard contained 5 deuterium's in the phenyl ring, the MRM reaction m/z 381->96 was used to measure the I.S. Typical responses for blank samples, LLOQ (10 pg/mL) and 0.1 ng/mL are shown in Figure 2.

The performance of the assay was characterized by assaying six replicates at serum concentrations of 0.01, 0.05, 1.0, 5.0, and 10 ng/mL. The results, shown in Table I, demonstrate that the assay has an accuracy and precision of 94% and 10% respectively.

Table 1. Analysis of human serum samples known amounts of CP-118,954: intra-assay parameters; 6 samples at each concentration.

Fortified Drug Conc. (pg/ml)	Mean Conc.found (pg/mL)	R.S.D. (%)	Mean Accuracy (%)
10	10.8	5.2%	108%
50	49.9	10%	99.8%
1000	1058	2.5%	106%
5000	5160	2.5%	103%

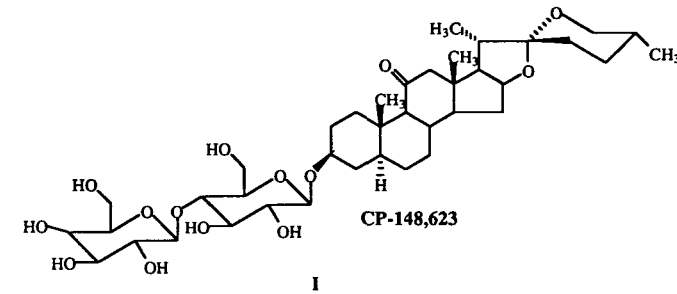
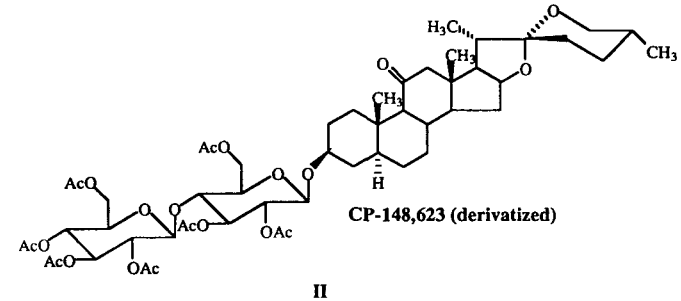
Groton, CT 06340

ABSTRACT:

CP-148,623 is a promising cholesterol sequestering agent currently undergoing clinical evaluation. Serum levels are expected to be low, and therefore a sensitive and specific method was required to support pharmacokinetics studies. The assay utilizes HPLC and atmospheric pressure chemical ionization tandem mass spectrometry (APCI-MS). The drug and internal standard, penta-deuterated CP-148,623, are extracted from 1.0 ml of serum after protein precipitation with acetonitrile, and then derivatized with acetyl chloride, increasing the molecular weight of each by 294 daltons. The protonated molecule of both drug and internal standard undergo collisionally-activated dissociation (CID) to form a specific product ion. Concentrations of CP-148,623 in serum are determined by monitoring this reaction. The upper and lower levels of quantitation are 500 ng/ml and 10 ng/ml, respectively, for the high volume assay and 15 ug/ml and 0.1 ug/ml for the low volume assay. The assay is robust and analyses have been performed on several thousand toxicology and clinical samples. In addition, an assay for the putative metabolite of CP-148,623, CP-154,528, has been developed in a similar fashion.





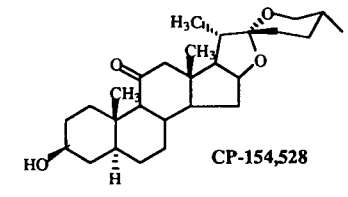


FIGURE 1: Structures of CP-148,623 and CP-154,528

Characterization of Metabolites of Ziprasidone in Human by LC-MS/MS

Chandra Prakash*, Amin Kamel, Wayne Anderson and Keith Wilner
Departments of Drug Metabolism and Clinical Research, Central Research Division, Pfizer Inc., Groton, CT 06340.

Introduction:

Ziprasidone, 5-[2-{4-(1,2-benzisothiazole-3-yl)-1-piperazinyl}ethyl]-6-chloro-1,3-dihydro-2H-indole-2-one hydrochloride hydrate, is a new neuroleptic agent undergoing investigation that displays a pharmacological profile indicative of atypical antipsychotic activity with little or no liability for motor side effects. It has extremely potent central serotonin 5-HT2 and potent dopamine D2 receptors antagonistic properties. Previous studies have shown that ziprasidone was extensively metabolized in laboratory animals, since < 2% of the administered dose was excreted in urine as an unchanged drug. This work was conducted to determine the metabolic pathways of ziprasidone in human subjects. HPLC, in conjunction with ionspray mass spectrometry and simultaneous monitoring the radioactivity, was used to detect and identify the metabolites.

Materials and Methods:

Four normal healthy male volunteers received a single oral 20 mg dose of a mixture of ziprasidone labeled with ^{14}C at the C-2 position of the ethyl group attached to the piperazinyl nitrogen and ^{3}H at the C-7 position of benzisothiazole (Figure 1). The use of two labels at these positions, not only facilitated the tracing of metabolites that were formed through cleavage of ziprasidone, but also aided in their identification. Blood, urine and feces were collected at various intervals for determination of total radioactivity and metabolite profiles in three matrices

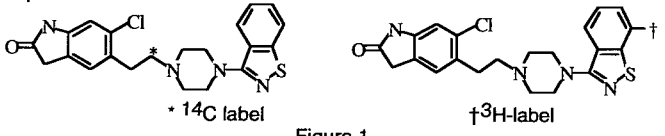

Figure 1

The analysis of the metabolites was performed on a SCIEX API III HPLC/MS/MS system using ion spray. HPLC was carried out on a YMC basic HPLC column (4.6 µm x 250 mm, 5 µm: YMC) with a binary mixture of 20 mM ammonium acetate (pH 5.0, solvent A) and methanol (solvent B). The mobile phase initially consisted of solvent A/solvent B (90:10) for 10 min. It was then linearly programmed to solvent A/solvent B (20:80) over 50 min. Chromatography was carried out under isocratic conditions for 7 min and then programmed back to the starting solvent mixture over 8 min. The effluent from the HPLC column was split and about 50 µl/min was introduced into the atmospheric ionization source via an ion spray interface. The remaining effluent was directed into the flow cell of β-RAM. The β-RAM response was recorded in real time by the mass spectrometer that provided simultaneous detection of radioactivity and mass spectrometry data. Collision associated dissociation (CAD) studies were performed using argon gas at a collision energy of 56 eV and a collision gas thickness of 6.5 x 10^{14} molecules/cm^2.

Results and Discussion:

A total of 8 radioactive peaks were detected in the chromatogram of a urine sample (0-24 h) from a male volunteer following oral administration of [^{3}H]- and [^{14}C]-labeled

ziprasidone. The metabolites were identified by ion spray LC/MS using a combination of parent, daughter, selected ion, and multiple ion reaction monitoring techniques. Ziprasidone and its metabolites gave the intense protonated molecular ions. CAD product ion spectra of protonated molecular ions provided a number of structurally informative fragment ions. CAD product ion spectra of monooxygenated isomeric metabolites (m/z 429) are shown in Figure 2. Based on the structures of the metabolites, four major routes of metabolism of ziprasidone were identified: 1) N-dealkylation of the ethyl side chain attached to the piperazinyl nitrogen; 2) oxidation at sulfur resulting in the formation of sulfoxide and sulfone; 3) oxidation on the benzisothiazole moiety (other than sulfur) and 4) hydroxylation on the 3-position and subsequent oxidation of the benzisothiazole moiety. The identified metabolites accounted for approximately 97, 64 and 98% of the total radioactivity extracted from urine, serum and feces, respectively.

PRECLINICAL DRUG SELECTION - APPLICATION OF IONSPRAY LC-MS AND LC-MS/MS.

*Michele A. Kelly, Guang Xiao, Gerald E. Greenberg, Sandra Kuzmich and Philmore Robertson. Ciba Geigy Corporation, Pharmaceuticals Division, 556 Morris Avenue, Summit, NJ 07901.

Information regarding the metabolism, cell penetration, bioactivation or other properties of compounds is frequently needed at an early stage in drug development in order to ensure optimal compound design and selection. The use of LC-MS and LC-MS/MS, coupled with a partial clean-up of the sample through extraction and/or rudimentary LC separation, can provide the needed information in a relevant time frame. Such timely feedback allows rational drug design to progress, accompanied by the vital information that can be obtained by coupling biological preparations with mass spectrometry. *In vitro* incubations with biological matrices are increasingly used in drug discovery in order to explain and/or predict results from *in vivo* models. The lack of availability of well-established analytical methods often preempts early compound evaluation, where information on stability and/or metabolism would be valuable for compound selection.

Due to the wide variety of cofactors, buffers, etc., required for *in vitro* incubations, sample clean-up or product ion monitoring are used in conjunction with LC-MS when interfering substances are evident. Three distinctly different examples are presented, which demonstrate the utility of LC-MS and LC-MS/MS to quickly deliver relevent information regarding drug candidates. These include the examination of the routes of bioactivation of prodrugs, identification of major routes of Phase I and Phase II metabolism of developmental compounds, and investigation and validation of a gut permeation model.

A PE Sciex API III instrument was utilized for all LC-MS analyses presented here. A Waters HPLC 625 LC system was interfaced on-line with the mass spectrometer. Gradient elutions were carried out using the mobile phases A:acetonitrile and B:10mM ammonium acetate, 0.1% formic acid (pH 3.5), typically from 20:80 to 90:10 (A:B). The HPLC flow rate of 1 mL/min was split in order to deliver approximately 40 µL/min to the ionspray interface. Typical ionspray MS conditions were as follows (positive ion mode): nebulizer flow = 40 psi, curtain gas flow = 1 L/min, interface temperature = 50 °C, ISV = 5 kV, OR = 70 V.

CGS 30440, a double prodrug of a dual inhibitor of angiotensin converting enzyme (ACE) and neutral endopeptidase (NEP), was examined in various *in vitro* incubation conditions in order to understand its routes of bioactivation *in vivo*. A comparison of product profiles from one hour incubations of CGS 30440 in rat and dog plasma shows that the high esterase activity in rat plasma resulted in the partial conversion of CGS 30440 to des-ethyl-CGS 30440, as well as to the intended, fully activated drug CGS 30008. A third product was identified as the disulfide dimer of CGS 30008. In dog plasma, CGS 30440 remained intact after the one hour incubation.

In vitro liver preparations examined at various time points were also utilized to probe the bioactivation of CGS 30440. Incubation in either rat liver homogenate or microsomes resulted in a more complex activation than that seen above in rat plasma. There were subtle differences in the two liver preparations, although they were qualitatively comparable. An additional product formed in rat liver, but not found in rat plasma, was identified as des-acetyl-CGS 30440. This product, containing a free thiol, also formed a disulfide dimer. In liver homogenate, the mono-des-ethyl disulfide was also detected. Des-ethyl-CGS 30440 was again present, and CGS 30008 was detected after an extended incubation period. Providing this information at an early stage in the development of CGS 30440 has aided in understanding the bioactivation process for this drug candidate.

A series of structurally related, arylamidine-containing compounds have been evaluated for efficacy as LTB_4 receptor antagonists. In support of preclinical evaluation of this series, the major routes of metabolism were determined *in vitro* for an N-hydroxy amidine-containing compound. Five metabolites of the N-hydroxy amidinewere present after incubation in rat liver microsomes. The compounds identified, in order of elution, were (A) oxidized and (B) hydroxylated parent drug, (C) amidine, (D) parent drug, (E) ketone, and (F) nitrile.

A characteristic fragment ion was observed for this class of compounds in the positive ion mode. This provided information on the site of metabolism using LC-MS only. The mass differences observed between the molecular ions and the fragment ions confirmed that the modifications shown for compounds C-F occurred on the amidine-containing portion of the molecule. The imino and keto metabolites

probably formed via N-reduction and oxidative transformation[1] pathways, respectively. The nitrile was an unusually lipophilic metabolite, eluting well after the parent compound. The N-hydroxy amidine was also investigated in a human Caco-2 cell line, where metabolism to its amidine was observed.

LC-MS/MS was utilized in the investigation of the metabolism of an early developmental drug. The unknown metabolites of this compound in certain *in vitro* situations were difficult to analyze using LC-MS, due to interfering components. A TIC of a full scan analysis of a Phase I/II incubation of parent drug in rabbit liver microsomes for four hours is shown in Figure 1. Interfering substances are evident, where detergent is masking out much of the baseline. Having analyzed pure parent drug by LC-MS/MS previously, a product ion of this drug was chosen for a precursor ion scan of related compounds. Figure 2 shows the increased selectivity obtained using this method upon injection of the same sample shown in the previous figure.

Using this precursor ion scan, the parent drug (P), Phase I metabolite (M), and their respective Phase II glucuronide conjugates were readily detected as major products. A constant neutral loss scan for 176 Da confirmed the presence of the two glucuronides. A subsequent one hour Phase II analysis of the parent compound in dog liver microsomes also produced a glucuronide conjugate.

The examples presented above represent the variety of pharmacological problems often encountered in early compound development. By exploiting the versatility of ionspray LC-MS and LC-MS/MS, information can now be obtained for use in drug selection, which was previously unattainable. Feedback regarding the bioactivation, metabolism or other properties of drug candidates aids in the drug selection process, where structurally similar compounds often require further means of differentiation beyond pharmacological activity. LC-MS in conjunction with *in vitro* biological preparations is a useful way in which to obtain timely information to facilitate drug discovery.

Time-of-Flight Secondary-Ion (TOF-SIMS) and Matrix-Assisted Laser Desorption/Ionization (MALDI) Mass Spectrometry are emerging as useful methods for the investigation of drugs and metabolites in real biological systems [1,2]. Mass spectrometry is a powerful tool for the analysis of drugs and metabolites that may prove to be a viable alternative to high performance liquid chromatography (HPLC) and immunoassays (e.g. Fluorescence Polarization Immunoassay (FPIA)) in the clinical laboratory.

Cyclosporin A (CsA) is a well characterized and extensively used anti-rejection drug with newer agents, such as FK-506, undergoing clinical trials. The therapeutic index of these agents can be improved by understanding the nature of their metabolism and pharmacokinetics. This report expands upon the initial CsA study [1] by monitoring the *in vivo* metabolism of the drug and quantifying the major metabolite, AM1 (M17) in whole blood extracts. Initial MALDI results of the *in vitro* metabolism of FK-506 using a hepatic microsomal system are also presented. FK-506 metabolism was investigated using Baboon microsomes because FK-506 will be used in xenotransplantation; thus it is important to understand how the drug is metabolized by other species that may serve as donors.

Figure 1A shows the HPLC trace of a transplant sample. The HPLC data indicates extensive metabolism of CsA which is supported by the high CsA FPIA/HPLC concentration ratio of 3.2. Figure 1B shows the TOF-SIMS spectrum of the same sample. The spectrum contains several Ag-cationized peaks which are not present in standard blood extracts (data not shown). The MALDI spectrum (Fig. 1C) obtained from the same blood extract clearly indicates the presence of several CsA metabolites. Thus, both TOF-MS methods are accurately detecting CsA and its metabolites when compared to the standard method, HPLC.

Quantification of CsA and its major metabolite by both TOF-MS methods was carried out on 8 transplant samples. The correlation coefficients (r_0) were determined to be 0.988 and 0.986 for the TOF-SIMS and MALDI methods (compared to HPLC), respectively. The quantification of AM1 by both TOF-MS methods resulted in r_0 values of 0.997 and 0.991 for the TOF-SIMS and MALDI methods, respectively.

Figure 2 shows the MALDI spectra of ether extracts obtained at several different *in vitro* reaction times (0, 10, 20, 30, 45, and 60 minutes) with their corresponding peak assignments and the adduct in parenthesis. Note the relative decrease in the FK-506 parent drug intensity and the appearance of several new species with increasing reaction time. The major peaks identified in the data matrix presented in

Figure 2 indicate the major metabolites of FK-506 are de-methylated, doubly de-methylated and mono-hydroxylated. These results are consistent with previously reported studies. A normalized intensity vs. reaction time plot (data not shown) indicates that the desmethyl metabolite is rapidly formed while the didesmethyl and mono-hydroxylated metabolites are formed at lower rates. Collectively, these results illustrate that TOF-SIMS and MALDI-TOF can be applied to real biological systems providing superior detection limits, specificity and speed of analysis over HPLC and FPIA.

The Analysis of Stable Isotope-Labeled Drug Metabolites Using LC/CRI MS and LC/ESI MS/MS

*Feng-Yin Hsieh[2], Charles A. Goldthwaite, Jr.[2], Brian Nobes[2], Robert F. Mayol[3], Lewis J. Klunk[3], Ajai K. Chaudhary[2], and Ian A. Blair[1,2]. Department of [1]Chemistry and [2]Pharmacology, Vanderbilt University, Nashville, TN 37232; [3]Bristol-Myers Squibb Co., Pharmaceutical Research Institute, Wallingford, CT 06492.

The use of radioisotopes as tracers in drug metabolism studies has long been recognized as a simple, sensitive and selective method. However, for a variety of reasons, an alternative to the use of radiolabeled drugs for metabolism studies in human subjects would be welcomed. An attractive alternative technique that avoids the use of radioisotopes is the use of stable isotopes, such as ^{13}C and ^{15}N, as tracers in isotopic substitution experiments. Therefore, there is increasing interest in the development of instrumentation for the analysis of stable isotope-labeled drugs, metabolites and xenobiotics. The technique of chemical reaction interface mass spectrometry (CRI MS) is an elegant tool for selectively detecting stable isotopes. The basic concept of CRI MS is to completely atomize and then oxidize an analyte within a microwave induced plasma (MIP) oven with the addition of reactant gas (such as SO_2) in the MIP oven. This produces an array of low molecular weight gaseous species corresponding to stable isotope oxidation products (*m/z* 44 for $^{13}CO_2$, and *m/z* 31 for ^{15}NO) which are detected by a quadrupole or magnetic sector mass spectrometer using the selected ion monitoring (SIM) method. Therefore, quantitative analysis can be carried out regardless the original structure of the compound. However, the destructive nature of CRI MS provides no structural information for the unidentified metabolites. Therefore, electrospray ionization tandem mass spectrometry (ESI/MS/MS) was employed for structural characterization.

The CRI MS system has been coupled with high performace liquid chromatography (HPLC) via a particle beam interface. The [$^{15}N/^{14}C$]buspirone *in vivo* metabolites were chosen as a model system to demonstrate the application of the LC/CRI MS technique in drug metabolism studies. Rat bile and urine samples were collected after dosing the aminals with [$^{15}N/^{14}C$]buspirone. and were directly analyzed using the LC/CRI MS system without requiring any further sample clean-up procedure. ^{15}N labeled species were selectively detected in the *m/z* 31 channel. The bile and urine samples were also analyzed using LC/radiomatic detection. The accuracy of the LC/CRI MS method was evaluated by comparing the results from LC/CRI MS with the results from the radiomatic detection. The structures of the conjugated buspirone metabolites were characterized using LC/ESI MS/MS.

The LC/CRI MS chromatograms showing the ^{15}N enriched channel (*m/z* 31; ^{15}NO) and the non-labeled nitrogen channel (*m/z* 30, ^{14}NO) from the analysis of [$^{15}N/^{14}C$]buspirone metabolites in rat bile are shown in Figures 1a and 1b, respectively. The radiochromatogram from the analysis of the bile sample is shown in Figure 1c. Four major metabolites were detected (in Figure 1a and 1c, metabolites 14' and 15' co-eluted), and they were identified as the dihydroxylated monoglucuronide (9' and 11') and monohydroxlyated monoglucuronide (14' and 15') anaogs of buspirone. In urine, the N-dealkylation product 1-Pyrimidinylpiperazine (1-PP, lmetabolite 1 in Figure 2a and 2c) was the major metabolite, and no significant conjugated metabolites were detected. Figures 2a, 2b, and 2c shows the LC/CRI MS chromatograms of the ^{15}N enriched channel, the non-labeled nitrogen channel, and the ^{14}C radiochromatogram, respectively. The LC/CRI MS chromatograms of the ^{15}N enriched channel (Figures 1a and 2a) are almost identical to the radiochromatograms (Figures 1c and 2c) from the analyses of [$^{15}N/^{14}C$]buspirone metabolites in rat bile and urine. The resolution of the LC/CRI MS system is superior to that of the LC/radiomatic detection. The non-labeled interferences in the bile did not affect the detection of the isotope labeled metabolites in the ^{15}N enriched channel (*m/z* 31; ^{15}NO).

These results show that the LC/CRI MS technique is a stable isotope sensitive and compound-independent detection tool, which is especially suitable for drug metabolism studies. Excellent correlations between the CRI MS and radioactive methods were found. The combination of the LC/ESI MS/MS with LC/CRI MS provides a powerful technique for the complete identification and structural characterization of newly discovered metabolites. Supported by Bristol-Myers Squibb and NIH GM31304.

Analysis of levobunolol and timolol in ocular tissues: an observation of orifice voltage dependent oxidation of dihydrobunolol to levobunolol

W. Luo[1], A. Acheampong[1], S. Lam[1], D. Tang-Liu[1] and A. Breau[2]
[1]Department of Pharmacokinetics, Allergan Inc, Irvine, CA 92715
[2]The Perkin-Elmer Corporation, San Jose, CA 95131

Levobunolol and timolol, non selective beta-adrenergic blockers, are commonly used for the treatment of open-angle glaucoma. Both drugs reduce intraocular pressure by suppressing the rate of aqueous humor production from the secretory site, namely iris-ciliary body (1). Posterior sites of action have also been proposed for glaucoma drugs that may lead to undesirable effects on optic nerve head perfusion (2, 3). The study was designed to compare the concentrations of timolol and levobunolol in aqueous humor, iris-ciliary body, vitreous humor, choriod/retina and optic nerve. Following a single drop of 0.5% opthalmic solutions into albino rabbit eyes, those tissues were collected. An LC/MS/MS assay has been developed to analyze the concentrations of timolol, levobunolol and its equipotent metabolite dihydrobunolol.

Blank tissues were obtained from untreated rabbits. The solid tissues were weighed, except aqueous humor, which was measured by volume. Each point of standard curve was prepared by spiking a known amount or volume of tissue or fluid with varying concentrations of drug. Timolol was the internal standard for analysis of levobunolol and dihydrobunolol. Levobunolol was the internal standard for analysis of timolol.

Tissue samples were each extracted with 1 ml of acetonitrile and shaking for 10 min. The acetonitrile layer was transferred to clean silylated test tube and evaporated to dryness under nitrogen. The residue was reconstituted in 1 ml of double-distilled water and 30 µl of 3 N NaOH and 5 ml of ethyl ether. The organic layer and evaporate to dryness under nitrogen. Reconstitute in 100 µl of double-distilled water and inject onto LC/MS/MS.

Samples were injected onto a YMC basic (4.6 X 3 mm) 3 µm particle size column. The mobile phase used was 80% MeOH, 20% 20 mM NH_4OAc, 2 mM TEA at a flow rate of 1.5 ml/min. A Sciex API III+ triple quadruple mass spectrometer was operated in the positive ion detection mode with an APCI interface. The MRM modes were set at 292/235.5 for levobunolol, 294/237.5 for dihydrobunolol and 317/260.5 for timolol.

During the development process of analyzing levobunolol and its major metabolite dihydrobunolol, the conversion of the metabolites back to parent compound was observed. A careful analysis of the various ion source parameters revealed that the orifice potential accounted for the observed oxidation. As shown in Fig, 2 and Fig. 3, at orifice setting 60 V, ion 292/235.5 split into two peaks, one of which matches the retention time of dihydrobunolol which indicted that it was the oxidation product of dihydrobunolol. The magnitude of this oxidation was proportional to the magnitude of the orifice potential used in the study. In order to analyze both compounds, a low orifice potential was used. However, the utilization of this low orifice potential compromised the detection of levobunolol.

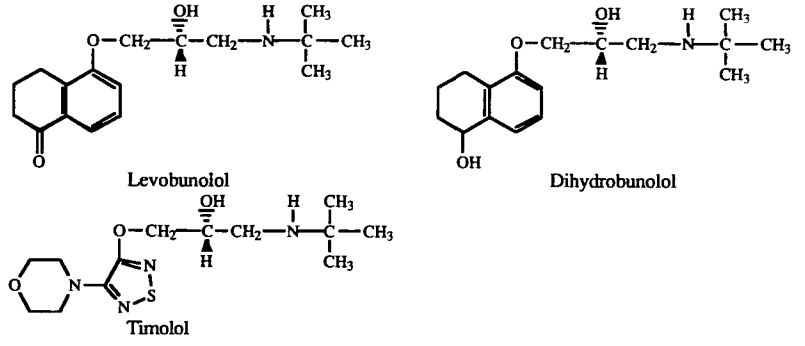

Fig. 1. Structures of levobunolol, dihydrobunolol and timolol.

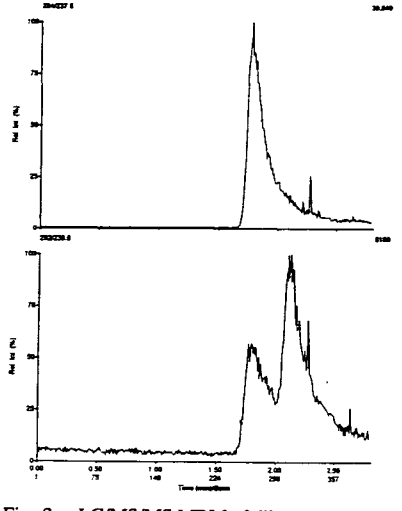

Fig. 2. LC/MS/MS MRM of dihydrobunolol (top) and levobunolol (bottom) at orifice setting 60 V. The first of the doublet peaks of ion 292/235.5 matches the retention time of dihydrobunolol, shows that the oxidation occurred at this orifice setting.

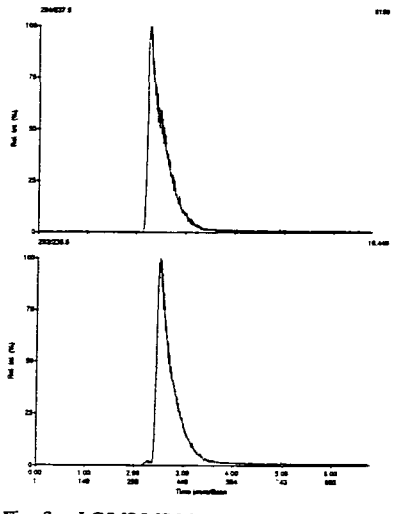

Fig. 3. LC/MS/MS MRM of dihydrobunolol (top) and levobunolol (bottom) at orifice setting 40 V. The doublet peaks of ion 292/235.5 disappeared at this condition indicates that the conversion dihydrobunolol to levobunolol did not occur at low orifice setting.

Metabolic Profiling using On-line Microdialysis Sampling with Tandem Quadrupole Mass Spectrometry

Robyn A. Rourick[1], Edward H. Kerns[1], Kevin J. Volk[1], Jeffrey L. Whitney[1], and Mike S. Lee[2], Bristol-Myers Squibb Company,
[1]Wallingford, CT 06492, [2]Princeton, NJ 08543

The rapid identification of drug metabolites is a vital component of the drug discovery process. To accelerate research, to reduce the use of living animal resources, and to minimize sample degradation it would be advantageous to analyze *in vitro* metabolic reactions on-line for drug metabolite profiling. Microdialysis sampling has demonstrated advantages for obtaining chemical information from biological systems. Originally developed for sampling neurotransmitters in the brains of living animals, it's use has been expanded into sampling of other tissues and physiological fluids in pharmaceutical research. Dialysate fluid provides a continuous sample of the drug and metabolites from the biochemical system sampled.

Here we describe a method for *in vitro* metabolic profiling using microdialysis sampling, tandem quadrupole mass spectrometry via an electrospray interface (1,2) and a systematic approach for metabolite identification. A metabolic profile was obtained for buspirone, an anxiolytic drug, in microsomal incubations using a model CMA/12 microdialysis probe and a CMA 100 syringe pump. Ammonium acetate (2mM) was used for dialysis fluid at a flowrate of 5 μL/min. Reactions were performed at 37 °C in a 1 mL Reacti-Vial equipped with a stir bar. The CMA 12 microdialysis probe was coupled directly to the electrospray interface of the Sciex API III tandem quadrupole mass spectrometer. Reactions were initiated by the addition of glucose-6-phosphate dehydrogenase in the buffered microsomal solution.

Prior to the initiation of microdialysis studies, a library of microsomal buspirone metabolites was generated using standard LC/MS and LC/MS/MS profiling methodologies (Figure 1). Full scan MS analysis during the LC/MS studies and microdialysis studies provided molecular weight information for the metabolites. Structural information was obtained for two compounds corresponding to the hydroxy and di-hydroxy metabolites via on-line microdialysis sampling. Comparison of the product ion spectrum of each metabolite to that of the parent drug provided information about the site of the metabolic transformation (Figures 2 - 3). The MS/MS fragmentation patterns indicated changes in specific substructures consistent with hydroxy buspirone and di-hydroxy buspirone.

In-vitro microdialysis sampling allowed real-time acquisition of metabolic information from microsomal incubations of buspirone. Furthermore MS/MS techniques on-line with microdialysis provided substructural insights about metabolic fate of buspirone.

Automated HPLC/Tandem Mass Spectrometric Approaches for Rapid Identification of Metabolic Pathways

Mark J. Cole, Jeffrey W. Gauthier, Elbridge W. Luther, Hassan G. Fouda

Drug Metabolism Department, Central Research Division, Pfizer Inc, Groton, CT 06340.

The availability of biotransformation data very early in the drug discovery program allows the chemists to tailor synthetic efforts toward blocking metabolically labile sites, provides structural information on active or toxic metabolites, and can guide the selection of the most optimum drug candidate for further development. Other important discovery and development processes, such as the selection of *in vivo* animal efficacy and safety models and the interpretation of toxicology and clinical findings, can also benefit from the early availability of comparative metabolism information. Traditional approaches to metabolite identification are time consuming and the data are often generated too late to have an impact on the discovery process.

We are exploring ways not only to provide biotransformation data on numerous prototypes at a discovery pace, but to also integrate and standardize experimental approaches and methodologies within the discovery process. A standardized chromatography system consisting of a general-use gradient mobile phase and dual narrow-bore columns allows the analyses of most compounds without prior development of individual chromatography conditions. In addition to saving significant development time, this system is portable between mass spectrometry and other laboratories, all chromatography data are easily correlated regardless of which laboratory they were collected in, and metabolism rates can be studied in other laboratories without further mass spectrometric work. An on-line diode-array detector provides a better representation of the relative abundances of metabolites, helps to further confirm metabolite structures, and provides a common type of data between mass spectrometry and chromatography laboratories. The heart of the system is a triple-quadrupole mass spectrometer sophisticated enough to simultaneously collect multiple mass spectrometric experiments, automatically tune itself on each new compound, provide control over switching valves, HPLC systems, and diode-array data collection, and encompass all of this with a programming language and direct control over all instrument parameters. The simultaneous collection of data from multiple mass spectrometric experiments, and the ability to collect these data automatically, significantly decreases the operator involvement with, and time required for, data collection. As a result, data are collected, analyzed, and reported rapidly at the pace of the discovery program.

What is Rapid Automated Biotransformation Identification (RABID)?

RABID is an HPLC/DAD/MS/MS instrument bundled with a suite of software packages that allows a user to collect many Phase I/Phase II data automatically and unattended with no *a priori* knowledge of the metabolism, chemistry, or mass spectrometric dissociation of the compound. The user must know the molecular weight of the compound, but does not necessarily need to know how to run the instrument to collect the data. Data interpretation and the experimental decisions resulting from interpretation still require an expert.

Much of the Data Collection Can Be Automated

- Many of the experiments are "knowledge-based", lending themselves to automation (for example, CAD product ion scans of MH+16 will look for hydroxylations/oxides).
- The Finnigan TSQ-7000 provides a programming environment, true instrument control over every parameter and element of the instrument, and the ability to communicate with, and control, other instrumentation.
- A single gradient chromatography system can be developed that will be suitable for a wide range of pharmaceutical compounds.

RABID Features

- Modular system: user can easily install different gradients, autosampler programs, add additional or different experiments (different CAD experiments, PAR/NL, CAD/MS/MS, etc.) or delete unwanted experiments
- GUIDE Interface: leads user through all steps of sample entry, instrument preparation, control of the program, and data acquisition
- Samples can easily be entered/deleted/changed at any time during normal operation. Clicking the "START" button at the end of the day will begin automated operation.

Analysis of Diuretics in Urine by HPLC/APCI/MS and CE/UV

Yuan-Ping Yang and Jentaie Shiea*
Dept. of Chemistry, Natl Sun Yat-sen Univ., Kaohsiung, Taiwan 804

Diuretics have been banned at major sporting events since the 1988 Winter Olympic Games Although very low detection limit can be achieved by GC/MS analysis, finding an universal derivatizing reagent for various diuretics is very difficult. The development of new analytical procedures without derivatization will then be very helpful in rapidly screening and confirming the diuretics in urine. Here, we report two analytical processes which potentially can be used in rapidly examining the diuretics from urine:

1 The diuretics in spiked urine samples were separated by a C18 RP-HPLC column and the LC effluent was directed into APCI/MS system for compound identification. A PE Sciex API 1 LC/MS system equipped with an atmospheric pressure chemical ionization (APCI) source was used. Figure 1 shows the mass chromatograms of twelve diuretics by HPLC/APCI/MS. The mass of pseudomolecular ion (MH^+) of each diuretic was chosen to obtain the mass chromatogram. It can be seen that all of the diuretics were successfully protonated in the APCI source. Although the diuretics can be rapidly separated and identified by HPLC/APCI/MS, high concentration of the phosphate salt in the mobile phase causes problems in efficiently sampling ions into the mass analyzer especially in long term operation. To solve the problem, the mobile phase with low salt content has to be developed in the future

2. Owing to its extremely high resolution capability and very short time required, capillary electrophoresis (CE) is used for the analysis of diuretics in urine The CE/UV system is consisted with an Applied Biosystems 270 A-HT CE system equipped with a PE model 1022 personal integrator. Figure 2 shows CE electropherogram of the diuretics mixture. It can be seen that fourteen diuretics were separated and detected by CE/UV in less than thirteen minutes. Since the retention time of the analyte in CE is not so reproducible, we then developed an analytical procedures to solve the problem. Because the retention time of the analyte changes in the solutions which contains different amount of SDS (so called micellar electrokinetic capillary chromatography), a retention ratio can then be calculated. The definition of the retention ratio is as follow

$$\text{Retention Ratio} = \frac{RT_{CE,diuretic} - RT_{CE,standard}}{RT_{MECC,diuretic} - RT_{MECC,standard}}$$

It was found that the value of the retention ratio is different for each analyte. This value can then be used in identifying particular analyte eluted from CE. Figure 3 shows the electropherograms of furosemide in the solution contain (a) 0 mM SDS and (b) 10 mM SDS Ethacrynic acid was used as the internal standard. Table 1 shows relative retention times and retention ratios of fourteen diuretics. It can be seen that a quite wide range of retention ratio is obtained for 14 diuretics (from -2 to 3).

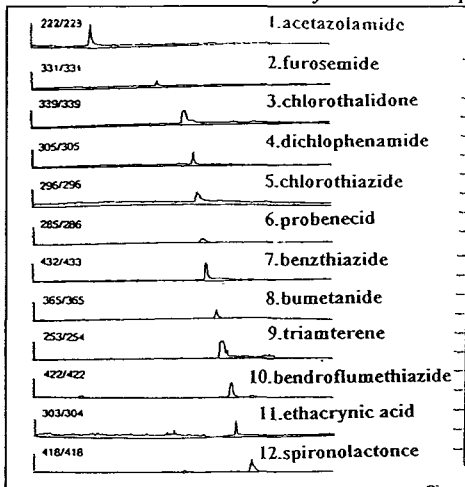

Figure 1. Mass chromatograms of 12 diuretics by HPLC/APCI/MS.

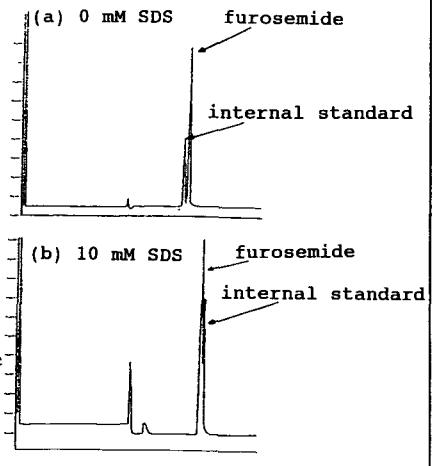

Figure3. CE electropherogram of bumetanide in (a)0 mM SDS, (b)10 mM SDS (internal standard : ethacrynic acid).

THE DETECTION OF CONCEALED DRUGS BY FIELD PORTABLE IMS AND GC/MS

Dean D. Fetterolf[1], Brian Donnelly[2], Thomas Jourdan[2], Forensic Science Research Unit[1], Chemistry Toxicology Unit[2], FBI Laboratory, Washington, DC

Introduction: Over the last two decades illicit drug distribution has grown from simple "drug pushing" where drugs were distributed by poorly organized individuals to today's well organized and well financed drug cartels. While traditional methods continue, new highly sophisticated smuggling techniques have been discovered.

The national drug control strategy calls for the development of new technology and the innovative adaptation of existing technology for use in the war on drugs. In the past few years, the FBI Laboratory has introduced several new tools into the agents' technological arsenal for use in support of drug investigations. The most successful tools have been a field portable ion mobility spectrometer, and a transportable GC/MS.

The forensic identification of trace physical evidence from drugs on a suspect's clothing, possessions, and conveyances in the field can provide the investigator with time-sensitive lead value information or probable cause.

Methods: The Barringer IONSCAN (Barringer Instruments, New Providence, NJ) is shown in Figure 1. Samples are collected by a small handheld vacuum onto a small teflon filter and thermally desorbed into the IMS (Figure 2) or extracted for GC/MS analysis. Using Ni-63 ionization, the nicotinamide internal calibrant also acts as a reagent ion of moderate proton affinity, thus offering enhanced selectivity. In the drift region, the ions are separated based upon their mobility. Temperatures for the desorber, inlet and IMS cell are 280° C, 290° C and 235°C, respectively. Sample, drift, and exhaust flows are 200 cc/min, 300 cc/min, and 500 cc/min, respectively. The self-calibrating, 5-second analysis can detect 5 ngs of cocaine and 15 ngs of heroin. Other drugs of abuse such as THC, LSD and methamphetamine are detected at comparable levels. Peak detection and alarm conditions are determined by a series of algorithms which examine peak location, size, and shape.

The Viking SpectraTrak GC/MS (Viking Instruments, Herndon, VA) is a ruggedized full featured Hewlett Packard MSD offering versatile sample introduction such as purge and trap, desorption tubes, headspace and GC analysis capabilities in a transportable package. As a matter of practice all positive field samples are confirmed in the field by the GC/MS or in the laboratory by MS/MS using deuterated internal standards.

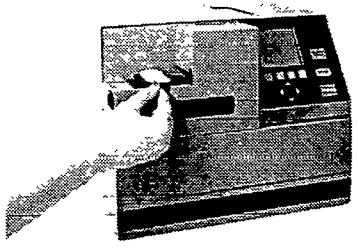

Figure 1. Field portable IMS

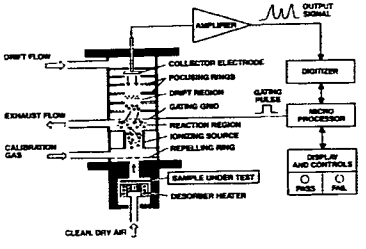

Figure 2. IMS Block diagram

Results: The IMS has proven successful on a routine basis in the field when operated by trained law enforcement investigators. To illustrate its' usefulness a few examples of real-world applications will be described. During the course of an investigation solvents and chemicals used for cocaine reprocessing and 355 pounds of injection molded polystyrene pipe fittings were recovered. Drug detection canines and cobalt thiocyanate field test kits proved negative. The plasmagram is shown in Figure 3. The plasmagram is plotted as intensity vs. drift time in milliseconds. The table on the left side is a list of common drugs, their mobility and drift times. The plastic pipe was determined to be 20-30% by weight cocaine. The portable GC/MS was used to confirm the IMS results and to identify the solvents.

In another investigation, a dog kennel (Figure 4) was intercepted upon entry into the United States. Mixed in the fiberglass matrix of the cage during manufacturing was over 3 Kg of cocaine which was undetected by drug canines and color test kits. Other unique concealments include cocaine hidden in railroad ties and hidden vehicle compartments.

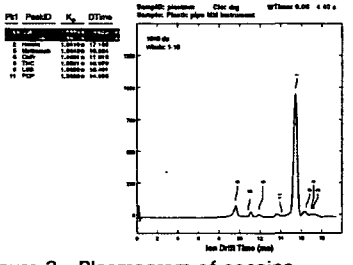

Figure 3. Plasmagram of cocaine.

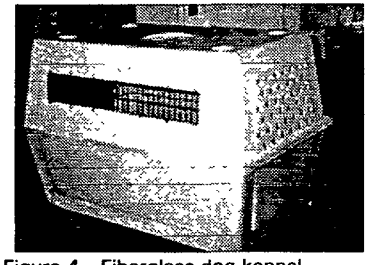

Figure 4. Fiberglass dog kennel

The forensic document examiner can often identify the type and amount of drug activity from seized clandestine drug records. Their interpretation is further enhanced by the use of the ISM to detect the presence of trace drug evidence.

A wide variety of other forensic and criminal justice applications of ion mobility spectrometry have been explored. They include probable cause, search and seizure, asset forfeiture, unusual concealments, probation and parole, correctional facilities, clandestine drug laboratory safety, fit for duty issues, and explosives detection.

Law enforcement agencies also become hazardous waste producers when they seize chemicals associated with the clandestine drug manufacturing. The transportable GC/MS permits the identification of the drugs and solvents without the need for shipping hazardous materials to the laboratory.

Conclusions: On-site crime scene analysis for trace physical evidence of drugs can provide the law enforcement investigators with time sensitive and important lead information. The IMS offers a rapid, sensitive, court proven screening method. From a procedural standpoint all positive field samples should be confirmed. Nationwide numerous arrests, prosecutions, and convictions can be directly attributed to the results of field analysis using portable mass spectrometers.

ANALYSIS OF "ECSTASY" AND OTHER DESIGNER DRUGS USING HPLC/APCI/MS

E.B. Hansen, Jr., M.I. Churchwell, C.R. Clark[1], J. DeRuiter[1], F.T. Noggle, Jr.[2], and D.R. Doerge, FDA, NCTR, Jefferson, AR 72079, [1]Dept. of Pharm. Sci., Auburn University, Auburn, AL 36849, [2]Alabama Dept. of Forensic Sciences, Auburn, AL 36830.

INTRODUCTION

"Ecstasy" is a street name for 3,4-methylenedioxymethamphetamine (MDMA). Monitoring abuse of MDMA and "designer drug" analogues of the parent drug, MDA, requires sensitive and selective analytical methods for their detection and confirmation in biological samples. Reported here is an HPLC method using electrochemical (ECD) and APCI-MS detection for the analysis of five MDA-derivatives, including Ecstasy, in human urine at levels as low as 5 ng/ml.

EXPERIMENTAL

HPLC

The HPLC system included a 7125 injector (20 μl loop, Rheodyne), a 600E system controller and pump (1 ml/min, Waters), a 250 X 4.6 mm I.D., 5 μ SCD-100 column (Synchrom, Inc.), and a mobile phase of 87% 0.1% formic acid/acetonitrile.

Electrochemical Detection (ECD)

ECD was performed using a 5100A Coulochem detector (ESA). The 5020 guard cell, set at +1.2 V, was placed between the column and a 5010 detector cell set at -0.1 V. Electrode 1 of the 5010 cell was monitored using Millennium Chromatography Manager software and a SAT/IN module (Waters). The guard cell was modified by replacing the steel tubing at the inlet and outlet of the cell with .005 mm I.D. Peek tubing.

Mass Spectrometry (MS)

MS was performed using a VG Platform benchtop single quadrupole mass spectrometer (Fisons Instruments/VG BioTech) equipped with an APCI interface. The HPLC effluent was introduced directly into the API source via a heated nebulizer probe using nitrogen as the nebulizing and carrier gas. Mass spectra were obtained in the positive ion mode, using full scans (m/z 100-400, cycle time 1 s) or selected ion monitoring (SIM, dwell time 0.2 s, span 0.02 m/z). To obtain mass spectra with fragment ions the cone voltage was varied between 10 and 40 V. The APCI source and probe temperatures 120°C and 400°C, respectively.

Sample Preparation

Urine (20 ml) was pH adjusted to 8.4 with phosphate buffer and passed through a strong cation exchange cartridge (PRS, Varian). The cartridge was washed twice with water and eluted with 1 ml of 1 M ammonium formate/acetonitrile (2:1) and analyzed by HPLC.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

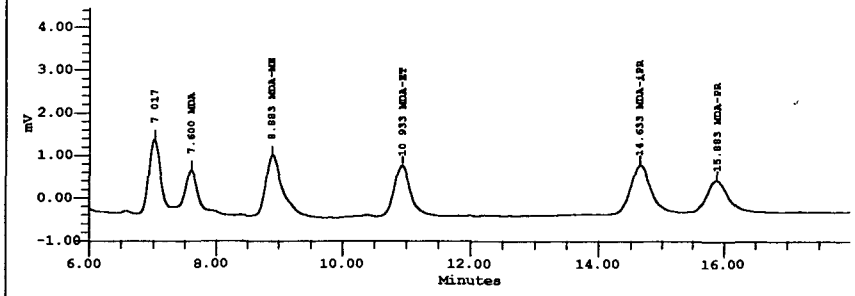

Figure 1. HPLC-ECD chromatogram from analysis of a 10 ppb spiked urine.

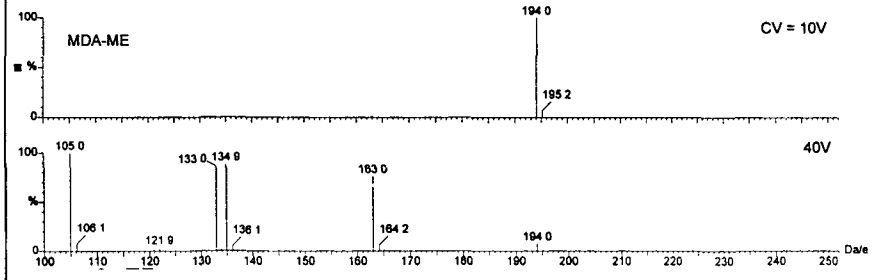

Figure 2. Cone-voltage-dependent fragmentation of MDMA.

RESULTS AND DISCUSSION

HPLC-APCI-MS and HPLC-ECD were successfully utilized to determine MDA and four "designer drug" analogs in human urine. The analysis provided baseline separation with a total run time under 18 min (Fig 1). The ECD in the configuration described appears very selective for compounds containing a methylenedioxy-moiety. The minimum detectable amount of these drugs using ECD was about 1 ng on-column. Using APCI-MS detection, $[M+H]^+$ions were obtained as the base peak with no significant fragment ions when the sampling cone voltage was set at 10 V. Analysis using varying cone voltages up to 40 V provided spectra containing diagnostic fragment ions (m/z 164,135,133,and 105) common for this class of drugs (Figure 2). The minimum detectable amount of these drugs by HPLC-APCI-MS analysis using selected-ion monitoring of the ions listed above is about 200 pg injected on-column.

These preliminary results indicate a level of quantitation for these drugs in urine as low as 5 ng/ml. With future modifications a minimum level of quantitation of 1 ng/ml or less is expected.

Immunoaffinity Extraction-LC/LC/MS/MS for the Determination of LSD Analogs in Urine

Jianyi Cai, Jack Henion
Analytical Toxicology, Diagnostic Laboratory, Cornell University, 927 Warren Dr., Ithaca, NY 14850

Remco van Soest
LC Packings, Baarsjesweg 154, 1057 HM Amsterdam, The Netherlands

Introduction

The determination of trace levels of analytes from complex matrices requires highly selective sample pretreatment techniques. Immunoaffinity extraction techniques are powerful tools in this field owing to their high specificity for targeted analytes which can also provide considerable sample enrichment. On-line trace enrichment eliminates tedious and time-consuming sample pretreatment associated with most LC/MS applications. The objective of this study is to evaluate the feasibility of coupling an immunoaffinity extraction system on-line with packed-capillary HPLC and tandem mass spectrometry (MS/MS). The system combines automated sample throughput with improved detection sensitivity. Tandem mass spectrometric detection offers additional selectivity and confirmatory information.

Due to its low dose and extensive metabolism, the determination of LSD and its metabolites in body fluids is a challenging task. Considerable effort has been directed towards the development of more sensitive and selective analytical methods. In this study, the direct analysis of trace levels of LSD, its analogs, and metabolites in human urine is demonstrated using an on-line immunoaffinity extraction-coupled column capillary HPLC-tandem mass spectrometry system.

Experimental

The mass spectrometer used was a PE Sciex TAGA 6000E API triple quadrupole mass spectrometer (Thornhill, Ontario) updated to an API-III. A column-switching system was developed, which involves three columns including an immunoaffinity column, a trapping column, and an analytical column. A protein G column with noncovalently-bound antibodies against LSD was used as the immunoaffinity column (2.1 x 3.3 mm, 30 µm, ChromatoChem, Missoula, MT). Both the trapping column (C-18, 0.5x15 mm, 5 µm, LC Packings, Amsterdam, The Netherlands) and the analytical column (C-18, 0.3x150 mm, 3 µm particles, LC Packings) were packed capillary columns. The use of packed capillary HPLC columns has several advantages over conventional HPLC columns, including improved detection sensitivity, and easy coupling to electrospray mass spectrometry.

On-line sample pretreatment involves several steps. The antibody column was primed by injecting antibody against LSD. PBS-diluted urine sample was then loaded onto the antibody column. After washing the antibody column with PBS, the bound analytes were desorbed from the antibody column and trapped onto trapping column. The trapped analytes were finally eluted from the trapping column to the analytical column and mass spectrometer for separation and characterization.

Results and Discussion

On-line immunoaffinity extraction coupled with capillary liquid chromatography-mass spectrometry (IAE/LC/LC/MS and IAE/LC/LC/MS/MS) were investigated and evaluated for the determination of LSD and its analogs in spiked human urine. LSD-positive human urine specimens were also analyzed using the described system. The two mass spectrometric operational modes (see Figure 1 and 2), selected ion monitoring (SIM) and selected reaction monitoring (SRM), as well as on-line UV detection were compared for the analysis of human urine spiked with LSD and it analogs at the 10 part per trillium (ppt) levels. Using SRM/IAE/LC/LC/MS, 2.5 ppt levels of LSD and several analogs in spiked human urine were detected. This is 20-fold below our previous limit of detection using solid phase extraction and SRM/LC/MS method.

Acknowledgments

We acknowledge Drs. R. Foltz and C. Nelson of Northwest Toxicology, Salt Lake City, UT, for providing us with several analytical standards and LSD-positive human urine specimens, Dr. R. Hammen of ChromatoChem for providing us with the protein G columns, and Dr. S. Salomone of Roche Diagnostic Systems for supplying several antibodies against LSD. Technical support from Dr. T. Wachs is greatly appreciated.

2 University of Berne, Berne, Switzerland.

LSD is a well known potent hallucinogen which was popular in the 1960's, and continues to be a significant drug of abuse today. LSD undergoes rapid and extensive metabolism such that only about 1% of ingested LSD is excreted unchanged in human urine.[1] Although the metabolism of LSD has been studied extensively, only a few minor metabolites have been identified in human urine[1] and human liver microsomes.[2] The major metabolic products have not been previously determined in human plasma or urine. 2-oxo-LSD has been reported to be a metabolite of LSD in laboratory animals and has been suspected to be a human metabolite.[3] However, 2-oxo-LSD, decomposes relatively rapidly in solution and has been difficult to identify in humans. In the present study, MS/MS was used as a means to identify new metabolites of LSD and products derived from the putative 2-oxo-LSD compound. A new major metabolite of LSD (2-oxo-3-OH-LSD) in human urine and plasma has been identified and is presumably derived from 2-oxo-LSD. The 2-oxo-3-OH-LSD structure was confirmed by comparison of CID spectra and GC retention time with authentic standard. Several other new metabolites have also been tentatively assigned. CID spectra and product-ion dissociation pathways of LSD, Nor-LSD, and 2-oxo-LSD models were initially studied.[4] Based on these model compounds, precursor and neutral-loss experiments were used to determine chemical degradation products of the 2-oxo-LSD standard. For instance, protonated molecules at *m/z* 328, 336, 338, and 356, were characterized as degradation products of 2-oxo-LSD and assigned as an amino ketone derivative of 2-oxo-LSD, unsaturated forms of 2-oxo-LSD (*m/z* 336 and 338), and 2-oxo-3-OH-LSD, respectively. GC/MS/MS and DCI/MS/MS was used to "screen" specifically for these products in urine extracts of participants in a LSD clinical study. Neutral-loss scans for elimination of the diethylamide moiety of the LSD molecule (NL 101) identified those metabolites or decomposition products which had undergone modifications in the ring system of the LSD molecule. Hydroxylated metabolites showed a characteristic neutral mass loss of 191u, corresponding to loss of diethylamide (101u) and TMSOH for TMS derivatives. Figure 1 shows an example of the mass chromatograms from selected-reaction monitoring of the 2-oxo-3-OH-LSD metabolite and the parent LSD drug in urine extracts. By comparison at this collection time, the intensity of the 2-oxo-3-OH-LSD metabolite is approximately 50 times greater than the intensity of LSD. Pharmacokinetic data for LSD and the 2-oxo-3-OH-LSD metabolite in human plasma is shown in Figure 2. The plasma profile of the 2-oxo-3-OH-LSD metabolite indicates that the metabolite can be detected in plasma for a significantly longer period of time compared with LSD.

Development of Methodology for Detection of Fluoxymesterone and Metabolites in Urine by GC/ECNI

Naxing Xu and J. Throck Watson, Department of Chemistry, Michigan State University
East Lansing, MI 48824

Fluoxymesterone, an anabolic steroid, was banned by the International Olympic Committee because of its abuse in sports. Fluoxymesterone is metabolized in man primarily by 6-hydroxylation, 3-keto-reduction, and via other pathways. Usually GC/EI/SIM is used to detect urinary anabolic steroids after TMS derivatization. More selective and sensitive quantitative methodology is proposed for urinary fluoxymesterone and metabolites based on ECNI with sample introduction by GC. The analytes are transformed to electrophilic species via an oxidation reaction. Preliminary results show remarkable discrimination against background in the detection of fluoxymesterone in the urinary matrix.

In this methodology, 6-methylprednisolone, a structurally similar compound, is added to the urine sample as an internal standard. The urine sample is extracted on a Sep-Park C-18 cartridge. The conjugated steroids are hydrolyzed by *Helix pomatia* obtained from Sigma. Fluoxymesterone and its metabolites are extracted with diethyl ether and evaporated to dryness under vacuum.

The dry extract is dissolved in 1ml CH_2Cl_2. 10 mg of anhydrous sodium acetate are used to buffer the acid liberated during the oxidation. An excess of the PCC(pyridine chlorochromate)/celite(1:2) is added to the vial. The reaction mixture is stirred and heated at 60°C for 5hr. The oxidized sample is cleaned up by 200 mg silica SPE column. The oxidized fluoxymesterone and its metabolites are eluted with 15% acetone in CH_2Cl_2. After evaporation, the sample is reconstituted in 100µl ethyl acetate.

A Finnigan 4600 GC/MS system was used for both EI and ECNI operation. Methane was used as buffer gas. The relative response of oxidized products under ECNI conditions are listed below:

steroid	characteristic ions of the oxidation product under ECNI	relative ECNI response
testosterone	286	1
6-methylprednisolone	312	350
fluoxymesterone	314, 334	500
6-OH-fluoxymesterone	350, 330	700
9-fluoro-17-methylandrost-4-ene-3,6,11,17-tetrol	350, 330	700
9-fluoro-18-nor-17,17-dimethylandrost-4,13-diene-11-ol-3-one	316	400

Fig. 1 illustrates the sensitivity and selectivity gained by using oxidation and ECNI. Shown in Fig. 1(a) is the total ion current chromatogram produced from an oxidized urine extract during GC/MS with EI ionization. EI is a non-selective mode of ionization which makes evident the large number of components

in the urine matrix. The selectivity of ECNI for electrophilic compounds is illustrated by comparison of Fig. 1(a) and 1(b). Only a few peaks are contained in the ECNI total ion current chromatogram of the same oxidized urine sample(Fig. 1b). The enhancement in sensitivity afforded by ECNI is also apparent by comparison of the integrated peak areas for oxidized fluoxymesterone and its main metabolites. This methodology shows great potential for the quantitative determination of fluoxymesterone and its metabolites in urine.

Ion Trap GC/MS and GC/MS/MS Measurement of Cocaine and Its Metabolites

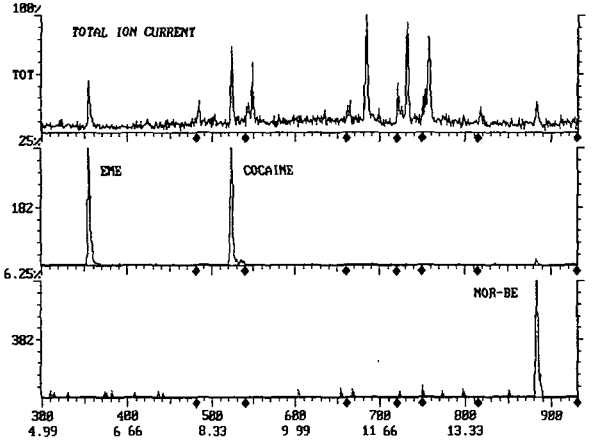
Larry D. Bowers and Kelly Fregien
Department of Pathology and Laboratory Medicine
Indiana University Medical Center
Indianapolis, IN 46202-5120

Recent developments in quadrupole ion trap technology have demonstrated the versatility of this approach to mass analysis. By applying various wave forms to the end caps and ring electrode of the trap, ions can be selectively stored, caused to undergo collision induced dissociation (CID), and ejected. As a result, GC/MS/MS can be relatively easily performed. In theory, the ion trap approach should provide improved detection limits. We report here on our studies of detection of small amounts of cocaine (C), cocaethylene (CE), benzoylecgonine (BE), ecgonine methyl ester (EME), norcocaine (NC0), and norcocaethylene (NCE). Our interest is to develop an analysis that will allow determination of cocaethylene pharmacokinetic profiles in single animal models. All studies were performed on a Varian (Walnut Creek, CA) Saturn III GC/MS system.

Two approaches to GC/MS/MS analysis were taken: electronic ionization (EI) MS/MS and selected ejection chemical ionization (SECI) MS/MS with acetonitrile as the reagent gas. The collision process was carried out in the non-resonant mode. In the EI case, the t-butyl-dimethylsilyl-derivatives of BE, EME, NC, and NCE were separated on a DB-5ms capillary column (J&W, Folsum, CA). For these derivatives, the (M-57)+ ion was isolated, collisionally dissociated, and the product ions scanned. For C and CE, the m 182 and 196 ions were used as parent ions. Each of the compounds required different collision energy for optimum product ion formation. The amplitude of the energy was programmed for change during each segment of the run to allow sensitive detection of all of the species.

Acetonitrile (MeCN) can be used as a reagent gas for SECI due to the low gas concentration required for CI in the ion trap. MeCN provided gentle ionization of these compounds resulting in predominantly protonated molecular ions (e.g.,m/z 304 (100); 182(10); 82(15) for C). For SECI/MS/MS, (M+H)+ was used as the parent ion and the most abundant product ion was monitored for quantitation (e.g., m/z 304→182 for C). Again, kinetic energy requirements for the various compounds differed, and thus the acquisition conditions were varied during the run to optimize detection.

Either technique provided increased sensitivity for the detection of C and its metabolites relative to GC/MS. A typical chromatogram is shown below illustrating the signals observed with 100 pg of a standard preparation. Detection limits on the order of 50 pg on-column were observed for the various cocaine metabolites using CI/MS/MS.



Selected Ion Storage and Tandem Mass Spectrometry of Anabolic Steroids

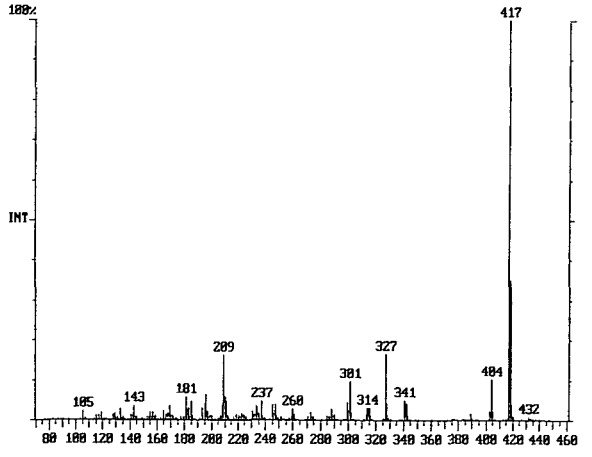
Larry D. Bowers
Department of Pathology and Laboratory Medicine
Indiana University Medical Center
Indianapolis, IN 46202-5120

The use of anabolic steroids (AS) continues to be problematic in sports. Improved limits of detection of AS and their metabolites are desirable. Traditionally, the trimethylsilyl-derivatives of AS are analyzed by selected ion monitoring (SIM) GC/MS to achieve sufficient limits of detection. This has required the simultaneous acquisition of numerous ions and the programming of multiple groups of ion collections. The operation of the quadrupole mass filter requires compromises between detectability and the number of ions that can be acquired. Quadrupole ion trap technology does not have this limitation, since ranges of ions ban be stored in (or specifically ejected from) the trap. The advantage of selected ion storage (SIS) is that only the ions of interest are stored, eliminating previously reported "space charging" effects. We report here on our study of SIS for the screening of AS. We have also studied GC/MS/MS as a means to improve limits of detection for confirmation analyses. All studies were performed on a Varian Saturn III GC/MS system (Walnut Creek, CA).

Several groups of trimethylsilyl-derivatives of AS were separated on a DB-5ms capillary GC column (0.25 mmx30 m; J&W, Folsum, CA). The 35 steroids were endogenous and potential exogenous AS or their metabolites. The SIS program was configured such that a range of ions (e.g., m/z 405-445) or a single ion of structural significance (e.g., m/z 143) was stored in the trap. Using the programmable acquisition tune events function, several such ranges could be programmed into the acquisition run as a function of time. Thus limited scan ranges could be adjusted to observe the ions of interest in the GC trace. This approach was significantly more sensitive than 20 ion SIM groups on an HP 5970. It was particularly used for compounds such as chlorodehydrotestosterone in which the specific isotopic pattern is useful for confirming the identity of the steroid. Unfortunately, a number of steroids whose derivatives are isobaric do not separate well by capillary GC (e.g., androstandione and epitestosterone). For this reason, MS/MS would be helpful in identifying the structure.

We investigated both non-resonant and RF resonant collision induced dissociation (CID). With appropriate adjustment of the energy, non-resonant excitation gave spectra which contained ions arising from the steroid nucleus (e.g., m/z 432→209 for testosterone-di-TMS) as well as characteristic TMS fragmentation (e.g., m/z 432→342).

Modulated RF resonant excitation specifically depleted the parent ion from the spectra. As shown in the Figure below, modulated RF resonance excitation gives rise to most of the ions observed in the non-resonant spectra. Detection limits for testosterone-di-TMS were 20 pg on-column.



Quantitative determination of the phosophodiesterase inhibitor CP-80,633 in human serum by HPLC/MS/MS

A. Kamel*, R. Schneider, K. Navetta, E. Luther and H. G. Fouda
Central Research Division, Pfizer Inc, Groton, CT 06340

CP-80,633 is a potent and highly selective inhibitor of phosphodiesterase type 4 (PDE4) which is implicated in the release of pro-inflammtory mediators. As such, it useful for the treatment of atopic dermatitis. Clinical evaluation of CP-80,633 required an analytical method for its quantitative determination in human serum. This presentation describes an assay which utilizes on-line HPLC and atmospheric pressure chemical ionization (HPLC-APCI) tandem mass spectrometry (MS / MS). A structural analog served as the internal standard for the assay. The drug and the internal standard are extracted from human serum and aliquots are injected onto a standard reverse phase HPLC column. The effluent from the HPLC column at 1ml/min is introduced into the atmospheric pressure source of a SCIEX API III mass spectrometer. The protonated molecular ion, generated by corona discharge chemical ionization, is subjected to collision induced dissociation to a specific product ion. CP-80,633 concentrations in serum are determined by the selected monitoring of the product ion from the drug and the internal standard.

The assay concentration range extends from 0.2 ng/ml to 50 ng/ml, and its precision and accuracy over that range are within 8%.

Protocols for DNA Mapping and Screening by MALDI MS by Jian Bai, Yan-Hui Liu, Xiaoli Liang, Mark G. Qian, and David M. Lubman, Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109-1055

INTRODUCTION Tremendous effort and progresses have been made in adopting MALDI MS as an alternative to elctrophoresis for DNA mapping, screening, and sequencing, which can be attributed to the developments of novel matrices, improved instrumentation, and sample preparation techniques, as well as the fundamental understanding of MALDI MS of DNA, among others. The presence of impurities in the samples can generally complicate the MALDI sample preparation process and cause degradation of the MALDI MS spectrum, further limiting the size of the DNA molecules that can be analyzed. This work intends to address some technical and experimental aspects of DNA mapping and screening using MALDI MS on a Nafion film substrate, including mass calibration, mixture analysis, as well as application of MALDI MS for the detection of genetic variations based on PCR amplification of DNA collected from buccal cells, blood cells, and other sources, particularly for the typing of DNA polymorphisms associated with genetic disorders

EXPERIMENTAL A linear TOF mass spectrometer was used for detection and 355 nm laser radiation for LD/I. PCR amplification was conducted using generic protocols using template DNA obtained from buccal cells collected from voluntary individuals, and blood cells. Digestion of PCR product was performed by adding enzyme directly in the cycled reactions. A commercial PCR purification kit was used for the purification of both PCR products and the digests.

RESULTS AND DISCUSSION

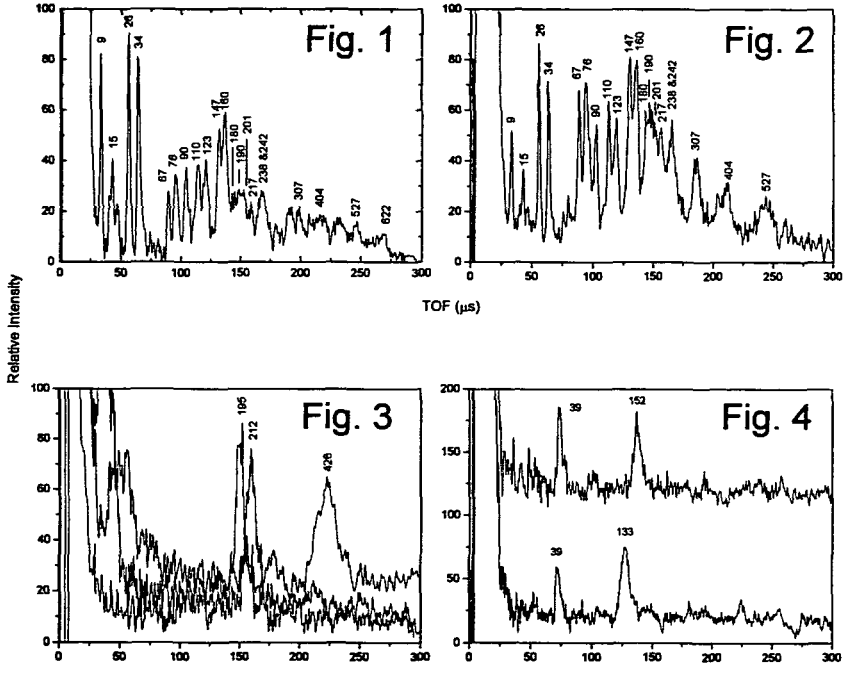
Mixture Analysis The ability of MALDI MS to analyze DNA mixture is limited by the fact that as the size of DNA increases the MALDI MS sensitivity drops rapidly. We believe that the formations of multiple adduct ions between Na^+/K^+ and DNA is one of the major factor accounting for these phenomena. All fragments in the *Msp* I digest of the pBR322 DNA ranging from 9 bp to 622 bp can be detected using the Nafion film substrate (Fig. 1), even though the identification of larger fragments is still not unambiguous. There also seems to be a clear drop of sensitivity at above 250 bp. This was later identified as due to the acidity of the Nafion film, which may render the DNA molecule unstable during MALDI, generating spurious peaks and degrading the sensitivity for larger fragments. This is confirmed by using neutralized Nafion film substrate with ammonia, with which much better signals for both small and larger fragments were obtained (Fig. 2).

Mass calibration The low resolution and that only ss-DNA were observed even for ds-DNA in MALDI is limiting the general applicability of the MALDI MS. It is impossible to resolve the signals from the two strands with different but complementary sequences. However the peak originated from a ds-DNA may represent the average of the two complementary ss-DNA. On the basis of this assumption, the average MW of any two ds-DNA stands will be n(k±0.25), by a mass deviation of only ± 0 25n, or 0 08% where n is the DNA size in bp, and k the average mass of the four nucleotide units. Liner regressions performed by taking the bp and TOF squared, and residue and statistical analyses indicate that the precision using these methods can be within 2 bp in the range of 9 - 622 bp, and within 1 bp (usually < 0.5 bp) in the range of 9 - 250 bp. The poorer precision in the broader range is caused by the increasing difficulty to determine the peak centroid of the larger fragments.

DNA Screening and Detection of Genetic Variations Several PCR products derived from human genomes ranging from 86 to 426 bp were analyzed and expected signals were detected by MALDI MS on the Nafion film substrate (Fig. 3). The 212 and 426 bp fragments were CA II and CFTR genes

amplified from buccal cell DNA. Detection of larger fragments was facilitated by using the neutralized Nafion film substrates. Typing of the RFLP were also performed on several genes including the carbonic anhydrase (CA) II and III genes, and cystic fibrosis transmemebranes regulator (CFTR) genes, by direct digestion of the PCR products amplified from bucall cells using restriction enzymes. Figure 4 show the spectra obtained with the CA II genes from two selected homozygous individuals.

CONCLUSION The results reported here using active substrate, such as Nafion, demonstrate that DNA mapping and screening with MALDI MS is becoming a reality, where large DNA fragments in complex mixtures can be detected, and DNA amplified from various DNA sources using different PCR procedures can be analyzed. The mass calibration scheme established is sufficient to determine the size of the DNA fragments of < 622 bp within 2 bp. DNA samples obtained from typical biochemical procedures and settings can be routinely analyzed with minimal processing. The method reported here can be a valuable alternative to electrophoresis for the detection of genetic variations based on PCR amplification for molecular pathology and linkage studies.



MALDI OF SYNTHETIC OLIGONUCLEOTIDES

Catherine Bentzley,[1] Murray Johnston,[1] and Barbara Lasrsen[2]
[1]Department of Chemistry, University of Delaware, Newark, DE 19716
[2]The DuPont Company, Science & Engineering Labs
P.O. Box 80228, Wilmington, DE 19880-0228

Introduction

MALDI-TOF is a valuable technique for the study of oligonucleotides. Synthetic oligonucleotides are important to the fields of molecular biology and medicine. The synthetic oligomers are used as probes in cDNA hybridization studies, primers in DNA sequencing and PCR amplification, as well as specific gene expression. Frequently, the synthetic oligonucleotides are used with no verification of the correct sequence or purity.

In this report, we analyzed numerous synthetic oligonucleotides to measure their molecular weight to initially verify their composition. We can consistently obtain the molecular ion for oligomers containing as many as 60 bases. The protocol we applied used 3-hydroxypicolinic acid (HPA) as the matrix (saturated solution) with 50-100 pmol/µl of sample which was treated with 0.5M ammonium citrate. Mass accuracy is <0.07% for all measurements which is sufficient to verify the base composition of the sample.

Providing composition verification of the oligonucleotides does not ensure that the sequence is correct. We have been developing enzymatic procedures to obtain sequence information. Shown in Table 1 and Figure1 is the digestion od a mixed base 24mer reacted for 9 minutes with Calf Spleen Phosphodiesteraseto obtain the 5' sequence os the bases. By digesting the oligomers with Calf Spleen Phosphodiesterase we were able to obtain the 5' sequence of the bases. Similar digests have been performed on larger oligonucleotides with moderate success It appears that the enzyme has a preference for particular base sequences especially thymine.

Conclusions

These values were acquired with <0.07% mass accuracy. The advantages of the techniques used here would allow for the routinue analysis of oligonucleotides using a UV laser.

Several oligonucleotides were digested to determine their base composition and sequence A procedure was developed to analyze the digestion of oligomers even for samples of mixed base compositions The same mass accuracy was expected for the digested units as was obtained for the molecular ion.

Improving Mass Resolution in MALDI-TOF Analysis of DNA

Kai Tang, Sequenom Inc , 101 Arch Street, Boston, MA 02110, USA
Timothy A. Worrall, and Robert J Cotter, Middle Atlantic Mass Spectrometry Laboratory, The Johns Hopkins University, School of Medicine, 725 N. Wolfe Street, Baltimore, MD 21205, USA
Hubert Köster, Faculty of Chemistry, Department of Biochemistry and Molecular Biology, University of Hamburg, Martin-Luther-King-Platz 6, 20146 Hamburg, Germany

While the mass range for detection of oligonucleotides by MALDI-TOF has been extended significantly (1), mass resolution in the high mass range remains poor. The major problems appear to be low desorption/ionization effiency and instability of molecular ions formed in the MALDI process, leading to losses of G, A and C bases through cleavage of the N-glycosidic bond. When such fragmentation is metastable and occurs in the acceleration region, considerable peak broadening results, which cannot be corrected or compensated by ion optical means. Therefore, our goal is to eliminate or at least minimize fragmentation during acceleration.

In our recent study, we observed that small DNA ions (up to 25-mer) are stable if an appropiate matrix (3-HPA + 10% ammonium citrate, dibasic) is used. We analyzed in a curved field reflectron TOF (2) a mixture of 12-mer, 16-mer and 20-mer with mass resolution of 1000 Neither prompt nor metastable fragments were present (figure 1). A 25-mer was also observed in a separate test under similar conditions with mass resolution of 900.

For longer DNA oligomers, metastable fragmentation was generally observed with a reflectron TOF (Vision 2000, Finnigan MAT). The most notable metastable ions resulted from the loss of a guanine base. For oligomers shorter than 60-mer, mass resolution in the reflectron was still high enough to routinely distinguish the molecular ions and the depurinated metastable ions. However, considerable broadening of the molecular ion peak was observed and probably resulted from the loss of much smaller metastable fragments which could not be resolved by the reflectron, or metastable decay in the ion source. For comparison, the metastable fragments were not observed when a linear TOF mass spectrometer (Kompact MALDI III, in linear mode, Shimadzu) was used

With the reflectron instrument, a degraded 60-mer was analyzed (figure 2) Fragments from the cleavage of the phosphodiester bond were correctly assigned from the 4-mer to 55-mer. This result demonstrates the feasibility to measure complex DNA mixtures by MALDI-TOFMS and is encouraging for applying the technique to DNA sequencing. Further, a mixture of synthetic ss-DNAs up to 50 bases long that mimic the sequencing ladder produced by ddTTP was analyzed, and detection sensitivity was determined at about 50 fmol for each ladder component (figure 3).

Probing the Stability of Phosphorothioate Oligodeoxynucleotides Using Matrix-assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry

Bing H. Wang *, Andre J. Bourque, Alexi B. Belenky, and Aharon S. Cohen
Hybridon, Inc., Milford, MA 01757

Introduction

Due to their nuclease resistance and the ability to promote Rnase H activity, phosphorothioate oligodeoxynucleotides (sODNs) are a group of promising antisense agents for the sequence-specific inhibition of gene expression. *In vitro* studies have shown the activity of sODNs against human immunodeficiency virus (HIV) and other viral targets. The inhibitory activity of sODNs against HIV *in vivo* is currently under clinical trials For therapeutic applications, the stability of sODNs has to be evaluated and the degradation products have to be identified, since they may lead to toxic side effects.

Although techniques such as anion-exchange high performance liquid chromatography (AE-HPLC) and capillary gel electrophoresis (CGE) are powerful techniques for separating mixtures of sODNs and their derivatives, it is tedious to ascertain the identity of individual components in a mixture using these techniques Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOFMS) has recently been applied to the analysis of sODNs (1) The much higher specificity of molecular weight information over that of migration time coupled with the knowledge of a sODN sequence prior to its degradation allows a rapid identification of the degradation products.

Experimental

A phosphorothioate 25-mer (GEM91) was synthesized in house. To obtain its thermal degradation products, an aqueous solution of the 25-mer was stored at 60°C for 2 months. Light-induced degradation products were obtained by storing a solid sample of the 25-mer in a light chamber of 1000 foot candles at 30°C for 2 months. In the *in vitro* enzymatic digestion experiment, the 25-mer was incubated with snake venom phosphodiesterase I (SVP I) at 55°C for 2 hours Samples from above sources were analyzed without further purification In the experiment involving *in vivo* enzymatic digestion of the 25-mer, the metabolites were obtained from the plasma of a Rhesus monkey collected 8 hours after subcutaneous injection of the precursor compound sODN products were extracted from the plasma by anion-exchange solid phase extraction followed by reverse-phase solid phase desalting.

A mixture of 3-hydroxypicolinic acid and N-(3-indolylacetyl)-l-leucine was used as the matrix (2) To reduce the formation of sodium and potassium adducts, the matrix solution was heated to 50°C for 15 min in the presence of cation-exchange resin in NH_4^+ form (200- 400 mesh) Negative ion mass spectra were acquired with a Bruker Reflex MALDI-TOF mass spectrometer in the linear mode All spectra were the summed results of 20 -30 laser shots

Results

Thermal degradation. Extensive sequence fragments were generated by prolonged heating (Figure 1) Cleavage invariably occurred on those glycosidic bonds that were attached to the ribose which had lost the base. Not surprisingly, purine bases are the favored sites of cleavage In contrast to pyrimydine bases, cleavage at purine base can produce a 5'-end fragment with the ribose residue attached, in addtion to the 3'-end and 5'-end fragment pair. This mechanism accounts for the production of peaks at *m/z* 1654, *m/z* 2304, and *m/z* 3553

Light-induced degradation. In contrast to thermal degradation, only small fragments (smaller than 12 bases) were observed from light irradiated samples The mechanism of the fragmentation is currently under investigation.

Enzymatic digestion. The mass spectrum of the metabolites collected from the monkey plasma 8 hours after the injection of the 25-mer consists of mostly peaks from a sequence ladder, which was generated by the successive removal of 3'-end phosphorothioate deoxynucleotides (Figure 2) The spectrum resembles closely that of the products produced by *in vitro* digestion of the 25-mer by SVP I. However, MALDI-TOFMS analysis of metabolites collected after 8 weeks of daily injection and 24 hours after the last injection showed that products from 5'-end digestion are also present. Significantly, oxygenated products were present among the metabolites.

Conclusion

The generation of degradation products or metabolites of GEM91 are environment dependent While degradation at 60 °C gives prominent depurination products, light-induced degradation tends to produce fragments smaller than 12-bases In a Rhesus monkey, 3'-exonucleases exhibited much higher activity than 5'-exonucleases. The last finding suggests that efforts should be directed towards the modification of the 3'-end of an antisense agent to increase its nuclease resistance

6-AZA-2-THIOTHYMINE: A GOOD MATRIX FOR THE ANALYSIS OF OLIGONUCLEOTIDES

P. Lecchi, H. M.T. Le, and L.K. Pannell, Lab. Analytical Chemistry, NIDDK, NIH, Bethesda, MD (USA)

The analysis of oligonucleotides has become important to this laboratory. In our research into the existing experimental protocols and matrices for MALDI, we found that it was hard to obtain satisfactory results. We decided to develop a MALDI method that would give consistent results with oligonucleotide samples. The use of 6-aza-2-thiothymine (ATT) as a matrix for MALDI has been reported (1), but not with oligonucleotide samples. Since ATT has a molecular structure closely related to that of purines, and has an UV absorption at the wavelength commonly used for MALDI (337 nm), it seemed a reasonable candidate to be tested.

All spectra were acquired on a KRATOS MALDI III (Shimadzu, Columbia, MD). After desorption and ionization, negative ions were accelerated at 22 KeV, in linear mode. Approximately 50 shots of the laser across the sample surface were averaged to produce the spectra shown .

Experimental protocols described for 2',4',6'-trihydroxy acetophenone (THA) (2), 3-hydroxy picolinic acid (3-HPA) (3) and ATT (4) were compared using a 16-mer oligonucleotide (TTTAGAGTCTGCTCCC). In all the three experimental protocols 1 µl of matrix solution was mixed on the sample probe with 0.8 µl of analyte solution. As internal standards, bovine insulin β chain and bovine insulin (peaks at m/z 3494.3 and 5732.0) were used. The MALDI spectra clearly show ed that ATT gave better resolution. To further compare the three matrices, the 16-mer oligonucleotide was run with ATT, THA or 3-HPA, 30 times for each matrix, in three different experiments. Statistical analysis shows that ATT gives the best resolution and reproducibility (Fig. 1).

With a mixture of oligonucleotides a clean spectrum is obtained at 10 pmoles/each. With as low as 0.1 pmoles, a spectrum that shows all of the analytes in the mixture is still seen. The longest nucleotides tested so far with ATT are 33 and 45 nucleotides in lenght, and molecular ion peaks were obtained. A crude deprotected 23-mer oligonucleotide (trytil-OFF) was analyzed with ATT, and the impurities and by-products of synthesis could be clearly seen.

A 12/16 nucleotide long, double-stranded (ds) DNA EcoRI adaptor was analyzed using ATT or THA as a matrix. No peak at the MW expected for the DNA duplex was seen with THA. With ATT, the intact ds-DNA peak is clearly seen, as well as those of the two dissociated single strands. The single-strand (ss) DNA specific enzyme Nuclease S1 was used to digest the ss-DNA present in the sample prior to ionization. The spectrum shows a significant reduction of the peaks corresponding to the dissociated ss-DNA, thus implying that dissociation of the DNA duplex did not occur during the desorption process.

In conclusion: a) ATT is an optimal matrix for the analysis of oligonucleotides; b) ATT gives better resolution, accuracy and reproducibility than THA and 3-HPA; c) ATT gives high sensitivity, tolerance to contaminants and good upper mass limit; d) Double-stranded DNA can be detected as an intact duplex when ATT (but not THA) is used as a matrix.

MALDI-MS AS A NEW TOOL TO MONITOR THE ACTIVITY OF NUCLEIC ACID MODIFYING ENZYMES

E. Nordhoff, F. Kirpekar, K. Kristiansen, P. Roepstorff, S. Hahner[1], F. Hillenkamp[1], R. Cramer[2], and R. F. Haglund[2]

UV-MALDI-MS analysis of DNA and RNA using 3-hydroxypicolinic acid as matrix has been applied for the study of the activity and specificity of different nucleic acid modifying enzymes[1,2]. Alkaline phosphatase catalyzes the removal of 5'-terminal monophosphate groups of DNA and RNA and of 5'-di- and 5'-triphosphate groups of RNA leading to reduction in molecular mass of 80 Da for each released phosphate group. Polynucleotide kinase catalyzes the transfer of the terminal phosphate group of ATP to the 5'-hydroxylated termini of DNA and RNA resulting in increase of molecular mass by 80 Da. T4-RNA ligase catalyzes the formation of an internucleotide phosphodiester bond between a 5'-terminal phosphate and a 3'-terminal hydroxyl group of linear oligo- or polyribonucleotides by the use of ATP. Depending on the reaction conditions, especially on the concentration of the educt species, and sequence length of the educts this reaction can generate either circular RNA or intermolecular ligation products. Circularization leads to a mass loss of 18 Da corresponding to the phosphodiester bond formed in addition (elimination of one water molecule). With UV-MALDI RTOF-MS using 3-hydroxypicolinic acid as matrix this mass difference has been resolved, e.g., for a RNA 20-mer. Ligation of two species of type M lead to a ligation product of molecular mass of 2M-18 Da.

Terminal transferase catalyzes a template independent addition of deoxyribonucleotides to the 3'-termini of single- or double-stranded DNA. The stepwise addition and the resulting size distribution after a chosen reaction time can be visualized by mass spectra. An example is given on the right side: mass spectra of the elongation of an octathymidylic acid after 3 min incubation with terminal transferase in the presence of (a) adenosine triphosphate and (b) 7-deaza-adenosine triphosphate are shown[3]. Specific exonucleases degrade stepwise oligonucleotides (DNA and RNA) either from the 3'- or the 5'-terminus. A time course of this activity by MS allows one to determine the sequence of oligonucleotides in a very elegant way[4,5].

T3- as well as T7 RNA polymerase transcribe DNA into RNA. If applied to a restriction-enzyme linearized DNA template exhibiting the corresponding promotor region large quantities of in-vitro RNA transcripts can be obtained and the sequence length of those can be determined by the specificity of the used restriction enzyme. However, the transcription of such templates does always lead to RNA products exhibiting a strong 3-heterogeneity. Premature termination of the transcription as well as unspecific elongation of the full length transcript, both highly depending on the template and used enzyme, were observed[6]. The complexity and kind of heterogeneity were characterized by MALDI-MS.

Study of PAH-DNA adducts by CF-FABMS

Sylvie Plante and M.J. Bertrand
Regional Center for Mass Spectrometry, Dept. of Chemistry,
University of Montreal, Montreal, Canada, H3C 3J7

Polycyclic aromatic hydrocarbons (PAH) are pollutants whose toxicity to several species has been proven. The formation of adducts between the DNA and PAHs is believed to induce processes such as mutagenesis, teratogenesis and cancerogenesis. This study examines the adducts formed betwen deoxyguanosine (dG) and Benzo[a]pyrene (BaP) (Figure 1). These adducts were synthesized electrochemically in this laboratory [1,2]. Subsequently, CF-FAB-MS and capillary LC/FAB-MS, under both positive and negative ionization modes, were used to analyse these compounds. As well, the conditions of the mobile phases were optimised with respect to the pH level and glycerol content. Since two different adducts are obtained (C8dG and C8Gua) and recovered during the synthesis, a chromatographic separation was undertaken. In LC/MS the intensity of the molecular ion was found to vary with the pH of the matrix. In the positive ion mode, an optimal signal is observed for a pH adjusted to a value of 2.0 using trifluoroacetic acid (TFA). When less acidic mobile phases are used, the signal weakens. For the negative ions, a better signal for both adducts is observed when the mobile phase pH is adjusted to a value 9.5 using sodium hydroxyde (NaOH). It is possible to vary the concentration of the FAB matrix (Glycerol) in the mobile phase in order to optimize the sensitivity of the signal. A mobile phase with 2% of glycerol was used for both ion modes. Similar results are obtained using mobile phases of 2% Gly, 60% EtOH, 38% H_2O, or 2% Gly, 60% ACN, 38% H_2O. The same pH values obtained under the CF-FAB conditions was used for the LC/MS experiments. The optimal flow rate used to separate both adducts was 2.0 uL/min. Figure 2 illustrates the mass chromatograms obtained under positive ionization. Chromatogram A corresponds to m/z 402, and chromatogram B to m/z 518. C8Gua has a m/z of 402 and, therefore, corresponds to one of the two peaks in chromatogram A. However, the mass spectrum of the peak in chromatogram B shows the molecular ion of C8dG, as well as a fragment at m/z 402 (Figure 3). This peak elutes in coincidence with one of the peaks in chromatogram A of Figure 2, which suggests that the other peak in the chromatogram corresponds to the C8Gua adduct. The mass spectrum of this peak confirmed an ion of m/z 402, however, no characteristic fragmentation is observed for this molecule under these experimental conditions. The parent-molecular ion of C8dG, at m/z 518, appears less intense than the fragment at m/z 402. The difference in mass between the both ion is that of a sugar ($C_5H_9O_3$). These results suggest that the two adducts are indeed separated and present in the mass chromatograms of Figure 2. The mass chromatograms obtained in the negative ion mode were very similar to those obtained for positive ions. This confirms that the pH of the eluent does not dramatically change the chromatographic conditions. A mass chromatogram of m/z 400 again shows two peaks, of which the second belongs to the C8Gua parent-molecular ion. Here again no characteristic fragmentation is observed in the mass spectrum for this adduct under these conditions. The mass spectrum (Figure 4) of the peak in the mass chromatogram of m/z 516, shows a peak at mass 400. Again, loss of a sugar molecule is deemed responsible for the ion of m/z 400. The intensity of this fragment is less than that of the molecular ion. In order to achieve the separation of the adducts, while also providing suitable FAB ionization conditions, the optimisation of certain parameters, such as the content of glycerol and the pH of the mobile phase was required. The best results were obtained using 2% of glycerol in the mobile phase, in both

positive and negative ion modes. The pH study demontrates that an acidic pH of 2.0 provides a better signal of adduct molecular ions under positive ionization, while a pH of 9.5 is favorable for negative ionization. The mass spectra of C8dG indicates the loss of a sugar entity from the molecular ion, under both positive and negative ionization modes, while no intense fragments were observed in the spectra of C8Gua.

MALDI-TOF Analysis of Steriod/PAH-modified DNA Adducts at the femtomole Level

J. K. Gooden,[1] M. L. Gross,[1] D. Stack,[2] P. Mulder,[2] K. Li,[2] E. Cavalieri[2]

[1]Dept. of Chemistry, Washington University, 1 Brookings Drive, St. Louis, MO 63130
[2]Eppley Institute, University of Nebraska Medical Center, Omaha, NE 68198

Covalent binding of polycyclic aromatic hydrocarbons (PAH's) and steroids to DNA to form adducts is one of the first events in the process of tumor initiation in carcinogenesis. Structure elucidation and characterization of these adducts provide important information that leads to further understanding of their biological metabolic pathways. In in vivo and in vitro steroid/PAH-DNA binding studies, the reaction products (adducts) are often of low amount (low picomole to femtomole).

Previous results from our laboratory have shown that the sensitivity of MALDI-TOF can be improved by proper matrix selection.[1] An increase in sensitivity can also be obtained with the use of *d*-fucose as a co-matrix.

In this study 4-phenyl-α-cyanocinnamic acid, **PCC**, 4-benzyloxy-α-cyanocinnamic acid, **BCC**, ferulic acid, **FA**, α-cyano-4-hydroxycinnamic acid, **4HCCA**, and 3-(2-naphthyl)-2-cyanoacrylic acid, **NCA,** were used in the determination of the limit of detection for two different DNA adducts dibenzocarbazole-5-*N*7Ade, and 4-hydroxyestrone-*N*7Gua. Matrices were used as saturated solutions of 1% TFA in 50% acetonitrile/water except for ferulic acid, which was used as a 0.14 M solution. Solutions of matrices utilizing *d*-fucose as a co-matrix were prepared as 0.5 M solutions in the same solvent for all matrices. Standard solutions of DBC-5-*N*7Ade , and 4-OH-estrone-*N*7Gau were prepared in methanol at 4 pmol/μL concentrations. Analyte and matrix were premixed before application to the sample plate.

Experiments were carried out on a PerSeptive Biosystems Voyager RP MALDI-TOF Mass Spectrometer equipped with a nitrogen laser. Ions were detected in positive ion mode at an accelerating voltage of 25 kV. PSD spectra were obtained under the same conditions. The limit of detection was determined by the lowest amount of analyte that would produce a signal to noise of 3 to 1 or better in three separate trials. The result of forty to sixty laser shots were averaged for each spectrum.

Increased sensitivity can be achieved when the matrix compound and the analyte are structurally similar. The limits of detection for DBC-5-*N*7Ade using **BCC**, **NCA**, and **PCC** is 125 fmol/μL or lower (Table 1). When these matrices are combined with *d*-fucose as a co-matrix, the limit of detection becomes 50 fmol/μL or lower. The lowest limit of detection was acquired with **BCC**/fucose at 17 fmol/μL. The DNA adduct 4-OH-estrone-*N*7Gua is composed of a polar purine base and a polar steroid. The limit of detection for this adduct using **4HCCA** and **FA**, both of which have polar groups separated by an aromatic ring, is 267 and 520 fmol/μL respectfully (Table 1). Using *d*-fucose as a co-matrix affords detection limits of 167 fmol/μL for **4HCCA**/fucose and 25 fmol/μL for **FA**/fucose.

Structural information from DNA adducts can also be obtained from Post Source Decay (PSD) analysis. An example of this analysis is the PSD of DBC-5-N7Ade, which is compared with the CAD spectrum of the same adduct, obtained on a four-sector tandem instrument. (Fig 1).

Tandem MS/MS for Determining Structural Isomers of PAH-DNA Adducts

J. Byun[1], I. Vidavsky[1], M. L. Gross[1], P. Mulder, K. Li[2] and E. Cavalieri[2] (1) Department of Chemistry, Washington University, One Brookings Drive, St. Louis, MO 63130, (2) Eppley Institute for Research in Cancer, University of Nebraska Medical Center, 600 South 42nd Street, Omaha, NE 68688-0362

Polycyclic aromatic hydrocarbons (PAHs) such as methylcholanthrene (MC), dibenzo[*a,l*]pyrene (DBP), and dimethylbenz[*a*]anthracene (DMBA) are carcinogenic because they give rise to PAH-DNA adduct formation. Our laboratory has demonstrated that tandem mass spectrometry is effective for distinguishing and characterizing these isomers.

The main goal of this study is to investigate the structural isomers isolated from reactions of DBP, 1,2,3,4-tetrahydro-7,12-dimethylbenanthracene (THDMBA), and MC radical cations with DNA, to identify the structure of fragment ions produced by CAD, and to understand fragmentation processes of modified DNA adducts.

The tandem CAD mass spectra were acquired by using a VG ZAB-T, a four-sector tandem mass spectrometer of BEBE design. A Cs^+ ion gun operated at 30 kV was used to desorb the ions from the probe. CAD spectra were obtained after precursor ion activation in the third field-free region (between MS 1 and MS 2) by addition of helium to attenuate the ion beam by 50 %.

DBP-Ade Adducts

Upon collisional activation (CA), the $[M + H]^+$ ions of *m/z* 436 from DBP-Ade adducts decompose to generate major fragment ions of *m/z* 419 $(M + H - NH_3)^+$, *m/z* 327 $(C_{24}H_{13}NC)^+$, *m/z* 314 $(C_{24}H_{12}N)^+$, *m/z* 302 $(C_{24}H_{14})^+$, *m/z* 300 $(C_{24}H_{12})^+$, *m/z* 287 $(C_{23}H_{11})^+$, *and m/z* 274 $(C_{22}H_{10})^+$. The most abundant fragment ion is of *m/z* 300 $(C_{24}H_{12})^+$, Fig. 1. The ions of *m/z* 302 and *m/z* 419 are of particular interest for distinguishing the different structural isomers.

As shown in Scheme 1, the generation of the *m/z* 302 ion from the parent ion of *N7*- and *N9*-adducts occurs by the cleavage of PAH-DNA bond. For *N7*Ade adduct, the formation of the *m/z* 302 and 419 ions is now more competitive because a six-membered ring intermediate is stabilized by hydrogen bonding. However, the relative abundance of the *m/z* 302 ion in *N9*Ade is larger compared to that of *N7*Ade because the proton attached at C_{10} position may not interact with other basic groups, leading to the greatest weakening of the C-N bond in this set of isomers. The relative abundances of the fragment ions $(C_{24}H_{14})^+$ at *m/z* 302 and $(M + H - NH_3)^+$ at *m/z* 419 are inversely related and serve as "finger-prints" of the various isomers to give information about the site of attachment of the DBP on the base.

THDMBA-7CH$_2$- and 12CH$_2$-N7Ade and Gua Adducts

The CAD mass spectra of the $[M + H]^+$ ions for the modified Ade (Fig. 2) and Gua adducts show several important fragment ions giving structural information. The prominent ion of *m/z* 259 fragments in a distinctive way, identifying the position of pyridine attachment to 1,2,3,4-TH-7,12-DMBA. When the attachment is at C_{12}, the fragment *m/z* 244 is more abundant, whereas for attachment at C_7, the fragment *m/z* 243 is more abundant (Scheme 2).

Methylcholanthrene(MC)-Base and Nucleoside Adducts

During CAD, the $[M + H]^+$ ion of MC related compounds decompose to generate several ions that are diagnostic of the adduct. All adducts give as the most abundant product ion of *m/z* 267. Unfortunately this fragmentation is so facile that different sites of attached of MC to the base cannot not be distinguished.

In conclusion, FAB MS/MS can be used to distinguish structural and/or positional isomers on the basis of the relative peak intensities and fragment ions. Our ongoing efforts include determination of these adducts formed *in vivo* studies by MS/MS, using continuous-flow and co-axial flow FAB as well as ESI to overcome some drawbacks generated in FAB MS/MS.

A GENERAL METHOD FOR DETERMINING ETHYLENE OXIDE AND RELATED N7-GUANINE DNA ADDUCTS BY GC-EC-MS.

Amir Abushamaa, Xiaoning Wang, Veeravagu Murugaiah, Abdul Naim, Manasi Saha, and Roger Giese. Department of Pharmaceutical Sciences in the Bouvé College of Pharmacy and Health Sciences, and Barnett Institute, Northeastern University, 360 Huntington Avenue, Boston, MA 02115.

INTRODUCTION:

The N7 position of guanine is a prominent site of attack on DNA both in vitro and in vivo by a variety of alkylating agents. Humans are exposed occupationally, chemotherapeutically or otherwise (e.g. smokers) to alkylating agents. For example, approximately 2.5 x 10^6 tons of ethylene oxide are produced annually in the United States, where 150,000 workers deal with it daily in various industrial processes [1986 figures]. Ethylene oxide is considered a probable carcinogen in humans. N7-G adducts potentially are a favorable class of DNA adducts for measurement since heating the DNA in water releases such adducts as free nucleobases. We are developing a general method for the detection of "small" N7-G DNA adducts by GC-EC-MS (Hewlett Packard 5988A).

RESULTS AND DISCUSSION:

Our scheme for detecting N7-G ethylene oxide and related adducts is shown in Figure 1. Starting with a 100 µg amount of DNA spiked with 100 pg of this analyte and a corresponding stable isotope internal standard, we obtained the mass chromatograms shown in Fig. 2 A, B. The triplicate analysis gave absolute yields of 9.7 ± 3.0% and 9.7 ± 3 3% (x ± SD) of final products, respectively, for the analyte and internal standard. Fig. 2C shows the corresponding analysis of a sample containing no DNA. The variation in peak symmetry is due to variation in column age and plotted peak height (see inset in Fig. 2C). The generality of the method was demonstrated by applying it successfully to 50 ng amounts of analogous methyl, benzene and styrene N7-G adducts. During this study a new mechanism (masking by contaminants) was discovered for evaporative loss of a trace analyte, especially after solid phase extraction. Using the scheme shown in Figure 3, the data shown in Tables 1 and 2 were obtained, which showed that such contaminants not only exist in the purest water routinely available, but are enhanced and vary significantly after solid phase extraction using different commercial packings.

CONCLUSION:

Previously we obtained a 17% overall yield preparatively when 20 mg of a pure sample of the N7-G ethylene oxide adduct was converted to the final derivative shown in Figure 1. Now, starting with about 10^8 less analyte and spiked into DNA, our absolute analytical yield is 9.7%. This method has been transferred to another laboratory where it is being used successfully to measure this adduct and animal and human samples. During the course of the work, it was learned that an evaporation can risk loss of a trace analyte from masking by packing-derived solvent contaminants. This tends to counteract the common strategy of redissolving a trace analyte by using a good solvent for it. This work was funded by a Grant from NIOSH (Centers for Disease Control and Robert A. Taft Labs).

LC/ESI/MS/MS Analysis of Hydroxyl Radical Modification of DNA

Eileen M. Kowalski,[1] Ajai K. Chaudhary,[2,3] and Ian A. Blair,[1,3] Departments of Chemistry,[1] Biochemistry,[2] and Pharmacology,[3] Vanderbilt University, Nashville, TN 37232-6602

The role of exogenous substances such as pollution, tobacco, and industrial chemicals in causing DNA modifications is well-studied. However, less emphasis has been placed on studying the effects of substances which occur naturally in the body. Endogenous oxygen free radicals induce a variety of adducts, many of which are not well characterized. Our laboratory is studying these adducts to determine their structures and their biological implications.[1,2] Recent studies in our laboratory have centered on developing LC/ESI/MS/MS methods to analyze DNA modified by hydroxyl radicals. The initial system for study involves ferrous ion and hydrogen peroxide, collectively known as Fenton's reagent. Calf thymus DNA (0.5 mg/ml) was incubated with 600μM $FeSO_4$, 600μM EDTA, and 3mM H_2O_2 at 37 °C for one hour to effect DNA modification. DNA was precipitated with ethanol and subsequently redissolved and enzymatically hydrolyzed using micrococcal nuclease, alkaline phosphatase, and phosphodiesterase I. After filtration to remove the enzymes, samples were analyzed by LC/ESI/MS/MS.

A Finnigan TSQ 7000 mass spectrometer equipped with an electrospray source was used for MS analysis. Tandem mass spectrometry was performed in constant neutral loss (CNL) mode with an offset of 116 mass units between the first and third quadrupoles in order to detect the loss of the deoxyribose moiety from the

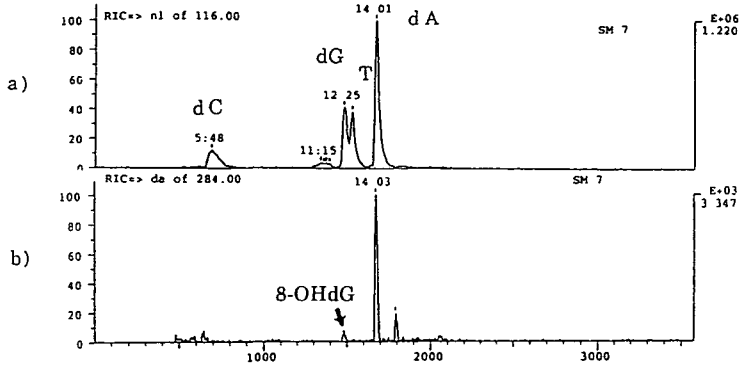

Fig. 1. Reconstructed ion chromatograms of LC/ESI/MS/MS analysis of Fenton-EDTA treated DNA. a.) CNL mass chromatogram of DNA hydrolysate. b.) Mass chromatogram of product ions of m/z 284.

analytes. Further information about modified DNA was obtained by product ion scans. An HP 1090 Series II LC system was employed for solvent delivery. Samples were analyzed using a Zorbax C-8 column (2.1 mm ID x 15 cm) with a two-component gradient. Component A was 5mM ammonium acetate and 0.04% acetic acid in water, and component B was 5mM ammonium acetate and 0.04% acetic acid in methanol. Analyses were performed using the following gradient: 0-5 min, 100% A; 10 min, 30% A; 12 min, 5% A; 25 min, 5% A; 30 min, 100% A. The flow rate was 0.2 ml/min. Under these conditions, all deoxynucleosides and adducts eluted within 15 minutes.

