First measurements have been performed by flow injection of 10 µl of sample solution (**Adenosin** in water or **Beet Sugar** in methanol/water) into the liquid flow of 1 ml/min 100% water or methanol/water prior to the eluent split at sample concentrations between 2.5 µg/µl and 156 ng/µl. In both solvent systems the moving wire interface showed a linear response between signal output at m/z = 44 and sample input (**Fig.1**)
For 2.5 µg **Beet Sugar** deposited on the wire an output signal of 25.7 Vs was obtained; taking into account the sensitivity of the Delta C (1 ion per 2000 molecules) and a split ratio of 10 to 1 at the open split, this corresponds to an overall yield of 20%, which means that 80% of the sample is lost during sample deposition, drying and combustion.

In order to test the capability of the moving wire interface for isotope ratio measurements, we made subsequent loop injections of **Beet** and **Cane Sugar,** both at 2.5 ug/ul in water with the following sequence: 5x Beet, 5x Cane, 5x Beet, 5x Cane.

Calculations of the delta 13-C vs PDB values from this measurement are shown on **Fig.1**. The delta value of Beet Sugar, known from sealed tube combustion to be -26.2‰ was used to calibrate the first data-point; the other values were measured relativ to this value. This result opens the perspective, to distinguisch between natural occuring variations of isotope ratios by LC Combustion IRMS.

OPTICAL SPECTROSCOPY VERSUS MASS SPECTROMETRY: THE RACE FOR FIELDABLE ISOTOPIC ANALYSIS

C.M. Barshick, J.P. Young, R.W. Shaw, D.H. Smith, and J.M. Ramsey
Chemical and Analytical Sciences Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6375

Several techniques have been developed to provide on-site isotopic analyses, including decay-counting and mass spectrometry, as well as methods that rely on the accessibility of optical transitions for isotopic selectivity (e.g., laser-induced fluorescence and optogalvanic spectroscopy). We have been investigating both mass spectrometry and optogalvanic spectroscopy for several years. Although others have considered these techniques for isotopic analysis, we have focussed on the use of a dc glow discharge for atomization and ionization, and a demountable discharge cell for rapid sample exchange. Our goal is a fieldable instrument that provides useful uranium isotope ratio information.

Diode Laser Excited Optogalvanic Spectroscopy

Precision and accuracy have been evaluated for several optical transitions. Samples that were enriched, natural, or depleted in ^{235}U were easily distinguishable from one another (see Table 1). Using a 150 mW diode laser at 832 nm, the measured $^{235}U/(^{235}U + ^{238}U)$ ratio for a depleted uranium oxide sample was improved to 0.0026 from 0.0035 (the value obtained with a 30 mW diode laser at 776 nm); this value is within 3.7% of the thermal ionization mass analysis value. The run-to-run reproducibility was ± 7.8%, an improvement of a factor of two over the 776 nm result. These results are sufficient for many applications where information about the isotopic composition of a sample provides the basis for further investigations. The success of this study has given us the incentive to begin construction of an instrument suitable for field analyses that will incorporate a high power 832 nm diode laser.

Ion Trap Mass Spectrometry

Because the ion trap laboratory was not designed to handle radiological samples, copper was used as a surrogate. Fifty runs of 10 μScans each were averaged to evaluate the precision; five of those trials are shown in Table 2. Although the run-to-run repeatability is better than 5%, there is some concern because the numbers are all biased low. Previous work on a magnetic sector mass spectrometer indicated that there should be no bias associated with the glow discharge, and it therefore may be related to the mass analyzer. Although only presently in the design stages, it is clear that the ion trap will be a powerful field tool because it provides simultaneous isotope ratio and elemental composition information.

Table 1. Optogalvanic data recorded using a 30 mW diode laser at 776 nm

Sample	Optogalvanic Values $^{235}U/(^{235}U + ^{238}U)$	Measurement Precision (percent)	Thermal Ionization Values $^{235}U/(^{235}U + ^{238}U)$
depleted UF_4	0.0034	± 11.6	0.00490 ± 0.00003
natural uranium metal powder	0.0090	± 14.4	0.00716 ± 0.00005

Alumatrane Revisited: Distribution of Oligomeric Ions in EI, CI, and LSIMS

Michael G. Bartlett, Scot A. Burns, David A. Bruce, and Kenneth L. Busch
School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400

The EI mass spectrum agrees with the earlier mass spectrum reported by Lacey and Macdonald with the exception of ions observed in our spectrum at *m/z* 389, 489 and 562. The conclusions of Lacey and Macdonald, *viz.* that this compound is dimeric in the gas phase, is immediately called into question by observation of these higher mass ions. Recently, Pinkas and Verkade reinvestigated the mass spectral behavior of alumatrane, and also report the ion at *m/z* 562 in their EI spectra, although they do not identify it. They do conclude that this ion indicates the presence of the tetrameric form of alumatrane in the gas phase. This conclusion is at variance with our identification of the *m/z* 562 ion as the product of addition of AlO^+ to the trimer. Pinkas and Verkade did not report higher mass ions in their EI mass spectrum, and we do not observe higher mass ions either. The EI mass spectrum of alumatrane does not contain a signal corresponding to the monomer (*m/z* 173) of alumatrane, and only a very weak signal corresponding to the dimer ion (*m/z* 346). The most abundant ions in the mass spectrum correspond to the loss of CH_3COH (*m/z* 302) and loss of CH_2O (*m/z* 315) from the dimer ion. Positive ion chemical ionization mass spectra of alumatrane reveal the presence of the gas-phase dimer ion as $[2M+H]^+$, and additionally as $[2M+NH_4]^+$ with ammonia reagent gas. In the methane and ammonia positive ion CI mass spectra, an ion at $[2M-H]^+$ is observed, representing dehydrogenation of the protonated dimer ion. Such ions are not unknown in positive ion CI, but are relatively uncommon. Their presence here (and in the LSIMS mass spectra to be discussed shortly) indicates that there may be a special stability for such ions. The structure of this ion remains to be established; loss of two hydrogens may occur from methylene groups within a single linkage, or a new bond may be formed between carbons in adjacent linkages. The added proton is conveniently considered to reside on the nitrogen to create a quaternary nitrogen charge localization. Despite evidence in the EI mass spectra for the trimeric form of alumatrane, the positive ion CI mass spectra contain ions only for the dimeric form.

The methane negative ion CI mass spectrum of alumatrane contains both $[2M-H]^-$ and $[2M+H]^-$ ions. Proton addition to form $[2M+H]^+$ in the positive ion mass spectrum is mirrored by hydride addition to form $[2M+H]^-$. There is a small signal for $[4M-H]^-$ in the methane NCI mass spectrum, but no analogous signal for $[4M+H]^-$. The ammonia NCI mass spectrum of alumatrane, in contrast, provides stronger support for the existence of higher order oligomeric ions. The mass spectrum contains abundant signals for the dimeric ion $[2M-H]^-$ at *m/z* 345 and the tetrameric ion $[4M-H]^-$ at *m/z* 691. There are also ammonia adducts associated with both the dimer $[2M+NH_3]^-$ and the tetramer $[4M+NH_3]^-$. This mass spectrum is similar to the ammonia NCI spectrum reported by Pinkas and Verkade with the exception of a higher relative intensity for the peak at *m/z* 389, identified here as $[2M+AlO]^-$ with a relative intensity of 70%. The same peak is present with only a 5% intensity by Pinkas and Verkade, and is not identified in their paper.

The negative ions $[2M+H]^-$, $[2M+NH_3]^-$, and $[4M+NH_3]^-$ are unusual. The $[2M+H]^-$ ion may represent an adduct of two negatively charged molecular ions with a single proton. Support for this formulation is found in the observation of the analogous $[2M+AlO]^-$, in which the AlO^+ replaces the proton. Ions $[2M+NH_3]^-$ and $[4M+NH_3]^-$ are not accompanied by $[3M+NH_3]^-$, although trimeric forms of alumatrane are seen in the electron ionization mass spectrum. The structures of these ions, and the processes through which they are formed, are under study.