Results obtained from DNA treated and analyzed as above are shown in Figure 1. CNL analyses show the presence of the four normal deoxynucleosides. However, LC/MS/MS analysis of m/z 284 (MH^+ of 8-OHdG) revealed that the hydrolysate contained 7,8-dihydro-8-oxo-2'-deoxyguanosine (8-OHdG), a common product of hydroxyl radical modification, which coeluted with thymidine and therefore could not be detected in CNL scans. This adduct generated *in vitro* had the same retention time and fragmentation pattern (Figure 2) as an 8-OHdG standard.

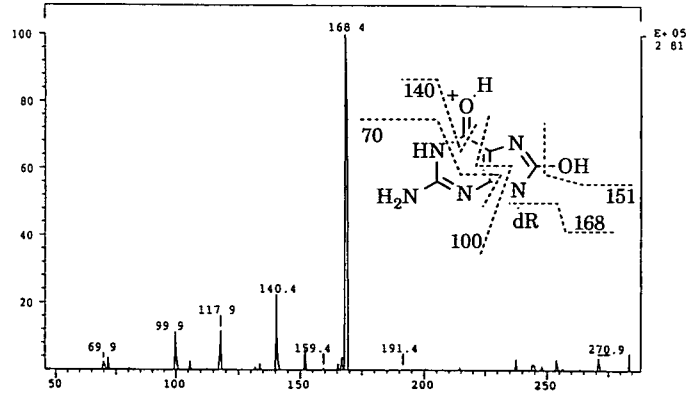

Fig. 2. LC/ESI/MS/MS analysis of 8-OHdG. Product ion spectrum of m/z 284.

The Fenton system will be used to develop LC/ESI/MS/MS methodology to detect and quantify DNA adducts. Since this method simplifies sample preparation, LC/ESI/MS/MS would facilitate analysis of a large number of samples.

Supported by NIH grants ES00267 and GM08320-06.

The Application of CE/ESI/MS/MS for Detection of IQ Adducts of DNA

Diane Rindgen[1], Robert J. Turesky[2], and Paul Vouros[1]
[1]Department of Chemistry and the Barnett Institute, Northeastern University, Boston, MA 02115
[2]Nestle Ltd. Research Center, Lausanne, Switzerland

Heterocyclic aromatic amines are formed in protein-containing foods such as meat and fish during normal cooking processes (1). 2-Amino-3-methylimidazo[4,5-*f*]quinoline (IQ) is a structurally representative member of this class of xenobiotics and has been shown to be a liver carcinogen in monkeys (2). Following metabolic activation, IQ covalently binds to deoxyguanosine forming a major adduct identified as N-(deoxyguanosin-8-yl)-IQ (dG-C8-IQ) and a minor adduct, 5-(deoxyguanosin-N^2-yl)-IQ (dG-N^2-IQ) (3, 4) We have evaluated the use of capillary electrophoresis/electrospray ionization/tandem mass spectrometry for detection of IQ adducts of deoxyguanosine-3'-monophosphate and present results obtained from the analysis of a synthetic sample containing both the C8 and N^2-adducts along with the examination of adducts formed *in vitro* with calf thymus DNA.

The results presented were obtained on a VG Quattro (Fisons Instruments, VG Biotech, Altrincham, UK) triple quadrupole mass spectrometer equipped with a VG electrospray source and capillary electrophoresis probe The probe was designed to allow for both a coaxial flow of sheath liquid and nebulizing gas (N_2). All analyses were performed in the negative ion mode using isopropyl alcohol as the sheath liquid at a flow rate of 3 μL/min. The coaxial and bath gas (N_2) flow rates were optimized at the start of each set of experiments CID and MRM were performed using argon as the collision gas. The CE high voltage was provided by a Spellman CZE1000R (Spellman High Voltage Electronic Corp , Plainview, NY) reversible high voltage power supply Capillary electrophoresis was performed in uncoated fused silica capillaries (*ca* 40 cm contained in the CE probe) using 10 mM ammonium acetate, pH 10 2 - 10.4 (adjusted with ammonium hydroxide), as the running buffer. Analyte injections were made hydrodynamically or by using the on-column sample preconcentration technique known as sample stacking (5, 6) The dG-C8/N^2-IQ-3'PO_4 standards and the IQ-modified calf thymus DNA were prepared as described in reference 4 and reconstituted in Milli-Q water (Millipore, Milford, MA) prior to mass spectrometric analysis. The *in vitro* adduct estimates were as follows: C8 - 45.6 ng, N^2 - 6.5 ng

The negative ion ESI normal scan mass spectrum of the synthetic adduct sample presented the expected MH^- ion at *m/z* 542.5 CID of *m/z* 542 produced two product ions at *m/z* 346 and *m/z* 195 (deoxyribose-3'PO_4) The ion at *m/z* 346 corresponds in mass to both the aglycone ion (A^-) formed by cleavage of the glycosidic bond and the MH^- ion of deoxyguanosine-3'PO_4 resulting from loss of the IQ moiety The CID spectrum of *m/z* 346 (Figure 1) was significantly different from the negative ion CID spectrum of unadducted deoxyguanosine-3'PO_4 which exhibited product ions at *m/z* 79 (PO_3^-), *m/z* 97 ($H_2PO_4^-$), m/z 150 (guanine) and *m/z* 195 (deoxyribose-monophosphate). Low pg level detection was possible for the targeted dG-C8-IQ-3'PO_4 adduct by monitoring the transition *m/z* 542 → *m/z* 346. The results of the MRM analysis of the dG-C8/N^2-IQ-3'PO_4 synthetic mixture are shown in Figure 2. A response for the C8-adduct was observed at 8 min however, it is unclear which additional signal corresponds to the N^2-adduct. Considering the isomeric relationship of the two adducts, it seems reasonable to speculate that the peak at 7.7 min, immediately preceding the C8-adduct response, is due to the N^2-adduct. The ratio of peak areas is consistent with the estimated quantities of each adduct. However, the area ratio of the 6.5 and 8 min peaks also agrees with the relative amounts of C8/N^2 adduct present in the sample. The behavior of the minor adduct under the conditions employed for these analyses could not be determined due to the lack of sufficient quantities of pure dG-N^2-IQ-3'PO_4 standard.

The mass electropherogram of *m/z* 542 obtained during a normal scan acquisition of the IQ-modified calf thymus DNA sample exhibited a peak at 7.4 min the spectrum of which showed *m/z* 542.5 and 346.5. CID of *m/z* 542 produced two product ions, *m/z* 195 and 346, which were also observed in the CID spectrum of the dG-C8-IQ-3'PO_4 standard. A single response was observed in the MRM scan of *m/z* 542 → *m/z* 346 which appeared at a migration time generally characteristic of dG-C8-IQ-3'PO_4. The mass spectrometric results obtained with a control DNA sample (no IQ modification) showed no interferences in the region of migration of the IQ adduct.

In conclusion, 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ) adducts of deoxyguanosine-3'PO_4 are amenable to analysis by on-line capillary electrophoresis/mass spectrometry using electrospray ionization in the negative ion mode. Low pg level detection was achieved by monitoring the transition *m/z* 542 → *m/z* 346. Although unambiguous detection of the dG-N^2-IQ-3'PO_4 adduct in the synthetic mixture was not achieved, the combined CE/MS data identified the dG-C8-IQ-3'PO_4 adduct and confirmed its presence in the *in vitro* IQ-modified calf thymus DNA sample

GC/MS Quantitation of DNA Oxidation Products

Chang-Hwan Oh and Charles R Iden

Department of Pharmacological Sciences, Health Sciences Center,
SUNY-Stony Brook, Stony Brook, NY 11794-3400

DNA oxidation is a natural, ongoing process which takes place in both nuclear and mitochondrial DNA. Chemical modification to deoxynucleotides occurs through interaction with oxygen free radicals or other activated oxygen species produced either chemically within the cell or by ionizing or non-ionizing radiation. A large number of oxidized purines and pyrimidines have been isolated and characterized, some of which have been shown to be potential mutagens. In its own defense, the cell maintains a family of repair enzymes which continually monitor the fidelity of the DNA sequence and repair errors such as oxidized nucleotides that are located Among these enzymes are the gene products of MutM, MutY, and MutT whose mechanisms of repair are under investigation. Of particular interest is the FPG protein which acts as a glycosylase and releases 8-oxoguanine (8-oxoGua), 8-oxoadenine (8-oxoAde), 2,6-diamino-4-oxo-5-formamidopyrimidine (Fapy-Gua), and 2,6-diamino-5-formamidopyrimidine (Fapy-Ade) from damaged DNA We have developed a GC/MS assay for selected oxidation products essential for this research and tested the protocols on known amounts of a synthetic oligomer containing a single 8-oxo-2′-deoxyguanine within the sequence The assay includes 2,6-diamino-8-purinol as an internal standard. We have carefully examined established procedures for release of the oxidation products (formic acid hydrolysis) and trimethylsilyl-derivatization of the nucleobases that are released

Standards 8-oxoGua, 2,6-diamino-8-purinol, and normal nucleobases were obtained from Aldrich. Fapy-Ade was purchased from Sigma Chemical Company, and Fapy-Gua and 8-oxoAde were synthesized using literature procedures Formic acid (Janssen Chimica) was diluted to 88% with Millipore water. All silylation reagents and solvents were purchased from Pierce Chemical Company. Stock solutions of the standards were prepared in 0.04 mM ammonium hydroxide and stored at -4 °C. A Hewlett Packard 5970 MSD GC/MS was used in the selected ion monitoring mode to quantify the selected oxidation products. The instrument is equipped with a Hewlett Packard 5890A gas chromatograph, and separations were obtained on a DB-5ms (30 m × 0.2 mm I.D., 0.33 μm film thickness) column using splitless injection (240 °C) and helium carrier gas (15 psig, 0 75 ml/min) The MSD was operated at 70 eV ionization energy, and *m/z* 354 (Fapy-Ade), 352 (8-oxoAde), 442 (Fapy-Gua), 440 (8-oxoGua), and 454 (internal standard) were monitored in the SIM mode.

Reaction conditions for the formation of volatile derivatives of the selected oxidation compounds using three different reagents for trimethylsilylation and one reagent for trifluoroacetylation were examined carefully. Many reaction conditions produced multiple TMS species for the standard compounds and were not appropriate for quantitative analysis. Final reaction conditions were selected such that only the fully trimethylsilylated compounds were produced for each standard. These were 5 ng each standard, 50 μl acetonitrile with 2% pyridine, 50μl BSTFA with 1% TMCS, 100 °C for 30 min. Product formation did not increase with increased reaction time or increased reaction temperature Sensitivity for each of the derivatized compounds is approximately one picogram injected onto the column. Stability of the internal standard has been established in both the hydrolysis and derivatization procedures.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

The full analysis was verified for 8-oxoGua by taking known quantities of a synthetic oligodeoxynucleotide containing a single 8-oxo-2′-deoxyguanosine residue and performing the complete analysis for 8-oxoGua. The sequence of the oligomer was 5′-GTTCA(8-oxo-dG)GTTGC-3′, and this material was purified in a double pass HPLC procedure prior to use. The internal standard (5 ng) was added to a measured quantity of oligomer, and nucleobases were released by 88% formic acid at 150°C for 1 h. The results for the analysis of five different quantities of oligodeoxynucleotide are shown in Figure 1. For quantities of oligomer greater than 1 μg the measured amount of 8-oxoGua corresponds very closely to the calculated amount of 8-oxoGua derived from the oligomer For small quantities of the oligomer, there appears to be losses in the procedure which lead to unusually low measured values of the nucleobase. In Figure 2 the amount of normal guanine released from the oligomer is compared to the amount of 8-oxoGua which is released. The curve is linear with a good correlation coefficient, indicating that as more of the oligomer is used in the analysis, the quantities of Gua and 8-oxoGua increase in a linear fashion, as expected.

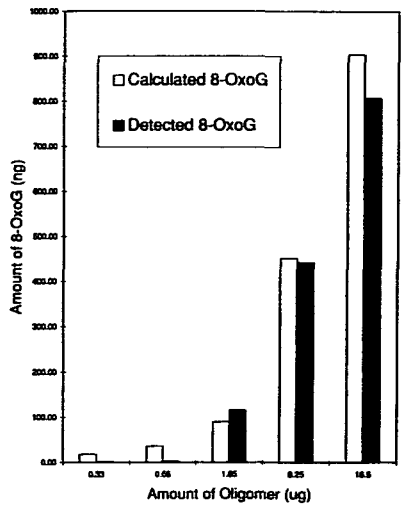

Fig. 1. Measured vs. calculated 8-oxoGua found in a synthetic oligodeoxynucleotide containing an 8-oxo-2′-deoxyguanosine residue.

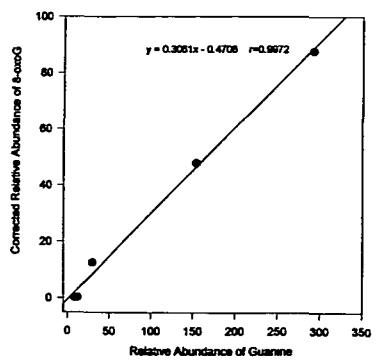

Fig. 2. Linear regression of the measured quantity of Gua and 8-oxoGua obtained from the synthetic oligomer. The oligomer contains two Gua and only one 8-oxoGua.

Capillary Isotachophoresis-Mass Spectrometric Determination of DNA Damage

Zhongxi (Zack) Zhao*, Amy C. Harms, Harold R. Udseth,
Alfred F. Fuciarelli, and Richard D. Smith
Chemical Sciences Department,
Pacific Northwest Laboratory, P.O. Box 999, Richland, WA 99352

Analysis of DNA damage as indicators of human exposure to radiation levels represents a challenge for trace analyses to analytical chemists. Mutagenesis is one possible outcome of DNA base modification arising from such damage. These modifications may lead to DNA misreplication which can initiate and promote carcinogenesis. Electrospray ionization mass spectrometry (ESI-MS) with high ionization efficiency and gentle nature can be used to identify and quantify these modifications and opens the opportunity to study structurally related factors in the damage to DNA. The radiation-damaged products are generally present in very low abundance, which requires a highly efficient and/or concentrating separation technique prior to mass spectrometric detection. High performance capillary isotachophoresis (CITP), with its zone self-sharping and concentrating capacities, can be utilized to distinguish the small amount damaged from the large excesses native free bases, nucleosides, and nucleotides. In combination with electrospray ionization, the potential exits to obtain extraordinary sensitivity.

In this presentation, the on-line coupling of reversed anionic capillary isotachophoresis to electrospray ionization mass spectrometry will be reported. Separation and identification of radiation damaged tetranucleotide using CITP-MS will be described. The tetranucleotide d(CGTA) was first X-irradiated in N_2-saturated aqueous solution. Then, the damaged products were fractionated by semi-preparative HPLC. Finally, on-line CITP-ESI-MS and tandem MS were used to provide the positional and structural information of the damaged products. In reversed anionic CITP, leading electrolyte was 7 mM HCl/13 mM ß-alanine and trailing electrolyte was 10 mM caprioic acid.[1,2] A coaxial sheath liquid interface was used. The sheath liquid was composed of 0.1% formic acid, 24.9% water, and 75% methanol. Single and double base damages were determined. The results indicate that cytocine was modified to uracil, hydroxyuracil and hydroxyhydrouracil; Guanine was modified to cyclo-guanosine. Thymine was changed to dihydrothymine and hydroxyhydrothymine. Figure 1 shows typical CITP-ESI-MS results for an LC fraction. CITP-tandem mass spectra of LC fraction #14 are listed in Figure 2. We are now applying this approach to study the radiation chemistry of large oligonucleotides and DNA.

Analysis of DNA base modifications in oligonucleotides using LC/ES MS.

A. K. Chaudhary[1,2,3], G. R. Reddy[2,3], J. L. Compton[1], L. J. Marnett[2,3], and I. A. Blair[1].
Departments of Pharmacology[1] and Biochemistry[2] and A. B. Hancock Jr. Memorial Laboratory for Cancer Research[3], Vanderbilt University School of Medicine, Nashville, TN 37232.

The involvement of exogenous carcinogens in effecting DNA modifications is well documented. However, DNA adducts produced from endogenous chemicals arising from normal metabolism, oxidative stress, and chronic inflammation are equally critical in carcinogenesis. Malondialdehyde (MDA), an endogenous product of lipid peroxidation, induces frameshift mutations and G to T transversions. The major MDA-DNA adduct at physiological pH is pyrimido- [1,2-a]-purine-10(3H)-one (M_1-dG). The tetrahydro analog of M_1dG is Propanodeoxyguanosine (P-dG). We have developed methods to quantitate and characterize this adduct in rodent (1) and human tissues (2) using GC/ECNCI MS. The complete characterization of this adduct in human liver using LC/ES MS/MS was also achieved.(3) Our laboratory is involved in construction of viral genomes containing M_1G and PdG to study the mutagenic potential of this adduct. Oligonucleotides, 5'-CGCXCGGCATG-3' (I) and 5-CGTXTCCG-3' represent mutation hotspots in *Salmonella typhimurium* hisD3052 gene. These oligonucleotides and a number of other modified and unmodified oligonucleotides have been synthesized. We report the use of electrospray (ES) ionization for the analysis of oligonucleotides. ES typically produced an envelope of charged states which allowed accurate determination of molecular weights. Salts of oligonucleotides formed a series of multiply charged anions under negative ES conditions. The molecular weight of oligonucleotides could then be calculated by transforming the charged envelope. PC-based software was developed for the characterization of these oligonucleotides from the observed multiply-charged peaks. LC/ES analysis was performed on a Finnigan TSQ-7000 mass spectrometer equipped with an electrospray source. The sample was introduced to the mass spectrometer through an injector positioned between the HP 1090 HPLC system and the source. The solvent composition was acetonitrile/water (50/50 v/v) containing 0.1% acetic acid at a flow rate of 50 microliter/min. The presence of acid in the mobile phase effectively leads to the shifting of the multiply charged envelope towards smaller charged states. ES source parameters were optimized to provide maximum ionization of a 7-mer oligonucleotide (5'-CGGCATG-3'). Multiply charged ions for 5'-CGCGCGGCATG-3' (Figure 1a) were observed at *m/z* 1118 (3-), 838 (4-), and 671 (5-) [observed MW = 3358, calculated MW = 3358)]. Similar ions were observed at *m/z* 1130, 847, and 678 for the modified 11-mer 5'-CGC-M_1dG-CGGCATG-3' (Figure 1b) [observed FW = 3394, calculated FW = 3394]. Modified and unmodified oligonucleotides ranging from 3-mer to 20-mer were analyzed. A series 11-mer oligonucleotides is shown in Table 1. The observed molecular weights for these modified and unmodified oligonucleotides were found to be within 0.02% of the calculated value. HPLC/MS was configured to provide on-line desalting of these samples. A PRP-1 column (2.1 mm i.d. x 150 mm) was used with mobile phase consisting of 15 mM ammonium formate/acetonitrile (80/20) at a flow rate of 200 µL/min. The column effluent was diverted away from mass spectrometer for first 7 min by an automated switching valve.

Micro electrospray MS/MS for the analysis of modified oligoribonucleotides

M. A. Wolter[1], M. S. Wilm[2], M. Mann[2], J. W. Engels[1]
[1]*Institute for Organic Chemistry, Johann Wolfgang Goethe-University, 60054 Frankfurt, Germany*
[2]*European Molecular Biology Laboratory, Meyerhofstr. 1, 69117 Heidelberg, Germany*

Mass Spectrometry especially tandem mass spectrometry techniques offer a fast and sensitive method to study the primary structure of oligonucleotides. It is applicable to all kinds of modified oligonucleotides once the principle fragmentation pathways are described. These pathways were studied for oligodeoxynucleotides (DNAs) by ion trap (1, 2, 3) and FTMS (4). This is of interest for the antisense (5, 6) and ribozyme (7) approach where modified oligonucleotides are used as highly effective drugs. The traditional methods for the sequence determination of oligonucleotides [Sanger, Maxam and Gilbert] are limited in accuracy and do not allow the analysis of modified oligomers. Specifically, 2'-O-methyl modified oligoribonucleotides (RNAs), which are used within the ribozyme as well as antisense approach, were chosen to test the performance of tandem mass spectrometry within these fields. Up to now, RNAs are only targets of very few MS/MS investigations. Di- (8, 9) and trimers (10, 11) were invested by FAB. Decamers were studied by ESI (12).

Measurements were done on a triple quadrupole (Sciex API III) equipped with an updated collision cell. The standard ESI source was replaced by a micro ESI source (13). The collision energy was optimized for each sample so that the high mass fragments exceeding *m/z* 1000 were produced with maximal intensity. This optimization procedure gave relatively low E_{LAB} settings. The dry samples were dissolved in water and 1 µl of the solution added to 2 µl of a 1/1 conc. NH_3 (aq.)/MeOH mixture. 1 µl of this final solution were sufficient for 45 minutes working time. The used fragment ion nomenclature is due to McLuckey et al. (1).

MS/MS CID spectra of the $[M\text{-}4H^+]^{4-}$ ions derived from 5'-r(AGUAGUCCCA)-3' and 5'-r(AmGUAmGUmCCCA)-3' can give extensive information on the sequence, types of the modifications and their locations. The mass differences between the depicted ions, allow to localize the modification sites. This information is present in multiple ions, to simplify matters some of these have been selected. The w-series are dominant and allow to determine the sequences and reading frames. For the same chain length w_i-fragments dominate d_i-fragments (14) and y_i-fragments dominate b_i-fragments. x_i, z_i and c_i fragments were not observed. These rules hold for all the RNAs we studied.

Collision induced fragmentation of multiply charged oligonucleotides can be used to identify type and location of modifications. The proper tuning of the collision energy is important to avoid extensive fragmentation but to produce still complete ion series.

ESI-MS of synthetic oligonucleotides and non covalent interactions studies

N. Potier and A. Van Dorsselaer
Laboratoire de Spectrometrie de Masse Bio-Organique, URA31-CNRS, Université Louis Pasteur, 67000 Strasbourg, France.

INTRODUCTION: Nucleic acids are highly charged polyanionic structures that are known to interact with a broad range of molecules like metals, drugs, proteins...These non covalent interactions play a crutial role in their structure and function in the cell. While X-ray cristallography or NMR are often difficult on such macromolecules complexes, we investigated the conditions for studying interactions between oligonucleotides and polycationic species by ESI-MS which is known to preserve non covalent associations[1].

A prerequirement to characterize non covalent complexes is to determine conditions allowing mass analyses of both polycationic species and oligonucleotides separately. Mass measurements of oligonucleotides larger than 10 kDa are quite difficult because of the formation of oligonucleotide-sodium or -potassium adducts which persist after ionization and desolvation. The presence of sodium adducts becomes a major problem in the case of large oligonucleotides where the resolution of the generally employed quadrupole analyzers is insufficient to resolve the different sodium adducts peaks leading to erroneous average mass measurements. Reduction of the amount of sodium adducts is thus crutial to obtain high quality spectra.

EXPERIMENTAL: A VG Bio-Q triple quadrupole mass spectrometer with a mass range of 4000m/z units was used to carry out negative electrospray ionization mass spectra. A probe equipped with a peak capillary was required to evoid residual salts contamination or acidity coming from classical fused silica capillaries. A potential of 2.2 to 2.8 kV was applied to the needle and the cone voltage value was typically set to 50V. The source was maintained at 50°C and nitrogen was used as nebulizing and drying gaz. The solutions were directly infused into the source at a final concentration of 20µM and at a flow rate of 2µl/min. For oligonucleotide/peptides interactions, oligonucleotides were dissolved in deionized water at a final concentration of 25µM, mixed with 0.2 mM polylysine peptide and infused into the source at a flow rate of 2µl/min. The optimization of the drying gaz rate is required to aid electrospray droplet desolvation.

RESULTS:

Mass measurements of synthetic oligonucleotides: After an intensive removal of salt ions[2], negative ion mass spectra were obtained on synthetic oligonucleotides up to 40 kDa (132-nucleotides)[3] with an accuracy of 0.01%. For large oligonucleotides (>50-mer), this desalting procedure can be repeated several times in order to enhance the displacement of sodium ions.

The high accuracy of mass measurements allowed also the characterization of oligonucleotides analogues such as phosphorothioate designed for antisense applications.

Oligonucleotide/peptide non covalent interactions: Recently, non covalent complexes between oligonucleotides and basic peptides have been observed by MALDI-TOF showing the utility of this complexes formation for the mass determination of acidic compounds[4]. Within the context of specific non covalent interactions studies between oligonucleotides and proteins, ESI-MS appears as a more appropriate technique.

Figure 1 displays the obtained mass spectra for ionic non covalent complexes between a 40-mer (MW=12292.4 Da) dessalted as previously described[3] and various polylysine peptides.

They reveals the very high affinity of polyamines for oligonucleotides insofar as they were able to displace the tighly bound sodium ions on the phosphate groups of the oligonucleotides and to form non covalent complexes which have persisted after ionization and desolvation. The complexes formation occurs through electrostatic interactions resulting from ionic bounds between positively charged protein side chains and the polyphosphate oligonucleotide backbone. The abundance and the number of the complexes ions increase with the number of lysine residues and the presence of organic solvent such as acetonitrile.

CONCLUSION: ESI-MS can be used routinely for the evaluation of oligonucleotide/peptide interactions when the interactions are known as ionic bounds. These ionic interactions are quite strong since neither the temperature (untill 70°C) nor the cone voltage value (untill 70V) were very critical.

Non-Covalent Associations of Metal Complexes with DNA Duplexes by ESI-MS

Amy C. Harms and Richard D. Smith
Pacific Northwest Laboratory, Richland, WA 99352
and
Yonchu Jenkins and Jacqueline K. Barton
Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, CA 91125

Transition metal complexes are being used as probes to determine the conformational structure of oligonucleotides, to recognize specific binding sites, and to probe the capability for electron transfer reactions in DNA strands. Non-covalent interactions, such as intercalation and hydrophobic groove binding of the metal complexes with oligonucleotide duplexes, provide the basis for probing DNA sequence and structure.

Electrospray ionization mass spectrometry (ESI-MS) has been used for the analysis of a wide variety of biomolecules, including oligonucleotides. Recently this technique has been utilized in the characterization of non-covalent associations. In this work we report the use of ESI-MS for the detection of non-covalent associations of several metal complexes with two oligonucleotide duplexes and compare these results with observations from solution.

Previous work has characterized the binding of several complexes to DNA in solution. $Ru(bpy)_3^{2+}$ has a negligible binding to DNA. $Ru(phen)_3^{2+}$ is an intercalator with a binding strength of $K=6.2\times10^3\ M^{-1}$ whereas $Ru(phen)_2dppz^{2+}$ binds more strongly with $K>10^7\ M^{-1}$. These complexes are seen to bind non-cooperatively with a four base pair site. Each of the metal complexes were added to the 12-mer duplex solution with a ratio of 1:1 duplex : metal The mass spectra showed a series of peaks corresponding to the bare single DNA strands, the bare DNA duplex, the single strands with one or more complexes, and the duplex with one or more metal complexes. Figure 1 shows the 12-mer combined with the complex with the lowest binding constant, $Ru(bpy)_3$. The spectrum shows that very little of the metal complex is bound to the DNA. In comparison, when $Ru(phen)_3$ or $Ru(phen)_2dppz$ was added the majority of the peaks contained these compounds, as is shown in Figure 2. When an excess of $Ru(phen)_2dppz$ is added, the reaction can be driven to produce primarily the [duplex + three metal] complex.

The same metal complexes were also studied with a longer DNA strand. The same series of peaks that were observed with the 12-mer were also seen with the 15-mer. As before, when $Ru(bpy)_3$ was added, there is more bare DNA than DNA-$Ru(bpy)_3$ complex. When $Ru(phen)_3$ was added, most of the DNA was observed to be associated with the metal. Figure 3 shows four $Ru(phen)_3$ complexes can bind to a 15 base pair duplex instead of the three complexes that were seen to bind to the 12-mer. This indicates that another binding site is available in the 15-mer.

Under appropriate ESI interface conditions, the mass spectra reflect the solution behavior of DNA-metal complexes in their binding strength and exclusion site size, verifying the specificity of the associations.

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial institute under Contract DE-AC06-76RLO 1830.

Chemical Sciences Department, Pacific Northwest Laboratory, Richland WA, 99352

Electrospray ionization mass spectrometry (ESI-MS) has become an important analytical method for characterizing proteins, peptides, and small biologically active molecules. One particular class of molecules that are amenable to analysis by ESI-MS are oligonucleotides. Oligonucleotide duplex and small molecule/oligonucleotide duplex noncovalent complexes have recently been studied by ESI-MS.[1-3] If ESI-MS is to become a useful technique in the analysis and characterization of small molecule/oligonucleotide duplex noncovalent complexes, a comprehensive understanding of the oligonucleotide duplex must be performed by ESI-MS . The goal of this research was to investigate the relationship between the melting temperature (ΔT) of an oligonucleotide duplex, ESI-mass spectra, and collision induced dissociation (CID).

A large number of small molecule/oligonucleotide duplex studies have been performed utilizing 12-base pair oligonucleotides. Our initial success in observing noncovalent complexes formed between known DNA binding small molecules and oligonucleotide duplexes of this size by ESI-MS,[3] led us to use 12-base pair oligonucleotides as models for the present studies. Several sequence specific and self-complementary 12-base pair oligonucleotide duplexes were designed, purified, and analyzed. Oligonucleotide duplex melting temperature measurements were obtained using UV/Vis spectrophotometry from solutions containing the buffer used in the ESI-MS experiments (30 mM ammonium acetate). Initial results indicate that the melting temperature of the duplex, a measure of stability in solution, is reflected in ESI mass spectra. Peaks corresponding to the noncovalent complex of the low ΔT duplex, were observed in low relative abundance, compared to the high ΔT duplex.

Similar results were observed for the collision induced dissociation (CID) of low and high melting temperature oligonucleotide duplexes. This data was acquired with a Finnigan TSQ 7000 instrument using Ar as the collision gas. For both oligonucleotides duplexes, the 5- charge state was mass selected for analysis. The CID results are shown in Figures 1 and 2. The low ΔT duplex is observed to dissociate into single stranded oligonucleotides much more readily than the high ΔT duplex. These results indicate that oligonucleotide duplexes with high melting temperatures are more stable than low melting temperature oligonucleotide duplexes in CID experiments, reflecting their greater stability in solution. These results suggest that ESI-MS experiments (ESI-MS and CID) may be useful in providing rapid, qualitative data on the stability of oligonucleotide duplex noncovalent complexes.

Characterization of oligonucleotide-peptide hybrids by MALDI and ESI MS

Marek Sochacki, Frank Bergmann, Steve Tam, and Hanspeter Michel
Hoffmann - La Roche Inc., Nutley, New Jersey, 07110-1199

INTRODUCTION

Hybrid compounds consisting of oligonucleotide and peptide components are currently *under investigation for their effectiveness in antisense therapy.*
Mass spectrometry is essential for the structural characterization of such compounds. Molecular weight determination of oligonucleotide-peptide hybrids was achieved from negative ion mass spectra with matrix assisted laser desorption ionization time-of-flight mass spectrometry (MALDI TOF MS). Structural characterization had to be done in multiple steps because of the simultaneous presence of both highly negative charged oligonucleotide and neutral or positively charged peptide components.

EXPERIMENTAL

Enzymatic digestion

Enzymatic digestion was performed by continuous introduction of substrate to the appropriate amount of enzyme during 10 minutes. For the digestion from 3'- and 5'-ends phosphodiesterase I (EC 3.1.4.1) from Crotalus adamanteus and phosphodiesterase II (EC 3.1.16.1) from calf spleen were used respectively.

MALDI and ESI mass spectra

Negative ion MALDI mass spectra were recorded on the BRUKER (REFLEX) TOF instrument in 2,4,6-trihydroxyacetophenone matrix.[1,2] Positive ion ESI mass spectra were recorded on the Finnigan MAT TSQ-700 instrument. Samples were introduced via a 6 cm x 0.1 mm ID capillary column filled with the C-18 reverse phase packing.[3]

RESULTS

Figure 1. shows the structure of the oligonucleotide-peptide hybrid compound which was chosen to verify the sequence of oligonucleotide as well as peptide parts.

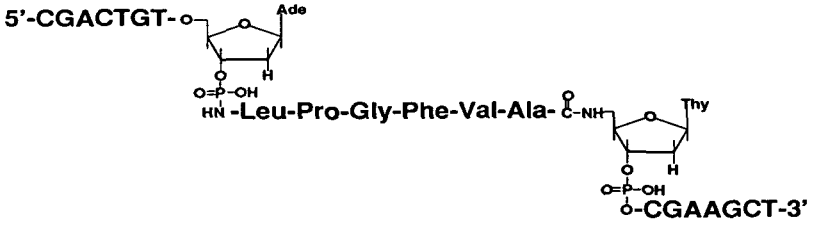

Fig. 1. Structure of the oligonucleotide-peptide hybrid compounds.

Appropriate digestion with phosphodiesterase I or II followed by MALDI TOF mass spectrometry gave the sequence confirmation from 3'- and 5'-ends of the oligonucleotide part.

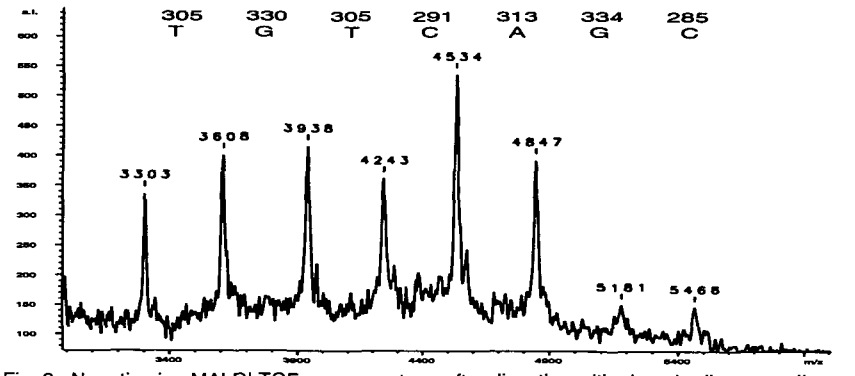

Fig. 2. Negative ion MALDI TOF mass spectrum after digestion with phosphodiesterase II.

Separation of the peptide part by LC allowed its characterization by ESI MS.

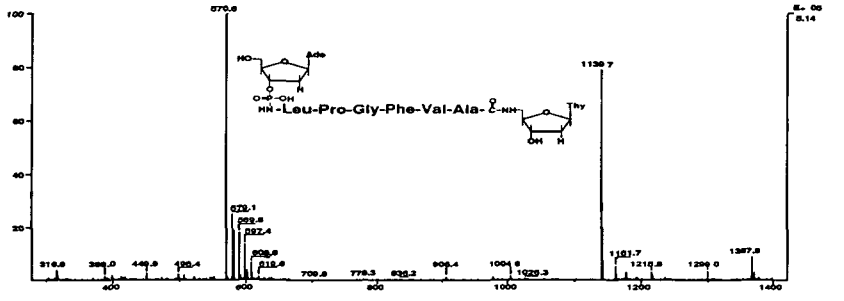

Fig. 3. ESI mass spectrum of the peptide part of the oligonucleotide-peptide hybrid compound.

Fragmentation induced by collisions with an inert gas gave the possibility to sequence the peptide part of the hybrid compound.

ROUTINE FAB MASS SPECTRA OF OLIGONUCLEOTIDES; ENHANCEMENT BY CROWN ETHERS

Han Le, Paolo Lecchi, Jane Sayer, Donald Jerina and Lewis Pannell
Laboratories of Analytical Chemistry and Bioorganic Chemistry
NIDDK, NIH, Bethesda MD 20892-0805

Introduction:

Over the past few years, there has been a significant increase in oligonucleotide research at NIH and requests for the analysis of synthetic oligomers has become a common occurrence. We had little success in running these samples by FAB, even when they had been ion exchanged into the ammonium form Residual alkali salts (esp. sodium) from the glassware, etc, caused sensitivity a large loss in sensitivity and often nothing was seen at all. Having used crown ethers in other applications, we decided to investigate the combination of crown ethers with common FAB matrices as a way to enhance the spectra

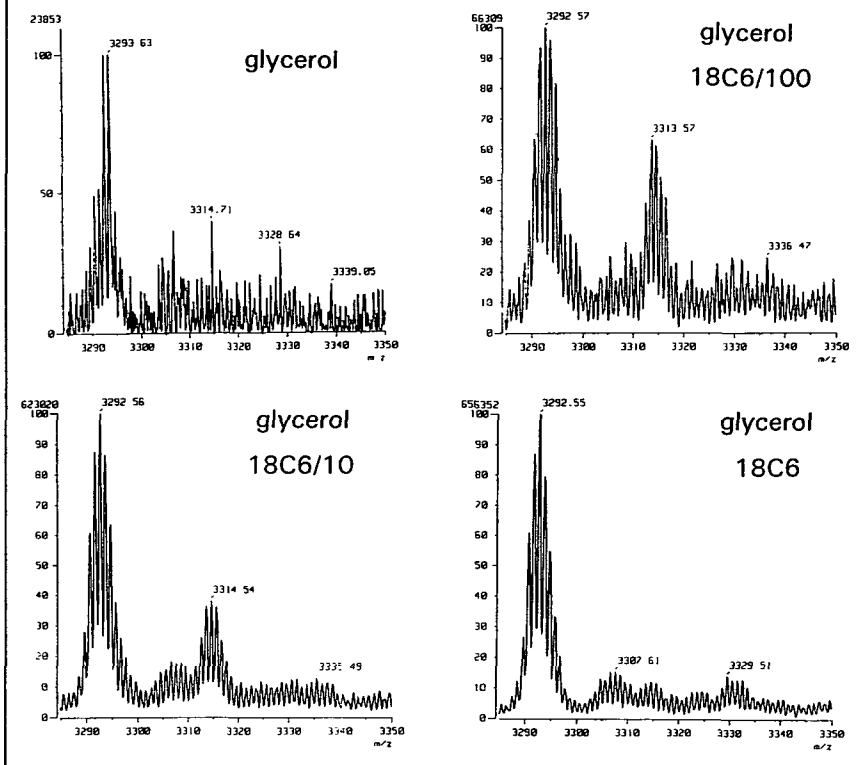
Method

Spectra were acquired on a JEOL SX102 mass spectrometer using 6keV xenon atoms Data was acquired in profile mode using electric field scans The results are the sum of approximately 14 scans spread over 0.6 minutes. The matrices used were glycerol, 3-nitrobenzyl alcohol (noba), "magic-bullet" (m-b) and thioglycerol.

The matrix (0 5μl) was applied to the probe, the sample (1μl) added, and then the crown ether (1μl) solution placed on top. A standard solution of both 15C5 and 18C6 crown ethers (10mg/ml) was prepared and then 10, 100, 1000 fold dilutions made of each

For a 9-mer oligonucleotide (GGTCACGAG, 1 8mg/ml, M-H 2762 5) which had not been well desalted, spectra were not obtained in any of the plain matrices employed although there was a very small response with noba. However, using glycerol matrix in the presence of crown ethers, good spectra could be obtained Increasing amounts of crown ether helped the spectra and reduced the amount of sodium adducts 18C6 was better at doing this than the 15C5 and the highest concentration used (10mg/ml) was best

With an ammonium exchanged oligonucleotide (CCTCGTGACCG, 2.4mg/ml) very weak spectra were obtained without the addition of crown ethers(see spectra on next page) However, in the presence of 18C6 or 15C5, noba, m-b and glycerol matrices all gave good spectra Increasing levels of sodium adducts were detected as the amount of crown ether was reduced. The limit of sensitivity was reached when the sample was diluted to 0 12mg/ml.



The limit of mass analysis was reached with a 16-mer oligonucleotide of m/z 4820 (TTTAGAGTCTGCTCCC, 0 9mg/ml) which gave the best results in noba and m-b without the addition of either crown ether Although the presence of the sodium adducts is obvious, crown ethers caused a loss of sensitivity rather than improving the result.

Conclusion:

Crown ethers can significantly enhance the spectra of oligonucleotides run under FAB The smaller oligomers give better spectra in glycerol but as the length increases, 3-nitrobenzyl alcohol and magic-bullet give better results.

Fragmentation of Multiply-Charged Oligonucleotides in Triple Quadrupoles

Steven C Pomerantz and James A. McCloskey
Department of Medicinal Chemistry, University of Utah, Salt Lake City, UT 84112

Introduction

The dissociation pathways of larger, multiply-charged oligonucleotides are complex [1], reflecting the conformational flexibility of the nucleotide chain, and the large number of proton-donating and -accepting functionalities that can interact with anionic phosphate groups, but on the other hand they contain all of the elements required for sequence determination (for leading references see ref. 2). To date, a sufficiently good understanding of the chemistry of dissociation of oligonucleotides is in hand [2] that putative sequences can generally be verified, but has not reached the stage that sequences of oligonucleotides of completely unknown structure can be routinely established [3]. Toward this latter goal, an understanding of the fragmentation behavior of oligonucleotides in the rf-only quadrupole collision cell has been sought. The goal of the present work is to gather evidence to allow for a comparison of the dissociation behavior of multiply-charged oligonucleotides in triple quadrupoles, quadrupole ion traps [2], FT-ICR [4,5] and, by extension, singly-charged oligonucleotides in MALDI-TOF [6] This research is compelled by the need to discern if the dissociation mechanisms in each of these instruments is different.

Collision Efficiency of Triple Quadrupoles

We have selected d(CGAGCTCG) for study, to compare mass spectra from CID in a triple quadrupole instrument with those acquired from a sequence isomer [d(GGACGTCC)] using an ion trap mass analyzer [1], and from the same compound using FT-ICR [4]. The present data shows that the extent of fragmentation induced by low energy collision, and thus the amount of structural information, appears to be greatest in triple quadrupoles. In contrast, FT-ICR mass spectra of this same 8-mer exhibit incomplete sequence ions from each terminus but with some overlap in the middle [4]. The a–Base b, d, y, and w ion series can be read completely from one terminus to the other, in apparent disregard of the reported propensity of base loss (A>T>G,C), which according to the proposed mechanisms from ion trap studies, is a necessary condition for the subsequent formation of b and d series ions (from a–B) and y series ions (from w) [2]. Regardless of the mechanisms of dissociation, sufficient fragmentation is obtainable to completely establish the sequence independently through several ion series. This information is straightforward to obtain using a triple quadrupole, by activation of essentially any abundant molecular ion.

Loss of Base is not a Prerequisite for Backbone Cleavage

In order to test the proposed hypothesis that loss of a base is a prerequisite first step in dissociation [2], the oligonucleotide tetra-pseudouridine-3'-phosphate (Ψ_4p) and the control sequences U_4p and dU_4p were synthesized. A consequence of the symmetry of the molecules is that the d and y ion series are isobaric, and in the case of dU_4p, the w and a-Base series are indistinguishable. Nevertheless, the sequence of all 3 oligomers can be completely established through the b, d/y, and w series ions. The notable result of these experiments is that the spectrum of Ψ_4p is completely devoid of any ions resulting from loss of the base moiety, including the 'pseudouracil' anion and ions corresponding to z-Base (the 3' counterpart to a-Base) which were observed in the spectrum of AAΨA (data not presented). It is not yet clear whether these data are indicative of thermodynamic, kinetic, or conformational effects.

Monomeric Units

The identities and structures of some of the ions observed in the mass range corresponding to nucleotide mono- and diphosphates were ascertained by isotopically labelling the phosphate backbone of d(CGAGCTCG). The labels were incorporated at either every position, or alternating positions. Little has observed [4] via FT-ICR that the ions that are assignable as pNp are actually a doublet of peaks consisting of both pNp and Npf where f is a furan arising from loss of substituents from the deoxyribose ring. In order to determine whether in fact both of these ions are produced, and if so their relative abundances, the per-^{18}O labelled octadeoxynucleotide was synthesized. Ions which bear 2 phosphate groups (pNp) would thus shift 4 Da, while ions which bear only one phosphate group (Npf) would only shift 2 Da toward higher mass. The data clearly shows that both ions are in fact produced, with a general trend being observed that pNp ions are generally favored over Npf ions. Delineation of the location of the phosphate group in nucleotide monophosphates was accomplished by synthesizing the same oligonucleotide with alternating labelled phosphates. In this construct, C and A residues are labelled on the 3' side, while G and T residues are labelled on the 5' side. The spectrum dramatically demonstrates that the ions are almost exclusively 5' phosphates.

Conclusions

- Triple quadrupole mass spectrometers are apparently more efficient at generating sequence-specific cleavages than trapped ion instruments. Oligonucleotides up to 8 bases in length can routinely be sequenced completely through via multiple ion series with a single stage of collisional activation.
- The loss of the base has been demonstrated to not be prerequisite for backbone cleavage of an oligonucleotide. It is not yet known whether this is a kinetic or thermodynamic effect, or even potentially a conformational effect. Further experiments and theoretical calculations are in progress in order to further elucidate these findings.
- Monomeric ions of the type Npf and pNp are both produced, with pNp apparently being favored Additional experiments will be required to determine whether this is a consequence of ion production or ion stability, or even whether some sort of sequence context affects the relative proportions of these ions.
- Monomeric ions which bear a single phosphate are almost exclusively pN and not Np. However, further experiments are warranted to ensure that some sequence effects have not biased this admittedly limited sample set

A New Approach for DNA Sequencing and Mutation Detection with ESI-MS

Hideya Terunuma[b], Yasuhiro Naito[a], Toshihiro Tsuneyoshi[a], Ryuichi Arakawa[d], Keiichiro Ishikawa[e], Yoshinori Koga[e] and Darwin J Prockop[d]

[b]Dept. Surgery, Suruganishi Hospital; [a]Dept. Biochem,Hamamatsu Univ. School of Med.; [e]Dept. Material Sci.,Shizuoka Inst. of Sci. and Tech; [d]Dept. Applied Chem.,Faculty of Engineering, Osaka Univ.; [e]Dept. Analytical Chem., Natl. Inst. Materials and Chem. Res., Japan; [d]Dept. Biochem. and Mol. Biol., Thomas Jefferson Univ., U.S.A.

Principles

Sequencing

The single strand DNA (ssDNA) are synthesized from deoxy nucleotides triphosphate(dNTP) of 4 types, dATP, dCTP, dGTP and dTTP. Each unit has unique M.W., 313.2, 289.2, 328.2 and 304.2 corresponding to the base, A, C, G and T, respectively. We assume that ssDNA of unknown sequence is digested from 3' end with the enzyme like Exonuclease III and form ssDNA mixture of various length fragments. Those fragments are applied to mass spectrometer (MS). If we calculate the molecular weight (M.W.) difference between nearest neighbor values, we can determine nucleotide sequence.

Mutation detection

Two ssDNAs, which are different from each other in only one nucleotide, are applied to MS for the M.W. analysis. Mass spectrum of them show two groups of ion fragment peaks which correspond to the two ssDNAs, demonstrating the detection of mutant DNA from wild type DNA by MS.

Materials and methods

Totally seven kinds of oligonucleotides were synthesized(shown in table 1). Sample solutions dissolved in 1% triethylamine and 80% acetonitrile were applied to MS, JMS-HX110(Nihon denshi co. Tokyo, Japan). For the demonstration of sequencing by MS, ssDNA mixture of two to five bases (HT1, HT2, HT4 and HT6), whose sequences are identical to the COL1A2 gene sequence around the mutation site of real osteogenesis imperfecta patient, were applied to MS for the determination of M.W. of each ssDNA.

For demonstrating the model experiment of mutation detection, a mixture of two ssDNAs, HT6(ACCCT) and HT7 (ACGCT), whose five bases (reverse complementary)sequences are wild type(HT6) and mutant type(HT7) of the COL1A2 gene, were also applied to MS for the determination of M.W. of each ssDNA.

Table 1 Specifications of synthesized ssDNAs. PM depicts each ssDNA, M.W. molecular weight, Seq sequence of ssDNA, mM concentration of the solution applied to MS in millimole/liter, and Qty total amount applied to MS in millimole, respectively.

PM	M.W.	Seq	mM	Qty (mmole)
HT1	541.4	AC	0.346	0.356
HT2	830.6	ACC	0.114	0.114
HT3	869.6	ACG	0.291	0.291
HT4	1119.8	ACCC	0.246	0.246
HT5	1158.8	ACGC	0.332	0.332
HT6	1424.0	ACCCT	0.337	0.337
HT7	1463.0	ACGCT	0.334	0.334

Results

For the model experiment of sequencing, mass spectrum of the mixture of four kinds of ssDNAs(shown in Fig.1 and Table 2) enabled us to determine the base type of 3' end nucleotide of each ssDNA. Mass spectrum of two ssDNAs mixture of wild and mutant type sequence showed clear two peaks(shown in Fig.2), indicating the detection of different DNA types.

Table 2 Subtraction of negative ion peaks of MS in Fig.1.

peak subtraction	corresponding base
1422.6 - 1117.5 = 305.1	Thymine; T
1117.5 - 828.4 = 289.1	Cytosine; C
828.4 - 539.3 = 289.1	Cytosine: C

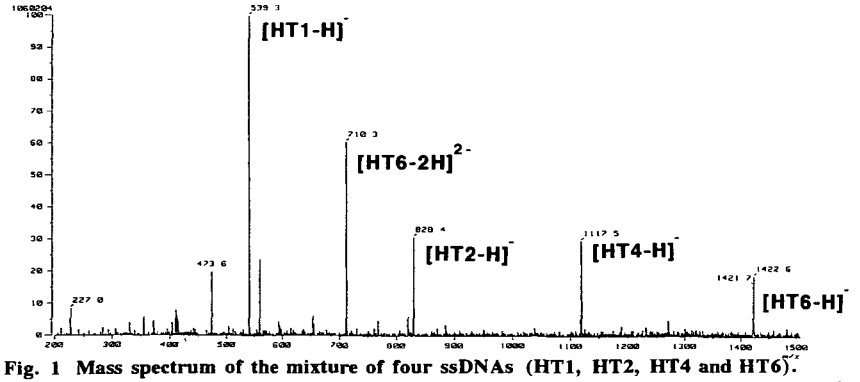

Fig. 1 Mass spectrum of the mixture of four ssDNAs (HT1, HT2, HT4 and HT6). The 1422.6 peak corresponded to M.W. of HT 6. The 1117.5 peak was consistent with HT4. The 828.4 and 539.3 peaks also agreed with HT2 and HT1, respectively.

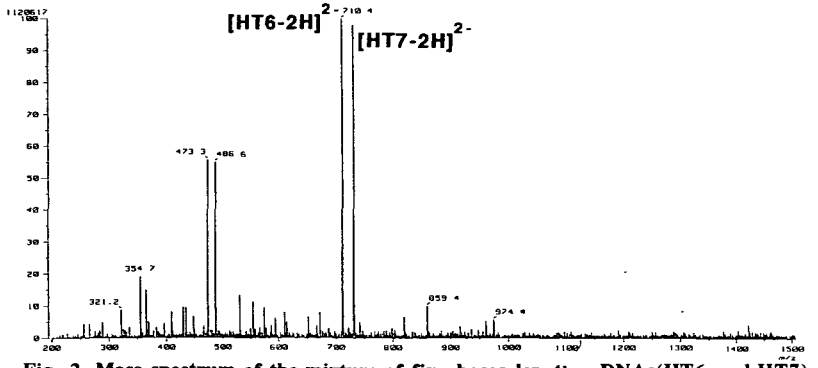

Fig. 2 Mass spectrum of the mixture of five bases length ssDNAs(HT6 and HT7). The 730.4 peak agreed with $[HT7 - 2H^+]^{-2}$ and the 710.4 peak also agreed with $[HT6 - 2H^+]^{2}$.

Electrospray mass spectrometry on a sector instrument for the analysis of small oligoribonucleotides

M. A. Wolter[1,2], J. W. Engels[2], L. Montanarella[1], S. Facchetti[1]
[1]Commission of the European Communities, Joint Research Center, TP290, 21020 Ispra, Italy
[2]Institute for Organic Chemistry, Johann Wolfgang Goethe-University, 60054 Frankfurt, Germany

For the antisense [1, 2] and ribozyme [3] approach the sensitive analysis of small modified oligonucleotides is needed. The 2'-O-methyl [4, 5] is one of the favored modifications within the ribozyme approach to stabilize the oligoribonucleotides (RNAs) against nuclease activity.

The traditional methods for the sequence determination of oligonucleotides (Sanger], Maxam and Gilbert) are limited in accuracy and do not allow the analysis of modified oligomers. In contrast, mass spectrometry can in principle detect any modification in the primary structure of oligonucleotides. While the molecular weight may confirm the presence of a modification, reproducible fragmentation schemes are needed to identify the modification side.

Electrospray has been fitted on sector instruments in 1989 [6]. Encouraged by the performance of this combination, we studied electrospray nozzle-skimmer fragmentation [7, 8] on a VG 70-SEQ hybrid mass spectrometer with EBqQ geometry and commercial ESI interface [9] (Fisons) for the fragmentation scheme of small RNAs. Unmodified and 2'-O-methyl modified RNA decamers were chosen to test the performance of the method.

For small DNAs in Fourier transform mass spectrometry, the spectra of nozzle-skimmer fragmentation are closely similar to the CID MS/MS spectra [10].

The nomenclature of McLuckey et al. [11] is used for the observed fragment ions. With flow rates of 0.5-5 µl/min the direct lens gives a two fold better response than the chicane lens. Thus, we were able to perform analysis in the picomol range. The voltage setting in an electrospray source for sector instruments can be rather critical [12]. However, in the mass range we studied, we do not observe any mass discriminatory effects due to the interface settings. The published settings are based on different interface geometries and therefore hardly comparable.

The difference in the molecular weight allows to distinguish a modified and unmodified RNA decamer. However, the kind and location of the modifications remain unclear. Multiple fragmentation series are generated when the potential during the expansion into the vacuum is increased. In analogy to the DNA fragmentation pattern [10], the w-series is dominant. However, represented by strong water- and base-loss signals the series do not cover the whole sequence. The modified and unmodified RNA decamers show significant differences in their fragmentation behavior. Because both give equal 5'-sequence ions until n=4, the 3'-terminus must be the same. In contrast, the fragmentation in the 5'-terminus, where the modifications are located, is completely different.

Electrospray nozzle-skimmer fragmentation can generate sequence specific fragments, representing not the whole sequence but additional certainty towards the modification site. Accuracy and resolution of the sector instrument in combination with the moderate charge states of the precursors allow a definitive fragment assignment. However, there is no complete and dominant fragment series which would allow the sequence determination of unknown RNAs, as it was the case for MS/MS experiments done on a triple quadrupole instrument [13].

FAB/MS Confirmation of Modified Deoxynucleotides in Small Oligomers

Robert A. Rieger and Charles R. Iden

Department of Pharmacological Sciences, Health Sciences Center,
SUNY-Stony Brook, Stony Brook, NY 11794-3400

The ability to incorporate a modified deoxynucleoside at any position in the sequence of a synthetic oligodeoxynucleotide is a powerful tool which can be used to examine the effects of novel structures in DNA. Oligomers may be used directly, annealed to a complementary strand, or placed in plasmids to study the reaction of polymerases, DNA repair enzymes, or other cell enzyme systems to this abnormal structure. Automated synthesis of oligomers with modified deoxynucleosides typically employs a 5'-dimethoxytrityl (5'-DMT)-protected nucleoside phosphoramidite which must be synthesized and characterized independently. Incorporation into an oligomer is successful when the modified deoxynucleotide is stable to the conditions of DNA synthesis. One method to verify deoxynucleoside stability is to expose the modified, 5'-DMT-protected monomer to each of the reagents from the solid phase synthesizer for a predetermined time interval and reanalyze the material by HPLC to see if degradation has occurred. This procedure works well in many cases, but with some substances analysis may become tedious and require further manipulation. To simplify this procedure, we have designed a short, test oligomer, 5'-TTXTT-3', which is used routinely to examine the stability of the modified deoxynucleoside. Their are several advantages in using this oligomer. Thymidine has no functional moieties that require protection, so final cleavage of the product from the resin should generate a pure oligomer which is uncomplicated by partial deprotection. Multiple products can only occur from a partially deprotected X moiety, if, indeed, it has a protecting group. Also, negative ion FAB/MS of small oligomers is uncomplicated and produces structurally significant fragment ions. Due to the palindromic nature of this sequence, masses of the 3'- and 5'-phosphate series are the same, and a simplified FAB mass spectrum is observed.

Oligodeoxynucleotides were synthesized on a Dupont Coder 300 DNA synthesizer. Commercial phosphoramidites and DNA reagents were purchased from Applied Biosystems Inc. (Foster City, CA). Modified phosphoramidites were synthesized using literature protocols. After completion of a synthesis, oligomers were cleaved from the resin in 28% NH4OH. Crude 5'-DMT-protected DNA was HPLC purified on a Waters 990 photodiode array HPLC system. Collected fractions were dried *in vacuo*, deprotected at the 5'-position, and analyzed on a Kratos MS890 mass spectrometer system. An Ion Tech saddle field fast atom bombardment (FAB) source provided 7 Kv xenon atoms for sample ionization. The mass scale was calibrated in the negative ion mode with cesium iodide (130-2000 amu) at a scan rate of 10sec/dec. Samples were dissolved in a glycerin matrix and scanned for approximately 3 minutes.

Recently, we have developed a series of modified 8-oxo-2'-deoxyguanosines for incorporation into oligomers for the study of DNA repair. One of these compounds, O^6-methyl-8-oxo-2'-deoxyguanosine, was placed in the X position of the test oligomer and the HPLC chromatogram of the 5'-DMT-protected product is shown in Fig 1. The chromatogram is dominated by failure sequences appearing near the void volume for this column. However, two significant peaks appear in the DMT region of the chromatogram at 35 and 40 min. These peaks were collected as fractions and analyzed by FAB/MS. The calculated molecular weight for the test oligomer, 5'-TTXTT-3' where X is O^6-methyl-8-oxo-2'-deoxyguanosine, is 1513. In the negative ion FAB mass spectrum for Peak A (Fig. 2a), an intense ion at *m/z* 1512 appears to be the negatively

charged molecular ion formed by loss of a proton. Sequence ions derived from cleavage of the 3'-carbon oxygen bonds (w series) and 5'-carbon oxygen bonds (d series) are present Ions at *m/z* 321 and 625 are monomers and dimers formed from the first two thymidine residues The ion at *m/z* 984 is a trimer and corresponds to an addition of 325 d to the dimer mass, exactly the mass of the O^6-methyl-8-oxo-2'-deoxyguanosine monophosphate. Two final thymidine residues are added to yield ions for the tetramer and pentamer at *m/z* 1288 and 1512 respectively. Thus, the desired oligomer was identified as Peak A, the modified base has been identified as the central base in the sequence, and the mass of the oligomer and the modified deoxynucleotide have been confirmed.

The negative ion FAB mass spectrum of the second fraction (Peak B) is shown in Fig 2b The apparent mass of this substance is 1647, derived from an apparent molecular ion at *m/z* 1646. This molecular mass is 134 d greater than that determined in the previous fraction. Since the phenoxyacetyl (PAC) group is used to protect the 2-amino group during synthesis and adds 134 mass units to the monomer, it must be suspected as the candidate to explain this apparent shift in mass. If true, the sequence ions that contain the modified base should also contain the additional PAC group and, therefore, exhibit the same shift in mass. Sequence ions at *m/z* 321 and 625 are the monomers and dimers, and appear unchanged from the previous mass spectrum. The ion at *m/z* 1118 representing the trimer is shifted by 134 d. from the mass of the trimer in the previous spectrum, and the modified deoxynucleoside containing the PAC protecting group appears responsible Addition of T to form the tetramer (*m/z* 1422) and pentamer (*m/z* 1646) behave normally. Thus, our conclusions are that the deprotection step in this case is not complete and must be reexamined and that FAB/MS analysis of short, test oligomers is an effective means to examine problems in DNA synthesis

Most macromolecular complexes studied by mass spectrometry are relatively small, on the order 10^3-10^4 Daltons. These studies rely on indirect evidence such as isotope exchange, charge state distribution, and changes in molecular weight to infer that native structure is retained in the gas phase. The question remains whether native conformations are preserved during the ionization/vaporization process and the vacuum of the mass spectrometer. A second issue, a vestige of the Manhattan Project where Calutron mass spectrometers were employed to separate uranium isotopes, is whether this technology can be used as a separation and collection device for biomolecules. Our work addresses these issues with the first direct observation of a supramolecular (4×10^7 Da) complex in which biological activity is preserved.

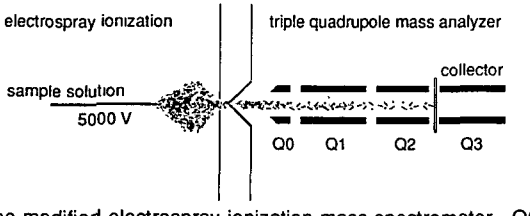

Figure 1. The modified electrospray ionization mass spectrometer. Q0, Q1, Q2, and Q3 represent four different sets of quadrupoles in the mass analyzer allowing for ion focusing and mass selection. The instrument was modified by placing an ion collector in the flight path of the ions between Q2 and Q3. The instrument was a Perkin Elmer SCIEX API-3 triple quadrupole mass spectrometer.

In order to detect large ions (>1,000,000 Da) which do not produce significant secondary electron emission, we have applied a concept analogous to that of the photographic plates originally used for ion detection. Instead of detecting secondary electrons or incident light from a phosphorous screen, the actual ions are physically collected whereby the isolated specimen can be directly examined by electron microscopy. Fig. 1 illustrates the basic design of the mass analysis instrumentation employed.

Figure 2. Two viruses were analyzed, tobacco mosaic virus (TMV) and rice yellow mottle virus (RYMV). TMV's rod-like structure has a diameter of 17.5 nm, a length of 300 nm, and a molecular weight of 40.5×10^6 Daltons. RYMV is 28.8 nm in diameter with a molecular weight of 1.5×10^6 Daltons. Post-analysis samples were found intact when viewed with an electron microscope.

To demonstrate mass selection for the viral studies, we utilized the radio frequency (RF-only) mode for Q0, Q1, and Q2 in the triple quadrupole mass analyzer. By lowering the accelerating voltage between Q0 and Q1, low mass ions drifted out of the analyzer before reaching the detector, while high mass ions retained sufficient momentum to reach the detector.

In the mass analysis process the virus particles were exposed to a number of conditions that could potentially damage tertiary or quaternary protein structure or the nucleic acid structure, resulting in a non-viable specimen. Since electron microscopy is limited in its ability to determine whether this damage had occurred, specimen viability after electrospray mass analysis was tested. The production of characteristic local lesions on the leaves of tobacco cultivar Xanthi NN plants inoculated with post-analysis TMV demonstrates that the virus retained infectivity.

This work has addressed two aspects of electrospray mass spectrometry. Retention of virus ultrastructure and infectivity provide direct evidence that native structure is conserved into the gas phase, producing results on ions forty times larger than any previously reported biomolecule and over a hundred times larger than any biomolecular complex. Secondly, higher accuracy for molecular weight determination and the ability to separate biomolecular complexes, while retaining viability, suggest that electrospray may be developed for *preparative mass spectrometry.* Recent improvements in sensitivity by micro electrospray further support the feasibility of using mass spectrometry for biomolecular purification.

Analysis of Oligonucleotides and their Analogues by Electrospray Mass Spectrometry

*Ling Chen, Lydia M Nuwaysir and Karen Fearon**
*Perkin Elmer, Applied Biosystems Division, Foster City, *LYNX Therapeutics, Inc., Hayward, CA*

INTRODUCTION The routine analysis of oligonuceotides by electrospray ionization (ESI) mass spectrometry provides a powerful and sensitive tool for quality control of the synthetic DNA's. A method is described for rapid on-line desalting and preconcentration of the oligonucleotides prior to ESI mass analysis. General application of ESI mass spectrometry in assaying oligonucleotide synthesis and QC/QA of oligonucleotide therapeutic products are discussed.

EXPERIMENTAL A PE SCIEX API 100 benchtop single-quadrupole mass spectrometer was used for this study and operated in the IonSpray negative-ion MS mode. The sample preparation method for oligonucleotides is ethanol precipitation from ammonium acetate as described in Ref. 1. This method, however, requires sample amount in the nanomole range to be handled easily. For desalting and preconcentration of dilute samples, we adapted the on-line approach previously used for protein/peptide samples (Ref. 2) for desalting of oligonucleotides.

Protocol Put the trap cartridge (LC packing pre-column) in place of the injector loop on a injector (Reodyne 7125). The oligonucleotide was desalted by washing the precolumn with 200 ul of 20mM ammonium acetate in water. The sample was then eluted for mass analysis by directing the LC effluent (10 mM ammonium acetate, 50% acetonitrile 50% water) through the precolumn by switching the injector valve. The results of the loop-wash protocol are shown below. ESI Spectrum of a 41 mer desalted by ethanol precipitation and analyzed by infusion is shown in Figure 1a and 1b. Large amount of sodium adducts reduced the sensitivity, mass accuracy and could overshadow the minor components of interest. The spectral quality was greatly improved by the on-line desalting protocol as shown in Figure 1c and 1d. No sodium adducts were observed.

ES Analysis of Oligonuleotide Analogues in Pharmaceutical Application For pharmaceutical applications, as well as in studies aimed at refining synthesis of oligonucleotide (ODN) and their analogues, it is necessary to address issues of product identification and purity, characterization of impurities and reproducibility of synthesis and purification methods. The routine analysis of oligonuceotides by electrospray ionization (ESI) mass spectrometry provides a rapid and sensitive tool for structure confirmation and quality control of the synthetic ODN's. The following ODN phosphodiester is designed for treatment of chronic myelogeneous leukemia. Various chemically modified compounds were synthesized to help prevent 3'-exonuclease degradation and to facilitate transport across membranes (cellular uptake). Correct synthesis of the desired modification were readily confirmed by ESI mass spectrometry (Fig.2a and 2b). Attention has focused on using phosphorothioate ODN's as "antisense" agents because the S-ODN's are resistant to degradation by nucleases, form stable duplexes and are now readily synthesized. The following S-ODN is designed for treatment of acute myelogeneous leukemia. 5'-
d(CpsCpsCpsTpsGpsCpsTpsCpsCpsCpsCpsCpsCpsTpsGpsGpsCpsTpsCpsC)
ESI mass spectrum is shown in Fig 2c. The families of much lower intensity ions seen in Fig. 2c are due to minor impurities. The peaks found at MW 6190 and 6174 Da correspond to the synthesis defects where either one or two phosphodiester (PO) linkages were formed instead of phosphorothioate (PS) linkages. The PO defects can be attributed to the incomplete stepwise sulfurization with S-Tetra in the solid-phase phosphoramidite method. Based on independent quantitation method (IEC data not shown), we believed that, in general, impurities in the S-ODN products are detectable in the ESI-MS if they are at least 1 mol-% of the material analyzed.

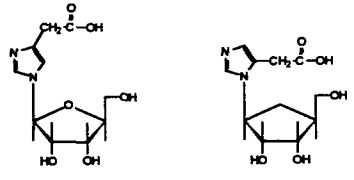
Detection of Imidazoleacetic Acid Riboside by FAB/MS and ESI/MS

Robert A. Rieger[1], D Meghanath Reddy[1], Boban Thomas[2], George D Prelli[2], and Charles R. Iden[1]

[1]Department of Pharmacological Sciences, Health Sciences Center, SUNY-Stony Brook, Stony Brook, NY 1179-3400

[2]Department of Pharmacology, School of Medicine, Mt. Sinai Medical Center, New York, NY 10029-6574

Imidazoleacetic acid is a potent agonist in biological systems and exerts numerous biological effects including analgesia, sedation, and reduction of blood pressure, body temperature, and motor activity. It is a normal constituent of plasma and urine and may exist as the free compound or in conjugated form where it is bound to a ribosyl moiety. Two isomers are possible depending on whether the acetic acid moiety is bound to the C4- (tele isomer) or the C5-position (pros isomer) of the imidazole ring. GC/MS methods for analysis of the two isomers have been developed and require trimethylsilyl-derivatization in order to increase volatility and decrease retention on GC columns. These methods have employed both EI and CI techniques and have achieved excellent sensitivity for biological samples



We have developed methods for the detection of imidazoleacetic acid riboside and ribotide in biological samples using FAB and ESI techniques. Both methods do not require sample derivatization; thus, the analysis can be simplified when compared to that for the GC/MS technique. FAB mass spectra were produced on a Kratos MS-890 mass spectrometer equipped with a DS-90 data system. Fast xenon atoms (7 kV) were generated in a Ion Tech saddle field source and were permitted to impact the sample dissolved in a 1:1 glycerine/thioglycerine or nitrobenzyl alcohol matrix. Mass spectra were acquired in the positive ion mode while the instrument was scanned repetitively over the range *m/z* 1500-130 at 10 sec/dec. Electrospray mass spectra were acquired in both the positive and negative ion mode on a Fisons Instruments Trio-2000 GC/MS instrument equipped with an electrospray ion source. Samples (10 μl) were introduce by loop injection into a solvent stream of methanol/water/ammonium hydroxide (90:9:1) flowing at 6μl/min. The instrument was operated in the multichannel analyzer mode with a scan time of 8 sec over the range *m/z* 80-600. Spectra are an average of 10-15 scans.

Perfused rat brains were collected and homogenized in 0.4 N perchloric acid and centrifuged at 50,000 g for 45 min. The total supernatant was made basic with 10 N KOH and centrifuged again at 50,000 g for 45 min. The supernatant was placed on a Waters C_{18} solid phase extraction column, drawn through with mild suction, and applied to a phenylboronate (PBA) extraction column. The column was washed with triethylamine and eluted with 3 ml 6 N formic acid. Samples were brought to pH 10 with NH_4OH and applied to columns containing conditioned AG-1-X8 resin in acetate form. Columns were washed with water

and eluted with 10 ml 10 N formic acid This eluate was desalted on a column of mixed anion-cation exchange resin (BioRad MSD 501) and dried on a vacuum centrifuge.

Positive ion FAB/MS analysis of the imidazoleacetic acid riboside and ribotide standards in a glycerin/thioglycerine matrix generate excellent mass spectra (Fig. 1). $(M+H)^+$ and $(2M+H)^+$ dominate the spectrum, and fragmentation is not abundant. BH^+ and BH_2^+ are not evident since they appear (*m/z* 126, 127) below the limit of the mass calibration. As expected, the tele- and pros-isomers cannot be distinguished by FAB/MS. When extracts from rat brain samples were analyzed under similar conditions, no peaks corresponding to the molecular ions of the riboside and ribotide were found. Even when a standard was added directly to the sample on the FAB probe, molecular ions still were not apparent in the mass spectrum. However, when the sample was trimethylsilylated (TMS) and the hydroxy groups were protected, peaks corresponding to the *tris*-TMS-derivative and the *tetrakis*-TMS derivative of imidazoleacetic acid riboside were present in the FAB mass spectrum Positive ion ESI/MS confirmed the presence of imidazoleacetic acid riboside in rat brain. Figure 2 shows the ESI spectra of a standard of the riboside, showing an intense molecular ion at *m/z* 258 and a sample generated from rat brain, also with a strong peak at *m/z* 258 and several background peaks nearby. Thus, this preliminary data indicates the presence of imidazoleacetic acid riboside in rat brain at detectable levels, while no evidence for the ribotide was found by these methods

Liquid Chromatography/Electrospray Ionization Tandem Mass Spectroscopy (LC/ESI MS/MS) Analysis of 1,2-epoxybutene Adducts of Purine Deoxynucleosides.

Sara J. Kambouris [1,2], Ajai K. Chaudhary [2,3,4], Ian A. Blair [1,2,4]

Department of Chemistry [1], Vanderbilt University, Departments of Pharmacology [2] and Biochemistry [3], A. B. Hancock Jr. Memorial Laboratory for Cancer Research [4], Vanderbilt University School of Medicine, Nashville, TN, 37232, USA.

Incomplete fuel combustion from mobile exhausts results in a major contribution of 1,3-butadiene (BD) to the environment. Stationary sources and tobacco smoke also contribute significantly to environmental BD. Formaldehyde and acrolein are the major products from the atmospheric breakdown of BD. BD causes tumors in mice and rats and has been classified as a probable human carcinogen by the U.S. Environmental Protection Agency (EPA) and the International Agency for the Research on Cancer (IARC). A major route of BD metabolism involves conversion of BD to 1,2-epoxybutene (BDO) and 1,2,3,4-diepoxybutane (BDO_2) primarily by cytochrome P450 2E1. BDO and BDO_2 are both genotoxic and carcinogenic. Studies on the characterization of DNA modification by BD and its metabolites are very limited. Two DNA adducts, 7-(2-hydroxy-3-buten-1-yl)guanine and 7-(1-hydroxy-3-buten-2-yl)guanine, have been identified after reacting BDO *in vitro* with guanosine.[1] 7-(2-hydroxy-3-buten-1-yl)guanine and 7-(2,3,4-trihydroxy-butan-1-yl)guanine have been detected in livers of B6C3F1 mice exposed to ^{14}C-BD.[2] To date, BDO_2-DNA adducts have not been characterized.

Methodology has been developed for the analysis of BDO adducts of purine 2' deoxynucleosides.[3,4] BDO was reacted with guanine (G) or adenine (A) at room temperature for 15 min in 0.1 M KOH solution. Unreacted BDO was removed by extraction with diethyl ether, and the resulting adducts were analyzed using LC/ESI MS/MS. Calf thymus DNA was reacted with BDO in phosphate buffered saline at 37 °C for 12 h. The DNA was then ethanol precipitated and hydrolyzed with 1 M HCl to release DNA bases.

LC/ESI MS/MS studies were conducted using a Finnigan TSQ-7000 interfaced with an HP series II liquid chromatograph. LC was conducted using a C8 column (4.6 mm x 250 mm; 5 um) maintained at room temperature with a flow rate of 500 uL/min. Solvent A was 5 mM aqueous ammonium acetate containing 0.01 % trifluoroacetic acid and solvent B was 5 mM ammonium acetate in methanol:water (9:1) containing 0.01 % trifluoroacetic acid. A linear gradient run as follows: 0 min, 5 % B; 2 min, 5 % B; 5 min, 15 % B; 20 min, 17 % B; 25 min, 50 % B; 30 min, 80 % B; 35 min, 90 % B; 40 min, 5 % B. Nitrogen was used as the sheath (70 psi) and auxiliary (20 psi) gas to assist with nebulization. A potential of 4.5 kV was applied to the ESI needle and the capillary was maintained at 240 °C in order to provide optimal desolvation of the ions generated by ESI. Mass spectrometer parameters were optimized, to obtain maximum sensitivity, without sacrificing unit resolution. MS/MS scanning was performed by setting the parameters in quadrupole 1 (Q1) to allow the parent ions (MH^+ ion of mono adducts of BDO, *m/z* 206 for A-BDO and *m/z* 222 for G-BDO) to traverse to quadrupole 2 (Q2). Collision induced dissociation (CID) was performed using argon, as the collision gas, at a pressure of 2.25×10^{-3} Torr in Q2. Quadrupole 3 (Q3) was scanned from 50 to 250 Da for the product ions generated from CID. Reaction of BDO with A resulted in seven A-BDO adducts with MH^+ ion *m/z* 206. CID was performed for ions with *m/z* 206 and product ion spectra recorded in Q3. A characteristic fragment ion with *m/z* 136, corresponding to the loss of BDO, was observed (Figure 1). LC/ESI MS/MS chromatogram of the ethanol supernatant, from calf thymus DNA incubated with BDO, showed two distinct peaks (Figure 2) corresponding to peaks 3 and 4. The preliminary evidence suggests that these adducts correspond to regioisomeric N-7 adducts for deoxyadenosine (dA) which can be spontaneously depurinated and released from the DNA backbone. These results are very encouraging and may help in the development of BD exposure biomarkers. LC/ESI MS/MS analysis of DNA hydrolyzate showed four distinct A-BDO adducts (Figure 3) which correspond to peaks 1, 2, 6 and 7. The absence of adducts 3 and 4, from DNA hydrolyzate, also strengthens the argument concerning spontaneous depurination of these adducts. We also have evidence for the formation of formamidopyrimidine (FAPY) adducts of A-BDO with MH^+ ions at *m/z* 224. Similar experiments were carried out with G. Eight G-BDO adducts were found by monitoring *m/z* 222. Two of these adducts were present in the ethanol supernatant of calf thymus DNA-BDO, and at least four adducts were present in the DNA hydrolyzate. In addition to these data, we also have some preliminary data suggesting the presence of cytosine-BDO and thymidine-BDO adducts in BDO treated calf thymus DNA.

A Study of Metal Ion Interactions with Nucleosides by LSIMS

G.J.C. Paul[1], T. Theophanides[1], J. Anastassopoulou[1], I. Marcotte[2], M.J. Bertrand[2], [1]National Technical University of Athens, Zografou 15780, Athens, Greece, [2]Department of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7.

Metal ions have been implicated in vital biological processes involving DNA and its component parts such as DNA replication/transcription processes and metabolic reactions. As well as providing information on intrinsic cation binding tendencies, the characterization of metal ion interactions with nucleic acid components such as nucleosides may be useful when considering more complex real situations. In this study, the interactions of metal ions with cytidine and guanosine are probed by liquid secondary ion mass spectrometry (LSIMS) with glycerol/DMSO as the liquid matrix. Complementary gas phase collision-activated dissociation (CAD) was also performed using helium as the collision gas.

Considering the alkali metals (X = Li^+, Na^+, K^+, Rb^+, Cs^+), a typical LSIMS mass spectrum for cytidine/NaCl is shown in Figure 1. In the molecular ion region, the ions MH^+, MX^+ and $(M-H+X)X^+$ are observed. The presence of BHX^+ indicates that metal bonding takes place on the base and CAD with MX^+ as the precursor supports this. Likewise, CAD of $(M-H+X)X^+$, as shown in Figure 2, yields BX_2^+ which suggests that both proton substitution by an alkali metal and metal ion attachment occur at the base. For guanosine, it is thought substitution takes place at the most acidic N1 site, with binding of the alkali metal shared between O6 and N7. For cytidine, however, proton substitution by the metal is expected on the sugar portion and attachment at the N3 position. Gas phase rearrangement of $(M-H+X)X^+$ upon CAD with subsequent alkali metal attachment to N1 may explain the formation of BX_2^+ for cytidine systems (Figure 2).

A characteristic LSIMS mass spectrum for the alkali earth metals (Y = Mg^{2+}, Ca^{2+}, Ba^{2+}) and nucleosides is shown in Figure 3. The major ions incorporating both metal and nucleoside are $G(M-H+Y)^+$ and $MG(YZ)^+$ where Z = Cl^- or NO_3^-. The enhancement of these species over $(M-H+Y)^+$ and $M(YZ)^+$ in LSIMS shows the co-ordination of the metal provided by two molecules is favored over single nucleoside binding. CAD of $G(M-H+Y)^+$ yields BY^+ as the major product ion. Similar to the alkali metals, it is believed that substitution occurs at N1 for guanosine, while gas phase rearrangement occurs for cytidine complex where the metal ion migrates on the sugar to the N1 position of the base. LSIMS data involving D-ribose shows proton substitution from the sugar by an alkali earth metal can indeed take place. The CAD spectrum of $MG(YZ)^+$ reveals that the monovalent $(YZ)^+$ species attaches itself to the base since $BH(YZ)^+$ is observed. Interestingly, a small peak corresponding to $G(M-H+Y)^+$ is also present which shows gas phase decomposition can contribute to the formation of this species in LSIMS.

Unlike the alkali and alkali earth metals, the trends observed in LSIMS for the transition metals are found to be metal ion-dependent. For Fe^{2+}/nucleoside systems, the mass spectral features mirror those of the alkali earth metals where complexation involving $(FeZ)^+$ and $(M-H+Fe)^+$ occurs. The LSIMS mass spectrum for Co^{2+}/guanosine is shown in Figure 4. In addition to the typical complexes formed when the metal is in the divalent state,

43rd ASMS Conference on Mass Spectrometry and Allied Topics

ionic species which contain Co^+ (M_nCo^+, n=1,2) are also observed. It is supposed that Co^+ formation in LSIMS is a consequence of beam-induced reduction in solution and that the resultant metal ions bind to the nucleosides in a similar manner to the alkali metals, although $(M-H+Co)Co^+$ is not observed. Analogous behavior is observed in the LSIMS for the Ni^{2+}/nucleosides systems. For Cu^{2+}/nucleosides, bare copper ions in the monovalent state predominantly complex the nucleosides. Cu^{2+} is known to have a high reduction potential which may explain the preferential formation of monovalent metal ion complexes for this metal relative to the other transition metals. Interestingly, $(CuNO_3)^+$ complexes are also observed in the mass spectrum where copper is present in the divalent state. The CAD data obtained for the ionic transition metal/nucleoside species are consistent with that for the alkali and alkali earth metals.

GAS-PHASE CHEMISTRY OF COMPLEXES BETWEEN TRANSITION METAL(II) IONS AND NUCLEOSIDE MONOPHOSPHATES

Jill H. Hamilton and Jeanette Adams, Department of Chemistry and the Emory University Mass Spectrometry Center, Emory University, Atlanta, GA 30322

Experiments were conducted to determine: (1) the gas-phase structures of complexes between transition metal(II) ions and ribonucleoside monophosphates; (2) whether monophosphate Me^{2+} complexes, in which $Me^{2+} = Mn^{2+}$, Co^{2+}, and Ni^{2+}, reflect solution or gas-phase structures and chemistry. MS^2 and MS^3 experiments were performed using a JEOL JMS-SX102/102A/E five-sector tandem mass spectrometer.

Metastable ion decomposition experiments show that the lowest energy decomposition pathway is expulsion of the sugar. This fragmentation results in ions that contain the base (B), the metal ion (Me^{2+}), and the phosphate group (H_2PO_4) $(B + Me^{2+} + H_2PO_4)^+$ ions. CID results in ions containing the metal ion coordinated to either the base $(B + Me^{2+} - H)^+$ or to the phosphate group $(Me^{2+}H_2PO_4)^+$. MS^3 spectra of the first-generation $(B + Me^{2+} + H_2PO_4)^+$ ions show that the $(B + Me^{2+} - H)^+$ and $(Me^{2+}H_2PO_4)^+$ ions are formed by decompositions of $(B + Me^{2+} + H_2PO_4)^+$ ions.

CID experiments performed at different amounts of main beam reduction show that the rate of formation of $(B + Me^{2+} - H)^+$ ions ($Me^{2+} = Co^{2+}$ and Ni^{2+}) out-competes the rate of formation of $(Me^{2+}H_2PO_4)^+$ ions for GMP and CMP at all energies. The opposite is true for UMP.

The gas-phase data show that transition metal(II) ions form chelates with ribonucleoside monophosphates. Evidence for chelate formation is established from the formation of $(B + Me^{2+} + H_2PO_4)^+$ product ions. The population of precursors from which $(B + Me^{2+} + H_2PO_4)^+$ ions arise must contain the metal ion coordinated to the base and phosphate group (Structure 1a-b). Both Structures 1a and 1b can give rise to the $(B + Me^{2+} + H_2PO_4)^+$. It is unlikely, however, that the $(B + Me^{2+} - H)^+$ ions arise from Structure 1a. The $(B + Me^{2+} - H)^+$ ions can, however, arise from Structure 1b, in which the base has been deprotonated, and bound to the metal ion.

In solution, transition metal(II) ions bind to both the base, at (N7), and to the phosphate group of purine ribonucleoside monophosphates [1]. Three metal-ion coordinating modes have been observed: (1) one in which the metal ion is directly coordinated to (N7) of the base and indirectly (via molecules of water) to the phosphate group (Structure 2); (2) one in which the metal ion is indirectly coordinated to the base and indirectly to the phosphate; (3) one in which the metal ion is directly coordinated to the base and phosphate group [2]. In pyrimidine monophosphates, however, metal ions are only directly or indirectly coordinated to the phosphate group and do not interact with the base [2]. These solution structures are not observed in the gas phase.

These results show that the gas-phase structures of complexes between ribonucleoside monophosphates and transition metal(II) ions are not the same as in solution. Solvent effects mask the intrinsic binding chemistry between the metal(II) ion and ribonucleoside monophosphates, chemistry that involves expulsion of the sugar. Solvent molecules reduce the strain energy that would accompany chelate formation by forming water bridges and by filling the remaining coordination sphere of the metal(II) ion.

In situ digestion procedures and analysis of the digest by capillary HPLC/ESI/MS

R. Falchetto, J. Shabanowitz, J. Lamer, and D. F. Hunt
Departments of Chemistry, Pathology and Pharmacology, University of Virginia, Charlottesville, VA 22901

Introduction

One of the most common and powerful resolving techniques in biochemistry is SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Handling of very small amounts of protein, which are resolved according to their molecular weights, is very convenient with SDS-PAGE and identification is possible by using easy staining procedures. Beside being a useful analytical tool, electrophoresis is also a powerful preparative technique. Proteins have been isolated from gels, digested by chemical or enzymatic methods, and the resulting peptides then fractionated and sequenced by Edman degradation. The method of choice has been to transfer the protein from the gel onto a solid support (1). We have combined these classical biochemical techniques with HPLC/ESI/MS analysis (2) of various proteins identified and isolated by SDS-PAGE, such as a drug-binding protein (3), transcription factors, tumor-specific proteins, and several others. To standardize our *in situ* proteolysis procedure, we have compared different kinds of digestion approaches and different types of membranes.

Methods and Results

Three types of transfer membrane were compared: PVDF, Nitrocellulose and Immobilon-CD (a PVDF-based membrane with a cationic surface). 140pmol of bovine ß-lactoglobulin were separated and transferred onto the membranes, cleaved *in situ* with 0.1µg trypsin, and aliquots of the digests analyzed by HPLC/ESI/MS. Protein immobilized on CD membranes was digested following the procedure described by Hess et al. (4) while protein immobilized on regular PVDF membranes was digested as described in (1) and (5). The amounts of peptide recovered from both membranes were approximately the same. However, the staining procedure for CD membranes was more cumbersome and less reliable than that used on PVDF membranes and, thus, CD membranes were not investigated any further. Next, two digestion procedures were compared on PVDF membranes: To prevent sequestering of the protease on "free" sites on the membrane the latter have to be blocked either by an inert polymer (PVP-40)(1,5) or by a detergent. We have chosen the hydrophilic detergent n-octylglucoside which is added to the digestion buffer at a 1% concentration. A small amount of this solution was added to the protein band for cleavage. Analysis of the digest by HPLC/ESI/MS, however, was severely hampered by the high amounts of detergent which eluted through the early part of the HPLC gradient and no reasonable comparison with the other digestion procedure could be done. Finally, digests of lactoglobulin on PVDF and nitrocellulose were compared using the procedure described in (1) and (5). The amounts of peptide recovered from the digests were plotted against those recovered in a solution digest of the same amount of lactoglobulin. Tryptic fragments were detected corresponding to 72% of the entire protein sequence.

The figure shows that PVDF gives better recovery than nitrocellulose (36% vs. 23%). Moreover, blank digests of membrane regions containing no protein showed a higher background generated by nitrocellulose membranes.

Data collected on 2.8pmol bovine lactoglobulin digested with trypsin (total initial amount 140 pmol)

ENZYMATIC FRAGMENTATION WITH IMMOBILIZED ENZYMES AND LC/MS ANALYSIS

Manfred Raida, Wolf-Georg Forssmann

Lower-Saxony Institute for Peptide Research (IPF)

Feodor-Lynen-Strasse 31, D - 30 625 Hannover, Germany

The LC / MS analysis of peptide fragments obtained by specific enzymatic or chemical cleavage, peptide mapping, is an indispensable tool for solving many analytical problems Amongst these are the identification of peptides or proteins by their typical fragment pattern, localization and characterization of posttranslational modifications, selection and characterization of fragments for overlapping sequence analysis, identification of genomic variants, analysis of synthetic peptides or recombinant proteins, and the assignment of disulfide bridges.

The fragments are usually obtained by cleavage in solution and then either applied directly to reversed-phase chromatography or freeze-dried to reduce the volume prior to separation These techniques have important limitations Large volumes of directly applied solutions have to be injected onto columns running at the low flow rates used in LC/MS analysis. Fragments may get lost due to adsorption on plastics. Autoproteolytic fragments of enzymes may result Nonspecific cleavage due to long incubation times may lead to errors in sequence analysis or in the interpretation of LC/MS analysis With unknown amounts of protein it is difficult to calculate an optimal enzyme : substrate ratio Particularly in the case of LC/MS analysis of low amounts of protein fragments these limitations lead to difficulties in the interpretation of results

The use of immobilized enzymes or enzyme microreactors helps to overcome the majority of these limitations In the recent years several attempts have been made to use immobilized enzymes in protein and peptide analysis. In many cases agarose or acrylamide based gels were used which are not compatible with high flow rates or increased pressure. The use of enzymes bound to wide-pore materials opens up new paths in the use of immobilized enzymes and the analysis of minor amounts of proteins and peptides.

In the experiments described here, synthetic large-pore materials with immobilized trypsin (POROSzyme, Perseptive Biotechnologies, USA) was used. The column used for the experiments is a 2.1 x 10 mm pressure stable column which allows high flow rates. Standard HPLC equipment with a minimal flow rate of 25 µl / min is used to transfer the peptides through the trypsin microreactor to the consecutive separation on 1 x 250 mm C-18 column The chromatographic separation was carried out using a double syringe pump with a flow rate of 20 µl / min, and a standard water / TFA and acetonitrile / TFA gradient system with an increase of 1 % per min. The column outlet was directly connected through a UV detector equipped with a capillary Z-cell to the electrospray interface of a triple-stage quadrupole mass spectrometer (API III, SCIEX, Toronto, Canada).

Horse hemoglobin or horse heart cytochrome C were chosen as test proteins for the experiments presented here. Concentrations of 1 µg / µl to 0 01 µg / µl were used in the experiments, the digestion buffers and transfer buffers were 50 mM / l ammonium acetate or ammonium formiate with 5 % methanol and a pH of 8.1 or 7 0. The trypsin microreactor was kept at 37° C throughout the experiment The eluate

from the trypsin microreactor was either collected and lyophilized for further separation or transferred on-line onto the C-18 separation column with a flow rate of 25 µl / min. After the total transfer of the protein, the separation column was equilibrated with 0 06 % TFA in 10 % acetonitrile and then connected with the separation HPLC and the electrospray interface.

The total digest of the protein was achieved within 30 minutes at a flow rate of 25 µl / min and a concentration of 0 1 µg / µl. Both increased flow rates or increased concentrations led to incomplete cleavage. Nevertheless all expected fragments could be observed even at high concentrations and flow rates alongside the intact protein. In on-line experiments the fragments of 20 pM cytochrome C could be identifed clearly by LC / MS using 1 mm ID columns.

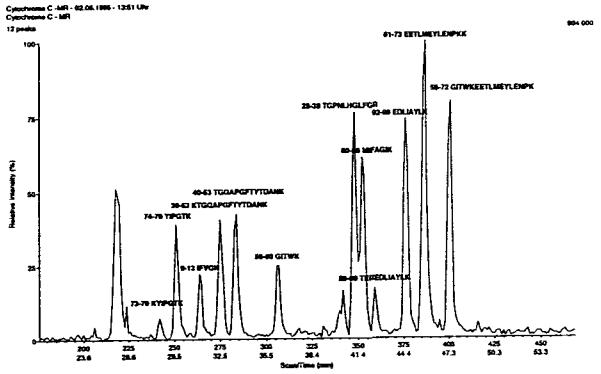

Figure: Total ion chromatogram of the tryptic fragments of 20 pM cytochrome C. The intact protein was transferred at a flow rate of 25 µl / min through the trypsin microreactor onto the 1 x 250 mm C-18 separation column and the fragments eluted by a linear water/TFA to acetonitrile/TFA gradient at 20 µl / min.

In the example shown here, all expected tryptic fragments from cytochrome C above four amino acids could be detected in the LC / MS analysis. The experiments were performed within 2 hours

The experiments show that enzymatic microreactors help to overcome the limitations of enzymatic digestion in solution and to increase sensitivity in the detection. In the experiments presented here the tryptic digest of cytochrome C was obtained within 30 minutes, nonspecific cleavage or autoproteolytic fragments were not observed.

Separation and Manipulation of Proteins using Polymeric μ-HPLC Columns On-line with Electrospray Ionization/Mass Spectrometry

Mark E. Hail[1], Bethanne M. Warrack[1], Susan C. Taylor[1], Sam Baldwin[2], Ken Stoney[2], and Mike S. Lee[1]

[1]Bristol-Myers Squibb Pharmaceutical Research Institute, P.O. Box 4000, Princeton, NJ 08543
[2]Michrom BioResources, Inc., 1945 Industrial Drive, Auburn, CA 95603

In the pharmaceutical industry, there has been expanding interest in the structural characterization of proteins, since proteins are most often the targets of new therapeutic drugs. Electrospray ionization mass spectrometry (ESI/MS) is unique when compared to other structurally informative methods (e.g. NMR or X-ray crystallography) in that information can be obtained rapidly on small quantities of sample. Unfortunately, the luxury rarely exists that the sample is highly pure or is dissolved in a solvent that is optimal for ESI/MS. For example, highly aqueous solutions or those containing high concentrations of involatile salts or detergents, often lead to poor signal-to-noise if direct sample infusion is attempted. In addition, protein mixtures often result in uninterpretable ESI/MS data due to overlap of the multiply charged ion envelopes.

For these reasons, we have developed methods using on-line ESI/LC/MS for protein/peptide characterization. Our strategy has focused on the use of 300-4000 Å polymeric (polystyrene divinylbenzene) microbore HPLC columns for separation and short polymeric protein/peptide "trap cartridges" for rapid desalting or preconcentration of biomolecules. It was found that utilization of these polymeric HPLC columns resulted in improved signal-to-noise and mass accuracy relative to infusion analysis, particularly for samples containing salts or protein mixtures. The polymeric packings are exceedingly rugged and are not harmed by injections of 70% formic acid, which is used after each analysis to wash remaining adsorbed protein from the columns and traps, preventing sample carryover.

Examples of the applicability of these methods to large hydrophobic proteins include cytosolic phospholipase A_2 ($cPLA_2$) and the microsomal triglyceride transport protein (MTP). $cPLA_2$ is an 85 kDa phosphorylated protein which is involved in the production of prostaglandins, and is thus the target of new anti-inflammatory drugs. ESI/LC/MS analysis of $cPLA_2$ revealed the existence of five peaks separated by 80 Da at the expected MW of this protein which indicates the presence of at least four possible phosphorylated residues. MTP is a noncovalently-bound heterodimer consisting of 55 kDa protein disulfide isomerase and a larger subunit with a MW of 97 kDa. Using polymeric μ-HPLC combined with ESI/MS we were able to separate these two subunits and deduce the origin of modification in this protein, which was yielding two slightly different active forms when purified from bovine liver. The two forms of the protein were found to be different on the large subunit due to C-terminal processing of the last two residues.

For situations when sample quantity is very limited, we have begun to evaluate a new enzymatic digestion method for peptide mapping experiments, whereby a protein can be injected and preconcentrated on a polymeric "trap cartridge" followed by digestion *in situ*. This work is similar to a previous study by Burkhart et al., who investigated digestion of proteins from enzymes immobilized on Poros™ columns (1). We have expanded these studies to investigate the more convenient "trap cartridges", which allow rapid buffer exchange and/or sample manipulation requiring only a syringe. The goal is to take advantage of the sample preconcentration ability of these "traps" and to eliminate the sample losses that occur during the many manipulation and transfer steps that are required for typical solution digestion procedures (e.g. buffer exchange, reduction, alkylation, etc.). Our early results indicated that *in situ* digestion with Lys-C protease yielded results comparable to those obtained from solution digests, with the *in situ* method resulting in the production of more partially digested fragments. However, as shown in Figures 1 and 2, the *in situ* digest is more complete and results in higher recovery of peptides when small quantities of

protein are used in the digestions. This is probably due to the avoidance of sample loss with the *in situ* method. In a separate experiment depicted in Figure 3, a complete peptide map of lysozyme was obtained after *in situ* reduction of its four disulfide bonds and subsequent digestion of the protein with Lys-C. Interestingly, when trypsin was used no digestion was observed for a number of test proteins under a variety of conditions. This suggests that results from digestions *in situ* will be dependent on how the protease is adsorbed to the packing (e.g. accessibility of enzyme active site).

In summary, the small polymeric "trap cartridges" and columns are a convenient means of preconcentrating, separating, and manipulating proteins for analysis by ESI/MS. The packings are exceedingly rugged and are ideally suited for high throughput analyses. It is also anticipated that these trap/alkylate/digest/elute *in situ* methods will allow future implementation of automation.

Comparison of a Quadrupole MS to a Reflectron TOF MS with Electrospray Ionization

Anatoli Verentchikov*, Frank Hsieh, Michael Tomany,
Stephen Gabeler, Marvin Vestal, Stephen Martin
PerSeptive Biosystems, Inc., 500 Old Connecticut Path, Framingham, MA 01701

The identification and characterization of novel factors of biological significance require the isolation, purification, and enzymatic digestion of smaller and smaller amounts of material. Integral strategies are being developed to reduce the sample quantity and volume, including immobilized reagents and capillary columns. These strategies require that the specifications of the mass analyzer include simultaneous sensitivity, resolution, mass range, scan speed, and mass accuracy.

A comparison was made between a quadrupole mass spectrometer and an orthogonal deflection - reflectron time of flight mass spectrometer [1] for these specifications when used in the analysis of peptides and proteins using electrospray ionization. The comparison was made using constant infusion, direct injection, and on-line LC methods.

Figure 1 shows the simultaneous sensitivity and resolution of the time of flight instrument with 5 femtomole of neurotensin (1673 amu) consumed. Figure 2 shows good sensitivity with a quadrupole at low resolution (below isotopic) and figure 3 shows marginal sensitivity when the quadrupole is tuned to resolve the isotopes. In both Figures 2 and 3, the mass range of the quadrupole instrument was reduced to 500 amu to achieve these results. The mass range of the time of flight analyzer shown in Figure 4 is well beyond the capabilities of the quadrupole tested (2400 amu). This spectrum repeats the work of reference [2]. Figures 5 and 6 compares the ultimate resolution achievable on both instruments for the +4 charge state of Melitin (2844.6 amu). Time of flight resolution was greater than 5000. Figure 7 is the TIC chromatogram of an immobilized enzyme digestion of Myoglobin followed by reverse phase LC separation at 1 second per full mass range scan [1]. The chromatographic separation produced 13 second peaks which are well sampled at 1 second per scan. The time of flight analyzer is well suited for LC/LC/MS experiments by providing this rapid scanning, full mass range detection, and isotopic resolution of the multiply charged proteolytic peptides. To obtain the same resolution and mass range using the quadrupole analyzer, the scan time required for high resolution became incompatible with the time scale of the reverse phase separation. Mass accuracy's were evaluated by measuring the standard deviation of mass determinations from each charge state of a multiply charged protein. Using 3 sigma for a 99% confidence, the quadrupole showed about 450 ppm (0.045%) and the time of flight showed about 50 ppm (0.005%). The accuracy and resolution of the time of flight instrument made molecular weight determinations much easier and reliable. Being able to resolve the isotopic distributions and their spacings makes the determination of charge state simple and direct as well as giving confirmation based on the isotope distribution pattern.

Peptide Mapping on a Nitrocellulose Membrane with Analysis by Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry by Jian Bai, Mark G. Qian, Yanhui Liu, Xiaoli Liang and David M. Lubman, Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109

Introduction It has been shown that proteins bound to membranes are amenable to chemical/enzymatic digestion followed by MALDI MS analysis for the identification of proteins, peptide mapping, and localization of modifications **(1-3)**. In the present work, we examine the use of nitrocellulose (NC) membrane for the mapping of CNBr peptides by MALDI/MS and compare nitrocellulose with Immobilon-N and Immobilon-CD membranes. NC is found to be versatile in such analyses due to its excellent retention of both small and large fragments during digestion and washing.

Experimental 1-D SDS-PAGE, electroblotting, and staining were performed under standard conditions. The thoroughly destained protein bands were cut into small pieces and washed before digestion in 10 µl of CNBr (0.5 M in 0.1 N HCl). The CNBr fragments still on the membrane were washed thoroughly, then extracted from the membranes with 10 µl of CHCA in water/acetonitrile (up to 2:3) with TFA (1.25 %). 2.5 µl of the extracts was applied and dried on the probe tip before MALDI MS analysis. An improved recovery procedure of CNBr peptides **(4)** from NC membrane using a dissolution method was also reported here In this method, CHCA prepared in acetone (1% TFA) was used to dissolve the NC for peptides recovering.

Results and discussion The NC membrane has better retention properties for both large and smaller CNBr fragments generated from the above procedures, and were not affected by additional reaction steps such as reduction/alkylation and additional washings. There is a loss of smaller CNBr fragments, and selective loss of larger CNBr fragments with Immobilon-CD and Immobilon-N membranes (Figure 1a & b) Direct extraction of the CNBr fragments from membranes without washing the membrane improved the recovery of smaller fragments; spurious and uninterpretable peaks arise in the MALDI/MS spectrum for β-casein in the case of using Immobilon-CD. Washing the membranes after digestion significantly improves the quality of the MALDI MS signal, particularly when low level proteins are digested on the membrane

CNBr digestion on the NC membrane can provide a better and direct means for further characterization of electroblotted proteins using MALDI MS. The extraction efficiency of the CNBr peptides from NC with the above described matrix/solvent system is still low This is demonstrated by comparing the result from the dissolution method (Figure 2a & b), where dramatically improved extraction efficiency was achieved. This method has been proven to be very effective for recovering proteins and their digests for MALDI MS analysis **(4)**

Conclusion MALDI/MS can provide a general means for the characterization of electroblotted proteins on membranes by incorporating chemical digestion methods directly on the membrane A nitrocellulose membrane with moderate binding capacity and excellent retention for both small and large fragments, is advantageous in cases where multiple reaction and washing steps are used. It effectively eliminates possible cross contamination between reactions and contamination at the final stage before MALDI/MS analysis. The incorporation of MALDI/MS with the membrane immobilization technique has provided a fast and effective means of peptide mapping based on chemical digestion without the use of conventional separation or fractionation methods.

Commercial laundry products are complex mixtures of cleaning agents. These mixtures typically consist of surfactants, builders, soil release agents, bleaches and enzymes. The most common enzymes used in these mixtures are a group of alkaline proteases known as subtilisins[1] Subtilisins have been extensively engineered to make them more suitable for laundry applications. The characterization of these enzymes can be accomplished with a variety of techniques. In the following two examples, various mass spectrometry methods (MALDI, PDMS, ESI, FAB, oa-TOF) are used in conjunction with chemical and enzymatic digestions to quickly identify specific mutations found in enzymes from commercial products.