Desorption chemical ionization (DCI) differs from chemical ionization in that the sample is placed on a heated filament placed directly in the ion source. The mass spectrum contains ions corresponding to the protonated dimer through the hexamer, appearing as ion pairs $[nM+H]^+$ and $[nM-H]^+$, as in the CI mass spectrum. In addition, the trimer and the pentamer (but not the dimer or the tetramer) produce an ion by addition of AlO. The AlO^+ can formally be considered as a replacement for the proton that would form $[nM+H]^+$, although the lack of reactivity for the dimer and tetramer suggest a different structural end result. Overall, although higher mass ions can be seen in the DCI mass spectrum, the intensities of these ions are low, and no special ion stabilities are evident.

The first unique feature of the LSIMS spectrum is the presence of the ion at *m/z* 174, corresponding to the protonated monomer. An ion for the monomer is not observed in mass spectra generated by any other ionization technique. A series of ions is observed at $[M_n+42]^+$ and $[M_n+102]^+$ in the LSIMS mass spectrum of alumatrane. This series begins with the dimer and is repeated in the trimer and tetramer clusters. Exact mass measurements show that these ions are additions of AlO and Al_2O_3 to the alumatrane oligomers 2M, 3M, and 4M. Oligomers consisting of 6 and 7 alumatrane molecules are contained within a more complex distribution of ions formulated as $[M_n+(AlO)_a+(Al_2O_3)_b]^+$. An addition of Al_3O_4 is separable into $(AlO+Al_2O_3)$. Similarly, Al_5O_7 is $[AlO+2(Al_2O_3)]$, Al_6O_8 is $[2(AlO)+2(Al_2O_3)]$, and Al_8O_{11} is $[2(AlO)+3(Al_2O_3)]$. The AlO group carries a charge, and Al_2O_3 can be considered as a neutral molecule. When more than one AlO^+ is added to the oligomer, a proton loss must occur to preserve the single positive charge, as in the ions at *m/z* 1112, *m/z* 1285, and 1345.

The product ion MS/MS spectrum of the ion at *m/z* 562 ($[3M+AlO]^+$) contains 3 fragment ions at *m/z* 519 (35 relative intensity), *m/z* 449 (20), and *m/z* 389 (100), representing the loss of AlO, $C_6H_{11}ON$, and an intact alumatrane molecule (M), respectively. As listed, the most intense fragment ion represents loss of alumatrane to form $[2M+AlO]^+$, The converse loss of AlO to generate $3M^+$ is observed with a lower relative intensity. The fragment ion at *m/z* 449 is formed in a dissociation of the parent ion in which we speculate that each of the three alumatrane molecules loses some portion of its organic linkage, and then regroups around a central Al_2O_3. The energy-minimized structure shows an ion in which the added AlO becomes a central, integral part of the ion, with reorganization of the bonding in each of the original alumatrane molecules The predominant loss of a single alumatrane molecule to form $[2M+AlO]^+$ is easily accommodated by cleavage and a slight rearrangement to form a bond between an aluminum and an oxygen that are in close proximity in this ion. The reluctance of such a structure to dissociate to $3M^+$ is also evident.

The energy-minimized structure for the ion at *m/z* 837, formulated as $[4M+Al_3O_4]^+$ shows a high degree of symmetry, with four alumatrane molecules converging in a central core in which all seven aluminum atoms are fully coordinated. The stability of such as ion must be the driving force behind the considerable rearrangements that would be required for its formation.

The LSIMS mass spectrum of the boron analog of alumatrane, borotrane, contains a sequence of ions that correspond to $[M_n+H]^+$ where n=1-6. However, there are no additions of oxygen, boron, or boron oxide molecules. Boron prefers to be coordinated by either three or four atoms instead of six like the aluminum atoms in alumatrane. The central boron molecule is already bound to the three oxygen atoms and to the nitrogen atom, its valency requirements are fulfilled without the formation of adduct ions.

Characterization of Supported and Unsupported Transistion Metal Complexes

M.G. Bartlett, D.A. Bruce, S.M. Thomas, M.G. White, J.A. Bertrand and K.L. Busch
School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400

Metal acetylacetonates (acac) can be analyzed using a number of ionization techniques including electron ionization (EI) and secondary ion mass spectrometry (SIMS). When using LSIMS for the analysis of metal acacs m-nitrobenzyl alcohol (m-NBA) was found to be the optimum matrix. m-Nitrophenyloctylether also worked well for these compounds but did not provide the same level of signal-to-noise, the exception being $Fe(acac)_3$, where the intensity of the molecular ion was improved by a factor of five versus m-NBA.

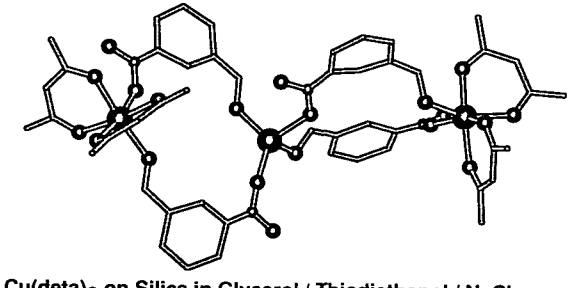
All of the compounds analyzed show the loss of an acac ligand as the most abundant fragment ion. The LSIMS mass spectra of these compounds all contain additions of metal atoms and additional acac ligands. However, there are several additional peaks in the LSIMS mass spectra of the acac's that are interesting to note. An earlier study of the LSIMS mass spectra cobalt(III) acac, states that there are no peaks in the spectrum that are associated with the matrix or are there any matrix adducts present. We find that the three samples where the metal atom has an oxidation state of +3 have no peaks that are composed only of matrix molecules, but adducts of the metal acac's with m-NBA exist as significant signals in the spectra. The mass spectra of the other acac's have considerable background ions that result from the matrix, as well as, adducts with m-NBA molecules. The matrix-sample adducts consist of between one and four m-NBA molecules. For adducts that contain more than one metal atom there appears to be a hydride abstraction for every m-NBA molecule that is added to the complex. The reason behind this is not clear, but the addition of these m-NBA molecules could follow the loss of the hydrogen on the alcohol group of the m-NBA molecule. Since, it appears that it is necessary to have two metal centers before the addition of a deprotonated m-NBA molecule is observed, it is likely that the m-NBA molecules are bridging between two metal centers, as is shown in Figure 1. The only example of an ion consisting of a single metal atom and m-NBA molecules is observed in the spectrum of copper (II) acac. In this case the neutral m-NBA molecules are observed to be added to the metal atom instead of deprotonated m-NBA molecules. In this case, it is likely that the copper ion interacts only with the nitro-group of the m-NBA molecule instead of interacting with both the nitro- and alcoxy-functional groups.

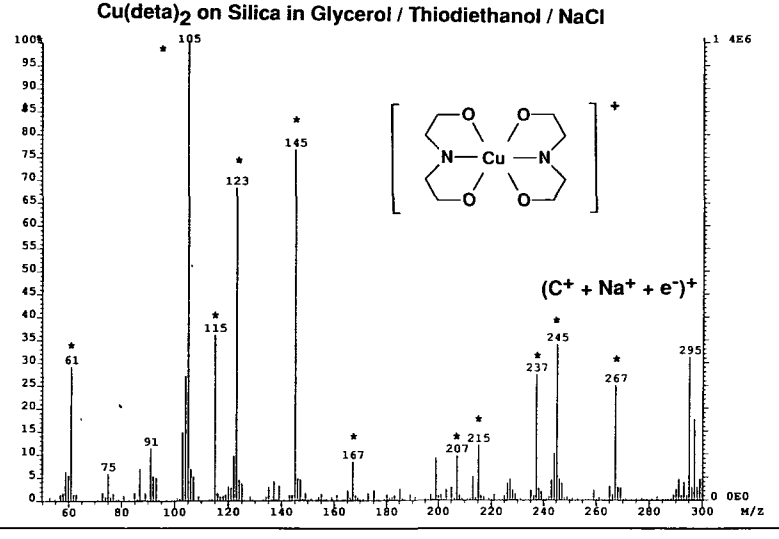
Three additional transition metal complexes were analyzed using LSIMS, copper (II) diethanolamine $[Cu(deta)_2ClO_4]$, copper (II) ethylenediamine $[Cu(en)_2(ClO_4)_2]$, and tris-cobalt (III) ethanolamine $[Co_3(eta)_6(ClO_4)_3]$. The copper complexes were determined to give the optimum response when analyzed using a 1:1 (v/v) mixture of glycerol/thiodiethanol as the LSIMS matrix. The cobalt complex provided the optimum response when analyzed using sulfolane as the matrix.