Enzyme A

Enzyme A was isolated from a laundry detergent purchased in Japan. After purifying the enzyme with HPLC, a portion of the enzyme was sequenced to determine the N-terminal amino acids. The first 28 cycles were identical to Savinase®, a common detergent protease Ionspray analysis of the intact enzyme gave a molecular mass of 26,724.5, quite different from that expected for Savinase (26,699 6). The intact enzyme was digested with cyanogen bromide in 0 1N HCl for 2 hours at 37°C in the dark. Subsequent ionspray analyses of the purified fragments are shown in the table below

Residues	Enzyme A	Savinase	Δ
1-117	11,405 3	11,406.6	+1 3
118-169	5,013 4	5,013.5	+0 1
170-216	4,705 3	4,706 0	+0 7
217-269	5,512.8	5,488 2	+24 6

The isolate containing residues 217-269 was sub-digested with trypsin (1μg, 0.1M NH_4Ac, pH=8 2, 37°C, 30 minutes) The resulting mixture was analyzed by PDMS and the table below summarizes the results

Residues	Enzyme A	Savinase	Δ
217-229	1234 4	1206.4	+28 9
230-241	1458 3	1457 6	+0 7
242-245	511 7	511 6	+0 1
246-269	2367 4	2369 6	-2.2

The mass difference of +28 in residues 217-229 could be a result of several single site mutations: A→V, Q→R, K→R, S→D, C→M and T→E. Several of these could be ruled out immediately due to lack of C, S and Q in the original sequence of this fragment However, a double mutation was also a possibility. Residues 246-269 also had a mass difference of -2 2. Although this is within the mass error of the instrument, we routinely get accuracies of ±1 Da in this mass range Therefore, we submitted both fractions for Edman sequencing The Edman sequencing results confirmed a single mutation in residues 217-229 and a double mutation in residues 246-269

217-229 ATPHVAGVAALVK
246-269 NTATGLGNTNLYGSGLVNAEAATR

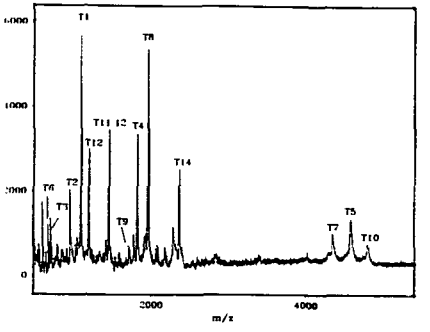
Therefore, the enzyme in this product was identified as a triple mutant of Savinase: A224V, S250G and S253N

Enzyme B

Enzyme B was isolated from a European laundry detergent. The intact molecular weight was found to be 26,824.8. Subsequent CNBr digestion and analysis of the isolated fragments gave peptides with the following molecular weights: 11,501 3, 5487 5, 5,043.7 and 4,707.1 These values were entered into MassMap®, a program from Finnigan MAT Ltd. used to search databases of digestion products that had been calculated according to specific cleavage rules[2] The results of the search gave three possible subtilisins as candidates. Of the three, only Subtilisin BL Alkaline Protease, or BLAP[3], had a molecular weight consistent with our measured value.

To confirm this identification, we digested the intact enzyme with a new immobilized trypsin column from PerSeptive Biosystems (Cambridge, MA). Intact enzyme B was passed through the Poroszyme® trypsin column in a buffer of 0.1 M ammonium acetate, pH = 8 2 at 50 μl/min. The resulting mixture was analyzed by PDMS . Using these measured masses, the MassMap search of the tryptic peptides also identified the enzyme as the BLAP protease. Merging the results of the CNBr and tryptic digests gave only three possibilities, all subtilisins, with the highest score given to BLAP. The results of the tryptic digest of enzyme B are summarized below·

Fragment	Residues	Enzyme B	BLAP
T1	1-10	1,102 0	1,101 3
T2	11-19	965.3	964.1
T3	20-27	719 0	718.8
T4	28-44	1,823 1	1,822.1
T5	45-92	4,591 1	4,591 1
T6	93-99	688 8	687 8
T7	100-143	4,355.0	4,353.8
T8	144-164	1,965 5	1,964.2
T9	165-180	1,713 4	1,710 8
T10	181-229	4,798 3	4,800 4
T11	230-231	n d.	275.3
T11 & T12	230-241	1,458 6	1,457 6
T12	232-241	1,202.7	1,201.3
T13	242-245	n.d.	511 6
T14	245-269	2,370 6	2,369 6



PD mass spectrum of tryptic digest of enzyme B

Conclusions

We have used several mass spectrometry methods along with enzymatic and chemical digestions to identify the enzymes present in commercial detergent products. Enzyme A was identified as a triple mutant of Savinase· A224V, S250G and S253N. We identified enzyme B as the BLAP protease, an enzyme identical to Savinase, but with five mutations: S97D, S99R, S101A, V102I and G157S. We have successfully applied these methods to many other products from all global regions, and have identified both wild-type enzymes and enzymes that contained only single-site mutations.

Introduction

Two dimensional polyacrylamide gel electrophoresis (2D-PAGE) is widely used for the high resolution analysis of complex protein mixtures. It is also used for preparative purposes, for instance, to obtain gene probe sequence. We previously developed a sensitive two step method for the structural analysis of proteins. The first step is 2D-PAGE separation followed by extraction of a stained protein spot from the gel The second step is the analysis digest of the protein using a capillary HPLC-ESIMS and MS/MS. We have utilized a newly developed bench top HPLC-Ion Trap MS^n system with this methodology for the identification of proteins in rat cerebellar extracts.

Experimental

Mass spectrometer: A Finngan MAT LCQ system equipped with an ESI source was used

Sample preparation: (1) A protein mixture extracted from rat cellebella was subjected to a 2D-PAGE (10 cm x 14 cm) separation. (2) Copper staining had to be used to visualize protein spots on the slab gel, since the recovery was higher than other staining methods (3) A spot was cut out from the slab gel and transfered into a polypropylene tube (4) The copper was removed from the gel piece with 0.025 M Tris-Gly buffer (pH 8.3) (5) The protein was extracted from the gel piece by shaking for 10 hours with 0 1 M Tris-Gly buffer (pH 8 8) containing 0 1 % SDS and EDTA. (6) An extract was subjected to a reversed-phase HPLC purification with a small column in order to remove contaminants from the slab gel and the reagents (7) A protein fraction was collected and the mobile phase was evaporated. (8) The protein was digested using Lys-C endoproteinase and then subjected to HPLC-ESI MS^n analyses.

HPLC conditions: A 1 mm x 150 mm ODS column was used. A 35 minute linear gradient elution from 100 %A (A 0 1 % TFA in water) to 70 %B (B 0.09 % TFA in water/acetonitrile = 1/9) was performed. The flow rate was 40 µl/min and the effluent was introduced directly into the ESI source

ESI conditions: The spray voltage was 4 5 kV.; N_2 was used for both the sheath gas (60 psi) and the auxiliary gas (5 unit) , A heated capillary was operated at a temperature of 200°C

Ion trap conditions: Ion injection time was 50 msec , Scan range was 300 - 1700 amu with 5µscans

Results and Discussion

The spot #246 in a brain protein map had previously been determined to be stathmin using HPLC-ESIMS/MS with the triple quadrupole mass spectrometer, an amino acid sequencer and a data base search Figure 1 shows HPLC-ESIMS chromatograms of Lys-C digests derived from the spot #246 (stathmin) and the spot #247 (unknown) The molecular weights of the two peaks indicated by ↓ differed by 80 Da, but the molecular weights of all other peaks were identical Since the spot #247 was observed to be more acidic than the spot #246 (stathmin) on the 2D-PAGE separation, it suggests that the spot #247 is phosphorylated stathmin. The two peptides indicated by ↓ correspond to Lys-C fragment 4 (29-40, ESVPEFPLSPPK) Figure 2 shows the MS/MS spectrum of Lys-C fragment 4 from the spot #247. This spectrum shows that the 37th Ser is phosphorylated This spectrum was obtained using a data dependent

experiment, which automatically performed zoom scans, MS/MS and MS/MS/MS of base peaks whose intensities were above threshold. As sufficient structural information could be obtained from this experiment, it is possible to eliminate peptide mapping using a normal MS scan, and hence reduce sample consumption. Enough material for structural analyses of proteins by HPLC-ESI MS^n with an ion trap mass spectrometer could be obtained from only one or two pieces of slab gel

Strategies for Identification of 2D Gel Proteins by Mass Spectrometry

Karl R. Clauser and Alma L. Burlingame
Department of Pharmaceutical Chemistry, Box 0446
University of California
San Francisco, CA 94143-0446

2D PAGE allows simultaneous separation and visualization of the myriad proteins present in a whole cell lysate, but requires protein identification to decipher the gel's information content. 2D PAGE difference mapping, i.e. comparing the lysates from: a) drug-treated cells vs. untreated cells, or b) diseased vs. healthy cells, is particularly useful when there are many differences in the proteins expressed and/or there is no way of isolating particular proteins in a more specific manner.

Peptide-mass "fingerprints" obtained by using MALDI to measure the peptide masses present in the enzymatic digest of a protein have been shown to be frequently capable of predicting the identities of proteins whose sequence already exists in a database (1-4). If a protein is truly an unknown, its sequence will not be in a database. Characterization of such a protein can then be done by obtaining peptide sequence, and cloning the gene. However, the growth of sequence databases fueled by the Human Genome Project will increasingly reduce the chances of discovering unknown proteins, and the ability to unambiguosly identify a protein through a database search will require data of increasing discriminating power. While peptide sequence data can establish protein identity with a high degree of certainty, peptide-mass data alone can predict protein identity with some ambiguity and / or uncertainty (5).

What remains to be seen is: can mass spectrometric approaches produce "fingerprint" data that yield information somewhere between the levels of complete peptide sequences and peptide masses alone which continue to give enough database discrimination power to routinely produce high-certainty protein identifications? Toward that end, we have sought to use MALDI in a reflectron instrument, VG TofSpec SE, to obtain peptide sequences from post-source decay (PSD) spectra. The unseparated peptides recovered from in-gel digestion of a 2D PAGE spot were applied to a MALDI target, selected parent ions were transmitted into the reflectron using an ion-gate, and PSD spectra of the products were obtained.

Financial support for this work was provided by NIH NCRR (Grant RR01614), the NSF Biological Instrumentation Program (Grant 8700766), the NIEHS Superfund Program (Grant E504705), UC TRDRP (Grant 2RT0089), NIH Grant CA 27903, and a UC Systemwide Biotechnology Grant.

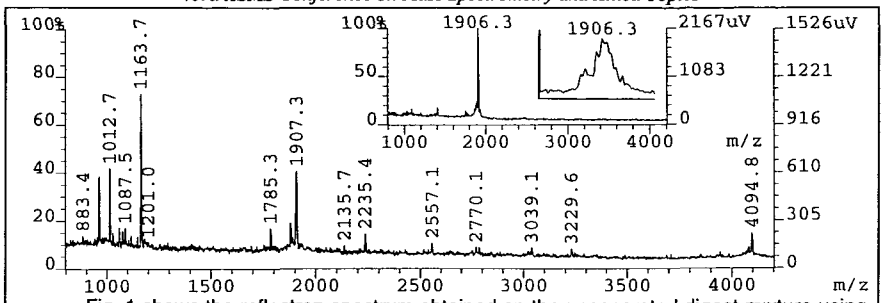

Fig. 1 shows the reflectron spectrum obtained on the unseparated digest mixture using an α-cyano-4-hydoxycinnamic acid matrix. By setting the ion-gate to 1907 Da, a ~15 Da mass window is selectively transmitted to the reflectron (Fig. 1 inset). Expansion of the region around the selected parent ion, reveals that two species (1906 Da and 1903 Da) are actually passed through the gate. The data obtained from the unseparated digest, were used as a peptide-mass fingerprint to search the Swiss-Prot database using PeptideScan (2). The highest scoring protein from this search, Heat -shock Protein 27 (HSP-27), contains a tryptic peptide of MH^+ = 1906.0, LATQSNEITIPVTFESR (□) and one of MH^+ = 1902.9, GPSWDPFRDWYPHSR (Δ).

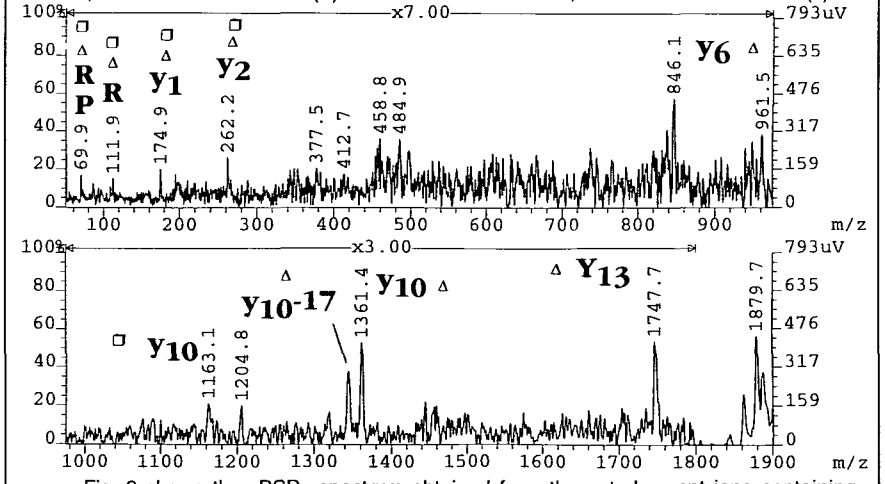

Fig. 2 shows the PSD spectrum obtained from the gated parent ions containing fragment ions consistent with both peptides. Note that relative intensities of the parent ions in Fig. 1 does not correlate with intensity of fragment ions observed in Fig. 7B). The spectrum is smoothed so that partially resolved isotope peaks appear as single "average-mass" peaks. In this case, only partial sequence information is present. While the peptide sequence of an unknown could not be derived, strong support is provided to the prediction of Heat-shock Protein 27 by peptide-mass database searching.

Mass Spectrometry of Proteins Directly Isolated from SDS Gels

Martina Schuhmacher, Markus Wunderlin and Michael Przybylski
University of Konstanz, Faculty of Chemistry, P.O. Box 5560 M732, 78434 Konstanz, Germany

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) is the most frequently used technique in analytical biochemistry and molecular biology for the separation and characterization of proteins. However, a considerable disadvantage of SDS-PAGE is the lack of efficient isolation and purification methods, suitable for subsequent structural characterization. One method to recover the separated proteins is electro-elution, in which sodium dodecyl sulfate (SDS) is usually present in large excess in the elution buffer. SDS complexes the proteins and highly disturbs mass spectrometric characterization. Electrospray mass spectrometric studies of protein-SDS-mixtures showed protein-SDS-adducts, so that exact molecular weight determinations of eluted proteins were only possible after removal of SDS. Proteins can be purified from SDS excess by ion pair extraction according to Konigsberg [1] which, however, has been found to be laborious, difficult to reproduce, and not suitable for subsequent mass spectrometric analysis.

We have developed a new method for the isolation of proteins separated by SDS-PAGE using electro-elution with a modified buffer system, suitable for direct mass spectrometric characterization An additional purification step is no longer necessary. After separation with SDS-PAGE (non-reducing-conditions) the proteins were stained with Coomassie Blue, the protein bands were cut out and proteins isolated by electro-elution using SDS-free ammonium acetate solutions (pH 8.0 and 2.5) as elution buffers. Depending on the net-charge of the proteins at the applied pH, they either move to the anode or to the cathode, and protein-SDS-complexes are dissociated during the elution. The isolated proteins were analyzed without further purification by ^{252}Cf plasma desorption (PD), electrospray (ES) and matrix assisted laser desorption / ionisation (MALDI) mass spectrometry. In the spectra obtained no SDS-adducts to the proteins were observed and the spectra were comparable to those of the native proteins.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

For standard isolation of proteins an ammonium acetate elution buffer with pH 2.5 was employed At this pH-value most proteins have positive charges, so that the polarity of the electro-elution system was reversed. The efficiency of this method was first demonstrated by ESMS and PDMS of model proteins (insulin, hen eggwhite lysozyme and serum albumin) and mixtures of myoglobins and lysozymes. For these proteins recovery rates ranged from 25 % to 58 % as was determined densitometrically after re-electrophoresis of the isolated proteins.

In first applications the effects of the reducing agents such as β-mercaptoethanol or dithiothreitol (DTT) during electrophoresis were studied with lysozyme ESMS of the isolated proteins showed the formation of mixed disulfides between protein and reducing agent. In the case of DTT the relative amounts of mixed disulfides were much lower than with β-mercaptoethanol. Furthermore, ubiquitin was cross-linked by carbodiimide leading to ubiquitin oligomers. After their separation by SDS-PAGE the oligomers were electro-eluted and characterized by MALDI-MS. In addition to the ubiquitin oligomers, side products were observed consisting of covalent carbodiimide adducts to the protein.

In a first bioanalytical application, hemofiltrate proteins were separated by SDS-PAGE and the proteins of the two most intensive bands were isolated. ESMS characterization of the protein isolated from the gel band between 10 kD and 14 kD yielded a molecular weight of 11.733 D The second gel band between 14 kD and 16 kD consisted of two different proteins that could not be separated by SDS-PAGE. The molecular weights of these proteins were 13 418 D and 14.725 D.

Sequencing peptides: post-source decay MS without scanning the reflectron.

Cordero M.M.; Cornish, T.J.; Cotter, R.J.
The Johns Hopkins University School of Medicine, Baltimore, MD 21205

This paper evaluates the sequencing capabilities of a recently developed MALDI-TOF curved field reflectron mass spectrometer.[1] (Fig.1) Its major advantage over other reflectron instruments used for post-source decay sequencing is that *complete* sequence information is obtained all at the same time, *without* scanning the reflectron or stepping the voltage.

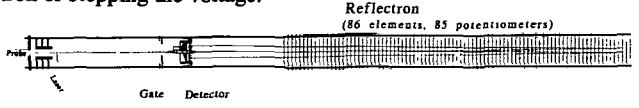

Figure 1 Coaxial Curved Field Reflectron TOF-MS

PSD products calibration is accomplished using the program TOFWARE (Ilys Software, Pittsburgh, PA). The calibration curve was generated from data points from the PSD MS of (Pro)14-Arg. This calibration curve is very close to the arc of a circular function and requires only the precursor ion mass to assign simultaneously all the product ion masses.

To obtain the PSD spectra shown in Figs. 1-3 typically 1-5 pmol of peptide were loaded on the probe after pre-mixing with a-cyano-4-hydroxycinnamic acid. Detection of fully developed PSD spectra in the low fmolar region was achieved for many of these peptides. A nitrogen laser was used for ionization, with 500 shots averaged per spectrum. For angiotensin II, precursor resolution is 2840 in a normal MS. In the PSD spectrum the precursor has a resolution of 1000 and the product ions have resolutions between 500 to 200 (lower resolution for lower masses).

In summary, high speed and high sensitivity sequencing of peptides can be achieved with the MALDI-TOF coaxial curved-field reflectron mass spectrometer. The curved field reflectron permits *multichannel* analysis of PSD products without the need for voltage stepping or reflectron scanning. The mass spectra can be easily calibrated by assigning the precursor ion mass. This is the first pass of the calibration and we are in the process of refining it.

EVALUATION OF PSD-MALDI AND CID-MALDI FOR STRUCTURAL ANALYSIS

Steven A. Carr, Gerald Roberts, Roland S. Annan, Mark E. Hemling, John Hoyes (1)
SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406 and (1) VG Analytical, UK

Post source decay (PSD) of MALDI-generated ions is a new and potentially useful method for producing structurally-informative fragmentation of biopolymers. We are using a new, high resolution, single-stage reflecting MALDI-TOF instrument (TofSpec -SE, Fisons-VG) equipped with a collision gas cell to investigate the PSD-MALDI and CID-MALDI behavior of a variety of biological molecules. This instrument has a 3.4 m effective path length and incorporates a three stage ion source and a Bradbury-Nielson ion gate for parent ion selection (see also MPB 076, J. Hoyes, et al.). A resolution of > 2000 (FWHM) has been achieved for mass-selected product ions produced by PSD-MALDI. This resolution is sufficient to determine monoisotopic mass up to at least m/z 1800 in the product-ion analysis mode, and it greatly reduces uncertainty in the mass assignment and structural interpretation of fragment peaks.
All product ion spectra were recorded using eight or fewer segments (25% reduction in energy with each step) and between 25 and 50 shots per segment. For CID, sufficient air was admitted to the collision cell to increase the source pressure from 2×10^{-7} mbar to 7×10^{-7} mbar (parent ion intensity decreased to ca. 1/3 of that without the gas). Calibration and segment stitching were performed automatically by the VG-Opus data system. The results obtained using a designed series of peptides, commercially available peptides, and isolated peptides, phosphopeptides and glycopeptides are summarized below.

FRAGMENTATION PROCESSES OBSERVED IN PSD:

- High quality PSD and PSD-CID spectra are obtained using 0.1 to 5 picomoles of peptide or glycopeptide.
- Normal PSD spectra are very similar to low energy CID spectra of singly-charged M+H ions. Abundant $\mathbf{a_n}$, $\mathbf{b_n}$ or $\mathbf{y_n}$ ions as well as internal acyl and immonium ions are observed.
- Strong $\mathbf{y_n}$, $\mathbf{b_n}$ and usually weaker $\mathbf{z_n}$ ions are observed in peptides which possess a basic residue (Arg or Lys) at or near the C-terminus (e.g. tryptic peptides).
- Cleavage C-terminal to acidic residues, especially Asp to form $\mathbf{y_n}$ ions is favored (as first noted by S. Martin et al.), while cleavage C-terminal to Pro to form $\mathbf{y_n}$ ions is not.
- Significant $\mathbf{a_n}$, $\mathbf{a_n+1}$, $\mathbf{b_n}$, and, if Arg is present, strong $\mathbf{a_n\text{-}NH_3}$ and $\mathbf{b_n\text{-}NH_3}$ ions are observed in peptides with basic residues at or near the N-terminus.
- The PSD mass spectra of peptides containing phospho-Tyr provide the sequence of the peptide including the location of the phosphorylated residue. An intense peak corresponding to the loss of HPO_3 is always present, as is a satellite 18 Da lower in mass due to loss of water.
- In the PSD spectra of glycopeptides, facile cleavage of the GN-GN bond of the inner core with charge retained on the shortened glycopeptide is observed. We also observe a novel through-ring cleavage of the linker HexNAc sugar (0-1 and 2-3 bonds cleaved) with the peptide portion again retaining the charge. The precise structure of this fragment is under study.

ADDITIONAL FRAGMENTATION PROCESSES OBSERVED IN PSD-CID SPECTRA:

- Abundant side-chain fragment ions of the $\mathbf{w_n}$, $\mathbf{v_n}$ and $\mathbf{d_n}$ type may be produced by CID in a collision cell in the instrument. These fragment ions are common to high energy CID spectra, but are generally absent in low energy CID spectra. For tryptic peptides ending in Arg the spectra represent a nearly ideal mix of simple to interpret sequence ions and side-chain cleavage ions. The $\mathbf{w_n}$- and $\mathbf{d_n}$-type ions are particularly important because they permit Ile to be distinguished from Leu.
- Obtaining PSD and CID spectra is very simple, only involving toggling on the collision gas. Both PSD and PSD-CID spectra are routinely obtained on the same spot of material.
- PSD is a dominant process which is very difficult to shut down completely. The matrix plays a critical role in determining the initial internal energy of the ions formed, and the use of "cooler" matrices such as sDHB (versus a-cyano) can reduce the amount of PSD observed in the PSD-CID spectra.
- It is likely that highly basic or fixed charge derivatives used previously in high energy CID-FAB to direct fragmentation will also be of value in enabling the observation of side-chain cleavages in the PSD-CID spectra of otherwise refractory peptides.

Peptide Sequencing: MALDI-TOF vs. ESI-3Q

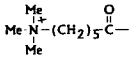
W. A. Jeffery, M. Bartlet-Jones, and D. J. C. Pappin, Imperial Cancer Research Fund, London WC2A 3PX, UK. A. Keane, M. Harrison, and J. S. Cottrell, Finnigan MAT Ltd., Paradise, Hemel Hempstead, Herts HP2 4TG, UK

Introduction: The aim of this poster is to provide a back-to-back comparison between MS-MS spectra obtained by two different techniques: Post Source Decay (Spengler, B. et. al., Rapid Commun. Mass Spectrom., 6, 105-8 (1992)) and Collision Induced Dissociation. Three peptides were analysed: (i) Native Glu-fibrinopeptide B, (ii) Glu-fibrinopeptide B modified to enhance CID fragmentation, (iii) Glu-fibrinopeptide B modified to enhance PSD fragmentation.

Experimental: PSD data were obtained using a Finnigan MAT Vision 2000 (matrix assisted laser desorption ionisation source + reflectron time-of-flight analyser). The matrix was DHB. Approximately 5 pmol of peptide was loaded onto the target, although only a small fraction of this was consumed. The mass scale was calibrated using Substance P as an external standard. The spectra shown here were acquired by stepping the reflector voltages down in 10 increments of 25%. The ion beam energy was 10keV.

CID data came from a Finnigan MAT TSQ7000 (electrospray source + triple quadrupole analyser). Samples were infused at concentrations between 0.1 and 2 pmol per µl. The collision gas was xenon.

Peptide Derivatisation: Peptides were modified to enhance the formation of A and B fragments by substitution of the amino terminus and basic residue side chains (Arg and Lys). For PSD, the N-terminus was a given a quaternary ammonium group carrying a fixed charge.



For CID, the N-terminal group was 3-pyridylacetyl, chosen to provide a mobile proton. Further details of this modification can be found in poster TPG265 (N. E. Sherman *et. al.*). In both cases, the derivatisation procedure results in loss of the N-terminal residue, (Glu). Thus, for an unknown, the first residue must be identified from the molecular weight shift between the native and modified peptides. Derivatisation also makes the peptide more hydrophobic.

Results

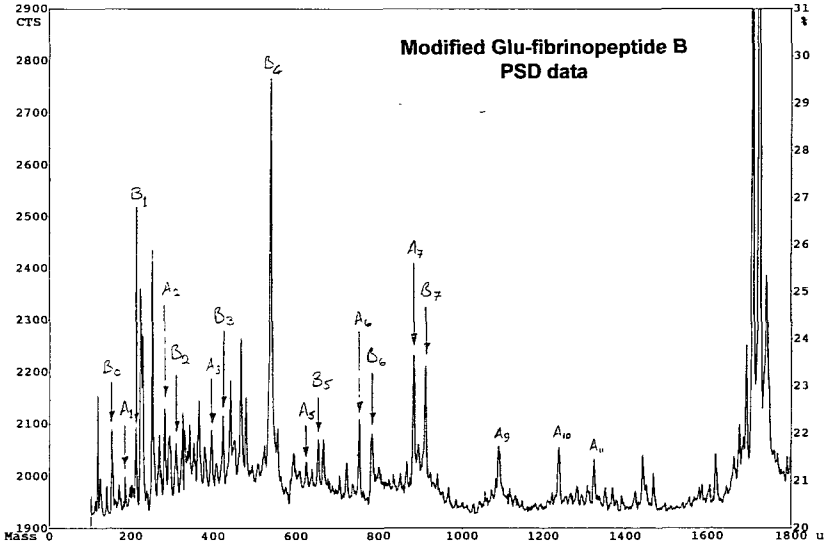
Native Glu-fibrinopeptide B:

- The two MS-MS spectra are surprisingly similar. Both show a strong series of 11 Y ions accompanied by weaker Z ions. The A and B series cover the residues which are missing from the C-terminal fragments, together with extensive overlap. Thus, both spectra provide coverage of the full sequence with extensive redundancy.

- The CID data were obtained from a very low concentration sample, 0.1 pmol per µl, so that the signal to noise ratio is lower than usual. The signal to noise in the PSD spectrum is good, considering that even lower levels of sample have been consumed, but the mass resolution is inferior, leading to less precise mass values.

Modified Glu-fibrinopeptide B:

- In the CID spectrum, the intensity of the Y ions is greatly diminished, and the B series now dominates. However, there are still a number of strong C-terminal fragment peaks present, particularly Y_1 to Y_4.
- The N-terminal fixed charge has completely eliminated C-terminal fragments from the PSD spectrum. Unfortunately, the A and B series are slightly patchy, and there are a number of peaks which have not yet been assigned.
- In both cases, the known mass of the N-terminal group makes it easy to identify the start of the A and B series. Given a reasonably complete series of sequence ions, this makes it much simpler to "read off" the sequence.



DEUTERATED TERMINATING AGENTS FOR LADDER SEQUENCE ANALYSIS BY LSIMS AND MALDI-TOF MS

Ricky D. Holland[1], M. Paul Chiarelli[3], David Vollmer[1], Martha Gay[2], James Sphon[2], and Jackson O. Lay, Jr.[1], Food and Drug Administration, (1) National Center for Toxicological Research, Jefferson, AR, (2) Center for Food Safety and Applied Nutrition, Washington, DC. and (3) Loyola University, Chicago, IL.

Introduction

A long standing approach to peptide sequence analysis is the Edman degradation method (1). A recently introduced variation for sequence determination by mass spectrometry involves the addition of a terminating agent to irreversibly block a portion of the peptide during each cycle. This method, referred to as "protein-ladder sequencing" (2), usually involves the use of MALDI-TOF MS to analyze a pool of chemically modified peptide fragments. This pool consists of peptide fragments, which differ only by the sequential removal of individual amino acids from the N-terminus. Sequence information is preserved in a representative portion of each cleavage-product based on blocking of some of the remaining peptide at each cycle using a terminating reagent, phenylisocyanate (PIC). Thus, the differences between fragment masses allow N-terminal peptide-sequence determination. The presence of one interfering peak using this method could result in mis-identifying two amino acids. A larger number of non-sequence related ions would likely make sequence determination for an unknown peptide impossible. The sequence terminating reagent provides an opportunity to incorporate a fingerprint for sequence related ions into each step of the peptide-ladder sequence approach. In this work we report the use of a mixture of PIC and d_5-PIC to incorporate such a fingerprint into the mass spectrum.

Experimental

Pyridine and Phenyisothiocyanate (PITC) were purchased from Pierce (Rockford, IL). PIC, α-cyano-4-hydroxycinnamic acid (matrix), all peptides, 1,1,1,3,3,3-hexafluoro- 2-propanol (HFIP) and glycerol were purchased from Sigma (St. Louis, MO). Trifluoroacetic acid (TFA) and trimethylamine (TMA) were purchased from Fluka (Ronkonkoma, NY). Acetonitrile was purchased from Baker (Phillipsburg, NJ). Ethyl acetate was purchased from Aldrich (Milwaukee, WI) and heptane from Fisher (Fair Lawn, NJ). Deuterated phenylisocyanate (d_5-PIC) was purchased from Bionetics Corporation (Jefferson, AR), an on-site synthesis contractor at NCTR.

The procedures for the peptide-ladder sequence method summarized below did not differ significantly from those published in reference 1 except for the use of both PIC and d_5-PIC. The coupling/ terminating step was carried out by adding 20 μL of PITC:d_5PIC:PIC:Pyridine: HFIP (30:0.5:0.5:76:4 v/v) and reacting for 3 minutes at 50°C, rather than using the reagents described in reference 2. The reacted peptide was dissolved in 20 μL of 0.1%TFA. One μL of peptide solution was mixed with 9 μL of a saturated matrix solution The matrix, α-cyano-4-hydroxy -cinnamic acid, was dissolved in a 2:1 mixture of acetonitrile:water with 0.1%TFA. One μL was placed on the sample pin and allowed to air dry. Spectra were obtained using a Vestec Lasertec (Houston TX) MALDI TOF MS in the positive ion mode using an acceleration voltage of 20 kV. From the same solution used to produce the MALDI TOF mass spectrum, 1 μL was removed and mixed on a stainless steel target with about the same amount of glycerol. LSIMS spectra (25 kV Cs ions) were obtained using a VG Autospec Q (Manchester, UK), magnetic sector-quadrupole hybrid operated as a magnetic sector instrument.

Results and Discussion

A modification of Chait's (1) peptide ladder sequence approach was used to provide a distinguishing "fingerprint" for sequence-related ions in the mass spectrum. Isotopic peaks were incorporated into sequence related ions based on deuterium in the blocking reagent. Each cycle of the peptide-ladder sequence produced two blocked products, one having 5 deuterium atoms, the other having none. With MALDI-TOF MS two partially resolved peaks differing by 5 amu were usually observed, corresponding to the average molecular weight (plus a proton) for the deuterated and non-deuterated sequence ions For ions greater than about 1400 amu, however, resolution was not adequate to separate both the d_0 and d_5 products. Because this mass difference was generated by reaction with the terminating reagent and was not observed in non-sequence related background ions, it provided a useful means for confirmation of the peptide sequence.

With LSIMS the spectra were more complicated because carbon isotopes were also resolved. Thus, the sequence ions typically showed prominent signals for the $^{12}C/d_0$, $^{13}C/d_0$, $^{12}C/d_5$, and $^{13}C/d_5$ products. Because of this higher mass resolution, isotope peaks were resolved even at the highest masses used in this study (about m/z 1700). This combined use of deuterated and non-deuterated terminating agents provides a fingerprint to aid in the identification of sequence ions from small peptides using the ladder sequencing method and mass spectrometry.

Characterizing Chemically- Generated Peptide Sequencing Ladders by ESI

Sanat K. Saha, James A. Carroll & Ronald C. Beavis
Skirball Institute for Biomolecular Medicine
Department of Pharmacology
New York University Medical Center
550 1st Avenue
New York, NY 10016

A new method for determining the primary structure of proteins and peptides was described recently that utilized the Edman degradation reaction to convert a single peptide into a collection of truncated peptides that all had the same C-terminus but were of different lengths[1] This peptide mixture was then analyzed using a mass spectrometer, allowing peptide sequence determinationby measuring the molecular mass differences between peptides that differed only by the N-terminal residue. Assigning a peptide sequence by measuring mass differences between adjacent peaks in a single operation was called "protein ladder sequencing".

The collection of peptides for ladder sequencing was originally generated by carrying out the Edman degradation reaction, using a mixture of phenylisothiocyanate (PITC) and phenylisocyanate (PIC) (95.5) as the Edman reagent. After one cycle, 5% of the original peptide was irreversibly protected with the PIC, leaving 95% of the peptide one residue shorter, ready for the next cycle. The reaction conditions used multiple step extraction process requiring considerable care.

Bartlet-Jones *et al.* have reported a novel volatile Edman degradation reagent, trifluoroethylisothiocyanate (TFEITC)[2] This reagent was synthesized specifically for use in the generation of a protein ladder sequencing mixture. Volatile trifluoroethylisothiocyanate can be removed by vacuum evaporation, eliminating the potential for sample loss involved in the original extraction procedure.

This paper describes research into the development new Edman reagents, that have the desirable volatility of TFEITC, and a reduced reaction rate at lysine side chain amino groups. A number of candidate isothiocyanate compounds were tested and evaluated using a standard set of reaction conditions. The best of these new candidate reagents, N-hexylisothiocyanate, was then used to evaluate the usefulness of electrospray ionization as an ion source for "reading" the sequencing ladders generated. Sequencing ladders generated with a peptide synthesizer were also examined to explore the general usefulness of electrospray ionization in analyzing peptide mixtures.

A survey of commercially available isothiocyanate derivatives revealed that isothiocyanates attached to aromatic groups reacted at a similar rate to PITC. Aliphatic isothiocyanates react at a slower rate than the aromatic derivatives. N-

hexylisothiocyanate had the best combination of reaction rate, volatility and ease of extraction. Aliphatic groups shorter than hexyl were too volatile, making them very dangerous reagents to work with in the laboratory. HITC had the additional property of reacting slowly with the e-amino group of lysine, resulting in simple ladder sequencing mass spectrum for lysine-containing peptides.

Isothiocyanate Derivative	Comments
Phenyl ITC	High Rection rate with N-terminal and lysine amino groups (involatile)
n-Hexyl ITC	Slowere reaction rate with N-terminal amino groups and much slower with lysine amino groups (volatile)
Cyclohexyl ITC	Similar to n-hexyl ITC (volatile)
2-Phenyl-ethyl ITC	Slower reaction rate than PITC (involatile)
3-Chloro-4-fluoro ITC	Low reaction rate (involatile)
Propyl ITC	Similar to n-hexyl ITC (volatile)
Pyridine ITC	Incompatible with reaction conditions used

Table 1 A comparison of the properties of several commercially available isothiocyanate derivatives for generating peptide ladders by the Edman reaction.

The electrospray spectra obtained using peptide ladders generated using n-hexylisothiocyanate as the Edman reagent showed that electrospray ionization coupled with a quadrupole mass spectrometer (Sciex API-1) could effectively read the sequencing ladders. Complicated ladders generated from peptide libraries could be read with little difficulty.

Introduction

Since its introduction in 1992 by Spengler and Kaufmann, Post Source Decay Matrix-assisted Laser Desorption/ Ionization (PSD-MALDI) has gained main interest as a very promising tool for sequencing peptides Conventionally, sequence analysis of peptides is done by Edman degradation, which is based on the analysis of PTH amino acids produced by the reaction between N-terminal amino acids with a free amino group and a derivatizing agent for those groups. Therefore, this degradation cannot be used for N-terminal blocked peptides C-terminal sequencing is nowadays a very challenging area for the identification of the amino acid sequence. However, as well as for N-terminal sequencing it requires a free carboxylic acid in the C-terminus So, particularly for N- and C-terminal blocked peptides PSD-MALDI could be a very valuable alternative to these conventional methods Here, we present results of PSD-MALDI on peptides that are blocked on both termini.

Methods

Sample Preparation: Matrix (2,5-dihydroxybenzoic acid) and samples (three biochemically active peptides· Luteinizing hormone releasing hormone, Levitide, Bombesin) were dissolved in 9 1 0 1% aeqeous TFA / acetonitrile Concentrations in solution were 10 g/l (matrix) and $5 \cdot 10^{-5}$ M (peptides) The sample amount loaded on target was ca 20 pmol

Experimental Setup. The MALDI-TOF instrument was a VISION 2000, Finnigan MAT It is operated under fully computer control and equipped with a PSD-software that allows semi-automatical processing of generating fragment spectra When starting a new experiment, the only information needed is the mother ion mass, the wanted reflectron drop and the lowest fragment mass expected The software calculates and sets all voltages, generates the different fragment windows and calibrates and puts them together automatically to a complete fragmentation spectrum Thus, results on the sequence of peptides can be obtained within about 20 min.

Results

Ion signals of the intact peptides could be obtained with a mass resolution of 3000-3500 and a mass accuracy of about 0.5 Da (fig.1) In the PSD mode, the entire sequences of all peptides could be verified by comparing the PSD-MALDI spectra and theoretical fragmentation patterns Mostly N-terminal fragments (A/*, B/* type) are observed (fig.2). The averaged mass accuracy of the fragment determination was better than 0.5 Da in all examined cases (table1) Also, the even more important value of the accuracy for the determination of the different amino acids in the sequence was calculated. It is derived by substracting the molecular weights from neighboring groups of fragments. As result, the masses of the different amino acids could be verified with an averaged deviation from the theoretical values of below 0 2 Da So, the determination of mass differences in those PSD-MALDI spectra is even more accurate than that of the absolute molecular weights The capability of sequencing N-and C-terminal blocked peptides by PSD-MALDI has clearly been demonstrated

BOMBESIN: pGlu-Gln-Arg-Leu-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH_2

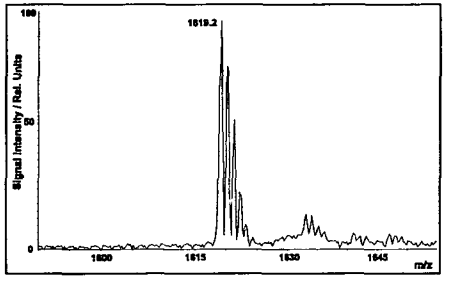

Fig. 1: Monomer signal peak in the MALDI spectrum of Bombesin (Theor. MW avrgd 1619 87 Da, monoiso 1618 81 Da). Sum of 10 laser shots The measured monoisotopic molecular weight is assigned. Mass accuracy 0 61 Da.

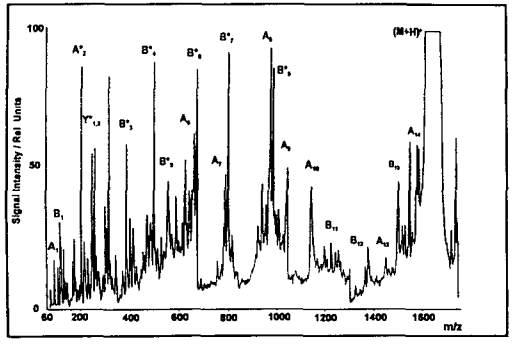

Fig. 2: Complete PSD-MALDI spectrum of Bombesin. Sum of 50 laser shots for each fragment window. Molecular weights for the different fragments are summarized in table 1

Table 1: Comparison of observed and theoretical molecular weights of the different fragments of Bombesin. The averaged mass accuracies for all fragments δm and for the determination of the different amino acids δm_{aa} is calculated

Fragment Description	A1	B1	A*2	B2	B*3	B*4	B*5	A6	B*6
Theo. MW / Da	84.1	112.1	195 2	240.2	379 4	492.6	549.6	652.7	663 7
Obs MW / Da	84 9	111.8	194 1	239.1	377 8	491 4	548 7	652 2	662.8

Fragment Description	B*7	A8	B*8	A9	A10	B11	B12	A13	A14
Theo MW / Da	791.8	967 1	978.1	1038 2	1137.3	1222 4	1359.5	1444 6	1575 8

Averaged mass accuracy for all fragments:

$$\delta m = \frac{\sum_{1}^{n}(m_i^{theo} - m_i^{obs})}{n} = 0\ 47\ \text{Da}$$

Standard deviation of the averaged value $\sigma = \pm 0.87$ Da

Averaged mass accuracy for the determination of the different amino acids:

$$\delta m_{aa} = \frac{\sum_{1}^{n}[(m_{i+1}^{theo} - m_i^{theo}) - (m_{i+1}^{obs} - m_i^{obs})]}{n} = 0\ 1\ \text{Da}$$

Standard deviation of the averaged value: $\sigma = \pm 0\ 95$ Da

An Evaluation of Peptide Fragmentation by MALDI-TOF PSD and MALDI CID MS/MS

Gregory W Adams, Katalin F. Medzihradszky, David A. Maltby, Steven C. Hall,
Alma L. Burlingame. Mass Spectrometry Facility, University of California,
San Francisco, CA 94143.
Robert H. Bateman, Martin R. Green, Anne Maisey. VG Organic, Manchester, M23 9LE, UK

Ample evidence has accumulated which supports the hypothesis that the efficiency of ionization of peptides and proteins by MALDI provides inherently higher sensitivity than other ionization techniques at present. In MALDI a large fraction of the analyte ions undergo post-source decay (PSD) in the field free drift path, and fragment ion spectra can be recorded using a reflectron time-of-flight instrument (VG TofSpec SE). Such PSD spectra allow for peptide sequence analysis in a similar manner to well documented collision-induced dissociation mass spectra recorded using tandem mass spectrometry. Using a combined hybrid magnetic sector and orthogonal acceleration TOF instrument (VG AutoSpec SE oa-TOF), CID spectra can be obtained from MALDI generated monoisotopic precursor ions. We have evaluated the relative behavior of a variety of peptides in both the MALDI-TOF PSD and MALDI CID mode using collisional activation at 800eV with Xenon.

Figures 1 and 2 illustrate the MALDI-PSD and MALDI-CID mass spectra of a synthetic peptide.

Observed Characteristics of MALDI-PSD spectra are:

- Similar to low energy CID fragmentation
- No side chain fragments (i.e. **d**, **v** and **w** ion formation)
- Basic amino acids control the fragmentation: preferential charge retention on the basic residue
- Unusually abundant **y** ions formed by cleavages at the N-terminus of Asn or at the C-terminus of Asp residues
- When Arg is present, significant fragmentation due to sequential neutral losses from **a**, **b** and **y** ions is observed, the neutral loss fragments can be categorized as:
  a) loss of NH_3 (17 Da), H_2O (18 Da) and NH=C=NH (42 Da) from **a** or **b** ions.
  b) **y** ions predominantly show loss of NH_3 (17Da), the ion formed this way is isobaric with a **z** ion.
  c) internal ions exhibit similar losses.
  In most cases, sequential neutral losses are observed.

Observed Characteristics of MALDI-CID spectra are:

- Mixed high energy and PSD-like fragmentation:
- Abundant immonium and related ions: amino acid composition of the peptides.
- However, CID spectra do not show side-chain losses from the molecular ion
- Side-chain fragment ions **d**, **v** and **w** are observed, depending on sequence position of the basic amino acid.
- However, when the basic amino acid is His or Lys, the relative abundance of these side-chain fragments is relatively low in comparison to the CID spectra acquired in LSIMS-CID experiments
- Abundant ions due to neutral losses. Unusually abundant **y**-17 ions for C-terminal ions formed by peptide bond cleavage at a Pro residue (These **y** ions cannot yield **z** ions).
- Unusually abundant **y** ions formed by cleavages at the N-terminus of Asn or at the C-terminus of Asp residues.

Interpretation of MALDI-PSD spectra generally yield partial sequences. When PSD sequence data is combined with observed molecular masses , protein database searching will lead to a more unambiguous protein identification. The advantages of MALDI-CID over MALDI-PSD include the ability to select a monoisotopic precursor ion, the CID spectra generally provide comprehensive sequence content and the high energy fragmentations can differentiate between the isomeric amino acids Ile/Leu.

A Novel N-Terminal Derivative Designed to Simplify Peptide Fragmentation

Nicholas E. Sherman*, Nathan A. Yates*, Jeffrey Shabanowitz, Donald F. Hunt
Department of Chemistry, University of Virginia, Charlottesville, Virginia, USA

William Jeffery, Mike Bartlet-Jones, Darryl J. C Pappin
Protein Sequencing Laboratory, Imperial Cancer Research Fund, London, UK

Peptide sequencing techniques, specifically micro-capillary HPLC combined with electrospray-ionization tandem mass spectrometry, are receiving considerable attention in the field of biochemistry due to their unique ability to analyze complex biological mixtures at or below femtomole levels. However, the successful interpretation or deduction of a peptide sequence from a collision activated dissociation (CAD) spectra can be a complex and time-consuming task

Proton mobility is generally accepted as the key requirement for obtaining structurally diagnostic CAD spectra Collisional activation of protonated peptides can lead to intramolecular proton exchange. This results in an equilibrium population of ions, which only differ in the protonation site. Peptide fragmentation occurs at these protonation sites, producing a variety of sequence fragments, usually dominated by y_n, b_n, and a_n ions. Competing processes, such as side chain rearrangements and cyclization reactions, produce additional ion fragments that often complicate the CAD spectra

Here, we describe the application of a new pyridine based derivative designed to enhance sequence ion intensity, reduce rearrangement products, and maintain ESI sensitivity. This unique N-terminal derivative directs fragmentation by supplying a mobile proton to the peptide backbone. Unambiguous identification of the first and second N-terminal amino acids is possible with the use of this pyridyl reagent because it allows for easy identification of b_1 ions In addition, the derivative further simplifies CAD spectra by blocking rearrangements that involve the N-terminus The water soluble, hydophylic, pyridine based reagent is used to acylate peptides at extremely low levels On-column derivatization can be performed with as little as 20 femtomoles of peptide Excess reagent and reaction by-products are easily removed by washing before commencing gradient elution.

Unusual Fragment Ions in the High Energy CID Spectra of Peptides Containing S-Alkyl Cysteine

Susan M. Wolf and Klaus Biemann, Department of Chemistry, MIT, Cambridge, MA, 02139

A review of the high energy CID spectra of a number of S-alkyl cysteine-containing peptides revealed the presence of many unknown peaks, the further investigation of which resulted in the characterization of a set of previously undocumented fragmentations which share as a common feature the scission of alkylcysteine thioether C-S bonds. It is expected that the information regarding sequence requirements for the formation of these ions will be useful for the optimization of computer-based algorithms employed for the automated sequencing of peptides from MS/MS data.

Experimental. The peptides used in this study were obtained from the proteinase K digestion of human serum albumin, trypsin digestion of RNase A, commercial vendors or synthetic preparation at the M.I.T. Biopolymers Laboratory. Proteins and peptides dissolved in 6M guanHCl 0.05M tris pH 8.0 were typically reduced with triethylphosphine or dithiothreitol and alkylated using a 5-10X molar excess of alkylating agent (4-vinylpyridine, iodoacetamide, iodoacetic acid, or 2-vinylquinoline) over thiols prior to clean-up via reversed phase HPLC. Proteins were then enzymatically digested and the resultant peptides isolated by reversed phase HPLC. High energy CID product ion spectra were obtained for FAB ionized precursors using an HX110/HX110 tandem four sector ($E_1B_1E_2B_2$) mass spectrometer at a collision energy of 7 kV using a collision cell floated at 3 kV and employing He collision gas to attenuate precursor intensities to 30%. Precursor ion scanning was accomplished by linked scanning of MS1 to detect 10 kV CID products formed in the first FFR.

Results. A number of MS/MS spectra of peptides containing pyridylethylcysteine (peC) show peaks which can be assigned as $[x_n$ - vinylpyridine$]^+$ where the nth amino acid is peC. For instance, the MS/MS spectrum of the pyridylethyl derivative of LNCR, a short peptide synthesized for the further investigation of these ions, demonstrates a prominent signal corresponding to the x_2-105 fragment at m/z 304 (Figure 1). A precursor spectrum for this ion indicated x_2 (or x_2+1) as the likely precursor. MS/MS spectra of source-derived x_2 and x_2+1 indicated that each of these ions was able to fragment to form the observed product at m/z 304. Presuming that the initial structure of x_n+1 is as depicted in Scheme 1, the formation of $[x_n$ - vinylpyridine$]^+$ from x_n+1 is easily rationalized mechanistically. Any formation of this ion from an x_n intermediate presumably involves rearrangement to give a similarly stabilized product, perhaps through an initial formation of a cyclic sulfonium ion prior to vinylpyridine loss. As further evidence for the identity of this fragment, the exact mass of the MS1 $[x_2$ - 105$]^+$ ion was determined to be 304.1086 which agrees well with the mass calculated for an $[x_2$ - vinylpyridine$]^+$ ion at m/z 304.1080. A review of the spectra of peC-containing peptides from a number of other sources showed that these fragments were observed in all peptides in which pyridylethylcysteine was situated N-terminal to a basic amino acid (e.g. lysine or arginine) but which did not itself constitute the N-terminal amino acid. Peptides containing cysteine modified with other common alkylating reagents were found to undergo an analogous fragmentation.

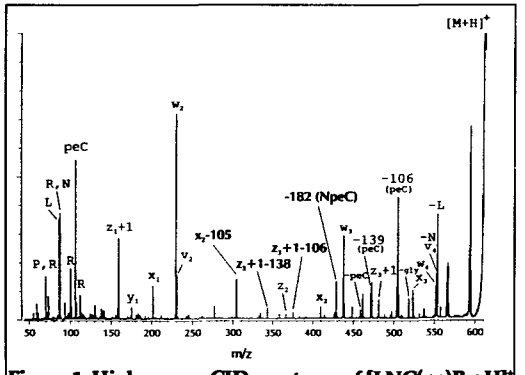

Figure 1. High energy CID spectrum of [LNC(pe)R +H]+

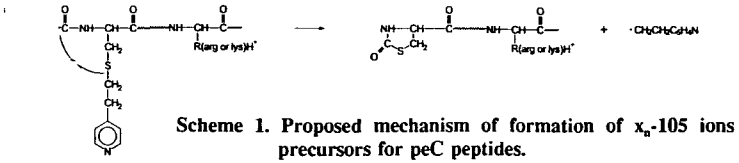
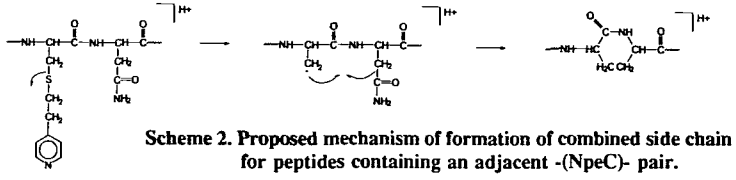


Scheme 1. Proposed mechanism of formation of x_n-105 ions from x_n+1 precursors for peC peptides.

In addition, it has been found that for peptides in which an S-alkyl cysteine is located directly adjacent to asparagine, aspartic acid or leucine, ions are observed which correspond to the combined losses of RS· with ·C(O)NH_2, ·C(O)OH, and ·CH$(CH_3)_2$, respectively. The structures of the combined side chain loss ions presumably represent stabilized 6-membered ring products as shown in Scheme 2. Aside from the circumstantial evidence linking certain sequences with the presence of these ions, other data support these assignments. For instance, the MS/MS spectrum of [LNC(pe)R + H]+ shows a peak at m/z 428 assignable as an -NC- combined side chain loss ion. The precursor spectrum of m/z 428 which contains two peaks, corresponding to $[M + H - pyrCH_2CH_2S\cdot]^+$ and $[M + H - 44]^+$, supports this conclusion. Also, peaks representing combined side chain losses of -LC- (711) and -CN- (710) appear at the same mass for all of the S-alkyl cysteine derivatives of LCNFYK and LCNFYR, indicating that the alkyl group, at least, is not present in these fragment ions.



Scheme 2. Proposed mechanism of formation of combined side chain loss ions for peptides containing an adjacent -(NpeC)- pair.

Not unexpectedly, fragmentations analogous to those recently described for methionine- and methylcysteine-containing peptides[1] have been observed. For instance, $[z_{n+1}$ +1 - $pyrCH_2CH_2S\cdot]^+$ ions (where pyridylethylcysteine is the nth residue) have been noted in the MS/MS spectra of C(pe)YFQNC(pe)PR, STMSITDC(pe)R, SITDC(pe)R and LNC(pe)R. In this case, such ions constitute a subset of a class of previously described ions in which w-type side chain losses occur from z_n+1 ions where the nth residue is positioned one amino acid to the N-terminal side of the fragmenting side chain[2]. In addition to these ions, the similar $[z_{n+1}$ +1 - $pyrCH_2CH_2\cdot]^+$ ions have been observed, the formation of which is easily rationalized as resulting in the formation of a stabilized closed shell 6-membered ring product. Also, as would be expected, the corresponding a_{n+1}+1-derived ions are observed in the MS/MS spectra of peptides containing basic sites N-terminal to the alkylcysteine position. Such fragments are also observed for peptides containing other S-alkyl cysteines. In most spectra in which these ions were observed at all (especially in the case of z_{n+1}+1-derived ions), this set of fragments tended to demonstrate a rather low relative intensity.

Surface-Induced Dissociation of Cyclic Peptides.

Ashok R. Dongré, Mark J. Hayward and Vicki H. Wysocki

Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284-2006
Agricultural Research Division, American Cyanamid Company, Princeton, NJ 08543- 0400

Cyclic peptides constitute a very important subgroup of biologically active compounds. The cyclic backbone fixes these peptides in a particular conformation which may lead to fixed secondary structure. These structures may exhibit specific properties that can lead to such applications as antibiotics or immunosuppresants. Classical sequencing techniques such as Edman degradation cannot be utilized for cyclic peptides due to lack of a free N-terminus. Therefore, with the advent of soft ionization techniques there has been increased interest in analyzing cyclic peptides by mass spectrometry.

Collision-induced dissociation (CID), both high and low energy, has been applied to sequence various biologically active cyclic peptides.[1,2] However, to obtain fragment ions from cyclic peptides at least two covalent bonds need to be cleaved which can require high energy deposition. In order to sequence cyclic peptides, it is neccessary to obtain a self consistent set of fragment ions. Surface-induced dissociation (SID) has been successful in sequencing linear peptides;[3] the advantages offered by SID such as high internal energy deposition, narrow energy distribution and its easy variability can be exploited to study fragmentation of cyclic peptides The current investigation deals with fragmentation of biologically active cyclic peptides related to Bacitracin and Telomycin complexes. Figure 1 represents an SID spectrum of Bacitracin A on a fluorinated alkanethiolate monolayer surface. The bacitracin A structure has a linear and cyclic portion making it more difficult to sequence and obtain a consistent set of fragment ions. Siegel and coworkers have performed a detailed investigation to elucidate the structure for Bacitracin A by CID.[2] In order to obtain complete sequence information they performed MS/MS/MS (nozzle-skimmer CID to elucidate the sequence of the linear portion followed by CID/MS on the cyclic portion to obtain its sequence). A single SID spectrum yields sequence ions both from the linear and the cyclic portion of the peptide without the need for the additional Cap-Skimmer fragmentation. The same ions as those observed by CID were obtained by SID. Figure 2 represents an SID spectrum of Telomycin on a octadecanethiolate monolayer surface. The proline and hydroxy-proline in the cyclic portion of the peptide render two amide bonds more facile which helps yield a consistent set of fragment ions making it easier to obtain the sequence of the cyclic portion.

The above results demonstrate the utility of SID to obtain structural information for cyclic peptides.

Peptide Sequencing at the Low Femtomole Level Using On-Line Membrane Preconcentration-Capillary Electrophoresis-Tandem Mass Spectrometry (mPC-CE-MS/MS)

Andy J. Tomlinson, Kenneth L. Johnson, and Stephen Naylor
Biomedical Mass Spectrometry Facility and Department of Biochemistry and Molecular Biology Mayo Clinic, Rochester, MN 55905, USA

Peptide sequence determination by mass spectrometry is a well-established technique. However, biologically active peptides that are currently presented for sequencing by MS techniques yield two major challenges. First, these analytes are usually components of complex mixtures and are not easily isolated by standard procedures. Second, such peptides are invariably present in extremely low concentrations (typically attomoles per microliter).

Initially, we developed CE-MS/MS conditions for this application. However, while such methods yield high analyte resolution, the concentration limits of detection of all CE-MS techniques were inadequate for detection of biologically derived peptides. These limitations motivated us to develop on-line membrane preconcentration CE-MS/MS (mPC-CE-MS/MS). This technique utilizes a hydrophobic membrane at the inlet of the CE capillary and enables the analysis of large sample volumes (tens of µL) without compromising analyte resolution or CE separation efficiency. Therefore, mPC-CE-MS/MS affords a very appropriate method for sequencing low concentrations of biologically active peptides.

From preliminary mPC-CE-MS/MS studies we found that the influence of subtle changes of CID conditions upon MS/MS data was greater when analyzing low fmol amounts of peptide than is often observed at higher (pmol) levels. Therefore, we systematically investigated the effects of CID parameters on the appearance of peptide MS/MS spectra.

Initially we evaluated the use of argon or xenon in the collision cell of our hybrid MS by analysis of ~70 fmol of the synthetic peptide SIINFEKLT (Figure 1). As expected, at the same collision energy (22 eV), xenon increased the attenuation of the doubly charged precursor ion. This tended to improve product ion yield and the overall appearance of the MS/MS spectrum of this peptide (Figure 1B).

We have also evaluated the effect of collision energy on peptide MS/MS (Figure 2). These MS/MS data were obtained using a xenon pressure of 1.5 x 10^{-5} mbar and a collision energy either of 18-22 eV or 26 eV. Clearly each spectrum yields partial sequence of the synthetic peptide SIINFEKL. However, since the quality of such data is dependent on peptide chemical nature, it is difficult to predict the optimal collision energy to sequence low levels of an unknown peptide. From these studies, we concluded that a collision energy ramp with scan is potentially most appropriate for this application.

Other factors that improve mPC-CE-MS/MS sensitivity include reducing the internal diameter of the PC-CE capillary. Smaller i.d. capillaries increase ESI performance. This greatly enhances the signal:noise of MS/MS spectra obtained by mPC-CE-MS/MS of low fmol amounts of peptide (Figure 3). Furthermore, esterification of acidic residues improves the efficiency of peptide ionization by ESI and MS/MS fragmentation processes which leads to more complete sequence upon analysis of ~40 fmol of peptide (Figure 4).

Introduction

In an earlier study with fast atom bombardment (FAB) ionization (Lindh *et al.*, Rapid Commun. Mass Spectrom., **8**, 797-803 (1994)) it was shown that the C-terminal derivatization of peptides with 4-aminonaphthalenesulphonic acid created a specific charge site on the peptide. Upon high-energy collision-induced dissociation (CID) the derivatized peptides fragmented only into C-terminal ions. Derivatization of the peptides combined with acetylation increased the sensitivity of detection by between one and two orders of magnitude. However, still a considerable amount of material (1-2 nmol) was needed to obtain CID spectra from which the amino acid sequence could be deduced. In the present study, we have determined the sensitivity of detection and fragmentation behaviour of the peptide derivatives by ES mass spectrometry.

Mass spectrometry

Negative-ion ES mass spectra were recorded on a VG AutoSpec-OA-TOF-FPD mass spectrometer. ES/CID linked scan (constant B/E) spectra were generated using helium as the collision gas in the first field free region gas cell at a pressure sufficient to give a 50% reduction of the parent ion-beam intensity (50% att.). CID spectra were also recorded using the orthogonal acceleration time-of-flight (OA-TOF) analyzer using xenon as collision gas at 50% att. The samples were introduced in a $MeOH/H_2O$ solution with continuous infusion.

Results

All the derivatized peptides could be detected on the hundred attomol-level using negative-ion electrospray ionization and focal plane array detection. During high-energy collision-induced dissociation, the peptide derivatives fragmented solely into C-terminal ions which greatly facilitates the interpretation of the spectra. The benefit of the derivatization procedure is shown for the peptide Glu-Leu-Gly-Gly-Gly (C-1). Figs. 1 and 2 show ES/CID spectra of naphthalenesulphonated C-1, recorded at the focal plane array detector and at the OA-TOF analyzer, respectively. The two ES/CID and earlier recorded FAB/CID fragmentation patterns are similar but have differences, partly due to the different collision energies used in the experiments. Almost a complete set of sequence ions "X, Y, 'Z, 'V and 'W are formed. The sensitivity of detection is much higher using ES/CID than FAB/CID. Sequence information can be obtained from as little as 50 fmol of material consumed.

Fragmentation Study of Small Non-Polar Peptides Containing NMeAla And Pro.

*Tomas Vaisar, * and Jan Urban*

Molecumetics Ltd., 2023 120th Ave NE, Bellevue, WA 98005, USA

Collision induced dissociation (CID) spectra of protonated peptides generally show main fragments of *a*, *b* and *y* type spread along the entire peptide chain. However, it was found that proline has a pronounced effect on the fragmentation pattern of protonated peptides opening low-energy fragmentation channel leading to *y* fragment ion with N-terminal proline.[3] This 'proline effect' was used to support a newly proposed fragmentation mechanism via an oxazolone-like intermediate.[4] The formation of *y* ions requires a transfer to the forming ion of the proton originating from a nitrogen of amide bond adjacent towards the N-terminus of the bond cleaved.[5,6]

We report on the fragmentation of a series of peptides with N-alkylated residues of the general structure H-Ala-Val-X-Leu-Gly-OH,with the following substitutions at the three position; Ala, NMeAla, Pro, L-pipecolinic acid (Pip) and D-Pip. The Pro residue was found to induce almost exclusively formation of a *y*-type ion with Pro at the N-terminus in peptides H-AVXLG-OH (X=P). Surprisingly, other N-alkylated amino acid residues (NMeAla and L-Pip) induce almost exclusively formation of *b*-type ion with N-alkyl residue at the C-terminus(Table 1). We suggest that this large difference in fragmentation should be attributed to the rigid five-membered Pro ring, a structure which disables transfer of proton to its C-terminal amide bond. We further suggest that N-alkylation on the more flexible systems, like NMeAla or L-Pip containing peptides, enhances transfer of proton from the N-alkylated amide bond's oxygen to the amide bond on the C-teminus of this residue either to N (conforming to 'classical' mechanism) or to O (according to mechanism via cyclic oxazolone-like intermediate proposed by Hunt). The striking difference in fragmentation pattern of peptides with L- and D- Pip implies the importance of an energetically accesible conformation of protonated peptide which facilitates the transfer of proton to certain amide bond.

Y_{n-1} ions were found in the spectra of compounds when there is no N-bound proton available for transfer to the forming ion (Fig.1). Deuterium labeling at the acetyl group revealed transfer from the acetyl methyl group. The ionizing proton also is retained by the *y* ion. When the deuteron is transferred to the tertiary nitrogen of Pro, there is clean incorporation of one deuteron observed, while for the transfer to the secondary nitrogen of Val the the ratio H : D approx. 1:1 is observed. When the N- bound proton is present

(AcAla at the N-terminus) there is no deuterium incorporation observed proving that this is a primary source of transferred proton in standard peptides.

DETECTION OF MODIFIED PEPTIDES IN ENZYMATIC DIGESTS BY μLC-APICID-MS AND DOUBLE-POLARITY HYBRID-SCANNING TECHNIQUE

Paul Jedrzejewski, Martina Schnölzer*, Wolf D. Lehmann
Central Spectroscopy Department and *Department of Cell Biology
German Cancer Research Center, Im Neuenheimer Feld 280, 69120 HEIDELBERG, Germany

Characterization of protein modifications is an important aspect in the analysis of protein structure and function. Post-translational modifications such as phosphorylation, sulfation, glycosylation, and N-terminal blocking are a means of cellular regulation of protein function. Non-biological modifications such as deamination, formylation, oxidation or coupling with acrylamide may also arise during sample preparation. The acrylamide modification may occur during polyacrylamide gel electrophoresis, where cysteine residues may be covalently modified, resulting in a mass increment of 72 da per cysteine residue.[1,2] Conventional protein sequencing methods are not suitable for detection of these protein modifications.

The use of APICID to generate specific marker ions for the detection of phosphorylation, sulfation and glycosylation was introduced by Carr and Huddleston.[3,4] In their investigations modified peptides were identified by employing a single-polarity hybrid-scanning technique for the detection of fragments and molecular mass of a single type of modification. Extending these studies, we have developed a new double-polarity acquisition scheme which allows for simultaneous determination of peptide mass and the presence of various peptide modifications. The technique utilizes APICID electrospray-MS to generate specific marker ions indicative of phosphorylation (-79, PO_3^-), sulfation (-80, SO_3^-), and acrylamide modification (+104, $[S\text{-}CH_2\text{-}CH_2\text{-}CONH_2]^+$). The scanning technique presented here uses polarity switching during a hybrid scan to detect various marker ions irrespective of their optimum polarity.

Fragmentation is controlled by modifying the APICID offset voltage. Optimum APICID conditions for each modification were determined by investigation of model compounds. During a hybrid scan, fragmentation is maximized at low m/z values by selecting marker ion-specific APICID offsets, whereas molecular mass information is obtained with the APICID offset turned off at high m/z values

In order to evaluate the on-line capabilities of this new double-polarity hybrid-scanning technique a tryptic digest of 100 pmol β-casein was spiked with cholecystokinin (sulfo-tyrosine) peptide and with a synthetic acrylamide-modified peptide. The resulting total ion chromatogram and the modification-specific single ion chromatograms at m/z -79, -80, and +104 are given in Figure 1. Each single ion chromatogram indicates the precise retention time for a specificly modified peptide, and the simultaneously obtained molecular mass information provides positive identification. In the double-polarity hybrid mass spectrum of the phosphorylated T6 fragment of β-casein (Figure 2), which was recorded in the LC-APICID-MS run shown in Figure 1, both the $[PO_3]^-$ -ion, specific for phosphate esters, and the $[M+H]^+$ of the intact phosphorylated T6 peptide can be recognized.

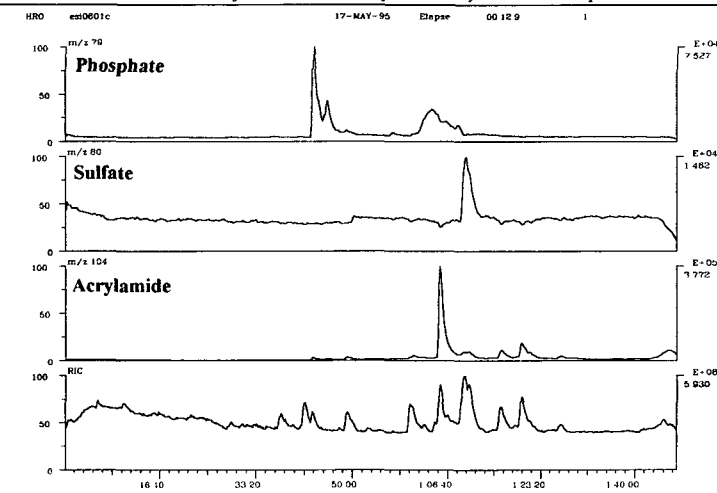

Figure 1: LC-APICID-ESI analysis of a tryptic digest of β-casein spiked with a cholecystokinin (sulfo-tyrosine) peptide and with an acrylamide-modified peptide; double-polarity hybrid-scanning was used for specific detection of modified peptides.

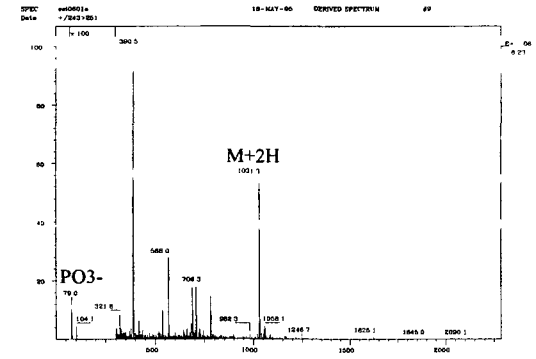

Figure 2:
ESI (double-polarity hybrid scan) mass spectrum of the phosphorylated T6 fragment of β-casein detected in the LC-MS run displayed in Figure 1.

Enzymatic Reactions on Membranes for the MALDI Analysis of Phosphoproteins

Pao-Chi Liao[1,2], Douglas A. Gage[2], and John Allison[1], Department of Chemistry[1] and Biochemistry[2], Michigan State University, East Lansing, MI 48824

We have previously reported a method to locate phosphorylation sites in a phosphoprotein with known primary sequence, using peptide mass mapping by combining specific enzymatic degradation with matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS) [1]. There are three steps to locate phosphorylation sites in a phosphoprotein: 1. degradation of the phosphoprotein into peptides by specific enzymatic or chemical reactions; 2. identification of the phosphopeptides by -80 (or multiples of -80) Da mass shifts in the mass spectra after dephosphorylation with alkaline phosphatase; 3. location of the phosphorylation sites by peptide mass-mapping. The second step, using the enzymatic dephosphorylation reaction, is a critical step in the analysis. The dephosphorylation reaction allows a phosphopeptide to be identified by mass shifts using simple mass measurements of the peptide before and after the dephosphorylation reaction. The procedure does not require an MS/MS technique. The enzymatic reaction is highly selective and sensitive. A further refinement of the experimental procedures for the enzymatic dephosphorylation reaction is discussed here. The goal is to minimize sample loss from manipulations and facilitate simple, rapid analyses. This is especially important when only picomolar amount of samples are available. Our procedure also provides a sensitive means to remove the impurities which may interfere with the enzymatic dephosphorylation reaction and/or the MALDI mass spectral analysis.

A protocol has been developed to immobilize low picomolar phosphopeptides on a supporting material, wash the sample when necessary, conduct enzymatic dephosphorylation, remove reaction buffers, then add matrix compound and analyze the final reaction products by MALDI *in situ*. The immobilization material must meet both requirements for efficient separations and be an effective interface to a MALDI mass spectrometer. Nylon-based membranes exhibit these properties [2]. The use of Zetabind (Cuno Laboratory Products), a positive charge-modified nylon membrane, is described here. 10 pmol of a phosphopeptide, KRP(pS)QRHGSKY-amide, was immobilized by air-drying the peptide solution on a piece of membrane fixed on a stainless steel probe with double-sided tape. The sample probe was washed with 0.5 mL 0.1% trifluoroacetic acid (TFA) solution twice to remove any water-soluble contamination. 2 μl of 50 mM NH_4HCO_3 buffer solution (pH 8.0) containing about 3 units of calf intestine alkaline phosphatase was applied to the sample probe. An incubation assembly was designed to prevent the reaction mixture from evaporation and used for the dephosphorylation reaction in a water bath at 37°C. After 4 hours of reaction time, the sample probe was washed with 0.5 mL 0.1% TFA solution twice to remove reaction buffers. Then, 1 μl of 20 mM α-cyano-4-hydroxycinnamic acid matrix solution (in a 1:1 solution of 0.1% TFA : acetonitrile) was added to the sample probe. When the peptide/matrix mixture was dried and cocrystallized on the membrane, the sample was subjected to analysis by MALDI. All MALDI data were obtained in linear mode on a ResearchTec time-of-flight (TOF) mass spectrometer (Vestec Corp., Houston, TX). The Figure below shows the expected -80 Daltons mass shifts in the MALDI mass spectra due to the loss of phosphate moieties after using this protocol.

This design is especially important when the peptide sample contains chemical substances which interfere with the subsequent dephosphorylation reaction and only a limited amount of sample is available. We have found that phosphopeptides purified from metal ion affinity columns may contain iron impurities which interfere with the dephosphorylation reaction. The problem can be avoided by this sample immobilization and washing protocol. A putative phosphopeptide, obtained from the tryptic proteolysis of sucrose-phosphate synthase (SPS), has been purified by Fe^{3+}-IDA affinity chromatography. The attempt of direct dephosphorylation reaction (without the immobilization on the membrane and subsequent washing procedure) failed to show a -80 Da mass shift by mass spectrometry. It was suspected that there are impurities in the sample that may interfere with the enzymatic activity of phosphatase. A "spike" experiment was carried on a pure phosphopeptide, KRP(pS)QRHGSKY-amide, and the expected -80 Da mass shift was not observed. Our protocol described here was used to remove the contaminations and overcome the interference problem. The protocol eliminates substantial sample clean-up procedure (e.g., dialysis, which may introduce sample loss), prior to MALDI-MS analysis.

Improved Low Energy CID Spectra of Peptide Ions Using Stepped Collision Potentials.

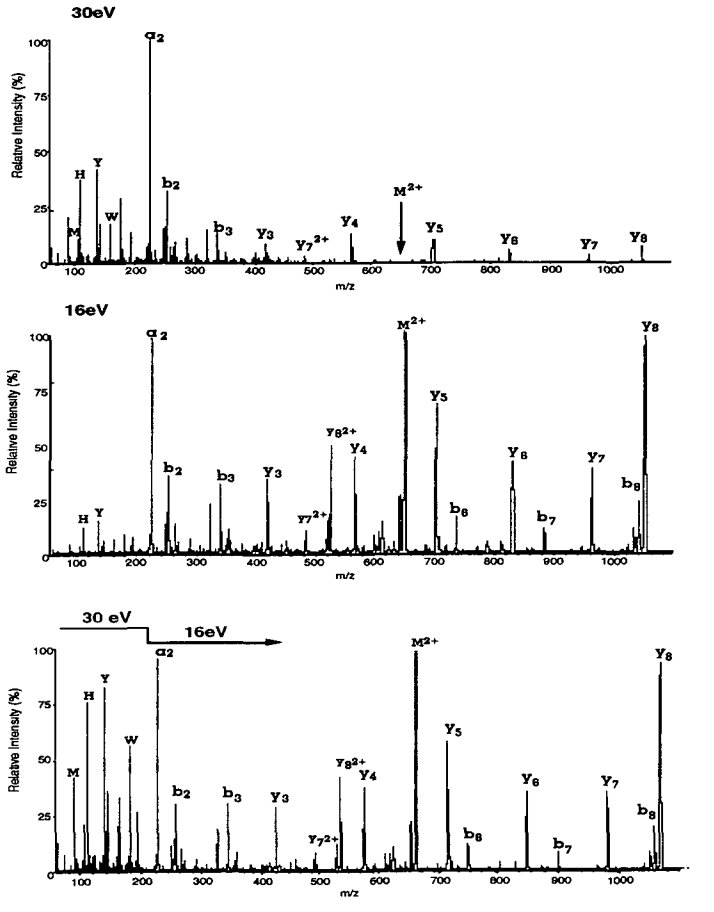
R.S. Annan and S.A. Carr
SmithKline Beecham Pharmaceuticals
King of Prussia PA 19406

The overall appearance of low energy CID spectra of peptide ions is largely dependent upon three factors: the peptide sequence, the collision energy, and the collision gas pressure. For a given peptide sequence, changes in the collision energy can dramatically alter the relative abundance of the product ions. Because of the multiple collision regime under which low energy CID operates, a product ion may decompose to a lower m/z fragment upon undergoing secondary collisions. Low m/z fragment ions, such as internal sequences and immonium ions have found new importance due to the recently introduced technique of searching peptide MWs against protein sequence databases. A short partial sequence of even two amino acids, or the presence of some of the less common amino acids identified via an immonium ion, together with the peptide molecular weight can either uniquely identify the peptide, or greatly reduce the number of peptide matches.

Unfortunately abundant immonium ions and low m/z internal sequences are frequently produced at the expense of high m/z sequence ions, giving rise to spectra which show a rapid fall off of fragment ions above the multiply charged precursor. This type of spectrum is of little use if coverage of the entire sequence is necessary, for instance to identify the site of phosphorylation in a peptide. We have found that ions higher in m/z than the doubly charged precursor are generally the most useful for sequencing purposes (for one, there is no charge state ambiguity), and therefore, we make every effort to maximize them. However, we do not want to give up an abundant yield of immonium ions. We have found that by recording the CID spectrum at two different collision energies a more even distribution of product ions results, with abundant immonium and high m/z sequence ions.

All CID spectra were recorded on a Perkin Elmer Sciex API III triple quadrupole mass spectrometer using either the standard articulated ionspray interface, or a custom built nanoliter flow ionspray interface (M. Mann EMBL). Peptide samples were reconstituted in methanol:water:formic acid (50:50:0.2) and infused into the MS using either a Harvard syringe pump operated at 2 μL/min, or the nanospray device where typical flow rates are on the order of 25–40 nanoliters per minute (1). The collision energy (E_{coll}) on the Sciex API III is determined by the difference in voltages (R0 and R2, respectively) applied to Q0 (RF only focusing rods prior to Q1) and Q2 (RF only collision cell) such that $E_{coll} = z(R0-R2)$, where z is the charge on the precursor. Thus recording a spectrum using different collision energies is accomplished by stepping the voltage on Q2 to a higher or lower value as Q3 is scanned from low to high m/z. All collision energies are reported as collision potentials, ie. the voltage difference between R0 and R2.

Figure 1 demonstrates that a more even distribution of fragment ions can be generated following CID if the spectrum is acquired using two collision potentials. Even under experimental conditions where one has the time to carefully optimize the parameters affecting CID (such as when using a nanospray interface), it is still generally beneficial to perform a two step CID experiment. Unfortunately, under the current software limitations, only one voltage can be changed with mass during a scan. Therefore, these experiments can only be done under conditions where the fragment ion spectrum is acquired at less than unit resolution, because operating in the higher resolution mode requires changing more than one voltage simultaneously. For normal ionspray operation, this is not a drawback, since this mode of operation provides the highest sensitivity. However, with the advent of nanoliter flow ES interfaces and the ability to



.Figure 1

signal average for long periods of time, with a small amount of sample, the acquisition of isotopically resolved fragment ions become realistic and, therefore, desirable.

The authors are grateful to Michael Huddleston for help with the nanoliter flow interface

Location of peptide phosphorylation sites by use of (+) and (−)ESI-MS/MS. M. Busman, K.L. Schey, D.R. Knapp, Department of Pharmacology, Medical University of South Carolina, Charleston, SC

Introduction Recently, rhodopsin and rhodopsin kinase phosphorylations have been studied by ESI-MS/MS and FAB-MS/MS.[1,2] In our studies of rhodopsin phosphorylation we have synthesized a series of reference phosphopeptides, corresponding to the peptides from the C-terminal region that could be isolated after enzymatic digestion of rhodopsin. A complete set of mono- and di-phosphorylated analogs of the fragment peptides ASTTVSKTE and TSQVAPA was synthesized.[3] Here we report the results of the analysis of these synthetic peptides by ESI-MS/MS and, in particular, the complementary use of experiments utilizing positive and negative ions, as well as different charge number ions, as precursor ions for CID.

Experimental. The preparation of the synthetic phosphorylated peptides has been previously described.[3] Peptides were analyzed by ESI-MS on a SCIEX API III triple quadrupole mass spectrometer. Solutions of the peptides were prepared at a concentration of ~1 x 10^{-4}M in 47.5/47.5/5 (v/v/v) methanol-water-acetic acid for positive mode (+)ESI-MS and 47.5/47.5/5 (v/v/v) methanol-water-piperidine for negative mode (−)ESI-MS. CID was carried out in the rf-only quadrupole region, Q2, to generate product ions from peptide precursor ions.

Results-Discussion The product ion spectrum for the $[M+H]^{+1}$ ion of T(p)SQVAPA is shown in Figure 1(a). Sufficient fragmentation information is not provided from the product ion spectra of the $[M+H]^{+1}$ ions alone to unequivocally assign location of the sites of phosphorylation on each peptide. The product ion spectrum for the $[M-H]^{-1}$ ion of T(p)SQVAPA is shown in Figure 1(b). While the product ion spectra from the $[M-H]^{-1}$ ions alone do not provide sufficient information to deduce the complete sequence of the peptides, it is apparent that the CID experiments on $[M+H]^{+1}$ and $[M-H]^{-1}$ ions provide complementary information, allowing assignment of the sequence, including site of phosphorylation.

The product ion spectra for the $[M+H]^{+1}$ and $[M+2H]^{+2}$ ions of AS(p)TTVSKTE are shown in Figure 2. Losses of H_3PO_4, indicated by a loss of 98 Th (or in the case of the doubly charged species, −49 Th) from the $[M+H]^{+1}$, $[M+2H]^{+2}$ and, where appropriate, the y- and b-type product ions are seen. The results of the CID experiments on the two charge states provide complementary information, allowing unequivocal assignment of the location of all sites of phosphorylation. Similar results were obtained from singly and doubly charged ions from the di-phosphorylated analogs of ASTTVSKTE, allowing location of both sites of phosphorylation in most of the peptides.

Figure 3 shows the CA(−)ESI-MS spectrum for angiotensin I. Based upon y-type fragment information in the spectrum, the complete sequence for the molecule can be assigned. Figure 4 shows the (−)ESI-MS/MS spectrum for leucine enkephalin. Notable in this spectrum is the presence of c-type fragment ions. The detection of c-type fragments in low energy tandem mass spectrometry experiments of ions produced by (−)ESI has been previously noted by Loo *et al.*[4] Sufficient information is available from the spectrum to assign the sequence of the molecule. The results of these experiments demonstrate the ability of the ESI-MS/MS technique to provide sequence information for small peptides. Such observations are contrary to previous observations of the apparent lack of backbone fragmentations upon CID of FAB generated negatively charged ions.[5,6]

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Conclusions The complementary use of different forms of the ESI-MS/MS experiment has been utilized to determine sites of phosphorylation in synthetic phosphopeptides based on sequences from the C-terminal region of rhodopsin accessible by enzymatic digestion. Sites of phosphorylation for most of the phosphopeptides could be determined. In the data presented here, many of the peptides yielded complete sequence information by the (−)ESI-MS/MS technique. The majority of the fragment ions detected could be rationalized in terms of cleavages of the peptide backbone. Only in a few cases were ions resulting from side chain cleavages a major contribution to the MS/MS spectrum.

Phosphorylation and N-terminal Acetylation of Phosrestin I in Fly Eyes

Tomoya Kinumi[1,2], Kenneth W. Jackson[1], Masayuki Kubota[2], Mamoru Ohashi[2] and Hiroyuki Matsumoto[1]
[1] The Univ. of Oklahoma, Health Sciences Center, Oklahoma City, Oklahoma.
[2] The Univ. of Electro-Communications, Tokyo, Japan.

INTRODUCTION Protein phosphorylation cascade plays important roles in cell signaling. In the photoreceptor cells of the fruitfly, *Drosophila melanogaster*, two-dimensional (2-D) gel analysis reveals at least three classes of phosphoproteins which undergo light-induced reversible phosphorylation. Two of these are named phosrestin I (PRI) and phosrestin II (PRII). PRI and PRII are homologous to mammalian arrestins which are known to inactivate G-protein-linked receptors such as rhodopsin and β-adrenergic receptor. Previously, the phosphorylation site of PRI had been determined to be Ser_{366} *in vitro*. In order to confirm that Ser_{366} is also the phosphorylation site *in vivo* and to study other post-translational modifications of PRI, we have developed a protein micro analysis technique using LC/MS after in-gel digestion of 2-D gel purified protein (1).

METHODS The phosphorylated form of PRI was isolated on 2-D gels from light-adapted *Drosophila* eye homogenates prepared from 3,000 flies. The PRI spots were visualized by a brief staining with Coomassie blue. The in-gel digestion was performed according to Rosenfeld *et al.* (2). The spots were cut out and incubated with water overnight and washed three times with 60% MeCN/H_2O. After washing, the gel spots were slightly dried, then 2 μl of TPCK-trypsin solution was applied (0.2 mg of TPCK-trypsin in 1 ml of 200 mM ammonium bicarbonate pH 7.8) for each gel spot. The spots were incubated in 0.2 ml of 200 mM ammonium bicarbonate at 27°C for 24 hrs. The resulting peptide fragments were extracted with 60% MeCN/0.1% TFA/H_2O and applied to a microbore C18 HPLC column (1 mm i.d. ×150 mm) The HPLC was directly interfaced with an electrospray ionization mass spectrometer (PE-Sciex Model API-III).

1) **Determination of the *in vivo* phosphorylation site.** We searched for the PRI tryptic fragment containing Ser_{366} (phospho-$PRI_{364-371}$: MKS(P)IEQHR, MH^+=1108.5) by single ion monitoring (SIM). For the authentic phospho-$PRI_{364-371}$, we synthesized the peptide MKSIEQHR and phosphorylated it to obtain MKS(P)IEQHR by using PRI kinase extracted from fly heads. The retention time of the putative phospho-$PRI_{364-371}$ was compared with that of the synthetic MKS(P)IEQHR by SIM.

2) **N-terminal modification of PRI.** We searched for the possible N-terminal tryptic fragment(s) using SIM. One of the N-terminal fragments was sequenced by CID. For CID analysis, the in-gel digested peptide fragments were partially purified by reversed phase HPLC. The purified fragments were applied to MS.

RESULTS 1) From the stored data of the PRI tryptic digests scanned from m/z=350 to 1200 on LC/MS, a single peak was extracted between m/z=1108 to 1109 (Peak A in Fig 1). [MKS(P)IEQHR, MH^+ = 1108.5]. The mass spectrum of the Peak A is shown in Fig 2. Peak A exhibited the same retention time as that of the authentic phosphopeptide MKS(P)IEQHR. Furthermore, co-injection of the PRI tryptic digests and the synthetic MKS(P)IEQHR resulted in a single peak. In the simulated tryptic digests of PRI, another peptide fragment, whose MH^+ is close to 1108.5, was expected. *i.e.*, PRI_{74-82}, FSKELILCR, MH^+ =1108.6. In order to eliminate the possibility that the Peak A represents PRI_{74-82}, we synthesized the authentic peptide, FSKELILCR, and measured its retention time. This peptide eluted 5 minutes later than the Peak A under the

conditions used. This result is consistent with our conclusion that the Peak A represents phospho-$PRI_{364-371}$, MKS(P)IEQHR.

2) The expected N-terminal tryptic fragment of PRI is MVVSVK. However, we failed to observe MVVSVK in the digests. Instead, we observed two related peaks, VVSVK and acetyl-MVVSVK in SIM (Fig 3). The peptide sequence of one of these SIM peaks, VVSVK, was confirmed by CID (Fig 4).

CONCLUSION 1) PRI is phosphorylated at Ser_{366} *in vivo* as predicted from the experiments which had been conducted *in vitro*. 2) There are two chemical species of PRI N-termini, one in which the initiation Met has been removed and the other in which the Met remains, but is acetylated. However, we observed no N-terminal fragment of PRI which remains intact.

This study demonstrates that combination of 2-D gel electrophoresis, in-gel digestion and LC/MS is a powerful tool to elucidate *in vivo* protein modification.

Electrospray FTICR Mass Spectrometry of Modified Peptides and Proteins

Joseph P. Nawrocki, Clifford H Watson and John R. Eyler
Department of Chemistry, University of Florida, Gainesville, Florida 32611

ABSTRACT

We have been investigating novel blocked and modified proteins using electrospray FTICR-MS. Modified peptides and proteins are readily analyzed via ESI and readily undergo CAD to provide structurally useful product ions. High resolution detection of the parent and product ions allows for the unambiguous identification of the amino acid residues and the identity of the modification This proves very useful for synthetic proteins as well as for novel proteins that may have been post-translationally modified Phosphorylation, one such modification, holds much interest in biochemistry Methods to easily study these proteins using positive ion ESI/FTICR-MS are currently being developed in our lab.

INTRODUCTION

ESI mass spectrometry has quickly become an important tool for the analysis of many biological samples Accurate mass determination has proven useful for synthetic peptides and proteins and for novel uncharacterized proteins The technique of CAD can yield much information about the parent ion, but can sometimes be ambiguous due to mass similarities between attached moieties including those from post-translational modifications, blocking groups and amino acids The combination of ESI with FTICR-MS allows for the differentiation between groups of similar nominal masses due to the high resolution of the instrument

Phospho-peptides/proteins hold much interest for study, but cannot usually be studied in positive ion mode Terminal phosphates, with pKa values of 1.0 and 6 5, are negatively charged under typical electrospray conditions Negative ion electrospray has only recently been achieved on our commercial FTICR mass spectrometer and conditions are not yet well characterized It has been shown that phosphate groups bind appreciably to certain M^{3+} and M^{4+} ions. [1,2] Such metals include Fe^{3+}, Sc^{3+}, Th^{4+} and Lu^{3+}. However, various other metals show no affinity for these proteins These metals should neutralize the negative charge or convert it to a net positive charge depending on the binding mechanism, provided these metals bind in the gas phase. Various conditions of concentration and pH are being examined to determine ideal binding conditions.

EXPERIMENTAL

Ions were produced via an electrospray source (Analytica of Branford, Branford, CT) mounted in the external source housing of a 7-tesla FTICR mass spectrometer. Ions were then transported via a series of electrostatic lenses. Samples were run at concentrations of about 5 x 10^{-5} M in water/methanol/acetic acid 49/49/2 CAD was accomplished by increasing the potential difference between the capillary exit and the first skimmer Running conditions included. capillary potential=-4 0kV, cylinder potential=-3.0kV and needle at ground potential Needle capillary distance usually varied between 10-15mm Calibration was done in heterodyne mode using fragment ions produced by ESI/CAD of bradykinin.

RESULTS

ESI/FTICR mass spectrometry has proven to be a very useful tool for the unambiguous determination of modifications on peptides and will be used to study larger modified proteins Figures 1 and 2 illustrate the determination of a blocking group on a synthetic pentapeptide A loss of 56 107 amu is indicative of tert-butyl blocking group which was used during synthesis This type of unambiguous mass determination will prove very useful for post-transnational modifications of larger proteins.

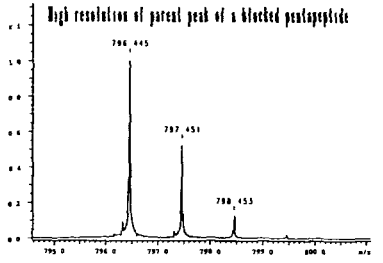

Figure 1. Blocked pentapeptide before CAD retaining all tert-butyl groups

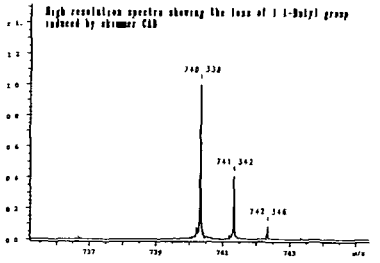

Figure 2. Blocked pentapetide after CAD showing the loss of one tert-butyl group

MASS SPECTROMETRIC PROTEIN IDENTIFICATION IN COMPLETELY SEQUENCED GENOMES

Matthias Mann, Ole N. Jensen, Ole Vorm, Peter Mortensen, Andrej Shevchenko, Tony Houthaeve, and Matthias Wilm
European Molecular Biology Laboratory
Meyerhofstr. 1, D-69012 Heidelberg, Germany

Introduction

The completion of many genome sequencing projects will change the focus of protein analysis in the near future. Since comprehensive DNA sequence information will be available for many species the major objective will be to identify a gene product and thereby the gene (open reading frame) associated with a given biological activity or function. Peptide mapping and peptide sequencing by mass spectrometric methods have potential for rapid identification of proteins by means of "peptide mass fingerprints" and "peptide sequence tags" combined with computerized searches in DNA and protein sequence databases. Completely sequenced genomes are ideal for mass spectrometric protein identification because the chances of assigning a "false positive" due to the absence of the correct protein sequence in the database are extremely low: There will always be at least one correct match.
To ascertain the applicability of current mass spectrometric techniques to protein identification in completely sequenced genomes we have investigated the requirements for unambiguous identification of proteins encoded in the genomes of vaccinia virus (200 open reading frames) and yeast (*Saccharomyces cerevisiae*, ~7000 open reading frames).

Experimental

Peptide mass mapping was performed using a Bruker Reflex reflector TOF mass spectrometer capable of post-source-decay (PSD) analysis. The instrument control and data acquisition software (LaserOne for Macintosh) was developed in-house. Matrix surfaces were prepared by the fast evaporation method using 4HCCA as the matrix compound (1). ES MS/MS was performed using the NanoES source (2) on a Sciex API III triple quadrupole mass spectrometer. Prior to NanoES MS/MS analysis peptide samples were desalted using custom made reversed-phase columns (Wilm *et al*, submitted). Database searches using peptide mass data and peptide sequence tags (3) were performed by PeptideSearch, a Macintosh application developed by us. Vaccinia-only, yeast-only, GenPept, and SwissProt databases were used. The software allows database searches to be performed using a variety of parameters, including peptide sequence tags. A "second pass" search feature allows rapid evaluation of high-scoring protein sequences.

Results

The fast evaporation method for sample preparation and an automated internal mass calibration procedure for MALDI reflector TOF mass spectrometry allow us to routinely obtain (monoisotopic) mass accuracies of 0.01% or better in the useful tryptic peptide mass range from m/z 600 to 2500. This improved mass accuracy puts a strong constraint on the subsequent database searches and greatly reduces the likelihood of detecting false positives.
We have also tested MALDI PSD reTOF for the generation of peptide sequence tags. Using a single PSD peptide sequence tag in combination with an accurately determined precursor ion mass uniquely identify the 14 kDa fusion protein in the vaccinia virus sequence database (Figure 1). Although further improvements are necessary, this technique has the potential to rapidly generate peptide sequence tags. NanoES MS/MS is another powerful method for producing several peptide sequence tags from a peptide mixture because it allows 30-45 minutes of MS/MS analysis time on a small volume (1 µL) of sample. We routinely use this method to identify proteins from yeast and other species.

Conclusion

MALDI reflector TOF MS and NanoES MS/MS can produce data that, in combination with database searching, unambiguously identify proteins in well-characterized genomes, such as those of vaccinia virus and yeast. The combination of MALDI MS for producing peptide maps and NanoES MS/MS for generating peptide sequence tags provides 1) good coverage of the protein sequence; and 2) protein specific sequence information.
In our experience, the requirements for unambiguous identification of a protein in sequence databases by mass spectrometric data are one or more of the following:

- More than 10 peptide masses determined with a mass accuracy of better than 0.01% of which 5 or more produce the same protein match and cover more than 10% of the protein sequence.
- Two or more peptide sequence tags producing the same protein match
- A combination of the above methods, i e. a peptide mass map (0.01% accuracy) and several peptide sequence tags.

Using these requirements we have to date identified more than 50 proteins from a variety of sources. We have not found the use of "limited" databases, *i.e.* species-specific databases to improve the search results significantly using the described mass spectrometric techniques. We recommend that searches be performed in an all-inclusive protein database because contaminating proteins such as human keratin (often found in protein preparations) also will be identified.
Having the above mentioned mass spectrometry and software tools available we now pursue developments to increase sample throughput and to investigate defined subcellular compartments and specific multiprotein complexes. The experience gained to date make us believe that mass spectrometry will revolutionize protein analysis in completely sequenced genomes.

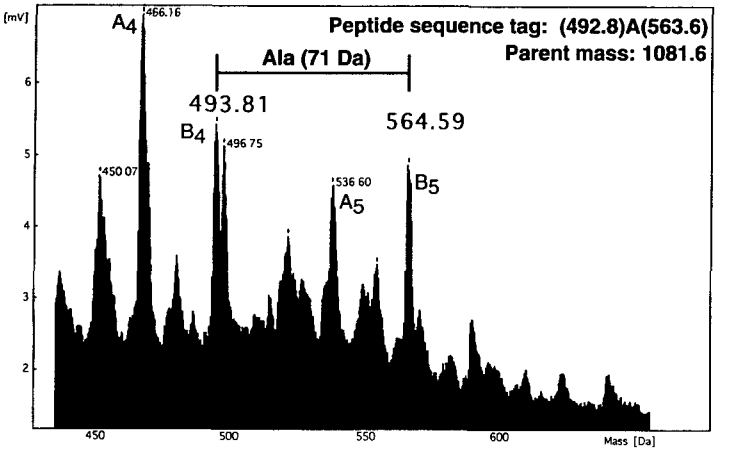

Figure 1. MALDI post-source-decay mass spectrum of a m/z 1082 peptide present in a peptide mixture. Pulsed deflection plates were used to remove ion signals outside a mass-window of approximately 50 Da centered around the m/z 1082.6 ion signal. The A/B ion seried were detected by noticing the characteristic 28 Da mass difference. The generated peptide sequence tag (492.8)A(563.6) in combination with the precursor peptide mass (1081.6 ± 0.1 Da) uniquely identifies the 14 kDa fusion protein in the vaccinia protein database.

USEFUL TABLES OF POSSIBLE AND PROBABLE PEPTIDE MASSES

M. Mann, European Molecular Biology Laboratory (EMBL)
Postfach 10.2209, D-69012 Heidelberg, Germany

Peptide masses are often calculated as "nominal" or integer masses obtained by setting the peptide masses equal to the added mass of the integer number of atomic constituents. However, it is well known that peptide masses are not arbitrarily distributed but exhibit a certain "mass offset" from the nominal mass. This mass offset depends on the mass considered and increases with increasing mass (Fractional Mass Values). Here the phenomenon is quantified by calculating all possible peptide masses in the range of 0 to 2000 Da and tabulating all actual peptide masses from sequence databases and practical uses of these mass distributions are suggested.
All calculations were done with the program "CompFinder" which runs on the Macintosh series of computers. CompFinder is normally used to calculate compositions corresponding tc measured masses or mass differences (see fig. 1). Calculations were done with 32 bit double values for amino acid molecular weights and performed for monoisotopic and average masses. Glutamyl and Lysyl residues were considered different but Isoleucyl and Leucyl were not counted separately. Computing times to find a 50 Da wide mass distribution ranged from less than a second below mass 600 to 18 hours at mass 2000 on a PowerPC Macintosh Fig 1 shows mass distributions obtained by calculating all possible peptide compositions around mass 500. The centroids of the distributions give the average mass offset at each mass. It is apparent from the figure that - particularly at small masses - the distribution of masses is quite narrow. For example, at mass 510 the width is only 0.25 Da, that is, all peptides with nominal mass 510 must be within 0.13 Da of the average mass offset. The area between the peaks is a "forbidden zone" where no peptide mass is possible.
The distributions were also tabulated for sequence databases like SWISS-PROT with identical results.

The data in the mass distributions can be summarized in the following formulas:
(1) $\Delta m = 0.00048 * m$ (monoisotopic)
(2) $\Delta m = 0.00115 * m$ (average mass)
(3) $Wm = 0.19\ Da + 0.0001 * m$

with Δm the mass offset in Da, m the mass in Da, and Wm the width of the mass distribution encompassing 95% of all amino acid compositions.

A computer program can mark unlikely mass values in the following way (monoisotopic case):

```
if (Abs((m-[m])-(m * 0.00048)) < (0.095 + 5*10-5 *m)) {
 //do nothing
}
else {
 MarkPeakInRed(m);
}
```

where Abs is the absolute value; m is the molecular weight in Da; [m] is the lower interger value of m and hence m-[m] is the mass offset (this works until mass 2000); MarkPeakInRead is a subroutine to display a peak value in red

Some possible applications include:
- Check peptide masses for outliers. For example, tryptic peptide masses which are more than 0.3 Da in error can be flagged as such.
- Check stability of mass calibration. If several peptide masses are in forbidden zones or unlikely zones the mass calibration has shifted.
- Find "non-typical" peptides, i.e. peptides with a substantial glyco part, peptides which contain two sulfur atoms such as peptides containing a disulfide bridge (personal communication A. Tolmachev, Moskow) and peaks which are not peptides at all (noise peaks or background).
- Estimate error from the peptide masses in a peptide map. It is possible to estimate the mass error without any other information than a table of measured masses.
- Improve calibration by eliminating linear mass errors.
- Avoid embarrasment; i.e. you can't measure mass 1000.0 ± 0.01 % Da (mono). :-)

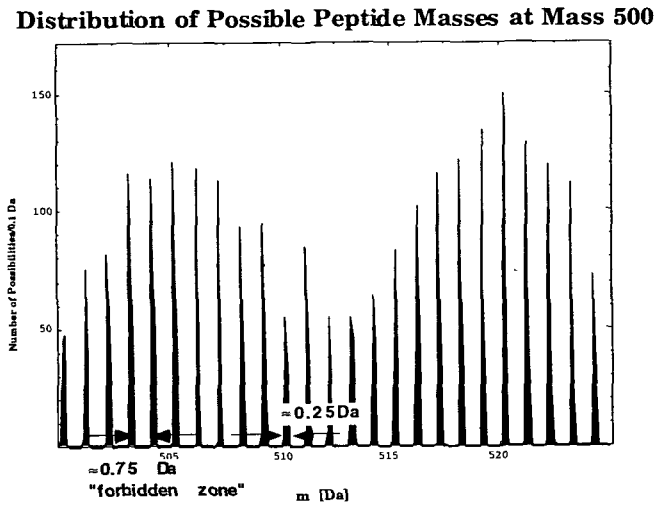

Figure 1

Analysis of Immuno-affinity Purified Proteins by Tandem Mass Spectrometry

David M. Schieltz, Jimmy K. Eng, and John R. Yates III
Department of Molecular Biotechnology, University of Washington, Seattle WA 98195

Traditionally, proteins have been identified through biochemical assays, immunoblotting or chemical sequencing. These methods can be time consuming and laborious. Our laboratory has developed methods for identifying proteins using MS/MS analysis of peptides generated by enzymatic cleavage of the protein. Using the SEQUEST program developed by Eng and coworkers(1), peptide tandem mass spectra are searched against possible sequences of amino acids in the protein databases. This allows for a rapid identification of proteins.

To demonstrate this approach, the antibody reactive against a conserved region of the v-H-ras protein was used to probe a whole cell S. cerevisiae lysate. Approximately 10 mg of the lysate was incubated at 4°C for 2 hours with the antibody-agarose conjugate. The antibody-agarose was washed with lysis buffer followed by an elution buffer consisting of 1 M acetic acid. The pH was adjusted to 8.5 with ammonium bicarbonate prior to digestion with trypsin.

Three microliters of the digest was loaded onto a 100 µm i.d micro-capillary column packed with Perseptive Biosystems POROS 10 R2. The fritted end of the column was inserted into the needle of the electrospray ion source on a Finnigan TSQ-700. The HPLC pump was programmed to ramp the organic phase gradient from 0 to 80% B in 30 minutes. Automated tandem mass spectra were acquired using a program written with the Finnigan Instrument Control Language (ICL). The program selects precursor ions from the MS scan when the intensity and signal to noise ratio exceeds specified values. Doubly charged species were assumed, therefore the collision offset and the mass range could be calculated for the product ions. The acquired tandem mass spectra were searched using the program of Eng and coworkers(1) against the OWL database v25.2 (100909 entries) which is a nonredundant database containing sequences from Genbank (NCBI), Protein Information Resource (NBRF) and NRL (Brookhaven National Laboratory).

Figure 1. shows the result of the search from the OWL database identifying the $(M+2H)^{2+}$ ion at m/z 813.9 as a peptide belonging to the ras2 protein. One other tandem mass spectrum was matched to a sequence from the ras2 protein and several other masses that were not selected for product ion scans fit the predicted masses of the tryptic fragments. Co-eluting peaks were present in the ion chromatogram that did not belong to the ras protein. The database search identified a yeast ribosomal protein from a doubly charged peak

43rd ASMS Conference on Mass Spectrometry and Allied Topics

at m/z 656. This methodology illustrates one of the consequences of the analysis of protein purification from cell lysates. Other proteins may bind non-specifically to the antibody or the agarose leading to multiple proteins being isolated. The presence of ras was substantiated even in the presence of a mixture of proteins. Approximately 6 kDa of the ras2 sequence was found in analysis of the MS/MS data and cursory inspection of the MS data.

The objective of this experiment was to demonstrate a new approach for the analysis and identification of immuno-purified proteins. To demonstrate this approach the ras gene product was used as the target for immuno-affinity purification from a whole cell lysate. The enzymatically digested proteins were analyzed by tandem mass spectrometry followed by database searching and protein identification with the MS/MS data.

Protein Database Searching with Ion Trap MS^n data

by Jimmy K. Eng, John R. Yates III, and David M. Schieltz

INTRODUCTION

Recent developments in the analysis of mass spectrometry data using protein databases has provided a powerful new tool for protein identification. Expansion of the databases as a result of the various genome projects will provide an important set of tools for the analysis of data from biological experiments. The ability to directly correlate fragmentation patterns from mass spectrometers to sequences in protein databases without extensive data evaluation will speed the interpretation of results and aid biological studies.

Application of the database searching program SEQUEST for protein identification and peptide sequencing utilizing spectra generated from MS^3 and MS^4 experiments conducted on an atmospheric pressure ionization quadrupole ion trap mass spectrometer is demonstrated. Such instruments are capable of multiple stages of mass spectrometry and can generate fragment ions that cover a significant portion of the sequence of a polypeptide or protein. This approach allows for the identification of polypeptides which are too large or highly charged to fragment in tandem mass spectrometry experiments.

EXPERIMENTAL

Spectra were acquired on a Finnigan MAT LC/Q ion trap mass spectrometer (San Jose, CA). Peptides were infused directly into the electrospray ionization source at a concentration of 2.5 pmol/mL in 1:1 0.5% acetic acid:methanol. Precursor ions were isolated in the ion trap and resonantly excited. A fragment ion was then chosen for further fragmentation.

RESULTS

MS^4 Example 1. An MS^4 experiment was conducted on an $[M+4H]^{+4}$ ion at m/z 872. The molecular weight of the peptide was 3482.8 u. Initially, an MS/MS spectrum was acquired for a precursor ion at m/z 872. From the MS/MS spectrum of m/z 872, a fragment ion at m/z 842 was selected for a subsequent stage of MS/MS analysis. A third MS/MS spectrum was generated by selecting an ion at m/z 1450 which was a fragment ion of m/z 1085 which in turn was a fragment ion of the original m/z 872 precursor ion. The three spectra were combined by summation and used to search the OWL composite protein database (version 25.2). Out of the 100,909 sequences in the OWL database, 503,043 peptides matched the input $[M+H]^+$ mass of 3483.8 within the specified ±1 u mass tolerance. The correct sequence HSQGTFTSDYSKYLDSRRAQDFVQWLMNT from glucagon was ranked in the top position. The (abbreviated) SEQUEST search results are displayed in Figure 1.

MS^3 Example 2. An MS^3 experiment was conducted on an $[M+3H]^{+3}$ ion at m/z 822. The molecular weight of the peptide was 2465.7 u. An MS/MS spectrum was generated from the precursor ion at m/z 822. The resulting fragment ions at m/z 768 and 505 were then selected independently for subsequent stages of MS/MS analysis. The combined spectrum, generated by summing the three spectra, was used to search the OWL database with the search results shown in Figure 2. Of the 100,909 sequence entries in the database, 518,504 peptides matched the input mass of 2466.7 within the specified mass tolerance of ±1 u. The correct peptide RPVKVYPNGAEDESAEAFPLEF from Corticotropin/ACTH was ranked in the 2nd position of the output list. Figure 3 shows the search results from SEQUEST when searching with the spectrum from a just the single stage of MS/MS on the precursor ion at m/z 822. For this case, the correct peptide was identified as the top ranked sequence.

CONCLUSION

The current results indicate that SEQUEST in conjunction with MS^n experiments can be an effective means of analyzing peptides that are not well suited for tandem mass spectrometry experiments. Particularly encouraging is the positive result achieved when searching with only the single stage of MS/MS of the ACTH precursor ion. Given that SEQUEST was able to correctly identify the peptide with the limited fragment ions from only one MS/MS stage, improvements in acquiring the MS^3 and MS^4 spectra and exploring better methods of combining the multiple spectra into one spectrum should make this method even more promising for protein sequencing. Additionally, tailoring the search algorithm to specifically consider the fragmentation patterns associated with MS^n spectra will also improve results.

ACKNOWLEDGMENT

Mass Accuracy Requirements to Map Proteolytic Peptides from a Protein

Pao-Chi Liao[1,2], Holly Rockensuess[2], John Allison[1], and Douglas A. Gage[2]
Department of Chemistry[1] and Biochemistry[2]
Michigan State University, East Lansing, MI 48824

Mass spectrometry has been an important tool for the identification of the proteolytic peptide fragments derived from enzymatic or chemical cleavages of a protein. If the amino acid sequence of a protein is known and the protein is cleaved by a protease or reagent with known specificity, then a set of possible proteolytic peptide fragments can be calculated, and the mass measurements of proteolytic peptides derived from this protein can be compared to the set of postulated peptide fragments. This analysis, "peptide mass mapping", allows rapid characterization of the amino acid sequences of proteolytic peptides by the use of mass spectrometric methods. This information can be used to confirm cDNA-derived protein sequences, and to locate the site(s) of post-translational and/or other chemical modification(s) of a protein (e.g., phosphorylation [1]). A computer program, "MSU MassMap", was written using Microsoft® Visual Basic™ for Windows™ to calculate the average masses of possible proteolytic peptide fragments from a protein, and the average m/z value of the mass spectral peak for the corresponding $[M+H]^+$ ion. The program computes masses for peptides from not only complete, but also partial digestion.

A procedure has been established to evaluate the likelihood of ambiguity in sequence assignments which may arise in peptide mass mapping analysis. All of the possible proteolytic peptides from a protein were calculated and sorted according to their mass values. Each adjacent pair of peptides were used to calculated the difference in mass values relative to their mass average, Δ_i/m, where Δ_i = (mass value of $peptide_{i+1}$ - mass value of $peptide_i$), m = (mass value of $peptide_{i+1}$ + mass value of $peptide_i$)/2, and $peptide_i$ is the ith peptide in the list. Each Δ_i/m for adjacent peptide fragment pairs was compared to the given mass accuracy of the mass spectrometer to determine if there is a potential ambiguity in sequence assignments. For example, given the mass accuracy of ±0.1% (1 ppt) of an instrument, if $\Delta_i/m < 0.2\%$ (2 ppt), then there is a potential ambiguity in sequence assignments for these two peptides. All the Δ_i/m were calculated and categorized into five subcategories: I. $\Delta_i/m =< 2$ ppm, II. 2 ppm < $\Delta_i/m =< 20$ ppm, III. 20 ppm < $\Delta_i/m =< 200$ ppm, IV. 200 ppm < $\Delta_i/m =< 0.2\%$ (2 ppt), and V. 0.2% (2 ppt) < Δ_i/m. Each category corresponds to a different mass accuracy requirement. The distribution of Δ_i/m in five categories was used to predict the likelihood of ambiguity in sequence assignments in the peptide mass mapping analysis of a protein.

It is expected that a large protein will generally have a larger number of possible proteolytic peptides than a smaller one. Since more peptides are likely to be found within a particular mass range, this might require increased mass accuracy for peptide

mass mapping. To evaluate how protein size affects the mass accuracy requirement, 200 protein sequences were obtained from the "Entrez" database and analyzed to evaluate the likelihood of ambiguity in sequence assignments. The molecular weights (MW) of the proteins range from 3-140 kDa. The protease used was trypsin and only proteolytic peptides within the mass range 500-5000 Da was considered. The calculation includes incomplete digestion products. The 200 proteins are grouped by their sizes (MW). The result shows that 0.1% (1 ppt) mass accuracy is generally suitable to perform peptide mass mapping for proteins with MW's in the range of 3-20 kDa. For 20-70 kDa proteins, a mass accuracy of 100 ppm may be necessary. For 70-140 kDa proteins, 10 ppm mass accuracy may be required.

If the proteolysis reaction is complete (all the cleavable sites are cleaved by the protease or chemical reagent), then the number of possible proteolytic peptides is greatly reduced. When the mass range of 500-5000 Da and trypsin are considered, our calculations show that 0.1% (1 ppt) mass accuracy is suitable to perform mass mapping for proteins with MW's ranging from 3-70 kDa in most of the cases, provided the proteolysis reactions are complete. For 70-140 kDa proteins, a mass accuracy of 100 ppm may be necessary in some cases. Incomplete proteolysis (i.e., some cleavable sites are not cleaved) is not uncommon. It would be advantageous in peptide mass mapping that a method is developed to ensure complete digestion. The absence of partial proteolytic fragments will allow mass spectrometers with modest (0.1%) mass accuracy to be employed for unambiguous peptide mass mapping of larger proteins. Some proteases may not be very specific in certain cases. Others, such as pepsin, have inherently less specificity. An extreme case, totally non-specific proteolysis, was considered. That is, the hydrolysis can take place at amide bonds between any two adjacent amino acid residues. When the mass range 500-5000 Da is considered, our calculation shows that none of the mass accuracies considered (from 1 ppt to 1 ppm) provides unambiguous peptide mass mapping for proteins in most of the cases (except for 3-10 kDa proteins) when the proteolysis reaction is totally non-specific.

Among the mass spectrometers available, the mass accuracy of different instruments varies. MALDI-TOF is reported to have at least 0.1% mass accuracy. A 10 ppm mass accuracy for peptides and proteins up to 5700 Dalton has been reported by MALDI-FTMS instruments [2]. From our analyses, one can predict the mass accuracy required to perform unambiguous peptide mass mapping in different situations. When dealing with a specific protein, one can use the computer program developed to evaluate the required mass accuracy for peptide mass mapping.

Protein Identification by Database Searching: A Bayesian Algorithm

Wenzhu Zhang and Brian T. Chait

The Rockefeller University, 1230 York Ave., New York, NY10021

The identification of isolated proteins is an important requirement for many biological investigations. Database searching using mass spectrometric peptide mapping has proved to be a sensitive and facile method for protein identification [1,2,3,4,5]. The method involves comparison of masses obtained in peptide mapping experiment with the masses calculated by applying the appropriate cleavage rule to each protein in a protein sequence database. The objective of this work is to use a Bayesian algorithm to rank the candidate proteins with probability.

Application of Bayes' Theorem: $P(k|DI)=\frac{P(K|I)P(D|KI)}{P(D|I)}$, where k is the hypothesis that the sample protein is protein k (protein k is an entry in the protein sequence database), D is data from a mass spectrometric peptide mapping experiment, I is background information (including all assumptions and prior information), $P(k|DI)$ is posterior probability for the hypothesis k in view of data D and background information I, $P(k|I)$ is prior probability for the hypothesis k given background information I only, $P(D|kI)$ is likelihood probability for data D given the hypothesis k and background information I, and $P(D|I)$ is a normalization constant.

Database of peptide fragments of proteins: The peptide database is derived from the OWL protein sequence database (> 80,000 proteins). For each protein k in the protein database, both complete and partial proteolysis digestion products are included in the peptide database. The partial peptide fragments contain up to 5 contiguous complete fragments. We found that extended partials are present in many digestions and the presence of the partials can provide useful information for the protein identification.

Probability calculation: Posterior probability for the sample protein to be protein k given data D and background information I has been derived by logical inference [6], and is given by

$$P(k|DI) \propto P(k|I)\frac{(N-r)!}{N!}\prod_{i=1}^{r} g_i\left(\frac{m_{max}-m_{min}}{2\sigma}\right)^r \exp\left[\frac{r}{2}-\frac{\sum_{i=1}^{r}(m_i-m_{i0})^2}{2\sigma^2}\right]$$

with normalization condition of $\sum_{k}^{database} P(k|DI)=1$, where the assumption is made that the sample protein exists in the protein database. In the above formula, N is the number of peptides generated in computer-simulated fragmentation of protein k, r is the number of hits (matches between the measured and calculated peptide masses), g_i is the multiplicity of the ith hit, $(m_{min}-m_{max})$ is the range of mass measurement, σ is the standard deviation of the mass measurement, m_i is the measured mass of the ith hit, and m_{i0} is the calculated mass of the ith hit.

The ranking of the candidate proteins is based the values determined for their posterior probability $P(k|DI)$.

Discussion: *Using data from multiple digestions:* When existing data are not sufficient to identify a sample protein, a different enzyme/chemical can be used to generate more data. The Bayesian algorithm naturally incorporates the new data into the inference for protein identity. In this situation, the prior probability before evaluating new data is the posterior probability for the old data. *Identification of components of a protein mixture:* The algorithm also allows identification of individual proteins in mixture of proteins. For this purpose, the protein sequence database is expanded to include entries that are combinations of single protein sequences.

Applications of a New Algorithm for Deconvolving Multiply Charged Spectra

V. J. Barclay, R. F. Bonner, *PE SCIEX, 71 Four Valley Drive, Concord, Ont. Canada, L4K 4V8*

L. K. DeNoyer, J. G. Dodd, *Spectrum Square Associates, 755 Snyder Hill, Ithaca, N.Y. 14850*

and D. N. Nguyen *Eli Lilly & Company, Lilly Corporate Center, Indianapolis, IN 46285*

Samples ionized by Electrospray Ionization (ESI) and IonSpray™ produce ions in a variety of charge states. For small molecules (< 3000 amu) only a few charge states are generated and the spectra can be interpreted with ease, but for large molecules (>10,000 amu) many charge states are generated and the resulting spectra can be difficult to interpret. This is especially true if the sample is a mixture or the spectrum is noisy.

Assuming Bayesian statistics and a Poisson noise process, we have developed a new algorithm, BioSpec Reconstruct, that uses maximum likelihood techniques to reconstruct the most probable zero-charge spectrum from multiply charged ion spectra.

In this report we briefly describe the new algorithm and the user interface and show that optimizing the weighting factor for the charge states can allow small signals to be accurately deconvolved even in the presence of larger signals. We show applications of the algorithm in a variety of areas of biological importance, such as: the determination of trace impurities in recombinant proteins, C-terminal protein sequencing, determination of glycoform heterogeneity, and the analysis of complex protein mixtures.

The algorithm is fast and effective even with low signal/noise data and with spectra from complex mixtures. The algorithm has been incorporated into our new data processing program so that the user is able to invoke the deconvolution algorithm directly and then manipulate the resulting zero-charge spectrum using standard tools such as thresholding, smoothing and centroiding.

Prior to maximum likelihood processing, the program automatically generates a charge distribution envelope (CDE) from the data; the user can modify this if required to optimize the processing. The CDE, which is shown as the dashed line superimposed on spectrum (a), acts as a weighting factor in the algorithm.

BioSpec Reconstruct is based on Bayesian statistics, which relates the conditional probability of two events.[1] In the case of a real-life spectrum, Bayesian statistics assumes that both the "ideal" or true unknown spectrum **u** and the equally unknown image noise **n** are *jointly most probable*. A Bayesian treatment of the zero-charge spectrum problem seeks both the true spectrum and the image noise spectrum which will maximize the joint probability P(**u**|**n**). The use of the standard multinomial probability law for obtaining the *a priori* probability of the object means that the entropy of the system is taken into consideration. The inclusion of further *a priori* knowledge about typical ESI spectra leads to "cross entropy;" and the method used is a Maximum Cross-Entropy method (MCE).

To give a context to the use of maximum cross entropy theory in spectral analysis, consider the basic relationship of the true or underlying spectrum **u** to its noisy recorded spectrum **y**:

$$y_m = \sum_k s_{mk} u_k + n_m = a_m + n_m. \qquad [1]$$

Here, s_{mk} is a point-spread function positioned around point k, n_m is the noise associated with each point m, and a_m is the noise-free signal image.

Let P(**u**|**y**) represent the probability of the set of **u**, given the set **y**. From a Bayesian perspective, the underlying "true" spectrum is an hypothesis whose probability, P(**u**|**y**), given the observed spectrum {**y**}, is equal to the ratio of the true and observed spectra, P(**u**) and P(**y**), and the probability (or likelihood) of data **y**, given the hypothesis **u**, P(**y**|**u**):

$$P(\mathbf{u}|\mathbf{y}) = P(\mathbf{y}|\mathbf{u})\,\frac{P(\mathbf{u})}{P(\mathbf{y})} \qquad [2]$$

Standard methods set P(y) = 1, and take the logarithm of equation [2]:

$$\ln P(\mathbf{u}|\mathbf{y}) = \ln P(\mathbf{u}) + \ln P(\mathbf{y}|\mathbf{u}). \qquad [3]$$

For the terms on the RH side of this equation, we assume multinomial statistics and Poisson noise characteristics; the latter substituted into Eq.[3] gives the maximum entropy[2] component. When the *a priori* estimate of the true spectrum **u** is not uniform, but instead is {Q_m}, then the term ln(P(**u**)) in Equation [3] should be replaced with the cross entropy function.

The algorithm assumes an initial uniform guess for the true spectrum, $u_m = Q$. An estimated image is created through the relation $y_m = \sum_k s_{mk} u_k$, the estimated image is compared with the data, and then our guess for u_m is updated.

Many different algorithms are used in image processing for updating u_m. Finding an efficient algorithm is the art of the method. The difficulties of this image restoration problem are all buried in the definition of the point-spread function s_{mk}. Our point-spread function is simply a classical multiple-image transformation. Classical imaging, without distortion, is either an enlargement, or a reduction, and can be described by the affine class of transformations.[3]

The most challenging ESI spectra to deconvolve are those which have several components present in small amounts such as in Figure (a), the spectrum of myoglobin which was partially digested using a carboxypeptidase mixture.[4] Figure (b) shows its deconvolution; note the small peaks are real. The mass differences between successive peaks can be attributed to the loss of the amino acid residues as noted. By comparison, the zero-charge spectrum found using an additive reconstruction technique would have too many spurious peaks which, due to the presence of other trace constituents, cannot be properly filtered.

Since the carboxypeptidases remove residues one by one from the C-terminus, we read backwards from the main peak in the figure to see that the sequence is ...LGFQG. This sequence fragment can then be used as input to a protein database searching algorithm. Even the small portion "LGFQG" is enough, in this case, to effect a rapid identification of myoglobin, the protein being digested.

Introduction

"...our methods of transmitting and reviewing the results of research are generations old and by now totally inadequate for their purpose."
V. Bush, The Atlantic 176 (1) (1945) 101.

Fifty years has passed since this was written and not much has changed in the way scientists obtain information. However, presently there are tools available to completely change the way scientific results are disseminated and make it easier to obtain information. For example, experiments are being made with electronic journals and the amount of information available from a wide variety of databases over the Internet is growing fast. The success of making a global scientific library easily available from anywhere is dependent upon the development of databases for the different types of scientific data as well as on the interconnection of all databases. Our contribution to this development is MassBank - a database for mass spectra of proteins.

Previously, no public database existed for mass spectra of proteins. However, there exists a large body of mass spectrometric data on proteins, including molecular masses, peptide maps generated by enzymatic digestion of proteins, as well as mass spectrometric fragmentation patterns of component peptides. A major proportion of the existing mass spectral data is never published and therefore inaccessible to the public, even though these mass spectra contain valuable information. Therefore, we have developed a prototype for a publicly accessible database where both published and unpublished mass spectra can be submitted and where the information can be accessed through a Word Wide Web server.

Description of the Database

A prototype has been developed of a database for mass spectra of proteins, enzymatic digests of proteins, and mass spectrometric fragmentation patterns of peptides. This database includes the mass spectra of proteins purified from natural sources (with the primary structure fully known, partially known, or unknown) and also mass spectra of recombinant proteins.

Tools are provided to search and analyze the mass spectra in the database on-line or to download the data and analyze it on the user's computer.

To enhance the utility of the database, a wide range of information about proteins from other databases are being made easily available during the process of examination of the mass spectral data. This information includes amino acid sequences, post-translational modifications, three dimensional structures, literature references, and positions on two dimensional gels. Tools are also provided to the primary structure of proteins with reference to the mass spectra in the database. These tools allow for the analysis of enzyme digests, amino acid compositions, hydrophobicities, post-translational modifications and mass spectrometric fragmentation.

The database is publicly accessible through a Word Wide Web server (URL http://chait-sgi.rockefeller.edu/). All submissions, searches and analysis of the mass spectra and protein sequences are done by filling out hypertext markup language (HTML) forms or through clickable maps. Figure 1 shows the interface for spectrum analysis. Simple operations on the mass spectra as zooming and "clicking" on peaks to obtain their mass are supported.

Conclusions

It is anticipated that within a few years the DNA sequence of the human genome will be known and this will leave a vast amount of protein chemistry to investigate. Mass spectrometry has the possibility to play an important role in the charcterization of proteins and therefore it is important to collect and organize the mass spectrometric knowledge. Therefore, we have developed a prototype for a database for protein mass spectra.

Introduction

This study involves the use of a single quadrupole, benchtop LC/MS system (Perkin Elmer - SCIEX API 100) for the characterization of protein tryptic digests. Three LC/CID/MS examples are presented demonstrating:

- The identification of sites of glycosylation in fetuin
- The identification of sites of phosphorylation in ß-casein and
- Protein characterization using rapid high/low orifice scanning and a sophisticated, automated data base searching routine.

These analyses involve the LC/MS of protein tryptic digests while simultaneously combining different polarity, scan and ion source conditions in a continuous loop. We call such experiments 'funky ramps' or mixed-mode experiments. This new functionality enables the sensitive, discrete and simultaneous determination of marker ions indicating sites of glycosylation or phosphorylation, the peptide molecular weight and the partial amino acid sequence, in a **SINGLE** LC/CID/MS analysis.

Experimental Conditions

For all analyses an ABD 140B syringe pump delivered a gradient from 0 to 40 % B in 30 minutes (A= 100% aqueous, 0.1% TFA; B= 100% ACN, 0.1% TFA) at 40 µL/min into the IonSpray source. An Aquapore ODS300 1 x 100 mm LC column was used. Low energy (normal declustering) CID/MS experiments were performed with an orifice-to-skimmer potential difference of 40 V, while high energy CID/MS experiments were performed with an orifice-to-skimmer potential difference of 90 V for positive ion mode and -200 V for negative ion mode.

Identification of Sites of Glycosylation - Fetuin

Methods have been developed to facilitate the location of glycopeptides in the LC/MS of tryptic digests of glycoproteins involving the observation of glycan marker fragment ions at m/z 204+ (HexNAc+) and m/z 366+ (Hex-HexNAc+)[1]. For the data described here these two fragment ions are produced by CID of glycopeptide molecular ions between the orifice and skimmer lenses. The present example involves the LC/CID/MS of a Fetuin digest while undertaking two experiments in a SINGLE LC/MS analysis: 1) full scan 400 - 3000 u under normal ion source conditions and; 2) **TRUE** SIM of the 204+ and 366+ glycopeptide marker ions under high energy ion source conditions. The former provides molecular weight information and the latter identifies where the glycopeptides elute. The two TIC's are shown in Figure 1 with the bottom trace indicating three major glycopeptides eluting at 21:52, 29:30 and 31:00 min respectively.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

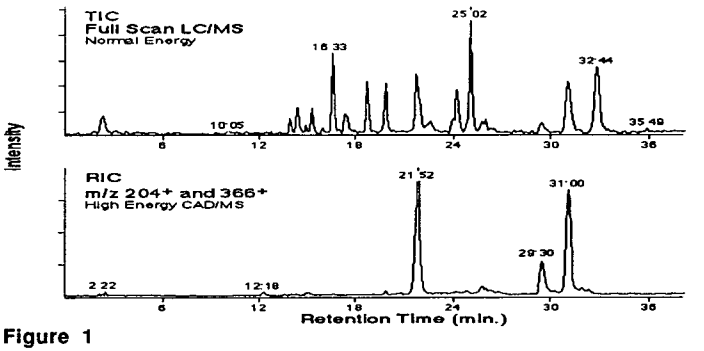

Figure 1

Identification of Sites of Phosphorylation — ß-Casein

Similar results were obtained for phosphorylated proteins when a digest of ß-Casein was analyzed by a SINGLE LC/MS analysis while two MS experiments were run in a consecutive loop. The two experiments were: 1) full scan 400 - 3000 u in the positive ion mode under normal ion source energies providing molecular weight information and; 2) SIM of m/z 79 (the PO_3^- marker ion indicating sites of phosphorylation)[2] in the negative ion mode, under high ion source energy conditions. This LC/MS run required a polarity reversal between each experiment which was performed because peptide molecular ions are usually more abundant in the positive ion mode while the marker ions are only observed in negative ion.

Protein Characterization Using Rapid High/Low Orifice Scanning – Cytochrome C

The analysis of proteolytic digests by LC/CID/MS is an important method for characterizing proteins. Once again, the ion source energy (ion-sampling orifice potential) is varied between high and low energy conditions with alternating scans; for both experiments full scan (300 - 3000 u) data is acquired. The two experiments (high and low energy) show almost identical TIC traces, as one would expect.
A plot of the IonSpray/MS spectra shows that the low energy (normal orifice potential) spectrum exhibits primarily molecular ions and the high energy experiment shows prominent fragment ions, as well as unfragmented precursors.
When the molecular weight of a tryptic peptide from the low energy conditions along with the *sequence tag*[3] from the high energy, fragmenatation conditions are entered (automatically using scripting) into the PeptideScan protein database search routine a list of known proteins containing the peptide and sequence tag is produced. For this analysis the sequence of 6 Cytochrome C variants were identified by searching the Swiss Prot. data base.

Interpretation of Peptide CID Spectra using Artificial Neural Networks

R. E. Scarberry, Z. Zhang, and D. R. Knapp
Medical University of South Carolina, Charleston, SC 29425

One of the major advantages in the use of high energy collision-induced dissociation (CID) tandem mass spectrometry for the determination of peptide sequence over the more traditional method of Edman degradation is the very short data generation time, which is typically only a few minutes. However, without some automated means for evaluating the data sets collected, the time saving is of little consequence since subsequent manual interpretation of the data can require hours to days of an experienced expert's time. The development of a reliable computerized system for rapid interpretation of CID spectra is, therefore, essential to exploiting the time saving advantage of the mass spectrometric approach to peptide sequencing.

The most extensively used program described to date[1] generates sequences in a stepwise fashion using a rule base of fragmentation knowledge for the evaluation of candidate sequences. A recently reported method[2] relies on classifying peaks using a pattern-based scoring function. The latter algorithm, by mathematically converting the classified ions to corresponding y ions, generates an idealized spectrum of only y type ions, which it then interprets in a conventional manner. Our program combines elements of both approaches with the use of artificial neural networks to classify ions. Two backpropagation networks are utilized: the first classifies peaks as being, or not being, one of the common ion types (a, b, c, d, v, w, x, y, z+1), while the second network assigns peaks to specific types. The classified peaks are then used to generate a transformed spectrum of y ions from which sequences are derived and evaluated iteratively using a fragmentation rule base.

The prototype algorithm has been tested on a set of CID spectra of forty-three reference peptides (containing approximately 2750 peaks). For twenty-six (60%) of the spectra, the correct sequence received the top ranking each time they were tested, while thirty-five (81%) ranked in the top five sequences each time they were tested. The program also successfully differentiated between the isomers isoleucine and leucine 64% of the time based on the observed masses of d and w ions. Work is underway to further explore this approach by training the neural networks on much larger data sets and by refining the rule base. This method offers the potential for an effective new approach to peptide CID spectra interpretation which could facilitate peptide sequencing by tandem mass spectrometry[3].

Overall Program Structure

The sequencing program display as it appears in the X/Motif environment. In the actual screen display, the peaks in the upper spectrum are color coded to indicate the ion type as determined by the neural network module.

Peak Matching Techniques for Characterizing Protein Heterogeneity

Kenneth L. Johnson[1,2], Melissa R. Snyder[2], Andy J. Tomlinson[1,2]
Franklyn G. Prendergast[2,3], Stephen Naylor[1,2,3,4].

[1]Biomedical Mass Spectrometry Facility, [2]Department of Biochemistry and Molecular Biology, [3]Department of Pharmacology, [4]Clinical Pharmacology Unit, Mayo Clinic, Rochester, MN 55905

The analysis of proteins by electrospray mass spectrometry often reveals mixtures of related species. The mass differences between species can often be linked to post-translational events such as phosphorylation, glycosylation, etc. While the mass shifts caused by these processes are well defined, ambiguity in the assignment of a mass difference between species can leave some question of what modification is being observed.

Sector and FT-ICR instruments have been used to mass measure individual isotopes of proteins as a means of more accurately measuring the protein's molecular weight[1-4]. Until recently this approach carried an increasing degree of uncertainty in assigning the all ^{12}C isotope as the molecular weight of the protein increased[4]. An alternative to isotopically resolving the protein is to centroid the isotopic envelope of one of the charge states.

We have adapted peak matching software from our Finnigan MAT 900 sector instrument to more accurately measure the mass differences between protein species. This approach centroids the isotopic envelopes of two species at a medium resolution (typically 2000-5000). A reference M_r value is assigned to one of the species which is used to calculate the M_r of the other specie. The peak match method requires 3 parameters: **1)** the m/z of the ion being measured as an unknown, **2)** the m/z of the ion to be used as the reference, and **3)** a M_r value (either experimental or reference) to be associated with the reference ion Initially a full scan spectrum is acquired to select these parameters before performing the following peak match steps:

- Sum and store 5 scans of the reference ion in Peak Match Register 2.
- Sum and store 5 scans of the unknown ion in Peak Match Register 1.
- Calculate the theoretical m/z value for the reference ion using the assigned M_r value.
- Calculate the unknown ion and convert it's m/z to an M_r value using the reference ion.
- Calculate the mass difference between the two M_r values.

These steps are repeated to calculate a mean and std. dev. for replicate measurements.

Figure 1 and Table 1 show results from this method using Ribonuclease B as a model. Experimental results were within +/- 0.2 mass units of published values with one exception

The method was applied to the analysis of a glycosylated protein, EDN, which is isolated from human eosinophils. Figure 2 and Table 2 show the spectrum and peak match results for this sample. Components of the sample differed by masses corresponding to known carbohydrate moieties.

This technique, which has been successfully demonstrated on proteins with well characterized classes of heterogeneity, is expected to be a valuable aid in characterizing the nature of less predictable systems such as adduction of xenobiotics to proteins.

IDENTIFICATION OF PROTEINS USING LC/MS/MS ON AN ION TRAP MASS SPECTROMETER

William S. Lane, Adrian P. Land*, Ian Jardine*, Mark E. Bier*
Microchemistry Facility, Harvard University, Cambridge MA 02138
*Finnigan MAT, San Jose, CA 95134

A principal function of a Protein Core Facility is to provide primary peptide and protein sequence information in a timely and an accurate manner, often when the sample is available only in very low amounts. It has been our experience that the majority of protein samples sent to the facility for sequence analysis are expected to be novel by the submitting investigator. In contrast to as recent as two years ago, more than 50% currently are found to have sequences already recorded in the protein databases. As the content of the databases continues to increase at a high rate, the proportion of samples containing novel sequence can be expected to decrease significantly.

Experiments were carried out on a new LC/MS/MS ion trap mass spectrometer (*LCQ*, Finnigan MAT, San Jose, CA) to determine its suitability for the rapid screening of samples for known sequence. For pure samples, peptide molecular weight (M.W.) information from a handful of peaks in a map can be sufficient to identify a protein (e.g., Pappin et al. '93). However, for mixtures of proteins, the sequence-specific information generated by MS/MS is required to identify each component within the mix (Yates et al. '94).

The ion trap is used as an intelligent on-line detector for peptide mapping experiments. The instrument was programmed for a three stage data dependent acquisition. Full scan MS data (unit resolution) are collected until the base peak ion exceeds an intensity threshold; this triggers acquisition of a ZoomScan (resolution sufficient to resolve isotope peaks for up to +4 ions), and then, a full scan MS/MS spectrum. (unit resolution), Figs. 2(a-c). Thus, for each chromatographic peak, the detector automatically determines the charge-state of the ion, and hence an accurate M.W., and then generates an MS/MS spectrum. The data can then be analyzed using database search algorithms, allowing identification of all major, known proteins present in the sample. M.W. information was analyzed using *MassMap* software (Finnigan MAT, Hemel Hempstead, UK) with a database built from the Swiss-Prot library. MS/MS spectra were searched against an 83,556 entry protein database (NCBI) using PepSearch (Finnigan MAT, San Jose, CA).

Enzymatic digests for several samples were analyzed using HPLC/MS/MS. Tryptic equine myoglobin was used as a reference standard, 10pmol of sample yielding 16 molecular weights and 13 MS/MS spectra during a 20 minute separation. The ensemble of molecular weight information correctly identified the protein. Nine of the MS/MS spectra yielded positive database identifications, with the remaining four spectra giving null results, no false negatives were obtained.

A user unknown sample submitted to the facility was digested with trypsin and analyzed using traditional off-line HPLC/fraction collection/Edman sequencing techniques. 10pmol of this digest was then analyzed directly using LC/MS/MS on the LCQ. M.W. data and MS/MS spectra were acquired for 10 components in a 30 minute separation. Of these, 8 spectra gave positive identifications as "26kDa Protein", more commonly known as interleukin-6 , in agreement with the more laboriously obtained off-line results. For this case also, *MassMap* was able to confirm independently the identification of the protein.

In order to mimic the challenging, but by no means rare, case, of a protein of interest buried under an excess of contaminant, a mixture of 2pmol myoglobin in 50pmol bovine serum albumin was analyzed. The base peak chromatogram for this separation is shown in Fig. 1, with an example of each scan in Figs. 2 (a,b,c). Database search results for this spectrum are shown in the table opposite. MS/MS spectra that yielded positive database identifications for myoglobin were obtained for 4 components of the mixture.

The sensitivity and specificity of this new LC/MS/MS technology will contribute greatly to the ever increasing demands made of Protein Core Facilities. Using automated technology, turnaround times for analyses of these samples can be reduced to several hours, with a corresponding reduction in the average cost per analysis.

High Sensitivity Protein Sequencing with ESI-FTMS

Ziqiang Guan, David J.Aaserud, Gary A. Valaskovic, Neil L.Kelleher, Peter B. O'Connor, Daniel P. Little and Fred W. McLafferty, Department of Chemistry, Cornell University, Ithaca, NY 14853

Low sample consumption, effective ion dissociation, and a comprehensive interpretation strategy are critical for making electrospray ionization/Fourier transform mass spectrometry (ESI/FTMS) a versatile, routine technique for protein analysis. For this, we describe advancements in: a)Achieving different and complementary fragmentation pathways using ultraviolet photodissociation for tandem mass spectrometry; b)Distinguishing b-type from y-type ions by their stabilities for more straightforward sequencing; c)A micro-ESI source with picomole volume, nL/min flow rate, and attomole detection limit.

Ultraviolet photodissociation (UVPD) is an attractive alternative for obtaining more sequence information, because infrared (IRMPD) and collisional activated dissociation (CAD) (nozzle-skimmer, SORI, SID) [1-3] produce similar sequence (b- and y- type) fragments, and leave sequence gaps. UVPD could proceed through the excitation of electronic states, while in IRMPD only vibrational excitations are involved. Fragment spectra by UVPD (193nm) of melittin and ubiquitin (8.6 kDa) show dramatic differenences from those by IRMPD and CAD. In the spectrum (Figure 1) shown here, c- and z- type ions are dominant, in contrast to b- and y- type ions by IRMPD and CAD. UVPD produces more than 12 new sequence informative fragments .

Identifying complementary pairs of fragment ions (mass sums equal to the MW value) is a key first step in sequencing; next each fragment is identified as b-type (N-terminal) or y-type (C-terminal). The IRMPD of ubiquitin [3] indicated that b-type ions are generally less stable than y-type ions. The generality of this rule for sequencing has been studied using larger proteins, such as carbonic anhydrase (29 kDa). IRMPD studies of three separate swift isolated molecular ion charge states of carbonic anhydrase, as well as IRMPD of all of the charge states of at once (Figure 2), show b-type ions from complementary pairs decomposing at shorter irradiation times. Nozzle/skimmer dissociation of carbonic anhydrase also shows b-type ions less stable than y-type. Extension of this method to identifying complementary pairs from fragments by MS^n should lead to even more sequence information.

A new approach to micro-ESI [4] combines the ease of use of the fused silica-capillary method [5] with the low flow rate (25 nl/min) of the glass capillary micro-tip approach [6]. Small inside diameter fused silica tubing (5-20 µm ID) is pulled to submicrometer dimensions (100 nm ID) using a micropipette puller with a CO_2 laser heat source, tip ID's are then increased to 1-5 µm with HF etching. These tips have a minimum volume < 200 pL and an ultra-low minimum flow rate, <0.25 nL/min. Figure 3 shows mass spectra of equine cytochrome c (12.4 kDa) in 2% acetic acid acquired with 2 µm ID tips made from 5 µm ID tubing. The top spectrum (S/N=400:1) shows isotopic resolution of the 16+ charge state for an 860 pL load of 10 µM (8.6 fmol) for a 3 s acquisition (150 amol consumed) delivered at 0.3 nL/min. The bottom spectra (S/N=60:1) shows the same charge state for a 216 pL load of 1 µM (216 fmol) for a 3 s acquisition (10 amol consumed) delivered at 0.23 nL/min. The detection limit with S/N of 3:1 is 10 amol loaded, 0.5 amol consumed.

Creatine Kinase (43 kDa) and Thiaminase I (42 kDa): Heterogeneity, Sequence and Active Site Location with ESI/FTMS

Troy D Wood, Neil L Kelleher, Daniel P Little, Einar K Fridriksson, Lorenzo H. Chen, Montie Borders, George L. Kenyon, Tadhg P Begley and Fred W McLafferty
Cornell University, Dept. of Chemistry, Ithaca, NY 14853-1301

Electrospray ionization/Fourier Transform mass spectrometry (ESI/FTMS) has emerged as a powerful method for structural analysis of proteins above 10 kDa[1]. It is applied here to enzymes larger than 40 kDa, including creatine kinase (ck) and thiaminase I.

Heterogeneity Rabbit muscle ck, which catalyzes transfer of phosphate from phosphocreatine to ADP, shows 3-band heterogeneity in isoelectric focusing gels[2] However, ESI-FTMS shows isotopic clusters in the molecular ion region (**Figure 1**, resolving power (RP) 110,000) that have isotopic peak abundances resembling those of a single component with three isozymes whose MW values differ by only 1 or 2 Da (e g., deamidations, NH_2 --> OH). ESI/FTMS of thiaminase, (**Figure 2a**; RP 70,000) which catalyzes the degradation of vitamin B_1, reveals heterogeneity invisible by SDS-PAGE Three species were observed at isotopic resolution [MW reported as $^{13}C_{26}$; 42,127.2, 42,198 1 (+ Ala), and 42,254 9 (+ GlyAla)] due to nonspecific cleavage of the first 28 N-terminal residues at three adjacent backbone sites during post-translational processing.

Sequence Nozzle-skimmer (NS) dissociation of ck molecular ions (**Figure 3**) produces many fragment ions readily predictable from the DNA-derived amino acid sequence. For thiaminase I, heterogeneous b ions were observed (**Figure 4**) and a sequence error was localized to 50 C-terminal residues out of 379 which prompted DNA resequencing Subsequent refinement yields a sequence consistent with 61 fragment ions observed with ~ 2 - 15 ppm mass accuracy

Active Site Such fragment ion data is particularly useful to identify enzyme active sites by comparison of fragmentation data sets between wild-type enzyme, and enzyme with its active site tagged by a reactive substrate mimic Fragments that shift in mass contain the tagged residue Phenylglyoxal covalently modifies an essential Arg residue of ck in the putative nucleotide binding site, and a chloropyrimidine acts as a mechanism-based inhibitor by irreversibly binding the active site nucleophile of thiaminase I (**Figure 2b**). ESI/FTMS shows molecular ions for underivatized, singly-, and doubly-derivatized ck (1.3 1), based on NS fragmentation data, the essential Arg is between residues 122-212 (380 total) Fragmentation of inactivated thiaminase I resulted in localization of the active site nucleophile to a 99 aa region (Pro^{79}-Thr^{177}) Additional efforts using tandem mass spectrometry are in progress to further define the positions of the essential Arg and the nucleophilic residue of thiaminase I

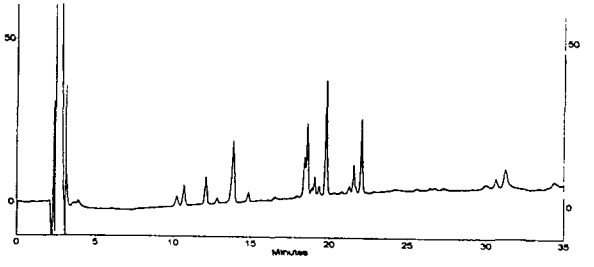
Peptide Mapping by LC/MS/MS Using a Triple Quad or Ion Trap Spectrometer

Samuel W. Baldwin[1], Ken Stoney[1], Adrian P. Land[2], Mark E. Bier[2], and Kevin Wheeler[2]
Michrom BioResources[1], Inc, 1945 Industrial Dr., Auburn, Ca 95603, and Finnigan[2] MAT, 355 River Oaks Parkway, San Jose, Ca 95134

Mass spectrometry is one of many tools for the biochemist, if properly used, it should provide more than one piece of structural information. Four common proteins (B-lactoglobin, cytochrome c, carbonic anhydrase, and myoglobin) were digested by various proteases (trypsin, endo lys-C, and endo glu-C) and used as test material for LC/MS and LC/MS/MS analysis. Common proteolytic digestion conditions resulted in partial or no digestion of some of the test proteins. RP-HPLC of proteins prior to digestion, addition of denaturants, and on-column digestion resulted in the ability to proteolyze the protein standards that were resistant to the digestion conditions.

MS and MS/MS analysis using a triple quadrupole and a LCQ benchtop MS/MS instrument provided more information than UV analysis and demonstrated the efficiency of proteolytic digestion. LC/MS analysis was used to map cytochrome C after proteolytic digestion. Automated MS/MS analysis from selected ions rapidly provided sequence information to confirm the cysteine containing peptide. A summary of MS analysis using the triple quadrupole and the LCQ benchtop ESI/MS/MS mass spectrometer is presented.

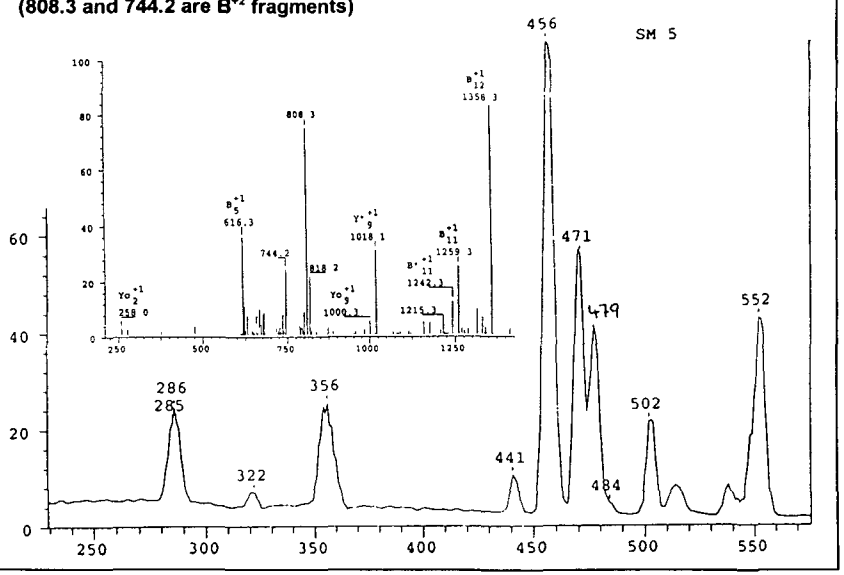
RP-HPLC of tryptic peptides of Cytochrome C in 0 1 M Tris, pH 8 1, 10% ACN UV detection at 214 nm.



Cytochrome c was digested by trypsin or endo lys-C and the peptides were separated by RP-HPLC. One-two ugs of protein were subjected to LC/ESI/MS analysis. MS analysis of the endo lys-C peptide map using the LCQ MS/MS instrument resulted in identification of all cytochrome c peptides except the N-terminal residues 1-7. MS/MS analysis of scan 502 identified the cys containing peptide (9-22). There were many incomplete digestion products. Analysis of a single MS/MS scan (479) of M/Z 804 using the LCQ pepmatch data system identified the sequence as residues 88-100. The additional lysine was located on the C-terminus of the peptide.

Multiple peptides under a single UV peak were observed in MS analysis for both endo lys-C and trypsin peptide maps of cytochrome c. Trypsin peptides were separated and analyzed using the TSQ 7000. The cysteine containing peptide 9-22 was observed prior to treatment with 4VP. After alkylation there was an absence of the 9-22 peptide with UV and base peak analysis A definitive peptide containing 1 or 2 pyridylethyl-cysteine derivatives was not observed and is under further investigation.

LC/MS of endo lys-C peptides of cytochrome C. Inset: LC/MS/MS of scan 502. (808.3 and 744.2 are B^{+2} fragments)



PROTEIN MOLECULAR WEIGHT DETERMINATION ON QUADRAPOLE AND ION TRAP SYSTEMS

Adrian P. Land, Kevin P. Wheeler, Iain C. Mylchreest, Mark Sanders, Ian Jardine
Finnigan MAT, San Jose, CA 95134

Protein molecular weight measurements were performed using quadrapole and ion trap mass spectrometers, where the ESI source on each analyzer was functionally equivalent. Relative sensitivity, mass range, mass resolution and mass accuracy (and precision) were measured. The quadrupole system used was the Finnigan MAT TSQ 7000 triple quadrupole, while the ion trap was the *LCQ* system.

In general, the results from both of these high performance systems for the analysis of proteins were similar. That is, protein molecular weights could be determined on either system at equivalent sensitivity with low pmol/uL protein sample concentrations, presented to the system by infusion or from an HPLC.At this sample level, both instruments were routinely able to determine molecular weights with both accuracies and precisions of better than 0.015%.

The 4,000 m/z mass range of the TSQ 7000 system is an advantage for the analysis of very large proteins, such as monoclonal antibodies, because the multiply charged envelope of these proteins often extend beyond m/z 2000 as shown in Figure1.

On the other hand, the ion trap has a unique higher resolution scan capability (ZoomScan) which allows increased resolution to be obtained over narrow mass ranges. An example of the separation of the alpha and beta chains of bovine and porcine hemoglobin using this ZoomScan technique is shown in Figure 2.

We have found that it is always advantageous to prepurify proteins before ESI/MS analysis to remove salts and reduce the complexity of protein mixtures. This can be conveniently carried out using reversed-phase HPLC with polymeric (PLRP-S, Michrom BioResources, Auburn, CA) columns. Following injection, the sample is washed free of salts (3mins at 2%B), followed by a rapid elution (2-95%B in 15 mins). An example of this technique is shown in the separation and molecular weight analysis of the alpha and beta subunits of bovine and porcine hemoglobin on the LCQ ion trap (Figure 3).

Both the quadrupole system and the ion trap system allow analysis of non-covalently bound complexes, as shown in Figure 4 for the analysis of the porcins heme complexes with the alpha and beta chains on the TSQ 7000 quadrupole system.

MS/MS in an Ion Trap/reflectron Time-of-flight Mass Spectrometer

Mark G. Qian, Yu Zhang, Jian Bai, and David M. Lubman

Department of Chemistry, The University of Michigan
Ann Arbor, MI 48109-1055

Introduction. There is currently a great deal of interest in the development of time-of-flight mass spectrometry (TOFMS) for the analysis of biologically important drugs, peptides, and proteins However, present limitations of this method include the lack of ion storage and MS/MS capabilities. Alternatively, the ion trap has become popular for such analysis using the electrospray ion source due to its relatively wide mass range, high duty cycle, and its ion storage and integration capabilities, which are important for sensitive detection. In addition, the trap operates at an elevated pressure (10^{-2}-10^{-4} torr), which can be conveniently used as an ion activation device to perform tandem mass spectrometry (MS/MS) through multiple collisions of the trapped ions with the buffer gas in the trap. However, there have been few reports to deal with the application of this method for peptide sequencing The main problems seem to be associated with the difficulties and complexities in terms of controlling the activation parameters and scanning high mass (m/z > 600) out of the trap without using an auxiliary radio frequency voltage, which may result in a deterioration of the mass accuracy, resolution and scan speed. In this work, we report the use of the ion trap/reflectron time-of-flight mass spectrometer (IT/reTOFMS) as a tandem mass spectrometer for accumulating, isolating, and activating multiply-charged peptide ions Single-frequency collisional activation of multiply-charged peptide ions has been studied for several characteristic peptides with m/z ranging from 700 to 1700

Methods. The electrospray-produced ions were injected and accumulated for a period of 500 ms and parent ions of interest were isolated by applying a multi-frequency AC voltage with amplitudes of 1.5-2 5 V_{pp} on the entrance endcap to eject unwanted ions. Isolated parent ions then underwent single-frequency collisional activation. The four time events, i.e., ion isolation, collisional cooling, ion activation, and collisional cooling, were controlled by a multi-step delayer/trigger which triggered a custom-built multichannel waveform generator For a typical MS/MS experiment, the four durations were typically at 20-30, 5, 20-30, and 20 ms, respectively. The first channel of the generator/combiner consists of five voltage-controlled oscillators (VCOs), while the second channel worked as a combiner to couple the single-frequency for activating isolated target ions. Since the MS/MS experiments described herein were carried out under the condition of q_z < 0.4, the corresponding β_z values of analyte ions were calculated using the approximated equation $\beta_z = [a_z + (q_z^2/2)]^{1/2}$[1] and the secular frequencies of analyte ions under a given q_z were therefore calculated from the equation $f_z = \beta_z\Omega/2\pi$.

Results. The electrospray spectrum of bradykinin, as shown in Figure 1a, is dominated by the doubly-charged peaks and a very weak singly-charged peak where the intensity is only ~10% of the former. The main reasons for this may include the intrinsic Coloumbic repulsion of the N-terminal site from the adjacent Arg[1] side chain or the relatively high pH in a 2% acetic acid solution. The lack of peaks from unwanted ions may ease the ion isolation process as evidenced in Figure 1b, which shows the spectrum of the same peptide after ejecting the singly-charged ions during the ion isolation process The CID fragmentation spectrum of bradykinin is shown in Figure 2. A low fragment ion peak intensity of

molecules with basic residues is a characteristic of low-energy CID spectra However, the CID spectrum shown in Figure 2 contains relatively complete complementary b and y pairs The lack of the doubly-charge product ions implies that one of the external protons must have been mobilized along the peptide backbone following collisional activation, even under the strong charge localization influence of the two Arg side chain amino groups. This CID spectrum shows similarity with the low-energy CID (70-250 eV) spectrum obtained on a triple-quadrupole tandem device using a moderate collisional energy[2].

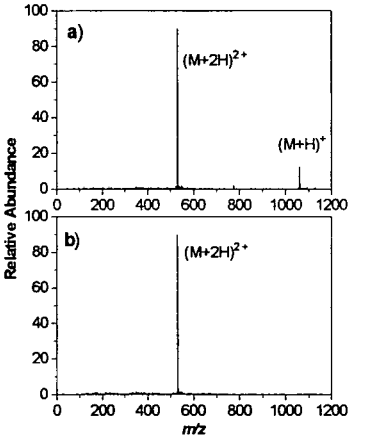

Figure 1

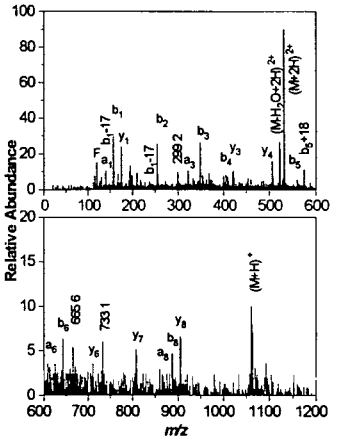

Figure 2

Conclusions. The results show that meaningful sequence information is available from this simple and relatively inexpensive tandem instrument with a sensitivity in the low picomole level Further, excellent resolution in the range of ~1,500 can be obtained for the fragment products due to the cooling effects of the buffer gas in the trap before analysis by the reTOF.

MS/MS of Alkali Cationized Peptides Using a Quadrupole Ion Trap

Tong Lin and Gary L. Glish
Department of Chemistry, University of North Carolina, Chapel Hill, NC 27599-3290

INTRODUCTION

It has been previously demonstrated by a number of groups that alkali cationized peptides dissociate by -OH transfer from the C-terminus to the adjacent residue with subsequent loss of the C-terminal residue. The ion that is generated, $(b_{n-m} + Cat + OH)^+$, may well have the structure of the peptide ion one residue shorter than the initial peptide ion. This reaction is often the dominant process for metastable ions, which suggests that the reaction is a low energy process. The quadrupole ion trap, due to the energetics and time frame of CID, often has high specificity and sensitivity for low energy processes. The purpose of this work is to investigate the potential of using the above reaction and MS^n with a quadrupole ion trap as a new approach to sequence peptides.

EXPERIMENTAL

A modified Finnigan ion trap and regular Finnigan Rev.B ITMS and ICMS-FL[1] software were used for the experiments. Peptides were dissolved in 20/75/5 H_2O/MeOH/acetic acid solution and were used at about 250 μM. Alkali cationized peptides were made by mixing ~1:5 molar ratio of peptides with sodium chloride or lithium chloride. Ions were generated by electrospray ionization. All the lenses voltages were optimized and the liquid flow rate was set at 1-2 μl/min. Helium was used as bath gas and to effect collision-induced dissociation at a typical pressure of 7×10^{-4} torr.

Leucine enkephalin was used as obtained from Sigma. Leucine enkephalin analogues: YGLFL, YGSFL, YGPFL, YGWFL, and YGRFL were synthesized in the protein synthesis lab in our department.

RESULTS AND DISCUSSION

Experiments using lithium and sodium cationized peptides on a quadrupole ion trap have demonstrated similar reactions to those observed previously on sector instruments. The major exception is that only the C-terminal residue and associated peptide linkages are involved in dissociations in any individual stage of MS/MS. It has been observed that the dissociation of $(M+Cat)^+$ ions can proceed almost exclusively by -OH transfer and loss of the C-terminal residue and only C-terminal dissociation is observed. High CID efficiency combined with the MS^n capabilities of the ion trap allow further stages of dissociation to be performed. This series of fragmentations is analogous to Edman degradation except that the cleavage occurs from the C-terminus instead of N-terminus. Figures 1 and 2 show two examples of this dissociation process. However, our preliminary results show that glycine complicates spectra by yielding many product ions when it becomes the C-terminal residue of the parent ion. This is not explained by any of the previously postulated mechanisms. It seems likely that the side chain has some kind of stabilizing effect on the -OH transfer and thus for glycine, without this stabilizing effect, other C-terminal dissociation process are more competitive.

Previously in the literature, two mechanisms have been proposed for the formation of $(b_{n-m} +Cat+OH)^+$ ions, Gross'[2] and Adams'[3]. Overall, our data including all the **a** and **b** types of ions fit Gross' mechanism more closely than Adams'. The dissociation pathway that loses the C-terminal residue is very general, and the product ions are consistent with Gross proposed mechanisms. We do not observe the loss of 88 u that was seen by Adams et al. when leucine is the C-terminal residue. That was a main piece of evidence used to support their mechanism. However, our experiments were performed with a quadrupole ion trap, in which the MS/MS conditions are substantially different from

sector instruments. Additionally, the ionization technique we used generates ions with less internal energy than the ionization technique used in previous studies. Thus it is not at all unlikely that we are sampling a different population of ions in our experiments.

This presentation shows the potential capability of using the quadrupole ion trap to sequence peptides. However, more research needs to be carried out. A broader study needs to be performed to investigate other combinations of amino acids to determine the general applicability of this approach along with its limitations.

Electrostatic interactions are long-range forces that play a key role in the function and conformation of biomolecules. We have recently developed a method[1-3] to quantitatively measure Coulomb energy through comparison of experimentally measured apparent gas-phase basicities (GB^{app}) to those calculated using a relatively simple model[2] in which charges are assigned to specific locations in the ion based on the combined effect of intrinsic basicity of protonation sites and total Coulomb energy in the ion. The magnitude of the electrostatic energy in an ion depends on ion conformation; for a given charge state, a fully denatured protein ion has less Coulomb energy than a tightly folded compact form. We present here, experimental results for lysozyme that indicate that both tightly packed and fully denatured conformations of proteins exist in the gas-phase.

Multiply protonated protein ions produced by electrospray ionization are introduced and collisionally trapped in a FTMS cell. Individual charge states of the protein are isolated with SWIFT and then reacted for increasing reaction delays. Rate constants are determined from the kinetic data for deprotonation of isolated charge states of the protein. We observe double exponentials for some charge states of the protein. For example, Figure 1 shows the decline in the 9+ charge state of lysozyme when reacted with the triethylamine (GB = 227.5 kcal/mol). These data require two rate constants for an accurate fit and suggests the presence of two stuctural isomers. From these rate constants, we assign values GB^{app} for each of the individual charge states.

Figure 2 shows the measured GB^{app} of lysozyme ions in its "native" (disulfide intact) and disulfide reduced form. Figure 2 also shows GB^{app} calculated using the "native" crystal structure and the linear conformation of lysozyme. Significant differences in the measured basicity between the "native" and reduced forms are observed for some charge states. For example, we measure a 17 kcal/mol difference in the GB^{app} of the "native" and reduced form of the 9+ charge state. Our electrostatic model indicates that this difference is consistent with calculated values for ions in a crystal structure and completely denatured conformation, respectively. In contrast, lower charge state ions formed from both these solutions have indistinguishable reactivities, indicating isomerization to a common structure which appears to be partially folded.

S-carboxymethylation of the cysteine residues in the disulfide-reduced lysozyme is used to confirm that all disulfide linkages are broken by the reducing agent dithiothreitol (DTT). The decline in the 9+ charge state of S-carboxymethylated has a rate of 1.6×10^{-11} cm^3/mol·sec and DTT-reduced lysozyme has a rate of 2.6×10^{-11} cm^3/mol·sec when reacted with triethylamine *simultaneously* in the ICR cell. Simultaneous reactions insures that both protein ions are exposed to identical base pressure. The S-carboxymethylated lysozyme appears to deprotonate somewhat slower than the DTT-reduced lysozyme which may be due to an inductive effect of the carboxymethyl group.

We are currently extending these measurements to probe the conformation of ribonuclease A, which also has four disulfide bonds, as well as proteins which do not have disulfide bonds but which have significant non-covalent hydrophobic interactions to determine if these ions have a folded conformation in the gas-phase.

STRATEGIES FOR ACCURATE MASS API LC-MS ANALYSIS OF COMPLEX MIXTURES

D. J. Pugh, A. R. Woolfitt and R. H. Bateman,
VG ORGANIC, Floats Road, Wythenshawe, Manchester M23 9LZ, U.K.

In most reports to date, high resolution magnetic sector electrospray and APCI LC-MS analyses have employed a continuous post - column infusion of a standard reference compound, such as PEG or PPG This approach is satisfactory for the accurate mass analysis of simple mixtures, but is less useful in the case of complex mixtures, which often contain unknown or unexpected components at low levels.

An alternative strategy is presented here, in which discrete post - column injections of the mass reference compound are made at approximately 10 minute intervals throughout the gradient LC-MS wide scan analyses of several tryptic digests of proteins, using the setup shown in Figure 1 All analyses were carried out using a VG AutoSpec hexapole API interface, and the instrument was scanned from m/z 1100 to 500 at 10 cycles per minute at a resolution of 5000 (10% valley). The reference material, a mixture of 0.1% (v/v) PPG 725 and PPG 1000, was injected using the complete loop filling method. Although some MS data were lost during the reference injections, the UV trace was not affected.

A horse cytochrome C tryptic digest was used to evaluate the method, and the mass accuracies obtained for the identified peptides are given in Figure 2 The tryptic peptides were mostly within 10 ppm of their expected values, confirming that the mass accuracy was satisfactory. Similar results for the cytochromes from rabbit and yeast, and for horse myoglobin, were obtained.

It has previously been suggested that the heme moiety in cytochromes exists as a radical cation under electrospray conditions, based on high resolution studies of the intact proteins, and a low resolution (1500 RP) analysis of a horse tryptic digest The 5000 RP accurate mass analyses of the horse, rabbit and yeast heme - containing peptides, figure 3, all support the earlier findings. All three ions are observed at 1 Da (~600 ppm) below the expected values based on the usually assumed $[M+2H]^{2+}$ composition, and all three are within 10 ppm of the $[M+H]^{2+}$ theoretical compositions.

More importantly, a number of subtle discrepancies that would easily go unnoticed at low resolution were also apparent in these accurate mass analyses For instance, an intense singly charged ion of mass 718 in the horse digest was of particular interest, because based on its nominal mass it would have seemed reasonable to attribute it to one of two peptides produced by one nonspecific cleavage and one tryptic cleavage. However, since its measured mass differed by 60 and 90 ppm from the two candidates, it was clearly neither of these. The ability to distiguish these relatively small discrepancies between the observed peptides and any theoretical sequences has important implications for correct sequence assignments.

By using a strategy of discrete injection of the reference material, as opposed to continuous infusion, the lower intensity components can be located easily, with significantly less chance of interference. Although part of the LC-MS run is lost, it is possible to repeat the analysis with reference injections made at different times if necessary

Quantitative Electrospray Mass Spectrometry of Oligonucleotides

Michael Greig*, Patrick Klopchin, Michael Winniman, Henri Sasmor, and Rich Griffey

Isis Pharmaceuticals
2280 Faraday Avenue
Carlsbad, CA 92008

Several types of synthetic failures or side reactions may occur during the synthesis of oligonucleotides. These products need to be identified and quantitated; in the case of GMP preparation for complete characterization of clinical samples or during synthesis of novel oligomers to research unexpected problems. The oligonucleotide's polyanionic backbone make these molecules perfect for ES-MS analysis but also results in a molecule with a strong propensity for multiple cation complexes The adduction of these cations not only reduces sensitivity, but creates multiple signals for each charge state, making it difficult or impossible to detect minor contaminants. Multiple cationic interactions have been dealt with by various means such as HPLC, dialysis, cation exchange or chemical additives. Instead of using sample and labor intensive techniques, we found the addition of a strong base can be used to suppress a majority of the salt adducts however this occasionally results in the reduction of detectable ion abundance Our solution to this loss of peak intensity is the co-addition of a second, weaker base. With both bases added, up to a ten-fold increase in peak intensity and almost complete suppression of salt adducts is observed. This allows for detection and quantitation of minor products whose composition is less than 1.5% of the total analyte.

The quantitation of oligonucleotide synthesis products including failure sequences and incompletely deprotected oligomers is presented ES-MS analysis of the various synthesis products is compared to analytical methods such as NMR, cation-exchange and reverse-phase HPLC, and capillary gel electrophoresis. Problems in the use of electrospray for quantitation of oligonucleotides are identified. These include CID loss of adenosine and pH dependent ionization differences of thymine containing oligomers

The use of chemical additives in ES-MS provides a method for characterizing and quantitating a variety of oligonucleotide synthesis products and side reactions. This method is rapid, requires minimal sample and sample preparation, and in a single assay gives results that presently require several analytical methods.

RAPID QUANTITATION OF EICOSANOIDS IN INFLAMMATION MODELS BY ES/MS/MS

Kevin L. Duffin, Alon Margalit, and Peter C. Isakson, Monsanto/Searle Research and Development, Monsanto Company, St. Louis, MO 63198

Assessment of eicosanoid levels in biological systems is important for understanding their role in cell function and pathophysiological events. Current methods of eicosanoid quantitation are limited by sensitivity, scope, or throughput. The development of a new method for eicosanoid assessment in biological samples by electrospray and tandem mass spectrometry in the multiple reaction monitoring (MRM) mode is described here. In this study, 14 biologically-significant eicosanoids and arachidonic acid (AA) were quantitated in a single sample. Complete sample analysis required two repeated injections of 5 µl with an analysis time of 1.5 min/injection. Limits of detection ranged from 0.5 pg for thromboxane B_2 (TxB_2) to 10 pg for 6-keto prostaglandin $F_{1\alpha}$ (6-keto $PGF_{1\alpha}$). The MS/MS method was used to explore eicosanoid production in 2 inflammation models: lipopolysaccharide(LPS)-stimulated human whole blood and carrageenan-challenged rat air-pouch. The most abundant metabolites in LPS-stimulated whole blood were prostaglandin E_2 (PGE_2), TxB_2 and 6-keto $PGF_{1\alpha}$; prostaglandins E_1, D_2, and $F_{2\alpha}$, and leukotrienes B_4 and C_4 were detected in lower amounts. Levels of TxB_2 and PGE_2 determined by MS/MS were similar to those obtained by immunoassay. The most abundant metabolites detected in carrageenan-challenged rat air pouch were PGE_2, 6-keto $PGF_{1\alpha}$, and TxB_2; substantial amounts of AA were also observed. The method described in this work is accurate and rapid and should greatly aid in evaluating the role of multiple eicosanoids in future biological studies.

Solid-Phase Extraction of Biological Samples. One ng of PGE_2-d_4 was spiked into each sample of 0.5 ml of the biological preparation, and solid-phase extraction was performed. The C18 cartridges (Bond Elute C18, Analytichem Int., Harbor City, CA) were pre-conditioned with 2 ml of methanol and 2 ml of H_2O. After the samples were applied, the cartridges were successively washed with 2 ml H_2O and 2 ml petroleum ether. The eicosanoids were eluted in 1 ml methyl formate. The methyl formate residue was evaporated under a dry N_2 stream and the samples were resuspended in 50 µl ethanol. The samples then were transferred to autosampler vials and stored under nitrogen at -80° C until analysis.

Mass Spectrometry. A Sciex API III triple-quadrupole mass spectrometer equipped with an atmospheric pressure ion source was used to sample negative ions produced from a pneumatically-assisted electrospray (ionspray) interface (Sciex Inc., Thornhill, Ontario). Eicosanoid standards that were dissolved in ethanol (1 µg/ml) were introduced continuously through the ionspray interface at a rate of 4 µL/min. The ionspray interface

was maintained at -4.5 kV with respect to the ion entrance of the mass spectrometer. As deprotonated eicosanoids entered the mass spectrometer, they were accelerated through a potential difference of 40 volts. Product ion MS/MS spectra of the deprotonated eicosanoid standards were acquired from 15 amu up to and including the mass of the parent ion. The argon target gas thickness was maintained at 2.3×10^{14} atoms/cm^2 and collision energies were adjusted to 30 eV with respect to the laboratory reference for this study.

Eicosanoids were quantified by delivering duplicate 5 µl injections of the samples through a 75 µm i.d. x 75 cm capillary to the mass spectrometer. A Hewlett Packard 1090 autoinjector (Hewlett Packard,Palo Alto, CA) was used to inject the samples into a 50 ul/min stream of ethanol. Injections were made every 1.5 min. The mass spectrometer was operated in the 'multiple reaction monitoring' (MRM) mode. In this mode experiments were performed using the same instrument conditions as used for the product ion MS/MS experiments. MRM experiments were performed by setting the first quadrupole to pass the $(M-H)^-$ of a selected eicosanoid while simultaneously setting the third quadrupole to pass a selected fragment ion of that eicosanoid. Up to 8 different eicosanoids were quantified in one experiment by adjusting the first and third quadrupoles to the selected masses in 0.3 sec increments/eicosanoid. The following masses were used to quantify the different eicosanoids:

Eicosanoid	Parent Ion	Fragment Ion (rel. abund.)
Arachidonic acid	303 (100)	**59(13)**
PGE_2	351 (7)	**175(10)**

Serum Albumin Determination using LC/MS with Affinity Chromatography

David M. Bunk and Michael J. Welch
National Institute of Standards and Technology
Gaithersburg, MD 20899 USA

With a goal of developing methods to produce clinical reference materials of serum proteins, we have been investigating the quantitative aspects of electrospray ionization mass spectrometry (ESI-MS) for protein analysis. Previously (1), we have demonstrated that for pure proteins (in the absence of a complex sample matrix) ESI-MS can yield excellent quantitative results, providing calibration curves linear over three orders of magnitude of analyte concentration with a precision of less than 5%.

These promising results from our model study have led us to the next stage of this project: the analysis of a protein in a complex matrix. For this stage, we chose human serum albumin (HSA) as our analyte. To introduce the serum samples into our Finnigan TSQ-700 triple quadrupole mass spectrometer equipped with an Analytica electrospray source, we used capillary reverse-phase LC/MS. LC/MS analysis of a reconstituted freeze-dried serum sample (produced by the College of American Pathologists) yielded an albumin electrospray mass spectrum distinctly different from that of a pure albumin standard (**Figure 1**). The molecular weight of the albumin from freeze-dried serum is higher and is distributed more heterogeneously than that of the albumin standard. Initially, we believed that this heterogeneous molecular weight distribution was the result of the non-covalent binding of small hydrophobic molecules to the surface of the albumin. But after exhaustive attempts to delipidate the freeze-dried serum, we were not able to "clean up" the observed molecular weight profile. We began to suspect that this distribution resulted from covalent adducts to the protein that occurred during freeze-drying This suspicion was confirmed when we analyzed a sample of fresh-frozen serum and obtained a molecular weight profile essentially identical to that of the albumin standard shown in Figure 1.

One of the important lessons that was learned from our model studies was that an internal standard was essential for good quantitation. Because our experimental plan included the use of antibody affinity chromatography to isolate the albumin from the serum matrix (to determine the effects of the matrix on quantitation), the affinity chromatography necessitated the use of a modified human albumin as an internal standard because any other protein would not bind to an anti-HSA monoclonal antibody. To prepare the internal standard, we biotinylated the one free thiol group of HSA, found on cys-34. Fortunately, because of the singularity of the reaction site, biotinylation of HSA did not alter the binding to the anti-HSA antibody and also served as an affinity tag for its facile purification using avidin/biotin on a monomeric avidin stationary phase.

Using the biotinylated HSA (bHSA) internal standard, we performed a quantitative determination of the albumin in fresh-frozen serum using LC/MS. The calibration curve obtained from this determination is shown in **Figure 2**. From this calibration curve, the concentration of albumin in the fresh-frozen serum sample was determined to be 3700±200 mg/dL. This concentration is within the

1. Bunk, D.M.; Welch, M.J. *Proceedings of the 42nd ASMS Conference on Mass Spectrometry and Allied Topics*, 1994, 1005.

expected range of normal serum albumin concentrations (3500-5000 mg/dL) but lower than the value of 4700±400 mg/dL that we obtained for the same serum sample using the conventional dye-binding assay (with bromocresol green). Additional work is planned to determine why LC/MS produces results different from the dye-binding assay and to characterize the covalent modification of HSA in freeze-dried serum.

Quantification of Pranlukast and SB 218663 in Plasma Samples Using LC/MS/MS

H.Bi, D. Lundberg, J. Pirhalla, C. McHugh and A. Marchese

SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

INTRODUCTION

Pranlukast (SB 205312, 4-oxo-8-[4-(4-phenylbutoxy)benzoylamino]-2-(tetrazol-5-yl)-4H-1-benzopyran, Figure 1a) is a potent and selective peptidoleukotriene receptor antagonist which is currently under development as a potential therapy for asthma at SmithKline Beecham Pharmaceuticals. A very simple, robust and high speed analytical method has been developed to quantify Pranlukast simultaneously with its inactive hydroxy metabolite, SB 218663 (Figure 1b) in plasma by ionspray LC/MS/MS. This new method has a very short run time of 0.6 min, which enables a single analyst to process two to three hundred clinical samples per day. This represents a major advance in terms of productivity and efficiency in quantitative bioanalysis.

EXPERIMENTAL

Sample preparation was accomplished by simple protein precipitation with acetontrile. Plasma samples (100 uL) were treated with an equal volume of acetonitrile containing SB 218658 (internal standard, Figure 1c). No evaporation process was involved. Following centrifugation (12,000 g) the supernatant was mixed with 50 uL of 10 mM ammonium acetate and 5 uL of the mixture were directly injected for LC/MS/MS analysis. Hitachi L-6000 and L-6200A HPLC pumps were used to deliver the mobile phase (10 mM NH_4OAc : acetonitrile, 25/75) to a Keystone BDS Hypersil C_{18}, 20 x 2 mm i.d. guard cartridge column at a flow rate of 250 uL/min. Column effluent was split approximately 1:4 before reaching the ionspray interface. A SCIEX API III Plus mass spectrometer was operated in negative ion and MS/MS mode. Collision energy of 30 eV and collision gas (argon) thickness of 300 $x10^{12}$ atoms cm^{-2} were employed. Data acquisition was performed using multiple reaction monitoring (MRM) in count-by-10 mode. The following precursor-to-product ion reactions, m/z 484 to 424 (Pranlukast), m/z 496 to 172 (SB 218663) and m/z 494 to 438 (internal standard), were monitored with 200 ms dwell time for each reaction.

RESULTS AND DISCUSSION

This rapid LC/MS/MS method was developed and validated to quantify Pranlukast and SB 218663 in plasma from five different species including man. The lower limit of quantification (LLQ) was 10 ng/mL for both Pranlukast and SB 218663 using a 100 uL aliquot of sample. The specificity of the assay was demonstrated by analyzing drug-free plasma samples (n>6 for each species). No endogenous interferences were found at the retention time of either of the analytes or the internal standard. The intra- and inter-assay precisions were better than 15% at all concentrations in plasma from all the species studied. Similarly, the intra- and inter-assay accuracies were within 15% of all the nominal concentrations. The recovery from plasma sample of different species was always better than 87%. This new method has been proven to be robust, sensitive, specific, accurate and reproducible. Due to the combination of a simple extraction method with a very short HPLC run time (0.6 min), the sample throughput has been significantly increased when compared with previous conventional HPLC/UV methods.

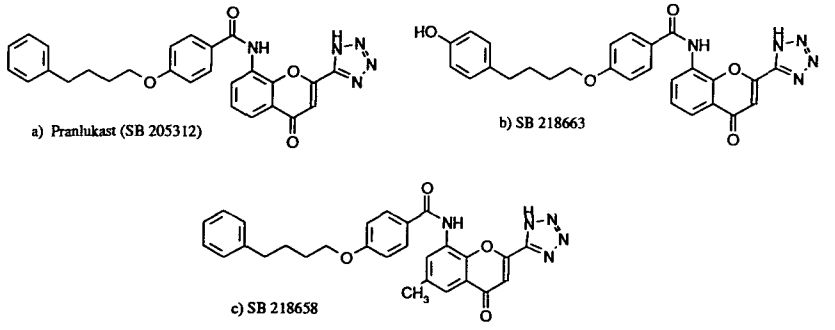

Figure 1. Chemical structures of Pranlukast, SB 218663 and SB 218658 (internal standard).

Application of Ionspray MS/MS Quantification of Beclomethasone Dipropionate

Karl S. Schorno and L. D. Winslow, Kansas City Analytical Services, 12700 Johnson Drive, Shawnee, Kansas 66216

Old analytical procedures for common drugs such as Beclomethasone Dipropionate (BDP), an antiallergic and aniti-inflammatory drug, are continually being upgraded to meet lower limits of detection necessary for todays assays. The quantitative analysis of BDP to 1 ng/mL has been reported by Girault, et. Al. (1991) using a liquid/liquid extraction and HPLC particle beam methane collision induced dissociation (CID) mass spectral analysis. We would like to report the development of a solid phase extraction HPLC API Ionspray Argon CID Mass Spectral analysis. The mass spectral analyses is fast and sensitive to less than 100 pg/mL using the ratio of analyte to internal standard. The instrument used for his assay is a PE/SCIEX API *III* + tandem mass spectrometer. The assay includes BDP, Beclomethasone 17-propionate (BMP-17) and 21-propionate (BMP-21), Beclomethasone (BOH), and Dexamethasone (internal standard). The HPLC-mass spectral analysis is carried out in less than 5 minutes per sample.

The presentation will cover only the development of the mass spectral method of the assay. Because all of the analytes are similar and give similar precursor and product ions in the ionspray analysis, only BDP will be treated in this presentation. A C18 SPE similar to that reported by Plezia (1985) was used for the isolation of the analytes from plasma.

The development of the mass spectral and HPLC conditions for the assay consists of the following:

1. Determination of Precursor Ions by Q1 Scan (full scan) infusion ionspray Mass Spectrometry
2. Determination of the Product Ions for multiple reaction monitoring (MRM) by Precursor to Product Ion infusion ionspray Argon CID Mass Spectrometry (Figure 1)
3. Determination of lower limit of quantitation (LLOQ) by HPLC-tandem mass spectrometry
4. Development a fast HPLC separation (less than 5 minutes per sample) that does not degrade the integrity of the mass spectral analysis
5. Establish linearity over the analytical range of interest (Figure 2).

A schematic of a portion of the CID fragmentation is given in Figure 3. The major product ions that are used in the MRM analysis are 521=>503 Daltons (BDP), 464=>447 Daltons (BMP-17 and -21), 408=>391 (BOH), and 392=>355 Daltons (Dexamethasone). With the exception of Dexamethasone each analyte loses water first. As noted in Figure 3, each analyte follows the same degradation path as BDP.

Linearity over the analytical range of interest is determined by a six point (in duplicate) calibration curve from the LLOQ to the highest concentration level analyzed. The calibration curve is linear for all analytes. The correlation coefficient is greater than 0.998 for each analyte quantitated.

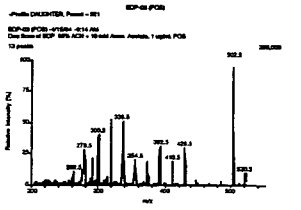

Figure 1. Precursor to Product Ion Mass Spectrum of BDP

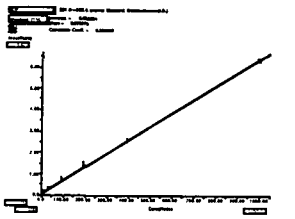

Figure 2. Linearity Curve for BDP.

Quantitative Analysis of Low Molecular Weight Biomolecules by MALDI-tof

M. W. Duncan and R. O. Lidgard, Biomedical Mass Spectrometry Unit, University of New South Wales, Sydney, 2052, Australia.

Introduction

Matrix-assisted laser desorption ionization (MALDI) mass spectrometry has proved to be an important tool in synthetic- and bio- polymer characterization, but applications for low molecular weight analytes i.e., less than 1000 Da have been restricted. Following investigations which demonstrated the general utility of MALDI (1) and our earlier work on quantitative applications (2), we have moved on to quantify low mass analytes in biological matrices.

Quantitation

MALDI has several significant limitations that become evident in quantitative applications. Variability in peak height or area, both shot-to-shot and sample-to-sample, is significant. This means that duplicate samples give widely disparate peak heights or areas, even for the same analyte loading. We have therefore employed stable isotope internal standards to 'correct' for this irreproducibity. The limited resolution available on our linear tof instrument (Finnigan Lasermat 2000) means that a minimum of three labelled atoms must be incorporated for the analogue to be a practical standard.

Results

We initiated our quantitative studies by attempting to determine the epinephrine (adrenaline; figure 1) content of a sample of phaeochromocytoma tumour tissue (a catecholamine secreting tissue). Using [$^2H_3$]-epinephrine as the internal standard (fixed concentration), a standard curve was obtained over the concentration range 2 - 1,500 pmol ($r^2 > 0.995$). A sample of tumor tissue was then ultrasonically disrupted in dilute acid containing the internal standard, and an aliquot was then examined by MALDI (figure 2). The epinephrine content of the tissue was calculated by reference to the standard curve and was found to be 26.70 ± 4.80 mg/g (c.f. the reported range of 0.08 - 50 mg/g.)

To further investigate the general applicability of the technique we have attempted to quantify some analytes in urine samples. Our preliminary results indicate that direct quantitation of abundant analytes such as creatinine and urea is possible, and that simple acid extraction of urine allows metabolites such as hippuric and α-amino-hippuric acids to be quantified. Less abundant urine components were not evident because of ion suppression as a consequence of the large excess of Na^+ and K^+ in the sample. Furthermore, we have found that some analytes are simply not amenable to MALDI analysis (as indicated by our attempts to analyse pure standards), and in our hands several relatively abundant urinary components could not be quantified. We suggest that sample clean-up/extraction, e.g., by HPLC or solid phase techniques, is a prerequisite for the quantification of most urinary metabolites, and we are exploring this avenue in more detail.

Conclusion

MALDI is a versatile ionization technique applicable to a wide range of analytes. In particular we have demonstrated that low mass analytes are generally amenable to this method, and the use of stable isotope labelled internal standards allows acceptable quantitation in some instances. Abundant urine, tissue or plasma analytes can be monitored and quantified directly (i.e.,without clean-up), but selective extraction and or work-up is required in most instances.

Quantitative Analysis of Angiotensin II by Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry

Anthony J. Nicola[1], Arkady I. Gusev[1], Andrew Proctor[1], David M. Hercules[1a], and Edwin K. Jackson[2]

Departments of: 1. Chemistry 2. Clinical Pharmacology
University of Pittsburgh, Pittsburgh, Pennsylvania 15260

a. Present address: Department of Chemistry, Vanderbilt University
Box 1822 Station B, Nashville, Tennessee 37235

Although Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry (MALDI) has been successfully applied for quantitative analysis of biomolecules[1-3], there are several problems still associated with this technique. These include sample heterogeneity, signal degradation, and insufficient linearity of the instrumental acquisition system. There are two major ways of compensating for these problems: use of an internal standard, and development of a sample preparation protocol which addresses improvement of absolute signal reproducibility. The present work focusses on sample homogeneity by application of a modified "fast-evaporation" sample preparation method[4], employing an internal standard, for quantitative analysis of Angiotensin II. The results will be compared to those obtained using the established method of sample preparation (using a multicomponent matrix[5]).

For the multicomponent matrix investigation, a mixture of 2,5-dihydroxybenzoic acid (DHB, 20 mg/mL) and 5-methoxysalicylic acid (MSA, 1 mg/mL) was used as the matrix. The matrix and analyte/internal standard (Angiotensin II: 90-6000 nM/ 1-SAR-8-Ile Angiotensin II: 660 nM) were premixed and deposited onto stainless steel substrates in volumes of 2-5 μL. For the fast evaporation technique, α-cyano-4-hydroxycinnamic acid (15 mg/mL in acetone) was deposited onto stainless steel substrates to make the matrix layer over the whole substrate surface. A mixture of matrix (α-CHCA, 10 mg/mL in 1:1 MeOH:H_2O) and analyte/internal standard (Ang. 2: 45-3000 nM/ 1-SAR-8-Ile Ang. 2: 330 nM) was then deposited onto the matrix layer.

An instrumental protocol to determine the optimum laser energy and to address the problem of signal degradation was established for the fast-evaporation method. Discarding the first ten laser shots and collecting the next forty laser single-shot mass spectra enhanced absolute signal reproducibility by 20-30%. Quantitative analysis of Angiotensin II using the fast-evaporation technique showed improved results over using a multicomponent matrix in several areas. Comparative results are presented in Table 1, and calibration curves are shown in Figures 1A and 1B. The relative standard deviations (RSD) of the analyte/internal standard intensity ratios (point RSD) were improved by a factor of three for the fast evaporation technique over the multicomponent matrix method. The RSD of the standard curve slope (slope RSD) was improved by a factor of two over use of a multicomponent matrix. Furthermore, the detection limit was lowered by a factor of two for the fast-evaporation technique. The precision of a single determination of concentration from the standard curve was improved by a factor of two in comparison to the multicomponent matrix method. We confirmed that mass resolution was

enhanced[4] by nearly a factor of two using the fast-evaporation method ($m/\Delta m$ = 2000), compared to using a multicomponent matrix ($m/\Delta m$ = 1150). The fast-evaporation method of sample preparation has thus proven itself to be a successful method for quantitative analysis by MALDI.

Table 1: Comparison of fast-evaporation and multicomponent techniques

Technique	Point RSD (%)	Slope RSD (%)	Corr. coeff.	Detection Limit (nM)	Precision[1]	Quant. Range (nM)
Fast evap. Ang. II	2-7%	2.2%	0.996	5.5	7% (1400 nM)[2]	45-3000
Multicomp. matrices Ang. II	10-20%	4.5%	0.976	11	16% (2740 nM)[2]	90-6000

Introduction

In quantification of macromolecules by MALDI-TOF, the use of an internal standard is critical. Determination of what constitutes a good internal standard is addressed in this report using bovine insulin as a model analyte. The means of measurement of the signal intenisty is also discussed, including the use of direct peak integration and non-linear least squares curve fitting (NLLSCF).

Experimental

A previously described [1] analytical protocol was used in the collection of spectra. Samples were prepared in a matrix consisting of 2,5-Dihydroxybenzoic acid (20 mg/mL), 5-Methoxysailcylic acid (2 mg/mL) and fucose (5 mg/mL) in a solvent of 9:1 water:ethanol (v/v). The matrix was mixed with the analyte solution in a 1:1 volumetric ratio deposited on a stainless steel substrate. Samples were visually monitored to determine good matrix crystals for analysis. Fifteen to twenty laser shots were discarded because of wild variations in the analyte to internal standard peak height ratio. The next 25 laser shots were collected and averaged before the selection of a new crystal and repetition of the process. This process was repeated to provide averaged spectra consisting of 200 averaged single-shot spectra.

Spectra were collected for bovine insulin with the following internal standards: bovine insulin chain B, horse heart cytochrome C, des-pentapeptide human insulin human arg-insulin and des-octapeptide porcine insulin.

Results and Discussion

Intensity measurement was accomplished by both direct integration of the analyte peaks following subtraction of a linear background and non-linear least squares curve fitting (NLLSCF) which is more completely described in reference [2]. Peaks used in the NLLSCF include $M+H^+$, $M+H-H_2O^+$, $M+Na^+$, $M+K^+$ and a broad peak corresponding to metastable decay products. A sample curve fitted insulin spectrum is shown in Figure 1.

Evaluation of the relative standard deviation of the slope of the standard curves shows very little difference between methods of intensity measurement. This was confirmed when the squares of the standard deviations of the slopes were compared with an F test, which revealed no difference between methods.

The standard curve statistics using the different internal standards are compared in Table 1. Des-pentapeptide human insulin was the most desirable internal standard, judged by comparison of the relative standard deviation of the slopes, and the simplicity of the intensity measurement. Of the remaining standards, bovine insulin chain B is formed in the fragmentation of the insulin molecule, thereby causing the apparent concentration of chain B to vary with laser intensity. Des-octapeptide insulin and horse heart cytochrome C yielded similar results, possibly as a result of imperfect inclusion of the peptides into the matrix, and

these results were shown by an F test to be significantly poorer than those seen for des-pentapeptide insulin. Arg-insulin, although providing good accuracy, was not completely resolved, thereby complicating the data analysis.

Thus, a recommended means of selection of an internal standard for quantitative MALDI includes the use of a molecule which has a sufficiently different mass that baseline resolution may be achieved between molecules.

"Use of Isotopic Surrogates in the Quantitation of Endogenous Analytes" Alexander M, Abolin C, Coopersmith B, and Zhang J. Sandoz Research Institute, East Hanover NJ 07936

ABSTRACT

As indicators of health status or therapeutic response to new treatments, the concentration of endogenous compounds is of interest to clinicians and drug development scientists. A major difficulty in developing quantitative methods for endogenous compounds is instrument calibration; specifically, how can an internal standard calibration curve for the endogenous analyte be constructed in the presence of high concentrations of the analyte itself?

Conventional clinical chemistry approaches have drawbacks. To obtain an analyte-free matrix for construction of a calibration curve, some investigators attempt to remove the endogenous analyte, use synthetic biologic matrixes or use external standardization in a solvent matrix. With these approaches, no assurance exists that either the recovery or the background obtained from such altered matrices will accurately mimic the unaltered matrix Chemical homologs of the endogenous analyte have also been used; however, there can be no assurance that the recovery or instrument response of the homolog surrogate analyte would be identical to the analyte itself.

The proposed solution takes advantage of mass selective detection by using a ^{13}C-labelled isotopic surrogate analyte of the compound of interest. The use of a ^{13}C-labelled isotopic surrogate with a sufficiently different nominal mass assures the same chemistry, hence the same recovery, chromatography and instrument response as the endogenous analyte. In addition, by using liquid chromatography with atmospheric pressure chemical ionization (APCI) instead of gas chromatography, sample preparation can be simplified by avoiding a derivitization step. Finally, this LC/APCI/MS approach can provide high sensitivity, wide dynamic range, ruggedness and automation.

As an example of the stable isotopic surrogate approach, an assay was developed for free (non esterified) palmitic acid in human plasma. Palmitic acid is the major endogenous free fatty acid in human plasma and its endogenous concentrations have been used as indicators of fatty acid metabolism

For this palmitic acid assay, $^{13}C_4$-palmitic acid was used as the isotopic surrogate analyte. The $^{13}C_4$-palmitic acid isotopomer was chosen because of its low natural abundance (<0.1%) and minimal isotope effects. Sample preparation for the standard curve was straightforward. After adding the perdeuterated internal standard ($^2H_{31}$-palmitic acid) and $^{13}C_4$-palmitic acid to 200 µL of an untreated sample, plasma proteins were precipitated with 400 µL methanol and filtered to remove solids. Lastly, 40 µL of the filtrate was injected onto the LC column. A binary mobile phase system was used for LC: Mobile Phase A was an aqueous solution of 2mM ammonium acetate with 0.2% added triethylamine, with pH adjusted to 7.8 with acetic acid; Mobile Phase B was 95% methanol / 5% acetonitrile (v/v). The LC conditions were: a Keystone BDS Hypersil 2 x 150 mm 3µ ODS column held @30°C was operated isocratically (80% B) at 0.35 mL/min. Palmitic acid and its isotopomers typically eluted in < 7 minutes. The APCI interface was operated at a vaporizer temperature of 400°C and a capillary temperature of 150°C, with a N_2 sheath gas pressure of 30 psi, no auxiliary gas, and a corona current of 6 microamperes.

Figure 1 shows a selected mass chromatogram of unadulterated human plasma. No signal was observed in either the M+4 or M+31 channels, demonstrating that neither the isotopic surrogate analyte nor the isotopic internal standard are affected by interferences from either endogenous palmitic acid or other matrix substances. Figure 2 shows a mass selected chromatogram of a human plasma sample spiked with $^{13}C_4$-PMA and $^2H_{31}$-PMA. The assay was validated to cover a concentration range of 124 to 282,000 ng/mL, as shown in Figure 3 Figure 4 presents endogenous palmitic acid levels found for 8 diabetic patients. The average value of ~30,000 ng/mL agrees with reported HPLC/UV determinations [1].

In summary, stable isotopic surrogate analysis is a novel approach for the determination of endogenous analytes, permitting calibration by internal standardization in unaltered biological fluids. Use of LC/APCI/MS permits analysis of underivitized analytes using simple sample preparation. This type of assay could be highly advantageous in a high volume clinical laboratory setting.

Electrochemical Aspects of Electrospray

Feimeng Zhou and Gary J. Van Berkel
Chemical and Analytical Sciences Division, Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831-6365

Electrospray mass spectrometry (ES-MS) has proven especially useful in the molecular weight determination and structural analysis of involatile, polar and thermally labile compounds. However, the mechanism(s) involved in the generation of gas-phase ions from species in solution during the ES process is not well understood. In this study, attention is given to the electrochemical processes that occur at the metal/solution interface in the ES capillary. Kebarle and co-workers postulated that the mechanism responsible for charge balance in the ES capillary was electrochemical in nature and that the ES source was in fact "an electrolytic cell of a somewhat special kind."[1] We demonstrated that the radical cations observed in the ES mass spectra of some easily oxidized organic compounds were formed via electrochemical oxidation in the ES capillary[2]. Recently, similar data from an ES-MS study of various metallocenes was also presented.[3] A better understanding about the electrochemical processes in ES is desirable because it might lead to means for improving ES-MS performance (e.g., improving dynamic range and detection limits), means to expand the range of analytes amenable to analysis and possibly the means to control or alter the ionic species observed in the gas-phase.

Comparison of a Controlled Current Electrolytic Cell and an Electrospray Ionization Source. A comparison of a controlled-current electrolytic (CCE) cell and an ES ionization source reveals that these two devices are analogous in terms of their configuration and operation. Examination of the parameters that govern the magnitude of the ES current (Hendricks' equation), i_{ES}, and those that govern the faradaic current (i_F) in a CCE cell are those relevant to the transport of charge between the two electrodes by the electrolyte in solution, viz, solution conductivity, electrical field at the ES capillary tip, and flow rate.

Novel ES Ionization Source Combined On-line with UV/visible Spectroscopy. Shown in Figure 1 is a schematic representation of the ES ionization source used in this work to acquire UV/visible spectra of the solution exiting the ES capillary. The photo diode array detector monitors products that are generated in the ES capillary from the model compounds prior to the spraying process By doing so, possible complications arising from gas-phase reactions are avoided.

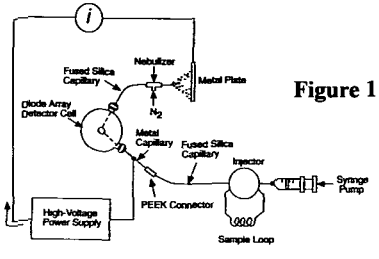

Figure 1

Experimental Verification of the Operation of an ES Ionization Source as a CCE Cell. (I) Effect of Varying the Solution Conductivity on the Extent of Analyte Oxidation. The effect of varying the ES solution conductivity on the magnitude of i_{ES} and on the extent of oxidation of nickel(II) octaethylporphyrin ($Ni^{II}OEP$) to its radical cation was determined

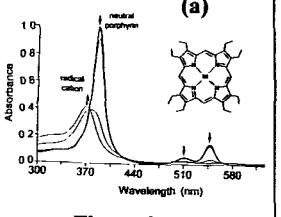

Figure 2

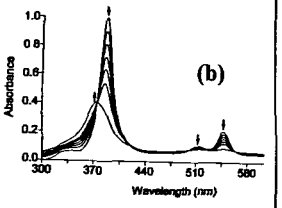
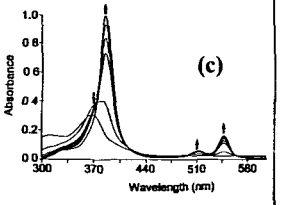
on the basis of five separate flow injection experiments in which the voltage applied to the ES capillary, the solution flow rate, and the concentration of $Ni^{II}OEP$ in the injected samples were kept constant, but the concentration of an added electrolyte (C_E), lithium trifluorosulfonate, was increased. The five UV/visible spectra of $Ni^{II}OEP$ shown in Figure 2a that were obtained during these experiments demonstrate that as C_E increased, i_{ES} increased, the amount of porphyrin oxidized also increased. The spectrum recorded when no electrolyte was added to the system is that of the neutral porphyrin (λ_{max} = 386, 510, and 548 nm), while that recorded when the electrolyte concentration was 9.0 mM is that of the porphrin radical cation (λ_{max} = 370 nm). This observation is in accordance with what is expected from a controlled-current electrolysis. It is worth noting that the data in Figure 2a represent the first direct proof that electrolysis of solution species can occur in the ES capillary *(ii) Effect of Varying the Voltage Applied to the ES Capillary on the Extent of Analyte Oxidation.*





The effect of varying the magnitude of the voltage on the magnitude of i_{ES}, and on the extent of oxidation of $Ni^{II}OEP$, was determined in an experiment in which a 5.0 μM solution of $Ni^{II}OEP$ containing 1.0 mM of electrolyte was continuously infused through the ES capillary and the voltage was varied from 0.0 to 5.0 kV As the magnitude of voltage increased, the magnitude of i_{ES} increased as expected from Hendricks' equation. The seven UV/visible spectra of $Ni^{II}OEP$ shown in Figure 2b demonstrate that as i_{ES} increased, in response to an increase of the ES voltage, the amount of porphyrin oxidized increased.

(iii) Effect of Solution Flow Rate on the Extent of Analyte Oxidation. With a relatively high electrolyte concentration (a few mM), the magnitude of i_{ES} is affected little by changes in the flow rate. This is analogous to the situation in a CCE cell. The effect of varying flow rate on the extent of $Ni^{II}OEP$ was determined in an experiment in which a 5.0 μM solution of $Ni^{II}OEP$ containing 1.0 mM of electrolyte was continuously infused through the system at values of flow rates, from 10 to 80 μL/min. The UV/visible spectra of $Ni^{II}OEP$ shown in Figure2c demonstrate that although the magnitude of i_{ES} changed little with flow rate, the fraction of porphyrin oxidized changed dramatically from essentially 100 percent at 10 μL/min to near zero at 80 μL/min Such a change in the proportion of porphyrin oxidized with changing flow rates indicates that the oxidation reaction is controlled by the rate of porphyrin mass-transfer to the metal/solution interface in the ES capillary, a phenomena expected from any types of electrolysis experiments.

Armed with the knowledge that the ES source operates as CCE cell, the means to maximize the efficiency of the electrolysis process for ionization of neutral analytes are at hand. Three requirements are key to utilizing the effect for this purpose: (1) the magnitude of the ES current must be sufficient to oxidize/reduce the molar equivalent of the analyte exiting the ES capillary, plus the molar equivalent of all other species present in the ES capillary, (2) the flow rate of the solution must be sufficiently slow to allow adequate time for the analyte to be transported to the metal/solution interface within the capillary where the redox reactions takes place, and (3) the steps taken to ensure the first two requirements must not inhibit the formation of gas-phase ions from the ions generated electrochemically in solution.

High-Frequency Synchronization of an Electrospray Current using a Pulsed Voltage

Charbonnier, F.; Rolando, C.; Sablier, M.; Saru, F.; Simonneau, G. *Ecole Normale Supérieure, Département de Chimie, URA 1679 du CNRS, 24 rue Lhomond 75005 Paris, FRANCE.* Hapiot, P.; Pinson, J. *Laboratoire d'Electrochimie Moléculaire de l'Université Paris 7, URA 438 du CNRS, 2 place Jussieu, 75005 Paris, FRANCE.* Beaugrand, C. *AIRND, 78230 Le Pecq, FRANCE*

In electrospray ionization, gaseous ions are directly obtained by solvent evaporation in charged droplets, formed from a liquid flowing through a capillary submitted to an electric field. At the capillary tip, connected to a high voltage supply, the emission of current (droplets) is actually a discontinuous phenomenon, the frequency of which can be observed by measuring current intensity. We recently described(1) an experimental device allowing studies of fast processes up to 1 MHz, for investigating the time-dependent behavior of the electrospray current. Various electrolytes and solvents were used and, in every case, a discontinuous and roughly periodic intensity was observed for the current at the needle. Instantaneous current amplitudes remain roughly constant. Averaged spray intensities are in the commonly described range (0,1 to 1 μA). They grow with increasing applied high voltage, due to the increase in frequency of current (droplet) emission.

We were able to show the existence of three main functioning modes, corresponding to three frequency ranges of applied voltage: 10 Hz to 1 kHz, 1 to 10 kHz and 100 to 500 kHz. These modes might be correlated with the « Cone Jet », « Multi Cone Jet » (2) and « Rim Jet » modes of droplet emission during the electrospraying of a liquid, so called commonly after the shape of the flowing liquid at the capillary tip.

These earlier experiments allowed us to define the high voltage ranges that produce a stable spray and, for each range, the spraying frequencies. Though it was possible to choose selected conditions to optimize the stability of the spray in such a « free » version, the DC voltage conditions were difficult to reproduce. By applying an alternating voltage superimposed on the DC electrospray voltage (figure 1), we have

been able to synchronize the electrospray emission mode near its own natural frequency. By this means, the high frequency emission process could be observed precisely and the spraying process could be maintained during several hours in a given mode with a complete stability). This synchronization can be made efficient even in the highest frequency range (100 to 500 kHz: Figure 2). The experimental observations reported here may be related to the increase and stabilization of electrospray emission current obtained when the needle is vibrated by using a piezo electric transducer at subsonic frequency (3).

Characterization and Implementation of Micro-Flow Electrospray Nebulizers

Thomas Covey PE/Sciex Concord, Ontario Canada

Purpose of this work was to examine the electrospray process in the sub-μL/min range. Particular attention was paid to determining the parameters most important for maximizing the efficiency of ion desorption and ion transmission steps. Operating the system at the very low flow proved to be revealing regarding the nature of the ionization process unmasking certain characteristics not observed at the more commonly used flows > 1μL/min.

Electrospray needles with inside diameters varying from 100μ to 3μ ID. were created from gold plated fused silica according to the method of Kriger & Cook (1). The addition of a gentle sheath gas was used to aid in the collimation and desolvation of the charged droplets. The width of the Taylor cone at the base where it contacts the fused silica was measured as a function of flow rate at successively increasing distances from the center ID bore of the capillary. With an infusion pump the flow was gradually increased and the ion current was monitored. Stable signal indicated electrical contact with the base of the Taylor cone was achieved. The base of the Taylor cone where electrical contact is made cannot be visualized microscopically because the film can be very thin where contact occurs.

Two distinct modes of low flow operation were identified with respect to the geometry of the Taylor cone produced at the tip. When the Taylor cone just bridged the inside diameter of the capillary ("bridge flow") the maximum ionization/ion transfer efficiency achievable for that particular capillary ID was attained. This occurred at the indicated flows for the following tubing ID's. For a 100μ capillary ≈600nL/min, for 50μ ≈300nL, for 20 μ capillary ≈100nL/min, for 10μ ≈ 60nL, for 5μ ≈ 40nL, and for 2μ ≈ 30nL. This last observation (2μ at ≈ 30μ) approximates the flows achieved by Mann & Wilm (2) with similar diameter drawn borosilicate capillaries flowing by virtue of their own electrostatic force. When the flow was reduced below these values the cone retracted within the capillary and produced extremely unstable ion current traces. When the flow was increased above these values the Taylor cone spread across the face of the capillary and eventually down along the outside sheath of the capillary for a distance of several millimeters. Under these "over-flow conditions" (base of cone > I.D. of capillary) ionization/ion transfer efficiency varies with flow as a result of the changing diameter of the charged droplet emitting from the cone, as predicted by Wilm & Mann(2). The efficiency is always sub-optimal but the signal remains constant as the mass flux compensates for the decreasing ionization/ion transfer efficiency giving the appearance of a concentration sensitive response. Under "bridge flow " conditions very small changes in flow result in proportional changes in ion current revealing the true nature mass of the ion evaporation process as a mass sensitive one. Apparently the inner edges of the capillary stabilize the size of the Taylor cone over a very narrow flow range preventing a change in the diameter of the ion emitting droplet with a change in flow. The ionization efficiency thus remains constant and variations in mass flux are reflected in changing ion current levels.

HOW ARE ELECTROSPRAY IONS BORN FREE? - DOLE VS. IRIBARNE REVISITED.

John B. Fenn and Joan Rosell
Virginia Commonwealth University, Richmond VA 23284-2006

Solute ions from charged droplets have been widely used as grist for the mills of mass analysis for almost 20 years. During that time most attempts to explain the ion formation have been based on one of two mechanisms: The Charged Residue Model (CRM) originated by Malcolm Dole, and the Ion Evaporation Model (IEM) later proposed by Iribarne and Thomson. The CRM holds that solvent evaporation and consequent Coulomb explosions ultimately produce droplets so small that each one contains a only a single analyte molecule that retains some of the droplet charge to become an ion when the last of the solvent leaves. The IEM assumes that before CRM's ultimate droplet stage is reached the droplet surface field becomes strong enough to lift an ion into the ambient gas. In a recent review Kebarle and Tang concluded that uncertainty remained but that they favored the CRM [1]. Here we examine *representative experimental observations that the CRM seems unable* to explain and conclude that in most cases the IEM probably applies.