In order to determine the composition of the transition metal complexes on the support surface we first attempted to analyze the sample directly. A few micrograms of the supported sample was placed directly on the direct insertion probe. The mass spectra of these supported samples, without the use of LSIMS matrices, only yields signals that correspond to the metal ions. Mixing the supported sample with a LSIMS matrix prior to analysis does not yield any ions that are associated with the transition metal complexes. However, we observed that sonicating the sample with a moderately polar organic solvent such as, methanol or acetonitrile remove neutral transition metal complexes (metal acetylacetonates) from the support surfaces. The organic solvent can then be placed on the LSIMS probe and evaporated prior to addition of the matrix. Although, the use of organic solvents can remove these neutral transition metal complexes, this method was not found to be effective for the removal of any of the transition metal salts. In addition, it was observed that the transition metal complexes could also be

removed simply by sonication with the LSIMS matrix prior to analysis. Since, this method was found to be as effective as the use of organic solvents, and far less time consuming, all data was acquired using this method.

In order to analyze the supported transition metal salts, sodium chloride was added to the LSIMS matrix and the supported sample prior to sonication. The sodium ions act as an ion exchange agent displacing the sample from the surface. The mass spectrum of $Cu(deta)_2^+$ is shown in Figure 2. Instead of the protonated molecular ion the sodiated molecular ion is observed at *m/z* 295. The identification of this ion is facilitated by the presence of the copper isotope pattern which is clearly observed in the ratio of the ions at *m/z* 295 and 297. Although sodium chloride was useful in removing $Cu(deta)_2^+$ from the silica surface it was not possible to remove any of the other transition metal salts from their supports using this method. This is due to other salts having a higher charge and consequently being more difficult to displace from the support.





A STUDY OF THE CLUSTER ION DISTRIBUTION FROM METAL NITRATES USING PDMS

The impact of MeV ions on solid surfaces causes the emission of atomic, polyatomic, cluster and molecular species whose mass, yield, radial velocity and angular distribution can be used to elucidate the mechanism of secondary ion (SI) formation Radial velocity and angular distribution measurements have contributed greatly to improvements in the understanding of the molecular ion formation process from organic insulators under MeV bombardment. However SI, in particular cluster ion, emission from non-molecular solids and the underlying chemical changes often induced within the fission track, are not well understood. Cluster ions (atom aggregates made up of smaller units) are of interest as they may contain chemical and structural information. A PDMS study of the composition, distribution and stability of cluster ions from metal nitrates was undertaken to probe the chemistry and physics underlying cluster ion formation from inorganics. A study of cluster ions from the ternary nitrates should provide additional information to that obtained from binary and mono-elemental systems. Moreover, nitrates are disposed to track formation and ion emission in PDMS because of their excellent insulating properties. A reflection geometry, plasma desorption mass spectrometer was used for these studies. Computer evaluations of cluster ion peak areas in total ion counts were made and the log of these areas were plotted against the cluster number n.

Two predominant positive cluster series were identified: the protonated metal-oxide based cluster series, $(MO)_nH^+$, and the metal excess cluster series, $(MO)_nM^+$

(M=metal atom). Cluster ion formation and growth is apparently initiated by the preferential formation of metal-oxide (MO) monomers at high temperatures and pressures ($\approx$ 4300k and 10^4 atm) within the infratrack plasma created by the fission fragment The formation of oxides is facilitated by their low (negative) heats of formation and high lattice energies relative to other possible reaction products. Generally, the intensities of the predominant clusters follow a roughly decreasing exponential function of cluster size with discontinuities or enhanced abundances at certain "magic-numbers" of n. For example, magic numbers for the $(MO)_nH^+$ clusters of the Group IIA nitrates, generally occur at n=2, 4, 6, 9, and 12 while those for the $(MO)_nM^+$ clusters are identical, except lowered by one unit. Also, for Co and Cd, the $(MO)_3^+$ ion is exceptionally stable. Since emitted clusters are accelerated to their full energies within a relatively short time ($\leq 0.01\mu s$ acceleration region), the intensity anomalies arise prior to emission and probably during the actual cluster ion *production process* within the fission track. Similar patterns in abundance maxima have been reported for $(CaO)_n^+$, $(MgO)_n^+$ $(CaO)_nCa^+$ and $(MgO)_nMg^+$ clusters generated in a gas aggregation source [1,2]. For the Group IIA nitrates, the abundance or stability patterns correlate with the energetically favored, *cubic-like* sub-units of the fcc bulk structure of the metal-oxide. In addition, the relative stabilites of the $(MO)_nH^+$ clusters from the various nitrates seem to be influenced by the ionicity and strength of the M-O bond.

Electrospray Ionisation of Polyoxoanions of W, Mo and Si in Aqueous Solution.

Scott G. Summerfield, Oliver W. Howarth and Keith R. Jennings.
Department of Chemistry, University of Warwick, Coventry, CV4 7AL.

Aqueous oxoanions of tungsten and molybdenum are of importance in a number of areas of chemistry including oxidation catalysis, paper production, solar energy conversion and as antiviral agents. On addition of hydrogen peroxide, the partial replacement of O^{2-} by O_2^{2-} occurs to yield peroxometalates. It is thought that the peroxo species play an active role during the catalysis process and currently, these metalates offer an environmentally superior method for the manufacture of paper from wood pulp. In many cases, the lifetimes of such species are pH and time dependent, ranging from hours to days, and their characterisation is difficult since a variety of species coexist in solution. The application of NMR to this area is restricted because of the insensitivity in detecting metals such as ^{95}Mo and ^{183}W coupled with the problem of working with long acquisition times for species having only a limited lifetime. However, many species have been identified by the careful use of these methods and ^{17}O studies [1].

Because electrospray ionisation (ESI) generates ions directly from solution, it may provide a rapid method for investigating the species present in these solutions. The results described show the electrospray ionisation of aqueous solutions of oxometalates performed in a VG Quattro II instrument.

The concentration of many peroxometalate species is usually too low to allow detection by means of NMR or other methods. In the case of electrospray ionisation, these ions are readily observed at low concentrations and may be identified by the shift in mass of the anion due the replacement of O^{2-} by O_2^{2-}. This has been used to investigate the reaction of aqueous hydrogen peroxide with powdered tungsten, the products of which have not been characterised previously. As shown in Figure 1, the reaction generates the $[W_6O_{19}]^{2-}$ anion. Adjacent peaks demonstrate up to 4 successive replacements of O^{2-} by O_2^{2-}. No previous studies have observed the $[W_6O_{19}]^{2-}$ anion in aqueous solution although this may have been due to the low sensitivity of other detection methods. Other species such as $[HWO_4]^-$ and $[HW_2O_7]^-$ are produced in large abundance and peroxidation of these species is also evident as shown in Table 1.

Electrospray ionisation provides a rapid method for characterising the aqueous solutions of metalates and peroxometalates. This technique offers many advantages including the possibility of identifying components present in low concentrations and the analysis of aqueous solutions before significant degradations can occur. The use of electrospray alongside NMR methods may provide a more powerful approach to understanding the chemistry of these complex systems.

STUDY OF THE STABILITY OF METAL ION - MACROCYCLE COMPLEXES BY ESI-MS/CID/MS

Calin G. Znamirovschi[a,b], Dinorah Frutos[b], and Christie G. Enke[a,b]

[a] *Department of Chemistry, Michigan State University, East Lansing, Michigan 48824-1322, USA*
[b] *Department of Chemistry, University of New Mexico, Albuquerque, New Mexico 87131-1096, USA*

Electrospray ionization mass spectrometry (ESI-MS) has lately emerged as an increasingly popular analytical method for inorganic and organometallic analysis [1,2]. The ability of ESI to convert solvated ions and ionic associations into gas phase ions with minimum or no fragmentation makes the method amenable to studying the interactions between metal ions and organic ligands in the gas phase.

We chose for this study two metal ions that exhibit contrasting behavior, K^+ and Ag^+, a "hard" and a "soft" cation, respectively Three analog macrocyclic ligands, 18-crown-6 (**L**), 1-aza-18-crown-6 (**L'**), and 1,10-diaza-18-crown-6 (**L"**) were chosen for their particular complexing trends toward K^+ and Ag^+.

In the ESI-MS experiments on the K^+ interaction with **L**, **L'**, and **L"** the predominant species present in the spectrum were the bare metal ion and the 1:1 complex ion. With an increase in the number of "soft" donors (i.e., nitrogen atoms) in the ligand, an increasing abundance of protonated uncomplexed ligands was found (Figure 1). This follows the decreasing trend of complex stability in solution (Table 1).

The study of Ag^+ interaction with the same series of macrocyclic ligands however, shows that Ag^+ is absent in the spectrum, the predominant ion being the 1:1 complex in the case of all three ligands considered. The larger abundance and a wider structural variety of protonated uncomplexed ligands are due to the increased proton affinity of nitrogen-containing ligands **L'**, and **L"**, respectively

Collision-induced dissociation (CID) studies provide additional information about the behavior of potassium and silver complexes in the gas phase. A unique dissociation pattern, with the bare metal ion retaining the charge, is noticed for K^+ complexes with all three ligands considered. There are no other charged or protonated fragments in the spectra Silver complexes however, undergo ligand-specific dissociation. Ag^+ is present in the CID spectrum of $(AgL)^+$ only. In the nitrogen-containing silver complexes, (i.e., $(AgL')^+$, $(AgL'')^+$) the high proton affinity of nitrogen atoms explains the absence of any silver-containing ionic fragment, except the dehydrogenated complex ions. Also, because the nitrogen-containing fragments are more likely to retain the charge, silver preferentially forms neutral **AgH**, and is therefore not part of any charged or protonated fragment in the spectra (Figure 2).

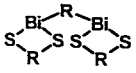
2. National Research Council, 1411 Oxford Street, Halifax, Nova Scotia, Canada, B3H 3Z1

Introduction: A number of bismuth containing compounds, eg. bismuth subcitrate, are known for their anti-*Helicobacter pylori (Hp)* activity and are used in the treatment of peptic ulcers [1,2]. However, the currently used preparations involve an uncharacterized, complex mixture of bismuth compounds [2]. We are currently investigating structurally simple, low coordinate bismuth compounds as part of a search for alternative treatments (Figure 1).

Figure 1-Compounds Examined

R = $(CH_2)_2$ (1), $(CH_2)_3$ (2), $(CH_2)_2S(CH_2)_2$ (3), $(CH_2)_2O(CH_2)_2$ (4)



R = $(CH_2)_2$ (5), $(CH_2)_3$ (6), $(CH_2)_4$ (7), $(CH_2)_2S(CH_2)_2$ (8), $(CH_2)_2O(CH_2)_2$ (9)

The low solubility of many bismuth compounds makes recrystallization extremely difficult; often a crystal structure cannot be obtained. NMR data is usually of little value because bismuth has a quadrupolar nucleus, resulting in very broad absorption peaks. Atmospheric pressure chemical ionization (APCI) is an effective technique enabling the mass spectral characterization of these compounds.

Structural information obtained from conventional and tandem mass spectrometry provide definitive evidence supporting structures **2** and **6-9** which have not yet been demonstrated by other techniques. Previously the known structures **1** and **3-5**, determined by crystallography, were used to infer the structures of **2** and **6-9**, prepared via a similar synthetic procedure.

Experimental: APCI spectra were obtained using a PE/SCIEX API-III$^+$ triple quadrupole mass spectrometer (PE/SCIEX, Thornhill, Ontario, Canada), equipped with a standard heated nebulizer interface. The mobile phase for flow injection analysis was 1:1 water:acetonitrile (MeCN) introduced at 200 µL/min. Fragment ion spectra used argon as collision gas.

Results: The major ions in the positive ion APCI spectra of **1**, **2** (Figure 2), **3** and **4** dissolved in DMSO or MeCN are $[M-Cl]^+$, $[M-Cl+A]^+$, and $[M-Cl+2A]^+$ (A=solvent). The relative abundance of the uncomplexed versus the solvated cations was found to be dependent on the orifice voltage. Fragment ion spectra (not shown) of the precursors $[M-Cl+A]^+$, and $[M-Cl+2A]^+$ show sequential loss of the solvent adducts. Bi^+ and BiS^+ ions are formed with increasing argon gas pressure.

The APCI spectra of the bridged compounds **5** (figure 3) or **9** dissolved in acetonitrile with 1% HCl show $[M+H]^+$ ions. Fragment ions formed from **5** include $BiS_2C_2H_4^+$ (and its MeCN adduct), $Bi_2S_3C_4H_9^+$ and $BiS_3C_4H_7^+$. The fragment ions $BiS_2C_2H_4O^+$, (and its MeCN adduct), Bi^+, and $BiS(CH_2)_2O^+$ are present in the spectrum of **9**. The fragment ion spectrum of the protonated molecular ion supports the proposed structure.

Conclusions: We have observed the first example of moisture stable bismuthenium cations using APCI mass spectrometry. This technique allows the analysis of low solubility bismuth compounds and often provides the only definitive evidence of their structure. Compounds **1-4** were found to form $M-Cl^+$ cations in solution. Protonated molecular ions for **5** and **9** were observed in their APCI spectra together with several fragment ions. Compounds **6-8** appear to be unstable in solution, forming a single ring fragment of the parent compound.

Several bismuthenium species form solvent adducts, which can be observed in their APCI mass spectrum. Future work will include determination of the relative strength of the solvent adduct - cation bond for various bismuthenium complexes by varying the orifice voltage. In addition, an LC/MS method to separate bismuth compounds is currently being developed.

Comparison of ICR cells with open geometry

F. Kuhnen, I. Spiess, K.P. Wanczek
Institut für Anorganische und Physikalische Chemie,
Universität Bremen

The use of open endcap ICR cells became more pronounced the last years. In physical aplications the open endcap ion trap was implemented mainly because of its accessibility towards particle beams or lasers. Open endcap ion traps are interesting for all techniques where ions are injected into the trap. Closed and open cylindrical ICR cells are similar but also have some characteristic differences. The analytical expressions for the trapping potential of a closed cylindrical ICR cell and for the trapping potential of a cylindrical ICR cell with open endcaps are of the same form if certain boundary conditions are assumed. For closed cylindrical ICR cells the endcaps are set to a trapping voltage of V_t, while the cylindrical surface is set to zero. With these boundary conditions the trapping potential is found to be [1.]

$$V(\rho, z) = V_t \cdot \left(1 - \sum_{k=1}^{\infty} \frac{4 \sin(k\frac{\pi}{2})}{\pi k \, I_0(\gamma_k r_0)} \cos(\gamma_k z) \; I_0(\gamma_k \rho)\right) \qquad (1)$$

$$\gamma_k = k\frac{\pi}{L}$$

where L and r_0 denote the length and the radius of the cell. Open cylindrical ICR cells consist of a central excitation and detection ring of zero voltage, while the trapping rings at both sides are set to a trapping voltage V_t. This configuration is assumed to be periodic with a period of 2L. These boundary conditions lead to the trapping potential

$$V(\rho, z) = V_t \cdot \left(\frac{L - z_0}{L} - \sum_{k=1}^{\infty} \frac{4 \sin(\gamma_k z_0)}{\pi k \, I_0(\gamma_k r_0)} \cos(\gamma_k z) \; I_0(\gamma_k \rho)\right) \qquad (2)$$

where L and z_0 denote the half total length and the half length of the trapping ring of the ICR cell. Fig. 1 shows the potential well depth in dependence of the aspect ratio $2z_0 / r_0$ for various 21 mm radius open ICR cells of different ratio of $2L / r_0$.