First we note that the CRM requires formation of at least one separate droplet for each ion produced. We then conclude that if an ES spectrum shows that any of the following conditions are met, the CRM cannot account for its ions: (A) The number of charges on an ion is less than both the number the parent molecule can hold and the probable number on the droplet from which the ion came; (B) The relative abundance of observed ions varies greatly with small changes in structure or composition of either its parent molecule or the droplet solvent; (C) There are no ions present from molecules abundant enough in the sample to be detected if they were the only solute species.

Figure 1 shows relative abundances for 10 tetra alkyl ammonium ions from 10 uM solutions of their bromides in 50-50 methanol water infused at 3 uL/min. A change of one carbon atom in the side chain changes abundance by a factor of up to forty! The sharp drop above 7 carbon atoms, due to "precipitation" of analyte as solvent evaporates, disappears (dashed curve) when analyte solubility is increased by a change of solvent to 50-25-25 n-propanol-methanol-water. these variations meet Condition B so the CRM cannot account for the ions.

Figure 2 shows the dependence of relative abundance for ES ions of Cu+ on the water content of dilute solutions of copper sulfate in acetonitrile. It's hard to understand how such small increases in water content can decrease the number of ultimate droplets by enough to account for the decrease in ion abundance. Once again condition B is met so that the CRM does not apply.

The two spectra in Fig. 3 show the coherent sequences of peaks characteristic of ES spectra for large molecules. To avoid rejection of the CRM by condition A above, the ions of each peak in Fig. 3 can have come only from droplets having the same number of charges as are on the ions of that peak. Thus, droplets must have been produced with charge states in the same relative abundances shown by the ions of the spectra. Those charge states go from 10 to 13 for ions of lysozyme in Fig. 3B and from 35 to 62 for alpha analyse in Fig. 3C. How can initially formed droplets possibly anticipate how many droplets

in each charge state they will have to produce for the particular analyte species they happen to contain. Even if they "know" a priori, *how can they control the evaporation-explosion sequence to produce* the droplet distributions required to avoid condition A?

Figure 4 shows the result of an experiment previously described in detail [2]. In brief, the increase in countercurrent gas flow rate (circle points) increases the droplet evaporation rate which increases the number of charges on the most abundant ion (ordinate values). With increasing flow rate of concurrent gas (triangles) the droplet evaporation rate and thus the number of charges on the most abundant oligomer both decrease. The CRM cannot reasonably account for this result but the IDM can, as shown in Ref. [1]

In sum, for these cases, and for many others, the ES spectral features can be more readily explained by the IDM than by the CRM.

Is Electrospray Ion Production Concentration Dependent?

Brad I. Coopersmith, Brenda H. Hamilton, Craig R. Abolin
Sandoz Phamaceuticals, 59 Route 10, East Hanover, NJ 07936

Liquid chromatography/electrospray ionization/tandem mass spectrometry (LC/ESI/MS/MS) at high liquid flowrates (>50 uL/min) shows much promise for high throughput quantitative analysis of many drugs and their metabolites. Upon cursory examination, LC/ESI/MS/MS calibration curves, such as that shown in Figure 1, produce a linear dynamic range of 2 to 4-orders of magnitude. While the coefficient of determination suggests a linear response ($r^2 > 0.99$), closer examination reveals significant deviation from the curve-fitted weighted regression line at both the high and the low ends of the calibration curve.

The relative response factor (RRF), defined as the standard concentration divided by the peak area ratio, is a more sensitive measure of the detector linearity than the coefficient of determination because it provides point estimates of the inverse slope of the calibration curve. The RRF should remain constant for an ideal linear calibration curve The RRFs from the data shown in Figure 1 is plotted in Figure 2. This response is typical of most LC/ESI/MS/MS calibration curves, the RRF was found to increase with increasing concentrations of analyte, thus establishing nonlinearity.

Any concentration dependency that is observed should be a direct result of the energetics of the ESI process Of the three stages of ESI (droplet formation, droplet desolvation, and gas-phase ion formation), only the droplet formation stage has been shown to be concentration independent [1]. Our studies focussed on the last stage, gas-phase ion formation, since this stage should possess the highest activation energy and therefore be the easiest to measure In order to quantitate the activation energies, three assumptions were made (1) gas-phase ion formation must be both energetically and kinetically favorable, thus transition state theory can be used to describe the rate of gas-phase ion formation; (2) from the design of the Finnigan MAT ESI interface used, any ions which are detected must be formed before exiting the heated capillary; and (3) the surface temperature of the droplet inside the heated capillary is proportional to the heated capillary temperature. These assumptions led to the following equation to estimate the activation energy required for gas-phase ion formation:

$$\text{Ln [Ion Signal]} = -\frac{\Delta G^{\ddagger}}{kT} + \text{Ln}\left[\frac{kT}{h}\right] \qquad (1)$$

Figure 3 displays the plot obtained from the above equation for 19 5 ng of sample (17 ng of analyte and 2.5 ng of internal standard) on-column The trend obtained from the slopes of plots of equation (1) as a function of analyte concentration is shown in Figure 4. While the absolute values of the slopes changed upon repetition of the experiment, the trend did not which suggests a distinct concentration dependency in the gas-phase ion formation stage.

Of the proposed mechanisms for this stage, only the Ion Evaporation Model [2] is supported by these data. According to that mechanism, the final droplet will partially desolvate and then expel an ion near the droplet surface into the gas phase due to the high electric field at that point Colligative effects (boiling point elevation) due to the high mole fraction of analyte molecules in the final droplet will affect the activation energy of this stage As the analyte concentration increases, the mole fraction of the analyte in the final droplets will increase, thus increasing the energy needed to desolvate the droplet to the point where gas-phase ion formation occurs.

Dependence of Charge State Distributions on Analyte Concentrations in Electrospray Ionization Mass Spectrometry

Guangdi Wang and Richard B. Cole*
Department of Chemistry, University of New Orleans
Lakefront, New Orleans, LA 70148

Earlier investigations [1,2] into the behavior of liquids under electrospray conditions showed that the total ion current follows a weak dependence on the conductivity of the sprayed liquid, given as: $I \approx H\sigma^n$, where H and n ($0.2 < n < 0.4$) are constants, and σ is the liquid conductivity. Solution conductivity can be enhanced either by addition of external electrolytes, or by increasing the concentration of a dissociating analyte in solution. In both cases the total ES ion current increases as a result, although the magnitude of the current increase is considerably less than the magnitude of the rise in concentration. We have shown [3] that upon addition of external electrolyte (not participating in charge attachment to/removal from the analyte), the charge state distributions of analytes do not change significantly despite a dramatic reduction in overall analyte signal response in the presence of increasing electrolyte signal intensity. Increasing the concentration of the analyte itself, present in salt form, represents a different means of influencing solution conductivity which merits a separate treatment.

The effect of analyte concentration upon charge state distributions in electrospray ionization mass spectrometry (ESMS) was investigated using four compounds which showed doubly charged and singly charged positive ions (gramicidin S, 4,4'-bipiperidine), multiply charged negative ions (Trypan Blue), or doubly charged and singly charged negative ions (eosin Y) in ES mass spectra. For each of the above compounds, the charge associated with analyte molecules was calculated to increase in solution with increasing concentration, yet the analyte charge state distributions in ES mass spectra were observed to monotonically shift toward lower values. In order to rationalize these observations, we introduce N/N_o, the ratio of the number of excess charges on all droplets produced by electrospray (N) to the total number of analyte molecules in all droplets (N_o). The N/N_o value decreases with increasing analyte concentration, indicative of an increasing number of ion-paired analyte molecules in the droplets. The lower N/N_o value is proposed to be an underlying factor critical to explaining the desorption of a higher proportion of gas-phase ions of lower charge state at elevated analyte concentrations. Furthermore, in comparing N/N_o values and observed analyte charge state distributions as functions of increasing analyte concentration, the decreasing ratio of N/N_o predicts a much greater extent of shifting of analyte charge states toward lower values than was observed. This implies that the actual degree of ion-pairing in droplets was considerably alleviated as compared to that indicated by the calculated N/N_o values. This finding conforms to a description of the ES process wherein uneven fission of droplets occurs at the Rayleigh limit, thereby generating offspring droplets of enhanced charge to mass ratio, hence an augmented N/N_o value.

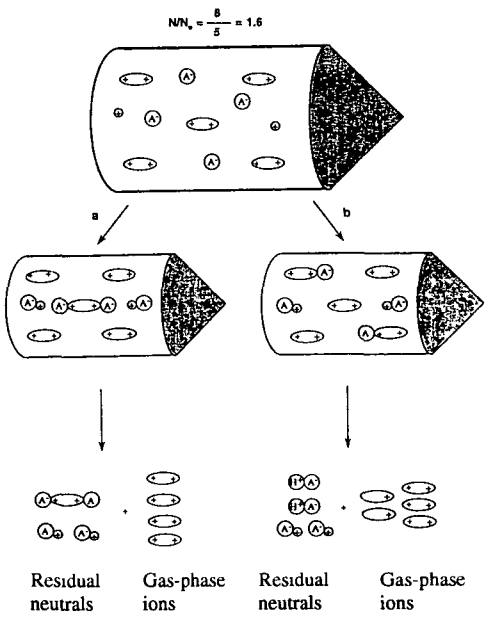

Figure 1. Schematic diagram of a portion of a charged droplet containing an excess of positive charges in the form of doubly protonated analyte (doubly charged ellipse) initially introduced in the neutral salt form with two anions attached. Droplet charging occurred by electrophoretic removal of anions (A^-) and by electrochemical production of cations (smallest circles). The droplet becomes smaller as solvent evaporates such that ions of opposite charge move closer together to eventually form contact ion pairs. The diagram depicts the relation between N/N_o (top) and the charge states of ES generated gas-phase ions (bottom). Pathway b corresponds more closely to experimental observations. Ellipses are horizontally oriented for visual clarity.

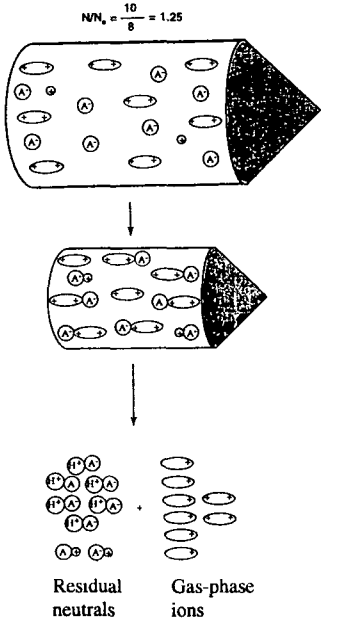

Figure 2. Schematic diagram of a portion of a charged droplet containing a higher concentration (relative to Figure 1) of the neutral salt form of the same dibasic analyte. The observed increase in the proportion of singly charged ES generated ions at higher concentration is attributed largely to the reduced N/N_o value.

Physical Processes of Electrospray

Willoughby, Ross; Sheehan, Edward; Mitrovich, Samuel
Chem-Space Associates. 75 Chapel Ridge Place, Pittsburgh, PA 15238

The current studies are an attempt to rationalize the physical processes associated with droplet formation and ion production in electrospray using thermodynamic models Previously we have evaluated the behavior of the electrospray needle cone-jets using the laws of conservation of energy, mass and charge to characterize the process of conversion of high electrostatic potential energy into high kinetic and surface energy in the primary droplet formation process of electrospray [1] This model treats the transition of effluent flowing from the high voltage needle into an aerosol, and ultimately into gas-phase ions as a thermodynamic change in state. Each step in this transition may be evaluated separately for boundary conditions, thresholds, and driving forces.

It has been well established that the deformation of the liquid surfaces in electrospray is attributable to "Rayleigh instabilities"[2], however, no comprehensive model has been put forth to explain the system behavior once the Rayleigh limit has been reached; particularly for isolated droplets.

The present studies attempt to tie the processes occurring in the aerosol to the processes occurring on the needle. One important question to be addressed in the our evaluation is the scaleability of processes occurring in electrospray Are the forces resulting in the formation and continuation electrospray cone-jets from needles the same as those from droplets? What are the similarities? What are the differences?

Evaluation of the Rayleigh theory for charge saturation of a liquid surface results in several interesting observations The saturation charge of a spherical (q_s) surface per unit mass is calculated to be less than the saturation charge of a cylinder (q_c) of equal mass The ratio of q_s:q_c is 0 94:1. This relationship accounts for the natural transition from the spherical to cylindrical geometry when a given system reaches the limit of charging. The observed conical liquid geometries on both needle tips and on isolated droplets in electrospray is physical evidence that charge saturated systems move from surface tension dominated geometries below charge saturation to electrostatic stress dominated geometries above the charge saturation limit.

Figure 1 shows the relationship between charge on a liquid surface and radius resulting from the application of high potential to an electrospray needle. The initial geometry is spherical; above the limit of charging the surface deforms in the "deformation region" to produce a cone. When the kinetic energy flow is equal to the surface energy flow in the highest field region of the cone, a cylindrical liquid jet emerges. The liquid jet subsequently relaxes back to spherical geometries in the lower field regions and primary droplets are formed.

Figure 2 shows the relationship between charge on a droplet surface and radius resulting from evaporation of an electrospray produced droplet. The initial geometry may be spherical; however as the droplet evaporates and the potential of the droplet increases, conical deformations result similar to needle cones.

Our experimental results and modeling studies indicate that the processes governing needle cone-jet formation are scaleable to the submicron droplet dimension.

ION MOBILITY SPECTROMETRIC / MASS SPECTROMETRIC INVESTIGATION OF ELECTROSPRAY IONS

R. Guevremont, K.W.M. Siu, and J.Wang, Institute for Environmental Research and Technology, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6

Ion mobility spectrometry is ideally suited to the investigation of the nature of electrospray ions; the separation of ions occurs at atmospheric pressure and detection of ions is a simple measurement of electrical current. Although the ion mobility spectrometer lacks resolution, it has the capability of separating and detecting ions over very wide range of size. A commercially available instrument (PCP Inc., West Palm Beach Fla.) was interfaced to an electrospray chamber via a 15 cm length tube 1/8 in. od. The tube ended within the 'reaction zone' of the IMS instrument and therefore was held at approximately +2000V in order to match the voltage level within the instrument. The electrospray chamber was flushed by 3L/min N_2 which entered the chamber concentrically to the exit tube leading to the IMS. Of this gas 1.5L/min carried the electrospray ions into the IMS, and 1.5L/min exited directly from the cell. This countercurrent of gas minimized the entrance of neutrals and large droplets into the IMS instrument. Because of the low mobility of electrospray ions of interest, the gating function was extended from the usual 1ms up to 8ms (note wide peaks in Figures 1 to 4). This permitted good sensitivity detection of ions with mobility as low as 0.2 cm^2/V-s. IMS/MS was performed on a different instrument (PCP Inc., West Palm Beach Fla.) which had an IMS cell with two gates 5cm apart, and a quadrupole mass spectrometer with range to m/z1200. The interface between the IMS and MS was an orifice approximately 25um in diameter. The mobility cell in the IMS/MS instrument was run at 200C.

Figure 1 illustrates IMS spectra of several tetraalkylammonium ions. The spectra are all characterized by ions of mobilities ranging from over 1.5 cm^2/V-s to as low as 0.2 cm^2/V-s. The ions of high mobility in electrospray of tetraalkylammonium salts are the tetraalkylammonium ion and an adduct between this ion and another tetraalkylammonium bromide. Figure 2 illustrates IMS (upper trace) and the IMS/MS with single ion monitoring of these ions from electrospray of tetraoctylammonium bromide. Unexpectedly, a considerable fraction of the adduct ion appears to be converted back into a simple tetraoctylammonium ion in the MS interface. Figure 3 illustrates the IMS spectra of tetraoctylammonium bromide as a function of concentration. At concentrations above 0.1mM (in which the adduct is detected in IMS), a conventional electrospray-MS measurement does not reflect the actual relative abundance of the tetraalkylammonium ion and its adduct. IMS spectra of several tetrabutylammonium salts including dihydrogenphosphate, hydroxide and acetate were acquired. In these experiments only the halide anion formed an adduct sufficiently stable to be detected.

Figure 3 illustrates the limitation in dynamic range usually observed in electrospray ionization. At low concentration the IMS spectrum is dominated by the tetraalkylammonium ion. The ion current detected for this ion ceased to increase once the lower mobility ions appear in the spectra. All of the traces in Figure 3 have equal scaling of the signals. Figure 4 illustrates the temperature-induced changes in the mobility of ions originating in the electrospray of 1.5 mM of tetraoctylammonium bromide solution. The ES cell is at room temperature, whereas the IMS spectrometer temperature is increased. The mobility of the large ion appears to <u>decrease</u> as the temperature of the IMS spectrometer is increased.

Principles and Design of Ion Traps for FT-ICR Mass Spectrometry

Alan G. Marshall* and Shenheng Guan*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State University, 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

* Member of the Department of Chemistry, Florida State University

Virtually all Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry experiments are based on ion confinement in a Penning trap: namely, a spatially homogeneous static magnetic field, B, and a 3-dimensional axial (along B) quadrupolar electrostatic trapping potential, $\Phi(x,y,z) = \Phi(0,0,0) + \text{constant}\cdot(2z^2 - (x^2 + y^2)$. The 3-dimensional axial quadrupolar electrostatic potential has the desirable property that the ion equations of motion separate into independent cyclotron rotation, magnetron rotation, and axial oscillation, and the frequency of each motion is independent of ion position in the trap. Of the many possible excitation and detection modes,[1] the most common is one-dimensional dipolar excitation, produced by a time-varying electric field, $\Phi(x) \propto x(t)$, with Fourier spectral amplitude at each ion cyclotron frequency of interest, followed by dipolar image current detection with the same electrode arrangement. Finally, ion magnetron-to-cyclotron conversion requires a two-dimensional rf potential of the form, $\Phi(x,y) \propto (x^2 - y^2)$.

Each of these three potentials may be generated by infinitely extended electrode arrangements, as shown in Figure 1.

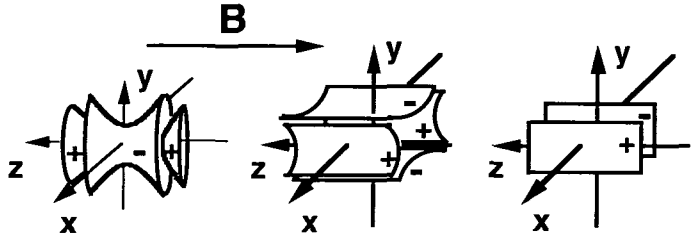

Figure 1. Electric potentials for: (left) ion trapping (three-dimensional axial quadrupolar); (middle) magnetron-to-cyclotron interconversion for ion axialization and cooling (two-dimensional azimuthal quadrupolar); and (right) excitation and detection (one-dimensional dipolar). The applied magnetic field, **B**, points in the negative z-direction.

The potentials actually produced by any of various (finite-size) ICR ion trap geometrical configurations (see Fig. 2) generally approximate one (but never all three) of the above potential fields.[2] For example, the "compensated" traps (Fig. 1f,g) apply different static potentials to concentric segments of the trap end cap electrodes to produce a more nearly 3D-quadrupolar electrostatic trapping potential. The "open" trap (Fig. 2n) is designed to open the end cap aperture to facilitate injection of

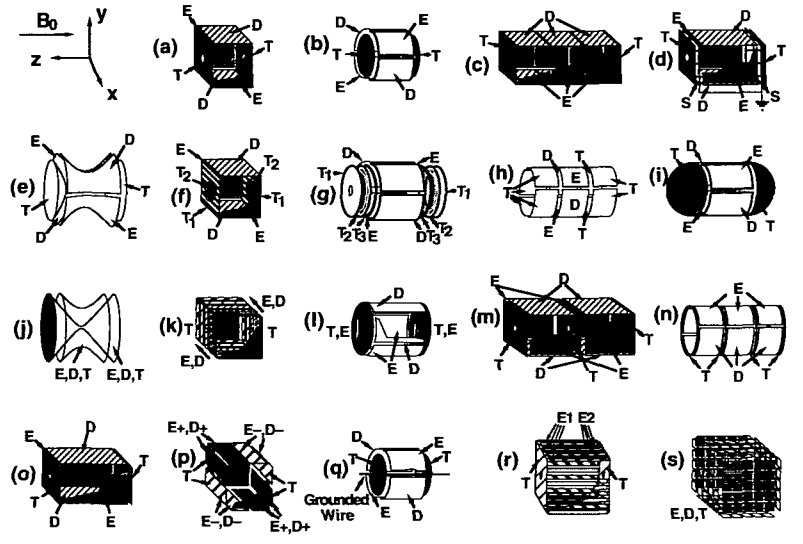

Figure 1. ICR ion trap configurations. E = Excitation; D = Detection; T = End Cap ("Trapping"); S = Screen. (a) cubic; (b) cylindrical; (c) three-section; (d) screened; (e) hyperboloidal electrodes; (f) and (g) end caps segmented to "compensate" electrostatic trapping potential; (h) open-ended; (i) hemispherical end caps; (j) two-electrode; (k) linearized for azimuthal dipolar excitation/detection; (l) infinity; (m) dual; (n) open; (o) elongated; (p) segmented for xz-excitation; (q) central wire; (r) filar electrodes;(s) "universal".

externally formed ions, while maintaining the electrostatic trapping potential (by applying the same d.c. voltage to end of the outer rings, which serve as "end caps", and by capacitively coupling all three segments together to produce a more spatially homogeneous rf dipolar excitation potential. The "screen" trap differs from the rest in that it is designed to produce a "particle-in-a-box" (rather than 3D quadrupolar) electrostatic trapping potential, so as to allow ions to spread out axially for increased dynamic range and reduced frequency shift due to the trapping potential. The most general design (also the newest) is the "universal" trap (Fig. 2s) described elsewhere in these Proceedings.[3] This work was supported by NSF (CHE-93-22824), NIH (GM-31683), and the National High Magnetic Field Laboratory at Florida State University.

ADVANTAGES OF HIGH MASS ACCURACY MALDI-FTMS FOR TRYPTIC MAPPING OF RECOMBINANT PROTEINS

John T. Stults
Protein Chemistry Department, Genentech, Inc., South San Francisco, CA 94080

Yunzhi Li and Robert T. McIver, Jr.
Chemistry Department, University of California, Irvine, CA 92717

The ultra-high mass resolution achievable by FTMS has been one of the primary and most recognized characteristics of the technique. The resolution achieved with MALDI-FTMS is no less impressive (1-3). High mass accuracy, in the absence of internal mass standards, is a feature of MALDI-FTMS that is routinely of far greater utility. Internal mass standards are required to achieve good mass accuracy (±0.01% = 100 ppm) with linear time-of-flight (TOF) mass spectrometry; however, the mass standard(s) must produce a signal of similar intensity to the analyte, which can require multiple cycles of sample preparation/measurement to achieve. Furthermore, for low analyte quantities, addition of a standard may suppress what little analyte signal was present initially. Thus high mass accuracy without an internal standard is a much more efficient means of analysis. An accuracy of 0.01% can be achieved routinely with reflector TOF instruments with external calibration. Much higher accuracy (<10 ppm) can be achieved with MALDI-FTMS with external calibration. Although most MALDI instruments to date are based on TOF analyzers, MALDI-FTMS is shown here to yield results for individual peptides with similar subpicomole detection limits, but with substantially greater mass accuracy.

Tryptic mapping is one of the primary methods for the detailed molecular analysis of proteins. Tryptic peptides are most easily identified by their mass, based on the known sequence of the protein from which they were derived (4). The accuracy of MALDI-FTMS yields much greater specificity in peptide identification than techniques with lower mass accuracy. The identification of amino acid modifications is also improved, and may include determination of the elemental formula of the modification. These same features permit the verification of correct peptide synthesis with equally high specificity. The ability to generate ions for multiple experiments from a single sample by MALDI-FTMS allows detailed questions to be answered for multiple peptides in a mixture. For example, narrowband excitation may be used when ultra-high resolution ($m/\Delta m$ >100,000) is needed. Fragment ion spectra may also be generated by collision-induced dissociation.

The data in this study were acquired with an IonSpec HiResMALDI FTMS instrument. Ions were produced in an external source (N_2 laser, DHB:fucose 1:1 matrix) and transported via a quadrupole ion guide to an elongated cell in a 4.7 T magnet. Argon was admitted to the cell by a pulsed valve immediately before ion injection in order to collisionally cool the ions. The mass axis was calibrated with a mixture of vasopressin, renin substrate, and insulin B-chain.

Replicate measurements of a series of synthetic peptides showed that mass accuracy with external calibration was ≤5 ppm with excellent reproducibility. Figure 1 shows the molecular ion region for 100 fmol of a synthetic peptide acquired with (a) 32K data points and (b) with 512K points (5 scans averaged for each). The resolution had little effect on the mass accuracy. The lower resolution observed for a 32K acquisition (~6000, FWHH) was more than adequate for isotope separation; the shorter transient required shorter data acquisition and Fourier transformation times, and required significantly less data storage than a longer transient. High resolution is also accompanied by a higher signal-to-noise ratio, another unique feature of FTMS, because the signal frequencies are essentially averaged for a greater length of time.

Table 1 lists the peptides observed and their masses for the tryptic digest of human growth hormone. Due to the mass dependence of the trapping delay time and the quadrupole rf voltage, the data were acquired in four segments. The T6-T16 peptide, m/z 3762, could only be observed with fucose present in the matrix to reduce fragmentation, and with a short acquisition time. Its higher mass error is due to its wider peak width and mass that lies above the highest mass standard used.

In conclusion, these preliminary experiments demonstrate that MALDI-FTMS routinely provides improved mass accuracy for peptides, including tryptic digests of proteins, in the absence of internal mass standards, yet with subpicomole detection limits.

EVALUATION OF DISSOCIATION TECHNIQUES FOR MALDI-FTMS OF OLIGONUCLEOTIDES*

Robert L Hettich[1] and Elizabeth A. Stemmler[2]

[1] Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120
[2] Dept. of Chemistry, Bowdoin College, Brunswick, ME 04011

The development of MALDI-FTMS has provided a convenient method of generating and trapping molecular ions for large biomolecules. We have optimized MALDI-FTMS for the generation of molecular ions for modified oligonucleotides up to 11-mers. In order to exploit the capabilities of FTMS for structural investigations, it is necessary to design and evaluate methods to examine these MALDI-produced ions in detail The focus of this presentation is to examine three methods of monitoring oligonucleotide fragmentation with MALDI-FTMS: 1) variation of the laser matrix compound, 2) variation of the time delay time between ion formation and detection, and 3) comparison of off-resonance dissociation methods (SORI) with on-resonance collision-induced dissociation All experiments were conducted with an Extrel FTMS-2000 instrument (3T magnet) equipped with a Nd:YAG pulsed laser (355 nm). MALDI experiments were conducted by mixing a few pmol of analyte with an excess of 2,5-dihydroxybenzoic acid (DHBA) or 3-hydroxpicolinic acid (HPA).

The extent of analyte fragmentation observed in MALDI-FTMS is dependent on the matrix compound used, and can be varied to provide either molecular weight or sequence information. This was demonstrated for a series of modified oligonucleotide 8-mers, obtained through collaborations with Drs Thomas and Connie Harris, Dept. of Chemistry, Vanderbilt University, Nashville, TN. MALDI-FTMS of d(AGGCGCCT) with DHBA did not yield molecular weight information, but rather generated primarily low mass fragment ions (m/z < 1000), providing sequence information about the first few nucleotides in this oligomer. In contrast, MALDI-FTMS with HPA generated an abundant molecular $(M-H)^-$ ion at m/z 2408, and lower abundances of sequence-specific Y-type ions, shown in Figure 1 These Y-ions were sufficient to verify the complete sequence of the 8-mer. Two other 8-mers with the same sequence, but with adducts on the third guanine from the 5' end, were also examined with DHBA and HPA MALDI-FTMS (HPA) was sufficient to identify the molecular weights, sequences, and adduct locations of these normal and modified 8-mers.

The amount of analyte fragmentation in MALDI-FTMS can also be controlled to some extent by the addition of a delay time between laser ionization and ion detection For example, the use of a 3 ms delay in the MALDI-FTMS (HPA) of d(A^{BPI}CGAGG), where A^{BPI} = benzo(a)pyrene diol epoxide adduct of deoxy-adenosine, yields primarily a molecular $(M-H)^-$ ion at m/z 2139. In contrast, the use of a 100 ms delay with the same experimental conditions yielded not only the molecular ion, but also a variety of abundant Y-type ions which were sufficient to resolve almost all of the oligomer sequence While the use of delay times provided extensive fragmentation information in some cases (such as modified hexamers), this technique was limited in utility for determining the complete sequences of larger oligomers (such as 11-mers).

Collisional dissociation experiments have proven to be very useful for probing the fragmentation of a variety of ions. However, some of the fragment ions observed in a MALDI-FT mass spectrum are difficult to dissociate with conventional CAD conditions. For example, MALDI-FTMS of pd(AGCT) generates a molecular $(M-H)^-$ ion at m/z 1252, and abundant fragment ions at m/z 939 (Y3) and 610 (Y2) While the m/z 939 is easy to collisionally dissociate with conventional CAD conditions, the m/z 610 ion, which corresponds to pd(CT), is difficult to dissociate in a similar fashion, as shown in Figure 2a The use of sustained off-resonance irradiation (SORI) experiments was examined as a method to improve the dissociation efficiency of these ions SORI of m/z 610 (pd(CT)) was found to be efficient for producing informative fragment ions for this Y2 ion, as shown in Figure 2b Based on these results, SORI was applied to a variety of other difficult-

to-fragment Y2 ions, and was found to be successful for the interrogation of these ions as well. The fragmentation information obtained in this way was used to determine that the Y2 ions fragment not only by elimination of a nucleic base and simple cleavage of the phosphate linkage, but also by complex rearrangement processes, including migration of a phosphate moiety to generate a (Y1 + HPO_3) fragment ion.

A Dual Chamber FT-MS Instrument with Electrospray, MALDI, Liquid SIMS Capability

Eric Gard, kirk Green, Sharron Penn, Steven Fannin, Elvira Camara, James Carroll, Jane Wu, and Carlito Lebrilla
Chemistry Department, Unversity of California at Davis, Davis CA 95616

The wide range of compounds analyzed by Mass Spectrometry today requires a variety of different ionization sources. This is because the various ionization techniques have different sensitivities for different classes of compounds. As a mass analysis technique FT-MS presents advantages like ultra-high resolution and high sensitivity irrespective of the ionization technique. One draw back of FT-MS, however, has been the inability to switch between the available ionization techniques. The dual chamber system, shown in Figure 1, offers nearly simultaneous ionization techniques, minimizes down time, and facilitates instrumental development. In addition, this FT-MS system utilizing a single superconducting magnet and one data acquisition system which represents a significant saving over two separate instruments. Each of the chambers rolls freely in and out of the magnet while under vacuum. This allows us to move the functional instrument into the magnet while the other is pulled out of the magnet for testing or alteration This is ideal for allowing instrumental modifications, source changes (FAB, MALDI, EI, ESI), and regular maintenance to take place on one instrument while the other is producing data.

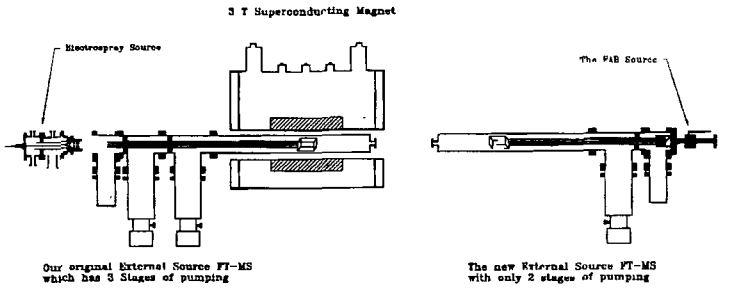

Figure 1: The dual chamber FTMS system.

Results for biomolecules ranging from Gramicidin S to Serum Albumin (~66,000 Daltons) obtained using the ESI source coupled with one chamber which utilizes five stages of differential pumping are presented in Figure 2 below. An example of the results for a obtained using the MALDI source coupled to the second chamber, which uses only two stages of differential pumping, are shown in Figure 3 below.

FT-ICR Mass Spectrometry of Very-Highly-Charged Atomic Ions

L. Schweikhard[1], B. Beck[2], St. Becker[3], P. Beiersdorfer[2], and S. R. Elliott[2]

[1]Johannes Gutenberg-Universität, Institut für Physik, D-55099 Mainz, Germany
[2]Lawrence Livermore National Laboratory, Livermore, CA 94551, U.S.A.
[3]Gesellschaft fur Schwerionenforschung, D-64220 Darmstadt, Germany

The electron beam ion trap (EBIT) at Livermore produces very highly charged atomic ions by successive ionization in collisions with an intense (up to 120 mA, 4000 A/cm^2), energetic (up to 200 keV) electron beam [1] The ions are trapped radially in the electrostatic field of the electron beam While it is on, and with the beam off by a 3-T magnetic field produced by a pair of superconducting Helmholtz coils. Axially, the ions are trapped by a bias potential on the top and bottom electrodes (see Fig. 1). The central electrode is 4.2 cm long and has a diameter of 1 cm EBIT was originally designed as an x-ray source [2], and six slots allow direct line-of-sight radial access to the trapping region for x-ray measurements.

For the present measurement, we made use of the access provided by the radial x-ray slots (see Fig. 2). We constructed two probes that could be inserted into the 2-mm wide slots. The probes each subtend only 25° and face each other 180° apart [3] For most measurements we used only one probe for excitation and the other for detection A typical transformed spectrum of highly charged 84Kr ions obtained with this arrangement is shown in Fig. 3. The spectrum was obtained by exciting with a 300-us sweep from 17.5 MHz to 19.5 MHz. The resonance peaks of $^{84}Kr^{34+}$, $^{84}Kr^{35+}$, and $^{84}Kr^{36+}$ are clearly seen

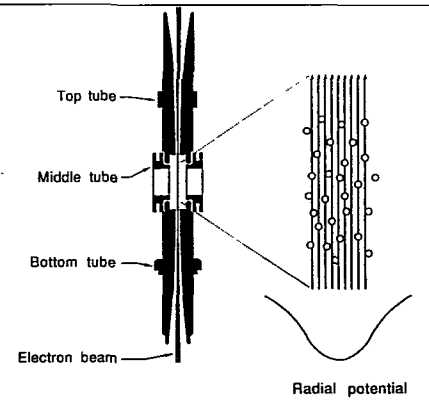

Figure 1. Schematic of the trap region (vertical cut). In the presence of the electron beam, ions are trapped in the space charge of the electron beam. In its absence, they are trapped axially by the potential applied to the top and bottom drift tubes and radially by the axial magnetic field.

Because the electrostatic field of the electron beam dominates the ion motion, it must be turned off during the ion cyclotron resonance measurement, i.e. during excitation and detection. We found that turning the electron beam off does not compromise the ion confinement needed for a successful measurement. Trapping times exceeding 1 s were found in the absence of the electron beam. We also found a decay time of 10 ms for the coherent ion motion after excitation. We estimate that there were as much as 10^5 Kr ions in the trap; in addition, there were at least as many ions from low-Z background gases such as hydrogen, carbon, nitrogen, and oxygen, as well as argon. The mass resolving power achieved (m/Dm(FWHM) ≈ 5 000) was limited by the number of digitization points of the Fourier transform (50,000 as determined by the LeCroy 9314L digitizing scope used for the measurements) and possibly by magnetic field inhomogeneities and/or by the large number of ions in the trap.

The use of the FT-ICR on an EBIT device holds several promises for future applications· First, as demonstrated, we can detect and measure different charge states and isotopes simultaneously. Second, using segmented trap electrodes for excitation and detection we will be able to determine the number of ions. Third, it should be possible to detect a single highly charged atomic ion. Finally, many measurements can be performed more quickly with the FT-ICR technique than with conventional diagnostics For example, we have been able to measure the relative abundance ratio of adjacent ionization stages twenty times faster with the ICR technique than by conventional x-ray methods. The FT-ICR method thus is becoming one of the most important tools for studying highly charged atomic ions in an EBIT device.

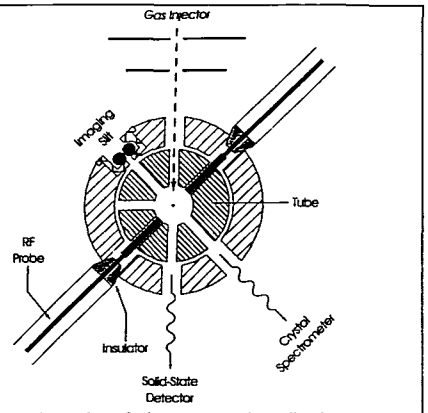

Figure 2 Schematic of the trap region (horizontal cut) showing the location of the two ICR probes as well as different x-ray instrumentation.

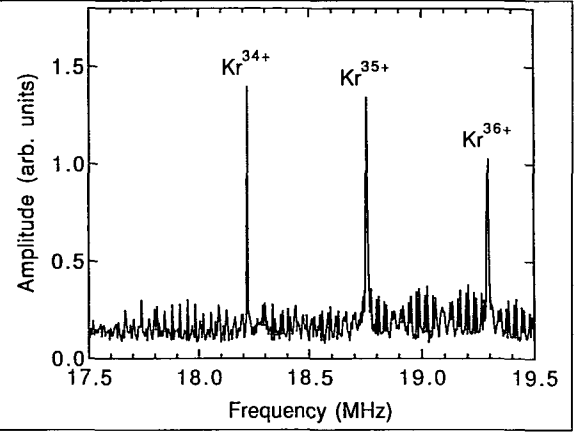

Figure 3. FT-ICR spectrum of highly charged krypton ions.

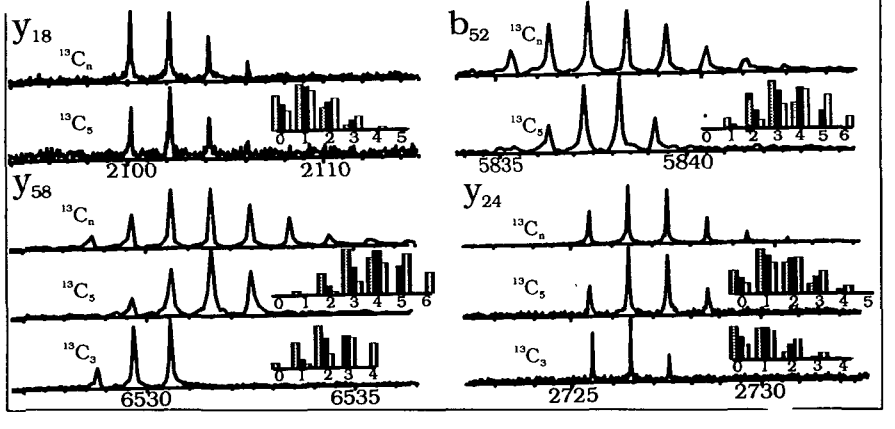
ESI/FTMS Instrumentation for Tandem Mass Spectrometry

Peter B. O'Connor, David J. Aaserud, Ziqiang Guan, Daniel P. Little, Gary A. Valaskovic, Troy D. Wood, Fred. W. McLafferty
Baker Chemistry Laboratory, Cornell University, Ithaca, NY, 14853

Classical methods for the structural characterization of large proteins and other biomolecules utilize condensed phase degradation reactions (difficult for subpicomole samples) and microseparations for limited resolving power (RP) and mass accuracy. Gas phase MW determination and sequencing is especially promising with ESI/FTMS (RP $>10^5$) using sequential ion separations and dissociations (MS^n), with femtomole samples analyzed despite poor efficiencies in MS^n and ESI. Improvements reported here include quadrupolar excitation (QE) for axialization of large protein ions, a capacitively coupled cell selecting single isotope peaks (RP = $3x10^4$) for MS/MS, micro-ESI, and 193 nm ion photodissociation for high efficiency production of complementary fragment ions.

The cylindrical open trapped ion cell exhibits coupling of axial and radial motions during irradiation due to excitation field inhomogeneities which causes ions be ejected from the cell during QE.[1] As shown earlier,[2] capacitively coupling the excitation field onto the trapping electrodes solves this problem, effectively achieving the ideal infinitely extended excitation electrodes. QE with this cell has allowed axialization of protein ions up to protein A (45 kDa). The capacitively coupled cell also makes possible high resolution SWIFT[3] isolation of single isotopic peaks up to 29 kDa.[4] This capability is very useful for isolation of single components of overlapping isotopic distributions for further study; however, single isotope peak isolation and fragmentation can also be used to determine the number of ^{13}C's in an isotopic peak for increased mass accuracy through resolution of the uncertainty in isotopic assignment associated with statistical samples of large proteins. For example, in Figure 1, fragmentation of the $^{13}C_3$ and $^{13}C_5$ isotopes of ubiquitin yields fragment isotopic distributions easily distinguished from the model distributions from fragmentation of the precursor isotopic peaks with +/- 1 heavy isotope.



Recent results by Ron Orlando et al[5] showed the power of doing both low and high energy dissociations for elucidation of large peptide structure. Analogously, we have implemented both IRMPD (low energy, 10.6 μm)[6] and UV (high energy, 193 nm)[7] photodissociation on our instrument and generated UV photofragmentation data for ubiquitin (Figure 1, 8.6 kDa), as well as melittin (2.8 kDa) and carbonic anhydrase (29 kDa). UV dissociation generates primarily C and X ions as opposed to the lowest energy B and Y ions typically formed. Ideally, we will use IRMPD for selective generation of small fragments, isolate them and then dissociate these small fragments with high energy UV photodissociation for generation of full sequence information.

Implementation of micro-ESI[8] using pulled silica capillary coated with a gold film allows routine spectral acquisition on femptomole quantities of material. 15 fmols loaded into the electrospray source allowed acquisition of both a molecular ion and a nozzle skimmer spectrum of Ubiquitin, while 0.22 fmols loaded yields signal/noise of 60:1 for Cytochrome C. This is by no means the lower limit on sensitivity.

Fragmentation of Labelled lysozymes and derivatives by FT MS

Carol V Robinson, Andrew Miranker,
Gary Kruppa and Christopher M. Dobson.

Oxford Centre for Molecular Sciences,
South Parks Road, Oxford, OX1 3QT, UK.

Introduction

Recently we have shown the power of ESI MS and hydrogen deuterium exchange labelling in the characterisation of protein folding intermediates[1,2]. Whilst it is possible to monitor populations of intermediates, and their evolution with folding time, it has not been possible to assign deuterated fragments within the protein sequence without the aid of enzymatic digestion and separation of the resulting fragments by HPLC[3] This method suffers from the inherent disadvantage that hydrogen exchange rates for peptides are considerably faster than for proteins since the overall tertiary structure of the protein affords considerable protection from exchange In this study we demonstrate the use of FT MS for the fragmentation and assignment of protein fragments within the protein sequence using a range of isotopically labelled proteins and solutions in which the tertiary structure of the protein is modified.

Results and Discussion

A comparison of the +11 charge state for the globular protein hen egg white lysozyme is shown in figure 1. The isotopic resolution available with this technique not only enables accurate determination of the mass of the fragment ion but also allows ready assignment of the charge of the fragment since the isotopic spacing is related to the charge state of the ion

(a) (b)

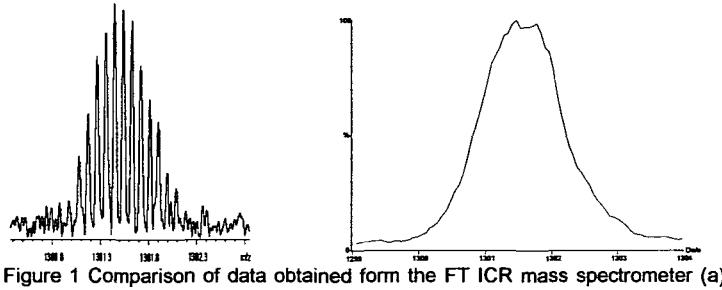

Figure 1 Comparison of data obtained form the FT ICR mass spectrometer (a) with data obtained on a quadrupole mass spectrometer (b).

Source to skimmer fragmentation of lysozyme yields some 51 fragments of which only 2 are triply charged, 15 are doubly charged and the remaining 34 are singly charged The presence of predominantly low charge state ions may reflect the relatively mild acidic conditions used to preserve the native state of this protein or the restrictions imposed on the conformation of the protein in the gas phase by the presence of the four disulphide bonds In order to investigate these effects lysozyme was introduced under a variety of different solvents known to produce dramatic changes in the tertiary structure of the protein, however, very little effect was seen on the fragmentation pattern of the protein. Greater effects on the fragmentation pattern were observed upon reduction and carboxymethylation of one of the critical disulphide bonds.

In order to utilise information obtained from fragment ion spectra it is necessary to assign the ions to specific regions of the protein A program was written to compute all possible fragments from this 129 residue protein and considers all a,b,c and x,y,z fragments and traces fragments through disulphide links and optionally allows disulphide cleavage. Such a program yields a total of 10^5 possibilities and despite the high mass accuracy afforded by FT MS a number of ambiguities remain In order to delineate these possibilities spectra were obtained from ^{13}C and ^{15}N labelled protein These isotopically labelled proteins allow unambiguous assignment of the protein since they enable the number of carbon and nitrogen atoms present in each fragment to be determined. Similarly, protein samples in which deuterium is incorporated show mass increases in fragments and allow the assignment of deuterium labelled regions of the protein during protein folding pathways

Conclusions

The results from this study suggest that the overall folding of the protein has little effect on the number and size of fragments seen but preliminary results have shown that for proteins in which disulphides have been reduced the fragmentation pathway is changed dramatically. The use of istopically labelled proteins reduces ambiguity in the assignment of proteins and thus allows individual regions of the protein to be monitored during protein folding pathways.

ESI-FTICR METHODS FOR BIOAFFINITY CHARACTERIZATION MASS SPECTROMETRY

James E. Bruce, G.A. Anderson, R. Chen, X. Cheng, D. C. Gale,
S. A. Hofstadler, B. L. Schwartz and R. D Smith
Pacific Northwest Laboratory, Richland, Washington 99352

The characterization of biomolecular associations for the determination binding and binding sites and elucidation of potential drug leads is a difficult problem spanning a diverse field of analytical methods. Current techniques that are based upon the formation of noncovalent associations generally require the removal of noncovalent complexes from solution and thus limit the applicability of these approaches. A technique that would allow the investigation of these complexes directly from solution and promote rapid screening of combinatorial libraries by direct observation of the complex(es) is attractive. Technical details of the new method called bio-affinity mass spectrometry (BACMS) which promises to promote a more practical approach than current techniques employed in combinatorial chemistry and affinity chromatography are presented.

The BACMS approach is based on Fourier transform ion cyclotron resonance (FTICR) mass spectrometry which, when coupled to electrospray ionization (ESI), allows the investigation of specific noncovalent complexes formed in solution. The unique attributes of ESI-FTICR, such as the well established high resolution, accurate mass analysis and MS^n capabilities with more recently developed techniques involving quadrupolar excitation (QE) and selected-ion accumulation (SIA)[1], permit the investigation of noncovalent interactions directly from solution, even at very low relative concentrations. ESI-FTICR mass spectra of bovine ubiquitin (M_r=8565) were acquired from direct infusion of a 1 1x10^{-9}M solution with broadband SIA over the *m/z* range of 1200 to 1740. This required the injection of 300 attomoles of ubiquitin, and similar results were obtained with the peptide, bradykinin. Much lower limits of detection are predicted based on the implementation of the low nL/min flow rate "microspray" ESI source of Mann et al [2] and the use of the quadrupole excitation-based remeasurement technique from Amster's group[3]. More importantly, however, this demonstrates the successful application of ESI-FTICR methods to the analysis of very low concentration solutions, such as will be encountered in the BACMS studies.

An important test for the new facilities involves the detection of low concentration species in the direct analysis of complex mixtures with widely varying concentrations since the noncovalent associations that can provide information on new drug leads may be formed only at very low relative concentrations. This can present difficulties for FTICR analysis given the inherent dynamic range limitations brought about by the maximum ion population that can be effectively addressed. The results of our new approach involving SIA to reduce this effect by sequentially removing species from our filtered or "colored" noise accumulation "mask" is shown in Figure 1 with a mixture of the proteins bovine insulin, bovine ubiquitin, and bovine cytochrome *c*, in concentrations of 9 x 10^{-5}M, 9 x 10^{-7}M, and 1 x 10^{-8}M, respectively. Figure 1(a) shows the mass spectrum obtained with SIA using broadband QE from *m/z* 1000 to 2000. Modification of the QE waveform to remove those frequencies corresponding to the 4+ and 5+ charge states of insulin produced the "accumulation mask" shown in Figure 1(b) and, with a 5 second accumulation, the mass spectrum shown in 1(c) This spectrum shows the 7+ charge state of ubiquitin as the largest peak. Removing the frequencies corresponding to the ubiquitin ions produced the mask shown in Figure 1(d). A 20 s accumulation with this mask produced the mass spectrum shown in 1(e), in which the largest peaks are now insulin-related impurities (even these species appear more concentrated than the cyctochrome *c*). However, the 11+ charge state of cytochrome *c* is detected with unit mass resolution as is

illustrated in the inset of this figure. These results demonstrate the successful application of SIA and BBQE to produce a significant extension of the dynamic range with FTICR. Importantly, these extensions can be made with any continuous source of ions and without any prior knowledge of the injected ion identities (other than an approximate *m/z* range), as is dictated by the BACMS technique.

Fast Metastable Ion Fragmentation In MALDI

Duane Reiber, John J. Lennon and *Robert S. Brown, Department of Chemistry and Biochemistry, Utah State University, Logan, UT 84322-0300

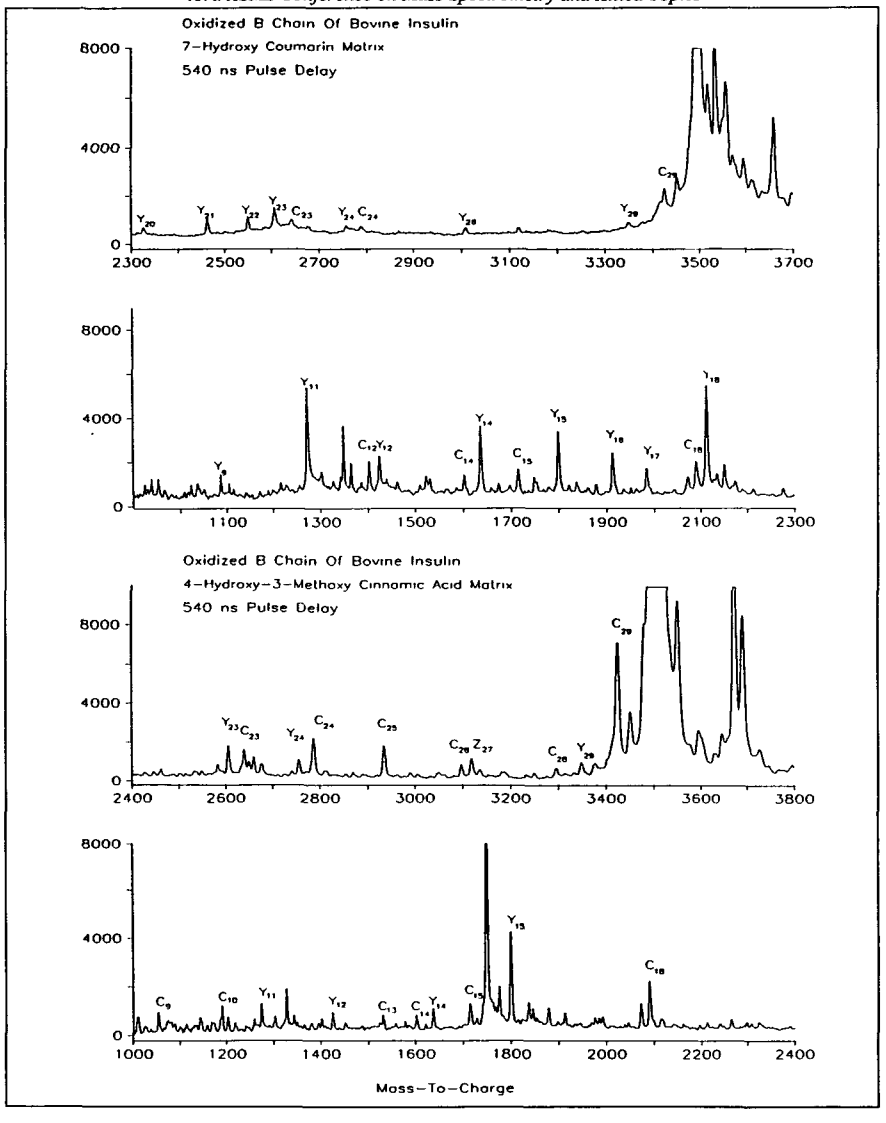
Until recently, matrix-assisted laser desorption/ionization (MALDI) has generally been considered a very gentle ionization method, producing predominantly intact protonated molecular ion species. This early view of MALDI has evolved into the understanding that a significant degree of metastable ion decay occurs with MALDI generated ions. This metastable ion decay is generally believed to result from both bimolecular collision processes and unimolecular ion decay. This delayed, post source decay (PSD) of MALDI generated ions has been exploited on the tens of microsecond time scale in reflecting time-of-flight (TOF) mass spectrometers to provide significant structural information for moderate sized peptides. In the conventional PSD experiment, it is not possible to distinguish between bimolecular and unimolecular decay processes. If the dense plume model for MALDI is correct, it is likely that significant activation of the MALDI generated ions occur due to energetic collisions between analyte ions and neutrals in the expanding plume of matrix molecules when continuous ion extraction is employed. This is supported by the similarity of PSD spectra obtained with reflecting TOF mass spectrometers and low energy collisional activation spectra. PSD spectra of peptides reported in the literature exhibit a, a-17, b and b-17 fragment ions.

One approach to studying the unimolecular decay process in MALDI is to utilize a delay between ion formation and ion extraction. This allows the initially dense matrix plume to expand sufficiently to reduce the collisional rates for the desorbed analytes. When this is implemented on a linear TOF mass spectrometer (337 nm), a small but significant degree of metastable ion decay is observed that is structurally different from what is observed with PSD spectra. With delayed pulsed ion extraction, amide bond cleavages leading to c, y and z type ions are observed. This fragmentation also occurs on a very fast time frame. Fragmentation appears to be complete by no later than 300 ns (current minimum pulse delay) after the laser event. No generation of PSD type metastable ions are observed with delays out to 2 µs. This is consistent with the suggestion that much of the PSD metastable ion decay is due to collisional processes. As with continuous ion extraction in a linear TOF mass spectrometer, any collisional metastable ions would not be observed with the delayed pulsed ion extraction experiment if the activation is associated with the ion acceleration process.

Substantial fast metastable ion decay has been observed for a variety of small to medium sized peptides including substance P, neurotensin and melittin. All peptides studied to date produce similar fragmentation results. Even cross-linked peptides such as (porcine) insulin can produce a limited amount of fast metastable ion fragmentation. For insulin, fragmentation occurs from the terminal ends and proceeds until a disulfide bridge is reached. The fast metastable ion decay spectrum of insulin is complicated by the two cross linked chains which each have two terminal ends from which fragmentation occurs. These fast metastable ion decay spectra can be easily mass calibrated (internally or externally) to produce mass accuracies of typically ±0.3 Da for peptides as large as insulin. Selected larger proteins have also been observed to exhibit fast metastable ion decay (cytochrome C and myoglobin).

This fast metastable ion decay appears to result from unimolecular ion decay processes associated with the ionization step in MALDI. One plausible mechanism that has been suggested in the literature is a very fast exothermic proton transfer reaction, presumably to an amide nitrogen. Rapid localized bond cleavage than occurs (randomly along the peptide backbone) prior to internal energy conversion within the molecule. This model is supported by the fact that the most significant differences are observed in the metastable ion decay species when chemically different matrices are employed. This difference in fragmentation can be observed in the fast metastable ion decay spectra obtained when ferulic acid and 7-hydroxy coumarin are employed as the MALDI matrix for the B chain of bovine insulin (Figures 1 and 2).

Finally, preliminary studies with a quadrupled Nd:YAG laser (266 nm) have shown similar fragmentation ions as that observed at 337 nm. Some overall increase in the absolute intensity of the metastable decay ions with the shorter wavelength laser has been observed in addition to an increase in the intensity for some smaller fragment ions. Studies are underway to acess the effects of both laser wavelength and pulse width on the fast metastable ion decay process.



Delayed Extraction in Matrix-Assisted Laser Desorption

W. Ens, R. G. Dworschak, V Spicer, K.G. Standing
Department of Physics, University of Manitoba, Winnipeg, Canada R3T 2N2

In general, time-of-flight mass spectra obtained by matrix-assisted laser desorption/ionization (MALDI) in a linear time-of flight TOF spectrometer are characterized by modest mass resolution and almost no structurally significant information. The resolution is usually limited by the initial energy spread and by metastable decay in the field-free flight tube, both of which are strongly influenced by the high dc extraction field strength normally used to acquire MALDI spectra [1,2]. Recently two groups have shown considerable improvement in resolution by using delayed extraction [3,4]. This decouples the ion desorption process from the extraction process, reducing metastable decay caused by collisions in the plume, and allows time-lag energy focussing as described by Wiley and McLaren [5]. We have obtained similar results using a delayed extraction pulse (1 - 4 kV) applied to the target which along with the first grid is at a potential up to 25 kV. A second grid is held at ground potential. The geometry is illustrated in Fig. 1 (d1 = 6 mm, d2 = 1.0 cm and L = 1.3 m). The length of the delay is typically between 1 and 3 µs.

Fig. 2 shows the molecular ion regions for horse and sheep myoglobin obtained with pulsed extraction in the linear mode. The molecular weights for these compounds differ by 28 Da; the resolution is approximately 1200 The doubly charged molecular ion of carbonic anhydrase (29 157 Da) is shown in Fig. 3 with dc extraction and with pulsed extraction. If the shoulder on the low time side of the delayed extraction peak represents a fragment, then it appears that the instrumental resolution is about 1200 for this peak as well.

The use of pulsed extraction with a reflecting TOF instrument is also expected to give improved performance, especially for larger proteins. While good resolution for peptides is possible with dc extraction, tails caused by metastable decay limit resolution for larger species Simply lowering the extraction fields reduces the metastable decay [2] but this introduces an increased time spread in the extraction region. Such a time spread can be avoided for a given mass by using pulsed extraction to focus the ions at some intermediate plane before entering the mirror. For optimum use of the mirror, this plane should be near the source, and this requires that the field is approximately the same in both regions. With our present geometry, only low extraction fields can satisfy this condition so we have not yet demonstrated high resolution in this mode. However, we have demonstrated that ions injected with a delayed pulse are much more stable than ions injected by a dc extraction field. Since the ions have time to decay to stable fragments *before* they are accelerated, rather than in free flight, the fragments appear in the ordinary TOF spectrum at their apparent mass. Fig. 4 shows the full spectrum of melittin and a small portion expanded to indicate the fragmentation. Similar sharp peaks corresponding to prompt structural fragments appear throughout the spectrum, but the two broad peaks are the only evidence for metastable decay. For higher molecular weight species like cytochrome C, as much as 95% of the signal disappears when dc extraction is used instead of delayed extraction. With a redesigned source geometry, we hope to exploit this improved transmission to obtain improved resolution for high molecular weight species.

Investigation of Selective Detection of Peptide Mixture by MALDI Mass Spectrometry

Wen Yu, James E. Vath, Bruce S. Tangarone and Hubert A. Scoble
Structural Biochemistry, Genetics Institute, One Burtt Road, Andover, MA 01810

The ability to detect femto-mole quantities of peptides from a complex mixture in the presence of common digest buffers is a distinct advantage of MALDI mass spectrometry comparing to other ionization modes. Many important applications, including protein identification by mass profiling [1], have been built upon such promise. In practice, the sequence coverage from the analysis of digest mixture often varies widely and seemingly mysteriously from case to case, though the relative abundance of the peptides seems to be reproducible once the MALDI conditions are held constant. Understanding this phenomena, termed "peptide detectability", is becoming more critical as MALDI mass spectrometry is being widely applied to the field of protein characterization and identification.

We have examined peptide detectability using a known mixture derived from the Lys-C digest of a recombinant glycoprotein. The matrix, α-cyano-4-hydroxycinnamic acid, was chosen as it is the most common matrix used for mass profiling in our experience. For each MALDI mass spectrum acquired from the peptide mixture at various dilution, the relative abundance of the peaks were transformed into a user defined peak intensity index ranging from 0 to 5. The indexes are then ploted against the hydrophobicity indexes of the corresponding peptides calculated from their amino acid composition and hydrophobicity established from the 3-D structure of the proteins [2]. The results for the dataset at the matrix/analyte (M/A) ratio of 10000 in Figure 1(A) suggest that the detectability of the peptide in the mixture is hydrophobicity dependent as more hydrophilic peptides are detected at higher abundance while the peptides absent from the MALDI mass spectrum tend to cluster around the hydrophobic region. The favoritism for the hydrophilic peptides seems to diminish for the data at lower M/A ratio as shown in Figure 1(B) since the peak intensity indexes of the detected peptides do not follow any pattern. This would point to the additional dependence of peptide detectability in the mixture on M/A ratio.

The peptides in the mixture can be categorized into those able to gain (Figure 1C) or lose (Figure 1D) preference for detection and others that are not effected. To understand the behavior of peptides at the point of M/A ratio = 420 (highlighted by the thick vertical lines), we looked at the recovery of peptides being included or excluded by the matrix on an individual basis as shown in Figure 2. This experiment clearly demonstrates that at a M/A ratio of 420, the hydrophobic peptides eluting later in the chromatogram were preferentially included into the matrix while the hydrophilic peptides at the earlier part of the chromatogram were nearly totally excluded. This is consistent with the trends observed in Figure 1C and 1D. We proposed that the selective incorporation of the peptide is the determining factor at low M/A ratio while the dissociation of peptide from the matrix molecules in the gas phase, which favors the hydrophilic peptide because of weaker interaction, plays a more important role at higher M/A ratio.

The same methodology was applied to the dataset collected from 5 mass profiling experiments. The probability that a given peptide in the digest mixture may or may not be detected by MALDI MS was found to be dependent on its calculated hydrophobicity and hydrogen binding tendency [3]. The estimated probability of detectibility can be included into the calculation of matching probability and likelihood ratio for better evaluation of the matching patterns during the mass profiling experiments.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

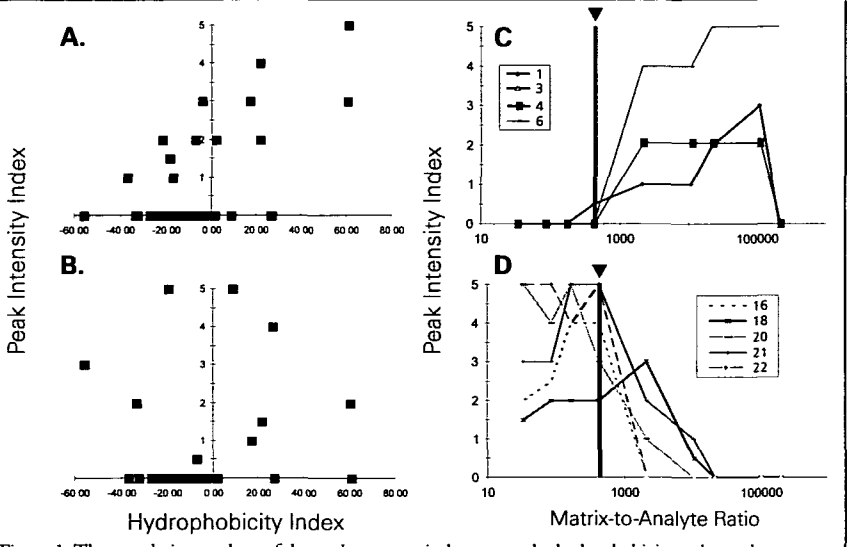

Figure 1. The correlation analysis of the peak intensity index versus the hydrophobicity index and matrix/analyte (M/A) ratio. The peptide mixture derived from the Lys-C digest of the recombinant glycoprotein was diluted with saturated solution of 4HCCA before analyzed by MALDI TOF MS in linear mode. A) M/A ratio = 10000 with 40 fmol per peptide, B) M/A ratio = 420 with 2 pmol per peptide, C) trends for peptide 1,3,4,6, D) trends for peptide 16,18,20,21,22 (same numbering as used below).

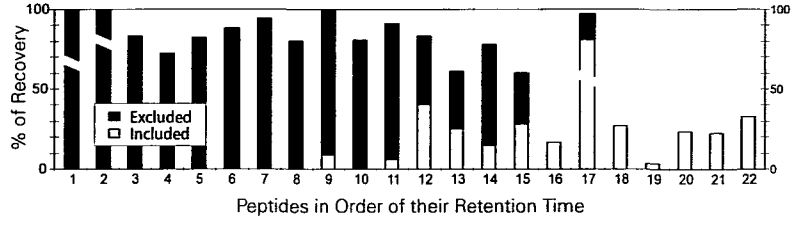

Figure 2. The partitioning of peptides within and outside the matrix crystals. The matrix particles prepared from the starting mixture at M/A ratio of 420 was washed with cold water over a 30 kD cutoff memberane several times before redessolving in 70% ACN. The washed and redessolved matrix were then seperated on RP-HPLC using establish conditions. The percent recoveries were calculated from the HPLC area compared to that of the starting material.

Examining MALDI Ion Formation at Various Laser Fluences

Ricky D. Edmondson, Karen K. Campo, and David H. Russell
Laboratory for Biological Mass Spectrometry
Department of Chemistry, Texas A&M University
College Station, TX 77843

We have observed that two thresholds exist for ion formation in MALDI. At low laser fluences(2mJ/cm^2) ions are only produced from the first laser shot on each spot. In order to generate more ions from this spot, fluences must be increased three to four times. Ions are then produced for many consecutive shots from that sample spot. The instrument used in this study was a PerSeptive Voyager Elite TOFMS. Spectra were acquired in the linear mode(2m drift tube) with an acceleration voltage of 30kV. Spectra of Mellitin and Vitamin B_{12} were each taken with alpha-cyano-4-hydroxycinnamic(ac4h) acid at both the high and low ionization thresholds. Each spectrum is the average of 25 shots. For the low fluence spectrum(fig 1,3) one shot is taken on 25 new sample spots and averaged, whereas in the high fluence spectrum(fig 2,4), 25 shots were averaged from one spot The enhancement in analyte/matrix signal and increased resolution is seen in the low fluence spectrum of Mellitin in figure 1. Vitamin B_{12} can provide some information on the energetics of ion formation. The high fluence threshold spectrum of B_{12} shows no intact molecular ion(figure 4), only the prompt fragment of the loss of the labile cyano ligand. However, the $M+H^+$ is a prominent peak in the low fluence spectrum(figure3).

These high resolution spectra obtained in the linear mode suggest that the ions formed at the low laser fluence threshold have narrow energy distributions. The B_{12} results support an argument that these ions are formed with lower internal energies.

We propose a model that the lower ionization threshold is a surface component and the higher threshold is a component of the bulk material.

Continuous Flow MALDI in an Ion Trap-Reflectron TOF Mss Spectrometer

Ling he, Li Liang, Xuhui Li, David M. Lubman
Chemistry Dept, The University of Michigan, Ann Arbor,MI 48109-1055

MALDI as an ionization method has been extensively studied in the static mode with solid matrices. Only a few research work has been done to explore the MALDI in the liquid and continuous mode. The possibility to combine the advantages of MALDI with the on-line separation techniques is the major driving force for this project

An novel ion trap/ReTOF mass spectrometer is used as the interface to perform MALDI in the continuous mode The instrument configuration is depicted in Figure 1. Samples are injected using a 4-port Reodyne injection valve with 5μl internal loop. Matrix solution (3-NBA:H20· acetonitrile Ethylene glycol = 8 40:50:40·2 v/v, containing 0 1% TFA) and the carrier solvent (H2O acetonitrile = 1:1 v/v, containing 0.1%TFA) are mixed through a mixing tee and the flow rate after splitting is typically below 3μl/min.. The flow probe transmits the sample/matrix mixture into a hole on the ring electrode of the ion trap The laser (266nm) comes from the counter position and ionizes the sample exited from the flow probe tip. After ions from several laser shots are stored and accumulated in the ion trap for a certain time, a DC pulse is applied to the end cap to extract all the ions out of the ion trap and into the ReTOF mass analyzer to measure the m/z It is demonstrated that this configuration can provide a resolution of more than 300 (FWHM) for neurotensin(Mw. 1672.9) and Gramicidin (Mw. 1140). Figure 2 shows the spectrum of neurotensin in the continuous mode. The detection limit is in the low picomole range for peptides with molecular weight up to 8500D. Signal of Cytochrome C is observed in the continuous mode. An analogue frequency scanning is applied to the entrance end cap to kick out the low mass ions before the stored ions are pulsed out of the ion trap. The background noise is reduced in htis way. Both the resolution and S/N ratio are improved by reducing the space charge effect. The pressure inside the ion trap is found to be the most important factor that influences both the resolution and the sensitivity. A whole spectrum can be obtained in one extraction pulse Quantitative analysis of neurotensin using gramicidin as the internal standard in the continuous mode shows there is a nice linear relation between log(Sn/Sg) and log(Cn/Cg) within a range of two orders of magnitude Single matrix and mixture matrix were both tried and there were not significant differences

In conclusion, a continuous flow MALDI system is built successfully by the hyphenation of an ion trap and a ReTOF mass analyzer. This system is ready for coupling with LC separation techniques such as capillary HPLC Also it is possible to couple this system to CE due to its low solvent flow rate required and high sensitivity obtained

LANTHANIDE OXIDE CLUSTER IONS PRODUCED BY LASER ABLATION*

John K. Gibson, Chemical and Analytical Sciences Division
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6375

Positive ions produced by XeCl excimer laser ablation of inorganic solids were studied by reflectron time-of-flight mass spectrometry to elucidate chemical speciation and the physical processes comprising ablation. The results are relevant to developing enhanced techniques for pulsed laser deposition of thin films and laser ablation sampling for materials analyses.

The initial emphasis has been on studying simple gas-phase inorganic clusters, which often exhibit novel chemistries and/or structures and provide a discernible bridge between the molecular and condensed states of matter. We have developed vacuum ablation of lanthanide oxalates (LnOX) as a source of lanthanide oxide cluster ions, representable as $Ln_mO_n^+$ ($m \leq 64$; $n \approx [3/2]m$). The LnOX mass spectra (shown for YbOX in Fig. 1) exhibit two primary cluster series, in both of which the Ln^{+3} oxidation state is predominant: $\{Ln^{3+}{}_mO^{2-}{}_{1/2(3m-1)}\}^+$ with m = 3, 5, 7, etc., and $\{Ln^{2+}Ln^{3+}{}_{m-1}O^{2-}{}_{1/2(3m-2)}\}^+$ with m = 4, 6, 8, etc. In addition to the Ln^{2+} sites in the latter series, other (minor) clusters exhibited compositions indicative of less-common lanthanide valence states, including those specified in Table I. The assignment here of discrete localized oxidation states assumes ionic cluster bonding, consistent with conventional lanthanide oxide chemistry. Alternatively, average lanthanide valences may be considered, as in Figure 2 in which are evident the singular tendencies of Tb to form the +4 oxidation state and Gd to form exceptionally metal-rich (low-valent) clusters which presumably comprise metallic Gd_p^o subclusters The genre of lanthanide oxide clusters being discussed apparently provides unique local atomic environments in which subtle distinctions between lanthanide electronic structures, including 4f occupancy, are clearly manifested. Solids which preserve distinctive cluster properties could offer routes to novel lanthanide nanomaterials, such as enhanced catalysts, with atypical chemical/valence states

Experiments are being performed to clarify the mechanism of ablation production of lanthanide oxide clusters, specifically whether formation is by intact ejection from the solid target or by aggregation of small species in the plume. The dramatic enhancement in cluster formation induced by the gaseous oxalate decomposition products (CO, CO_2 and H_2O) suggests a gas-phase aggregation mechanism. Accordingly, it was shown that the concentration of clusters relative to small ions is enhanced in the (cooler) tail of the plume. As additional evidence for gas-phase aggregation, we have prepared mixed lanthanide oxide clusters, such as $La_4Ho_3O_{10}^+$, by ablating physical mixtures of oxalates; the most plausible explanation for atomistic mixing from physically blended solids is by aggregation in the plume

Given its exceptional sensitivity and sample utilization efficiency, pulsed laser ablation mass spectrometry is ideally suited to studying scarce and/or radioactive materials such as transuranium actinides. The demonstration in the present work of clear manifestations in oxide cluster chemistry of subtle distinctions between lanthanide electronic structures particularly suggests this approach for micro-scale investigation of otherwise inaccessible actinide chemistry.

The Role of Solubility in the Preparation of Synthetic Polymer Samples for Analysis by Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry

Richard C. King, Robert Goldschmidt, Yansan Xiong and Kevin G. Owens*, Department of Chemistry, Drexel University, Philadelphia, PA 19104
Scott D. Hanton, Air Products & Chemicals, Inc., Allentown, PA 18195

Sample preparation is considered to be an art in matrix-assisted laser desorption/ionization (MALD/I). The analysis of synthetic polymers, which possess a wide range of chemical properties, presents significant issues in the development of sample preparation methods. While discussed peripherally by numerous groups, the issue of solubility is one that must be addressed in order to successfully analyze a wider range of samples. It will be demonstrated here that solubility is the key to solid-state (crystal) sample preparation.

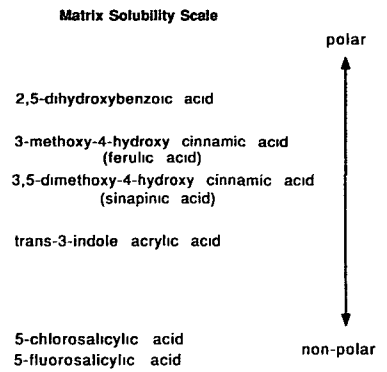
Three solubility issues must be considered: the solubility of the analyte in the solvent, the solubility of the matrix in the solvent, and the solubility of the analyte in the solid matrix crystal. Changes in synthetic polymer solution solubility as a function of the molecular weight in different solvents is well-known[1]. Solvent fractionation, accomplished by slowly adding a non-solvent to a polymer solution, is used to separate polymer samples into fractions of different molecular weight. Anything that affects solubility: temperature, solvent composition, ionic strength, polarity, acid or base character, the presence of other sample constituents, will affect the incorporation of the sample into the matrix crystal and therefore the success of the MALD/I experiment.

A number of different solubility metrics are in use in various disciplines[2]. Many of these are calculated from readily measured molecular properties. One of the earliest is the Hildebrand[3,4] solubility parameter (δ), which was developed to quantify "polarity" and to predict interactions between non-polar materials. Due to the strict limitations of the applicability of Hildebrand parameters to non-polar solvents, they have been augmented with a three-tier delineation in terms of the hydrogen bonding capability (poor, medium or strong) of the solvent. In practice, the Hildebrand parameter of solvents within each class are compared to predict solute/solvent interactions. Later Hansen[2] proposed an additional solubility metric that attempts to quantify the dispersion (δ_d), polarity (δ_p), and hydrogen bonding (δ_h) characteristics of each solvent independently. Hansen parameters are tabulated for a large variety of solvents as well as polymer systems, and are widely used as a guide to polymer solvent selection.

In separations science, Rohrschneider[5]/McReynolds[6] constants are widely used to classify gas chromatographic stationary phases. A series of test compounds is used to quantify the various types of molecular interactions between analyte and stationary phase. Tables of McReynolds constants exist, allowing for an informed choice of stationary phase for the desired separation. In a similar fashion, Snyder's polarity index[7] (developed using three test solvents) is widely used to select the appropriate liquid chromatography mobile phase. Although there is currently some discussion about the correctness of some of these metrics[8], the presence of some kind of solubility standard greatly simplifies the practice of these techniques.

In this presentation we present an empirical classification of several popular MALD/I matrices (see below) based upon our results with a number of different synthetic polymer chemistries. Several points are clear from this work. First, there is a large gap in matrix "solubility parameter" between trans-3-indoleacrylic acid (IAA) and 5-chlorosalicylic acid (CSA). Second, there is a need for a matrix more polar than 2,5-dihydroxybenzoic acid (DHB).

In this work two techniques were employed independently to study the analyte-matrix solvent system. Fluorescence microscopy was used to demonstrate the incorporation of the analyte in



the matrix crystal. Ultraviolet MALD/I experiments were used to confirm the success of the sample preparation method. Polymers investigated include polyethylene glycol (PEG), polytetramethyleneglycol (PTMEG), polydimethylsiloxane (PDMS), polymethylmethacrylate (PMMA), polyethyleneterphthalate (PET) and polystyrene (PS). A wide range of solvents of varying polarity (solubility parameter) has been studied with several matrices, including DHB, IAA, 5-fluorosalicylic acid, CSA, and 2,4,6-trinitrophenol. The discussion in this presentation will focus on two key areas: solubility of the analyte in the solvent and solubility of the analyte in the matrix crystal.

Samples are normally prepared as dilute solutions. Note, however, that the solubility characteristics of the solution may change dramatically as the sample crystallizes. Factors that change the sample drying rate, including choice of solvent, heating, or pressure (e.g., drying under vacuum), will affect the incorporation of the analyte in the matrix crystals. As crystallization is a physical separations method, those things that affect the sample drying rate will obviously have an impact on the results. Additionally, sample preparation steps such as ion exchange, solution buffering, complexation using metal salts or binding proteins, or the addition of matrix additives are discussed as having a direct effect on the incorporation of the analyte by changing the solubility characteristics of the sample solution.

Solubility is demonstrated to be key to the analysis of synthetic polymer systems. Although most proteins can be analyzed using well-known sample preparation methodologies, it is likely that methods developed here for the analysis of synthetic polymers will be useful for the analysis of strongly hydrophilic or hydrophobic biological materials.

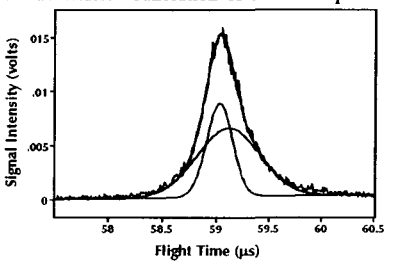
MECHANISTIC IMPLICATIONS OF MALDI ION SIGNAL PROFILES

Gary R. Kinsel
The University of Texas at Arlington, Department of Chemistry, Arlington, TX 76019

Ricky D. Edmondson and David H. Russell
Texas A&M University, Department of Chemistry, College Station, TX 77843

Profile analysis of bovine insulin cluster ion signals produced by MALDI in a TOFMS are found to consist of two distinct Gaussian profiles. For all cluster ion signals the two component fits consist of a broad profile which contributes to the poorly resolved base of the ion signal and a sharp profile which contributes to the improved resolution of the ion signal half-width. Calibration of the mass spectrum from the masses of the cluster ion signals and the flight times of the sharp component of the two component Gaussian fit using the TOFMS calibration equation ($TOF = k(m/z)^{1/2} + b$) yields significant improvements in the linearity of the calibration plot over calibration attempts using the flight times of the maximum cluster ion signal intensities. In addition, calibration using the sharp component of the two component profiles returns an average instrumental offset parameter, b, of 1.0±15 ns. This value reflects complete agreement with the expected line delays between firing of the desorbing laser and triggering of data collection. The overall error in flight time assignment (and mass assignment), determined by back calculation of the cluster ion flight times using the calibration parameters determined from linear regression, is significantly improved (see figure 1)



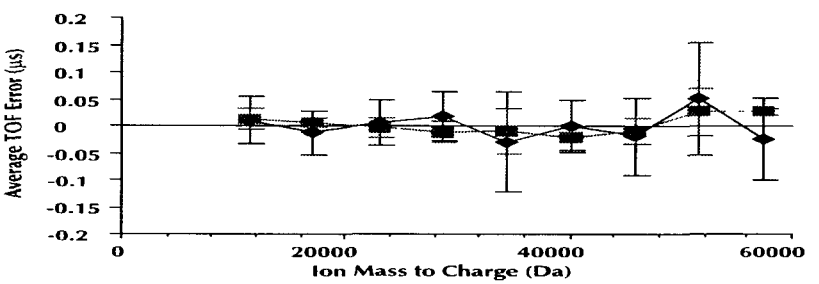


Figure 1 Errors in calculated ion flight times from spectrum calibration using (♦) flight times of maximum cluster ion signal intensity and (■) flight times of sharp component of two component Gaussian fits Average % error of flight times calculation for six spectra over entire mass range is 0.02% and average error in mass assignment is 0 04% for calibration using the sharp component

Two important insights are drawn from calibration using the sharp component of the ion signal profiles and the resulting calibration parameters. First, **NO** significant systematic mass dependent ion energy is associated with the desorption of the ions which make up the sharp component of the ion signal. A mass dependent ion energy would result in both curvature of the TOF vs. $(m/z)^{1/2}$ calibration plot and a

value for the instrumental offset parameter inconsistent with the experimental approach. Second, ion formation must be prompt *i.e.* within ten to fifteen nanoseconds of the desorbing laser pulse. Otherwise, delayed ionization would result in an inappropriately large offset parameter. From these results we conclude that the mechanism of formation of the ions contributing to the sharp component must involve prompt, laser induced surface ionization of the analyte followed by emission of the analyte ions with a constant (not necessarily thermal), mass independent initial kinetic energy.

Interpretation of the dynamics of ion formation for the ions which make up the broad component of the asymmetric ion signals is more complex. It is found that the flight time of the centroid of the broad component gradually shifts from longer flight times relative to the sharp component at low mass (< 20 kDa) to shorter flight times relative to the sharp component at high mass. Although mechanisms such as adduct formation or metastable decay could explain one observation or the other, neither process can independently explain the entire trend observed. Instead, we interpret the dynamics of formation of the ions making up the broad component in terms of neutral material accelerated to a constant entrainment velocity followed by delayed gas phase ionization of this material. This combination of dynamic processes yields ions with total energies, $E = E(acc) + 0.5(m/z)^{1/2}v(ent)^2 - FP(gpi)$, where E(acc) is the total acceleration voltage, v(ent) is the entrainment velocity, F is the source region electric field and P(gpi) is the point in the source region where gas phase ionization occurs. Using an iterative regression approach values of v(ent) and P(gpi) were varied to arrive at values which yielded calculated flight times for the broad component in agreement with experimentally observed flight times (see figure 2)

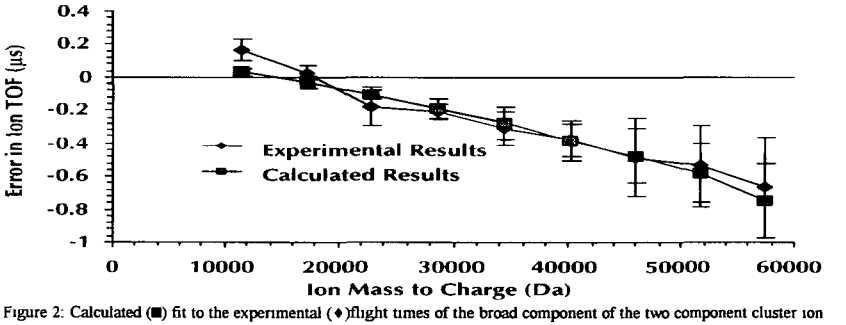

Figure 2: Calculated (■) fit to the experimental (♦)flight times of the broad component of the two component cluster ion signals by allowing the ionization to occur from entrained neutral material in the gas phase above the probe surface. Best fit for experimental flight times recorded in 6 mass spectra over the entire mass range yields v(ent) = 830±130 m/s and P(gpi) = 30±10 µm with an overall average % error in flight time agreement of 0 1%

Although these results reflect studies of bovine insulin cluster ion signals, the proposed two component mechanism of ion formation applies in general to MALDI analyte ion formation. Evidence for the two component mechanism of ion formation has been obtained for non-clustered ions from expected shifts in relative flight times of the broad and sharp components as a function of source region electric field, changes in the yield of high energy ions as a function of source region electric field and shifts in flight times of broad and sharp components as a function of flight tube length. Furthermore, the two component mechanism proposed for ion formation in MALDI is supported by previous studies of the kinetic energies of MALDI ions by electrostatic analyzer TOFMS.

DISSECTING MALDI-TOF MASS SPECTRA

John Allison, Pao-Chi Liao, Gary Lavine & Joseph Hiller
MSU/NIH Mass Spectrometry Facility
Michigan State University, East Lansing, MI

Hundreds of MALDI mass spectra have appeared in the literature, documenting unprecedented detection and analyte mass limits. Most of these spectra either represent single transients, resulting from single laser shots, or are the sum/average of 20-200 transients. The implication in presenting either is that they represent *the* results of the MALDI experiment - while absolute intensities vary with each laser shot, the spectra are essentially the same. We have found that this is not necessarily the case. Relative intensities change with time, and it is appropriate to consider a collection of spectra, rather than a single spectrum, as best representing the MALDI experiment. With multiple spectra, a variety of correlations of peak intensities with each other, and in time, can be made - not unlike what is done in other MS experiments that yield time-dependent spectra such as GC/MS.

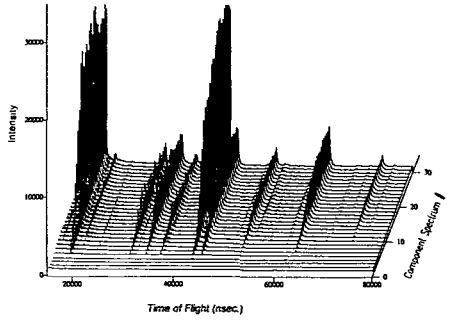
In many MALDI MS experiments, when multiple transients are summed, conditions are changed during the acquisition process to maximize the signal in each transient. The approaches used include moving the laser beam across the target surface as transients are being acquired, and/or changing laser power. One reason why such approaches may be required is that a focused laser spot is traditionally used, and a small fraction of target crystals are irradiated. The small laser spot also contributes to problems in reproducibility in the MALDI experiment, since mass spectrometrists are always searching for "hot spots" on the target that yield intense ion currents.
The first change we have made is to increase the spot size. When a larger area is irradiated, more reproducible results are obtained between samples. Also, many spectra can be generated without having to either move the laser or change the power. We call this "Big Spot MALDI". The second change we have made is to accumulate a series of "component spectra" in an experiment. Each component spectrum represents the sum of 10 successive transients. With this approach to the accumulation of data, we have begun to analyze a number of features of the experiment, in an attempt to better define MALDI.

One feature that is of particular interest is the power/resolution relationship. To date we have explored this in the context of the linear MALDI TOF experiment. It is "common knowledge" in the MALDI MS community that the best resolution can be obtained under low laser power conditions. Higher powers yield lower resolution. However, higher powers are necessary in some cases, especially when mixtures involving analytes over a wide MW range are being analyzed. Higher MW analytes require higher powers for the desorption/ionization process to occur. When many

spectra are obtained, using a variety of powers above threshold, one always observed signal decay as a function of time. As peak intensities decrease, resolution increases. Thus, if high powers are used, peaks are initially intense and exhibit low resolution. In subsequent spectra, intensities drop and resolution increases. Thus, it is possible to obtain "low power" resolution in "high power" experiments. Such observations suggest new possibilities for mixture analysis in MALDI, in which many spectra are accumulated, and each component need not be evaluated (mass most accurately determined) in the same spectrum.

Another experiment that we have evaluated is referred to here as a "Power Titration". In this experiment, one begins at the lowest power at which any ions are formed, usually only matrix ions. Ten transients are summed into a single component spectrum (again using Big Spot MALDI). The power is then stepped to a higher value, and a second component spectrum is obtained. Many component spectra, representing a range of laser powers, are collected. This is a complex experiment when a single large spot is used - at a fixed power, the total ion current for successive component spectra would decrease. However, increasing power tends to yield *more* intense signals. The result is a series of spectra that are very sensitive to matrix, analytes, and target preparation procedures. It represents yet another trajectory through the power/time/spectra surface on which we work in MALDI.

We are not suggesting here that MALDI results need be obtained in a time-dependent way. For many applications, single spectra suffice for providing the chemical information required. However, if the identification of minor components in a mixture is a problem, if a wide range of MW's in a single mixture are encountered, and/or if the resolution and mass accuracy obtained is insufficient, such approaches may lead to improved results.



Power titration results for a multicomponent peptide mixture containing the following components (in order of increasing MW): bradykinin, angeotensin, melitin, insulin b chain, insulin, cytochrome C and myoglobin. In some cases, both the singly and doubly charged peptides are observed. The portions of the spectra representing low mass matrix peaks are not shown.

MALDI Sample Preparation Techniques by X-ray Photoelectron Spectroscopy

DS Jones, KS Robinson, SP Thompson & P Humphrey

Kratos Analytical, Barton Dock Road, Manchester, M41 7LD, UK.

Sample preparation techniques for Matrix Assisted Laser Desorption Ionisation (MALDI) are being investigated by a number of groups[1,2,3] in order to improve the uniformity of coverage, reproducibility and ease of application of sample & matrix. This paper reports the investigation of the surface chemistry of MALDI samples which have been prepared by a number of different methods as described in the literature. Analysis of the surface was carried out by X-ray photoelectron spectroscopy (XPS) in order to confirm coverage and investigate the surface concentration of proteins.

Samples were prepared from specific proteins (BSA and β-casein) and sinapinic acid was used as the matrix. They were analysed in a Kratos Kompact MALDI III.

The comparison in figure 1 shows the sample preparation method as proposed by Xiang & Beavis has several advantages in terms of both absolute signal level and relative stability.

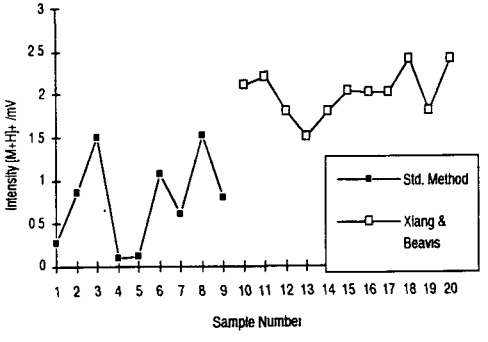


Figure 1 - Comparison of sample preparation methods for MALDI of BSA with sinapinic acid

It was decided to investigate this sample method by XPS. The MALDI sample was prepared as above and analysed in a Kratos Axis HSi Electron Spectrometer. The spectra of the protein and the matrix were each measured by themselves to obtain characteristic spectra. The sinapinic acid, being free of nitrogen, simplified the elemental analysis as the N1s could be used as a direct marker for the protein.

The three spectra are shown in figures 2-4. The β-casein spectrum clearly shows a significant nitrogen peak which is virtually absent from the sinapinic acid spectrum alone. The protein also contains small amounts of sulphur which are visible in the spectrum. More subtle

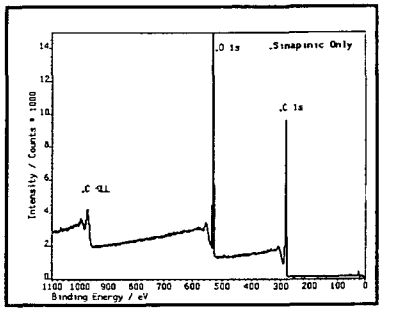

Figure 2 - XPS spectrum of sinapinic acid

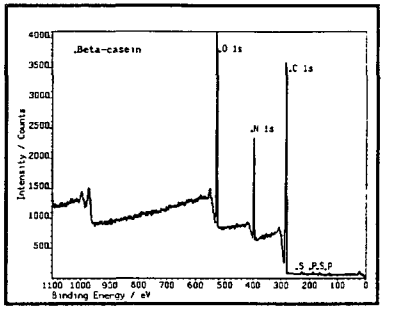

Figure 3 - XPS spectrum of β-casein

differences were also seen in the high resolution scans of the C1s orbital which could be correlated to the different forms of carbon present in the two molecules. It can be seen immediately that despite the sinapinic been present in vast molar excess the spectrum of the prepared MALDI sample is virtually identical to the spectrum of β-casein alone.

The level of β-casein as determined from quantitiation of the N1s signal indicates that there is a significant enhancement of the surface concentration of sample protein when compared with the bulk concentration suggesting segregation of the sample to the surface during crystallisation.

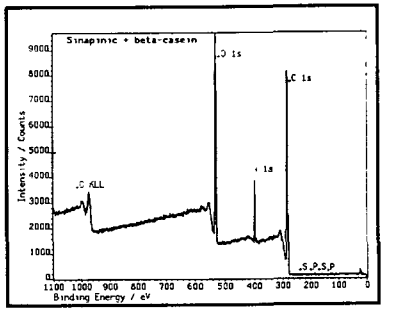

Figure 4 - XPS spectrum of MALDI slide of β-casein with sinapinic acid

SIFT STUDIES OF THE REACTIONS OF H_3O^+ AND $H_3O^+ \bullet H_2O$ WITH A SERIES OF SULFIDES AND THIOLS

Ted L. WILLIAMS, Lucia M. BABCOCK, Nigel G ADAMS, and Brian K. DECKER, Chemistry Department, University of Georgia, Athens, GA 30602.

H_3O^+ is an important ion in the molecular synthesis in interstellar clouds, being one of the nine ions detected. H_3O^+ and $H_3O^+ \bullet H_2O$ are dominant ionic constituents of the D-region of the terrestrial ionosphere and of importance in the earth's stratosphere. Sulfur is the ninth most cosmically abundant element after H, He, O, N, Ne, Si, Mg. Sulfur containing compounds comprise 13% of the species detected in the interstellar medium. The oxygen containing analogs have also been detected as have larger oxygen containing compounds. Thus, it seems reasonable that larger sulfur containing compounds will be present also. Many sulfur compounds are anthropogenic pollutants in the terrestrial atmosphere. For example, the paper and pulp industry emits H_2S, CH_3SH, C_2H_5SH, n-C_3H_7SH, iso-C_3H_7SH, $(CH_3)_2S$, $CH_3SC_2H_5$, and C_4H_4S.

The reactions of these last mentioned sulfur compounds with H_3O^+ and $H_3O^+ \bullet H_2O$ were studied using a selected ion flow tube (SIFT). The reactant ions were produced in a high pressure microwave discharge in H_2O and separately injected into the flow tube A sufficient pressure of H_2O was used to quench any excitation in the ions. Low injection energies were used to minimize fragmentation of $H_3O^+ \bullet H_2O$. Reactant sulfur compounds were then introduced into the flow and the parent and product ions detected by a downstream mass spectrometer. Rate coefficients and product ion distributions (%) were obtained in the usual manner (Smith and Adams, 1988). Rate coefficients are considered to be accurate to within ± 25% and product distributions to within ± 5 %.

Rate Coefficients, k, ($cm^3\ s^{-1}$) for H_3O^+ and $H_3O^+ \bullet H_2O$ Reactions with Sulfur Compounds

	H_3O^+	$H_3O^+ \bullet H_2O$	
Reactant Neutral	k	k	Ion Product Distribution (%)
Thiols			
CH_3SH	1.8(-9)	1.7(-9)	100% $CH_3SH_2^+ \bullet H_2O$
C_2H_5SH	2.0(-9)	1.9(-9)	100 % $C_2H_5SH_2^+ \bullet H_2O$
n-C_3H_7SH	2.3(-9)	2.0(-9)	70 % $C_3H_7SH_2^+ \bullet H_2O$ 30% $C_3H_7SH_2^+$
iso-C_3H_7SH	2.3(-9)	2.1(-9)	5 % $C_3H_7SH_2^+ \bullet H_2O$ 95% $C_3H_7SH_2^+$
Sulfides			
H_2S	1.4(-9)	1.3(-12)	---------
$(CH_3)_2S$	1.7(-9)	1.7(-9)	100% $((CH_3)_2S)H^+$
$CH_3SC_2H_5$	2.4(-9)	2.2(-9)	100 % $(CH_3SC_2H_5)H^+$
C_4H_4S	1.8(-9)	1.4(-9)	100 % $(C_4H_4S)H^+$

All of the H_3O^+ reactions proceed by proton transfer, consistent with the reaction energetics. The rate coefficients that were obtained are typical of proton transfer reactions, i.e., collisional or close to the collisional rate. With the exception of the H_2S reaction, the $H_3O^+ \bullet H_2O$ rate coefficients were consistently slightly smaller than the H_3O^+ rate coefficients which is consistent with the larger reduced mass of $H_3O^+ \bullet H_2O$ system than that of H_3O^+ system. This trend is in agreement with the previous studies of Fehsenfeld et al. (1978) and Bohme et al. (1979) of H_3O^+ and $H_3O^+ \bullet H_2O$ with oxygen containing compounds. Though direct proton transfer was seen for the H_3O^+ reactions, only half of the $H_3O^+ \bullet H_2O$ reactions proceed by direct proton transfer. This occurs when the proton transfer reaction is exothermic, the energy available in the reaction being smaller than the equivalent H_3O^+ reaction by the cluster ion dissociation energy. When proton transfer is endothermic as in the case of CH_3SH and C_2H_5SH, the primary product is of the form $(RSH)(H_2O)H^+$, with the secondary product being $(RSH)_2H^+$. The second product confirms that the proton is most likely contained within the sulfur component, i.e., $RSH_2^+ \bullet H_2O$, as expected. For the cases where the proton transfer reactions are thermoneutral or close to thermoneutral, a combination of the above two processes is seen:

$$H_3O^+ \bullet H_2O + RSH \rightarrow RSH_2^+ + H_2O$$
$$\rightarrow RSH_2^+ \bullet H_2O + 2H_2O$$
$$RSH_2^+ + RSH \rightarrow (RSH)_2H^+$$

This behavior is observed for both of the propanethiols. Such ligand switching/rearrangement was previously seen in two $H_3O^+ \bullet H_2O$ reactions with CH_2O, CH_3OH by Fehsenfeld et al. (1978) and one with dimethyl methylphosphonate by Passarella et al. (1987).

Using laser induced fluorescence, we have also shown, consistent with previous data, that OH reactions with sulfur containing compounds, i.e., H_2S, n-C_3H_7SH, and iso-C_3H_7SH, are fairly rapid. Therefore, these compounds will be mainly destroyed before they reach the stratosphere and D-region where most of the H_3O^+ and $H_3O^+ \bullet H_2O$ exist. Thus, reaction with these ions would have to occur in the troposphere. In regions where $H_3O^+ \bullet H_2O$ coexist with sulfur containing compounds, the water clusters would catalyze the formation of sulfur clusters for those species for which proton transfer with $H_3O^+ \bullet H_2O$ is thermoneutral or endothermic. Any detection of these clusters would thus be evidence for the existence of the related neutral sulfur compound. From this information, trace neutral compositions could be measured as has been done previously for other species (Viggiano 1993).

In the interstellar medium, recombination of H_3O^+ with electrons forms OH (65 %), H (100 %) and presumably some H_2O (Adams et al. 1991.), serving as a loss process for H_2O. However, in the presence of sulfur containing compounds, H_3O^+ can react by proton transfer to produce H_2O. Therefore, depending on the fractional abundance of the sulfur containing compounds and the competition between H_3O^+ recombination and proton transfer, the H_2O to OH ratio would be enhanced.

Unimolecular Kinetics of $CHClF^{\bullet}$ by Variable-Time Neutralization-Reionization Mass Spectrometry

Martin Sadílek and František Tureček
Department of Chemistry, Box 351700,
University of Washington,
Seattle, WA 98175-1700

Hydrochlorofluorocarbons (HCFC), which are currently being introduced to replace chlorofluorocarbons (CFC), undergo oxidative degradation in the troposphere that lowers the amount of HCFC reaching the stratospheric ozone layer. However, an unknown fraction of surviving HCFC molecules is lifted to the stratosphere, where they undergo photolysis by UV solar radiation to form chlorine atoms. The complementary HCFC radicals retain part of the excitation energy and may further fragment to generate $Cl^{\bullet}$, HCl, $F^{\bullet}$ or HF. These secondary dissociations of excited HCFC radicals have not been studied so far. We report the results of a mass spectrometric study that addresses unimolecular dissociations of $CHClF^{\bullet}$ radicals prepared by fast collisional neutralization of $CHClF^{+}$ cations utilizing the new method of variable-time neutralization-reionization mass spectrometry abbreviated here as VT-NRMS *(1,2)*.

Dissociations of $CHClF^{\bullet}$ and $CHClF^{+}$ were studied with a tandem quadrupole mass spectrometer described previously *(3)* and modified for kinetic studies *(1,2)*. Radicals are generated from precursor ionization energies. In one series of experiments the radicals were allowed to drift for a fixed period of time (4.1 μs), and the neutral species were reionized to cations, mass-analyzed, and detected. In variable-time measurements, the neutral and ion lifetimes were varied between 0.41 and 2.59 μs by carrying out reionization in a segmented drift region (conduit) whose parts were floated at appropriate potentials *(1,2)*. Phenomenological rate constants were obtained by fitting equations for unimolecular kinetics to match the experimental ion relative intensities.

An overall NR spectrum of $CHClF^{+}$, obtained with C_6H_5Cl/O_2 at 70% ion beam transmittance (**Figure 1a**), shows abundant survivor $CHClF^{+}$ ion of 20% relative abundance, indicating that the $CHClF^{\bullet}$ radical is stable on the time scale of our observations (4.1 us). The most intense peaks correspond to CF^{+} at *m/z* 31, $CHF^{+\bullet}$ at *m/z* 32 and Cl^{+} at *m/z* 35. Weaker peaks of $HCl^{+\bullet}$, CCl^{+}, $CHCl^{\bullet+}$, and $CClF^{+\bullet}$ appear at *m/z* 36, 47, 48 and 62, respectively, while very weak peaks of $C^{+\bullet}$, CH^{+}, and F^{+} are found at *m/z* 12, 13, and 19, respectively. There is no peak of $HF^{+\bullet}$ at *m/z* 20. Hence the $CHClF^{\bullet} \rightarrow HF + CCl^{\bullet}$ fragmentation does not occur significantly although it has the lowest reaction enthalpy. This indicates a presence of a barrier for the reaction.

NR spectra of $CHClF^{+}$ ($IE_v(CHClF^{\bullet}) = 9.16$ eV) were obtained by neutralization with di-n-butyl ether, chlorobenzene, di-n-butylamine, aniline, and N,N-dimethylaniline of vertical ionization energies decreasing in the range of 9.45, 9.10, 8.45, 8.0 and 7.45 eV. The overall NR spectra show only little dependence on the neutralization gas ionization energy with the exception of di-n-butylamine which induces slightly increased fragmentation.

More dramatic effects are observed in the C_6H_5Cl/O_2-NR spectra of $CHClF^{+}$ generated by charge-transfer ionization with $N_2^{+\bullet}$ in a high-pressure ion source (**Figure 1b**). The latter spectrum shows a substantial increase of the survivor ion intensity and much lower relative intensities of CF^{+}, $CHF^{+\bullet}$, and Cl^{+}. This is attributed to thermalization of the $CHClF^{+}$ precursor ion, which is estimated to have on average <20 kJ mol^{-1} internal energy.

By contrast, ion relative intensities are not effected much by different exoergicities of

neutralization.

VT-NRMS measurements allow us to distinguish between the fragmentation of the neutral radical (k_N) and the reionized cation (k_i) as shown in **Table 1** for neutralizations with di-n-butyl ether and N,N-dimethylaniline. The rate parameters indicate similar contributions from neutral and ion decompositions in the formation of Cl^{+} and CHF^{+} fragments due to simple bond cleavage. $CHCl^{+\bullet}$, CCl^{+} and HCl^{+} are formed mainly by ion dissociations, in agreement with the respective reaction endothermicities and considering energy barriers for the eliminations of hydrogen chloride and hydrogen fluoride. The CF^{+} fragment may be formed by a consecutive dissociation from reionized $CClF^{\bullet}$. The increased exoergicity in the neutralization step does not change the rate parameters significantly.