The trapping potential can be expanded into polynomials of the form

$$V = V_t \sum_{k_{even}=0}^{\infty} C_k \left(\frac{r}{r_0}\right)^k P_k(\cos(\theta)) \qquad (3)$$

When (z_0 / L) equals 1/2 then an open ICR cell has the same representation in polynomials as a closed ICR cell. By appropriate choice of the trap dimensions, the potential can be shaped to achieve certain variations in the polynomial representation of the potential.
Open ICR cells are an extension of analytical applications in FT-ICR, since they allow the trapping potential to be taylored for certain purposes with the variation of the relative center electrode to trapping ring size. As the polynomial approximations of the trapping potential are valid only in the center of the cell, the full performance of these cells can only be used with some sort of ion cooling, especially the z motion has to be cooled, since a wide distribution of amplitudes of the z motion means also a wide distribution of radial electrical field. The excitation behaviour is sensitive towards the proportion of the inner excitation and detection ring so that an elongated arrangement shows less coupling of radial to axial excitation.

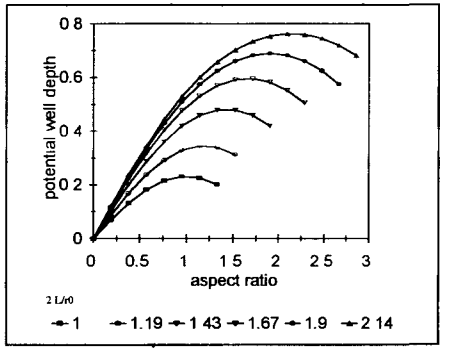

Fig. 3 potential well depth of a cylindrical open ICR cell vs $2z_0 / r$ for different ratio L / r_0 .

PO Box 330440, D-28334 Bremen, Germany

Magnetic traps

In magnetic traps ions are trapped by static magnetic (**B**) and electric fields (**E**) An ion moving with the velocity v in the presence of this fields **E** and **B** is subjected to the Lorentz force given by

$$F = m \cdot \frac{dv}{dt} = q \cdot \mathbf{E} + q \cdot v \times \mathbf{B} \qquad (1) \qquad\qquad \omega_c = q \cdot \mathbf{B}/m \qquad (2)$$

In a strong homogeneous magnetic field, ion motion in the x-y-plane assumes circular orbits with cyclotron frequency (ω_c) Equation 2 describes the fundamental relationship in ICR mass analysis.
Ion motion in the z-direction along the magnetic field lines is restricted by applying a continuous potential to trapping electrodes positioned at right angles to the magnetic field Ions oscillate in the potential with the trapping frequency (ω_t)

$$\omega_t = \sqrt{\frac{k \cdot q}{m}} \qquad \omega_{eff} = (\omega_c^2 + \omega_t^2)^{1/2} \qquad \omega_L = \omega_{eff} + \omega_m$$

Observed is an effective frequency ω_{eff} which is a superimposition of the frequencies ω_c and ω_t. One important consequence of the applied trapping field is the generation of a second form of radial motion in the cell, the magnetron motion (ω_m). The magnetron motion leads to new frequencies ω_L The cyclotron motion of the ion ensemble has a random phase With resonant energy absorption from an applied field to the side plates, the ions get into phase coherent cyclotron motion This motion induces an image current in the detection plates. This detected current is amplified, digitized and stored for data processing. Fourier transformation of the acquired signal yields a frequency spectrum in which the frequency of the peak is indicative of ion mass

Electric traps

A standard quadrupole ion trap consists of three hyperbolic isopotential surfaces The geometry of the device is described by the relationship $r_0^2 = 2 \cdot z_0^2$. In a normal mode of use an rf oscillating potential is applied to the ring electrode and zero to the end cape electrodes to generate a three-dimensional rotationally symmetric quadrupolar electric field.
For this field the motion of the ion can be expressed by Mathieu's second-order differential equation.

$$\frac{d^2u}{d\xi^2} + (a_u - 2q_u \cos 2\xi)\, u = 0$$

U represents the radial and axial coordinate axes, r and z respectively and ξ is a dimensionless quantity equal to $\Omega t/2$, Ω being the radial frequency of the alternating potential. The dimensionless parameters a and q are given by

$$a_z = -2a_r = \frac{-8eU}{mr_0^2\Omega^2} \qquad\qquad q_z = -2q_r = \frac{-4eV}{mr_0^2\Omega^2}$$

where V is the zero-to-peak amplitude of the rf-potential and U is the d.c potential. For a trapped ion, its trajectory must be stable both radially and axially. The stability of a trajectory can be portraited by a stability diagram. The values of β_r and β_z at any point in the stability diagram determine the frequency spectrum of stable ion trajectories, where β_u is a function of the parameters a_u and q_u The frequency

spectrum is given by

$$\omega_{u,n} = (n + \beta_u/2) \cdot \Omega \qquad n = -\infty, \ldots, -1, 0, 1, \ldots, \infty \qquad \omega_{u,0} = \beta_u \Omega/2$$

ω is defined as a secular frequency of nth order, for n = 0, the fundamental frequency is given by $\omega_{u,0}$
The form of the ion trajectory in the r,z plane has the general appearance of a Lissajous curve, with a superimposed micromotion of frequency $\Omega/2\pi$ (Hz)

A new structure for a FT Ion Trap used in electrical and combined mode

Peter Engelmohr and Karl Peter Wanczek
Institute of Inorganic and Physical Chemistry, University of Bremen
PO Box 330440, D-28334 Bremen, Germany

A ion trap with a **new electrode structure** for the generation of an exact three dimensional quadrupolar electric field will be presented In normal ion traps with hyperbolic electrodes it is not possible to generate an exact three-dimensional quadrupole electric field, because of the finite size of practical electrodes. Y Wang and K P. Wanczek (1) have shown that there exists other possibilities to generate such a field It can be generated by closed boundaries with continuously varied potential, in the ideal case by simple cone-shaped boundaries with linearly variable potential. Equation (1) is the general solution of an arbitrary curve of a three dimensional quadrupole field

$$\left[\frac{(dz/dr)r^2+2zr}{2r-4z(dz/dr)}\right]^2+\frac{1}{4}r^2-\frac{1}{\left[(r_0^2/\phi_{q0})b\right]^2}r^2(r^2+4z^2)=0 \qquad (1)$$

In the simplest case, with b=0, it follows that ϕ_q=const and from eq (1) hyperbolic isopotential surfaces are obtained (eq 2) This describes the classical Paul trap The second most important case is given by equation 3

$$r^2-2z^2=const \qquad (2) \qquad\qquad b=const=\frac{d\phi_q}{ds} \qquad \phi_q=bs \qquad (3)$$

Eq (3) corresponds to the potential values which vary linearly along the plane curves The plane curves are rotationally symmetric about the z axis and there exists a simple rhombic closed plane curve to generate a quadrupole field.

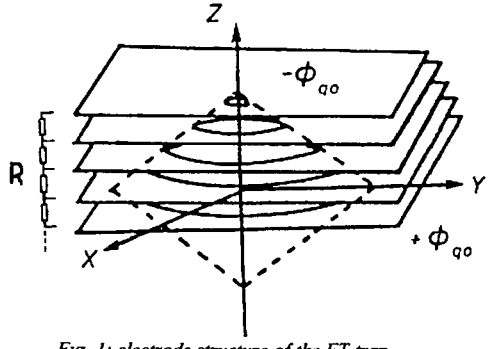

Fig. 1: electrode structure of the FT-trap

43rd ASMS Conference on Mass Spectrometry and Allied Topics

To build the cone-shape closed boundary with linearly variable potential, we constructed the new electrode structure for the generation of an exact three dimensional quadrupolar electric field To realize this, we use 13 metallic sheets of 0 5mm thickness with circular holes to form the inner surface of a cone To get exact circular holes in the electrodes they are burned with a laser into the metallic sheets The biggest hole in the middle has a radius of r_0 = 15 mm and the distance between the electrodes is 1 2mm

In a normal mode of use an rf oscillating potential is applied to the first, middle and last electrode to generate a three-dimensional rotationally symmetric quadrupolar electric field. Because of the symmetry of the device there are two electrodes with a zero potential, these can easily be used for detection. Within the cone shaped boundaries, an ideal homogeneous field in the direction of the symmetry axis can be generated and superimposed without interaction with the quadrupole field. This field can be used for excitation of the kinetic energy of the stored ions and this gives way to a detecting method which can be compared with FT-ICR mass spectrometers.

The motion of the ion ensemble has a random phase With resonant energy absorption from an applied field to the excitation plates (first and last electrode in fig.1 with 180^0 phase shift) the ions get into phase coherent ion motion. This motion induces an image current in the detection plates and the difference of the signals is formed for the transient This detected current is amplified, digitized and stored for data processing. Fourier transformation of the acquired signal yields a frequency spectrum with very high resolution in which the frequency of the peak is indicative of ion mass The great advantage of the recording of the transient is this non-destructive simultaneous detection procedure. Experimental studies with this new electrical FT trap are prepared

Results

In the first Experimental studies with this new electrical FT trap we used the trap as a normal ICR-cell to check the detection behavior of the new electrode structure

The first and last plates are used as trapping plates with 5 Volts and all the others are used for detection (to get a larger detection surface). The constant voltage traps the ions along the z-axes, and in the xy-direction the ions are trapped by the magnetic field of 7 02 T. With this geometry it is only possible to get a signal of the trapping motion v_z along the z-coordinate axis of the ions

It is not possible to detect the cyclotron motion because of the right angle between the motion of the ions and the detection plates. But we have done the experiment only to show that it is possible to store ions in this new trap. The trapping frequency of H_3O^+ ions with a frequency of 82 kHz has been measured. The total observation time of the transient is several milliseconds with the pressure of $1*10^{-8}$ mbar. The ions are created by electron impact ionization in the trap For the excitation a frequency sweep from 20 to 300 kHz within 1ms is used

The first experiment shows that it is possible to store and detect ions in this device The next steps will be to store the ions only with the quadrupolar electrical field and to use only two detection plates as it is described in this poster.

Another subject that need to be studied is the behavior of the new quadrupole FT-trap as a combined trap. This kind of a trap has large stability regions for positive and negative ions with large mass differences and also a trap with the advantage of non destructive ion detection with high mass resolution

Characterisation of a Multi Purpose Open Endcap ICR Cell

I. Spiess, F. Kuhnen, K.P. Wanczek.
Institut für Anorganische und Physikalische Chemie,
Universität Bremen

Two different concepts of ICR cells with open endcaps are introduced. The ICR cells consist of a central trapping ring, two adjacent correction rings and two outstanding trapping rings. The "cubic" arrangement is compared with an elongated arrangement. In the "cubic" arrangement the length of the inner trapping ring and the correction ring equals the trap diameter (fig. 1). For the elongated arrangement the ratio of length of inner trapping ring and correction rings to the trap diameter is 4:3 (fig. 1).The centerline potentials of both cells are shown in fig. 2.
When the potential is expanded into polynomials of the form

$$V_t(\rho, z) = V_0 \sum_{k=0}^{\infty} C_k \left(\frac{\rho}{r_0}\right)^k P_k\left(\frac{z}{\sqrt{z^2+\rho^2}}\right) \qquad (1)$$

C_2 is the quadrupolar part of the trap potential which is a good aproximation of the trapping potential in the center of the trap. C_2 corresponds to the frequency shift of the trap like

$$\alpha = -\frac{C_2}{\pi r_0^2 B} \qquad (2)$$

where α is the frequency shift in Hz V^{-1}.
In a 7 Tesla magnet, transients of the ^{132}Xe Isotope are aquired. These are processed with Fourier transformation and magnitude calculation for different applied trapping voltages to analyse the slope of the reduced cyclotron frequency with respect to the applied trapping voltage. Relation 2 is then applied to calculate the experimental factor C_2 of the cell (Table 1). For the elongated arrangement, 3 different C_2 coefficients can be measured. The trapping can be achieved with the trapping rings set to V_t and the rest to 0 Volts, with trapping- and correctionrings set to V_t and the rest to 0 Volts and the correction rings alone set to V_t and the rest of the cell to 0 Volts.
The elongated arrangement is usefull for the simultaneous trapping of positive and negative ions, if a negative voltage is applied on the correction rings, while the trapping ring is held on a positive voltage.
It is obvious, that the theoretical and experimental C_2 values are different with a factor of approximately 2.5. This can be

explained with the flat part of the potential in the area of the trapping rings. In that region, there is a very low radial electrical field, so there is a contribution to C_2 of zero. Therefore the averaged experimental C_2 is smaller than the theoretical factor. To obtain the optimum performance, the z motion of the ions has to be cooled, to restrict the ion motion to that area of the cell, where the quadrupolar approximation of the trapping potential is valid.
An interesting feature is the simultaneous trapping of positive and negative ions, where the ion capacities of the potential wells can be tuned to match the intensities of positive and negative ions.

Examples in Hierarchies of Optimally Triple Frequency Focused FTMS Cubic Traps

D. L. Rempel and M. L. Gross, Department of Chemistry, Washington University,
1 Brookings Drive, St. Louis, MO, 63130-4899

In the trap of a Fourier transform mass spectrometer (FTMS), unavoidable variations in cyclotron, magnetron and z-mode amplitudes are mapped to detected frequencies via an excitation event. In the normal cubic trap, this map is not constant resulting in degraded peak shapes which can be improved through compensation schemes in which the trapping electrodes are segmented with selected voltages applied to the segments. A theoretically determined first order triple frequency focusing scheme in which each trapping electrode has four segments has been shown [1].

First order triple frequency focusing is defined as follows. The Hamiltonian for a single ion was simplified by using a canonical transform computed by the Deprit perturbation series while in action-angle coordinates. The mode frequencies were obtained as a function of the action coordinates. The cyclotron frequency derivatives with respect to the cyclotron, magnetron and z-mode actions were computed at a fixed nonzero cyclotron-mode amplitude (in this case, 30% of maximum) while the magnetron and z-mode amplitudes are at zero. If the three derivatives are zero then we say that we have first order triple frequency focusing.

The first order triple focusing scheme that was shown in [1] is not unique. The three segment-separating radii in the example are free variables so that there is a solution for each reasonable combination of radii. Some solutions are clearly better than others. If one uses as a criterion of goodness the volume of mode amplitudes for which the frequencies do not deviate by more than, say for example, +/- 12.5 ppm then one can ask if there is an optimal combination of radii that maximizes the volume. Larger volumes are desirable to accommodate broader distributions of mode amplitudes. This is particularly important for the magnetron-mode amplitude distributions which become large at high mass.

The first order triple focusing schemes are also mass dependent. In the solutions computed so far, solutions computed at high mass show excellent behavior when evaluated at lower masses while the reverse is not always true.

A combination of radii that maximizes the mode-amplitude volume has been found at 10% of the critical mass. This solution is significant in that the linear size of the volume at 10% critical mass is about the same as the linear size of the volume at 1% critical mass for the first reported first order triple focusing scheme. The solution together with a frequency surface evaluated at 10% of the critical mass is shown in Fig. 1.

Other criterion may include the smallness of the magnitudes of higher derivatives of the cyclotron frequency with respect to the mode actions. One might consider the three second derivatives obtained from the three already used first derivatives differentiated with respect to the z-mode action as a predictor of good peak shape, for example, as an alternative to the volume criterion. The solution together with a frequency surface evaluated at 10% of the critical mass is shown in Fig. 2. A better peak shape is expected from the simpler surface and the solution is more practical because the electrode voltage ratios are lower. Also the solution was constrained so that the difference in consecutive radii was more than 2% of the trap size. Notice that the IZN, IMN, ICN sizes are almost as large as those acheived in Fig. 1.

Naturally, one is lead to seek the solution for which all six of the significant second derivatives are zero. This would be an example of a second order triple focused trap. One has been found for the case when the trapping plates have ten segments each. This solution is not unique because the nine segment-separating radii are free variables. If one considers additional criterion, an optimal second-order solution can be found...

Thus, by considering different combinations of criteria, hierarchies of optimal solutions are established.