Figure 1: C_6H_5Cl/O_2 (70% transmittance) $^{+}NR^{+}$ mass spectra of
(a) $CHClF^{+}$ from 70-eV EI of $CHClF_2$ at 10^{-5} Torr.
(b) $CHClF^{+}$ from $N_2^{+\bullet}$ charge-transfer ionization of $CHClF_2$ at 0.2 Torr N_2.

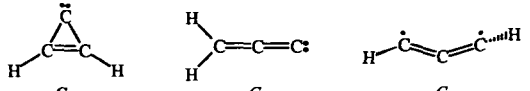
Astrophysical Thermochemistry: The Heats of Formation of C_3H_2 Isomers.

Leonard J. Chyall and Robert R. Squires

Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393

Astronomers have been interested in the C_3H_2 potential energy ever since cyclopropenylidene (**1**) was detected in interstellar space.[1] Spectroscopic evidence for the presence of the isomeric species propadienylidene (**2**) has also been reported.[2] However, the other linear isomer propargylene (**3**) has thus far eluded detection.



C_{2v} C_{2v} C_2

1 2 3

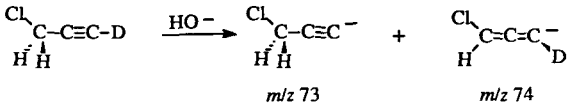
Molecular orbital theory predicts cyclopropenylidene to be the global minimum on the C_3H_2 potential energy surface, while the other two stable isomers are higher in energy. For example, calculations at the G2 level of theory suggest that the $^1A_1$ ground state of propadienylidene and the $^3A''$ ground state of propargylene are 13.5 and 16.4 kcal mol^{-1} higher in energy than **1**, respectively.[3] Because of the widespread interest in these molecules, and the need for experimental verification of the theoretically predicted stability ordering, we have undertaken gas-phase thermochemical investigations of the C_3H_2 isomers.

The proton affinity and absolute heat of formation of cyclopropenylidene (c-C3H2) have been derived from the translational energy threshold for endothermic proton transfer from c-$C_3H_3^+$ to ammonia in a flowing afterglow triple-quadrupole instrument.

$$c\text{-}C_3H_3^+ + NH_3 \longrightarrow c\text{-}C_3H_2 + NH_4^+$$

The cyclopropenium cation $C_3H_3^+$ was prepared in a helium flow reactor at room temperature by the reaction of ionized ethylene with acetylene, and from dissociative electron ionization of bromocyclopropane. The kinetic energy dependence of the cross sections for proton transfer from this ion to ammonia and other neutral amines was characterized in a triple quadrupole mass analyzer (Figure 1). The threshold energy for the reaction with ammonia was determined to be 23.3 ± 1.8 kcal mol^{-1}. Combining this with the known proton affinity (PA) of ammonia (204.0 ± 1.0 kcal mol^{-1}) gives a value for PA(c-C_3H_2) of 227.3 ± 2.1 kcal mol^{-1}. From the measured proton affinity and the known heats of formation of c-$C_3H_3^+$ and the proton, the 298 K heat of formation of cyclopropenylidene is determined to be 119.5 ± 2.2 kcal mol^{-1}. This value is slightly higher than a previous experimental estimate[4], but is in good agreement with the 298 K heat of formation predicted by high-level molecular orbital calculations.

Reaction of 1-d_1-propargyl chloride with hydroxide produces ions of *m/z* 73 and *m/z* 74 in approximately a 1:1 ratio.



m/z 73 *m/z* 74

The ion of *m/z* 73 (presumably the 3-chloroacetylide ion) was collisionally activated with argon and the appearance energy for chloride ion was measured (Figure 2).

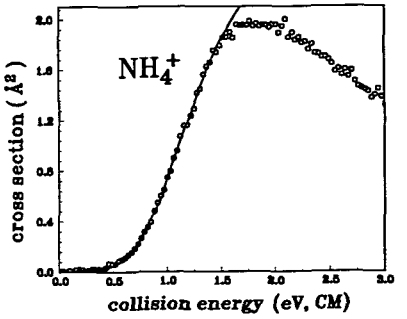


Figure 1

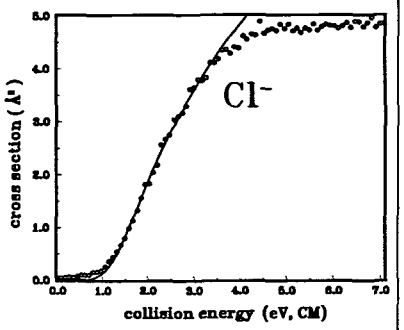

Figure 2

The enthalpy change of 29.0 ± 2.0 kcal mol^{-1} for this process was used as part of a thermochemical cycle to determine a value of 124.0 ± 3.5 kcal mol^{-1} for the heat of formation of propadienylidene. The measured heat of formation of propadienylidene is 4.5 kcal mol^{-1} higher than that obtained for cyclopropenylidene. This difference in heats of formation of the two isomers is much lower than the 13.5 kcal mol^{-1} difference that is predicted by G2 molecular orbital theory.

Oxidation Reactions of Cationic Vanadium Clusters Studied Using Guided Ion Beam Mass Spectrometry.

M. T Rodgers, J. B Griffin and P. B. Armentrout, Department of Chemistry,
University of Utah, Salt Lake City, UT 84112

The kinetic energy dependence of reactions of V_n^+ with O_2 was studied using a guided ion beam mass spectrometer that has been described in detail elsewhere.[1] Thermochemical analysis of the observed product cross sections is treated as discussed previously.[2,3] The chemistry observed for reactions of V_n^+ with O_2 is quite complex. The reactions are facile and have large cross sections (in excess of 100 $Å^2$ at low energies) which drop off with increasing collision energy. Product cross sections are often multi-featured indicating that the corresponding product ions are formed by more than one reaction pathway. Monoxides dominate the chemistry of the smallest clusters as can be seen for the reaction of V_4^+ with O_2 shown in Figure 1. The chemistry observed in the larger clusters, those containing five or more atoms, is remarkably similar and quite complicated as a result of an increased number of possible products. However, the observed chemistry is dominated by dioxide formation. The major product channels observed for the reaction of V_8^+ with O_2 are shown in Figure 2 Lifetime effects begin to play a role in clusters containing as few as seven atoms, but significantly alter the observed product yields for clusters containing ten or more atoms. The number of bare metal cluster fragments observed and the cross sections for their production decrease with increasing cluster size.

One of many minor reaction pathways observed for all clusters is production of the parent monoxide. Assuming that there is no barrier to reaction (no evidence exists for one in cluster systems), bond energies of vanadium monoxide cluster ions, $D(V_n^+\text{-}O)$ can be determined from measurements of the corresponding reaction thresholds by making use of the following thermodynamic cycle.

$$\begin{array}{ll} V_nO^+ + O \rightarrow V_n^+ + O_2 & -E_0 \\ \underline{O_2 \rightarrow O + O} & \underline{D(O-O) = 5\ 12eV} \\ V_nO^+ \rightarrow V_n^+ + O & D(V_n^+ - O) \end{array}$$

Formation of V_nO^+ is thermoneutral or exothermic for $n \leq 4$, therefore $D(V_n^+\text{-}O) \geq 5.12$ eV and cannot be determined explicitly. In the larger clusters, where $n \geq 5$, formation of V_nO^+ is endothermic making direct determination of $D(V_n^+\text{-}O)$ possible. Threshold energies and bond dissociation energies for the vanadium monoxide clusters are summarized in Table 1.

In all but the smallest clusters, $n \geq 5$, the primary reaction process at low energies is exothermic loss of two vanadium atoms from the oxygen adduct (i.e., formation of $V_{n-2}O_2^+$). As the collision energy is increased, competitive dissociation of this product results in further loss of either a vanadium atom or of vanadium oxide to produce $V_{n-3}O_2^+$ and $V_{n-3}O^+$, respectively. In all cases,

Lett.* **49**, 183 (1977).; R. G. Gilbert and S. C. Smith, *Theory of Unimolecular Recombination Reactions* (Blackwell Scientific, Oxford, 1990).

vanadium atom loss is the preferred reaction pathway. Estimates of bond energies of vanadium dioxide cluster ions, $D(V_n^+\text{-}O_2)$ have been obtained by comparison to CID data for the bare metal cluster cations and are summarized in Table 2. Direct determination of the dioxide bond energies is not possible for clusters where $n < 10$ because the di-oxygenated parent ion is not observed until n=10. This is the result of lifetime effects associated with the unimolecular dissociation of these species. The values obtained for the dioxide bond energies indicate that O_2 dissociatively binds to the metal cluster. The large difference in the monoxide and dioxide bond energies may be the result of suppression of the V_nO^+ product channel resulting in an increased apparent threshold and a decreased apparent bond energy. Therefore, the monoxide bond energies may represent lower limits rather than actual bond energies.

Chemisorption of Hydrogen Molecules on Vanadium Cluster Cations

G. Dietrich[1], K Dasgupta[3], H -J. Kluge[4], M. Lindinger[2], K. Lützenkirchen[1], L. Schweikhard[2], and J. Ziegler[2]

[1]Johannes Gutenberg-Universität, Institut für Kernchemie, D-55099 Mainz, Germany
[2]Johannes Gutenberg-Universität, Institut für Physik, D-55099 Mainz, Germany
[3]Bhabha Atomic Research Center, Bombay 400085, India
[4]Gesellschaft für Schwerionenforschung, D-64220 Darmstadt, Germany

Due to the simple structure of the hydrogen molecule studies of its adsorption on cluster surfaces are particularly attractive for an understanding of the interaction on a microscopic level. Several publications dealing with transition metal clusters and their reactivity with hydrogen or deuterium are found [1].

In this contribution we report on the reaction between vanadium cluster ions V_n^+ and hydrogen. Clusters are produced by laser vaporization, injected into a Penning trap and stored for variable reaction duration. For identification, product ions are ejected out of the trap and detected by time-of-flight mass spectrometry. For a detailed description of the experimental setup see ref. [2].

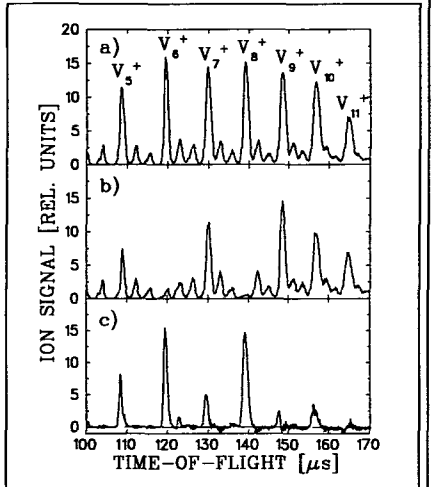

Fig. 1: Mass spectra with (b) and without (a) RF-excitation of the vanadium clusters (n = 5-11) at a hydrogen pressure of 8×10^{-6} mbar and a storage period of 360 ms. The peaks in the difference spectrum (c) represents the intenisties of the naked cluster ions V_n^+.

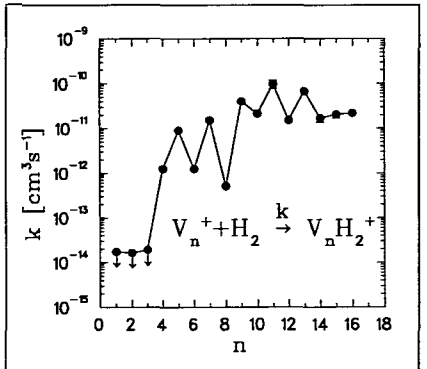

Fig. 2: Absolute rate constants k for the reaction of hydrogen and vanadium cluster ions (n = 1-16). For n = 1-3 only an upper limit could be measured.

The reaction rate constants for n = 1-16 were determined at a hydrogen pressure of 8×10^{-6} mbar. Difference spectra are obtained by substracting two spectra, one with and one without radial ejection of the bare vanadium clusters (fig. 1). The normalized intensities in the difference spectra represent those clusters which did not react with hydrogen during the storage period. Thus the absolute rate constants for the first reaction step are achieved (fig. 2) and an obvious odd-even effect can be recognized for n = 4-14. For the smaller clusters an upper limit is given.

Another item of interest is the maximum number of adsorbed hydrogen molecules m as a function of cluster size n. Saturation is achieved at a hydrogen pressure of 1.6×10^{-5} mbar and a storage period of 760 ms. In figure 3 the average number $\langle m\rangle$ is shown for n = 4-17. A linear increase can be seen for the system $V_nH_m^+$, $n \geq 10$. The slope represents the ratio $\langle m\rangle/n = 3/2$. The lower region shows an evident odd-even effect towards the takeup of H_2.

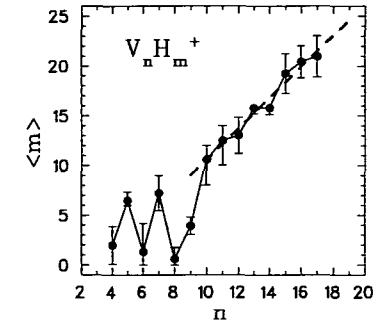

Fig. 3: Average number of adsorbed hydrogen atoms on vanadium clusters under saturation conditions (storage period of 760 ms, $p = 1.6\times10^{-5}$ mbar). The dashed line with the slope $\Delta\langle m\rangle/\Delta n$ = 1.5 has been fitted to the data with n = 10-17

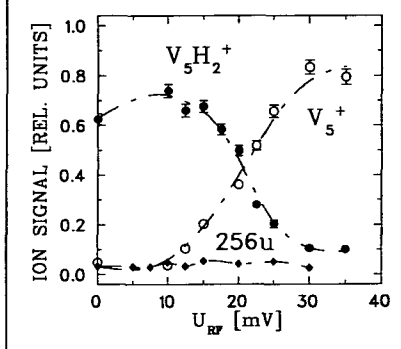

Fig. 4: Collision induced dissociation of $V_5H_2^+$ on argon ($p = 1.4\times10^{-6}$ mbar). The data shows the relative ion signal for $V_5H_2^+$ (●), V_5^+ (○) and "256 u" (= $V_5H_1^+$, ♦). with increasing excitation voltage U_{RF}. The dashed lines are to guide the eye.

The question of molecular versus dissociative chemisorption of the hydrogen molecules is addressed, as an example, for the adsorption of a single hydrogen molecule on a vanadium pentamer. Dissociation of the selected species $V_5H_2^+$ is induced by acceleration with a rf-field and collisions with argon atoms (fig. 4). The only products observed are the selected ions and the naked pentamers. No vanadium pentamer ion with one hydrogen atom attached is detected. (A trace amount at 256 u, which is independent of the collision energy, is fully explained by the isotopic distribution of vanadium.) By comparing the threshold energies of $V_5H_2^+$ with the known one of V_5^+ [3] the relative separation energy can be calculated as 1.9±0.3 eV. This result is in agreement with the calculated V-H binding energy [4] and leads to the assumption that the hydrogen molecule is adsorbed dissociatively

Metal Ion/Molecule Chemistry Using a Radio Frequency Glow Discharge Source

Ritchie C. Eanes, Steven J. Christopher, and R. Kenneth Marcus

Department of Chemistry
Howard L. Hunter Laboratory
Clemson University
Clemson, SC 29634-1905

Radio frequency glow discharge mass spectrometry (rf-GDMS) has been used as a reliable technique for the direct elemental analysis of a variety of solid samples ranging from metals to glasses. The glow discharge is a reduced pressure plasma which relies on cathodic sputtering to generate gas-phase atoms from a solid sample target, which subsequently undergo a separate ionization step. The glow discharge may be a promising source for analyte specific ion-molecule chemistry where the plasma's unique ability to generate predominantly ground state metal ions holds an advantage over other more traditional sources employed in ion-molecule chemistry. Of the more traditional sources for metal ion formation, electron impact suffers from the fact that a suitable volatile complex, usually involving a metal carbonyl, must be used. Surface ionization from a heated filament also involves the use of a volatile metal salt and is limited to some of the less exotic metals in the periodic table. Laser ionization methods are prone to a more violent type of ionization event as compared to the glow discharge. This, in combination with the fact that laser ionization usually involves the formation of multiply charged species, may complicate or inhibit desired ion molecule chemistry.

The importance of ion-molecule chemistry to the analytical community has grown steadily in recent years. Freiser has used metal ion chemical ionization reagents to determine isotopolog and isotopomer distributions for perdeuterated napthalene [1], a problem that might be difficult to solve with high resolution NMR spectroscopy. Amster and co-workers have used sequential laser ablation steps to produce Fe ions that react efficiently with volatilized peptides [2].

Preliminary studies have shown that Fe ions emanating from the glow discharge react with cyclohexane in the collision chamber of a double quadrupole MS facilitating the formation of various Fe-alkene complexes as described by Eller and Schwarz [3]. Figure 1 shows a high sensitivity background scan for Fe prior to the

introduction of cyclohexane reactant gas. Figure 2 displays the spectrum obtained after cyclohexane was introduced into the collision cell of our double quadrupole MS system. The peak at m/z 128 is indicative of an Fe-pentene complex [3]. Also seen is a stable Fe-butene complex (m/z 112). The structure displayed in figure 2 resembles one of two stable bis(olefin) complexes formed after collisionally activated dissociation of an $FeC_6H_{12}^+$ ion [4].

Generation and Characterization of Silacyclopentadienyl Complexes of Iron

D. J. Kardash*, S. Kloos, P. Boudjouk, and D. B. Jacobson
Center for Main Group Chemistry, Department of Chemistry
North Dakota State University, Fargo, North Dakota 58105-5516

There is considerable interest in generating metallocenes with a heavier group 14 element (Si, Ge, Sn) incorporated in the ring since these complexes may exhibit unique redox chemistry. Coordinated group 14 metallacyclopentadiene complexes have been investigated in great detail because they are reasonable precursors to group 14 η^5-metallacyclopentadienyl species. However, this approach proven to be unsuccessful. Tilley and co-workers recently reported the synthesis and characterization of the first stable η^5-metallacyclopentadienyl complexes with germanium $[(\eta^5\text{-}C_5Me_5)Ru\{\eta^5\text{-}C_4Me_4GeSi(SiMe_3)_3\}]$ (**1**) and silicon $[(\eta^5\text{-}C_5Me_5)Ru\{\eta^5\text{-}C_4Me_4GeSi(SiMe_3)_3\}]$ (**2**) incorporated in the ring.

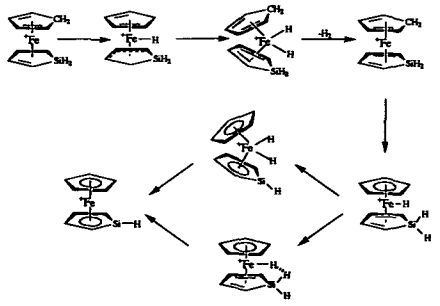
Although it is very difficult to synthesize coordinated silacyclopentadienyl compounds in solution, they may be readily generated in the gas phase by reaction of transition metal ion complexes with silacyclopentanes. However, reactions of Fe^+ with simple silanes are complex where $Si(Me)_2H_2$ undergoes exclusive 1,1-dehydrogenation from the Si atom and silacyclobutane yields exclusive ring cleavage. However, reactions with unsaturated silacycloolefins may be much simpler with initial coordination to the site of unsaturation that would direct subsequent dehydrogenations to yield diene and dienyl complexes. In accord with this hypothesis, silacyclopent-3-ene yields exclusive dehydrogenations with $FeC_5H_6^+$ and $FeC_5H_5^{+\cdot}$, reactions 1 and 2.

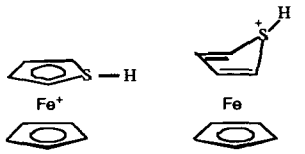
$$FeC_5H_6^+ + H_2SiC_4H_6 \longrightarrow (C_5H_5)Fe(SiC_4H_5)^+ + 2H_2 \qquad 1$$

$$FeC_5H_5^+ + H_2SiC_4H_6 \xrightarrow{0.60} [(C_5H_5)Fe(SiC_4H_5)]H^+ + H_2 \qquad 2a$$

$$FeC_5H_5^+ + H_2SiC_4H_6 \xrightarrow{0.40} (C_5H_5)FeSiC_4H_4^+ + 2H_2 \qquad 2b$$

A proposed general mechanism for reaction 1 is presented below and predicts formation of a metallocene ion $(C_5H_5)Fe((SiC_4H_5)^+$ (**3**). The structure of **3** may consist of either the η^5-silacyclopentadienyl complex **3a** or an η^4-diene structure **3b**. A cationic germacyclopentadienyl

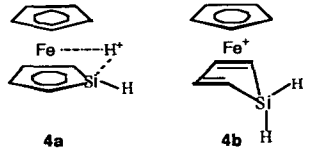




3a **3b**

complex, (germacyclopentadieneyl)$Fe(CO)_3^+$, has been isolated and spectroscopic studies suggest that it has an η^4-diene structure. $Fe(C_5H_5)_2^+$ yield characteristically simple CAD and photodissociation spectra with sequential loss of the C_5H_5 units. In contrast, **3** yields complex CAD spectra with H_2, SiC_2H_2, (H_2 + FeH), and FeC_4H_5 losses observed. This complexity in fragmentation suggests that coupling between the two groups occurs upon collisional activation.

The above dehydrogenation mechanism predicts that $FeC_5H_5^+$ should yield the protonated metallocene $[(C_5H_5)Fe(SiC_4H_5)]H^+$ (**4**) As with **3** the CAD spectra of **4** are complex with H_2, (FeH_2), (H_2 + FeH), and SiC_4H_5 losses dominant. The most likely structure for **4** is with protonation on the Si atom. Tilley and coworkers determined the X-ray structure of the protonated metallocene, $[(\eta^5\text{-}C_5Me_5)Ru\{\eta^5\text{-}C_4Me_4GeSi(SiMe_3)_3\}]H^+$. They found that it has the general structure of a protonated metallocene with protonation on the ring-silicon atom and with significant interaction with the metal (agostic M-H-Si bonding). The five membered C_4Si ring of the silacyclopentadienyl ligand is planar and the Si ring atom appears to have considerable sp^2 character. Therefore, **4** may consist of either **4a** or **4b** or a structure intermediate between these to extremes.



4a **4b**

The proton affinity (PA) of the corresponding neutral metallocene, $(C_5H_5)Fe(SiC_4H_5)$ (**5**), was probed by proton abstraction by reference bases. **4** does not undergo proton transfer to bases with PA'S less than that of $N(CH_3)_3$ (PA = 225.1 kcal/mol), however, facile proton transfer occurs with $N(CH_3)_2C_2H_5$ (PA = 227.5 kcal/mol) and stronger bases. This allows the PA of **5** to be bracketed between 225.1 and 227.5 kcal/mol with a value of 227 ± 3 kcal/mol assigned. This value is considerably larger than that for the PA of $Fe(C_5H_5)_2$ (207 kcal/mol).

To our knowledge, **5** has by far the highest reported PA of any organotransition metal complex. The high PA of this complex relative to $Fe(C_5H_5)_2$ (ca. 20 kcal/mol difference) may be reflective of silicon's propensity for sp^3 hybridization. The π-bond energy for C=Si species (35.6 kcal/mol) is significantly less than that for the corresponding C=C species (65.4 kcal/mol). This supports a structure for **4** consisting of silicon protonation with little agostic bonding (i.e., **4b**). However, the results of Tilley and co-workers support a structure with significant agostic bonding.

Structure and reactivity of $Fe(CN)(C_3H_5Cl)^+$ complexes

Capron, L.; Mestdagh, H.; Rolando, C.; Sablier, M.
Ecole Normale Supérieure, Processus d'Activation Moléculaire U.R.A. 1679
24, rue Lhomond - 75231 Paris cédex 05 (France)

The reactivity of transition metal complexes in the gas phase is very dependent on the nature and number of ligands. Study of the reactivity of $Fe(CO)_n^+$ ions with allyl chloride has shown the occurrence of ligand coupling (for a number of CO ligands n = 4,5) in the resulting metal complex $FeC_6H_{10}Cl_2^+$ (1). In the course of our investigations dealing with ion-organic radical reactions, we have been able to generate a new kind of metal-carbon bond leading to $M(CN)^+$ complexes by reaction of bare metal cations of the first row with cyanogen iodide and bromide (2). In a similar way, the iron carbonyl cations $Fe(CO)_n^+$ have shown a similar reactivity towards cyanogen iodide, affording iron cyanogen complexes $Fe(CN)^+$ and additionally have led to the formation of $Fe(I_xC_yN_y)(CO)_n^+$ complexes (x=1-2, y=1-3, n=0-3).

We report here the reactivity of these $Fe(I_xC_yN_y)(CO)_n^+$ complexes with allyl chloride C_3H_5Cl which results in a different type of gas-phase coupling involving the (CN) ligand.

$Fe(I_xC_yN_y)(CO)_n^+$ complexes were generated in the EI/CI source of a multiquadrupole MS/MS/MS mass spectrometer by electron impact on a mixture of the corresponding molecular species ($Fe(CO)_5$ and ICN). The resulting cations $Fe(I_xC_yN_y)(CO)_n^+$ were then mass selected in the first analyzer and guided to the first collision cell where they were allowed to react with allyl chloride. Either another reaction or collisionally activated dissociation with argon were carried out in the second collision cell after selection of product ions in the second analyzer. The final products were then detected by scanning the third analyzer. The pressure in each of the collision cells could be varied in the mTorr range.

The following reaction scheme was established for the $Fe(CN)(ICN)^+$ complex

$$Fe(ICN)CN^+ + C_3H_5Cl \rightarrow \underset{158^+-160^+}{FeCNC_3H_5Cl^+} + ICN$$

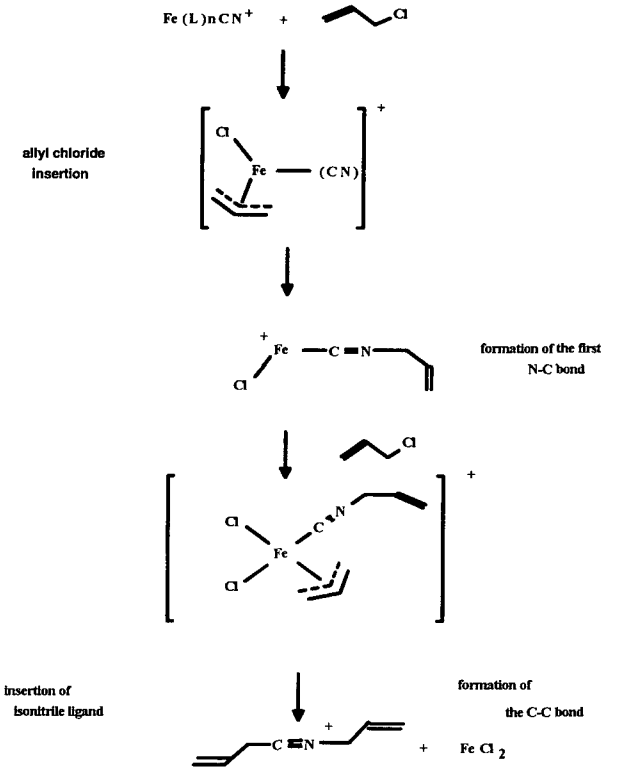
$$FeCNC_3H_5Cl^+ + C_3H_5Cl \rightarrow \underset{108^+}{C_7H_{10}N^+} + FeCl_2$$

The reaction of $Fe(CN)(ICN)_2^+$ or $Fe(ICN)_2^+$ complexes with allyl chloride afforded the same successive product ions $FeCNC_3H_5Cl^+$ and $C_7H_{10}N^+$.

The final product $C_7H_{10}N^+$ was shown to be identical with a C_3H_5-C=N+-C_3H_5 structure resulting from the reaction of $C_3H_5^+$ ion with allyl cyanide. Therefore its formation requires the formation of two new bonds, one C-C bond and one N-C bond.

In order to establish the structure of the intermediate $FeCNC_3H_5Cl^+$, its reactivity and CAD spectra were compared to those of isobaric complexes generated by reaction of iron precursor cations with allyl cyanide, propenyl cyanide (leading respectively to two isomeric cyanide complexes $(C_3H_5CN)FeCl^+$) or allyl isocyanide (leading to an isocyanide $(C_3H_5NC)FeCl^+$ complex). Of these three isomeric ions only the isocyanide complex gave the $C_7H_{10}N^+$ ion when reacted with allyl chloride. In addition, its CAD spectrum was identical with that of our intermediate, whereas those of the two cyanide complexes were different (also distinct from each other). Therefore we concluded that the $FeCNC_3H_5Cl^+$ intermediate is the isocyanide complex $(CH_2{=}CH{-}CH_2{-}N{=}C){-}Fe{-}Cl^+$.

The following scheme is proposed for the formation of the $C_7H_{10}N^+$ cation :



These successive gas phase N-C and C-C bond formations are very close to well-known organometallic reactions in solution which lead to alkyl isocyanide complex formation through cyanide complex alkylation and insertion of isocyanide ligand into a metal-carbon bond (3).

Ethylene Insertion and Hydrogenolysis Rates of $[(C_5Me_4)SiMe_2(N\text{-}t\text{-}Bu)ZrMe^+$

*Hayes, T W., Alameddin, N. G ; Richardson, D E , Eyler, J. R , Watson, C H.
Department of Chemistry, University of Florida
Gainesville, Fl 32611-7200

The chemistry of various Ziegler-Natta zirconocene complexes have been extensively studied in solution to determine the effects of ancillary ligands upon their ability to polymerize olefins. The study of the gas phase reactions allows mechanistic information to be obtained concerning the metal-olefin interaction in the absence of secondary effects due to solvation and ion pairing with the counterion.[1]

In an ongoing investigation of the gas phase reactions and kinetics of metallocene complexes,[2] the reactions of $[(C_5Me_4)SiMe_2(N\text{-}t\text{-}Bu)ZrMe^+$ (Fig 1) with ethylene have been studied with Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS) It was expected that the open metal coordination center resulting from the silicon bridging and amide coordinating ligand would lead to enhanced reactivity over related complexes

In a typical experiment the air sensitive catalyst was loaded into a glass capillary tube through the use of a glove box and affixed to the end of a solids probe. The probe was then inserted into the main vacuum chamber until the catalyst was about 20 cm from the ICR cell. A catalyst pressure of 3 0-4 0×10^{-8} torr was set by heating the probe Ethylene was leaked into the vacuum chamber by a precision leak valve to give a total pressure of 2.0-5 0×10^{-7} torr. The cationic metallocene complex was generated by electron impact in the ICR cell and after a thermalization period all unwanted ions were ejected, thereby isolating the isotopic distribution corresponding to the metallocene Following a variable reaction period all ions were excited and detected An IonSpec Omega data system was used to collect and store the data

Ideally, for a given reaction, a set of spectra taken at varying reaction times are generated and by following the ion abundances with time, a pseudo-first order rated constant can by extracted In reality, complex dimerization reactions occur which complicate the analysis Through the use of double resonance techniques partial assignment of the reaction scheme (Fig 2) was possible although constraints were required on rate constants k_5-k_7 to keep them consistent with previously studied zirconocene insertion reactions. The experimental data were fit from kinetic models based on the experimentally determined reaction pathways. The equations are solved analytically and a nonlinear least squares fit was used to extract the pseudo-first order rate constants The rate constants, combined with the pressure of the neutral reactant, give the second-order rate constants

A typical data fit (Fig 3) and the rate constants determined (Table 1) are shown It is apparent from the decay of the catalyst that both a reactive and unreactive species are present in a ratio of 3.1 The rate constant of the insertion of ethylene (k_1) is consistent with that of a previously studied zirconocene catalyst $Cp_2SiZrMe^+$ and 40 to 240 times more reactive than non-bridged species (see Table 2) The enhanced reactivity of the silicon bridged species is consistent with the idea that the silicon acts to "tie-back" the cyclopentadienyl and N-t-butyl ligands, thereby reducing the steric hindrance encountered by the ethylene molecule upon insertion The "tie-back" effect should be even more pronounced in insertion reactions involving bulkier olefins such as isobutylene.

Further study of the insertion of olefins and their deutero analogs into $[(C_5Me_4)SiMe_2(N\text{-}t\text{-}Bu)ZrMe^+$ is underway to determine kinetic and mechanistic insights.

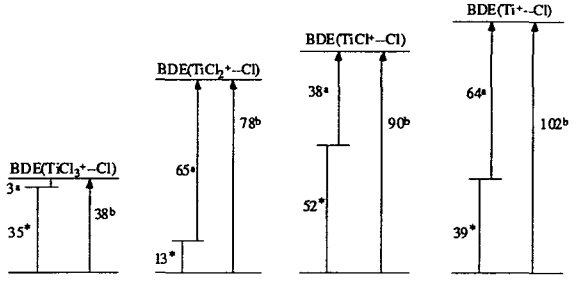
Gas Phase Reactions of +1 and +2 Chlorotitanium Ions With Isobutene

Kurt Kneen, George E. Leroi, and John Allison

Department of Chemistry, Michigan State University, East Lansing, Michigan 48824

When $TiCl_4$ is subjected to 70 eV electron impact ionization, the full series of $[Ti(Cl)_n]^+$ ions (n=0-4) and $[Ti(Cl)_n]^{+2}$ ions (n=0-3) are formed. The chemistry of the singly charged ions, with a variety of organic compounds, changes dramatically as a function of n [1,2]. For example, when n=4, the ion reacts with oxygen containing organic compounds predominantly by ligand substitution, with the organic molecule displacing a weakly bound Cl atom. With olefins, the ion was found to be unreactive. When n=2,3, the ions react with olefins by elimination HCl, and cleavage of skeletal bonds. $TiCl^+$ ions react by eliminating H_2. Using an ion beam mass spectrometer, we have been able to observe additional chemistry. By studying the chemistry between the singly charged chlorotitanium ions and isobutene, we have been able to observe additional chemistry and have found the ions to more reactive than previously thought. $TiCl_4^+$ reacts with isobutene by ligand substitution, displacing a Cl atom, with the elimination of HCl. $TiCl_3^+$ reacts by eliminating not only a single HCl molecule but 2 HCl molecules. $TiCl_2^+$ reacts by forming a charged complex with the olefin, eliminating HCl, and undergoing charge transfer to generate $C_4H_7^+$. $TiCl^+$ reacts by eliminating H_2, CH_4, C_2H_5, and HCl & H_2.

We have also performed collision-induced dissociation experiments on the $TiCl_n^+$ ions to determine bond dissociation energies (BDE's). We have compared our results (BDE's of $TiCl_n^+$ ions generated by 70 eV EI) to BDE values of ground-state $TiCl_n^+$ ions. The differences are shown in the following figure.



a) BDE's determined during this study (70 eV EI), b) BDE's determined by Kiser et. al. (ground state values)[3], *difference in BDE's and represents the approximate internal energy of the ion.

This allows us to estimate the internal energy of the ions as a result of the ionization process. With these approximations, as well as the additional chemistry that was observed, we have been able to modify some conclusions drawn from earlier work. For example, based on the earlier work, the BDE($TiCl^+$--C_4H_6) would have a lower limit of 42.8 kcal/mole. With our results we have been able to assign a lower limit of 95.6 kcal/mole. We have also been able to assign lower limits to BDE's of addtional complexes such as $TiClC_4H_7^+$, $TiCl_2C_4H_7^+$, and $TiClC_2H_3^+$.

Using the saddle-field source, we were able to generate doubly-charged chlorotitanium ions in unusually high abundances. This allowed us to study the chemistry between these +2 ions and isobutene. Our study has found that dissociative charge transfer dominates the chemistry between isobutene and each +2 chlorotitanium ion resulting in the generation of $C_4H_7^+$ (losing a H atom), $C_3H_5^+$ (with the loss of CH_3), and/or $C_3H_4^+$ (representing the loss of CH_4). Because the generation of a small potential gradient through the octopole was necessary to detect the organic ions, reliable measurements of the translational energy were not possible.

ELECTROSPRAY MASS SPECTROMETRY (ESI-MS) OF METAL CHELATES

Andrew R.S. Ross+, Michael G Ikonomou* and Kristin J. Orians+
+ Department of Chemistry, University of British Columbia, Vancouver BC, Canada
* Contaminants Science Section, Institute of Ocean Sciences, Sidney BC, Canada

Metal chelates play an important rôle in regulating the free ion concentration and bioavailability of certain metals (e.g. Fe, Ni and Cu) in natural waters. The study of such complexes as they exist in solution requires *in situ* methods of analysis. The ionisation properties of electrospray (ESI) preserve solution conditions and permit the analysis of dissolved ionic species by mass spectrometry. ESI-MS of dissolved metal chelates can provide structural information which may assist in interpreting data obtained using other techniques. The aim of this study was to evaluate ESI-MS as a method for detecting metal chelates in solution under natural conditions. Experiments were performed using a VG Quattro tandem mass spectrometer.

Changes in ion yield as a function of ESI-MS interface conditions were first studied using 8-hydroxyquinoline (Hox) complexes of Cu^{2+} and Fe^{3+}. Positive ion electrospray (ESI+) mass spectra of 50/50 2mM NH_4OAc/MeCN solutions (pH 6.7) containing 100 µM ligand and 50 mg/L metal included peaks corresponding to $[M(ox)_n + H]^+$ and $[M(ox)_{n-1}]^+$ ions (Fig. 1a). To establish whether or not the ligand-loss reaction.

$$[M(ox)_n + H]^+ \rightarrow [M(ox)_{n-1}]^+ + Hox \qquad (1)$$

was due to collision induced dissociation (CID) in the ESI source, the focus lens potential was varied between 10 and 60 volts and the intensities of the peaks due to $[M(ox)_n + H]^+$ and $[M(ox)_{n-1}]^+$ ions recorded (Fig 2). Results show that the relative intensities of these ions are highly dependant on focus potential, and imply that $[M(ox)_{n-1}]^+$ ions are formed by fragmentation in the ESI-MS interface rather than as a result of solution equilibria. MS/MS experiments (Fig. 1b) confirmed that fragmentation of the protonated ligand ion (Eq. (1)) and reduction of the metal cation[1] (e.g. $[Fe^{III}(ox)_2]^+ \rightarrow [Fe^{II}(ox)]^+$) can both result from CID. Mild ESI-MS interface conditions (focus potential = 20 V) were subsequently used during the analysis of similar solutions containing model ligands and selected metals (Table 1).

In many instances ions corresponding to identifiable metal chelates were not observed, possibly as a result of the instability of the complexes at neutral pH, or inability to acquire charge in solution (a prerequisite for ESI-MS detection). For the metal chelates detected, however, ESI-MS determined the molecular weight and metal:ligand ratio of the complex, confirming the oxidation state and coordination number of the metal cation. Replacing MeCN with MeOH improved resolution towards Cu chelates (especially for binuclear complexes and weaker ligands) by reducing competition from solvent molecules. Cu and Fe complexes with Hox were successfully detected in 50/50 seawater/MeCN (pH 8) through the formation of Na^+ rather than H^+ adducts.

These results demonstrate the ability of ESI-MS to detect metal chelates in a variety of aqueous media. The combination of ESI-MS detection with HPLC separation techniques for the study of interactions between natural ligands and metal cations in environmental samples is currently under investigation

Gas-Phase Actinide Ion Chemistry: Reactions of Th^+ and U^+ with CH_4 and C_2H_6

Joaquim Marçalo, João Paulo Leal, and António Pires de Matos

Departamento de Química, Instituto Tecnológico e Nuclear
P-2686 Sacavém Codex, Portugal

The gas-phase reactivity of the actinide series ions Th^+ and U^+ with methane and ethane were studied by Fourier transform ion cyclotron resonance mass spectrometry (FTICR/MS), using an Extrel (Waters) FTMS 2001-DT spectrometer. The metal ions were produced by laser desorption/ionization of pure metal pieces and the reagents were admitted to the instrument through a leak valve; argon, introduced through pulsed valves, was used for collisional cooling of the metal ions.

Th^+ ions dehydrogenated methane with a rather low efficiency (k/k_L = 0.014) to form $ThCH_2^+$, implying that $D(Th^+–CH_2) \geq 460$ kJ/mol With ethane, single and double dehydrogenations were observed, producing $ThC_2H_4^+$ and $ThC_2H_2^+$ (relative intensity ca 1 1) with a moderate efficiency (k/k_L = 0 124), indicating that $D(Th^+–C_2H_4) \geq 136$ kJ/mol and $D(Th^+–C_2H_2) \geq 312$ kJ/mol. In the absence of collisional cooling, minor products like ThH^+, ThH_2^+, $ThCH_2^+$, and $ThCH_3^+$, either endothermic or corresponding to processes with high kinetic barriers, were also observed in the ethane reaction The facile oxidation of the products of both reactions by residual water and oxygen dominated the secondary steps, indicating that the primary products of the methane and ethane reactions are unreactive with these gases.

U^+ ions were found to be essentially unreactive with methane and ethane The formation of oxygenated products from background water and oxygen was the main process observed either in the presence or absence of thermalization, although in this last case inefficient formation of dehydrogenation products was also observed with both reagents

The results obtained in the reactions of Th^+ and U^+ with methane and ethane, as well as those previously obtained with benzene and other arenes [1], not unexpectedly show similarities to the reactivity of the early *d* transition metal cations [2,3] and the lanthanide cations La^+, Ce^+, and Gd^+ [1,4,5] However, the differences in reactivity between Th^+ and U^+ reported herein, appear to indicate that simple electronic arguments (ground state configuration of Th^+ - $5f^06d^27s^1$, ground state configuration of U^+ - $5f^36d^07s^2$, low-lying

configurations at 0.04 eV - $5f^36d^17s^1$ and 0.57 eV - $5f^36d^27s^0$) may not be sufficient to explain the reactivities of actinide ions with hydrocarbons, and significant electronic effects in the reactivity along the actinide series can be anticipated.

Gas-Phase Reactivity of Transition Metal Cations with Atomic Species

Angeli, C.; Leymarie, N.; Mestdagh, H.; Rolando, C.; Sablier, M.
Ecole Normale Supérieure, Processus d'Activation Moléculaire U.R.A. 1679
24, rue Lhomond - 75231 Paris cédex 05 (France)

Whereas a large number of ion-molecule reactions, as well as various atom-molecule reactions, have been studied in the gas phase, there is a scarcity of experimental data concerning the reactivity of ions, particularly metal or metal-containing ions, with free atoms such as hydrogen and nitrogen or with radical species (1).

Interest in the knowledge of such processes is two-fold : (i) Astrophysical : free atoms, the most abundant of which being H·, are important components of the interstellar medium, and electropositive elements such as transition metals are likely efficiently photoionized to positive ions; therefore metal ions might react with free atoms or radicals under interstellar conditions and perhaps play the role of catalysts (2). (ii) Chemical : reactions of free atoms with metal-containing ions may lead to new organometallic species or provide useful thermochemical data.

The reactivity of iron pentacarbonyl cations $Fe(CO)_n^+$ (where n is the number of CO ligands, n=0-5) with molecular and atomic hydrogen/nitrogen have shown that $Fe(CO)_n^+$ cations do not react with molecular gases. With the discharge on, a product appeared due to replacement of a CO ligand by a H or a N atom (3). The present communication reports further information on the reactivity of metal carbonyl ions with atomic hydrogen.

Investigation of the reactivity of various transition metal carbonyl ions (chromium, molybdenum, tungsten, manganese, ruthenium) showed that most of them react more or less efficiently according to the same scheme as iron :

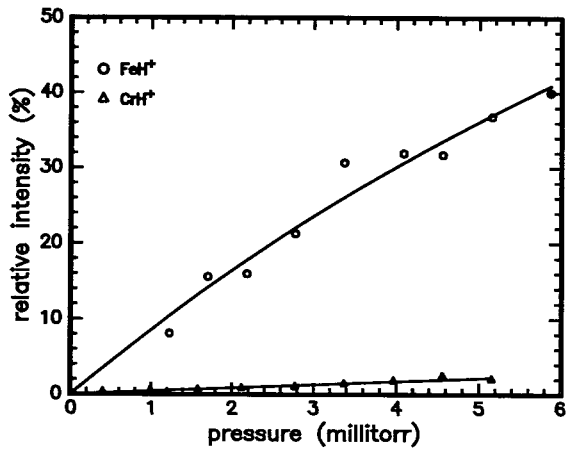
$$M(CO)_n^+ + H^\cdot \rightarrow M(CO)H_{n-1}^+ + CO$$

None of the bare metal ions (n = 0) reacted with either molecular or atomic hydrogen. The reaction efficiencies for MCO^+ cations follow the order Fe >> W > Cr ≥ Mo ≥ Ru. $MnCO_n^+$ ions are completely unreactive. For the first row transition metals Cr and Fe, the maximum reaction efficiency was found for MCO^+ ions (n = 1) and decreased steadily with increasing n; $Fe(CO)_5^+$ and $Cr(CO)_n^+$ (n = 3-6) gave no detectable product. On the contrary, in the case of heavier metals, the maximum reaction efficiency corresponded to n = 2 (W, Ru) or 3 (Mo).

In the course of our investigations, we have recently been able to increase the dissociation efficiency by more than one order of magnitude, using an improved fitting device. With our enhanced means of producing $H^\cdot$ concentrations with good reproducibility, it is now possible to measure relative rate constants.

Results for the reaction of iron monocarbonyl cations $FeCO^+$ and chromium monocarbonyl cations $CrCO^+$ with atomic hydrogen are presented below (see figure). The rate of formation of the major reaction product FeH^+ or CrH^+ is proportional to H_2 pressure in both cases. The ratio of the corresponding apparent rate constants is $k_{Fe}/k_{Cr} = 21 \pm 6$

Assuming a residence time of approximately 0.7 ms (corresponding to thermal velocity along the cell axis) for ions in the cell, the apparent first-order rate constant versus H_2 pressure is $3.95 \pm 0.4 \times 10^{-12}$ $cm^3.molecule^{-1}.s^{-1}$ for the reaction of $FeCO^+$ ions with atomic hydrogen. According to the classical Langevin capture collision cross section model, the maximum rate constant value for this reaction was calculated to be 2.1×10^{-9} $cm^3.molecule^{-1}.s^{-1}$ versus $H^\cdot$ pressure. The ratio of these two values is of the order of magnitude of the estimated average $[H^\cdot]/[H_2]$ ratio in the cell : ca. 0.2%, considering that the "useful" zone corresponding to the beam coming from the discharge (a few percent dissociation ratio) is about 1/20 of the cell length.



Therefore, the rate constant for the reaction of $FeCO^+$ ions with $H^\cdot$ is likely close to the Langevin value. This reaction is actually the fastest that we have observed among the reactions of various organic cations with $H^\cdot$.

The question remains, whether the lower reactivity observed for chromium and other metals is due to slow reaction of MCO^+ in its fundamental state, or to rapid reaction of a slightly populated metastable excited state.

In order to study which electronic structure of the metal carbonyl cation is involved from a theoretical point of view, calculations on the adiabatic energy curves of Fe(CO)+ corresponding to the states ^6D, ^4F, ^4D of Fe^+ and $^1\Sigma^+$ of CO have been performed using Multireference Quasi Degenerate Perturbation Theory (CIPSI algorithm) to take into account the electronic correlation. Equilibrium geometry (R_e) and bond energy (D_e) for the ground state ($^4\Sigma^-$ correlating to ^4F excited state of Fe^+) are in good agreement with those of experimental determinations (4) (for which only D_e is actually available) and theoretical calculations (5). Spin orbit interaction and dynamics of dissociation are under study to determine the possibility of transition between states with different spins during the dissociation.

NASA Ames Research Center, Moffett Field, CA 94035

Prompted by the synthesis of $^{+}P(OCH_3)_3C_6H_4^{\cdot}$ and related distonic ions by Smith and Kenttämaa[1] and by the study of the metal ion complexes Fe(phenyl)$^{+}$ and Fe(o-benzyne)$^{+}$ in our laboratory,[2,3] we have recently generated a metal-containing radical cation, $^{+}FeC_6H_4^{\cdot}$, using FT-ICR-MS. Laser desorbed Fe^{+} reacts with 1,4-diiodobenzene to form 1-Fe-4-iodobenzene ($FeC_6H_4I^{+}$), which is then subjected to sustained off-resonance irradiation (SORI). Loss of $I^{\cdot}$ from $FeC_6H_4I^{+}$ then yields Fe(p-benzyne)$^{+\cdot}$, i.e., $^{+}FeC_6H_4^{\cdot}$. In order to identify and distinguish Fe(p-benzyne)$^{+\cdot}$ from its isomer Fe(o-benzyne)$^{+}$ and Fe(3-ene-1,5-hexadiyne)$^{+}$, collision-induced dissociation and selected ion-molecule reactions of Fe(p-benzyne)$^{+\cdot}$ were studied and compared with those of Fe(o-benzyne)$^{+}$ and Fe(3-ene-1,5-hexadiyne)$^{+}$. Generations of Fe(*o*-benzyne)$^{+}$ have been reported previously. Fe(ene-hexadiyne)$^{+}$ was produced by the reaction of Fe(1,5-hexadiyne)$^{+}$ via dehydrogenation. Both experiment and theory strongly support the view that this new radical cation is an organometallic distonic ion, $^{+}FeC_6H_4^{\cdot}$.

The experiments were performed on a prototype Nicolet FTMS-1000 Fourier transform mass spectrometer, equipped with a 5.2 cm cubic trapping cell and a Varian 1 Tesla electromagnet. Fe^{+} was generated by laser desorption-ionization of the pure metal target using a Nd:YAG laser. 1,4-diiodobenzene, a solid sample, was introduced into the cell at a pressure of ~0.8-1x10^{-7} Torr through a Varian leak valve accompanied by heating the sample and inlet system to ~ 70-100 °C. Other Neutral reagents were pulsed into the cell through General Valve Corporation Series 9 solenoid pulsed valves. Background argon, kept at ~2.0 x 10^{-5} Torr, served as the collision gas for thermalization and for collision-induced dissociation (CID) or SORI excitation.

Collision-induced dissociation experiments gave Fe^{+} as the only fragment for all three isomers, however, yielded three different energy profile, revealing their unique structures and indicating that D°(Fe^{+}- o-benzyne) > D°(Fe^{+}- p-benzyne) > D°(Fe^{+}- ene-hexadiyne).

The neutral reagents used for the ion-molecule reaction studies include some alkenes and halogenated compounds, which have been used for the study of Fe(o-benzyne)$^{+}$, as well as methyl disulfide and methyl diselenide, which have been shown to be good indicators of distonic ions, transferring $\cdot SCH_3$ or $\cdot SeCH_3$, respectively, to the radical site of many organic distonic ions. The distonic ion is observed to exhibit different reactivity from that of its isomeric structure Fe(o-benzyne)$^{+}$ and Fe(ene-hexadiyne)$^{+}$. Although methyl disulfide is observed to react with Fe(p-benzyne)$^{+\cdot}$ exclusively by charge exchange, the characteristic transfer of $\cdot SeCH_3$ from methyl diselenide to this distonic cation is observed. These two reactions, however, were not observed for the other two isomers. Another interesting reaction is with allyl iodide, given that allyl iodide has a low homolytic C-I bond dissociation energy (40.7 kcal/mol) and iodine atom abstraction is commonly observed for other radicals upon reaction with allyl iodide. The distonic ion is observed to abstract $I^{\cdot}$ from allyl iodide and so is Fe(ene-hexadiyne)$^{+}$, while Fe(o-benzyne)$^{+}$ is not. However, SORI excitation on the iodine abstraction product $FeC_6H_4I^{+}$ of Fe(p-benzyne)$^{+\cdot}$ yields loss of $I^{\cdot}$ to reform the distonic ion and a minor product FeI^{+}, while that of Fe(ene-hexadiyne)$^{+}$ only yields FeI^{+}. These facts indicate that $I^{\cdot}$ abstraction for Fe(p-benzyne)$^{+\cdot}$ takes place at the radical site and not at the metal center, while on the contrary, the iodine abstraction is at the metal center for Fe(ene-hexadiyne)$^{+}$.

D°(Fe^{+}- p-benzyne) is estimated to be 66±10, 71±10, and 80±10 kcal/mol from different experiments and relevant information. Density functional theory calculations further support the experiment results. The calculated D°(Fe^{+}- p-benzyne)=73.3 kcal/mol, in line with the estimated value.

This is the first example of what we expect will be a new class of organometallic distonic ions. This preliminary study reveals a whole new area of organometallic ion chemistry. In addition to the usual metal-center initiated reactions, the radical site may operate either separately or in concert with the metal center to open new reaction pathways.

Gas-Phase Isomeric Differentiation Study of $FeC_7H_7^+$

Young C. Xu, Edna Garcia, and Ben S. Freiser*
H. C. Brown Laboratory of Chemistry, Purdue University, West Lafayette, In 47907
Charles W. Bauschlicher, Jr.*

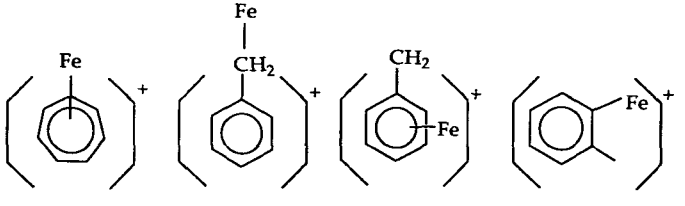
Three isomeric structures of $Fe(C_7H_7)^+$, i.e., Fe(tropylium)$^+$, Fe(benzyl)$^+$, and Fe(tolyl)$^+$, formed from different neutral precursors are studied with the FT-ICR-MS and by the theoretical calculations. Of particular interest is the role of the metal in stabilizing the tolyl ligand, given that the unmetallated tolyl ion, $C_6H_4CH_3^+$, rearranges to benzyl ion on the time scale of the FT-ICR-MS experiments.[1]

All experiments were performed on a prototype Nicolet FTMS-1000 Fourier transform mass spectrometer, equipped with a 5.2 cm cubic trapping cell and a Varian 1 Tesla electromagnet. Laser desorption-ionization was used to generate the metal ion Fe^+. Neutral reagents were obtained commercially in high purity and were introduced into the cell either through General Valve Corporation Series 9 pulsed solenoid valves or Varian leak valves. The isolation of the desired ions were accomplished by using swept double resonance ejection pulses.

Ions with the empirical formula $Fe(C_7H_7)^+$ were generated by three synthetic routes: (1)reaction of bare metal Fe^+ with cycloheptatriene; (2)reaction of Fe^+ with iodobenzene to form Fe(phenyl)$^+$, which then reacts with toluene; and (3)reaction of Fe^+ with chlorobenzene to form Fe(benzyne)$^+$,[2] which then reacts with methyl iodide.[3] The hypothesis is that these three reactions result in the formation of Fe(tropylium)$^+$, Fe(benzyl)$^+$, and Fe(tolyl)$^+$, respectively.



Fe(tropylium)$^+$ I | Fe(σ-benzyl)$^+$ IIA | Fe(π-benzyl)$^+$ IIB | Fe(tolyl)$^+$ III

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Energy resolved collision-induced dissociation and photodissociation experiments unequivocally distinguish Fe(tropylium)$^+$ from Fe(benzyl)$^+$ and Fe(tolyl)$^+$, clearly showing that the Fe(tropylium)$^+$ has the highest stability and strongest Fe^+- C_7H_7 bond energy among the three. Both experiments fail to clearly differentiate Fe(benzyl)$^+$ and Fe(tolyl)$^+$, which might indicate the rearrangement of Fe(tolyl)$^+$ to Fe(benzyl)$^+$ prior to dissociation. However, the three isomers, especially Fe(benzyl)$^+$ and Fe(tolyl)$^+$, can be distinguished by their ion-molecule reactions with p-xylene and methyl iodide and by the subsequent CID on their product ions. Scheme I and II illustrate the ion-molecule reactions of Fe(benzyl)$^+$ and Fe(tolyl)$^+$ and the CID fragmentation results on reaction product ions.

Additionally, the Fe^+- C_7H_7 bond energies are bracketed as 73 kcal/mol < $D°(Fe^+$- tropylium) ≤ 129±5 kcal/mol, 71±5 kcal/mol ≤ $D°(Fe^+$- tolyl) < 111 kcal/mol, and 55±5 kcal/mol < $D°(Fe^+$- benzyl) ≤ 63±5 kcal/mol. *Ab initio* calculations yield $D°(Fe^+$- tropylium) = 86.8 kcal/mol, $D°(Fe^+$- tolyl) = 84.4 kcal/mol, and $D°(Fe^+$- benzyl) = 69.4 kcal/mol, which support the experimental results.

In summary, our results show that Fe enhances the stability of tolyl ion. Thus, metallated tolyl ion can be retained for at least seconds, while, for comparison, tolyl ion itself rearranges to the more stable benzyl structure in under 1 ms on the time scale of FT-ICR-MS. Upon activation, however, Fe(tolyl)$^+$ rearranges to Fe(benzyl)$^+$ prior to dissociation.

Experimental and Theoretical Studies of $Nb_6C_7^{0/+}$

Samuel A. Lee, Steven Z. Kan, Young Hie Kim, Ben Freiser*
Marina Miletic, Richard E. Bleil and Sabre Kais*

H. C. Brown Laboratories of Chemistry
FTMS Cluster Research Group
Purdue University
West Lafayette, IN 47907

The chemistry of $Nb_6C_7^+$ with various reagents, including H_2O, CH_3CN, CH_3OH, and C_6H_6, is studied using a FTICR mass spectrometer coupled to a supersonic expansion source. For reaction with H_2O, sequential attachments up to 4 water molecules occur. The 5th and 6th water molecule attachments were observed but they do not grow to be base peaks. (Fig. 1) For reactions with CH_3CN, CH_3OH, and C_6H_6, intense 4 attachments are observed. Rate constants for the reactions with H_2O, CH_3CN, CH_3OH, and C_6H_6 are determined to be 5.15×10^{-10}, 3.66×10^{-11}, 1.5×10^{-10}, 2.39×10^{-11} cm^3 $molecules^{-1}$ s^{-1}, respectively using pseudo-first-order kinetic plots. Multiple excitation collisional activation (MECA) on $Nb_6C_7^+$ resulted in loss of Nb-C and Nb-C_2 units.

Ab initio calculations of Nb_6C_7 support the hypothesis that Nb_6C_7 has four active sites and 2 less active sites. A proposed structure of Nb_6C_7 consists of two cubes with one carbon at the exact inversion center of the D_{2h} symmetry (Fig. 2). Four of the six niobium atoms are equivalent but different from the remaining two. Furthermore, these four equivalent niobiums have bonds with only three surrounding carbons, while both of the remaining niobium atoms bond with five nearby carbons. The Mulliken charge distribution shows that four of the niobium atoms have a calculated partial charge of +0.055880, and the remaining two niobium has a charge of +.243986.

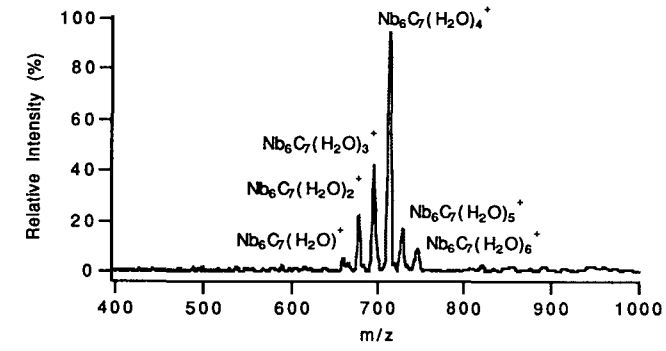

Figure 1. Reaction of $Nb_6C_7^+$ with water

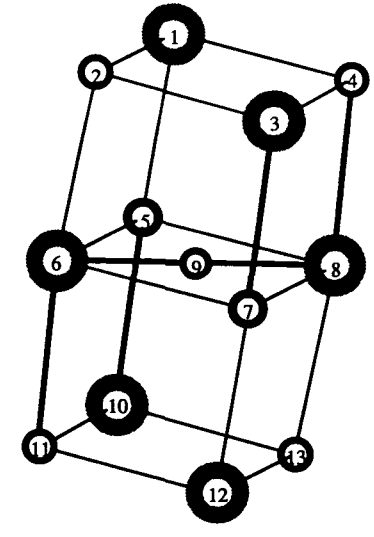

Figure 2. Calculated structure of Nb_6C_7 with a D_{2h} symmetry from Hartree-Fock calcualtions. A small and solid circle represents a carbon atom and and a gray circle a niobium atom, respectively.

GENERATION AND REACTIVITY OF YTTRIUM-CARBON CLUSTER IONS

Steven Z. Kan, Samuel A. Lee, and Ben S. Freiser
Department of Chemistry, Purdue University, West Lafayette, IN 47907 USA

In 1992, Castleman and co-workers reported the production of the ionic transition metal-carbon clusters, $M_8C_{12}^+$ (M = Ti, V, Zr and Hf).[1-4] Like the observations of pure carbon clusters such as C_{60} and C_{70}, these metal-carbon clusters were observed as "magic" peaks in the mass spectra obtained from a supersonic expansion ion source.[5] These intense peaks are indicative of the high stability of these clusters which are proposed to have symmetrical, cagelike structures with the geometry of a pentagonal dodecahedron. $M_8C_{12}^+$ species are thus termed metallo-carbohedrenes, or met-cars for short. Like fullerenes, met-cars are of both fundamental interest and hold promise as a new class of important materials and, hence, have become the focus of both theoretical and experimental investigations. Along with these species, metal-carbon clusters of other stoichiometries such as $Ti_8C_{11}^+$, $Ti_8C_{13}^+$, $Ti_7C_{12}^+$, $V_{14}C_{13}^+$, $V_{14}C_{12}^+$, and $Nb_4C_4^+$ have also been examined.[6,7] Here we report on the yttrium-carbon system in which a broad range of metal-carbon cluster ions are observed.

All of the experiments were performed on an Extrel FTMS-2000 Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer equipped with a 3 Tesla superconducting magnet. A Smalley compact supersonic expansion ion source equipped with a Jordan PSV fast pulsed valve and a Balzers 300 l/s turbopump was used to generate metal-carbon cluster ions. **Figure 1** shows a schematic set-up of the instrument. A Nd:YAG laser (Quanta Ray DCR - 2), frequency doubled to produce 532 nm light and set to have a 10 ns pulse width and ~30 mJ/pulse power, is used for desorbing a pure yttrium target to generate metal plasma. The disk target is driven by two stepping motors such that a spiral path is followed in order to expose a fresh metal surface for laser desorption at the beginning of each FT-ICR event sequence. In the mean time, helium seeded with 2% methane at a backing pressure of ~200 psi is introduced from the fast pulsed valve. The time between the laser pulse and the gas pulse is controlled so that a high-pressure burst of the gas mixture arrives at the metal target region right after the laser is fired. The metal plasma generated by laser desorption is cooled by the helium/methane gas mixture and complete dehydrogenation occurs in this process to produce metal-carbon cluster ions. The potential on the front trapping plate of the ICR cell is dropped from 9.8 V to 4.5 V to allow the decelerated ions to enter the trapping cell and then raised back to 9.8 V to trap and detect the metal-carbon cluster ions.

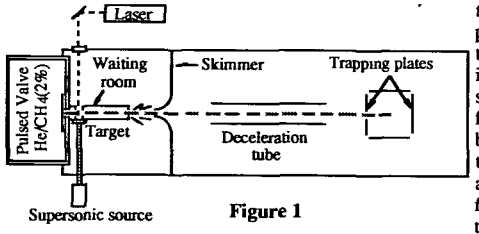

Figure 1

Figure 2 illustrates the yttrium-carbon cluster ions formed by varying the timing between the laser pulse and the gas pulse. The neighboring ion peaks are 12 mass units (carbon) apart. Yttrium-carbon clusters containing up to eleven metal atoms could be generated. Unlike the vanadium/carbon and the titanium/carbon systems that have been examined previously, the number of carbon atoms corresponding to a particular size metal atom cluster also varies over a greater range. $Y_4C_7^+$ is one of the local maximum peaks for the yttrium-carbon clusters containing 4 metal atoms. Its high intensity is indicative of its higher stability relative to its neighboring clusters in the same group (4 metals).

Collision-induced dissociation (CID) on $Y_4C_{7,8}^+$ and $Y_3C_{7,8}^+$ yields loss of Y and YC_2 group. Both $Y_4C_7^+$ and $Y_4C_8^+$ abstract a bromide from CH_3Br, reaction 1. The $Y_4C_{7,8}Br^+$ formed do not react with CH_3Br further and yield $Y_4C_{7,8}^+$ upon CID. $Y_4C_7^+$ and $Y_4C_8^+$ have 39 and 43 valence electrons, respectively. It is possible that the unpaired electron in each of the ions pairs with a bromide to form a σ bond and the reaction is terminated since all the other electrons become paired. Supporting this are the

reactions of $Y_3C_{7,8}^+$ (36 and 40 valence electrons, reaction 2) where bromide abstraction does not occur.

$$Y_4C_{7,8}^+ + CH_3Br \rightarrow Y_4C_{7,8}Br^+ + CH_3 \quad (1)$$
$$Y_3C_{7,8}^+ + CH_3Br \rightarrow Y_3C_{6,7}(H)Br^+ + C_2H_2 \quad (2)$$

Interestingly, while $Y_4C_{7,8}^+$ dehydrogenate water, reactions 3, $Y_3C_{7,8}^+$ undergo sequential reactions with water to form yttrium-oxygen cluster ions and acetylene molecules, reactions 4 to 7 for $Y_3C_8^+$. *Ab initio* calculations are underway to test the stabilities and the structures of the Y-C clusters and to explain why these clusters are in general different from other transition metal carbon cluster ions.

$$Y_4C_7^+ + H_2O \rightarrow Y_4C_{7,8}O^+ + H_2 \quad (3)$$
$$Y_3C_8^+ + H_2O \rightarrow Y_3C_6O^+ + C_2H_2 \quad (4)$$
$$Y_3C_6O^+ + H_2O \rightarrow Y_3C_4O_2^+ + C_2H_2 \quad (5)$$
$$Y_3C_4O_2^+ + H_2O \rightarrow Y_3C_2O_3^+ + C_2H_2 \quad (6)$$
$$Y_3C_2O_3^+ + H_2O \rightarrow Y_3O_4^+ + C_2H_2 \quad (7)$$

FT-ICR Studies of the Structures and Reactivities of Metal-Carbon Clusters

Y. G. Byun, C. S. Yeh, S. Afzaal, S. A. Lee, S. Z. Kan, and Ben S. Freiser
H. C. Brown Laboratory of Chemistry, Purdue University, West Lafayette, Indiana 47907

Castleman and co-workers were the first to report the growth of the unusual met-car clusters. A new class of transition metal-carbon clusters with the stoichiometry M_8C_{12} (M=Ti, V, Zr, Hf, Cr, Fe, Mo, and Nb), Nb_4C_4 and $M_{14}C_{13}$ (M=Ti, V) has become a focus of intense research area.

Th, D_{2d}, and T_d structural isomers of M_8C_{12} were proposed. In order to study the coordination chemistry of $V_8C_{12}^+$, water, acetonitrile, and benzene were chosen to be reacted. Surprisingly, $V_8C_{12}(H_2O)^+$ reacted with water through dehydrogenation to form $V_8C_{12}(OH)_2^+$. $V_8C_{12}(H_2O)(OH)_2^+$ and $V_8C_{12}(H_2O)_2(OH)_2^+$ were also formed at longer reaction times, with water truncation occurring at four attachments, $V_8C_{12}(H_2O)_2(OH)_2^+$. Acetonitrile and benzene underwent sequential association reactions, yielding mass spectra that truncated sharply at $V_8C_{12}L_4^+$ (L=CH_3CN, C_6H_6). Thus, these results obtained under low pressure conditions were consistent with either the D_{2d} or T_d structural isomer.

$Nb_4C_4^+$ is one of the smallest cubic crystallite structures (2x2x2) in the transition metal-carbon cluster family. This $Nb_4C_4^+$ reacted with both water and methanol through two competitive pathways . These two pathways depended on the cooling gas, argon. In the absence of a cooling gas, $Nb_4C_4^+$ was observed to attach a maximum of four solvent molecules, $Nb_4C_4(OH)(H_2O)_3^+$ and $Nb_4C_4(OCH_3)(CH_3OH)_3^+$ at longer reaction times. With a cooling gas, $Nb_4C_4(OH)_2(H_2O)_2^+$ and $Nb_4C_4(OCH_3)_2(CH_3OH)_2^+$ at longer reaction times were produced. Ab initio calculations indicated that Nb_4C_4 has a slightly distorted cubic structure.

$V_{14}C_{13}^+$ and $V_{14}C_{12}^+$ were found to react with water, undergoing both the elimination of H_2 molecules and association reaction mechanisms to yield $V_{14}C_{13}(OH)_2(H_2O)_6^+$ and $V_{14}C_{12}(OH)_2(H_2O)_6^+$. However, loss of $2H_2$ was also observed to form $V_{14}C_{13}(OH)_4^+$ for $V_{14}C_{13}^+$. $V_{14}C_{13}(OH)_4^+$ then reacted with water through association reactions to yield $V_{14}C_{13}(OH)_4(H_2O)_4^+$. In contrast to the water reactions, $V_{14}C_{13}^+$ and $V_{14}C_{12}^+$ reacted

with acetonitrile through addition reactions. Also seen were the combination reaction products, $V_{14}C_{13}(CH_3CN)_7(H_2O)^+$ and $V_{14}C_{12}(CH_3CN)_7(H_2O)^+$ which were formed by reactions with background water. In both water and acetonitrile cases, mass spectra showed that truncation occurred at all eight ligands attached to the $V_{14}C_{13}^+$ and $V_{14}C_{12}^+$. The reaction products observed here support the fcc unit cell structure.

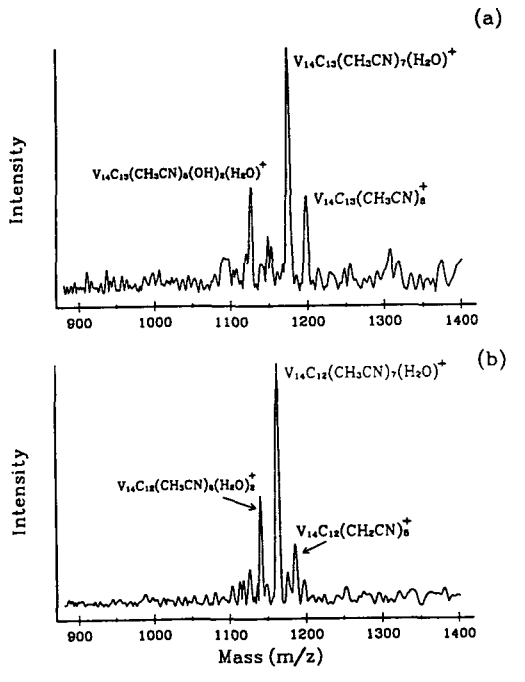

Figure. (a) Reactions of $V_{14}C_{13}^+$ with CH_3CN (~ 1.6 x 10^{-6} torr) for 6 seconds; (b) Reactions of $V_{14}C_{12}^+$ with CH_3CN (~ 1.9 x 10^{-6} torr) for 7 seconds

Gas-Phase Ion-Molecule Reactions of Lanthanides with Crown Ethers

Forest M. White, Tianpei Xin#, and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State University, 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

*Member of the Department of Chemistry, Florida State University
#Department of Chemistry, Berea College, Berea, KY

We report gas-phase ion-molecule reactions of lanthanide ions, M^+ (e.g La, Ho, Pr, Sm, and Gd) with neutral 18-crown-6 ether. Previously, the lanthanide ion electronic configuration was found to control the reaction pathways and distribution of the product ions for reactions of lanthanide ions with tri-*t*-butylbenzene.[1] Here, FT-ICR mass spectra were acquired in the source compartment of a dual-trap 3.0 tesla Extrel FTMS-2000 (Extrel FTMS/Waters, Madison, WI) equipped with an automatic solids insertion probe. Metal ions were generated by laser desorption with a Nd:YAG laser (Surelite II, Continuum Inc., Santa Clara, CA) operating at 1064 nm with a pulse width of 7 ns. A constant pressure of crown ether in the source-side ion trap was generated by dissolving the 18-crown-6 in acetone and applying it to the back side of a standard Extrel probe tip. After allowing the acetone to evaporate, praseodymium metal was applied to the front of the probe tip with double-sided adhesive tape. This configuration gave a fairly constant pressure of ~5 $\times 10^{-8}$ torr (background pressure ~2 $\times 10^{-8}$ torr) for ~1 h. After desorption of the metal ions, a variable length time delay allowed for reactions of the metal ion with crown ether neutrals. Following formation of metal:crown ether fragment complexes, collision-activiated dissociation yielded metal oxide ions which could subsequently be isolated and allowed to react again with crown ether neutrals. In this way, "hot" (reactions within several milliseconds after desorption) metal oxide ions with crown ether neutrals and "cold" (reaction at least 5 seconds after desorption) metal oxide ions reactions with crown ether neutrals could be compared.

Figure 1 shows the results of PrO^+ ions reacting with 18-crown-6 neutrals. Praseodymium ions are representative of the lanthanide ion series as a whole—each of five different lanthanide ions followed the same reaction pathway. The first mass spectrum (after only 10 ms reaction period) shows only Pr^+ and PrO^+ ions, whereas the middle spectrum (500 ms reaction period) demonstrates the first step in the reaction pathway, namely fragmentation of crown ether neutrals on formation of an adduct with PrO^+ ions. Ions corresponding to $PrO(C_2H_4O)_n^+$ (n = 0-5) were observed. The bottom spectrum demonstrates a second reaction pathway, namely addition of an intact neutral crown ether to the metal:crown ether fragment complex, giving ions corresponding to $PrO(C_2H_4O)_n^+$ (n = 7-11).

This work was supported by NSF (CHE-93-22824) and the National High Magnetic Field Laboratory at Florida State University.

Gas Phase Reactions of Pt^+, Au^+, and Hg^+ with Small Hydrocarbons

W.S. Taylor* and A.S. Campbell, University of Central Arkansas, Conway, AR 72035
L.M. Babcock and Christopher Linder, University of Georgia, Athens, GA 30602

Introduction

The chemistry of the third-row metal ions has received growing interest over the last several years. It has been shown by us[1] and others[2-4] that these ions display considerably greater reactivity than their first- and second-row homologues. In a previous study focusing on the chemistry of the group 11 ions with C_2H_6, C_3H_8, and n-C_4H_{10}, we observed that Au^+ exhibits bimolecular chemistry not seen with either Cu^+ or Ag^+.[ref] The key feature of these reactions is that when thermochemically favorable, hydride abstraction occurs exclusive of all other product channels This indicates that there is little or no kinetic barrier to hydride abstraction, and that the thermochemistry of this product channel indirectly governs access to other product channels. In order to test this behavior with other systems we have examined several systems which are exoergic (or nearly so) with respect to hydride abstraction: Au^+ + i-C_4H_{10}, and Pt^++ C_2H_6, C_3H_8, n-C_4H_{10} and i-C_4H_{10} In addition, several reactions which are endoergic with respect to hydride abstraction were examined: Hg^+ + C_2H_6, C_3H_8, n-C_4H_{10}, and i-C_4H_{10}

Experimental

The reactions in question were examined using a drift cell reactor and a flowtube equipped with a flowing afterglow (FA) source and a SIFT source. These instruments represent thermal (near-thermal in the case of the drift cell) environments For the flowtube work, metal ions were either injected directly into the flowtube or were mass selected in the SIFT source and then injected into the flowtube. Reactant ions are carried through the flowtube by a He flow of approximately 10 slm pumped by a Roots Blower The total pressure in the reactor is approximately 0.5 torr Neutral reactants are injected downstream and the reaction is monitored with a quadrupole mass filter In the drift cell studies, ions are transported via ion optics to the cell which contains 1 torr of a He/hydrocarbon mixture in a ratio of 10^4/1. Ions are drawn through the gas mixture by an electric field established by a set of guard rings. Reactant and product ions exiting the drift cell are monitored with a quadrupole mass filter. Effective temperatures in the drift cell are manipulated by altering the drift voltage. In all experiments, metal ions were produced by a dc glow discharge Au^+ and Pt^+ ions were formed by a sputter-bombardment process in which the metal to be studied serves as the cathode in the discharge. Hg^+ ions were produced by venting Hg vapor directly into the discharge plasma

Results and Discussion

A summary of the reactions carried out in this work is given in Table 1. Note that several of the Au^+ reactions examined previously with the FA were examined again using the drift cell and the SIFT In all cases, the observed products are consistent with our earlier work. The reaction of Au^+ with i-C_4H_{10} carried out in the drift cell indicates that hydride abstraction is the dominant product channel Also, the reactions of Hg^+ with C_2H_6 and n-C_4H_{10} exhibit no evidence of hydride abstraction. Indeed, Hg^+ does not appear to react with C_2H_6 under these conditions Hg^+ is depleted by n-C_4H_{10}, but no mercury-containing products are observed. Hydride abstraction does not appear to be significant in the Pt^+ reactions regardless of exoergicity Instead, H_2 elimination dominates product formation. All of the Pt^+ reactions exhibit initial formation of a Pt^+·alkene species which is itself depleted in a secondary H_2 elimination. Similar behavior was observed with both the drift cell and in the SIFT

Table 1: Summary of Reactions

Reaction	Products	Method	Temperature (K)*
Au^+ + C_2H_6	$Au^+{\cdot}C_2H_6^+$ $Au^+{\cdot}C_2H_4^+$	FA	300
Au^+ + C_3H_8	$C_3H_7^+$	FA	300
		SIFT	300
		Drift Cell	310
Au^+ + n-C_4H_{10}	$C_4H_9^+$	FA	300
		SIFT	300
		Drift Cell	320
Au^+ + i-C_4H_{10}	$C_4H_9^+$	Drift Cell	320
Pt^+ + C_2H_6	$Pt^+{\cdot}C_2H_4$ $Pt^+{\cdot}(C_2H_4)_2$	Drift Cell	310
Pt^+ + C_3H_8	$Pt^+{\cdot}C_3H_6$ $Pt^+{\cdot}C_3H_4$ $Pt^+{\cdot}(C_3H_6)_2$	Drift Cell SIFT	310, 340 300

Hg^+ + C_2H_6	none observed incorporating Hg	Drift Cell	300
Hg^+ + n-C_4H_{10}	none observed incorporating Hg	Drift Cell	320

* effective temperatures reported for drift cell reactions

The specific H_2 elimination chemistry exhibited by each system is unique While the Pt^+/C_2H_6 system displays simple sequential H_2 elimination resulting ultimately in the formation of $Pt^+{\cdot}(C_2H_4)_2$, the reactions with C_3H_8, n-C_4H_{10}, and i-C_4H_{10} are more complex This is illustrated by the formation of $Pt^+{\cdot}C_3H_4$ from the reaction of Pt^+ with propane. Possible structures for this species include a Pt^+·allene complex or a hydrido-platinum cyclopropenyl structure. Also notable is the formation of the Pt^+·butadiene complex This species is not only observed in the Pt^+/n-C_4H_{10} system, but in the Pt^+/i-C_4H_{10} system as well, where it likely results from a metal-induced isomerization

GLOW DISCHARGE/SIFT STUDIES OF GAS PHASE METAL IONS: REACTIONS OF MG^+

Christopher B. Linder, A. Leigh Dalton, and Lucia M. Babcock, Department of Chemistry, University of Georgia, Athens, GA 30602
William S. Taylor, Department of Chemistry, University of Central Arkansas, Conway, AR 73027

Gas phase reactions of Mg^+ with several (26) small neutral molecules have been examined using the newly developed glow discharge (GDIS)/SIFT apparatus which provides a clean source of Mg^+. It has been shown that Mg^+ reactions with small hydrocarbons, H_2O, and other small neutrals are crucial to understanding lower ionospheres of the giant planets.[1] While MgNC has been observed in circumstellar shells, pathways to its production are not known. Theory[2] and spectroscopic studies[3] have determined bond dissociation energies (BDE's) and structures for several Mg^+-L complexes, but no kinetic studies have been done. Moreover, BDE's for several ligands lie within experimental or calculational error of each other, and the exact ordering is not known We present a survey of reactions of 26 ligands with Mg^+ and detailed kinetic studies for four of these. Ligand switching reactions have been carried out *for several pairs of ligands to determine relative ordering of Mg^+-L bond strengths*

The only products observed for any reactions between Mg^+ and the ligands, L, are cluster ions $Mg^+(L)_n$ with varying degrees of clustering. Of the 26 ligands examined, 16 cluster with Mg^+: C_2H_2, C_2H_4, C_2H_6, C_3H_4, C_3H_6, c-C_3H_6, C_3H_8, C_4H_{10}, CO_2, H_2S, CH_3SH, CH_3OH, $(CH_3)_2O$, CH_3CN, C_6H_6, and $(CH_3)_2CO$. Reactions which proceed more efficiently are reflected in formation of higher clusters. Kinetics of clustering support this observation. Ten of the ligands examined (SO_2, H_2O, NH_3, H_2, N_2, NO, N_2O, NO_2, CH_4, CO) were found not to cluster directly with Mg^+ under our experimental conditions, and upper limits on rate coefficients have been determined.

For clustering reactions proceeding via collisional stabilization, the observed bimolecular rate coefficient is a function of pressure We have measured rates of reaction for Mg^+/L reactions as a function of (He) for L = CH_3OH, C_3H_6, C_3H_8, H_2S, and CH_3CN Apparent bimolecular rate coefficients are a function of (He) and are well below the collision rates, showing that these reactions are not saturated

In virtually all mass spectra of Mg^+/hydrocarbon reactions, a peak corresponding to $Mg^+(H_2O)$ was observed. However, our kinetic studies indicate that H_2O does not cluster directly to Mg^+. Therefore the cluster must be formed in a switching reaction; for example:

$$Mg^+(C_3H_8) + H_2O \longrightarrow Mg^+(H_2O) + C_3H_8$$

We formed $Mg^+(C_3H_8)$ upstream and added H_2O downstream confirming the switching reaction. The rate coefficient obtained is $k \geq 1.7 \times 10^{-9}$ cm^3 $molec^{-1}$ s^{-1}. A limit of $k \geq 1.4 \times 10^{-9}$ cm^3 $molec^{-1}$ s^{-1} for the switching reaction

$$Mg^+(C_3H_6) + H_2O \longrightarrow Mg^+(H_2O) + C_3H_6$$

has also been determined. Lower limits for are reported for k since formation of the Mg^+/hydrocarbon complex may not be complete prior to addition of H_2O. However, the rate coefficients are significant fractions of the theoretical rate, k_{ADO} (1.9×10^{-9} cm^3 $molec^{-1}$ s^{-1} for both), indicating that switching most likely occurs at the collision rate.

We are in the process of continuing our ligand switching studies, including more detailed quantitative studies, but the general Mg^+-L bond ordering obtained thus far is as follows:

$$\text{hydrocarbons} < H_2O < CH_3OH < NH_3$$
$$H_2O < C_6H_6 < NH_3$$
$$H_2O < (CH_3)_2CO < NH_3$$

We have employed the newly developed GDIS/SIFT to examine reactions of 26 ligands with Mg^+. Our results support the picture of weakly bound $(Mg^+\text{-}L)_n$ complexes of ground state Mg^+ obtained from theoretical[1] and spectroscopic[2] studies. Rate coefficients as well as the extent to which clusters form parallel the magnitude of the electrostatic Mg^+-L interaction as indicated by the ion-induced dipole (Langevin) or ion-dipole (ADO) capture rates as well as by bond dissociation energies (where available). The notable exception is H_2O for which we *observe no cluster formation despite a strong electrostatic interaction and the fact that* $Mg^+(H_2O)$ forms readily in switching reactions. This same behavior is noted for NH_3 which does not cluster to Mg^+ directly, but is more strongly bound than acetone, methanol, and water according to our switching studies. We also observe only small amounts of the n=1 cluster for CO_2 despite its BDE of 14.7 kcal mol^{-1}, and H_2S associates with Mg^+ only very slowly despite strong electrostatic interactions. Because these anomalies are observed for small ligands (H_2O, H_2S, CO_2, and NH_3) with fairly large BDE's, it is likely that k_d for $(Mg^+\text{-}L)^*$ is large, and collisional stabilization cannot compete under our experimental conditions. Castleman[4] observes formation of water clusters of Mg^+ up to n=5 and of $MgOH^+(H_2O)_5$ in his flow tube; this is attributed to direct clustering via the Lindemann mechanism. We see no evidence at all for direct formation of any water clusters by association reactions under similar flow tube conditions (i.e. P_{He}, T, and P_{water}) In Castleman's experiments, Mg^+ is produced by laser vaporization of solid Mg in the flow tube itself. In our work, Mg^+ is produced under the much less energetic conditions of the glow discharge source, and then selectively injected into the flow tube via the SIFT No undesired ions or neutrals enter the reaction region. Furthermore, energetic species such as Ar metastables and electrons do not exit the source/SIFT region to enter the reaction zone.

REACTIONS OF SINGLY-CHARGED METAL IONS WITH CYCLOPENTENE

Jinsong Ni[1] and Alex. G. Harrison
Department of Chemistry
University of Toronto
Toronto, Canada

The development of a tandem mass spectrometric method, involving reactive collisions in a quadrupole collision cell, to study the reactions of metal ions with organic substrates is reported. This approach has been evaluated by studying the reactions of singly-charged trasnsition metal ions with cyclopentene.

The transition metal ions Sc^+ through Cu^+ were produced by fast atom bombardment (7-8 keV Ar^o) of the appropriate solid metal chloride depositied on the FAB probe. Although all metal salts were found to give singly-charged metal ions, the chlorides gave the best yields. After mass-selection of the metal ions by the double-focussing (BE) stage of a hybrid BEqQ mass spectrometer,[2] the metal ions were decelerated and introduced into the r.f.-only quadrupole collision cell at low ion injection energy where they underwent reaction with cyclopentene. The ionic reaction products were mass analyzed by the final quadrupole Q.

Table 1 summarizes the spectra observed for an incident ion energy of 3 eV (lab scale) and an indicated pressure of $3x10^{-5}$ torr cyclopentene. The Mn^+ ion is largely unreactive with cyclopentene. The major primary product for Sc^+, Ti^+, V^+, Fe^+, Co^+ and Ni^+ is $M^+(C_5H_6)$ involving reductive H_2 elimination from the $M^+(c\text{-}C_5H_6)$ complex. Cr^+ and Cu^+ show only clustering to form $M^+(C_5H_8)$. The $M^+(C_5H_6)$ product reacts further to produce $M^+(C_5H_5)_2$, presumably the ionized metallocene, except for $Co^+(C_5H_6)$ which also produces $Co^+(C_5H_6)_2$ and $Ni^+(C_5H_6)$ which clusters to produce $Ni^+(C_5H_6)(C_5H_8)$. Where comparison is possible these results are in good agreement with earlier results obtained by ICR techniques,[3,4] indicating that the present tandem MS method is a viable method for studying metal ion reactions.

The mechanism of formation of $M^+(C_5H_6)$ is illustrated schematically in Scheme 1. Thermochemical arguments indicate that the failure of Cr^+ and Cu^+ to dehydrogenate cyclopentene results from the fact that insertion of the metal ion into the C-H bond is endothermic in these two cases, presumably as a result of the d^5 and d^{10} configuration of Cr^+ and Cu^+, respectively.

This work will appear in Int. J. Mass Spectrom. Ion Processes.

C_5H_8 ISOMER DISTINCTION BY METAL ION REACTIONS

Jinsong Ni[1] and Alex. G. Harrison
Department of Chemistry
University of Toronto
Toronto, Canada

It is well-established that the positive ion electron ionization (EI) mass spectra of unsaturated hydrocarbons provide little isomer distinction because of rapid rearrangements in the molecular ions.[2-4] Since transition metal ions frequently show distinctive reactions with organic molecules,[5] we have undertaken a study of the reactions of singly-charged transition metal ions with the C_5H_8 isomers cyclopentene, 1-pentyne, 2-pentyne, 1,3-pentadiene, 1,4-pentadiene, 2-methyl-1,3-butadiene and 3-methyl-1,2-butadiene to evaluate the potential of metal ion reactions to characterize the hydrocarbon isomers.

The transition metal ions Sc^+ through Cu^+ were prepared by fast atom bombardment (7-8 keV Ar^o) of the appropriate solid metal chloride deposited on the FAB probe. After mass-selection of the metal ion by the double-focussing (BE) stage of a hybrid BEqQ mass spectrometer[6], the metal ions were decelerated and introduced into the r.f.-only quadrupole collision cell at low ion injection energies where they underwent reaction with the C_5H_8 neutral. The ionic reaction products were analyzed by the final quadrupole Q.

The reactions of the transition metal ions with cyclopentene have been described in the previous paper (WPA 021). With the remaining C_5H_8 isomers Cr^+, Mn^+, Ni^+ and Cu^+ reacted mainly by clutering to form $M^+(C_5H_8)$ and $M^+(C_5H_8)_2$. Fe^+ and Co^+ showed a variety of products resulting from C-H and C-C bond insertion followed by fragmentation as well as simple clustering. The greatest isomer distinction was obtained for the reactions of Sc^+, Ti^+ and V^+. The two figures summarize the results obtained at 3 eV incident ion energy and a nominal C_5H_8 pressure of $3x10^{-5}$ torr for the reactions of Sc^+ and Ti^+ with six C_5H_8 isomers. A complex distribution of products is observed under these conditions which can be rationalized qualitatively in terms of C-H and C-C bond insertion followed by fragmentation. However, the distribution of products is quite strongly dependent on the isomer indicating that the reactions of the early singly-charged transition metal ions show considerable potential in characterizing unsaturated hydrocarbon isomers.

Radiative Association Rate and Bond Strength of Metal Ion-Neutral Complexes

Yen-Peng Ho and Robert C.Dunbar*
Chemistry Department, Case Western Reserve University, Cleveland, OH 44106

Introduction

Gas-phase reaction of transition metal ions with hydro-carbons has been an active area for decades. *Several techniques have been applied to measure metal-ligand bond energies. This includes collision-induced* dissociation, ligand exchange reactions, and photodissociation methods. Here we propose another approach to obtain metal-ligand binding energies by using a metal-ligand association technique. In the low pressure region where collisional stabilization of the association complex is not important, the reaction efficiency is normally determined by the competition between infrared radiative stabilization and back dissociation of the activated complex. Since the redissociation rate is a strong function of binding energy of the complex, measuring the low-pressure association rate gives an accurate method to evaluate the binding energy.

Methods

The association experiments were carried out in the Fourier-transform ion cyclotron resonance mass spectro-meter, using an IonSpec data system. The ions were trapped in a one inch cubical cell with a magnetic field of approximately 1.4 Tesla. The metal ions were produced by focusing the 532 nm light pulse (generated by a Nd.YAG laser) onto a metal plate attached to a sample holder near the cell. Neutral molecules were introduced through a leak valve For the reaction of Cd^+ and benzene, only the $Cd(C_6H_6)^+$ product was observed. For the association of Ag^+ with C_6H_6, both $Ag(C_6H_6)^+$ and $Ag(C_6H_6)_2^+$ were formed. This is also true for the association of Ag^+ with isoprene and 2-pentene The intensities of metal ion and ion complex were monitored as a function of reaction time to derive the association rate constant The time-plot for the association of Cd^+ with benzene at 300 K and 4.0×10^{-8} torr is shown in Fig. 1. The curves are fits of data to a pseudo first-order rate law. The apparent rate constant is 5.02×10^{-12}cc molecule^{-1} s^{-1}. The time-plot for the association of Ag^+ with benzene at 300 K and 2.0×10^{-8} torr is shown in Fig 2. Consecutive reaction kinetics was applied to the three Ag+ complexes to get the calculated curves. As shown in Fig. 2, the fit gives an apparent association rate constant of 2.46×10^{-11} cc molecule^{-1} s^{-1} for $Ag(C_6H_6)^+$ formation

The apparent bimolecular rate constant K_2 is defined as the rate $d[M^+]/dt$ divided by the neutral density. A linear pressure-dependent equation for k_2 can be derived as shown in the eq. (1)

$$k_2 = k_{ra} + k_3[N] \qquad (1)$$

k_3 is the termolecular rate constant k_{ra} is called the *radiative association rate constant* and is independent of neutral density. This rate constant was obtained by measuring the pressure-dependent k_2 and extrapolating to zero pressure, or measuring the apparent rate in the low pressure region (~2×10^{-8} torr) where the collisional stabilization is negligible. For example, the k_2 vs pressure plot shown in Fig. 3 gives an intercept of 2.41×10^{-11} cc molecule^{-1} s^{-1} which corresponds to the radiative association rate constant (k_{ra}) of $Ag(C_6H_6)^+$.

Results

To obtain the complex binding energy a thermal phase space model was used[1]. When the association efficiency is low enough, kra as given in eq (2) can be calculated in terms of densities of states for the complex and for the reactants. Since the density of states for the complex is a function of dissociation energy, a fit of calculated association rate constant kra to experimental results gives the dissociation energy of the complex ion. The calculations were performed using Klippenstein's phase space program[1].

The association reaction of Cd^+ with benzene and the association reactions of Ag^+ with benzene, isoprene and 2-pentene were studied. The k_r's and corresponding binding energies (E_o) are listed in Table 1 The binding energy of $Cd(C_6H_6)^+$ is lower than those of silver ion complexes The similar binding energies for the three Ag^+ complexes might suggest the electronic effects are not important in those systems. To check the validity of our method, the binding energies for $Ag(C_6H_6)^+$ from several studies are given in Table 2 for comparison. The value (1.31 eV) derived from charge transfer experiments is somewhat too low and the value (2.39 eV) from photodissociation seems too high. All the other values including ours are similar and fall into the range between 1.5 and 1.75 eV.

Conclusions

The binding energy for $Ag(C_6H_6)^+$ obtained in this work (1 74 eV) is a reasonable number compared to the previous studies. This gives us confidence in the E_o assignments for $Cd(C_6H_6)^+$, $Ag(isoprene)^+$ and $Ag(2\text{-pentene})^+$ *which are 1.55, 1.73 and 1.61 eV respectively. Furthermore, the sensitive dependence of radiative association rate* on the binding energy offers another approach to determining metal ion-ligand bond strengths.

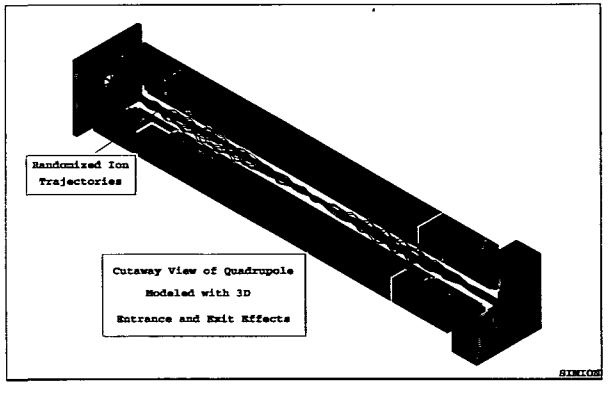
SIMION 3D Version 6.0

David A. Dahl
Idaho National Engineering Laboratory
PO. Box 1625, Idaho Falls, ID 83415

Introduction: SIMION 3D Version 6.0 is the latest version of the SIMION PC ion optics simulation program developed by the author for use on IBM compatible personal computers. Its new features and capabilities significantly broaden its applicability to ion optics and related experimental problems. Complete instruments can now be simulated. The new 3D capability allows simulation of quadrupoles including end regions, 3D ICR cells, and 3D source and detector geometry. Enhancements in user programming allow simulations involving viscous or collisional cooling for ion mobility simulations. A new charge repulsion capability allows detection of the onset of charge repulsion problems as well simulating things like combined repulsion and cooling effects in ion traps.

Discussion: The new version of SIMION has been rewritten in C. It is a 32 bit virtual DOS program that can run as a DOS application in DOS, Windows (3.xx, 95, or NT), and OS/2 (2.x or Warp). The program is based on a 32 bit GUI developed by the author for in-house data system development. Unlike previous FORTRAN versions of SIMION, this version is complete. It and its GUI, device drivers and DOS extender are all bound together into a single .EXE file.



The program makes use of potential arrays to simulate the electrode and/or pole geometry of electrostatic and/or magnetic simulation problems. These arrays can be either 2D (planar or cylindrical) or 3D planar asymmetrical. Individual arrays can contain up to 10 million points. A new geometry language (with compiler) supplements the interactive Modify function for defining complex electrode/pole geometry.

Fields are calculated (refined) via finite difference techniques. A new skipped point refining method developed by the author provides refine times that are proportional to n (Where n is the number of points in the potential array). This significantly reduces large potential array refine times over traditional n^2 finite difference methods.

Instances (3D images) of these potential arrays are projected into a ion optics workbench volume of up to eight cubic kilometers. As many as 25 potential array instances can be defined within an ion optics workbench volume. Potential array instances can be arbitrarily scaled, positioned, and oriented within the workbench volume. This allows complete instruments to be modeled.

All potential array instances are viewed as 3D objects within the workbench. SIMION has quick 3D visualization capabilities that allow the user to switch views, cut into instances to see inside, and more. Ions can be flown separately or in groups and viewed as rays or moving dots as appropriate. The user environment is highly interactive, allowing the user to switch views, adjust voltages, move instances, and etc. while ions are flying.

User programming has been enhanced with an expanded language, compiler and built in development system. The new user programming model allows user programs to read and change potentials, gradients, accelerations, and ion state parameters. This allows effects like viscous drag to be modeled with facility. Potential energy surfaces can now be updated via user program control. This allows observation of ion motions while the potential energy surface undulates (e.g. in an ion trap).

Initial Results: Various beta versions of SIMION 3D have been in use within the community for about six months. SIMION 3D has simulated the Phi-Evans TOF instrument using voltages that are within a few percent of the as-built instrument. It has been successfully used in the design of new commercial ion sources and detectors. The formation of cooled ion crystal structures in ion traps have be simulated with crystal structure and size in good agreement with experimental observations (illustrated below). Our group's personal experience with this new version has been positive. It appears to simulate our ion optics problems with voltages that are within few percent of the as built.

MacSimion Past, Present and Future

D. C. McGilvery and R. J. S. Morrison
Department of Chemistry, Monash University, Clayton, Victoria, Australia 3168

Ion trajectory simulation programs such as MacSimion are useful tools for understanding existing ion-optical designs and evaluating new ones. Although MacSimion operates in just two dimensions, it suffices for problems with planar or cylindrical symmetry, such as an ion source with tall narrow slits, a set of quadrupole rods, or an aperture lens system. Many real systems possess no simple symmetry or have overlapping regions with different symmetries. The interface region between an ion source and a quadrupole mass analyzer, or that between the latter and an AC-only quadrupole (as in a triple quadrupole instrument) are examples which require a full three dimensional treatment.

Small 2D calculations use arrays of perhaps 100 by 200 points to represent a single plane of a problem This often only provides a minimal rendering of the electrode geometries but is adequate to produce semi-quantitative results. One expects the same minimal calculation in 3D to require tens of megabytes of memory, with refine times running into many hours. High performance computers using RISC processors would appear to be attractive platforms on which to tackle such simulations.

A native code version of MacSimion for the PowerMac was evaluated for numerical simulations by building an energy-compensating electrostatic mirror Ion trajectories in the mirror are shown in Fig 1 Ion flight times in the mirror have been incorporated into analytical calculations in Mathematica to simulate a reflectron time-of-flight mass spectrometer [1,2] The RISC platform was found to out-perform earlier CISC processors by as much as a factor of five in the MacSimion phase of these calculations.

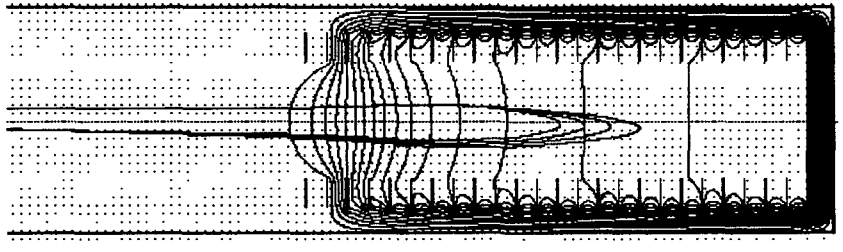

Fig. 1 Electrostatic mirror for energy compensation in a reflectron TOF mass spectrometer

MacSimion 3D is a new program we have developed, allowing a system of electrodes to be set up in 3D The memory requirements for a simulation are (4n+2) xyz bytes, where x, y and z are the dimensions and n is one greater than the number of time-dependent waveforms in the problem Laplace's equation is solved iteratively on the three-dimensional grid by a relaxation process (refining) until satisfactory convergence is reached. To improve execution speed the procedure initially operates on a coarse grid and progresses to maximum resolution near the end of the refining operation, which typically takes about one hour for an array containing 10^6 grid points. The resulting potential distributions can be exported into, and examined using the 3D visualization package, Dicer.

During ion trajectory calculations we compute a 64 term interpolating polynomial for the potential which has the form $V = \sum_{i,j,k} c_{ijk} x^i y^j z^k$,$(i,j,k \le 3)$ A new set of coefficients c_{ijk} are required each time the ion moves into a new cell (defined by the 8 grid points immediately surrounding the ion). Standard Runge-Kutta integration routines are used to compute the trajectory.

To illustrate the capabilities of MacSimion 3D, numerical simulations of ion motion in selected regions of a triple quadrupole instrument [3] have been undertaken. The complete instrument is far too complex to handle as a single entity, and must be decomposed into smaller, more manageable problems. Fig. 2 shows an ion trajectory in the region between a source and a mass analyzer. The system was represented using two 91x91x100 arrays to store the electrodes in a grid with a spacing of 0.2 mm. In the first array the rods were held at ground potential, while in the second array the source electrodes were grounded. Potentials were computed using the additive property of solutions to Laplace's equation and a modulation function to apply the appropriate ratio of DC and RF potentials to the rods.

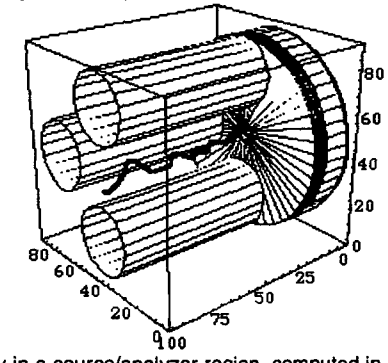

Fig.2 Ion trajectory in a source/analyzer region, computed in MacSimion 3D

We have also modelled the interface region between the first analyzer and the collision cell in a triple quad, which needs three arrays. Memory and time constraints currently restrict the physical volume of regions which can be studied in MacSimion 3D to about 10 cm^3 We are currently exploring the use of phase space methods [4] to compute ion trajectories near the center of the mass analyzing quadrupoles. We anticipate that future work will focus on a hybrid approach combining numerical calculations with these phase space methods, thereby greatly enhancing the usefulness of such 3D simulations

The Practical Application of Data Controlled Mass Spectral Analysis

Douglas C. Stahl, Kristine M. Swiderek, Michael T. Davis & Terry D. Lee
Beckman Research Institute of the City of Hope, Duarte, CA 91010

Introduction

Compounds of interest often occur in minute quantities and as components of complex mixtures. For this reason, a primary focus of chemistry research has been directed toward increasing the sensitivity of mass spectrometry, HPLC, and sequence analysis. The physical connection of multiple isolation and analysis steps has reduced sample losses and has greatly increased the quantity and quality of structural information that can be obtained from a single sample. However, the volume and complexity of data generated by these improved analytical techniques currently limits its effective and efficient use toward the solution of problems. After completion of an analysis, an interpretation of collected data is usually necessary to determine how to proceed with the next analysis. A post-analysis evaluation of data often reveals information that could have been used to optimize analyses in real time. There is no established technique for using previously collected data to control subsequent data acquisition. In addition, there is no established technique for targeting a specific subset of information in a complex mixture, or for selectively discriminating against subsets of information that are known or not of interest. The loss of information between tandem analyses has been minimized through the development of a logical interface between physically connected analytical methods. A mass spectrometer data system was used to continuously evaluate incoming spectral data against a variety of user definable variables. The resulting conclusions were used to modify analyses at subsequent steps. Using computer programs developed in our laboratory, we have prepared examples of "data controlled" experiments that exploit the existing capabilities of a mass spectrometer data system to increase the effectiveness and efficiency of tandem analyses.