SHORT-BORE CONCENTRIC TUBE SOURCE FOR COUPLING HPLC TO ESI/FTICR

C.J. Harper*, J.J. Drader, V.L. Campbell, L. Stevenson, D.A. Laude
Dept. of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712

INTRODUCTION

Although there are several instrument designs in the literature for coupling liquid chromatography/electrospray ionization sources (LC/ESI) to quadrupole mass analyzers, there are few demonstrated for Fourier transform ion cyclotron resonance mass spectrometers (FTICR). The main obstacle to introducing any external ion source to an FTICR system is transportation of ions into the strong magnetic field while achieving low pressures in the detection cell for optimal FTICR performance. In overcoming this obstacle, many research groups have utilized a series of differentially-pumped vacuum stages that are separated by conductance limits. However, each stage of pumping adds more length to the source inlet, causing the ionization region to be positioned outside of the magnetic field. As a result, complicated ion focusing optics are needed to transfer the ions across the magnetic field gradient into the trapped ion cell. In order to overcome this problem, a concentric tube vacuum chamber has been developed which positions the ionization source within the magnetic field. This technique takes advantage of the magnetic field as a force to confine the radial motion of the ions making their transfer through the conductance limits more efficient. Further improvements have been made to this design by the addition of a mechanical shutter. The shutter, which covers a 5 mm conductance limit, is rotated away from the orifice during ion injection and then rotated over the orifice to block the flow of ions and neutrals to the detection region. Pressures for detection with the shutter closed are in the 10^{-9} Torr range, constituting a two order of magnitude drop in pressure.

The addition of the shutter has greatly enhanced the performance of our FTICR instrument. For example, the spectrum in Figure 1 shows the high resolution capabilities of the new shutter instrument. This spectrum is of the +14 charge state of horse heart myoglobin (MW = 16951 Da) and has a mass resolution of ~300,000 at 1233 m/z. Before installation of the shutter, mass resolution was limited to ~100 at 1233 m/z due to the high pressures in the analyzer cell. Furthermore, because a much larger conductance orifice can be used in the shuttered region, the sensitivity of this instrument has been enhanced by more than 40-fold. For example, spectra with a S/N of approximately 9 can be achieved with only 22 attomoles of bovine insulin and only 88 attomoles of horse heart myoglobin.

DEVELOPMENT OF SHORT-BORE ESI FOR CHROMATOGRAPHY

Because the concentric tube/shutter design offered higher sensitivity and better resolution than previous instruments, we decided to develop this instrument for use with on-line separation techniques. However, the long length of the electrospray probe needed to position the source within the magnetic field makes coupling this source to chromatography impractical. In particular, the probe length in the concentric tube design is 72 inches and an additional 36 inches of Teflon tubing is needed to connect the probe to the syringe pump for sample delivery. Therefore, the sample must pass through 9 feet of tubing before reaching the electrospray needle which results in greatly deteriorated chromatographic resolution. Consequently, a "short-bore" ESI source was designed and built as pictured in Figure 2. As shown, the probe length has been shortened to 12 inches. This was achieved by removing one stage of differential pumping and by shortening the length of the remaining stages to their practical limit. Nevertheless, when the shutter is closed, pressures in the detection region reached the mid-10^{-8} Torr. In addition to the shortened length, the design also includes a larger diameter probe. This was done so that, as shown in Figure 3, the separation column

could be easily placed within the probe thus further shrinking the distance from column to electrospray needle to less than 2 inches.

In order to evaluate the new short-bore instrument, flow injection experiments were first conducted to optimize shutter manipulation, data acquisition, and other factors. The data presented in Figure 4 represent a 1μL injection of 10 μM bradykinin, for which the +2 charge state was monitored, at a flow rate of 5 μL/min. Sample was delivered from the injector to the spray cavity by 10 feet of 0.007" I.D. polyether ether ketone (PEEK) tubing. This experiment emphasizes the loss of chromatographic resolution that results from passage through lengthy amounts of tubing. For example, the elution profile of this analysis is approximately 4 minutes long which corresponds to an elution volume of 20 μL; however, the injection volume was only 1 μL. Based on estimates of the area under the elution profile and calculations made from injection time, it can be shown that the spectrum in Figure 4a taken at time 13:64, the most intense part of the profile, consumed approximately 40 femtomoles of sample. By extrapolation, the amount of sample consumed in Figure 4b for time 15:52 (at the trailing edge of the profile) was only 7 femtomoles with a signal-to-noise ratio of 5. Because these spectra were not acquired under ideal conditions, it is expected that additional improvements to the instrument will increase the sensitivity making detection of attomole quantities routine. This preliminary data obtained from flow injection experiments shows that the short-bore design presented here is capable of achieving chromatographic analysis. However, further improvements to the current instrument should result in enhanced performance. For example, the installation of a cryopump in the analyzer region will reduce the pressures below 10^{-8} Torr for better mass resolution capabilities and a faster duty cycle. In addition, optimization of the instrument for compatibility with faster HPLC flow rates will be necessary.

Observation of Collective Oscillation and Motional Averaging for Control of Magnetron Motion in FT-ICR V. H. Vartanian and D. A. Laude, The University of Texas at Austin, Austin, Texas 78712-1167

Collective oscillation and motional averaging of ions is observed in an open cell by virtue of the axially dependent radial electric field which reverses orientation The magnitude of the inward-directed radial electric field increases with axial displacement and acts concertedly with the Lorentz magnetic field. As ions are radially focused to the center of the cell during oscillation in the well, magnetron motion is reduced and cyclotron frequency increases. In experiments in which the ion axial amplitude increases, cyclotron frequency increases from the reduced to nearly the unperturbed frequency without peak broadening, indicative of coulombically-coupled axial motion. Modulation between the reduced and unperturbed frequencies is controlled by an axial cooling delay. A suspended trapping event maximizes the ion z-amplitude, increasing cyclotron frequency. Axial excitation is also used to promote coherent axial motion in the single-trap electrode open cell, and cyclotron frequency dependence on axial displacement is observed. Cyclotron frequency is observed up to 300 Hz above the unperturbed frequency in a nested trap. The magnitude of the frequency shift increases with ion number as space charge increases the axial extent of the ion cloud, allowing ions to spend more time in the inward-directed radial field.

A collection of trapped ions with a distribution of axial positions or amplitudes would be expected to encounter different average radial electric fields. During the detection process the ion ensemble would then exhibit cyclotron frequency peak broadening as a result of oscillation within the potential well. However, peak broadening does not occur as a result of z-axis oscillation since the trapping frequency is usually much greater than the magnetron frequency. Rather, motional averaging of the radial electric field during ion z-axis oscillation yields an average radial electric field that, while reducing cyclotron frequency, does not generate peak broadening [1-3]. If the ion z-amplitude or the radial displacement changes due to collisional damping of the axial motion or growth in the magnetron radius during the detection process, peak broadening results. Yet, even under experimental conditions likely to produce broadening, no variation in cyclotron frequency is observed. When detection immediately follows electron ionization at low pressure, ions are formed with a uniform distribution of z-axis amplitudes. Consequently, ions experience different radial electric fields in the trapping well, yet no peak broadening results.

The absence of peak broadening under typical experimental conditions can be attributed to the effect of coulombic-induced coupling between ions. Coupling has been observed in Paul traps for different ions in which the collective rather than the independent axial motions results in a single frequency resonance at intermediate position between two individual frequencies [4]. The strength of the coupling is a function of the number of ions and their difference in frequency. Coupling occurs even more strongly for ions of like mass. Coulombic-coupled cyclotron motion has also been observed in an FT-ICR cell [5].

Experiments were performed using a single-trap electrode and an open nested trapped-ion cell having four collinear trap electrodes, within a 3.00686 Tesla, 150 mm warm-bore superconducting magnet. Either benzene or dichloromethane were introduced through a precision leak valve and ionized with a 60 eV, 5 uA electron beam for 5 ms. Ions produced along the centerline of the cell experienced various radial electric field environments during axial oscillation in the cell. Cyclotron frequency was measured as a function of delay time to evaluate the effect of the radial electric field.