Materials and Methods

Ultra low flow LC/ESI/MS and LC/ESI/MS/MS analyses were performed using a microscale HPLC system built by the authors (1, 2, 3). On column UV detection was performed at 200 nm using an ABI 759A UV/VIS spectrophotometer (Applied Biosystems, Inc. Foster City, CA) equipped with a capillary flowcell holder. All mass spectrometry was performed on a Finnigan TSQ700 triple sector quadrupole mass spectrometer using the ICIS data system version 7.2. Programs for data acquisition and data system control were developed using Finnigan Instrument Control Language (ICL) version 7.27 (4).

Results and Discussion

Example 1

Various amounts of a standard mixture were loaded onto the micro flow LC/MS system to determine how much structural information can be obtained in an automated mode during a single analysis and to evaluate the sensitivity limitations of data controlled analyses. Data controlled LC/MS/MS analyses on all ions above a user-defined signal to noise threshold were performed. At 1 pmol and 500 fmol eight of nine ions were selected by the computer and resulted in interpretable MS/MS spectra. One ion was not selected because its low signal to noise ratio. Loading 200 fmol, six of nine ions were selected by the computer and yielded interpretable spectra and at 100 fmol four of nine ions were selected. Three of those four ions yielded partial sequence information. The fourth ion yielded a complete sequence. Using signal to noise ratio as the criteria for ion selection, the practical limitation of data controlled MS/MS studies is defined by the sensitivity of the instrument. Partial protein sequence information can be obtained automatically with as little as 100 fmol of sample and more structural information can be obtained by performing repeated analyses with progressively lower signal to noise threshold values.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Example 2

LCMS analysis of a synthesized peptide showed its mass to be 64 amu higher than expected (expected mass = 10,342). A tryptic digestion was performed to check for a mass difference on the peptide level. Under the assumption that the mass difference is caused by a single amino acid exchange, a list with all expected masses was preloaded and MS/MS was automatically performed on all ions that differed by the observed 64 amu shift. The doubly charged ion of only one peptide was automatically selected for MS/MS. The resulting MS/MS spectra indicated a valine/tyrosine exchange in position 87 of the polypeptide corresponding to a mass shift of 64 amu. By continuously evaluating incoming data against a list of expected masses, it is possible to isolate discrepancies, minimize analysis time, and reduce the volume of data. This could be used to easily confirm and localize site directed mutagenesis or posttranslational modifications of a protein.

Assuming the mass difference is caused by multiple sequence errors, a list with all expected masses was preloaded and MS/MS spectra on all masses that differ from the expected values were automatically acquired. Seven masses were selected by the program for MS/MS. Six of the seven were identified as either unspecific cleavage products of the polypeptide, or were associated with minor contaminants. The MS/MS data for mass 1242 indicated a valine/tyrosine substitution. Unexpected masses can be automatically isolated and selected for MS/MS in real time and the structural analysis of an unknown component in a sample contaminated with a known component can be performed.

Example 3

Structural analysis was requested on a minute quantity of unknown protein that had been separated and digested in SDS gel in the presence of detergent. A single LC/MS analysis was performed to generate a list of candidate masses. These potential peptide masses were preloaded into a list and a data controlled MS/MS analysis that searches each spectrum for masses contained in the list was performed. The list was loaded with 26 candidate masses. 11 masses were automatically selected for MS/MS analysis. Three of the 11 masses were derived from the detergent. One peptide MS/MS spectrum could not be interpreted. The remaining five peptide MS/MS spectra yielded interpretable data. A database search using the resulting sequence resulted in a match with the known protein transferrin. 13 of the 26 masses originally entered into the list matched masses associated with transferrin. Without additional data analysis, MS/MS was performed on detergent peaks as well as peptide peaks. All time spent on the analysis of detergent peaks minimized the change of obtaining structural information on peptides.

The MS/MS analysis of detergent peaks seen in the analysis described above, helped to establish a "fingerprint" MS/MS spectrum for that detergent. An additional ICL program was written to detect the fingerprint spectrum when it occurs. When the MS/MS fingerprint was detected, the mass spectrometer immediately returned to normal scan mode. Otherwise, MS/MS spectra was collected on the mass for as long as possible. LC/MS/MS was performed on all signals above the signal to noise threshold. The MS/MS analysis of detergent peaks was terminated after one scan, and the detergent masses were recorded so that they will be rejected in all following scans. Approximately 84 detergent peaks were detected and eliminated from further consideration. 17 peptide MS/MS spectra were obtained. Four of those spectra were uninterpretable, Of the remaining 13, four corresponded to transferrin. The remaining nine could not be matched with a known protein. Data controlled LC/MS/MS analysis of all masses above a threshold signal to noise value will yield the maximum amount of data when combined with the automatic detection and elimination of data related to contaminants. Lists of contaminants can be created once and used for the analysis of many samples. This method could be used to discriminate against detergents and contaminants associated with in-gel digestions, digestions of proteins on membranes, and preparation of cell lysates.

Possible Use of a Time Domain Signal Inverse Algorithm in FTICR-MS

Michael V. Gorshkov* and Richard T. Kouzes

Environmental Molecular Sciences Laboratory
Pacific Northwest Laboratory, Richland, WA 99352

*Member of the Institute of Energy Problems of Chemical Physics, Russian Academy of Sciences, Moscow, Russia 117829

The most widely used numerical method for spectral enhancement is the Fourier transform (FT) [1]. There are several algorithms that have been developed to improve FT spectra [2]. We developed a time-inverse algorithm (TIA) for rapid signal prediction into negative time. The resulting time-domain signal then consists of two juxtaposed parts: the original signal and the time-inverted one. In FTICR, the post-excitation phases of different ions are the same and equal to the phase of the excitation field. The assumption is made that the ion motion will be the same for $t < 0$ as it is for $t > 0$ (Fig.1). From these assumptions, we may elongate the real time-domain signal f(t) to obtain: $f_{Inv}(t) = f(t)$ when $t > 0$ and $f_{Inv}(t) = f(-t)$ when $t < 0$. The TIA frequency spectrum $F_{Inv}(\omega)$ is the convolution of frequency spectra from cosinusoid $S_{Inv}(t)$, boxcar $\Pi_{Inv}(t)$, and exponential $E_{Inv}(t)$ functions, respectively: $F_{Inv}(\omega)=S_{Inv}(\omega)*\Pi_{Inv}(\omega)*E_{Inv}(\omega)$. It was found from analysis of the shape of $E_{Inv}(\omega)$ function that the spectral amplitude of the TIA signal will be doubled, the peakwidth will be narrower by factor of $\sqrt{3}$, and the noise level will be a factor $\sqrt{2}$ higher. Thus, resolution and signal-to-noise level will be higher. Fig.2 shows an example of an unresolved doublet, and the same doublet after applying the TIA method. In Fig.3 the mass spectrum from bovine insulin $[M+4H]^{4+}$ protonated molecular ion is shown. Ions were formed by ESI (7T FTICR at Pacific Northwest Laboratory [3]). It was also found that the TIA method may be used for the case of quadrature detection as well. In practice, the phases of ion motions may not be the same when detection is started. For the TIA method, the initial phase is crucial to the correct juxtaposition of the original and predicted signals. Related artifacts can be eliminated by phase correction in the complex FT spectrum of the original signal. For the original signal each individual phase ϕ_i may be rotated in the corresponding FT spectrum $F_i(\omega)=Re_i(\omega)+i\,Im_i(\omega)$ to obtain pure absorption $A_i(\omega)$ and dispersion $D_i(\omega)$ spectra that correspond to $\phi_i=0$. The phase rotation procedure is described by the following expressions [1]: $A_i(\omega)=Re_i(\omega)\cos\phi_i - Im_i(\omega)\sin\phi_i$; $D_i(\omega)=Re_i(\omega)\sin\phi_i+Im_i(\omega)\cos\phi_i$. We found the following advantages of the method: (1) increase in resolution and signal-to-noise ratio; (2) simplicity of the algorithm. The TIA method may be helpful for analysis of low resolution and unresolved spectra especially in low field FTICR.

This work was supported by Associated Western Universities under the Grant DE-FG06-89ER-75522 with the Department of Energy and by Pacific Northwest Laboratory.

HOMOLOGOUS SERIES PLOTS: A NEW SLICE THROUGH THE GC/MS DATA SET

Gregory G. Dolnikowski, and Brian Smith,
Jean Mayer USDA-HNRCA at Tufts University, Boston MA 02111 and
Spectros Associates, Mendon MA 01756

We have developed a computer program that takes a new slice through the GC/MS data set. The new slice is called a homologous series plot because it passes through all the ion current maxima that are caused by a homologous series of compounds eluting from the GC while they are being detected by a scanning MS.

The program for extracting homologous series plots from GC/MS data is written in Array BASIC and runs under GRAMS/386, which is a general-purpose data system for lab instruments sold by Galactic Industries. The user first finds two peaks which may be part of an homologous series using the total ion chromatogram and mass spectra. The user then enters into the program the scan number and m/z value for each peak. The program determines the equation of the homologous series slice based on the scan numbers and on the natural log of the m/z values. The program then extracts the correct m/z values from each mass scan in the data file according to the equation of the slice, assembles the m/z values into a single file, and stores the new file. Finally the program draws a homologous series plot of ion abundance versus m/z on the computer screen.

Data for this presentation were collected using a HP 5980 Series II GC/HP 5988A MS. The fused silica capillary column in the GC was 30 m long, 0.25 mm i.d., and coated with DB-5 stationary phase. The oven was programmed from 75°C to 325°C at 10°C per minute. The MS was scanned from 250-650u repetitively, and methane positive ion chemical ionization (PCI) was employed for detecting the sample.

Figure A shows the total ion chromatogram (TIC) of an extract of lipids from a marine organism. The lipids have been saponified, reduced, and derivatized to fatty acid methyl esters and fatty alcohol acetates. Under methane PCI, fatty alcohol acetates form $(MH - CH_3COOH)^+$ ions as the base peak of their mass spectra. A homologous series plot (Figure B) of the $(MH - CH_3COOH)^+$ ions indicates that there is a seven member homologous series of fatty alcohol acetates from C_{20}-C_{32} present in the sample. A similar homologous series plot of the $(MH)^+$ ion of the fatty acid methyl esters reveals a homologous series with eight members ranging with some gaps from C_{15}-C_{24}.

The homologous series plot is useful for visualizing an entire homologous series of compounds in complex chromatograms that may contain unresolved peaks or other homologous series. In chemically noisy chromatograms, the homologous series plot can often detect peaks that can not be distinguished using the TIC.

THE DETERMINATION OF ELEMENTAL COMPOSITION BY LOW RESOLUTION MS/MS.

Jia-shen Wang
Clairol Inc., Stamford, CT 06922

In theory, elemental compositions can be derived by MS based on the isotopic patterns of molecular ion clusters[1]. In a routine application, this technique is very useful for elements such as Cl and Br and to some degree for elements such as S and Si. An accurate determination of the carbon content of a compound, however, is a challenge. The method described here is an approach which determines the carbon content of a compound based on the known neutral loss peaks of the $[m+1]^+$ daughter spectra.

THEORY

The M+1 peak in a molecular ion cluster contains one heavier (by 1u) isotope for those elements which have heavier (by 1u) isotopes. The peaks of the daughter ions of these M+1 ions, therefore, appear as pairs (different by one mass unit), because the heavier isotope will be present either in the ion or neutral fragments. A peak intensity ratio (I_H/I_L) of the high (I_H) and low (I_L) mass peaks is

$$(I_H/I_L) = \sum m_i X_i / \sum n'_i X_i \qquad \text{..... (1)}$$

where X_i is the relative abundance of the heavier isotope of element X and m_i and n'_i are the numbers of element X in the ion and neutral fragments, respectively. This equation is derived based on an assumption that there are no isotopic effects in the formation of these ions. The elemental composition of a compound will be obtained, once all m_i's are solved, *since the sum of m_i and n'_i is the content of the respective element in a compound.* All m_i's in Equation (1), however, can not be solved, simultaneously. Fortunately, an approximation can be made since the terms related to carbon in Equation (1) are by far much larger than the terms of all the others. Thus equation 1 is reduced to the form:

$$(I_H/I_L) = m_c/n'_c \qquad \text{..... (2)}$$

The carbon content of a compound, therefore, can be determined by using Equation (2), since the value of n'_c is known. This is because the respective neutral loss is known. Subsequently, the possible compositions of a compound can be limited to a very small number, and evaluated with other information.

EXPERIMENTAL & PROCEDURE

The mass spectrometer used here is a Finnigan TSQ-7000 MS/MS system. The sample is introduced by a direct insertion probe (solid probe). The calculations are done by computer using standard spreadsheet softwares. The procedure of the analysis is summarized in three steps: (1.) Use $[m]^+$ ion to adjust the experimental conditions, (2.) Measure the intensities of the peaks (pair) of $[m+1]^+$ daughter spectra where the neutral losses are known, and (3) derive the possible compositions and use equation (1) to evaluate the answers.

RESULTS & DISCUSSION

Figure 1a.

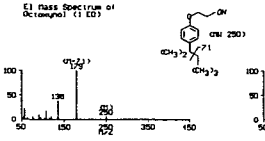

Figure 1b.

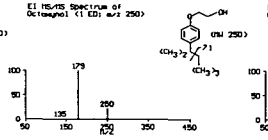

Figure 1c.

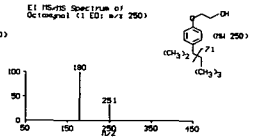

Figure 2a.

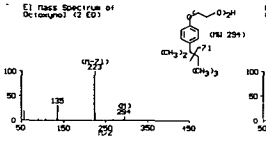

Figure 2b.

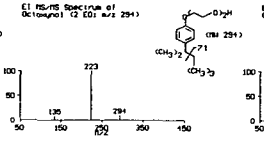

Figure 2c.

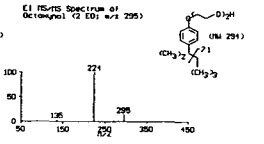

Two compounds with similar structures were selected to test the method. The EI mass spectra are shown in Figures 1a and 2a. The neutral loss (C_5H_{11}) of the base peaks is common for these compounds. The daughter spectra of $[m]^+$ of the respective compounds are shown in Figures 1b and 2b. The spectra indicate that, under the selected experimental conditions, the interfering ions are negligible. The daughter spectra of $[m+1]^+$ are shown in Figures 3a and 3b. The carbon contents are calculated to be 16.03 and 18.14 by equation 2 with the respective peak ratios. The experimental errors (0.03 and 0.14) are from two sources. One is due to the approximations of equation 2. This one can be solved by trial-and-error with equation 1 for possible compositions. The reduction of equation 1 to equation 2 causes negligible errors in most cases for hydrogen and oxygen. The other is just experimental error. This error is minimized by data averaging. With the current example, a 10% error in peak intensity measurement will cause an error of one carbon. This issue does not appear to be a problem with the results obtained here.

SUMMARY

The method shown here to determine the carbon content of a compound is based on the capabilities of an MS/MS system and the knowledge of many common neutral losses which have been established. While the example shown here is a simple C-H-O compound, the method can be applied to much more complex compounds which can also include other elements.

THE USE OF PM3 MOPAC SEMIEMPIRICAL CALCULATIONS TO PREDICT PHOTOINDUCED PROTON-TRANSFER IN H-BONDED CLUSTERS

Mary Gimon Kinsel, Yong Huang, Damon C. Barbacci and David H. Russell
Laboratory for Biological Mass Spectrometry, Department of Chemistry, Texas A&M University, College Station, Texas 77843

Photoionization of substituted aromatic acids in amine clusters $M(NR_3)_n$, where R = H, CH_3 or C_2H_5, generated using a supersonic nozzle yields both protonated amine clusters $H(NR_3)_m^+$ (m<n) and radical cation species $M^+(NR_3)_n$. We have studied the proton-transfer from several aromatic acids including the MALDI matrices 4-hydroxy-3-methoxycinnamic acid (ferulic acid) and α-cyano-4-hydroxycinnamic acid. We are interested in the value of semiempirical calculations as interpretive tools in the study of photoinduced chemistry in hydrogen-bonded clusters. In this poster we present preliminary calculations (PM3-type) on hydrogen-bonding of the solvent molecules to the aromatic acid and the effects of solvation on the thermodynamic properties of the cluster.

Semiempirical Calculations

The semiempirical calculations were performed using MOPAC version 6.0 (CaChe Worksystem) running on a MacIntosh Quadra 900. The starting geometries of the substituted aromatic acids were obtained using the Molecular Editor Program. One, two, and three solvent molecules were allowed to approach the polar substituents along the reaction coordinant defined by hydrogen-bonding donor and hydrogen-bonding accepter moities of the aromatic acid and solvent molecules. The thermodynamic properties of the system were calculated as a function of the distance between these two groups.

Results and Discussion

Figure 1 shows a slice of the resulting potential energy surface obtained when an ammonia molecule approaches the phenolic hydrogen of ferulic acid that is already hydrogen bonded by two additional ammonia molecules. The potential energy surface has a minimum at a distance of 1.8A which corresponds to the most stable hydrogen-bond formed. The hydrogen bonding of three ammonia molecules at the polar substituents of ferulic acid results in a net lowering of the ionization potential by approximately -0.5eV. The solvent identity was changed to methylamine and analogous calculations were performed. In this case the ionization potential was lowered by approximately -1eV. We are currently

investigating the effects of solvation at alternative sites on the aromatic acid including the π-clouds of the aromatic rings.

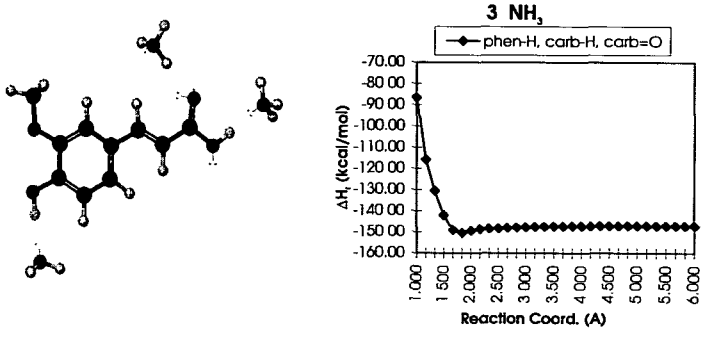

Figure 1: Ferulic acid solvated by three ammonia molecules. The graph depicts the energy of the system as one ammoniz molecule approaches the phenolic hydrogen of ferulic acid.

Future Studies

Experimental results show that as the basicity of the solvent molecule increases, there is a decrease in the abundance of the solvated radical cation and a corresponding increase in the abundance of protonated solvent ion signal in the TOF mass spectrum. We are investigating this observation in detail by calculating the heats of formation of the solvated aromatic acid radical cations as well as that of the solvated proton. Our ultimate goal is to apply this type of experiment combined with the results of semiempirical calculations to explore the mechanism of matrix assisted laser desorption/ionization as a proton transfer process within a cluster environment.

Application of a Fuzzy Logic Peak-finding Algorithm for GC/MS Analysis

Peter Sander, Bruker-Franzen Analytik GmbH,
Postfach 33 01 26, 28331 Bremen, Germany

In order to speed up the evaluation of GC/MS analysis and to also improve common GC/MS evaluation techniques a fuzzy logic-based peak-finding algorithm has been developed. Advances are given in a wide range of GC/MS analysis[1]:

First, GC/MS analysis according to standard procedures (e.g., EPA VOAs) requires positive identification of the target compound spectra and "up to 10 organic compounds of greatest apparent concentration". Here, interference of overlapping substance peaks, especially of those not listed in the target compound list, increases the time to complete the evaluation significantly. Second, "field" applications of GC/MS (e.g., task force for chemical spills, accident or fire on chemical plants or other hazardous material sites, ...) have to account for complex mixtures of numerous substances and also require a fast and reliable analysis to ensure fastest possible response. In these cases the novel *Dissect* algorithm is indispensable to perform quickly and reliably the complete GC/MS evaluation.

Methods:

The fuzzy logic based algorithm, named *Dissect*, is using the maximum amount of information available from the GC/MS measurement to separate mass spectra of overlapping compound peaks without any user-interaction.[1] Fuzzy logic permits to implement the decision-making process of interpreting and evaluating mass spectra into a reliable, automatic algorithm. The result of this algorithm is a list of all substance peaks along with a short chromatographic track of each individual substance, its mass spectrum, and its integrated area. The resulting mass spectra are background-subtracted and without contributions of neighboring, overlapping substances, thus enabling an unambiguous and accelerated identification in a mass spectral library.

Results:

The novel *Dissect* algorithm can be included in an evaluation procedure to determine the amounts of calibrated substances as well as the intensity of all other containing compounds. Fig. 1 shows the result of a combined evaluation procedure. The sample has been taken at an inspection well of a waste disposal site for hazardous materials. The evaluation procedure performed here evaluates calibrated VOA compounds by their (single-ion) target ions and all other compounds by *Dissect*. The result of the evaluation procedure is listed in Tab. 1. VOA compounds evaluated by their target ions are listed here with a 'Peak Name' (e.g., *Toluene* (peak# 21), *Ethene, chloro-* (peak# 2), ...). All other compounds in this list were previously not known. These compounds have been evaluated by *Dissect* and identified by library search in the mass spectral library of the *National Institute of Standards and Technology*. Note, that among others the two major components of this sample (*Disulfide, dimethyl* (peak# 19) and *1,3-Butadiene, 1,1,2,3,4,4-hexachloro-* (peak# 52)) are compounds not listed in the EPA's list of VOAs. A standard evaluation procedure relaying on the evaluation of VOAs only will not list these hazardous compounds. The *Dissect* algorithm performed this evaluation automatically, reliable, fast, without user-interaction, and, as already pointed out, without previous knowledge about what compounds to expect.

Conclusion:

The *Dissect* algorithm is a valuable addition to standard GC/MS analysis by delivering previously not known compounds instantly. The qualities of this algorithm also allow to use shorter GC columns and/or faster temperature ramps, reducing the total time for a complete GC/MS analysis even more. For "task force" applications of GC/MS – facing the challenge of identifying numerous compounds as fast as possible to ensure fastest possible response – the *Dissect* algorithm is irreplaceable by performing the task of evaluation fully automatically and delivering the complete list of compound spectra for an unambiguous identification in a mass spectral library.

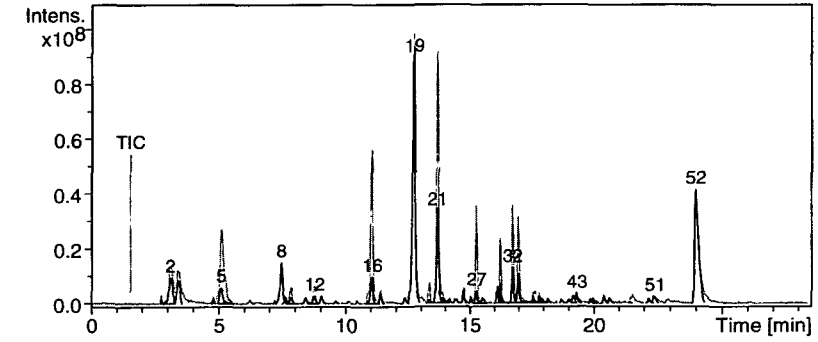

Fig 1 On-site GC/MS analysis with Bruker EM 640. Evaluation of VOAs and all other compounds by *Dissect*.

Peak #	Area [%]	Peak Name	Substance Name from NIST Library Search
19	33.4		Disulfide, dimethyl
52	16.1		1,3-Butadiene, 1,1,2,3,4,4-hexachloro-
21	9.5	Toluene	Toluene
2	4 5	Ethene, chloro-	Ethene, chloro-
3	3.4		Methanethiol
16	3.0	Trichloroethylene	Trichloroethylene
32	3.0	Ethylbenzene	Ethylbenzene
33	2.7	Xylene	Benzene, 1,3-dimethyl-
5	2.1	Ethene, 1,1-dichloro-	Ethene, 1,1-dichloro-

Software Tools for the Analysis of High Resolution Mass Spectra

Price, John M., Myers, James D., Rockwood, Alan W.,
Van Orden, Steven, Williams, Ernest L.

Environmental Molecular Sciences Laboratory,
Pacific Northwest Laboratory,
Richland, Washington.

We present a suite of software tools for the analysis of the high resolution mass spectra of large molecular weight species. This program, called MERCURY, includes tools for:

- the prediction of isotope distribution patterns for arbitrary molecular formulas, including fragment ions
- a prototype automated wavelet transform algorithm for assigning the charge states of spectral features
- a "protein editor" to conveniently generate molecular formulas for biopolymers and biopolymer fragment ions from sequence information
- the assignment of protein sequences by computer assisted interpretation of ladder sequences from collisionally activated dissociation (CAD) data.
-

MERCURY uses new high speed methods for the calculation of the isotope distributions of fragments of arbitrary molecular formula and charge.[1] The algorithm uses Fourier transform methods to generate the transformed mass (or mu-domain) representation for the input molecule, which may be used to calculate theoretical isotope distributions. This tool swiftly calculates the distributions in high resolution mode, giving the distribution over all the isotopic peaks of a molecule or fragment at speeds considerably faster than existing algorithms. The speed arises from two factors. The isotope distribution of a compound can be thought of as the convolution of the distributions of all the elements in the compound. Since convolutions done in the mu domain reduce to a multiplication of vectors, it is much quicker to calculate them there. Similarly, for a compound containing n atoms of a given element, the isotope distribution would be an nth order complex convolution, which reduces to computing the nth power of the mu domain spectrum, which, if done in polar coordinates, reduces further to computing a scalar power of the magnitude, and a rotation of the polar angle. Performing these calculations in the mu domain and then transforming to the m/z domain greatly reduces the computational effort required. Ultrahigh resolution (a mass defect spectrum of a single isotopic peak) calculations are also implemented. This calculation requires a further digital filtering step. The program shown incorporates the above methods into an efficient algorithm coded in C. Under the Windows operating system, the code can be used as a dynamic link library and called from other languages. We have developed a graphical front end using Visual Basic that allows manipulation of fragment formula and charge, the line widths, and the choice of gaussian or lorentzian line shapes. The code also allows for specification of the

43rd ASMS Conference on Mass Spectrometry and Allied Topics

center mass and mass range of the calculated spectrum, allowing easy comparison with experimental spectra. The program uses a modifiable database of isotopic abundances, allowing calculation of isotope distributions for labeled compounds.

A prototype tool automatically assigns charge states from isotopically resolved and partially resolved mass features. This tool makes use of wavelet packet transforms to find the characteristic spacing of isotope structure within a peak cluster. Because of the localization of the wavelet basis functions, this method offers advantages over methods that rely on Fourier transforms. We have investigated the use of several wavelet bases, including the Daubechies series, as well as local trigonometric transforms. In both cases, as the spatial resolution of the transform nears the width of isotope distributions in a CAD spectrum, the isotope peak frequency can be discerned. The fundamental frequency is then interpreted as the fragment's charge. Our algorithm uses an initial guess, f, of the fundamental isotope frequency to make initial charge state assignments across the spectrum. Peaks above a threshold (typically 60-80% of the maximum peak) are identified in the frequency spectrum of each spatial bin. Peaks within f/2 of each other are considered to be part of the same band. Once the frequency bands are identified, the centroid of the band is determined. Charge states are defined as the nearest integer to the sum(Cj/j). The initial guess is then refined using the centroids of the fundamentals and overtones and the charge assignments, using f=Sum(WiSum(Cj/Nj)) where f is the new frequency, Wi is the total signal in the ith spatial bin, Cj is the centroid of the jth overtone band, and Nj is the charge assignment*overtone number (fundamental=1, seconds harmonic=2,...). The assignment process is then iterated to improve the assignment. Initial guesses of the single charge isotope frequency within 25% of actual converge well for spectra with S/N >50.

Using the protein sequencing functions, the user may interactively construct amino acid chains and specify cleavage mechanisms. The program then generates theoretical ladder sequences based on a user selected peak., identifies probable matches in the experimental data, and labels the matches graphically. The user specifies the m/z tolerance defining a match and can graphically compare the calculated mass of these fragments to experimental results. The program also has a user modifiable database of fragment masses and identities which can be used by the built in search algorithm to automatically assign ladder sequences of amino acid fragments from a given spectral feature. The current algorithm searches for all matches that could arise from one or two database fragment chains.

Processing MALDI time-of-flight data : A Maximum Entropy Approach.

David J.Reynolds, Elaine Scrivener, Peter J.Derrick and Richard T.Gallagher.
The Institute of Mass Spectrometry, University of Warwick, Coventry, CV4 7AL, UK.

Introduction. Matrix assisted laser desorption ionisation (MALDI) is a powerful technique for the analysis of intact molecular ions of high mass species such as proteins. In this technique a small amount of analyte is mixed with a large molecular excess of matrix compound. A laser pulse is then applied to the sample which causes the desorption of intact analyte-matrix ions (1,2). The pulsed nature of this technique has made it ideal for time-of-flight (TOF) instruments.

The method of maximum entropy (MEM) (3) reduces a raw data set to one which contains the least amount of information consistent with the original, subject to certain constraints. Unlike other techniques, such as Fourier transform, MEM iteratively approaches the solution by predicting the original data on the basis of its solution and subsequently modifying this guess until agreement is reached. The MEM process has been successfully applied to electrospray data and has been shown to provide significant spectral enhancement (4,5). In contrast to electrospray MALDI does not give rise to a series of multiply charged peaks (although some clustering can occur) and therefore does not possess the inherent reproduction of data of the former technique. The method of data collection does, however, contain many independent data sets that are normally summed together to produce an averaged spectrum. These may be used to improve the performance of the *Maximum Entropy Method* (MEM)(1).

Maximum Entropy Method (MEM) The Maximum Entropy Method determines the most likely underlying spectrum by eliminating inconsistent data by an iterative process. The resultant spectrum will have the maximum configurational entropy consistent with the original data set. A Gaussian blurring function was used with the full width at half maximum (FWHM) being approximately determined by the isotopic envelope. As with electrospray data processing, the programme provides routines for the emulation and subsequent elimination of instrumental and isotopic broadening. An example of the iterative process is shown in figure 1.

Experimental. A Kratos Kompact MALDI III time-of-flight mass spectrometer was used in reflectron mode at +20kV accelerating potential to analyse a mixture of Pig Cytochrome C (12231Da) and Chicken Cytochrome C (12238 Da) mixed at a ratio of 1:1. For each sample Bovine Insulin was used as a calibrant and sinapinic acid used as the matrix. Sample conc. was 10^{-5} molar, and the matrix was 0.1 molar. Samples were collected over 100 laser shots.

Results and Discussion. The data obtained from each acquisition was processed using a Maximum Entropy software routine developed in-house and run on a Sun SPARC station IPC computer. The software processes a window of 3000 data points around the selected area of interest. An applications

of this software on the chosen sample mixture is shown in figure 6 and 7 which show the difference between the original data obtained at a resolution of 1500 to the processed data at up to 7000 (FWHM).

Conclusions We can report the development of a MEM programme for the time-of-flight mass spectrometer which utilises the independent data sets and its application to data produced by MALDI-TOF. Significant resolution enhancement has been obtained allowing the deconvolution of a mixture of pig and chicken cytochrome C, which differ by only 7 Daltons, to be fully resolved.

Introduction

Current artificial neural networks do not perform all of the same functions as their biological counterparts. They are, based on similar concepts in the hope that some of the flexibility and power of the human brain would be reproduced. The basic building block of the neural network is the artificial neuron or node. Each neuron performs a summing, thresholding, mapping or nonlinear transformation function on an input data set. Neurons are organized into layers; input, hidden and output, with connections between layers. Each connection has a weighted strength, much like a valve or programmable circuit array that attenuates or magnifies transferred signals. The weights can be changed by a set of learning rules that modifies the weights in response to the input signals and the value supplied by the transfer function. Learning rules allow the neuron's response to change with time, depending upon the nature of the input signals. This is the means by which the network adapts itself to the data and so organizes information within itself. In short, this is the human brain counterpart of learning. The essence of neural networks is to embed learning and processing algorithms into parallel interconnected architectures. As a result, a neural net computations are faster and more robust compared to serial computers. The back-propagation method determines the interconnections between layers in a multilayer neural network where only the input and output neurons and layers are known. This model is applied to determine the interconnections for the hidden layer. The input is propagated through the network and the output is computed. The output is then compared with the known output and an error valued is determined. The error value is then propagated back through the network passing through each layer and appropriate weight changes are made. A multilayer neural network can be trained to perform non-linear transformations which are very difficult to model by conventional algorithms. We can train a neural network to perform these complex operations by presenting input and output pairs. The neural network gradually learns the input/output relationship by converging its internal energy states into a minimum.

Methods

Inoculation and Growth of Mycobacterial Cultures: Mycobacterial was inoculated into 5 mL of BBL 7H9 broth with glycerol. The liquid cultures were allowed to grow for 21 days at 37 C with a 8% carbon dioxide atmosphere. They were then autoclaved at 121 C and 16 psig for 1 hour to kill the mycobacteria.

Cell Separation from Broth: Autoclaved culture tubes were centrifuged at 3000 rpm for 15 min to pellet mycobacteria after which ~90% of the 7H9 broth was aspirated, avoiding aspiration of mycobacteria clumped at the bottom the tube. Four mL of deionized (DI) water was added to the culture tube to "washed" the specimen three more times to eliminate approximately 99% of the broth. With a mix of ~0.5 mL of DI water and cells remaining in the tube, 10 uL of 10 ng/uL octadecanol-d_{37} was added as internal standard.

Extraction of Alcohols from Mycobacteria: The washed mycobacteria were lysed with 2 mL of 5% sodium hydroxide (in DI water/ methanol, 1:1) for 30 minutes at 70 C. The lysate with 3 mL of hexane. The hexane layer was collected and evaporated to dryness under nitrogen.

Derivitization of Alcohols: Anhydrous pyridine (50 uL) and 10% pentaflurobenzoylchloride (PFBO) (50 uL) in acetonitrile were added to each dried tube followed by vortex mixing. The reaction was allowed to proceed at room temperature for 30 minutes after which 1.5 mL of DI water and 1.5 mL of hexane were added to the reaction mixture to separate the fatty alcohols from excess derivatizing reagent. The mixture was vortexed vigorously for 5 minutes and the hexane layer containing the fatty alcohols was collected and evaporated to dryness under nitrogen. The residues were reconstituted with 100 uL of acetonitrile.

GC/MS Conditions: Data was collected on a Finnigan 4500 GC/MS (Finnigan MAT, San Jose, CA) equipped with negative ion detection capabilities.The GC column was a 15 m x 0.32 mm i.d. crosslinked dimethylpolysiloxane with a 0.25 µm film thickness. The mass spectrometer was operated in the negative chemical ionization mode with methane (Matheson 99.99%) as the reagent gas at an ionizer pressure of 0.95 torr which corresponded to an analyzer pressure of 1.1×10^{-5} torr. Prior to analysis each mycobacteria is studied to determine what fatty alcohols are characteristic of the species. Using the Selected Ion Monitoring mode, 15 different preselected m/z outputs are obtained from the GC-MS analytical run. Prior to the hybrid neural net analysis no software signal processing was done on the mass spectral data.

Neural Network Data Acquisition: The study was run on a PC 486 computer (50 MHZ clock speed). The detected spectral signals were digitized and sent to a personal computer for training or analysis. A customized neural network software package (Physical Optical Corporation, Torrance, CA) was used to recognized the GC/MS spectra. The neural network first preprocesses the input spectrum, performs a nonlinear transformation to extract the chromatographic features and then classifies the results. The neural network software was written in C language and occupies less than 100 kbytes of memory. A backpropagation model is used to train the neural net for recognition of the species of mycobacteria tested. The training time is less than 15 minutes. The fast convergence of the training is mainly due to the optimum preprocessing algorithm and the proper selection of the hidden layer neurons in the hybrid neural network. After training the hybrid neural net is ready for operation. Seven output neurons represent the seven different species of mycobacteria evaluated. Each output neuron gives an output value normalized between 0 to 100 that indicates the confidence of the classification result. (See Table). By testing the neural net with a set of known data, proper calibration and threshold values can be set. The neural net can then be challenged with blinded specimens.

Results: The hybrid neural net was trained and applied to 11 unknown test data. Challenge test results are shown in the Table. The results demonstrate that using the hybrid neural network for data processing results in the correct assignment of all 11 specimens. Assignments are made in less than a second.

Conclusion: We utilized a hybrid neural network for detecting and species identification of mycobacteria by gas chromatography-mass spectrometry. This optimized hybrid neural network consists of a windowed cross-correlation algorithm that extracts the signal peaks in the chromatogram and a multi-layer feedforward neural net for feature recognition. We trained and tested the hybrid neural net for classifying mycobacteria into 7 species. The results demonstrate that the hybrid neural net, by careful design of both preprocessing algorithm and the neural network architecture, is capable of correctly identifying the specimen.

Evaluating EI Mass Spectral Library Search Results

O. David Sparkman
O. David Sparkman & Associates, 4045 Eagle Ridge Drive, Antioch CA 94509

As the size of various collections of electron ionization mass spectra increases, there is a continuing and increasing propensity to rely on the results of computerized library searches. The results of these computerized searches do not necessarily account for a spectrum that is the result of two or more different compounds. Examination of the Reconstructed Chromatographic Peak will not always be an indicator that more than one compound is present. The reliability of the numerical confidence factors placed on the search results by the computer, no matter how high, should be questioned with respect to an actual visual evaluation of the mass spectrum.

A good example of how a "good search result" can lead to an incorrect conclusion is shown in the following example of the analysis of a mixture of volatile organic compounds by GC/MS. While the library search results were well within the positive match criteria set by the description of the program, the identification was incorrect.

A GC/MS analysis was performed on a mixture of volatile organic compounds using the purge and trap method described in US EPA Method 524.2 for the analysis of drinking water. Figure 1 shows a portion of the Reconstructed Total Ion Current Chromatogram (RTICC) indicating the presence of at least eight different compounds. It is clear from an examination of the shape of Peak 1 that it represents at least two different compounds There is nothing about the shape of any of the other remaining six peaks that indicates the presence of more than one compound. An identification was attempted of the spectrum that represented the apex of Peak 3 in the RTICC (Figure 2). This spectrum was a good candidate for analysis by library search because of the apparent lack of a molecular ion peak.

The spectrum was compared against the NIST/EPA/NIH Mass Spectral Library. This library is composed of 74,827 spectra of 62,235 compounds All are 70 eV spectra collected on a variety of different types of mass spectrometers.

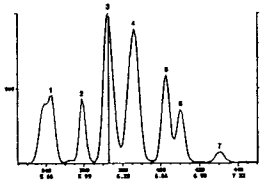

Figure 1

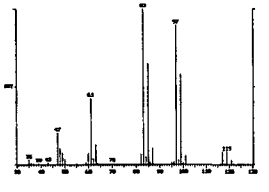

Figure 2

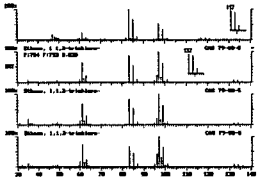

Figure 3

Figure 3 shows the unknown spectrum at the top and the spectra of the first three matches. The first three matches from a comparison with 74,827 spectra are all of the same compound as indicated by the Chemical Abstracts Service (CAS) Registry Number in the upper right corner of each spectrum.

The confidence levels for these particular library search results are very high. The manual accompanying the software states that values of 800 to 900 for all three indicators give a high probability that the spectrum of the unknown and the library spectrum are the same compound. The three values in the upper left of the best match, along with the first three matches all being

the same compound, indicate a high probability that the unknown spectrum is that of 1,1,2-trichloroethane.

However, a closer examination of the unknown spectrum and the best match indicated something much different. Besides differences in the intensity of major peak clusters, the unknown spectrum has a cluster of peaks with a nominal m/z value of 117. This cluster does not appear in any of the spectra of the first three matches. The appearance of this cluster indicates that it represents an ion that contains three atoms of chlorine. All of the spectra of the first three best matches have a cluster of peaks with an identical pattern and intensity to that of the unknown's cluster at m/z 117 with a nominal m/z value of 132 (the molecular weight of 1,1,2-trichloroethane). It is obvious that the three best matches are of the same compound; but, it is not so obvious that the unknown spectrum is of that same compound.

The RTICC Peak was re-examined. This time, a scan near the base on each side of the peak was examined. As seen in Fig. 4, Peak 3 appears to consist of at least two different compounds

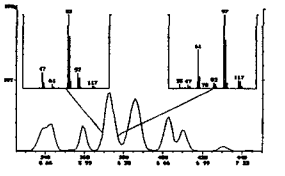

Figure 4

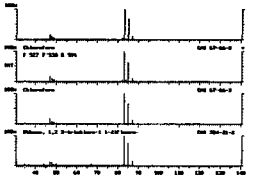

Figure 5

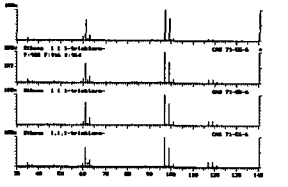

Figure 6

Figures 5 and 6 show the result of selective background subtraction followed by library searching. Both the examination of the unknown spectrum as compared to the library search spectra and the numeric confidence levels provide the closest to an unambiguous identification of the two compounds in this mixture without doing a direct comparison of the two unknown spectra with spectra obtained on putative samples of the identified compounds.

Similarly, you can have a low set of numeric indicators as to the correctness of the search; and, the result is an identification of your unknown

A computerized library search will generally yield an answer. Do not be too quick to accept the answer as an unambiguous identification of the analyte or reject it as not being possible due to low numeric indicators of correctness.

The quality of the results from a computerized library search is dependent on:

* the quality of the spectra in the library;
* whether the spectra in the library are searched as complete or condensed spectra;
* the search algorithms; and
* the quality of the submitted spectrum.

Weakness in any of these areas must be compensated for by careful examination of both the submitted and library spectra. Additional information about the sample's origin and characteristics of the identified compound can be used to increase the confidence of, or even confirm, any identification based on mass spectral data alone.

Substructure Identification by Library Searching

Stephen E. Stein, Dmitrii V. Tchekhovskoi
NIST Mass Spectrometry Data Center, Gaithersburg, MD 20899.

A new computer method for identifying structural features of a compound from its electron-ionization mass spectrum has been developed. Like other "nearest neighbor" (KNN) [1] methods, it extracts structural information from compounds in a reference library whose spectra are most similar to a submitted spectrum It uses algorithms similar to those used for compound identification [2] and is therefore relatively easy to implement and relies on match factors already familiar to many users It generates readily understood substructure present and absent probabilities for a wide range of structural features.

Some significant differences between the present system and two well-developed interpretive search systems, SISCOM [3] and STIRS [4], are:

1) Match Factor Computation: A single match factor measures the similarity of the unknown and a library spectrum: $MF = 1000\left(\sum A_U^{1/2} A_L^{1/2}\right)^2 \Big/ \left(\sum A_U \sum A_L\right)$ (sums are over all peaks, A_U and A_L are abundances for unknown spectra and library spectra, respectively).

2) Match Factor Weighting. Contributions of retrievals are weighted by their relative 'distance' from the submitted spectrum [5]. The weight of the retrieval of rank **r** (**r**-th member of a hit list) is $w_r = 2^{\frac{MF(r)-MF(1)}{75}} \Big/ N$; normalization factor N is such that $\sum w_r = 1$. (75 is empirical constant to optimize the substructure identification). The overall weight W_S of substructure S is the sum of weights of retrievals that contain the substructure.

3) Absolute Probabilies. These were derived using a large test set comprised of one spectrum of each of the 7891 compounds in the NIST Selected Replicates Library. Probabilities of the substructure occurrence were derived from W_S values derived from searches of the 1992 version of the NIST/EPA/NIH reference library (61,500 compounds).

4) Screening: An efficient means of rapidly locating similar spectra reduced search times to levels comparable to those typical of traditional library-search identification methods.

5) Substructure Absent Probability: These are determined in the same manner as substructure-present probabilities.

If the molecular weight of the unknown compound is supplied, identification of certain substructures can be improved by including 'neutral loss' peaks. Slight modifications of the present method permits the identification of chemical formula, molecular weight and number of rings + double bonds.

Two sets of substructures were used for testing. One contained the most common structural groups employed in earlier studies. Results of test studies are discussed below. A second group of substructures was comprised of most common sets of up to 10 connected atoms found in NIST/EPA/NIH library. This allows the extraction of a large fraction of all structural information contained in hit lists.

Comparisons of the present method with earlier STIRS and KNN results [1] are shown in the Table. Separate studies [5b] show that that a principal reason for the superior performance of the present system is simply due to the use of a larger library. For **KNN** about half of the improvement is due to the use of optimized algorithms.

Table

Sharing Corporate Mass Spectral Data Bases

J. L. Little, W. M. McSpadden,
Eastman Chemical Company
Kingsport, TN, 37662-5150
Tel. No. 615-229-8685

Goal/Current Status. Our corporate mass spectral database is composed of 29,500 spectra and 15,500 structures. Our goal is to share this database between all of our mass spectrometers (35 instruments, 60 users) within Eastman Chemical Company. Our corporate and various commercial databases are used extensively in our research, development, industrial hygiene, and environmental work. The instruments, located in Tennessee, Texas, and Arkansas, are connected by an ethernet network. Our instruments employ data systems from a variety of manufacturers including Finnigan (PDP-11, UNIX), Hewlett Packard (DOS, UNIX), and VG (VAX workstations).

We have two approaches for reaching our goal. One involves the transfer of data to a host computer for processing and the other employs local processing of the data.

Approach #1: Processing Data on Host Computer. Data files are transferred to a host computer in Tennessee for processing and the results are displayed on the user's local computer (see References 1-3). The VG OPUS software is employed for data processing and a "user-friendly" VAX DCL interface is employed for file transfer/conversion. This is the preferred approach and is employed by users whose primary responsibility is mass spectrometry. This approach allows searching of databases by substructure, advanced data processing capabilities, and the automatic addition of user spectra to the corporate database

There are several disadvantages to this approach. The user must have a network connection and must learn an additional software package. Also, the files must be transferred/converted which requires 1-30 minutes depending on file format and file length.

Approach #2: Processing Data Locally. The second approach (see References 4) is to process the data locally on a PC (DOS/Windows) employing standard software from Hewlett Packard (HP). Our corporate database and structures were transferred to the HP format. This approach only displays structures with library results and does not allow searches of the databases by structure. The advantages of this approach are that most of the targeted users already employ the HP data system for their mass spectrometry analyses and no file transfer/conversion is required.

There are several disadvantages to this approach. The HP software will search multiple libraries, but only the results from one library at a time are displayed. The PBM search algorithm is used for the searches and gives poor results in many cases for the electron impact spectra of "low-level" ("noisy") components. The structures displayed do not show hydrogens attached to nitrogen, oxygen, sulfur, etc. This is a limitation of the HP software and not the MOL files created by the Exographic's software from the SMILES files.

Creation of HP Electron Impact Mass Spectral Data Base for DOS and UNIX computers. Our corporate library is maintained on our VAX mainframe in the VG OPUS format. Entries added to individual's OPUS libraries are automatically added to the corporate library daily. This process is described in Reference 4.

A variety of programs were used to transfer our VG OPUS corporate library to the HP UNIX and DOS formats. The programs include the VG OPUS Specbase utility, VAX DCL macros, user-written C programs, Palisade MASSTransit, and HP Windows utilities. The process employed is described in Reference 2.

The data base files are identical for the HP UNIX and DOS computers. The HP binary data base was created on the UNIX computer because the conversion time was significantly smaller. The HP UNIX software required approximately 33 hours to convert 29,500 entries and could create the data base in two steps. The total process was estimated to take 30 to 60 days of computer time on the HP DOS/Windows computer and 30 step! Our corporate data base can be searched on the HP UNIX computer system. However, no attempt was made to create a UNIX structural data base.

Creation of HP Structural Data Base for DOS and UNIX computers. Structures are added to all our VG OPUS corporate data base entries when the electron impact mass spectrum is entered (see References 1-3) The structures are drawn with a drawing package that is part of the VG OPUS software. The structures are saved in SMILES format.

The HP software requires structures be in a MOL format. A variety of programs were used to transfer structures in SMILES format in our corporate library to the MOL format. The process for this conversion is detailed in Reference 4 The programs include the VG OPUS Specbase utility, VAX DCL macros, user-written C programs, Palisade MASSTransit, MDL ISIS Draw, Exographic's Consystant, HP Windows utilities, and a user-written HP macro.

The HP DOS/Windows software uses the CAS number in the electron impact data base to cross-reference to the CAS number and structure in the structural data base. If the CAS number of the library result is found in the structural data base, the library entry is displayed with structure. None of our entries are assigned CAS numbers. Our entries were assigned "pseudo-CAS" numbers of between 1 and 49-99-9. The first real CAS number is 50-00-0 for formaldehyde. The last digit in the CAS number is a "parity" check, but we do not employ a parity check in our numbering system which gives us a factor of 10 more "pseudo-CAS" numbers.

ARTIFICIAL NEURAL NETWORKS FOR IDENTIFYING COMPONENTS IN MIXTURES BY MASS SPECTROMETRY

Jackson O. Lay, Jr. and Jerry A. Darsey
FDA, NCTR, Jefferson, AR; University of Arkansas at Little Rock, Little Rock, AR

INTRODUCTION

Spectral libraries are used as a rapid means of identifying unknowns (1). Identification is based on a comparison between the unknown spectrum and spectra in the library. Algorithms used range from simple geometric techniques to probability-based matching methods that incorporate known relationships (2,3). Strategies that rely on comparisons between unknown and reference spectra are based on the assumption that the unknown spectrum represents a single component. Because a skilled interpreter may recognize components in a mixture-spectrum by inspection, a computational system designed to mimic human thought might have distinct advantages, especially if it was "self-training". An artificial neural network (ANN) is such a computational system. It has been defined as "a computing system made up of a number of simple, highly interconnected processing elements, which process information by its dynamic state response to inputs" (4). ANNs do not store information in separate memory arrays; rather they "learn" by taking weighted sums of inputs and comparing their results to known outputs after application of an appropriate transfer function. The result of this process is that information is stored in a weighed distribution of connections between the same set of inputs and outputs (4-6). Although "self-training" requires minimal intervention or knowledge of computational methods, this initial step involves many calculations. The weighted distribution of connections generated in the training, however, can be transported between computers and used to identify inputs (e.g. unknown mass spectra in this instance) in a few seconds. In a related study, an ANN was used for the interpretation of infrared spectra (7). In that study the emphasis was on the identification of functional groups. We report the use of ANNs to identify individual mass spectra from mixtures after training the ANN using spectra from pure compounds. The ANN output values were compared to Similarity Index values.

EXPERIMENTAL METHODS

Spectra of 6 compounds were obtained from the PC version (4.0) of the NIST/EPA/NIH MS data base. The ANN was trained using metolachlor (I), metribuzin (II), methyl parathion (III), alachlor (IV), and 2,6-dichloro-N,N-dimethyl-benzamide (V). Di(2-ethylhexyl)-phthalate (VI), was included in some mixture-spectra but was not used to train the ANN. Mixture-spectra were obtained by summing the intensity values at each mass from each component. The mixtures included two binary mixture-spectra for compounds I+II, and III+IV, and two ternary mixtures, I+II+III, and I+II+VI. The spectra of selected components were multiplied by weighing factors to produce unequal mixtures. These mixtures included spectra corresponding to the following compositions: III(60%)+IV(40%), I(90%)+II(10%), and III(90%)+IV(10%).

The ANN software was NNETS (VAX version) written at NASA. The architecture was as follows: (1) Input: 300 nodes (m/z 1 to m/z 300); (2) Output: 5 nodes for compounds I-V; and (3) One hidden layer with 15 nodes that connect all input and output nodes and "learns" the values needed to identify I-V. The ANN was programmed by entering the intensity of each mass, from 1 to 300 daltons, in the corresponding numbered node. For training, output nodes were assigned a magnitude of 0.9 (compound present) to the output mode corresponding to the correct compound and 0.1 (compound absent) to the remaining nodes. The mixture-spectra were evaluated using the ANN and the Extensive Search algorithm from the NIST/EPA/NIH MS database.

RESULTS AND DISCUSSION

For spectra corresponding to similar contributions from each component, both the ANN and the NIST/EPA/NIH "Extensive Search" method provided evidence regarding the presence of individual compounds in the mixtures. The finding of a high Similarity Index value by the NIST/EPA/NIH search program, but no positive response by the ANN for one of the training compounds not present in a test mixture-spectrum, suggests that the ANN has a different and complementary selectivity for discriminating against false positive responses. Both the difference in selectivity and the near instantaneous response to input (spectra) after training suggest that neural network computing may be a useful complement to existing methods for the interpretation of spectra from mixtures.

DESIGN OF A COMPUTER-CONTROLLED MAGNETIC SECTOR MASS SPECTROMETER

[1]Robert B. Cody, [2]S. Makino, [2]T. Asada, [2]K. Yoshidome
[1]JEOL USA, Inc., 11 Dearborn Rd., Peabody, MA 01960
[2]JEOL Ltd., Musashino 3-1-2, Akishima, Tokyo, Japan

Introduction. Effective computer control of a high resolution mass spectrometer can be complex. Support of both research and routine analysis requires both interactive and automated tuning and data acquisition. The computer must control the ion source, the magnetic and electric sectors, focusing lenses, slits, gas supplies, probe, inlet and detector conditions.

We have developed a fully automated mass spectrometer with a user interface that makes extensive use of graphical instrument diagrams. Tuning is facilitated by ion optics which use quadrupole lenses to maximize ion transmission and minimize the number of control parameters. A deterministic approach to auto-tuning mirrors the procedure followed by a human operator.

Methods. The mass spectrometer ion optics are based upon a QQBQE design that makes use of DC-quadrupole lenses to control beam shape and maximize ion transmission. This design minimizes the number of elements that need to be controlled to achieve high-resolution mass spectra. The procedure for tuning the mass spectrometer is very systematic and reproducible and therefore easy to program.

The auto-tuning times were determined for standard reference compounds for several ionization modes at both low and high resolution conditions (resolution = 1000 and resolution = 10,000, respectively). The reported times correspond to full tune-up from a completely untuned starting condition ("full tuning") and partial tune-up starting from a previously stored parameter set ("quick tuning").

User Interface For Instrument Control. The user interface is mouse- and window-driven and based upon extensive graphical instrument diagrams. Parameters are grouped according to functionality. Parameter groups are reached through a central window (called the "Mode Controller") that represents the overall instrument configuration and status. Windows that control parameter groups can be accessed through any of three redundant means. These consist of (1) menu choices, (2) icons and (3) pushbuttons next to a symbolic representation on the "Mode Controller". This redundancy avoids the common problem of having only one way to get to a particular display. The user interface operates as a X-Windows / Motif application to permit operation of the mass spectrometer over a network.

Auto-Tuning Scripts. Auto-tuning is based upon a grid-search procedure defined by the operator in a script file. The script defines (1) which parameters are tuned, (2) the order in which the parameters are tuned, (3) the range over which a parameter is swept, and (4) whether or not pairs of parameters are to be optimized simultaneously. This "simultaneous"

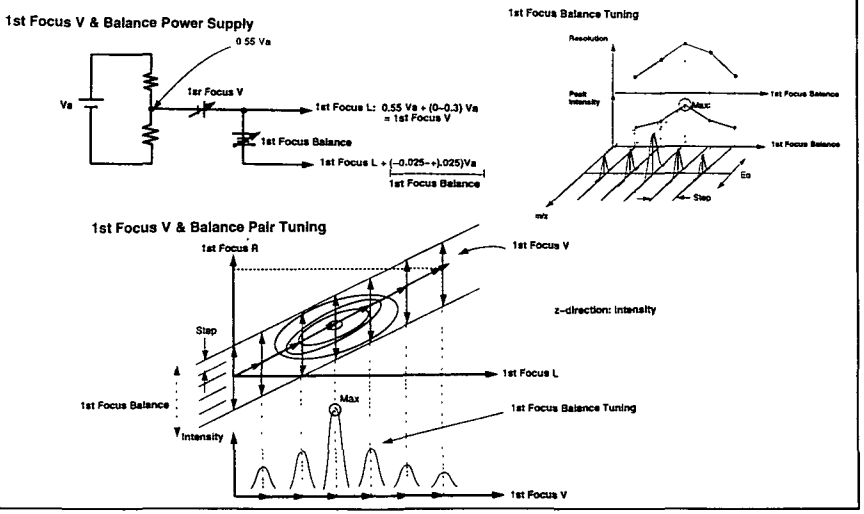
tuning is useful for optimizing the three ion source lens pairs: left and right focus 1, left and right focus 2, and upper and lower deflector.

Once a valid set of instrument parameters has been determined, these parameters can be loaded and used as a starting point for "quick tuning" a few selected parameters. The remaining parameters are stable over long periods of time and do not need frequent re-adjustment.

AUTO-TUNING TIMES

Ionization Mode	Full Tuning	Low Resolution Quick Tuning
EI	1 min. 5 s.	14 s.
CI	1 min.	15 s.
FAB	1 min. 27 s.	23 s.
FAB (FD source)	1 min. 41 s.	22 s.
FD	50 s.	15 s.

Ionization Mode	Full Tuning	High Resolution Quick Tuning
EI	2 min. 26 s.	17 s.
CI	2 min. 27 s.	17 s.
FAB	3 min. 14 s.	22 s.
FAB (FD source)	2 min. 50 s.	27 s.



A High-Performance FT-ICR Mass Spectrometer Data System

Michael W. Senko, Jesse D. Canterbury, Shengheng Guan,* and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State U., 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

* Department of Chemistry, Florida State University

A flexible high-performance FT-ICR data system (**M**agnet laboratory **I**on cyclotron resonance **D**ata **A**cquisition and analysis **S**ystem, **MIDAS**) has been designed and constructed with VXI architecture and a personal computer running Microsoft Windows. Emphasis is on flexible hardware and software for generating complex event sequences while maintaining ease of use.

Timing is controlled by an Interface Technologies 96-channel digital pattern generator with 40 ns time resolution and 8,192 distinct events. Events are linked in tables which may be looped and nested to produce sophisticated experimental sequences. An in-house instrument controller converts the digital output of the pattern generator into four 12-bit voltages, four 8-bit voltages, eight TTL triggers, and eight pulsed-valve current sources. Frequency-sweep ("chirp") and SWIFT ion excitation waveforms are created by a Hewlett-Packard arbitrary waveform generator with 256K 13-bit words. The time-domain signal is acquired with a Hewlett-Packard 10 megasample/second digitizer with 4M 16-bit words, and on-board digital heterodyning capability. All processing is performed on the host computer (90 MHz Pentium®), which executes a fast Fourier transform in less than 5 seconds for 256K data .

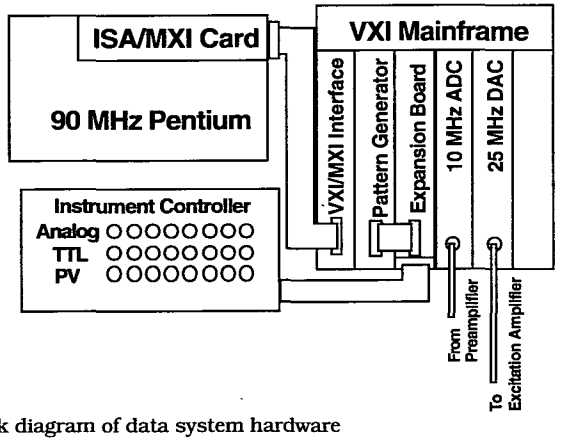


Figure 1. Block diagram of data system hardware

Individual programs for acquisition, analysis and wave form generation have been created by use of National Instruments Lab Windows/CVI, which produces stand-alone Windows executables. The acquisition program allows for simple creation and editing of experimental sequences by use of an intuitive graphical interface designed to minimize user input. Data files are stored in a custom format that uses ASCII text for all experimental parameters to simplify data access, and standard binary format for data to minimize storage requirements.

The analysis program allows for simultaneous viewing of multiple data files in resizable windows. Standard Windows drawing programs may be used for publication quality output: spectra are copied to the clipboard in vector format by use of an external module created with Borland Delphi and Pinnacle Publishing Graphic Server SDK. Customized analysis routines can be written in any language that supports dynamic data exchange (DDE) for communication with the DDE server in the analysis program.

Future work will focus on improvements to the acquisition module for the support of more complex experimental sequences, optimization of the analysis program to reduce memory requirements and expanding the functionality of the DDE server. This work was supported by the National Science Foundation (CHE-94-13008), NIH (GM-31683), and the National High Magnetic Field Laboratory at Florida State University.

High Performance Data System for Ion Trap Mass Spectrometry

Gregor Overney and Christie G. Enke
Department of Chemistry, University of New Mexico, Albuquerque, New Mexico 87131-1096

Kevin Hart and Marc B. Wise
Organic Chemistry Section, Chemical & Analytical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37831

We have developed a universal, high performance data system for an ion trap mass spectrometer to support advanced ion trap experiments such as fast scan rates (> typical 5000 *u/s*), large mass ranges (> typical 650 *u*), high mass resolution (> typical 1 *u* resolution), custom waveform applications, coordination with direct sampling interfaces, and exploration of new scan modes in a customizable software and hardware environment.

All software components of the data system are programmed using LabVIEW® version 3 [2] extended by modules written in WATCOM's 32 bit C compiler version 10 to increase performance. LabVIEW was selected because it is an icon based programming environment with a wide range of pre-programmed data acquisition drivers. The main menu structure consists of five points: calibration of system, definition of experiment, running of experiment, data displaying and analysis, and utilities During the definition of the experiment, a scan function editor (SFE) is used to multiplex several experiments (e.g., alternating EI/CI scans). The SFE is programmed with LabVIEW® using an array with dynamic memory allocation to store a large number of single scan tables. An important feature during the running of the experiment is the fast mass peak finder (MPF) program. The MPF is entirely written in ANSI C and appended to the LabVIEW main program using the concept of code interface nodes (CINs). CIN modules allow fast program execution of time critical jobs such as mass peak finding. In addition, an optional Savitzky-Golay (S-G) smoothing [3] can be used to improve the reliability of the MPF. Especially very small peaks, hardly distinguishable from the back ground noise, can easily be made accessible to MPF after S-G smoothing.

The dynamic experimental control has been possible through a real time buffer access. Each of the VXI [1] hardware components for data acquisition has its own high speed memory buffer. The hardware modules are interconnected via the VXI bus and are the C-size format. The VXI bus is often encountered in industrial measurement and test applications such as auto emissions monitoring and chemical process control. We are using an embedded 486 VXI host controller from National Instruments, a 16 bit, 500 kSamples/sec ADC/DAC from Kinetic Systems (two

boards), a Tektronix 25 MSamples/sec Arbitrary Waveform Generator (AWG), and a 48 channel Digital I/O module from Tektronix. The ADC board V207 from Kinetic Systems is used for synchronized data acquisition of microscans using internal VXI TTL trigger lines. Three additional channels of the V207 board are available for digitizing other experimental parameters. The DAC board V285 from Kinetic Systems is generating the signals for the primary RF generator (mass selection). Filament gating (monitored by internal VXI TTL trigger lines), multiplier on/off, calibration gas on/off, filament on/off, and valve control of CI-gas are controlled by the Digital I/O board VX4801 from Tektronix. The AWG board VX4790A from Tektronix generates signals for the end-cap waveform amplifier responsible for MS/MS features.

This data system also integrates the direct sampling interfaces developed at ORNL for environmental monitoring of volatile organic contamination of air, water and soil. It can also be extended for acquisition of MS/MS and MS^n spectra. An option for remote control of the instrument using TCP/IP will be implemented using LabVIEW's network protocol library.

We thank all members of the research group of Prof. Enke for their suggestions and interest in this project. This project is part of a subcontract between The University of New Mexico and Martin Marietta Energy Systems, Inc. as specified in proposal SS259. This work was supported by the Offices of Technology Development and Arms Control, U.S Department of Energy, under contract DE-AC05-85OR21400 with Martin Marietta Energy Systems.

Programming the Teledyne Filtered Noise Field System

N.J. Clarke, D. Hoekman* and J.F.J. Todd
The Chemical Laboratory, University of Kent, Canterbury, Kent, CT2 7NH, Uk
**Teledyne ET, 274 Terra Bella Ave, Mountain View, CA 94043, USA*

I. Introduction

The Teledyne Filtered Noise Field(FNF) unit allows a supplementary AC field to be applied to the end caps of a quadrupole ion trap mass spectrometer. This field can be customised by the operator and allows the user to retain specific ions of interest whilst ejecting all other ions from the trap simultaneously. This is achieved by applying a broad range of radio frequencies in a single waveform. These frequencies come into resonance with the secular frequencies of the trapped ions and cause their trajectories to become unstable by imparting energy. The ions are then lost either through holes in the end cap electrodes of the ion trap or by colliding with the trap walls. The waveform can be customised so that "notches" or areas of zero amplitude can be created within the waveform. These notches correspond to mass/charge values for the ions of interest, and when the waveform is applied it ejects all ions which come into resonance but leaves any others untouched.

The controlling software for the Teledyne is written in FORTH and a program has been developed allowing the user to automate the use of the system as well as control parameters which are normally fixed.

II. Experimental

II.1 General Information

The software was written using the version of FORTH supplied by Laboratory Microsystems Incorporated (LMI). The original code for the Teledyne control software written by Teledyne ET and permission to use or alter it was obtained.

The aim of the project was to reduce the amount of user input required to set up the system and to automate the calibration and recording of the data. Further it was hoped to develop a program which would be able to intelligently produce a customised waveform from a series of *m/z* values provided by the user. This would lead to the possibility of automated tandem MS using the Teledyne unit to isolate and dissociate the ions of choice. The *m/z* values are passed to the computer via a text file set up by the operator beforehand.

II.2 Description of Program

The system starts by loading in the *default* waveform for the program. This waveform has a known number of *components*, all of which are set to a standard amplitude of 100 percent. The overall gain of the system is set to a predetermined value, normally 2000, and the system then automatically calibrates the waveform. This calibration uses two frequency and mass values to carry out a standard calibration of the waveform, determining a *m/z* value equivalent to each frequency present.

Once this is complete the system opens the file containing the *m/z* data. The filename is provided by the user, either directly within the program code, or interactively on running the

program. If this file does not exist the program displays an error and terminates. Once the file is open the first data item is read onto the stack. The format of this file is specific; the first entry within the file is the number of masses that are to be isolated: on each succeeding line the *m/z* value to be isolated is placed by itself and the line delimited by a carriage return.

For each *m/z* value read in turn the following procedure is applied: the system calculates the mass for each subsequent frequency within the waveform and compares this to the *m/z* value read from the file under examination. The program then scans the *m/z* value list which has been set up during calibration and checks for the closest match. This is classed as the centrum of the window and set to zero amplitude. The frequencies above and below are then converted to *m/z* values and if they lie within a user defined range surrounding the centrum they are also set to zero. The way the calibration is carried out means that at the high mass end of the scale the mass gap between frequencies components is quite large, often over 20 mass units. At the lower end of the range however each *m/z* value will be represented by several frequency components as the resolution of the system increases. This weighting of the frequencies means that the *window* notched into the waveform at the lower end of the mass range will cover more components of the waveform but actually covers a smaller mass range than the same sized window at a higher mass range. The program realises this and uses a weighting principle to reduce the size of the frequency window applied at the higher end of the mass range. Once the window of frequencies has been notched out of the waveform the program repeats the entire procedure for the next *m/z* value in the file. As the end-of-file marker is read the waveform is updated and ready to be applied to the system. The usual triggering system of two pulses supplied from the ion trap is used to implement the waveform.

III. Results

The system has been tested and encouraging results have been obtained. The program produces identical results to those obtained by human operators in most cases. Further work is underway to couple the ITMS system directly with the Teledyne to allow a feedback loop to be exploited. This would enable the Teledyne to "fine tune" the waveform for optimum isolation and peak intensity.

A High Speed Data Acquisition System for Fast GC-MS

A Gilbert[1], P Atherton[1], S Hanson[1], L Lu[1], S Smith[1], A Preston[2]
[1]Fisons Instruments V.G.Organic, Manchester, U.K.
[2]University of Manchester, Manchester, U.K.

Fast Gas Chromatography can produce peak widths of substantially less than one second for individual components. The use of a scanning mass spectrometer as a detector in these circumstances requires that the spectrometer and its associated data acquisition system be sufficiently fast to faithfully capture the peak profile, and avoid distortion of the spectra when the intensity is changing rapidly. 10 spectra per peak is generally considered sufficient.

Time of Flight (TOF) mass spectrometry has the ability to produce thousands of spectra per second, and has been available for many years, however its use as a chromatographic detector has been limited, until recently, by the availability of electronics systems able to digitise TOF data, and the prohibitive size and cost of computers with sufficient power to process the data in real time. Relatively few references to fast GC-MS can be found in literature

A system (fig 1) has been constructed capable of acquiring, processing, and storing up to 100 scans per second. These data can then be manipulated using a standard MS data system (V.G. MassLynx).

Data are digitised using a 200 MHz 8 bit analog to digital converter. Successive flights are averaged to provide the required number of spectra per second. A DEC Alpha processor detects and assigns masses to peaks, which are stored to a local disc controlled by a transputer subsystem.

The system is housed in an industry standard P.C. which provides networked access for users. This effectively decouples the acquisition data storage from any user activity.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Results show GC-MS of a solvent mixture with all components eluting in under 1 minute with specta acquired at 35 per second.

Display and Manipulation of Three-Dimensional Plots of Ion Trap Data

Li, Rebecca; Hoekman, Don; Wilson, Ray; McHugh, Sean; Karr, Dane
Teledyne Electronic Technologies, Scientific Instruments, Mt. View, CA 94043

The development of graphics-oriented data systems and high resolution video displays and printers allows mass spectrometry data to be displayed in a variety of new and interesting formats. By combining these features with a research-grade ion trap data system, capable of acquiring and storing full-scan profile data, we may display true three-dimensional plots representing both ion trap peak intensity and peak shape.

In addition to conventional plots representing mass, intensity, and time, ion trap experiments may generate three-dimensional data plots representing peak shape, intensity, and virtually any ion trap parameter, adding an extra dimension of information to the displayed data plots.

Data may be displayed using the following rendering methods, in order of complexity:

Wireframe
- Simple and fast - no hidden surface removal or shading.

Painted
- Fast - flat shading and depth sorted.

Partial Hidden Surfaces
- Fast - wireframe rendering with primitive hidden surface removal.

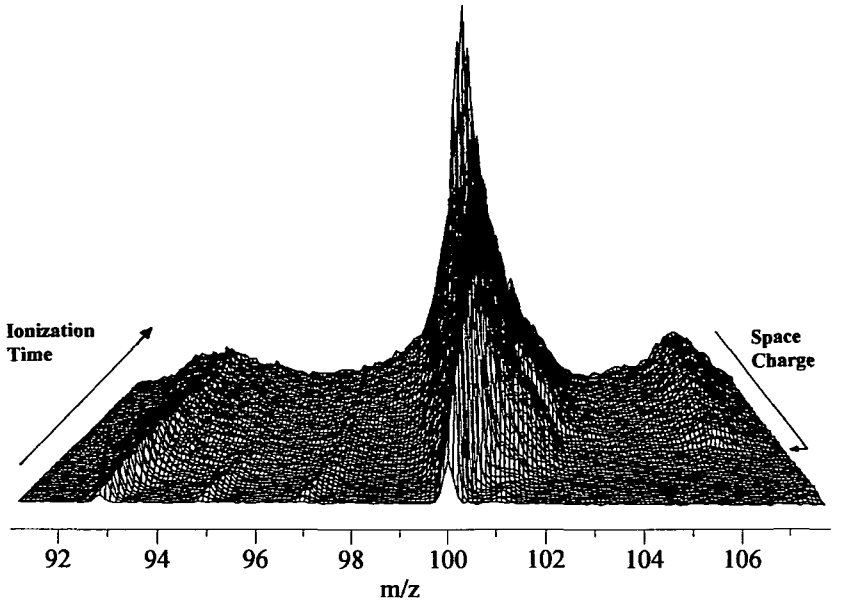
Flat Z Buffer
- Fast - flat shading with more accurate hidden surface removal.

Full Z Buffer
- Slow - phong shading algorithm with accurate hidden surface removal.

The display of true three-dimensional plots, representing raw mass spectrometry data, allows us to peer one level deeper into the nature of the ion trap.

Just as a finished quantitation report, containing compound names and amounts is derived from a series of individual mass chromatograms, the mass chromatogram is derived from a series of spectra, the spectrum is derived from a series of mass peaks, and each mass peak is derived from a collection of individual ions. It is at this most fundamental level that we have explored, where characteristics of the ion trap mass spectrometer may be displayed in a manner both educational and entertaining.

43rd ASMS Conference on Mass Spectrometry and Allied Topics



Three Dimensional Plot of Profile Data of m/z 91 to 108 as a Function of Ionization Time

Notice the intense broadening of the m/z 100 peak, and its shift to the higher mass range of the plot, as it passes into the space charge region. Also note the disappearance of the smaller peaks upon passing the space charge threshold, and the appearance of peak data at the m/z 106 position that only emerges upon passing the space charge threshold.

Interactive Setup and Control of Ion Trap Mass Spectrometry Experiments

Wilson, Ray; Hoekman, Don; McHugh, Sean; Li, Rebecca
Teledyne Electronic Technologies, Scientific Instruments, Mt. View, CA 94043

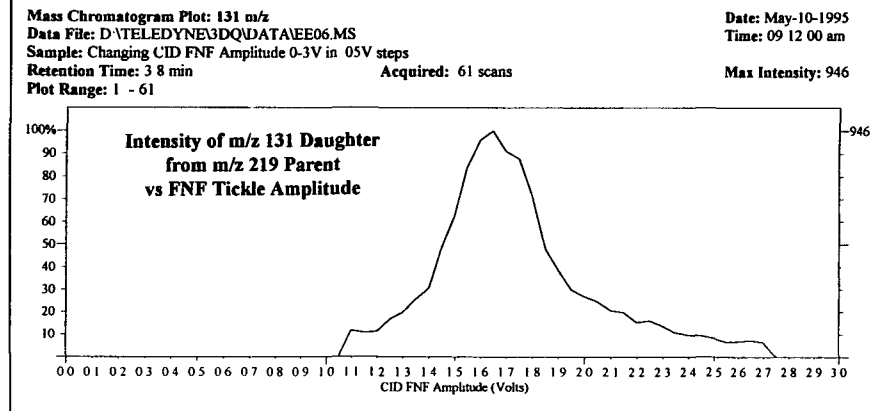
Experiments with research-grade ion trap mass spectrometers have typically involved the manual adjustment of one or more parameters in an ion trap scanning function, followed by the manual interpretation and display of the results.

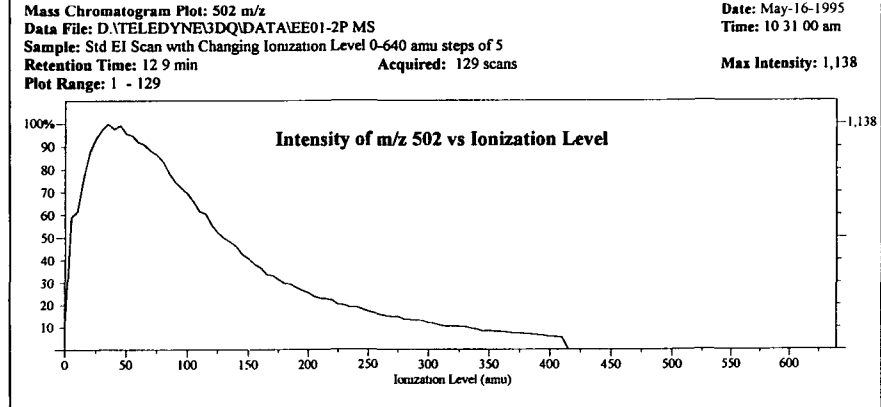
We have developed a graphics-oriented experiment program designed to simplify the construction, execution, and data reporting operations involved in typical ion trap mass spectrometry experiments, providing a simple method to investigate and plot various functions of an ion trap. The experiments may vary from such things as a plot of multiplier linearity, to the conversion efficiency of an MS/MS/MS experiment as a function of CID tickle time.

To use the experiment editor from the 3DQ *Discovery* software, the operator first selects the parameter to be investigated, followed by its initial, final, and incremental value. The experimental parameter may either be pre-defined, or selected from any table in any scan function. Therefore, any of the following parameters may serve as the basis for an automated ion trap experiment:

Ionization time	Pump oscillator frequency
Ionization trapping level	Pump oscillator phase
Emission current	Pump oscillator offset
Multiplier voltage	Pump oscillator slope
Microscans	Prime oscillator frequency
Scan rate	Prime oscillator phase
Scan range	Prime oscillator offset
FNF waveform amplitude	Prime oscillator slope
FNF waveform time	MS/MS tickle time
Post-ion FNF time	MS/MS tickle amplitude
RF level for any table	Time for any table
FNF amplitude for any table	FNF time for any table

Due to the software intensive nature of the ion trap scanning function, the number of possible mass spectrometry experiments that may be performed is virtually unlimited. Therefore, the experiment program has proven itself to be a very convenient tool for investigating and plotting various characteristics of ion traps. This improved capacity to quickly generate experimental data has given us a better insight into the performance of the ion trap, while freeing us from the burden of manually deciphering an often overwhelming collection of data.





Automating Mass Spectrometry with AppleScript (WPB 046)

Ron Bonner[1], Lyle Burton[1], Matthias Mann[2] and Matthias Wilm[2]
[1]PE-SCIEX, 71 Four Valley Drive, Concord, ON, Canada L4K 4V8
[2]EMBL, Heidelberg, Germany

Over the last few years Apple Computer® have been developing a system of sending messages between application programs known as Apple Events®. Programs can generate Apple Events to be sent to themselves or to other programs or they can be generated by a high-level scripting language called AppleScript. Appropriately written programs can support AppleScript at several levels:

- Scriptable. Scriptable programs can be controlled directly from a user-written script; they contain a "dictionary" which describes the available Apple Events and parameters. This dictionary can be opened by Apple's Script Editor which is also used to write scripts.

- Recordable. If a program is recordable then the recording feature of the Script Editor can be used to automatically generate a script from operations performed by the user. This facility is very useful when a series of operations are to be repeated several times since a simple script can be generated quickly. It is especially useful when learning the scripting language.

AppleScript is very powerful, straightforward to use and learn, and is able to control multiple applications. Our new data processing program described here, MultiView, is both scriptable and recordable.

Programs that are not scriptable can still be controlled from an AppleScript—to a certain extent—by using a program such as PreFab Player™. This program essentially records user operations in terms of mouse clicks and key presses that can later be "played back" under script control.

This presentation gives four main examples of the use of AppleScript to process data. The first, "Find Metabolites", automates an operation that is common in the identification of metabolites, namely plotting the XICs of expected masses based on the mass of the parent drug and the mass offsets of likely metabolites. The second, "Start PeptideScan with Tags", illustrates the ability to control several programs from a single script. It transfers mass values from the MultiView program to the PeptideScan program which searches a database for the peptide sequence.

The third example, "Auto MS/MS", shows the use of PreFab Player to control the data acquisition software, which is not properly scriptable, in the analysis of peptide mixtures using the MicroSpray ion source. This device allows 1µL of a sample to be sprayed for upwards of thirty minutes giving enough time to perform many experiments. The device can, however, demonstrate high chemical background signals that make location of the molecular ions difficult, but if the peptide mixture is derived from the tryptic digestion of a protein, the y_1 ions should be at either m/z 147 (C-terminal Lys) or 175 amu (C-terminal Arg). A precursor scan for these species will often reveal the molecular ions of the peptides; these can be used as the precursor ions in product ions scans. The script demonstrates the automation of this procedure.

The final example exploits an important feature of AppleScript applications—the ability to periodically perform some action, in this case examining the contents of a folder to determine if there have been any new items added. Once again different applications and

now two separate AppleScripts are involved. These scripts implement a "Walk-up" API machine, *i.e.* routine users enter sample information at any time and the samples are run when the machine is free.

The package consists of three components:

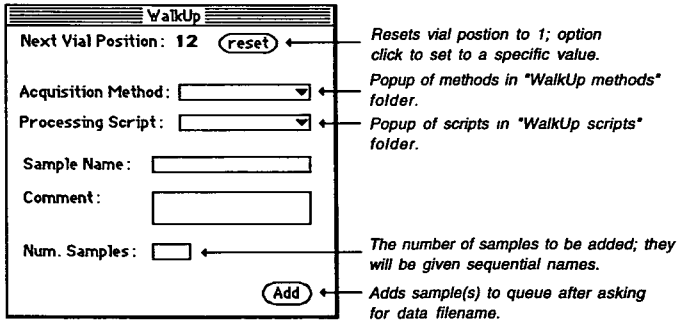
- A user interface module (shown below) that allows the user to specify that a number of samples have been added to the autosampler, to name the samples, to specify the final destination folder (which could be on another computer), and to select the acquisition and post-processing methods. This application builds a text file which can be loaded into the acquisition program. While this module could have been implemented using a program such as "FaceSpan" which supplies a user-interface to scripts, it was decided to implement this as an application written in C.

- A "Sample File Watcher" script which checks for a new batch text file every ten seconds. If a new file exists (and the instrument is free), PreFab Player is used to load the batch and start the acquisition.

- A "Data File Watcher" script which checks for a new data file every ten seconds. If one is found it is moved to the final destination folder and processed with the selected script.

In operation, an experienced user builds the acquisition methods and the data processing scripts, places them in specific folders and starts the "WalkUp" application. This in turn starts the two watcher scripts. A routine user adds one or more samples to the autosampler, fills in the information in the "WalkUp" program and clicks the "Add" button.

This package can be used with any PE Sciex API instrument and allows great flexibility because of the ability to choose the acquisition and processing methods from a simple user interface.



A New Mass Spectrometry Data Processing Program

R. F. Bonner and L. L. Burton

PE Sciex Instruments, 71 Four Valley Drive, Concord, Ontario, L4K 4V8, CANADA

We describe the development of a new data processing program that has been designed with several objectives:

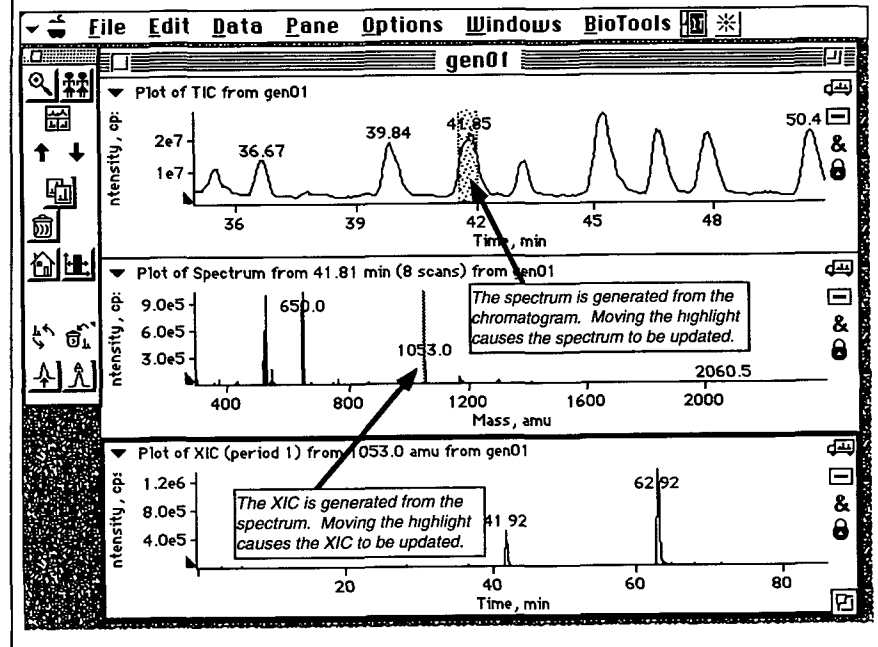
- Ease of use: it is important that the user interface be intuitive and that it does not intrude between the analyst and the operations being performed. The system should be responsive and minimize the amount of typing that is required.
- Flexible: it should be possible to view data in different ways so that the various features can be emphasized as needed. The user should be able to 'browse' the data while searching for the important details.
- Comparison: since much data processing involves comparing data sets, these operations should be as direct as possible.
- Visualization of linkages: when data is derived from other data, the linkages should be emphasized so the user remains aware of the source of any particular data set.
- Interpretive tools: the user should be assisted in the interpretation of the data. It should also be possible to confirm the interpretation.
- Automation: there should be a straightforward mechanism for automating operations. Ideally the user should be able to record operations and play them back later (recordable) as well as being able to write scripts directly.

The program provides users with a variety of ways to examine complex data sets obtained from LC/MS analyses, in either general or specific ways. The User Interface is built around the concept that a window can be divided into separate regions (called 'panes') each of which contain data—either different data that is to be compared, or the same data treated differently. Panes can display data from the same file or different files and are created whenever new data is opened or generated. The panes are initially placed in default positions, but can be rearranged by the user as desired.

Virtually all of the common data processing operations are available with mouse clicks, either on icons that are in each pane or on a tool palette; pane icons deal with operations that involve two panes (such as subtraction that requires a source and a target pane), while the tool palette contains single pane operations. The latter include zooming a pane to the full size of the window, hiding, deleting and copying. In order to ease data comparison, panes can be locked together so that any zoom or scroll operation on one is repeated for all the others. Panes also contain a pop-up menu of commands that are specific to that pane; this again eases the process of manipulating data and allows easy access to common commands.

There are a variety of ways to 'browse' the data: spectra are generated from chromatograms and a marker shows the origin of the spectrum—if the marker is moved the spectrum will be updated. Similarly SICs are generated from spectra and can be changed by moving the highlight. These operations can also be performed from contour displays. Browsing is illustrated in the figure which also shows the tool palette and the pane icons.

All operations can be automated and results obtained can be transferred to other programs via scripts which are written using AppleScript®, an object-oriented, high-level language developed by Apple®. Scripts can be generated by writing them directly with a script editor, but can also be produced by recording operations. Since scripts can control multiple application programs, very powerful automatic processing can be implemented (see also WPB047).



In addition to the traditional tools for displaying and processing data, the program contains a variety of new features that are designed to allow the analyst to more rapidly focus on the areas of interest and interpret the data:

- Contour displays that allow instantaneous color control so that an entire data set can be 'visually thresholded' and small peaks or noise immediately ignored. Contours can be linked to spectra and SICs allowing the user to interactively examine the data.
- Cluster analysis. The user can specify isotope patterns that are of interest and filter the data to obtain a subset containing ions that match the given pattern. This is especially powerful when used with the contour displays and is of importance in drug metabolism studies, environmental analysis, etc. The algorithm can be configured to perform a 'software neutral loss experiment' by looking for mass differences that may or may not be within the same scan, i.e. related components can be found even if they are separated by the chromatography.
- Interpretive tools. The program contains tools to interpret data, especially product ion spectra obtained from peptides, and includes the ability to visualize the interpretation. This is achieved by linking different views of the same data so that predictions made by one algorithm can be visually confirmed by another. The result is a powerful system for exploring the mass spectrometry of proteins, peptides, drug metabolites, etc.

These new capabilities provide users with powerful but simple ways to process data from many sources, such as drug metabolism, peptide sequencing and peptide mapping.

Automating Pharmaceutical API/LC/MS/MS Quantitation

Michael Wakefield, Klaus Weissenberg, Finnigan MAT, San Jose, CA

Introduction

Expanding FDA regulations and the trend towards lower dosage drugs has increased the demands on the analytical departments of every Pharmaceutical company. API/LC/MS/MS has become the analytical technique of choice for quantitative analysis of a product progressing through clinical trials. The demand to analyze hundreds of samples per week requires the entire quantitative process to be automated if meaningful results are to be delivered in a reasonable time frame. We have developed a new, intuitive and "easy to use" user interface for automating the entire quantitative process, called QuanGuide. The flow of the quantitation process using QuanGuide will be described and an example of a typical pharmaceutical assay will be presented.

Quantitation Process Flow

Processing quantitation data post acquisition involves three major steps:

1. Create a "Master Quan File" for processing standards, QC's and unknowns.
2. Create a calibration curve manually or automatically.
3. Process QC's and unknown samples manually or automatically.

QuanGuide is a shell that operates on top of the ICIS Quan environment. It is a software program Tcl/Tk developed at the University of California, Berkeley. It's designed to allow quicker creation of user interfaces in the UNIX programming environment. We have implemented Tcl/Tk to create a "user friendly" interface for ICIS Quan that will guide novice and experienced users through the entire quantitation process.

Generating Summary Quantitation Reports

The AutoQuan menu of QuanGuide includes the capability to create a single summary quantitation report from multiple quantitation files generated from an assay. The analyst simply creates a namelist of the quantitation files to be summarized, presses the QuanSummary report button and a summary quantitation report is generated. This report is saved as a quantitation file and as a tab delimited text file in a separate directory. This file can then be easily transferred to a networked computers spreadsheet or LIMS database for further manipulation.

Conclusions

Automating the entire quantitation process has been simplified with the development of QuanGuide. It has streamlined the setup, use and automation of the ICIS Quantitation package. Coupled with the Finnigan MAT TSQ 7000 and the API source, excellent accuracy and precision are attainable for any LC/MS assay.

A New Multi-Vendor "CLP-Like" Report Generator for GC/MS Data

Adam Patkin, The Perkin-Elmer Corporation
761 Main Avenue, Norwalk, CT 06859-0257

INTRODUCTION

In the late 1970's the US EPA promulgated a GC/MS reporting format for its Contract Laboratory Program (CLP). While having no legal status beyond that specific program, in which only a relatively small number of laboratories participated, these formats have become the *de-facto* standard for reporting environmental data.

The GC/MS CLP reports consist of a set of tabular "Forms" and supporting graphical chromatographic and spectroscopic data. Official CLP laboratory analysis must perform the CLP protocol exactly. "Industrial CLP", or "CLP-like" analyses are very similar, but can differ slightly in calculation details and deliverables. Software programs for the latter are somewhat simpler and less expensive.

This paper will discuss Aquarius 2000™, a new Microsoft Windows™ based program designed to produce these "CLP-like" reports quickly and easily.

Aquarius 2000 is based upon the widely used Aquarius™, which ran on HP RTE operating system mini-computers. Aquarius was written by ETC, Corp., a large environmental laboratory, and introduced in 1983. Aquarius 2000 was also written by ETC (now Astrix Software Technology, Inc.) and developed in conjunction with Perkin-Elmer.

OVERVIEW

- Based upon the industry-standard Aquarius Software
- US EPA environmental reports
- Industrial CLP ("CLP-like") deliverables for GC/MS
- High productivity, high throughput
- Single-user, single GC/MS
- Multi-user, multi-GC/MS networked GC/MS laboratory
- Microsoft Windows
- IBM PC-compatible computers

FEATURES

- Fast and flexible report production
- High-speed processing
- Automated Tentatively Identified Compound (TIC) Searching
- High-speed calibration and quantitation
- Powerful data review
- Distributed Parallel Processing
- Security, aids GLP and GALP compliance
- Automatic data archiving to removable media
- Supports the Perkin-Elmer Q-Mass 910 GC/MS
  - also HP ChemStation™
  - many other GC/MS systems with optional software

DISCUSSION

The software emphasizes high productivity and ease-of-use. Productivity is enhanced by *Distributed Parallel Processing*, a software approach that enables various processing tasks to execute on remote computers for enhanced system performance. The Windows interface facilitates simple processing of Sample Delivery Groups (SDG's). A "copy and paste" approach to target compound lists expedites and simplifies construction of customized "Industrial CLP" reports within the software, rather than requiring customized macros

Aquarius 2000 has been designed for the high-volume laboratory. Related tasks are placed in close proximity. Large push-buttons have been emphasized to simplify operation and avoid "hiding" features under multiple menus. Special care has been taken to minimize the number of keystrokes required for common tasks.

Automated Matrix Assisted Laser Desorption as a Tool for QC Applications

Paul Humphrey & David C Dingley
Kratos Analytical, Barton Dock Road, Urmston, Manchester, M41 7LD, UK.

Matrix assisted laser desorption ionisation (MALDI) is now becoming established as an immensely powerful analytical tool for peptides and proteins and its uses encompass reaction monitoring, product confirmation and routine quality control. This has resulted in the need for a cost effective solution for the modern laboratory combining a high-performance, laboratory-priced package offering a high degree of automation.

(i) Fully-automated "Sweet-spot" location

One of the apparent weaknesses of MALDI to a new user is the variable shot-to-shot reproducibility. This is partly due to the fact that the matrices crystallise unevenly with varying degrees of sample inclusion. The MALDI process itself can be used to find the sweet-spot. This slide is scanned beneath the laser while the data system monitors the secondary ion signal of the mass range of interest. Typically 20 - 50 laser shots are taken across the sample and the intensity of the analyte ion signal is plotted against laser shot.

The spectrum is then collected from the maximum in the analyte ion chromatogram. The selection of the sweet-spot from the chromatogram can be manual or left entirely to the data system. The procedure is shown schematically in figure 1.

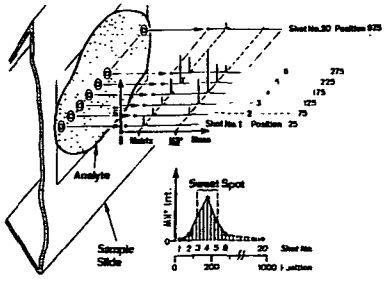

Figure 1 - Schematic of "Sweet-spot" locating

(ii) Fully-automated laser power threshold tuning

With the exception of sample preparation, which is external to the instrument, the most important parameter in the MALDI experiment is the laser power.

The threshold behaviour of the MALDI process is well known. If the laser power is too low there will be no ion emission and minimal damage to the sample by the laser irradiation. As the laser flux is increased, ion emission occurs and a spectrum begins

to appear. Increasing the flux further will result in further ion emission and a more intense spectrum is obtained. The excess energy will result in a broadening of the analyte ion peak thus reducing the practically obtainable mass resolution. Adduct formation is also more likely. As the laser flux is increased again the signal rises but at the expense of resolution. At extreme powers the peaks are very broad and the signal may actually fall due to either the detector signal saturating and subsequent instability or by actual depletion of the $[M+H]^+$ channel by increasing ion fragmentation. A high baseline is usually also seen due to the time-unresolved fragment ions. The laser threshold behaviour is shown schematically in figure 2 with insets of MALDI spectra of substance P acquired at the positions indicated.

The ideal power is then just above threshold which can be selected automatically by a method similar to that described above. This time the laser power is ramped while the data system again monitors the secondary ion signal. The analyte ion chromatogram will then show a threshold curve and the appropriate position on the curve can then be selected manually or automatically. This procedure can be performed separately or in conjunction with the procedure described in section (i) and typically thirty samples can be analysed in less than 20 minutes with no manual intervention being necessary.

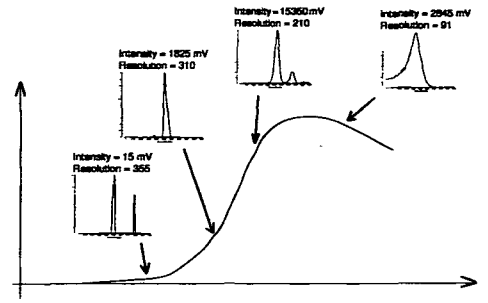

Figure 2- Laser threshold behaviour

(iii) On-line peptide digest database searching

One approach to protein analysis is to perform a protein digest (which can be carried out on the sample slide) and acquire a MALDI spectrum of the digest fragments. The masses of these can then be selected from the spectrum and used as the search elements for a search of a protein database. Using predictive software, which theoretically digests sequences withh a defined protease, all protein sequences in a database are theoretically digested using the appropriate enzyme and matches are sought between the resulting fragments and those observed in the MALDI spectrum. Searching can be performed locally or at a remote location using internet connections. The software then reports a list of possible fits ranked with a 'goodness of fit' actor. The tolerance of the search matching can be adjusted and variations such as missed cleavages can be taken into account.

Evaluation of TICfilt as a Software used in LC/MS analysis.

A. Carrier, D. Zidarov and M.J. Bertrand, Regional Center for Mass Spectrometry, Department of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7.

A significant challenge facing LC/MS techniques is making reliable compound identification at low level or in complex samples, where the background signal generated by the mobile phase can lead to misinterpretation. Indeed, the solvents and buffers present in the mobile phase produce a substantial background signal that can cause problems in locating weak elution peaks of unknown compounds in the TIC. A background treatment algorithm, TICfilt, was recently developed to detect weak eluting peaks in the TIC and to facilitate the identification of unknown analytes (1). In order to broaden the scope of application of TICfilt, data generated by different ionization processes commonly used in LC/MS analysis were treated. Experiments were conducted with various mobile phase compositions to study the influence of the background generated and the effect of the algorithm on the quantification was also studied. In order to illustrate the ability of TICfilt to extract peaks from the background and to enhance the quality of the mass spectra the algorithm has been applied to different LC/MS data sets generated under different ionization conditions such as IonSpray™, APCI, CF-FAB and DLI using an in-source μ-TSP interfaces (2). The treated data obtained demonstrate how the algorithm eliminates the effect of heavy background and permits the extraction of compounds from the background signal. The results from these experiments clearly indicate that regardless of the ionization technique employed for the LC/MS analysis, TICfilt can successfully extract significant ions from the overall signal. For example, the use of a liquid matrix associated with fast atom bombardment ionization produces important background ions that can lead to problems in interpreting the mass spectra of unknowns. The algorithm was used to treat CF-FAB data and the results obtained for a deoxyadenosine sample are shown in Figure 1. The elution peak for deoxyadenosine was found to be clearly distinguished from the background signal of glycerol that corresponds to the major ions of the raw mass spectrum (Figure 1a). The treated spectrum (Figure 1b) shows a base peak at m/z 252 that corresponds to the parent ion of deoxyadenosine. Experiments were conducted with various mobile phase compositions to study the influence of the background signal generated. The results obtained with different compositions (0,25,50,75,100%) in two chromatographic systems, acetonitrile/water and hexane/ethyl acetate, indicate that the performance of TICfilt is independent of the signal generated by the mobile phase. The elution peak corresponding in the treated data to the analyte injected was found to be clearly distinguished from background signal. The influence of TICfilt on the quantification was studied by injecting various quantities of chloroaniline

(normal phase) and phenylhexane (reversed phase) ranging from 10 to 1000 ng in the scanning mode. Figure 2 A) (chloroaniline) and B) (phenylhexane) represent the calibration curves for the elution peak before and after treatment of the TIC. The results indicate that the linearity of the calibration curves for both compounds is preserved and that TICfilt is independent of the concentration of the analyte injected. The subtraction process minimizes the effect of solvent noise and interferences in the data and maximizes spectral quality both in the total ion chromatogram and in the mass spectra. TICfilt is in all aspects equivalent to single ion chromatograms without requiring any information on the nature of the eluting compound.

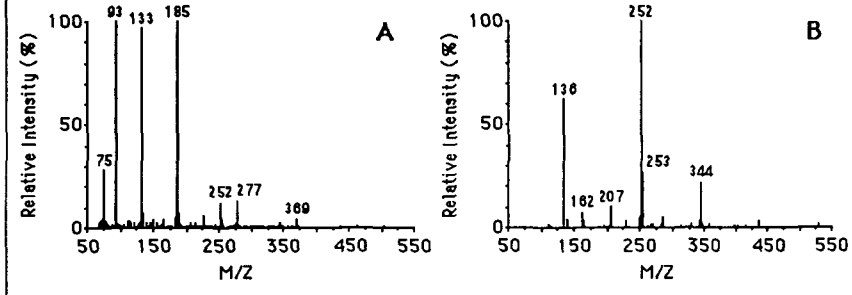

Figure 1. Mass spectrum for a 300 ng injection of deoxyguanosine obtained by CF-FAB. A) original TIC, B) TIC treated by TICfilt.

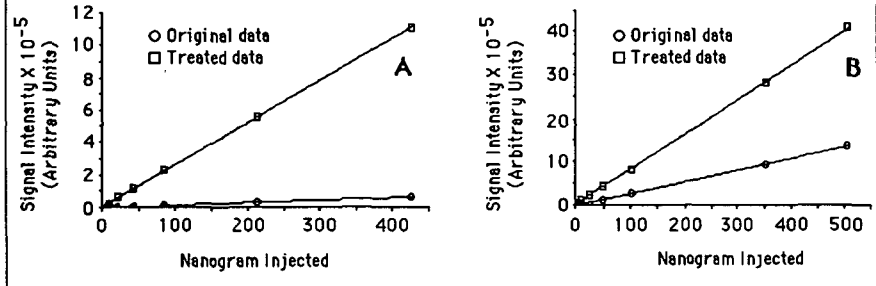

Figure 2. Calibration curves before and after treatment for a) chloroaniline and b) phenylhexane

Direct Temperature resolved Mass Spectrometry (DTMS) as a Tool to Study Painted Art: a case study of "De Eendenfamilie" by W.Maris, a 19th century Dutch impressionist painter.

Jaap J.Boon[1], K-J. van den Berg[1], J. Pureveen[1], G. van der Doelen[1], Karin Groen[2], J. van Och[3] and A. van Grevenstein[3]. MOLART-project for Painted Art, FOM Institute for Atomic and Molecular Physics, Kruislaan 407, 1098 SJ Amsterdam, NL. fax. 31-20-6684106 (2) Centraal Laboratorium voor de Studie van Voorwerpen van Kunst en Wetenschap, Amsterdam, NL. (3) Stichting Restauratie Atelier Limburg, Maastricht, NL.

Mass spectrometry can play a unique role in the definition of the current condition of art objects because of its low sample requirement and its sensitivity for a wide range of chemical compounds. Questions to be addressed are not only the chemical composition of the original materials used by the artist but also the molecular changes that are taking place after completion of the art work due to ageing, environmental effects and restoration. DTMS (Direct -i.e. in source- Temperature resolved Mass Spectrometric analysis [1]) using a resistively heated platinum/rhodium filament probe is presently the most versatile technique used to profile the chemistry of minute paint samples [2,3] because it gives information about the chemical composition as well as about the ways in which the compounds are chemically bound. The temperature resolution allows the separation into mobile "free" fractions and chemically bound fractions, which require a higher appearance temperature. Mass spectrometric analysis of the different layers (varnish, paint layers, ground, canvas and lining materials) obtained by dissection under a microscope visualises the molecular "cross-talk" between the layers.

DTMS was applied to samples taken from De Eendenfamilie (Family of Ducks, Van Abbe Museum, Eindhoven, inv. nr. 83) by W.Maris (1844-1910), a typical representative of the Dutch Impressionist "Haagse School" (The Hague School). The painting has been made in high impasto with paints which are presently unusually soft. This makes restoration and varnish removal with solvents a hazardous operation. The painting has not been wax or glue lined and has kept its original canvas support. Paint and varnish samples were analysed by DTMS (using a Jeol SX102A B/E-MS) and PYGCMS (using a FOM4LX-Curie point pyrolysis unit mounted on a Carlo Erba 8565 HRGC coupled to a Jeol DX303 E/B-MS). A cross section of a paint chip was investigated by reflected light microscopy and SEM-EDAX for elemental analysis.

The painting was found to be covered with a yellowed varnish with an unusual DTMS spectrum indicative a possibly aged synthetic methylcyclohexanone resin [5] (DTMS points to homologous ion series with an mass increment of about 110 Da) and a small amount of residual highly oxidised natural Dammar resins, most likely an earlier varnish. Paints investigated were a chocolate brown paint (8 µm) with vermilion (HgS) and Prussian blue (ferriferrocyanate), on top of an olive green paint (40 µm) with Naples yellow (lead antimonate), lead chromate, Prussian blue and zink white. The organic fraction of these paints contains beeswax and is depleted in binding oil derived components because the concentration of C16FA, C18FA and azelaic acid is very low. The paint layers are isolated from a chalk priming ground by a thin partly cracked layer of lead white (15 µm). The ground layer (100 µm) was very much enriched with fatty acids possibly originating from drying oil absorbed from the poorly drying upper layers. SEM and DTMS shows that no "drying" transition metals are present in the ground. Figure 1 shows the DTMS spectra from a paint sample in the lower right hand corner of the painting which could be separated with a dissecting microscope into sample A (top layer), B (olive green paint and attached lead white layer) and C (chalk ground).

Varnish removal test. A[1] presents the DTMS after superfast varnish removal (isooctane/ethanol (1/1); exposure time 2 seconds) using a home made solvent suction device. The DTMS shows that with this approach not only the aged synthetic varnish but also fatty acids from the paints (note m/z 256 and 284) are selectively removed, whereas the beeswax additive consisting of odd long chain hydrocarbons and wax esters remains. The loss of fatty acids from the painting is undesirable. Changing the polarity of the cleaning solvent to a lower polarity (less ethanol) could leave the fatty acids but may lead to selective extraction of the waxes. Since the paint is presently coated with a synthetic varnish, it is likely that it has been "cleaned" earlier most likely involving loss of paint constituents in the process.

Softness of the paint. Beeswax is mostly found in paintings which have been lined with a new canvas support. In this case the wax is impregnated in existing well cured oil paint layers. In the 19th century painters have added waxes and other additives to their paint in order to improve the brushability or to obtain certain topographical effects (impasto)[4]. Maris must have modified his paints for that reason by addition of wax. Beeswax is a polymerisation inhibitor of the binding oil and may lead to long drying times. The high amount of fatty acids in the ground layer points to absorption of the binding oil from the paint layers which must have happened at an early stage of the production of the painting. Undersaturation of the paint layers with binding oil relative to "drying" agents such as the lead antimonate pigment in combination with the added beeswax is thought to be the main reason for the unusual softness of the paint which never dried properly. This scenario is confirmed by the composition of a brown well dried hard paint clot on top of the frame which is devoid of bees wax. Further tests with PyGCMS in the presence of tetramethylammoniumhydroxide for direct transalkylation of fatty acids and diacids shows that the soft paint layers have unusually low azelaic acid concentrations, a C9 diacid formed by oxidation from the polyunsaturated fatty acids in drying oil [5], compared to the hard paint.

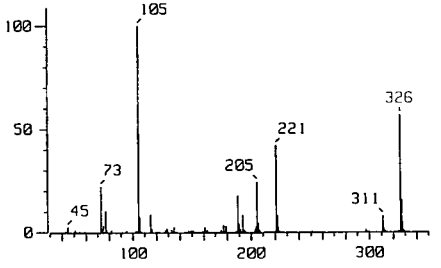
HPLC-FAB-MS and GCMS study of aromatic components of "gum benzoin" resins.

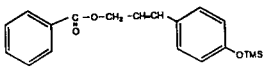
I.Pastorova, C.G. de Koster aand J.J. Boon
FOM-Amolf, Kruislaan 407, 1098 SJ Amsterdam, The Netherlands

" Gum benzoin" resins originating from North Sumatra were studied by modern analytical techniques because of their commercial value for the local population. It is known, that these resins contain some valuable aromatic esters, but until now, studies of these type of compounds involved an alkaline hydrolysis step, concentrating therefore on the free acid and alcohol content.
We omitted the hydrolysis step and analysed the resins both with and without a derivatisation step.
For GC/MS measurements, the resins were silylated with BSTFA and dissolved in DCM prior to on-column injection. The following compounds were identified:

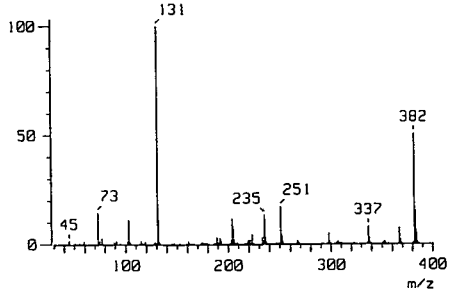
benzyl alcohol	benzoic acid	p-hydroxybenzaldehyde
vanillin	cinnamic acid	p-coumaryl alcohol
coniferyl alcohol	cinnamylbenzoate	benzylcinnamate
cinnamylcinnamate	p-coumarylbenzoate	4-hydroxy-3-methoxybenzoic acid
coniferylbenzoate	p-coumarylcinnamate	coniferylcinnamate
pinoresinol	triterpenoic acids	

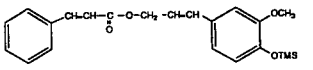
The identification is based purely on comparison of mass spectra of the silylated compounds with reference data from libraries. P-coumaryl and coniferyl esters of benzoic and cinnamic acids are unique to these resins, therefore no reference spectra of their TMS derivatives are available. Identification was based on interpretation of mass spectra, structure of the abundant fragment ions and mechanisms of their formation were proposed [1].





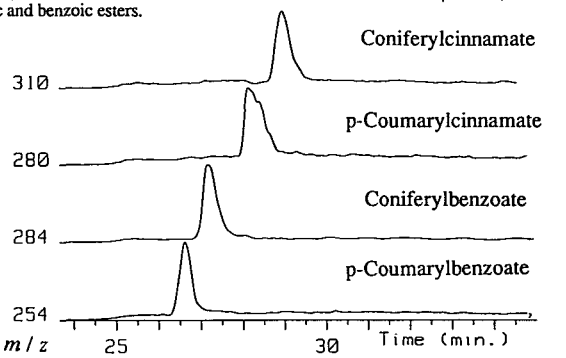
p-Coumarylbenzoate



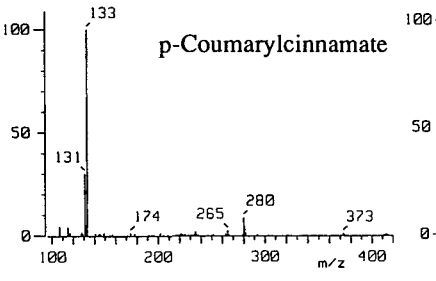


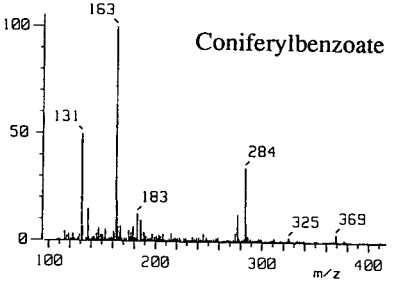
Coniferylcinnamate

To confirm the structure of these unique esters, the underivatised resins were dissolved in acetonitrile and injected on a RP-C18 column and HPLC-frit-FAB+ MS was performed. Glycerol was used as the matrix, acetonitrile and water as eluents. We focused our attention primarily on the detection of the cinnamic and benzoic esters.



In the mass spectra we can observe a relatively strong molecular radical cation, a phenomenon observed in positive FAB spectra of different organic molecules [2,3].
The fragments in the mass spectra are typical for p-coumaryl (m/z 133) and coniferyl (m/z 163) alcohols [4].





Conclusions

1) GC/MS of TMS derivatives of "gum benzoin" proved to be a powerful tool for analysis of these type of samples. Many unique aromatic components were identified, based on the fragmentation patterns in their mass spectra.

2) HPLC-FAB-MS results confirmed the proposed structure of the aromatic esters.

3) The formation of the abundant molecular ion (radical cation) will be studied further with model compounds.

DEVELOPMENT OF A REFERENCE CORPUS FOR GC/MS ANALYSIS OF VEGETABLE ADHESIVES FROM ARCHAEOLOGICAL ORIGIN

REGERT M.*, DELACOTTE J.-M.#, ROLANDO C.#
Ecole Normale Supérieure, Département de chimie, URA 1679
24, rue Lhomond, 75005 Paris
* Musée du Louvre, Laboratoire de recherche des musées de France, EP97
16, rue des Pyramides
75041 Paris cedex 01

INTRODUCTION

Black and amorphous organic residues have been discovered for many years in archaeological prehistoric sites. Some of them were used as adhesives either to repair ceramic potteries or to secure a spearhead on a shaft of wood for example, during the paleolithic and the neolithic periods. Our purpose is to identify the natural origin of these adhesives in order to infer the technology of prehistoric people.

The organic residues consist of complex molecular mixtures of biopolymers and volatile compounds. The only biomarkers, *i.e.* characteristic molecules for a species, a genus or a family, can give us some information about the natural origin of the material. However, a set of biomarkers is necessary to find the natural origin of the investigated archaeological samples. Moreover, these markers must be quite stable in time

Some biomarkers are more or less distributed in nature. For example, the triterpenoid betulin is often thought to be characteristic of birch bark ; but a publication shows that a lot of species contain this molecule[1]. In order to find criteria to understand the natural origin of archaeological samples, we have analysed actual products which probably were used by neolithic people as glue.

We present here a comparison of results from MS and GC/MS analysis of different natural samples (resins, oils, beeswax) after derivatization. Beeswax and oils are not really adhesive but they could have been mixed with resins or tars to improve their properties such as plasticity or stickiness.

METHODS

Reference samples : the samples (about 5 mg) were ground in an agate mortar, then extracted with 1 ml of dichloromethane. In all cases, the samples were entirely soluble.
MS analysis : sample analysis was performed with R10-10 Nermag.
GC/MS analysis : sample analysis was performed after diazomethane methylation with GC/MS instrument (Finnigan 46 ; GC Varian 9611) equipped with a (25m X 0.25mm) CP Sil 5CB (25µm) column from Chrompack using EI+ ionization.
Temperature programs :
Beeswax, fir and pistachio resins : 1mn : 60°C ; 20°C/mn : 60 to 150°C ; 4°C/mn : 150 to 310°C ; 310°C during 30mn.
Pine resin : 1mn : 80°C ; 4°C/mn : 80 to 200°C ; 2°C/mn : 200 to 250°C ; 4°C/mn : 250 to 310°C.
Linseed oil : 1mn : 60°C ; 4°C/mn : 60 to 280°C ; 280°C during 10mn.

RESULTS

- *Resins* : in all the studied resins, we identified either diterpenoids (pine and fir) or triterpenoids (pistachio). But in some cases, these terpenoids are common to different species. In particular, almost all the biomarkers usually considered as characteristic of the pine resin also pertain to the fir resin. However, the fir resin contains some higher molecular weight markers which could be used to distinguish the two genuses
- *Beeswax* : beeswax doesn't really contain biomarkers but a set of hydrocarbons, fatty acids and esters. It has been shown that the hydrocarbons were damaged with time whereas esters seem to be quite stable[2]. Even if esters can't be considered as biomarkers, their distribution can indicate to us the presence of beeswax in the sample. We can only see one ester on our chromatogram because of the limitation in temperature of the column but the mass spectrum of beeswax shows the presence of the other esters.
- *Oils* : all the oils (lin, poppy, olive) contain the same fatty acids and fatty acids are important in nature. So, fatty acids can't really be used to identify the natural origin of archaeological samples. The oils also contain sterols which are good biomarkers , but they are present in small quantities in the oils. So we can imagine that they could be difficult to find in old samples except in well preserved samples.

CONCLUSION

Based on the analysis of reference natural products probably used by prehistoric people to make glues, we can propose methods of study and interpretation of archaeological adhesives.

Concerning an unknown sample, we can first study the mass spectrum of the sample in order to make a first hypothesis. The preliminary results from mass spectrometry permit us to distinguish triterpenoid from diterpenoid samples and those containing beeswax or oil. After derivatization choice (in some cases, trimethylsilylation is necessary, for birch bark tar, for example), GC/MS permits us to identify the biomarkers and the other constituents. It is important to note the necessity to develop a wide reference corpus since many markers are present in different species (pine and fir resin, for example). In absence of biomarkers (beeswax), it is necessary to work on very stable compounds in order to obtain characteristic chromatographic profiles. These first results obtained on reference products should permit us to find the nature of archaeological adhesives in order to understand the management of these products by prehistoric people

Terminal Group Effects on the TOF-SIMS Spectra of Polydimethylsiloxanes

Xia Dong and David M. Hercules[1]
Department of Chemistry, University of Pittsburgh, Pittsburgh, PA 15260
[1]: Present address: Department of Chemistry, Stevenson Center, Box 1822, Station B, Vanderbilt University, Nashville, TN 37235

Introduction:

The degradation mechanism of polydimethylsiloxanes (PDMS) has been studied by electron impact[1] and pyrolysis mass spectrometry[2]. These studies, however, have focused on the low mass range. Time-of-flight second-ion mass spectrometry (TOF-SIMS) offers the advantage of high resolution and high sensitivity in the high mass range. We have previously examined the effect of molecular weight on the fragmentation of PDMS by TOF-SIMS[3]. The purpose of the present research is to investigate the effect of terminal groups on PDMS fragmentation by TOF-SIMS.

Experimental:

PDMS spectra were obtained using time-of-flight secondary-ion mass spectrometer, TOF-SIMS III (Ion-Tof GmbH, Münster, Germany). The samples were prepared by casting thin films on etched silver. The targets were bombarded by 10keV Ar^+ beam with the pulsed primary ion current varying from 0.3-0.5 pA. The total collection time was 300 s.

Results and Discussions:

PDMS terminated by trimethylsilyl, silanol, aminopropyl and amidepropyl groups were investigated. The low mass range spectra of PDMS were very similar. The characteristic peaks of end groups were observed in the spectra of PDMS terminated by trimethylsilyl, aminopropyl and amidepropyl groups. The PDMS silanol spectrum did not show the peak characteristic of hydroxyl group.

A major difference in the spectra is observed in the mass range from 600 -1000 Da. Spectra of PDMS in this mass range are shown in Figure 1. The spectrum of trimethylsilyl terminated PDMS has been discussed in detail before[3]. The major series detected in the spectra of PDMS terminated by silanol groups are linear oligomer and cyclic fragment cationized by silver. Two intense clusters are observed in the spectrum of aminopropyl-terminated PDMS. One corresponds to the intact linear oligomer cationized by silver, the other to a linear fragment formed by loss of the aminopropyl group from oligomer but not cationized by Ag ($[nR+116]^+$). Similarly, the spectrum of PDMS amidepropyl contains two intense clusters, an intact linear oligomer cationized by silver and a linear fragment with intrinsic charge formed by the loss of the amidepropyl group from the oligomer ($[nR+158]^+$).

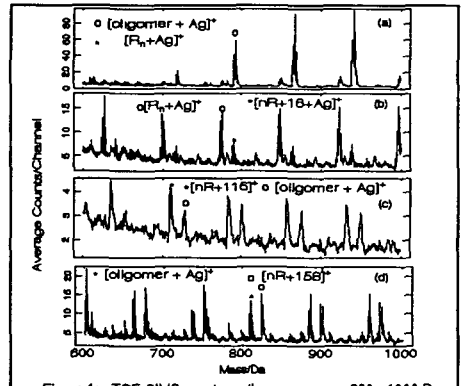

Figure 1: TOF-SIMS spectra in the mass range 600 - 1000 Da for PDMS with different terminal groups
(a):silanol-terminated (b): trimethylsilyl-terminated
(c): aminopropyl-terminated (d): amidepropyl-terminated

The linear fragments observed in the spectra of PDMS aminopropyl and amidepropyl have structures containing an intrinsic positive charge instead of being neutral fragments cationized by Ag^+. Large fragments with intrinsic charge are rarely observed in the TOF-SIMS spectra. Both the amino and amide groups contain one nitrogen atom. This indicates that the presence of nitrogen in the end group has some effect on the fragmentation of PDMS. One interesting phenomenon is that the intensity of a linear fragment with intrinsic charge decreases with increasing mass range. In the mass range above 1200 Da, the dominant fragment peaks are silver cationized cyclic fragments which are also the major fragments in the spectra of PDMS trimethylsilyl and PDMS silanol.

Figure 2 shows detailed patterns of PDMS terminated with aminopropyl and trimethylsilyl groups in the mass range above 1200 Da. The intensity of the cyclic fragments compared to the oligomer peaks in the spectra of aminopropyl-terminated PDMS is higher than for PDMS with a trimethylsilyl group. This indicates that desorption of intact oligomer is more difficult for aminopropyl- terminated PDMS. The factors controlling desorption of intact oligomer are not well understood, and may be related to the conformation of the polymer chain on the substrate. Since the amine group contains a nitrogen atom with a lone pair of electrons, which tends to form a complex with silver, PDMS aminopropyl may interact more strongly with the silver target, thus making the desorption of the intact oligomer more difficult.

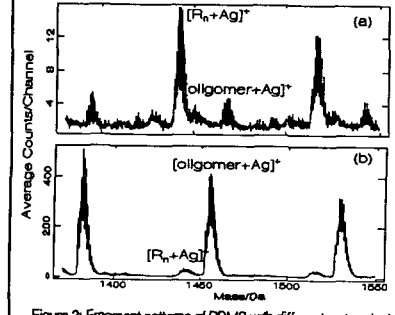

Figure 2: Fragment patterns of PDMS with different terminal groups in the mass region above 1200 Da
(a): aminopropyl-terminated M_n=1900 Da
(b): trimethylsilyl-terminated M_n=2000 Da

Conclusions:

Effects of end groups on the fragmentation of PDMS have been observed. In the spectra of aminopropyl and amidepropyl-terminated PDMS, large linear fragments with intrinsic positive charge which do not appear in the spectra of trimethylsilyl and silanol-terminated PDMS are observed. The relative intensity of the cyclic fragment of aminopropyl terminated PDMS is higher than that of PDMS trimethylsilyl with similar molecular weight. This may be caused by the strong interaction between amine group and silver substrate.

Application of ESI MS for the Analysis of Polysulfide Polymers

Armelle Buzy, Andrea Mahon, Terry J. Kemp and Keith R. Jennings
Department of Chemistry, University of Warwick, Coventry, CV4 7AL, U. K.

Few previous studies have been reported of the analysis of polymers by electrospray ionisation mass spectrometry (ESI MS) [1]. In this work, ESI MS is used to characterise liquid polysulfide polymers (LPs) that are widely used as high performance sealants in industry. Their characterisation is of considerable importance in identifying the photochemical processes that they undergo and which can result in the failure of the seal. Chemically, LPs are polymers of bis-(ethylene oxy) methane containing disulfide linkages of the general structure: $H(SC_2H_4OCH_2OC_2H_4S)_nH$.

Ten individual LPs, with a nominal molecular weight (nMW) ranging from 1000 to 8000 Da and differing in the percentage of branching agent, have been studied in this project. No apparent major differences between the various grades were detected by ^1H, ^{13}C NMR and IR spectrometry and, to date, no data have been obtained by means of Matrix-Assisted Laser Desorption Ionisation (MALDI). These LPs, however, form singly-charged species by ESI MS, when dissolved in 0.5 % NH_4Cl THF/MeOH. The ESI spectrum obtained for one LP of nMW 1000 Da (LP-1400C) is shown in Figure 1. In addition to the series corresponding to the expected structure (labelled A in Fig. 1) up to 7 other series were also observed (labelled B to H), each series yielding peaks at mass intervals of the monomer unit (166 Da). Similar types of complex distributions were observed in the ESI spectra given by all LPs studied. These series were tentatively assigned to compounds that are based on 'anomalous' repeat units containing either fewer or additional S atoms, oxymethylene and oxyethylene unit. This is not unexpected in view of the method of preparation of LPs [2]. The CID spectra of selected ions of each series were recorded in order to confirm these assignments. They are reported in Figure 2 for Series A (expected series) and B (one fewer S-atom). Additional fragments observed in the CID spectra for Series B to H compared to Series A allowed one to confirm the composition of the individual ions. Characterisation of higher nMW (> 4000 Da) polymers was prevented by the absence of peaks due to multiply-charged ions. Furthermore, no difference in MW distribution was observed for LPs with nMW of 1000, 2600 and 4000. Although this could suggest that ESI discriminates against ions at higher m/z values, it is also possible that the higher mass components are less soluble and so may not have been present in the sample that was ionised.

In summary, ESI MS has been shown to be a very useful technique for revealing and identifying the compounds of closely-related structures that are present in each sample of low nMW LPs polymers and should be suitable for monitoring their photodegradation.

A 5-component mixture of four antioxidants (Irganox 1076, Irganox 3114, Hostanox 03 and Irganox 1010) and a UV absorber (Tinuvin 327) of RMM 300-1200 daltons has been analysed by mass spectrometry and a comparison made of results obtained using various ionisation techniques. The ionisation techniques used were electron impact (EI), chemical ionisation (CI), liquid secondary ion mass spectrometry (LSIMS), field desorption (FD), electrospray (ESI) and matrix assisted laser desorption/ionisation (MALDI). Collision-induced dissociation (CID) spectra of molecular ions generated by EI, CI, LSIMS and FD were then obtained by means of tandem mass spectrometry (MS/MS). The internal energy effects of the precursor ions formed by these techniques are compared. ESI-MS/MS spectra are also presented.

The FD-MS spectrum of an equimolar mixture of polymer additives is shown in Figure 1. The ideal technique for the quantitative mass spectrometric analysis of a mixture of polymer additives is FD-MS. Matrix effects make LSIMS and UV-MALDI unsuitable as ionisation techniques for these analyses.

The high energy FD-MS/MS spectrum of Irganox 1010 (RMM 1177) is shown in Figure 2. The fragment ions at m/z 219 and 203 are characteristic of Irganox compounds with a 4-alkyl-2,6-tertiary-butylphenol structure. The proposed mechanism of generation of m/z 203 from m/z 219 is shown in Scheme 1. The characteristic fragment ions in the high energy MS/MS spectra of the antioxidants studied (Irganox compounds and Hostanox 03) aid structural elucidation. Other mechanisms are proposed and are consistent with results from precursor ion scanning experiments.

Precursor ions generated by different ionisation techniques generate high energy MS/MS spectra that differ quantitatively. The spectra indicate that the structures of precursor ions generated by EI, CI, LSIMS and FD are the same. Precursor ions with higher internal energy before collision give rise to a MS/MS spectrum with more intense lower mass fragments.

The fragment ions in low energy ESI-MS/MS spectra are not as characteristic of the class of additives. For example, the ions at m/z 219 and 203 are often not prominent at these collision energies. Probing the mechanisms of formation of fragment ions in low energy MS/MS spectra is aided by the ease of performing precursor ion scanning experiments on the triple quadrupole instrument.

Average Mass and End Group Information on Polymers By Means of LSIMS and MS/MS.

Tony T. Jackson[1], Jim H. Scrivens[2] and Keith R. Jennings[1].
[1]Department of Chemistry, University of Warwick, Coventry, CV4 7AL, U.K.
[2]ICI Materials, PO Box 90, Wilton Centre, Middlesbrough, TS90 8JE.

The introduction of soft ionisation techniques such as matrix-assisted laser desorption ionisation (MALDI) and developments in instrumentation has increased the interest in the analysis of polymers by means of mass spectrometry. Mass spectra of ions produced by means of MALDI give mean mass values and mass envelopes that correlate well with other techniques of analysis such as gel permeation chromatography. Currently, very few laboratories are able to undertake tandem mass spectrometry experiments with ions generated by MALDI and it is therefore difficult to obtain end group information. The combination of accurate average mass measurements, mass envelopes and end group information can, however, be achieved by carrying out two experiments. First, the mass values are obtained with MALDI spectra. Ions of the same mass as those present in MALDI spectra are then generated by liquid secondary ion mass spectrometry (LSIMS) or field desorption (FD) in a sector instrument and collision induced dissociation (CID) experiments performed yielding fragment ions in the CID spectra that can give end group information.

The classes of synthetic polymers studied include polymethyl methacrylates (PMMA) and polystyrenes (PS). UV-MALDI spectra were obtained by means of a TOFSPEC time-of-flight mass spectrometer (VG Organic) and LSIMS and FD spectra were acquired by means of a ZAB-T four-sector mass spectrometer (VG Organic). The calibration for MALDI experiments was obtained from a mixture of polystyrenes covering the mass range of interest.

Figure 1 is the UV-MALDI-MS spectrum of PMMA 2010 in linear mode. The ions generated are $[M+Na]^+$ and $[M+K]^+$ adducts. A similar distribution is observed in reflectron mode, with improved resolution. The LSIMS-MS/MS spectrum from $[M+Na]^+$ for the n=20 oligomer, m/z 2025.8, is shown in Figure 2. The fragment ions aid end group characterisation, as demonstrated by the scheme in Figure 2. A mechanism for the loss of methanol and carbon monoxide from m/z 224, generating the m/z 164 fragment ion, is shown in Scheme 1. MALDI-MS spectra of PMMA samples with different end groups was also presented.

The ions in MALDI-MS spectra of polystyrene samples were all assigned as adducts with silver, $[M+Ag]^+$. End group information was obtained from the FD-MS/MS spectrum of polystyrene 1700. The low ion currents generated by FD makes MS/MS spectra difficult to obtain.

MALDI-MS spectra of polystyrene 7600 and 95,000 obtained in linear mode were also presented.

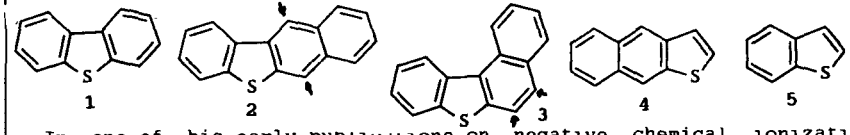
MASS SPECTROMETRIC ANALYSIS OF ALKYLATED BENZOTHIOPHENES BY NEGATIVE CHEMICAL IONIZATION WITH OXGEN

Herbert Budzikiewicz and Georg Drabner

Institut für Organische Chemie der Universität zu Köln
Greinstraße 4, D-50939 Cologne, Germany

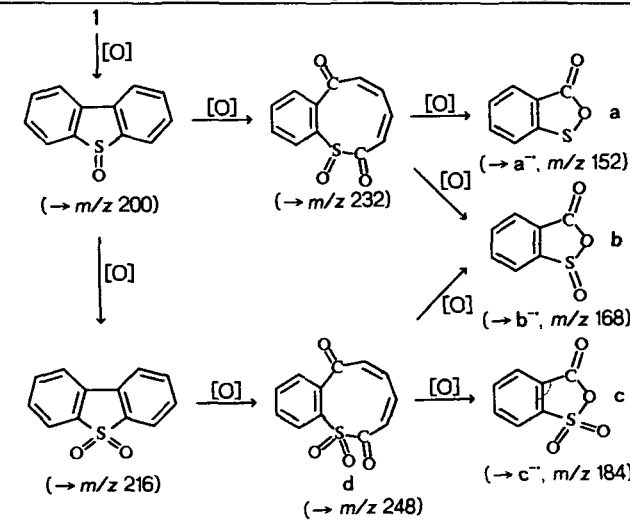
Crude oil contains besides alkyl thiophenes also benzo- and dibenzothiophenes substituted with methyl and/or ethyl groups. These compounds are indicators for the origin, age and the prevailing geological conditions during the genesis. Alkyl thiophenes can readily be analyzed by EI mass spectrometry: The ratio of the benzylic cleavages of the side chain without and with back-transfer of one hydrogen atom allows to differentiates between substitution in 2- and 3-position. In cases where the result is not clearcut due to secondary effects (e.g., additional substituents) transformation into the corresponding sulfones in most cases will give a definite answer: 3- but not 2-alkyl thiophenes show benzylic cleavage with back-transfer of two hydrogen atoms. From thiophenes with annelated benzene rings only molecular masses, but no structural information can be obtained by EI mass spectrometry. We searched, therefore, for an alternative method.



In one of his early publications on negative chemical ionization (NCI) Hunt *et al.* reported that dibenzothiophene (**1**) yielded $[M + 32]^-$-ions most likely due to the formation of a sulfone in addition to M^- and some species of lower mass which must have benn formed by degradation of the ring system. Reinvestigation of the NCI(O_2) spectrum of **1**, its d_8-analog and of a series of oxidation products lead to the following conclusions: The bulk of the ions observed does not stem from gas phase reactions of **1**; they are rather the result of a series os surface catalyzed oxidation and oxidative degradation reactions the products of which are then ionized. *Inter alia*, the ion *m/z* 184 is not M^- of **1** but of *o*-sulfobenzoic acid anhydride (**c**) (cf. Scheme 1, where the major processes are depicted).

As can be seen from Scheme 1 one of the benzene rings is degraded yielding the ions **a**, **b** and **c**. Unsymmetrically substituted derivatives of **1** will give two series of ions which allow to recognize which groups are located in which benzene ring. For benzo[*b*]naphtho[*d*]thiophenes there is a competition between the formation of the sulfone ($[M + 2\ O]^-$) and oxidation of the central benzene ring resulting in a quinone ($[M + 2\ O - 2\ H]^-$; see arrows in **2** and **3**). A *p*-quinone ion is more, an *o*-quinone ion is less abundant than the sulfone ion.

Naphthothiophenes (e. g. **4**) are isomers of **1**. Having a central benzene ring they also can form quinones (*p* prferred over *o*). Sulfone formation is only of secondary importance which seems to be typical for compounds with a terminal thiophene ring. $[M - O - H]^-$ (phenolate) ions which can be found occasionally in the spectra of the compounds discussed before compete especially with the formation of *o*-quinones.



Scheme 1.

Degradation of the thiophene ring leads to ions in the lower mass range. Benzo[*b*]thiophene (**5**) and it s alkyl derivatives show pronounced $[M + O - H]^-$ formation and degradation of the thiophene ring which allows to distinguish betwee n substituents in 2- and 3-position. Alkyl thiophenes do not give any useful NCI(O_2) spectra as only uncharacteristic degradation products can be seen.

In summary, as depending on the structure different oxidation products (sulfone, quinone, phenolate) are responsible for the most abundant ion in the upper mass range NCI(O_2) should be used only in combination with another ionization method which yields M^- or M^+ (EI, CI). Structural information may then be obtained by this method.

Characterisation of Cyclic PET Oligomers by LC-MS

Hilary Yates, Jim Scrivens, Julie Hedley, Mike Taylor
ICI Wilton Research Centre, PO Box No 90, Wilton, Cleveland, England

INTRODUCTION

The combination of chromatographic separation techniques with a mass spectrometer as a detector provides a specific, sensitive and quantitative approach to mixture characterisation. Atmospheric Pressure Ionisation (API) has emerged recently as providing the most universally applicable solution in situations where thermal labilities or involatilities would rule out GC-MS. A recent application of API LC-MS has involved a mixture of cyclic poly ethylene terepthalate (PET) oligomers. Cyclic PET has been the focus of effort in the polymer films industry as an alternative to the traditional linear polymer , due to the variation in processing requirements and product properties potentially offered. LC-MS characterisation supports and enhances field desorption results of cyclic PET oligomers.

EXPERIMENTAL

A spherisorb S50DS2, 250x4.6mm column has been used for introduction of the oligomers to the mass spectrometer at a flow rate of 1ml / minute in acetonitrile / water mobile phase (gradient). A Finnigan MAT TSQ 7000 triple quadrupole mass spectrometer has been employed in APCI mode of positive polarity. 25eV and 35eV ion source voltages were used for 'soft' and 'hard' ionisation respectively. Collision energies of 30eV argon were used for MS-MS experiments. Field desorption data was obtained on a VG Organic ZAB2 SE double focussing mass spectrometer.

RESULTS

Figure 1 displays the mass chromatograms of eluting oligomers ionised by APCI in positive polarity in the presence of traces of ammonium salt. All have been ionised as $M + NH_4^+$. Collision induced dissociation under conditions *described has resulted in MS-MS of each cyclic oligomer, illustrated by the* case of pentamer in Figure 2 . A major loss of 576 Da is observed, indicative of a cyclic trimer neutral. A cyclic trimer loss has been observed consistently for all cyclic PET structures studied where n > 3. This mechanism for dissociation, ie. ejection of a cyclic neutral by a cyclic oligomer of PET has not been previously reported.

LC-MS Characterisation of a Surfactant Complex Mixture

Hilary Yates, Jim Scrivens, Julie Hedley
ICI Wilton Research Centre, PO Box No 90, Wilton, Cleveland, England

INTRODUCTION

Atmospheric Pressure Ionisation has recently emerged as a widely applicable mass spectrometric interface to liquid chromatography. The combination of the LC separation with the specificity and sensitivity of mass spectrometry has proven an invaluble tool in the analysis of industrial complex mixtures. One successful illustration has involved the analysis of Alkyl Polyglycosides (APG) which are a range of surfactants derived from sugar and natural alcohol which are currently being investigated as a 'green' alternative to the traditional non-renewable resource formulations. The exact composition of the final APG product is dependent on alcohol type, feedstock ratios and exact processing conditions, with the resulting product in all cases being extremely complex.

EXPERIMENTAL

A Spherisorb S50DS2, 250x4.6mm column has been used for introduction of the mixture to the mass spectrometer at a flow rate of 1ml / minute in acetonitrile / water mobile phase (gradient). A VG Organic Quattro triple quadrupole has been employed in negative ESI mode. Comparitive results have been obtained by positive APCI in the presence of traces of ammonia 30 and 50eV ion source voltages were used for 'soft' ionisation and source induced fragmentation respectively. Collision energies of 30eV argon were used for MS-MS experiments. Off-line LC detection employed a Varex 11a light scattering detector.

RESULTS

By negative ESI, ionisation was found to occur by loss of hydrogen, ie $(M-H)^-$ with subsequent loss of water. This water loss was not however observed under 'soft' conditions in the case of the mono glycoside. The equivalent observation was made when ionisation was carried out under positive APCI mode with ammonium salt added to encourage cation attachment. Increased sensitivity was also observed in the presence of ammonium. The mass chromatograms obtained under the latter conditions for the alkylated components are displayed in Figure 1. The deconvolution of oligomers and isomers for both the alkylated and saccharide product has revealed previously undetected coelutions which have been critical to quantitative specification of final products.

MASS SPECTROMETRY OF POLYOXYALKYLENE BLOCK COPOLYMER SURFACTANTS

H.T. Kalinoski*[1], L.O. Hargiss[1], B.J. Shay[1] and P.J.W. Schuyl[2]
[1]Unilever Research US 45 River Road Edgewater NJ 07020 USA
[2]Unilever Research Laboratory Vlaardingen The Netherlands

Block copolymers of ethylene oxide (EO) and propylene oxide (PO) possess properties of both polymers and surfactants. Through modification of molecular weight, block size and EO/PO ratio, the physical and surfactant properties of mixtures can be tailored to meet a range of requirements. This has led to a great variety of applications and commercial products containing these materials. Complete characterization of surfactant mixtures requires detailed information on chemical and molecular structure of components. A number of analytical and spectroscopic techniques are applied in the characterization of EO/PO block copolymers (1), but the use of mass spectrometry has been limited by the average molecular weights (up to 15,000 Daltons) and low volatility of these surfactants. The development of electrospray ionization (ESI)(2) and MALDI-TOF (3) mass spectrometry present new opportunities for surfactant characterization.

Size exclusion chromatography (SEC) provides a powerful approach for the determination of average molecular weights and molecular weight distributions of polymer mixtures (1). Unfortunately SEC determinations generally utilize standards of known molecular weight and composition (as similar to the analyte mixture as possible) for molecular weight and composition assignments. Such standard materials are uncommon for copolymers such as the EO/PO surfactants. As separation in SEC is determined by molecular size in solution, the technique is more reliable for larger, higher molecular weight materials. EO/PO block copolymers are small by conventional SEC standards. The situation for EO/PO copolymers is further complicated by the fact that they are surfactants, with hydrophilic and hydrophobic portions on the same molecule. This can lead to aggregation and micelle formation, increasing apparent size in solution and confounding efforts to produce meaningful SEC data.

For these reasons, mass spectral techniques based on ESI and MALDI were examined to augment the amount and type of information available from more traditional polymer characterization techniques. The techniques both offer the possibility of coupling to SEC (4,5) either on- or off-line. The conditions required to obtain useful information from a series of representative EO/PO copolymer surfactants were evaluated. The parameters influencing each technique were probed and the appearance of the resulting mass spectra examined. Directions for future work with these techniques for such complex mixtures are suggested.

Both ESI and MALDI-TOF are directly applicable to the mixture and structural characterization of EO/PO block copolymer surfactants. In both cases, cationization with sodium is the primary source of ions present in mass spectra. Mixtures of different composition and molecular structure can be distinguished from one another using either technique. Due to spectral complexity at higher sample average molecular weights, MALDI-TOF may be more applicable to the characterization of higher molecular weight (over 3000 Daltons) mixtures. Calculations of mixture average molecular weights can be made from mass and intensity data produced in electrospray mass spectrometry, with good agreement to expected values. Both singly- and doubly-charged ions can be used in these calculations. It may be that higher molecular weight EO/PO copolymers are more likely to attach two sodium ions, yielding more representative mass spectra and better determinations of average molecular weights. This is similar to results found in work on homopolymers (6). Conditions used for ESI should be applicable to coupling with SEC, to increase the amount of information available from both techniques for EO/PO copolymer surfactants. Lower sample concentrations should be used to obtain best size exclusion. Sample preparation has a profound effect on the appearance of MALDI-TOF mass spectra of EO/PO surfactants. Further work is planned to examine the causes and implications of sample preparation.

DIFFUSION OF ARGON IN POLYIMIDE AND ITS CARBON FIBER LAMINATES *

Michael A. Grayson, McDonnell Douglas Corporation, St Louis MO 63166

The diffusion of argon in neat and carbon fiber laminates of a thermoplastic polyimide was determined by precision abrasion mass spectrometry (PAMS) (Ref 1). In this method, samples that have been exposed to the diffusing species in a controlled environment are periodically removed and loaded into the PAMS apparatus mounted on the ion source housing of a time-of-flight mass spectrometer. The measurement is accomplished by drilling a hole through the sample with an end mill while continuously recording an ion characteristic of the diffusing species and the position of the tool in the sample. The distribution profiles thus obtained can be mathematically fitted with a solution to Fick's law, thereby permitting determination of diffusion coefficients. Sample coupons approximately 3 by 12 by 25 mm were cut from panels of the neat resin, $[90°]_{8S}$ uniaxial, $[+15°/-15°]_{4S}$ cross-ply, and $[+45°/0°/-45°/90°]_{2S}$ quasi-isotropic laminates and dried to constant weight. The samples were placed in special vessels that could be evacuated and back-filled with argon. The vessels were placed in ovens at four different temperatures in the range of 45 to 120°C. At selected times, a coupon was removed from the argon atmosphere and the distribution profile of argon through the thickness of the sample was measured by PAMS. Several measurements were made in each sample and the results deconvoluted, averaged together, and folded about the midpoint. It should be noted that this method of determining the diffusion coefficient does not need to be corrected for edge effects. This is because the holes are drilled in the samples at a sufficiently large distance from the edge that edgewise diffusion of argon cannot affect the distribution profile at the point of measurement. The diffusion coefficient was calculated by using a least-squares fit of a series solution of Fick's law to the measured distribution profile. The value of diffusion coefficient that gives the best fit to the experimental data is taken as the diffusion coefficient for the sample under those conditions of temperature, exposure time, and sample thickness. In theory, for a given exposure temperature, the value of the diffusion coefficient should be invariant with exposure time. Therefore, the various experimentally determined values at different times at one temperature can be averaged together to obtain the diffusion coefficient. A typical distribution profile of argon in the $[+45°/0°/-45°/90°]_{2S}$ carbon fiber polyimide laminate after it was exposed to one atmosphere of argon for 70 hours at 120°C is shown in Figure 1. It is a composite of three separate holes that have been averaged together and folded about the mid-point. Note that the measured concentration is not shown near the surface of the laminate. As soon as the laminate is removed from the argon atmosphere, desorption of argon commences. In the time it takes to remove the sample from the argon atmosphere, load it into the mass spectrometer, evacuate the instrument, and stabilize the operation of the mass spectrometer; the initial 0.25 mm of the surface of the laminate has developed a concentration profile that reflects desorption of argon. These experiments were performed on a variety of material forms to compare experimental results with previous theoretical calculations of the diffusion coefficient in materials with and without reinforcing carbon fibers (Ref 2). In addition, this approach will serve to reveal any anomalous behavior of diffusion in the laminates. According to Shen and Springer, (Ref 2) the diffusion coefficient of a laminate can be calculated based on knowledge of the diffusion coefficient in the neat resin and the volume fraction of carbon fibers according to the relation:

$$D_n = \left(1 - 2\sqrt{V_f / \pi}\right) D_r \,. \qquad \text{Eqn. 1}$$

Where: D_n is the diffusion coefficient normal to the plane of the fibers in a laminate;
D_r is the diffusion coefficient in neat resin;
V_f is the volume fraction of fibers in the laminate.

One can see that as the volume fraction of fibers increases from 0 to 1, the value of D_n will decrease from D_r to a small number. Typically, laminates of the type in this study have fiber volume fractions on the order of a half. According to Eqn 1, the diffusion coefficient normal to the plane of the fibers should be approximately 20% of the diffusion coefficient in the neat resin for all laminates irrespective of layup. The results of the diffusion coefficient measurements are shown in the Arrhenius plot in Figure 2. Note that all of the material forms have about the same activation energy for diffusion of argon, 43kJ/mol, as evidenced by the nearly constant slopes of the lines fit to the data. However, the laminates have lower diffusion coefficients compared to the neat resin. In theory, all of the laminates have the same volume fraction of fiber, so the rate lines for the diffusion coefficient should be shifted down by the same amount. Shen and Springer's prediction based on a volume fraction of fiber of 0.5 is shown as the bold line close to the experimental data for the quasi-isotropic laminate. There is enough data from these measurements to indicate that there is a statistically significant difference in the diffusion of argon in the quasi-isotropic laminate compared to the uniaxial and +/-15° layups. Precision abrasion mass spectrometry was used to measure the diffusion coefficient of argon in neat polyimide and several of its laminates of different layups. The values of diffusion coefficient are in the range normally expected for gas diffusion in polymers. The shift to lower values of diffusion coefficients in the laminate forms follows Shen and Springer's theoretical prediction. There is an anomaly in the behavior of the quasi-isotropic laminate compared to the other laminates which warrants further study.

THE CHARACTERISATION OF COMMERCIAL LUBRICANT FORMULATIONS

Jim Scrivens, Hilary Yates, Alan Bunn, Paul Tayler, Malcolm Beckett, Mike Taylor, Richard Jennings

ICI Wilton Research Centre, PO Box 90, Wilton, Cleveland, England, TS90 8JE

INTRODUCTION

Modern lubricant formulations are complex mixtures of base esters, antiwear additives, corrosion inhibitors and other modifiers. Their characterisation poses a difficult analytical challenge. A major market for these products is in the replacement of traditional CFC based refrigerants by modern alternatives. Conventional lubricants such as mineral oil are incompatible with the new refrigerants.
Soft ionisation mass spectrometry (CI,LSIMS and FD), coupled with tandem mass spectrometry where required, has been used in conjunction with GC-MS and NMR in order to characterise these formulations. Statistical analysis of the soft ionisation data has provided further information regarding the detailed composition of the complex esters. This combination of experimental approaches provides a powerful method for the characterisation of these materials. A number of different types of polyol are used in the manufacture of the base esters with tetra and hexa esters the most common. The acids used, in general, vary in carbon number and in isomeric distribution and this leads to considerable complexity in the product.

EXPERIMENTAL

Proton and ^{13}C NMR spectra were obtained on JEOL GSX 400 and GX 400 spectrometers. GC-MS results on a VG Organic Trio-1 quadrupole mass spectrometer. The CI, LSIMS and FD soft ionisation spectra were collected using a VG Organic ZAB-T four sector mass spectrometer of BEBE geometry (in two sector mode). The CI spectra were obtained by introducing the sample via a heated probe, programming the temperature, and averaging the resulting spectra. FD spectra were obtained using 13 m activated carbon emitters supplied by Linden ChroMasSpec (Bremen). The emitters were programmed from 0-40 mA, or until the signal disappeared. Product ion mass spectra were also obtained on the ZAB-T using 4000 eV collision energy with argon as collision gas and using an array detector.

RESULTS

Figure 1 shows FD and NH_3 CI spectra for a tetra acid formed from pentaerythritol and a mixture of C8, C9, C10 and C11 aliphatic acids. The agreement between the two methods is very good with the CI data giving the most reproducible results. The FD data however shows fragment peaks at lower mass corresponding to $[RCO]^+$ which makes qualitative identification of the acids present easier. Table 1 shows the results of a statistical analysis of this data which gives a result of 66.9%C8, 17.6% C9, 12.8% C10 and 2.7% C11.

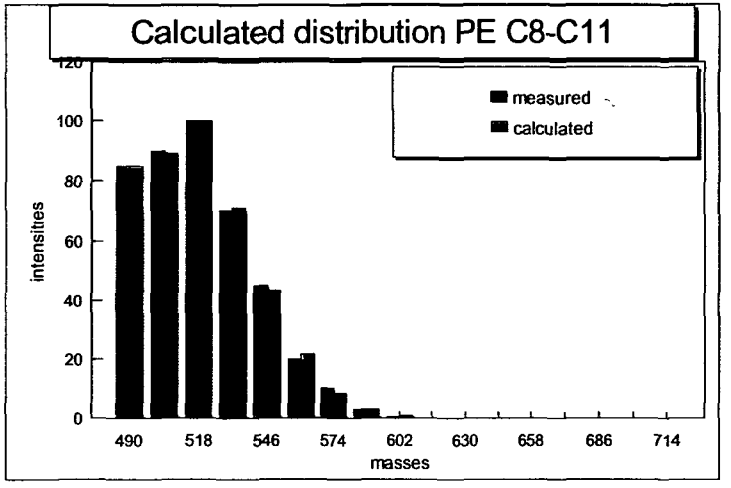

Table 1

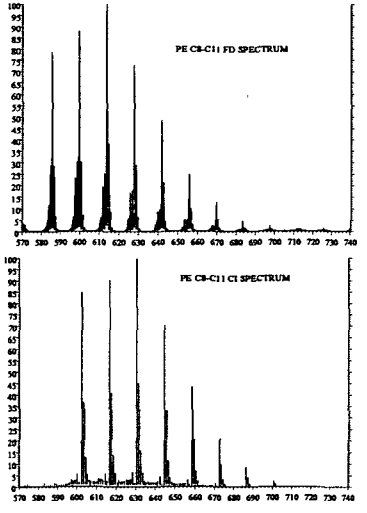

Figure 1

CONCLUSIONS

A combined NMR and MS approach has been used successfully to characterise a series of lubricant formulations. NMR is extremely useful in isomeric differentiation and in identifying polyol and acid type. Both CI and FD ionisation methods give similar results with CI having the edge in reproducibility. Product ion spectra have been used where neccessary to aid interpretation. A statistical approach to the calculation of expected mass spectrometric intensities has been found to give useful results for both tetra and hexa ester systems. Quantitative information regarding carbon number of acid used has been derived. A comparasion of data obtained from tetra and hexa ester can indicate whether a common acid feedstock was used in their manufacture.

IMPACT OF CONVERSION LEVEL ON HYDROCARBON TRANSFORMATION IN FLUID CATALYTIC CRACKING PROCESSES STUDIED BY COMBINED CHROMATOGRAPHY AND MASS SPECTROMETRY

Kuangnan Qian, Robert H. Harding and Xinjin Zhao
W.R. Grace Co.-Conn., Washington Research Center, Columbia, MD 21044

INTRODUCTION

A fundamental understanding of the impact of feedstock properties on catalyst performance and on the molecular transformation in the fluid catalytic cracking (FCC) process has been of great interest to both petroleum and catalyst manufacturers. For the latter, this understanding provides an important guide toward the design and improvement of catalyst structure and formulation to achieve desired product performance. The level of conversion (conversion wt%) is an important measurement of optimized catalyst performance. Combined chromatography separation and mass spectrometry provides an effective tool to study the impact of conversion level on hydrocarbon transformation and to identify the nature of hard-to-crack molecules and their contributions to the bottoms yield.

EXPERIMENTAL

The feed selected for this study is a low sulfur (0.3%) petroleum fraction (450°F+). The feedstock was cracked by an FCC catalyst in a Riser unit at two different conversion levels (73.6% (Run A) and 67.1% (Run B), respectively). The heavy cycle oil (HCO or bottoms) and the light cycle oil (LCO) from the two different conversions, together with the feed, were characterized by combined clay-gel elution chromatography (ASTM D2007) and mass spectrometry. The oil samples were separated by clay-gel into saturates, aromatics, polars and asphaltenes. The saturate and aromatic fractions were analyzed on a Finnigan TSQ 700 mass spectrometer equipped with a Varian 3400 GC. The mass spectrometric data of the two fractions were processed using group-type methods as described in ASTM D2786 and D3289. The polar fraction was analyzed by low voltage (12 eV) probe mass spectrometry.

RESULTS AND DISCUSSION

Analyses of the LCO products from the two different conversions showed that alkyl naphthalenes are the most abundant species in the LCOs, followed by paraffins, alkyl benzenes and 1-4 ring naphthenes. The increase in conversion results in significant reduction of paraffins, particularly the iso-paraffins, but has no impact on the concentration of aromatic molecules. The results indicate that the LCO yield is strongly affected by the total concentration of di-aromatics in the feed.

Analyses of the bottoms from the two different conversions showed that tri- and tetra-aromatics are the major hydrocarbon types in the bottoms (Figure 1). The higher conversion increases the concentration of heptane-insolubles by 38%, suggesting the formation of highly condensed hydrocarbon structures by the FCC process. The increase in conversion has the most impact on saturate hydrocarbons (more than 50% reduction). Compared to the feed, significant reductions of mono- and di-aromatics were observed, mostly due to the cleavage of the long chain aromatics into short chain benzenes (gasoline) and naphthalenes (LCO). It is interesting to note that the concentrations of 3+ ring aromatics in the bottoms are as high as that in the feed, suggesting that the bottoms yield is closely related to the total concentration of 3+ ring aromatics in the feed.

The impact of conversion level can be measured by the relative change (RC%) in concentration of a chemical component at the two conversions: RC% = (Run B -Run A)/Run A × 100. As shown in Figure 2, the impact of conversion level decreases sharply as the aromatic type changes from mono-aromatics to tri-aromatics and changes very slowly afterwards. Note that the higher conversion actually

increases the concentrations of the "core" aromatics (phenanthrenes, pyrenes, benzopyrenes, etc.) in the bottoms. The aromatics in the bottoms are found primarily to be methyl/ethyl substituted species.

The analyses also show that the conversion level has little impact on the aromatic sulfurs.

Benzocarbazoles were found to be the predominant nitrogen compounds in the bottoms. Overall, the catalytic cracking reduces all nitrogen compound types in the bottoms, particularly the carbazoles. The fact that we did not detect a significant amount of carbazoles in the LCO fractions suggests that most of the short-chain carbazoles have been absorbed by the catalyst and are converted into part of the coke.

Quantitative Analysis of Reformulated Gasoline by Mass Spectrometry

D. Drinkwater and V. Nero
Texaco Research and Development
P.O. Box 509
Beacon, NY 12508

Reformulated gasoline (RFG) is a new product offered in the United States since January 1, 1995 in an effort by the EPA to meet the Clean Air Act. RFG is a highly-designed product with tight specifications for aromatics, benzene, oxygenate content, distillation properties, sulfur content, toxics content, and vapor pressure. Because of all the new regulatory requirements on this product, a number of new analytical techniques have been specified for its analysis, including GC/MS for total aromatics,. Data from the EPA and proposed ASTM methods for RFG analysis are presented, along with data suggesting a number of extensions and improvements on these methods. The accuracy and precision of these methods are evaluated

The use of micro-bore and mini-bore capillary GC columns for quantitative analysis provides a number of advantages over conventional capillary columns In addition to the decreased elution time provided by the more efficient separation, the decreased capacity of these columns may be used to increase the dynamic range of the mass spectrometer, thus improving calibration linearity and accuracy The smaller inside surface area and shorter length of these columns leads to a much reduced phase bleed level in the ion source, lengthening the time between ion source cleanings and, therefore, instrument recalibration. The decreased gas flow through the narrow-bore columns greatly improves the gas load into the ion source, as well as simplifying the running of these columns at high split ratios for neat samples such as gasolines.

The extension of the GC/MS method for total aromatics to report other RFG regulated parameters such as benzene and oxygenate concentrations is particularly important for refinery laboratories with limited space, manpower, and time resources Data is presented comparing GC/MS results on benzene and oxygenates with the mandated analysis techniques, both measured in a refinery setting by refinery personnel. The high precision and accuracy of the mass spectrometry data suggests that the mandated GC/MS method can replace both the benzene and oxygenate analyses which are currently mandated by GC methods, thus replacing three instruments and analyses with one

Figure I. shows a partial reconstructed m/z 120 ion chromatogram of the C9H12 isomers using the fast chromatography method (20m x 0 10mm ID x 0 4 um DB1 column, 0.1 second scans m/z 70-170). Figure II. shows the agreement between benzene concentration in gasolines by Method D3606 and GC/MS measured at four different laboratories (including refinery data measured by newly trained personnel).

Characterization of Acidic Components in Midway Sunset Crude Oil

George W. Haas, Leroy Ellis, Jerry E. Hunt, and Randall E. Winans

Chemistry Division, Argonne National Laboratory, Argonne, IL 60439

The crude oil from the Midway Sunset Field in California contains 70% non-distillable constituents called resid. Analysis of Midway Sunset crude components using standard analytical techniques such as GC and GC-MS is difficult due to the complex and intractable nature of the resid. Acidic components in crudes are of importance because the presence of these compounds results in problems related to pipe corrosion and waste-water contamination. Detailed characterization of the acidic components of Midway Sunset crude using high-resolution electron impact (HREI) and chemical ionization (HRCI) mass spectrometry have been undertaken.

Experimental

The Midway Sunset crude was subjected to an analytical separation involving six steps. 1). Extraction of the acidic components with sodium hydroxide/methanol. 2). Back extraction of nonacidic components with *n*-hexane. 3). The base extract was then filtered and centrifuged to remove precipitated asphaltenes. 4). The acid extract (3.5% w/w) was chilled for 24 hours at ≈-20 °C, resulting in precipitation of some species. 5). The acid extract, referred to as Fraction A, was decanted from the precipitate. 6). Acidic Fraction A was then methylated using diazomethane in methylene chloride before analysis.

The GC-MS run was acquired with a Hewlett Packard 5970 MSD fitted to a 5890 Series II GC. A fused silica capillary column (DB-5 MS) of 60 m in length with an ID of 0.25 mm was employed with oven conditions of 50 to 300 °C at 4 °C/min.

The full-scan HREIMS and HRCIMS data were acquired with a Kratos MS50TC triple analyzer mass spectrometer of EBE design. The results for all of these experiments were obtained at ≈12k dynamic resolution at a scan rate of 10 s/decade. The ionization energy for the HREI experiments was ≈70 eV using high-boiling perflurokerosene (PFK) as the internal calibrant. The reagent gas used for the HRCI experiments was isobutane with poly-(dimethylsiloxane)-methyl terminated (MW 770) as the internal calibrant. A direct-insertion probe was used to vaporize the samples into the gas phase with a maximum temperature of ≈400 °C and a source temperature of ≈200 °C.

Results and Conclusions

A GC chromatogram (see **Figure 1**) of the methylated acidic Fraction A shows a broad, unresolved hump. This unresolved complex mixture indicates the presence of a large number of components in the final methylated acidic Fraction A.

The HREI and HRCI mass spectra display a distribution of ions ranging from 100 to ≈500 u (see **Figures 2** and **3**), which is very similar to the GC-MS run. The most striking distinction between the spectra is the distribution of more abundant higher-mass ions in the HRCI mass spectrum as compared to the HREI mass spectrum. This is attributed to the softer CI process. The higher mass components which are observed in the 400 to ≈500 u range for the HREI data, are not seen in the HRCI data. Bar graphs of the mol % vs rings + double bonds calculated from the HREI and HRCI data, indicate less hydrocarbon (HC) content from the HRCI result in comparison to the HREI result (attributed to the softer CI process). A homologous series containing mono-, di-, and trioxygenated compounds are observed by both ionization techniques, which are suggested to represent methylated phenolic and carboxylic acid constituents. Also identified are sulfur and sulfur-oxygenated containing species along with other

heteroatom constituents. The sulfur-oxygenated series are tentatively identified as thioacid esters. HREIMS and HRCIMS data have been used to provide detailed information on compound classes and carbon numbers.

PYROLYSIS-PHOTOIONIZATION MASS SPECTROMETRY

C.W. Bookwalter, D.L. Zoller and M.V. Johnston
Department of Chemistry and Biochemistry
University of Delaware, Newark DE 19716

Pyrolysis mass spectrometry has been performed by photoionization with coherent vacuum ultraviolet (VUV) radiation. Pyrolysis mass spectra are often difficult to interpret owing to the complex distribution of ions formed Much of this complexity can be ascribed to the heterogeneity of samples typically analyzed or to the numerous reaction pathways accompanying pyrolysis. Indeed, information of this type is often the goal of a pyrolysis experiment. However, fragmentation induced by the ionization process can also be extensive and often obscures useful information. VUV photoionization with 9.6 to 10.5 eV radiation minimizes fragmentation by photoionizing just above the ionization threshold.

The pyrolysis-photoionization technique was used to obtain spectra for n-tetracontane and cholesterol. In a typical 70 eV EI spectrum, n-tetracontane and cholesterol show extensive fragmentation. Figure 1 shows the 10 5 eV photoionization mass spectrum of n-tetracontane with a probe temperature of 375°C. Relatively little fragmentation and an intense molecular ion peak is observed. Cholesterol has a narrow temperature range within which it is stable as a gaseous molecule. However, similar to the n-tetracontane spectrum, little fragmentation and an intense molecular ion peak is observed for cholesterol at 150°C.

The pyrolysis-photoionization technique was then extended to polymer samples. Figure 2 shows the 10.5 eV photoionization mass spectra of a polybutadiene sample (Mw = 450,000) at two different temperatures. With probe temperatures between 325-400°C, the relative intensities of peaks attributed to β(C-C) bond cleavage are more intense than those arising from other pathways. With probe temperatures above 400°C, higher energy process occur and the preference for β-cleavage disappears. Pyrolysis products from a polystyrene oligomer (M_W = 45,000) were also identified using this technique. Polystyrene showed three series of peaks corresponding to different fragmentation pathways for each oligomer.

Different classes of coal have different levels of sulfur and aromatic hydrocarbons. Both Wyodak and Illinois #6 coal samples were analyzed using pyrolysis-photoionization mass spectrometry. A temperature ramp from 100-860°C at 20°C/min in conjunction with 10.5 eV photoionization was used for these experiments. Wyodak is classified as a subituminous coal while Illinois #6 is classified as a highly volatile, class C coal. Wyodak is a younger coal containing more aliphatic chains than Illinois #6. In addition, Wyodak is known to contain less sulfur (<1%) than Illinois #6 (>3%). Both of these differences were reflected in the mass spectra. Wyodak gives peaks in the high m/z range (396, 424, 452...) separated by 28 Da which are not observed in the Illinois #6. This suggests the presence of compounds containing a series of only odd or only even length aliphatic chains. In addition, Illinois #6 contains peaks at m/z 34 (H_2S), 48 (CH_3SH) and 64 (S_2). Wyodak contains some of these peaks (m/z 34 and 48) but with much less overall intensity.

THE ACCURACY OF CHEMICAL TYPE ANALYSIS USING A DYNAMIC BATCH INLET SYSTEM

S. G. Roussis and A. S. Cameron
Imperial Oil, Sarnia Research Centre, Sarnia, Canada, N7T 7M1

Hydrocarbon chemical type analysis by mass spectrometry is a very useful analytical technique that provides information about the chemical composition of petroleum samples. Important industrial processes are based on the results obtained from standard ASTM (American Society for Testing and Materials) mass spectrometric tests. These tests are based on standard 70 eV Electron Ionization experiments that produce highly repeatable and reproducible results. The sample is typically introduced into the mass spectrometer via an inlet system that does not permit any compositional change, partial loss or contamination of the sample in the introduction step. The industry's standard sample introduction system is a large, all-glass heated system that allows the continuous flow of the sample from a large expansion volume (~1L - 2L) to the mass spectrometer via a heated capillary transfer line. Sample introduction is achieved with high temperature glass valves that control the flow of the sample to the mass spectrometer.

A simplified introduction system that allows the dynamic introduction of hydrocarbon samples to a mass spectrometer, consists of a small expansion unit that can be easily installed in the oven of most commercial gas chromatographs. The expansion unit is interfaced to the injection port and to the mass spectrometer via deactivated fused silica tubing. The advantages of the simplified batch system are: (i) transportability, (ii) simplicity, (iii) suitability for automation, (iv) low cost, (v) ease of operation and maintenance. The historical data obtained with the standard ASTM test methods are important, therefore, a critical aspect, prior to the acceptance of the dynamic batch inlet system as the standard sample introduction system, is the accuracy of the results compared to the existing static batch inlet. The present study examines the results obtained with the dynamic batch inlet system compared to the accepted results obtained with the static batch inlet system.

A heated (300°c) large expansion unit (1L) from Brunfeldt Co. (Bartlesville, OK) was used for the static analyses. The samples were introduced into the expansion unit using an ampoule or gallium frit inlet. A schematic of the dynamic inlet is shown in Figure 1. A small expansion unit (2 cc) was installed in the GC oven of an HP GC/MS instrument. All temperatures in the systems were kept at 300 °C. Each sample inlet system was coupled with a 5970 HP MSD mass spectrometer. The 10-800 m/z range was scanned at a rate of 0.5 scans/sec.

Typical standard and in-house modified ASTM test methods were used for the evaluation: ASTM-D2786 (Saturates), ASTM-D3239 (Aromatics), ASTM-D2789 (Naphthas), Middle Distillate and Total Oil Analysis. An example of the repeatability and reproducibility of the new bulb system compared to the static inlet is shown in Table 1, for methods D2786 and D3239. Equivalent repeatability is demonstrated by both systems. No significant difference was observed between the two methods. The reproducibility of the results obtained by the static and dynamic inlets in our lab, is equivalent or better than that of the reference ASTM methods. That is, the results obtained by either inlet system are within the same margins of error as the results obtained by the static system in different labs. Similar results are obtained for the other test methods.

The average absolute difference between the results obtained with the dynamic and static sample introduction methods was less than 1.5% (Fig. 2). An example of the difference of the mean values for ASTM-D3239 is shown in Fig. 3. Comparison of the MS results (D2786, Middle Distillate, Total Oil

tests) and the results obtained by SFC and HPLC methods, showed an average absolute difference of less than 1.5% This demonstrates a very good agreement between the MS and the chromatographic techniques. For such comparisons, the ASTM guidelines should be followed in selecting the proper MS test based on the nature of the sample.

IMPROVING THE REPRODUCIBILITY OF PYROLYSIS MS TECHNIQUES

S. G. Roussis and J. W. Fedora
Imperial Oil, Sarnia Research Center, Sarnia, Canada, N7T 7M1

The analysis of the majority of volatile samples is primarily accomplished with established techniques (EI, CI). These techniques are based on the direct vapourization of the sample, upon heating, in the ionization source of a mass spectrometer. Typical analytical techniques, able to analyze non-volatile samples are those that allow the desorption of components from the solid or liquid phase directly to the gas phase. Field Desorption (FD) and Desorption Chemical Ionization (DCI) are two of these techniques. Fast Atom Bombardment (FAB) has been more successful in analyzing polar samples than non-volatile hydrocarbon samples. Limited information is available for the capabilities of the newer ionization techniques (Electrospray Ionization, ESI; Matrix Assisted Laser Desorption Ionization, MALDI) to characterize the non-volatile hydrocarbon samples. ESI of mixtures of compounds produces complex mass spectra, consisting of multiply charged ion species, that may be difficult to interpret. MALDI has the potential for ionization of non-volatile hydrocarbon samples, but extensive research is required to determine the appropriate matrix compounds that will permit the unbiased desorption of all sample components. An important requirement in the characterization of the non-volatile samples using direct desorption techniques without prior chromatographic separation, is the use of ultra high resolution (>50,000), for the separation of high molecular weight isobaric peaks.

In the past, pyrolysis techniques have been used for the analysis of non-volatile samples. Pyrolysis techniques supply enough thermal energy to cause bond rupture. Hydrocarbon macromolecules with very high molecular weights are thus broken into smaller parts that are volatile enough to be analyzed by standard 70 eV Electron Ionization. This approach is very useful when *molecular weight distribution information is not required. The major problem with pyrolysis techniques* is the difficulty in generating reproducible results. In the present work, the experimental parameters affecting reproducibility have been studied, and optimum conditions have been determined that permit reproducible analysis.

A pyrolysis unit (Thermex, Ruska, Houston TX) coupled, via a heated transfer line, to a Hewlett Packard 5971 GC/MS system, was used for the experiments. The sample was weighed into a fritted quartz ampoule and was placed into a temperature programmable pyrocell. The vapourized material was swept through the heated transfer line to the head of the GC column, where it was cold trapped. The pyrolysis step was followed by conventional 70 eV EI GC/MS analysis. The GC/MS parameters remained fixed throughout the series of experiments. A schematic diagram of the Ruska pyrocell used for these experiments is shown in Figure 1. The effect of several pyrolysis parameters on the reproducibility of pyrolysis was studied using model polymers (i.e. cis-polybutadiene, polyethylene, etc.). The pyrolysis parameters were: (i) pyrolysis temperature, (ii) heating rate, (iii) final pyrolysis time, (iv) interface temperature, (v) purge pressure, and (vi) sample preparation.

The interface temperature, purge pressure, final time and the method of sample preparation affected the total ion current of the mass chromatograms. The percent yield of the monomer was affected by the heating rate and the final pyrolysis time. These two parameters appear to have the most significant effect on the pyrolysis products, for a given pyrolysis temperature. A higher percentage of monomer is produced at faster heating rates and at longer final pyrolysis times. The optimum experimental conditions obtained are presented in Table 1.

The results obtained in this study demonstrate that furnace-pyrolysis GC/MS can be used reproducibly for the analysis of polymers. Repeat analyses of cis-polybutadiene performed on different

dates are shown in Fig. 2. Optimum furnace-pyrolysis conditions were determined that are independent of the sample preparation method (Table 2). The % standard deviation of the method, at optimum conditions was found to be less than 8%.

Analysis of Pyrolysis Residues from Poly(vinyl alcohol)

R. T. Pogue, K. L. Ackley and V. Majidi
University of Kentucky, Department of Chemistry,
Lexington, KY, USA 40506

INTRODUCTION

Homes, automobiles, clothes and other necessities are all made up, in some part, from polymeric compounds. One problem with this widespread polymer use is that most polymers are flammable. Because of this, polymeric materials can accelerate flame propagation. The result of this accelerated propagation is that the amount of time it takes for flames to consume a structure may be drastically reduced. Non-flammable polymers can provide solutions in many of these cases, however, many of these polymers generate toxic gases at high temperatures. Therefore, personal injury may be caused by inhalation of harmful fumes rather than by the flames. For these reasons, it is important to gain a better understanding of the thermal processes which occur in polymers so that safe materials can be designed and produced.

Most studies investigating the pyrolysis characteristics of polymers focus on the gases evolved from the polymer as temperature is increased. Hyphenated techniques such as thermogravimetric analysis-mass spectrometry (TGA-MS) and thermogravimetric analysis-infra-red spectroscopy (TGA-IR) are used to add qualitative information to the quantitative traces obtained during normal TGA. The intent of our research is to study the residue (or char) which is left after a polymer has been heated. To characterize these chars, we are using laser desorption mass spectrometry (LD-MS). In addition to LD-MS, we have found that collection of the semi-volatile materials evolved from the polymer, and subsequent GC-MS analysis, help to give a more complete explanation of the processes which are taking place. We have chosen a series of poly(vinyl alcohols) (PVA) as the subject of our study because of the widespread use of these compounds and their derivatives.

DISCUSSION

Prior to beginning the bulk of our work, it was determined that TGA and TGA-MS of several PVA's should be conducted to determine if it was appropriate to use a model molecular weight or if full investigation of all molecular weights was necessary. Upon completion of these studies, it was determined that the 78 % hydrolyzed poly(vinyl alcohol), with average MW = 2000 Da, would be a suitable model. Subsequent experiments were carried out using this material.

The TGA traces discussed above were used to determine the appropriate temperatures for charring. Chars were produced by preheating the ceramic furnace and placing a known amount of PVA inside. The polymer was heated for several hours isothermally in order to allow the entire sample to pyrolyze. Laser desorption mass spectrometry of chars created at different furnace temperatures did not produce ions from unmodified PVA.

The literature reports that several low molecular weight compounds have been isolated during the pyrolysis of poly(vinyl alcohol) (1). We have found, however, that GC-MS analysis of the semi-volatile materials collected at different charring temperatures indicates the presence hydrocarbons containing greater than 20 carbon atoms. Results also indicate that the composition of the semi-volatile mixture varies greatly depending upon the temperature at which the char is made.

TPD MS OF CHEMICALLY MODIFIED ULTRAFINE OXIDES

Professor **Valeriy A. Pokrovskiy**
Institute for Surface Chemistry, National Academy of Sciences,
Pr. Nauki 31, 52022 Kiev, UKRAINE

The abilities of modern methods for the study of surface phenomena are strongly limited in the case of dispersed oxide systems. The limitations are caused by the large surface area and by the variety and lability of active sites on the surfaces, i.e. just by those properties which make oxides diverse and promising matrices for technical applications. Very few mass spectrometry studies of molecules bound by the active sites and of reactions in adsorption layer of ultrafine oxides are availiable in the literature [1]. Study of decomposition of different groups bound to ultrafine oxide surfaces caused by heating or by their interaction with particular environment is of interest as such materials are widely used in chemical industry and their stability has a great importance for many applications in material science, medicine biotechnology and agriculture.

EXPERIMENTAL. TPD MS technique has been developed, for the purposes of surface chemistry studies on pyrogenic oxides by analogy with previous works [2,3]. The samples were placed in a quartz-molybdenum tube and evacuated then attached to the ion source of a mass spectrometer MI-1201 (Sumy, Ukraine).

A computer-aided system was used for the automation of experiment and treatment of mass spectrometric data. During the experiments the continuous record was made of selected components of mass spectra simultaneously with the temperature increase controlled by a computer program. The TPDMS information was represented either as a set of mass spectra, or as a set of temperature dependences of mass spectrometric components.

DESORPTION MODELS. For the interpretation of thermograms we assume that desorption equation is as usual

$$d\Theta/dt = -k\Theta^n \qquad [1]$$

where Θ is the surface coverage, n is the reaction order (assumed to be known from experimental data) and the desorption rate is

$$k = k_o \exp(-E_d/k_b T) \qquad [2]$$

where E_d is the activation energy of desorption, and k_o the pre-exponential factor (both parameters considered to be known from experiments). At the initial condition $\Theta_{t=0} = 1$ we have the solutions of Eq [1]

$$\Theta(t) = \exp(-\Phi(t)) \quad \text{for } n = 1$$
$$\Theta(t) = 1/(1+\Phi(t)) \quad \text{for } n = 2 \qquad [3]$$
$$\Theta(t) = 1/(1+2\Phi(t))^{1/2} \quad \text{for } n = 3$$

where

$$\Phi(t) = \int_0^t k\,dt \qquad [4]$$

The desorption rate (which is directly proportional to ion current) from Eqs [3] can be obtained as

$$d\Theta(t)/dt = -k\exp(-\Phi(t)) \quad \text{for } n = 1$$
$$d\Theta(t)/dt = -k/(1+\Phi(t))^2 \quad \text{for } n = 2 \qquad [5]$$
$$d\Theta(t)/dt = -k/(1+2\Phi(t))^{3/2} \quad \text{for } n = 3$$

The Eqs [5] show the typical temperature dependences of ion current, the second-order desorption curve being nearly symmetrical, the first-order curve decreasing faster in the high-temperature side, the converse being true for the third-order process.

DISCUSSION. The main features of samples studied in our experiments are large surface area (hundreds of square meters), amorphous structure and non-porosity of pyrogenic oxide surfaces. The adsorption capacity provides desorption of up to 1% weight the sample. The result is a gain in sensitivity about million in comparison with bulk samples. All the experimental scheme of temperature programmed desorption for ultrafine samples becomes similar to a thermal analysis experiment with mass spectrometry of volatile products of decomposition. This similarity has a fundamental base because surface processes are involved in most of the topochemical reaction models in thermal analysis [4]; on the other hand, typical pictures of thermal decomposition accompanied by multi-channel chemical reactions in adsorption layers were repeatedly observed in our TPD experiments.

Ultraffine oxides show interesting and unexpected effects in thermal desorption and decomposition of surface complexes including phase transitions in adsorption layer. Application of various known multi-parameter models [5] to systems of such a kind has the implicit danger that they provide adjustment to experimental data and foster an illusion of understanding, irrespective of the adequacy of the model [6].

The advantage of our simple approach is that results are obtained in analytical form which facilitates the computer treatment of experimental thermograms.

Thermogravimetric analysis is important to the chemical industry in understanding the weight loss that occurs when a material is heating to a specific temperature under a given environment. However, there is always a missing piece of information in this analysis and that is the composition of the compound involved in the weight loss. To address this problem a Mettler Model TA-1 Thermogravimetric Analyzer (TGA) has been interfaced to a Hewlett-Packard 5970 mass spectrometer (Figure 1). The mass spectrometer (MS) is connected to a Swagelok tee via a 23 cm length of .075 mm ID fused silica capillary tubing which serves as a leak into the MS A 75 cm length of 0.5 mm ID fused silica capillary encased in a resistively heated stainless steel tube serves as a transfer line from the TGA and is also connected to the tee butting against the MS leak capillary. The final leg of the tee is connected to a vacuum pump which is outfitted with a throttle valve which can be used to control the gas flow from the TGA and the gas flow into the MS. The MS is controlled by a Teknivent Vector II data system which runs on a 486 computer operating under an OS-2 based operating system. This Vector II data system has the capability of recording up to 16 analog channels and this feature is used to monitor the temperature (T), weight loss (TG) and differential thermal analysis (DTA) data from the TGA. Having the Vector II data system collecting data from both the MS and the TGA makes it particularly convenient in displaying the data since all the information can be manipulated and displayed with the same data system. In most TGA systems it is common to plot the measured parameters (i.e. weight loss, DTA) versus temperature rather than time as is common in most MS data systems. The conversion of the X-axis from time to temperature in the MS data system was accommodated by the development of a subsystem (PRMTTIME) that reads the temperature channel from the TGA and then uses this information to convert the time axis to a temperature axis. This allows the plotting of the TGA data as well as the MS data versus temperature.

This system has been applied to variety of projects. The most common application is the plotting of weight loss and DTA curves versus various m/z values characteristic of anticipated decomposition products (water, carbon dioxide, carbon monoxide, etc.) as shown in Figure 2 for calcium oxalate. Another application is the identification of unknown compounds evolved during a given temperature regime. The library search feature of the Vector II data system aids in the identification of these compounds A particularly nice feature of coupling the TGA to a data system designed for GC/MS applications is that many of the features for processing chromatography data are applicable to TGA and MS data. As a case in point, the capability to integrate ion current peak areas was used to assess the amount of water retained by a certain polymer system. The Mettler TA-1 accommodated this analysis by being able to handle gram quantities of polymer allowing low levels of absorbed water to be determined. In conclusion, a state of the art data system has been used to combine two pieces of good, but somewhat dated, equipment and has rendered them very useful in resolving a variety of problems confronting the chemical industry.

Improved Performance of a Quadrupole Based Glow Discharge Mass Spectrometer

Robert E. Valiga, Douglas C. Duckworth, David H. Smith
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6375

Introduction

Glow discharge mass spectrometry (GDMS) has experienced most of its commercial success in trace multi-element analysis using sector-based mass spectrometry. In most cases, the mass resolution available with these instruments allows elements of interest to be analyzed, even in the presence of polyatomic interferences (e.g., ArC+, ArN+, ArO+). Because quadrupole mass filters have little more than unit resolution, background equivalent concentrations (BEC's) for many elements can be quite high (1-100 ppm). Because of this, many have discounted quadrupole GDMS as a useful trace analysis technique. In this work, we have explored methods of reducing the polyatomic interferences.

Experimental

A Fisons Gloquad mass spectrometer was used with an argon or a neon discharge gas. The sample used in the experiments was a NIST high purity gold standard.

Results

Initially, analysis of the gold standard was done using argon as the discharge gas. High polyatomic interference peaks were encountered. Evacuation and bake out of the discharge gas delivery system gave only a limited reduction of the interferences. We investigated using background subtraction but discovered that the interferences varied unacceptably over a 5 hour period. We decided to use neon as the discharge gas to see how the interferences generated by it would differ from those of argon. Perhaps some method could be developed to negate interferences by using two discharge gases. The figure and table on the next page show the results of this study. As is evident, the Gloquad was capable of sub-ppm analysis. Following conversations with the getter manufacturer, it was concluded that the most probable cause of improved performance with neon was due to a higher getter temperature, which removed contaminants more efficiently. The higher temperature was the result of neon's higher thermal conductivity. The effects of contaminants in the discharge gas have been studied by others. However, the high purity (sub-ppb to low ppb) discharge gas required to effectively eliminate the interferences has not been previously achieved. We have designed and ordered a high purity discharge gas delivery system for use on the Gloquad.

Conclusions

High purity discharge gas is required to significantly reduce polyatomic interferences in GDMS. It is anticipated that we will be able to demonstrate sub-ppm quantification capabilities in quadrupole GDMS with the new high purity discharge gas system.

ELEMENTAL QUANTIFICATION BASED ON SECONDARY SPECIES IN THE GLOW DISCHARGE

Goodner, Kevin L.; Eyler, John R.; University of Florida, Gainesville, FL 32611-7200
Barshick, C. M.; Smith, David H.; Oak Ridge National Laboratory, Oak Ridge, TN 37831-6375

Introduction. A barrier to absolute quantification in glow discharge MS, as in other types of inorganic MS, is the presence of polyatomic interferences. While it is possible to suppress, eliminate, or discriminate against these interferences, we took a different route. Instead of trying to correct for these interferences, we used the "interferences" to quantify the metal concentration. By quantifying the argides (MAr^+), dimers (M_2^+), and doubly charged species (M^{+2}) of our analyte (which were not interfered with), we were able to achieve equal or better accuracy and precision than when we use the M^+ [1].

Experimental. A VG-9000 reverse geometry Nier-Johnson double focusing glow discharge mass spectrometer was used in these experiments. For optimization of the method, NIST aluminum SRMs 601, 602, 603, and 604 were used. For testing of the method on an unknown, NIST SRMs 644 and 1190 were used as standard and unknown, respectively.

Results. Before performing any experiments, we characterized the possible test species at constant pressure and power. All of these species behave in a similar manner, increasing with increasing power, at constant pressure. Since the concentrations of these ions ultimately depend on the corresponding metal atom density, these results can be attributed to the increase in sputter atomization that accompanies either the increased current (incident number of ions) or increased voltage (incident ion energy), or both. Magnesium oxide, aluminum oxide, and copper oxide all mirror the oxygen ion signal, but titanium oxide behaves differently. Since titanium is among the more aggressive oxygen getters, it competes more favorably for the relatively scarce oxygen atoms than the other metals; hence the TiO signal is correspondingly higher. As the power increases, the other metals can compete more favorably for the oxygen. At constant power, two different trends are observed, that of the singly-charged metal ions and that of the other test species. It has been shown by Hess et al. that metal ions mirror the argon metastable population, increasing to a maximum and then decreasing with increasing pressure. This is the trend seen for the M^+, but not the other species. As pressure increases the voltage decreases and with it the atom density.

As seen in Table 1, the M^+ species gave excellent accuracy (<5% relative error), due to lack of interferences and high concentrations of the analyte. The average errors found using MAr^+ and M^{+2} were around 15%, except for Cu^{+2}, where the error is much higher (due to its higher second ionization potential). The errors associated with the dimers averaged ca. 40% relative error, due to species interfering with the dimers. However, this will not always be the case. Table 2 shows molybdenum concentrations obtained using species containing $^{95}Mo^+$ and $^{96}Mo^+$. Using these doubly-charged and molecular species, a 15% relative error was found, compared to the 24% relative error found when $^{95}Mo^+$ and $^{96}Mo^+$ were used. This confirms the usefulness of this approach. The error associated with using all the molybdenum isotopes versus the ^{95}Mo and ^{96}Mo (52% versus 24%) suggests that these two isotopes were interfered to a lesser extent than the others.

Conclusions. Metal argides, metal dimers, and doubly-charged metal ions have been shown to be useful for quantification when the singly-charged analyte is obscured by interference peaks. This technique gives reasonable accuracy (ca. 15% relative error) for elemental compositions approximately 0.1% or greater of the sample. While this technique should be used with caution, we have demonstrated that it gives the analyst a viable alternative in those cases where it is impossible to address interferences in other ways.

Reduced Mass Range Ion Trap Mass Spectrometry for Atomic Ions

C.J. Barinaga, G.C. Eiden, D.W. Koppenaal
Pacific Northwest Laboratory*
Richland, Washington 99352

P.H. Hemberger
Los Alamos National Laboratory
Los Alamos, New Mexico 87545

In an attempt to apply some of the real and perceived advantages of quadrupole ion trap mass spectrometry to elemental/isotopic mass analysis a prototype Inductively Coupled Plasma-Ion Trap Mass Spectrometer (ICP-ITMS) has been built with a linear quadrupole between the vacuum interface and the ion trap. Initial results (1,2) show some promise for ICP-ITMS to be a useful technique. However two limitations are the charge capacity and dynamic range of the standard Finnigan ITMS.

The mass range for the standard ITMS is approximately 640 m/z which exceeds the range needed to cover the atomic ions of elemental and isotopic analysis. If one keeps the RF voltage, RF frequency, and the q_{eject} the same then the controlling equation

$$m/z = 4\,V \,/\, q_{eject}\, r_o^2\, w^2$$

indicates that decreasing the mass range to one half (~315 m/z, covering the entire elemental range) would require a trap of radius r_o=1.44. The larger trap should be able to accomodate a greater number of ions before experiencing significant space charge effects. Given the same number of acquisition channels and scan rate (channels/sec) the reduced mass range should also enable greater mass scale resolution.

A 1.44 r_o trap was designed and machined at LANL for PNL based on the Finnigan ITD trap electrodes. Utilizing the standard ITMS ceramic spacer/insulators, l = 0.180", an "unstretched" trap is produced. One of these traps has recently been installed in PNL's ICP-Q_L-Q_T (ICP-ITMS).

This first report of a larger than standard trap applied to atomic ions will show some very preliminary data based on brief operational experience. Initial indications are that the characteristics of the ICP-ITMS with standard trap apply to the large trap also. These include a significantly attenuated argon ion beam and an absence of plasma and sample matrix polyatomic ions. Reasonable initial mass spectra were obtained with the 1.44 r_o trap (see Figure 1). It appears that more ions (and 44% bigger ions!) can be injected before noticable space charge effects (i.e., peak degradation) occur. Although ions appear at approximately twice their m/z, consistent with the above equation and the data system, the resolution to date appears no better than the standard trap.

Future work will be directed to more completely characterize this enlarged trap for elemental/isotopic applications in regard to space charge limits and effects, ion injection efficiency, mass resolution, and analytical utility.

Reducing Energy Dispersion in Plasma-Source Sector-Field Mass Spectrometry

Thomas W. Burgoyne, Gary M. Hieftje, and Ronald A. Hites
Department of Chemistry and School of Public and Environmental Affairs,
Indiana University, Bloomington, IN 47405

Introduction

Energy dispersion is a critical component of focusing in sector-field mass spectrometry. One method of accelerating the ion beam in plasma-source, sector-field mass spectrometry is to float the source and to set the desired accelerating potential on the sampling plate. Although studies have been conducted with the interface floated at a few tens of volts, little is known about the beam energy and beam-energy dispersion when the sampler is set at higher potentials. Beam-energy measurements were made on a sector-field plasma-source interface of an inductively coupled plasma that will soon be used with a Mattauch-Herzog mass spectrograph.

Methods

Ions are accelerated by setting the first vacuum stage to the accelerating potential. To eliminate unwanted discharge, the first-stage roughing pump operates at the first stage potential and a capacitor couples the sampling plate to the torch housing (this capacitor is not needed when a "torch shield" is used).

An energy-analyzing Faraday cup measures the beam energy roughly 20 cm down from the third-stage orifice. A voltage (which we will call the stopping potential) on a grid in front of the Faraday cup was ramped and the ion signal was measured as a function of the stopping potential. The average beam energy and energy dispersion (measured at FWHM) were calculated from the derivative of the signal versus grid stopping potential curve.

During all of the ion beam energy measurements, the forward RF power was maintained at 1.35 kW, with the reflected power less than 5 W. The outer, intermediate, and central-channel argon flow rates were 14, 1.06, and 1.00 L/min, respectively. The first, second, and third stage vacuum regions were 0.8, 1×10^{-4}, and 1×10^{-6} torr, respectively. An average scan length was 70 sec. Deionized water was introduced at 1 mL/min and ion optics were grounded unless needed to boost signal levels.

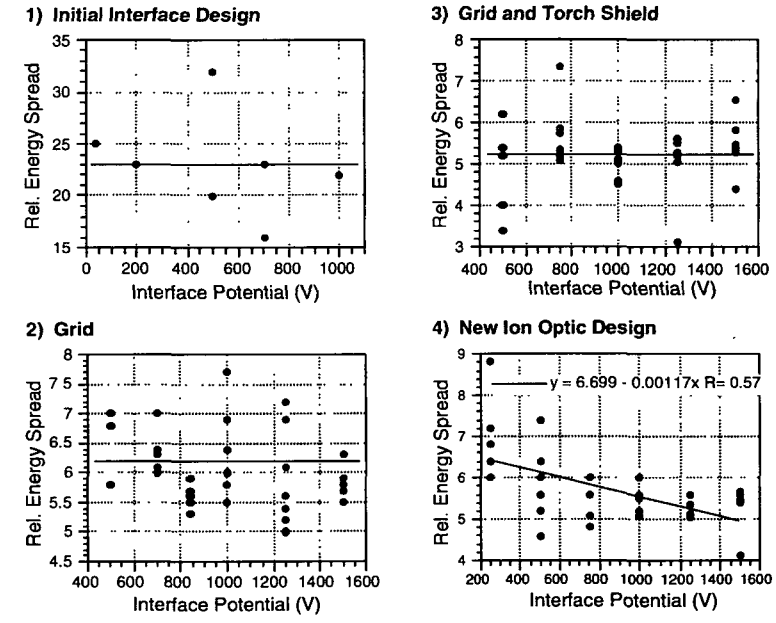
The beam energy was measured under four different instrument configurations: 1) Measurements were first performed with the initial instrumental design. 2) A grid was placed behind the skimmer (roughly 1 cm from the third-stage orifice). This grid was hypothesized to provide a shorter and more uniform accelerating region in the second stage. 3) A torch shield was installed to eliminate an orifice-linked discharge. The grid behind the skimmer was in place during this experiment. 4) A new ion-optic configuration was designed which consists of a third-stage orifice roughly 2 cm from the skimmer orifice followed by a linear acceleration region. The ion lenses consist of an einzel lens followed by a quadrupole doublet.

Results

The results are best represented as plots of the relative energy spread versus the interface potential (see graphs below). The initial interface arrangement (Graph 1) resulted in a 23 ± 5% energy spread. Adding a screen behind the skimmer (Graph 2) reduced the energy spread dramatically to 6.2 ± 0.63%. Unfortunately, this reduced the signal level as well. Ion simulations demonstrate that fewer ions enter the third stage orifice with the grid in place. Adding a torch shield (grid installed, Graph 3) additionally reduced the energy spread to 5.2 ± 0.78%. The Student's t-test indicated that addition of a torch shield made a statistically significant difference. The new ion optic design reduced the energy spread without sacrificing signal level (Graph 4). More importantly, the energy spread with this new ion optic arrangement is a function of the interface potential. A mass spectral comparison with the initial and new ion optic design also displays the reduced energy dispersion.

Conclusions

The above experiments demonstrate that energy dispersion can be a serious problem in the sector-field mass spectrometer interface. Because the energy spread was independent of the interface potential with the initial design, we assume that the energy dispersion originated from the interface - most probably in the second stage. A likely scenario is that the beam extracted from the second stage has both plasma and ion beam characteristics. Accelerating the "plasma-beam" unevenly over a 5-cm distance (as in the original design) resulted in a very large energy spread. Accelerating more evenly and over a shorter distance (with the grid installed) dramatically reduced the energy spread and the signal level. The addition of a torch shield also helped to reduce the energy spread. Because the torch shield eliminates the orifice-linked discharge, the plasma extracted into the second stage is less dense, and the beam energy is affected accordingly. The newly designed ion optics took into consideration the above experiments. The distance between the second and third stage apertures was decreased (to roughly 2 cm) and the ion beam acceleration takes place in the third vacuum stage over a 5 mm distance. This ion optic arrangement reduced the beam energy spread which, importantly, is now a function of the interface potential.



Insulator Surface Potential Measured by TOF-SIMS

X. Q. Guo and R. T. Short
Oak Ridge National Laboratory, MS6365, Oak Ridge, TN 37831

A technique has been developed to determine the electrostatic surface potential of insulating samples which are subject to analysis by secondary ion mass spectrometry (SIMS). A special three-stage reflectron time-of-flight (TOF) mass spectrometer was used to simultaneously obtain mass spectra and to measure the shifts of TOF peaks resulting from changes in the sample surface potential. The measured shifts were then used to determine the surface potential of insulators and the effectiveness of charge compensation to a precision of a few volts.

Besides the nominal acceleration potential, secondary ions can gain excess energy from surface charging (for insulators) as well as from sputtering processes (initial ion kinetic energy). If the extraction region is small, it is impossible to distinguish whether the excess energy is obtained from the sputtering process or sample charging; once ions enter the flight tube, it is only the total energy of ions which affects the flight time. However, the flight time of ions through the extraction region does depend on where the excess energy comes from, since sputtering is related to initial ion velocities, and sample charging to the acceleration of ions in the extraction region. In "conventional" TOF mass spectrometers used in SIMS, a small extraction region is normally used (typically a few mm), and the kinetic energy distribution of ions can be compensated by use of a reflectron. Thus the shifts of peaks in the spectra when surface potential varies by a few volts are generally negligible. For this reason, in the present experiment the extraction distance was chosen to be large, about 25 mm.

Shifts of flight time due to initial ion energy are of the same order as those due to surface charging. Thus, a method must be used to compensate for initial ion kinetic energy effects while retaining the shifts due to charging. This excludes the use of linear TOF mass spectrometer for such studies. It has been proven both theoretically and experimentally that a three-stage ion mirror with the right ratio of electric field strengths for the second and third stages ($E_3/E_2 = 0.895$ for our apparatus) can compensate flight times of ions with different energies in both the extraction and field-free regions [1]. In Fig. 1. the calculated flight time of ions differs by less than 10 ns for an energy spread of 50 eV, showing good energy compensation. Shifts of peaks due to charging greatly surpass this distribution of flight times. Therefore, the present technique (three-stage ion mirror with large extraction distance) allows us to separate sputtering processes from surface charging, and shifts of TOF peaks can then be related directly to surface charging.

In this experiment, TOF spectra were obtained using various sample potentials by biasing a conducting sample. TOF peak positions and shapes were calculated by folding in secondary ion kinetic energy distributions. Good agreement was achieved between the calculations and the experimental data (see Fig. 2). Next, spectra from insulating samples, such as Teflon and mica, were obtained, using low energy electrons (30 eV) for charge compensation. By varying the electron current, the extent of surface charging was changed, resulting in various shifts of the TOF peak positions. In Fig. 3a, the K ion peak positions as a function of electron current (voltage dial setting) are plotted. By comparing these shifts to those at known sample potentials, the surface potentials were determined as a function of electron current (see Fig. 3b). These results demonstrate that surface potentials can be measured to within a few volts using this technique.

RESONANT LASER ABLATION - THIN FILM AND MULTILAYER ANALYSIS

While most laser ablation mass spectrometry has been performed with fixed frequency lasers operated at high fluxes, there has been recent interest in the use of tunable lasers to enhance the ionization yield of selected components in an analytical sample. Resonant laser ablation (RLA) uses a single tuned to a one- or two-photon resonant transition in the analyte of interest, and performs simultaneous ablation and ionization with modest intensity laser pulses for monitoring specific elements of interest. Recently, Ledingham's group [1-3] and our own [4-5] have begun systematic study of the RLA process on a variety of materials. Advantages of RLA, in addition to the use of a single laser, include: (1) simplification of mass spectra by enhancement of the signal of the analyte of interest, (2) improvement in the absolute detection limits resulting from the enhanced ionization efficiency over non-resonant ionization and (3) improvement in the relative sensitivity as a result of the decrease in the ion signal obtained from other components with the sample.

Depth-resolved information concerning the composition of layered and multilayered structures is important in semiconductor and optical applications. In some instances, dopant and impurity distributions at the ppm and ppb levels may be important for performance. We demonstrate that RLA has potential use in the profiling of thin layer and multilayer structures.

In order to generate tunable light, a XeCl (308 nm) excimer laser was used to pump a dye laser (Coumarin 460). The dye laser produced pulses at 10 Hz which exhibited a 12 nsec pulse duration, pulse energies of 1-5 mJ and a 0 35 cm^{-1} bandwidth (FWHM) The dye laser pulse energies were attenuated to 5-25 μJ/pulse. The samples used were silicon (110) wafers coated with either 20 Å ± 10 Å or 100 Å ± 10 Å of high purity copper (99.9995%).

Constant dye laser irradiation on the sample results first in a rise in the RLA copper signal, followed by a decline, as shown in the Top Figure for 100 Å Cu film on Si (110). The fall in the copper RLA signal is believed to be due to removal of the copper thin film within the region of laser irradiation. For a 20 Å Cu film on Si (110), about 5 times fewer shots on average were observed for exhaustion of the RLA copper signal Ion signals were typically obtained at low laser pulse energy, and material removal rates of the copper were found to increase monotonically with increasing laser fluence (Bottom Figure). For a given laser fluence, the time required to exhaust the signal from a thin film is directly related to the film thickness.

Submicrogram Sensitivity LC-Combustion-IRMS Based On A Moving Belt

Richard J. Caimi and J. Thomas Brenna
Division of Nutritional Sciences
Cornell University
Ithaca, New York

Application of Gas Chromatography-Combustion-IRMS to most biological molecules is difficult due to thermal instability and low volatility. In order to extend CSIA to these molecules, Caimi and Brenna (1993, 1995) developed an interface that coupled liquid sources with high precision combustion IRMS instrumentation. The primary limitation of this interface design was poor sensitivity due at least in part to the inability of the wire transport to capture more than 1% - 3% of the total analyte supplied. In an attempt to improve the sensitivity of the moving transport interface the authors have constructed an interface employing a continuous nichrome belt.

The prototype moving belt interface was constructed using a variable speed DC powered drive motor with a 95:1 gear ratio (Dayton , Chicago USA) operated at 5.75 cm sec^{-1} . A continuous nichrome belt (1.5 mm x 0.08 mm x 115 cm) was used as the transport. This belt first passes through a cleaner furnace (900°C) purged with a parallel flow of O_2 (15 ml min^{-1}) then loops around a pulley and enters an enclosed coating block. In the block, solution containing the analyte of interest is converted into a heated (150°C) pneumatic spray directed at the belt at a 45° angle. Solvent remaining after the coating process is subsequently evaporated as the belt passes through a 12 cm drying oven (200°C) that is purged with He gas (100 ml min^{-1}). Analyte molecules deposited on the belt are then combusted into CO_2 and H_2O in a CuO charged furnace maintained at 850°C. This furnace consists of a quartz tube (~2 mm i.d. x 20 cm) that has two He purge inlets (leading and lagging flows) that are maintained at approximately 30 ml min^{-1}. A third port is used to sample the products of combustion and transfer them to a 10 cm long Nafion™ based water trap. The dried CO_2 remaining is then transferred via a 2 m long x 0.1 mm i.d. fused silica capillary to the ion source of a Finnigan MAT 252 GIRMS instrument operated with a source pressure of 1 x 10^{-6} Torr and an accelerating potential of 8 kV.

An SSI (State College, PA, USA) HPLC pump equipped with a 10 ul injection loop was used as the liquid source. All analyses were performed in the flow injection mode using Optima hexane (Fisher, Pittsburgh, PA, USA) as the carrier solvent at a flow rate of 0.5 ml min^{-1} . Linoleic acid analytical standards of graded isotope ratio were isotopically calibrated prior to LCC-IRMS flow injection analysis by loading 2 mg of standard into 6 mm Vicor tubes containing 200 mg of CuO and 25 mg of Ag flake, evacuating, and baking at 850°C for 3 hours. Standard tubes were then analyzed by conventional dual inlet analysis. Signals for m/z 44, 45, 46 were processed by vendor-supplied software.

Flow injection analysis was used to assess the accuracy and precision of the isotope ratio measurements, the linearity of the isotope ratio versus quantity of analyte, and the linearity of signal area versus quantity of analyte. The accuracy and precision of the isotope ratio measurements were assessed using replicate injections of isotopically calibrated linoleic acid (2.5 ug) standards with graded $^{13}C/^{12}C$ ratios. The linearity of isotope ratio and signal area versus the

quantity of analyte loaded was evaluated using multiple injections of standards containing between 250 ng and 5 ug of natural abundance linoleic acid. All isotope analyses were calibrated versus an internal standard using both the Finnigan ISODAT data system and a commercially available non-linear regression program (Jandel) previously used by Goodman and Brenna to recover isotope ratios in the presence of low signal or poor chromatographic resolution.

The average peak area for the belt interface is 114.5 V s (2.5 ug load) while the previous interface designs yielded peak areas of 2.6 V s, 14.5 V s, and 58.4 V s (50 ug loads). This represents ~ a 40 fold increase in sensitivity attributed to the ability of the belt to capture a larger proportion of the total analyte.

Signal linearity was assessed for analyte loads ranging from 25 ng to 5 ug. At loads significantly higher than 5 ug the m/z 46 Faraday cup saturated. Although injections of as little as 25 ng of analyte yielded signals clearly discernible from baseline noise, peaks could not be accurately detected until the 250 ng level. However, the sensitivity of the interface was shown to be linear (R^2 = 0.9932) over the range of 250 ng to 5 ug.

In previous designs it had been observed that the precision of isotope analyses degraded, and apparent isotope ratio increased below analyte loads of 1ug. Analysis of varying analyte loads in the present system resulted in similar trends. In an attempt to improve the accuracy and precision of the isotopic measurements curve-fit analysis was employed. Attempts to fit peaks with a single peak function yielded poor fits while simultaneously using two peak functions to fit a single peak improved the R^2 values. The best fits (i.e. best R^2) were obtained by fitting each peak with a combination of two Non-linear Chromatography peaks, however data processing with this function is extremely slow. Therefore a combination of two Exponentially Modified Gaussian (EMG) peaks was used. On average Peakfit analysis improved the precision of SD (δ 45) by an average of 0.42 ‰ . The accuracy of the isotope ratios was improved on average 0.5 ‰ by Peakfit analysis, however the accuracy still deviated systematically from the true isotope ratio for both the vendor and Peakfit analyses. Due to the systematic nature of this deviation, simple linear calibration should restore the isotope ratio to the correct value.

Finally, the accuracy and precision of the interface over the natural abundance range was examined . No significant difference was found in the average precision of SD (δ 45) for data analyzed by Peakfit analysis (SD (δ 45) = 0.479) and the vendor supplied software (SD (δ 45) = 0.481). The average accuracy as compared to dual inlet analysis was however improved significantly using Peakfit analysis. The vendor supplied software on average overestimated the δ 45 by 1.624 ‰ while Peakfit analysis on average overestimated the δ 45 by only 1.244 ‰. As observed in the assessment of linearity with varying analyte loads, the isotope ratio varied systematically with varying isotope ratio and therefore simple linear calibration should help restore isotope ratios to the true value.

LC Combustion Interface for High Precision Isotope Ratio Mass Spectrometry

***P. Dobberstein** and W. Brand*, Finnigan MAT, 28197 Bremen, Germany

Since its introduction [1] and commercial realisation [2], GC Combustion Isotope Ratio MS (GCC-IRMS) has generated increasing interest of scientist from different disciplines as for instance organic geochemistry and metabolism research and meanwhile has become a well established technique. The limitation of gas chromatography to less polar, volatile and relatively low molecular weight components is a restriction, which can be overcome by applying a LC combustion technique in place of GC combustion.
Quantitative removal of the solvents, especially in case of organic solvents, prior to the combustion is a prerequisite for obtaining high precision, therefore the moving wire principle [3] is the method of choice.

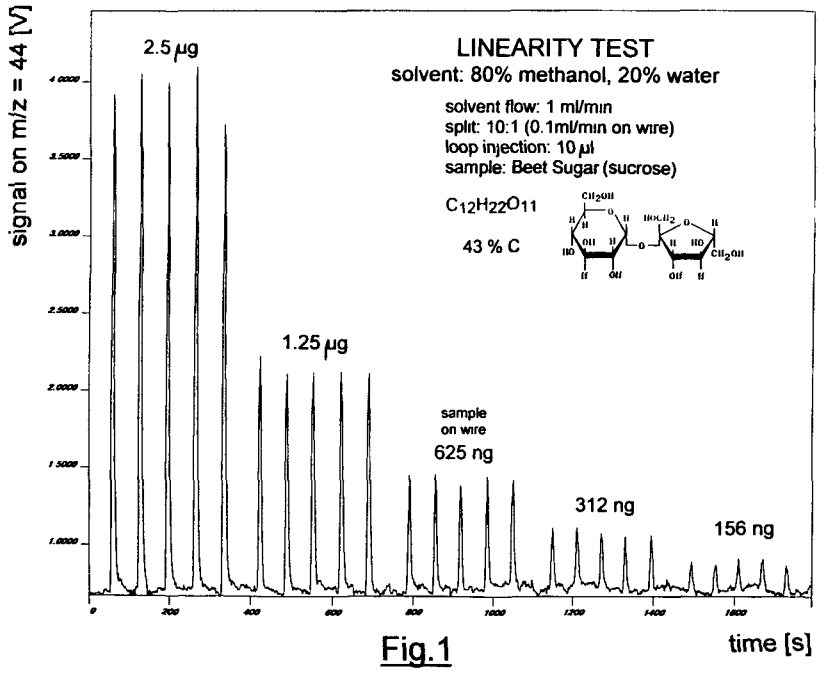

Fig.1

43rd ASMS Conference on Mass Spectrometry and Allied Topics

The HPLC eluent is splitted 10:1 and the remaining flow of typically 0.1 ml/min is contineously deposited on a moving wire (0.25 mm diameter Ni), which then passes a drying stage for solvent removal. The wire afterwards moves into and a combustion oven, where the carbon atoms of the sample deposit are quantitatively converted into CO_2. A He gas stream, passing the combustion oven, carries the CO_2 via a Nafion water trap to an open split interface, where typically 10% of the CO_2 is sniffed via a fused silica capillary into a Delta C isotope ratio ms.