Cells with closed endcaps produce a radial electric field that is outward-directed at every position along the z-axis and is responsible for the destabilizing magnetron motion that results in eventual ion loss. However, in open cells, reversal of the radial electric field occurs at increased z-axis displacement. The radial electric field for the single-trap also exhibits a similar shift in orientation at increased z-amplitude. Ions with significant z-amplitude exhibit cyclotron frequency approaching the unperturbed frequency.

Presented in Figure 1 are a series of frequency shift profiles for ions formed in an open cell and allowed to cool to the center of the cell. For each of three trap potentials (3, 5, and 8 V), a 100 µs suspended trapping event is applied in which the trap electrodes are grounded during which time the z-amplitude of the ions increases. Trap potentials are then reinstated and the effective cyclotron frequency detected as a function of cooling delay. In this plot, ions having greater axial amplitudes are shaded increasingly darker. As ions undergo large z-amplitudes, a cyclotron frequency (591.607 kHz) close to the unperturbed cyclotron frequency (591.618 kHz) is detected, but as collisional cooling increases, ions collisionally relax to the center of the cell where cyclotron frequency decreases. The rate of cyclotron frequency decrease is a function of trap potential, as ions collapse more rapidly to the center of the cell.

In a more stringent test to verify that the observed shift in peak frequency is a function of axial position, peak position was measured as a function of axial cooling delays (D1-D3) at constant trap potential following consecutive suspended trapping events (S1-S3) for the same ion population. Presented in Figure 2 are frequency shift plots for three consecutive 100 µs suspended trapping events followed by 5 second cooling delays. Each suspended trapping event increases the reduced cyclotron frequency close to unperturbed frequency as the ion population undergoes a significant radial stabilizing force from the applied trapping field. Furthermore, the peaks do not exhibit broadening, indicating coulombic-coupling. Resonant excitation at the trapping frequency may also be used to axially expand the ion cloud, increasing cyclotron frequency (Figure 3). After the ion cloud is cooled to the center of the cell, excitation various excitation levels allows ions to penetrate the regions of radial stability at increased z-axis displacement.

An open cell can be constructed in which ions spend a greater time in the regions of the cell where the radial electric field works in concert with the Lorentz magnetic force. The potential well and radial electric field profile for a nested trap shown with outer trap electrodes biased to -6 V and inner trap electrodes biased to +3.5 V is shown in Figure 4, producing a shallow potential well. The shallow well increases the time positive ions spend in the inward-directed radial electric field at the well extremes at the expense of time spent in the center of the cell. The radial electric field at increased z-axis amplitude becomes increasingly inward-directed because of the effect of the negative bias on the outer trap electrodes. Negative ions or electrons trapped in the outer trapping wells also increase the cyclotron frequency of positive ions, as the negative ion space charge acts concertedly with the Lorentz magnetic force. In conventional closed cells, increasing ion number results in a linear reduction in cyclotron frequency. Cyclotron frequencies have been observed in the nested trap that surpass the unperturbed cyclotron frequency by up to 300 Hz, with the magnitude of the shift a function of ion number (Figure 5).

Investigations of Gas Phase Ion-Ion Reactions in an FTICR Trapped Ion Cell

*T.A. Torres, E. Stevenson and D.A. Laude
Department of Chemistry, The University of Texas at Austin, Austin, Texas 78741

The gas phase study of ion-ion reactions are investigated using Fourier transform ion cyclotron resonance (FTICR) mass spectrometry in a novel trapped ion cell that simultaneously confines both positive and negative ions (1). An open-ended cell geometry with twin, oppositely biased trapping electrode rings creates overlapping potential depressions to house both types of ions. In contrast with previous cell designs that were impractical for ion-ion studies, this cell does not promote ion quenching at the boundaries (2) and has a broad mass range for trapping. These attributes allow the low pressure reaction chemistry of positive and negative ions to be monitored over periods of several seconds. The study of reactions between ions of dissimilar charge magnitude are presented here. Specifically of interest are the reactions of multiply protonated electrospray ions with anions.

The open cell presented in Figure 1 is a variation of a shimmed cell design with two trapping electrode rings on either end of the interior excitation and detection electrodes (3). The cell was constructed of 0.030 in. thick x 2 in. i.d. OFHC copper tubing sectioned and mounted with aluminum cylinders. The total length of the cell was 75 mm with the excitation/detection electrodes 25 mm long, the inner set of traps 5 mm long, and the outer set of traps 16 mm long. All electrodes were separated by 2 mm air gaps.

An FTICR/ESI/LD/EI system used to perform all experiments. Briefly, the multi-electrode cell was mounted into a 3.0 T superconducting magnet controlled by an Odyssey based data station. A concentric tube network was used to interface the electrospray ion source to the spectrometer. A Nd:YAG laser operating at 1064 nm was used to generate laser desorbed ions at 1×10^{8} W cm^{-2} power densities. Electron ionization (EI) mass spectra were performed at 5×10^{-7} Torr and samples introduced to the system were ionized by a 3μA, -60 eV beam of 10 ms durations.

A potential well diagram using SIMION is shown in Figure 2. Here the potential depressions are produced by applying -5V to the outer traps and +5V to the inner traps. Two separate potential wells for positive and negative ions are formed. Nested within the negative depression is a central positive well formed by the application of the positive voltage to the inner pair of electrodes. The two small potential lobes form two regions into which negative ions are trapped. Variations in the potential well depth can be achieved by altering the applied potentials. The positive, negative, and combined EI mass spectra of chloroform are presented in Figure 3. These spectra indicate that the trap provides a stable environment for each type of ion.

The type of ion-ion reactions of interest are those that generate charged product ions rather than a neutralized product. Specifically, the reaction of the multiply charged protein, melittin, generated by electrospray ionization with laser desorbed metallic gold ions was studied. The melittin ions were sprayed into the laser desorbed plasma of negative gold ions. The inner trap plates were set at potentials of -0.15V and the outer traps to +4.0V. More definitive information can be drawn about charged product formation by examining relative abundances of the bare ions and product ions as the reaction time is raised. The decreasing

abundances of both the melittin (4+) and the gold (1-) ions after 1 and 20 second reaction delays indicate a loss of reactant ions. Additionally, the formation of a charged product of increasing abundance at 263 m/z seems to indicate that melittin (4+) ions have undergone reaction with gold ions.

A more extensive study of the ion-ion chemistry of proteins with metals is planned. In addition, the reactions of organic anions with proteins can be investigated with the incorporation of quadrupolar excitation (QE). QE has proven to be an effective means of axializing an ion of specific m/z. This will enable us to selectively isolate reactant ions for enhanced control of product formation.

FTICR/TOF for Measuring Large Ion Populations in Penning Traps

E.G. Schmidt and D.A. Laude
The University of Texas at Austin, Austin, Texas 78712-1167

The ability to evaluate the evolution of an ion cloud stored in the trapped ion cell over the course of an FTICR experiment is important when developing new analytical instrumentation and methodologies. Especially when evaluating ion populations formed under high space charge conditions or in non-ideal regions of the trapped ion cell, FTICR detection itself provides limited or suspect information because of dynamic range constraints or inappropriate parameter selection.

To be presented are results from the construction of an FTICR with time-of-flight detection that permits a more detailed evaluation of spatial and kinetic energy distributions for ions formed under non-ideal conditions. As a first example, laser desorbed metals formed under plasma ignition conditions and allowed to cool in the trapped ion cell are evaluated. The ability of quadrupolar excitation (QE) to assist in shaping the ion cloud for detection is considered.

Experimental

A 4.7 Tesla vertical bore superconducting magnet with 98 mm originally employed for NMR was reconfigured to accommodate an FTICR vacuum chamber. Laser desorption was used to create the desired ion populations. A 1.4 m time-of-flight path to an electron multiplier (ETP, Auburn, MA) supported above the superconducting magnet was created. This added flight length was necessary in order to operate the detector. Time-of-Flight spectra were collected using a digital oscilloscope. Quadrupolar excitation (QE) was accomplished using an external relay circuit to rapidly switch between quadrupolar and dipolar excitation.[1]

Conventional FTICR data was acquired using broadband swept excitation following ionization and a cooling delay. During this delay, a pulsed valve could be opened to introduce buffer gas to 1×10^{-5} Torr to perform quadrupolar excitation (QE). A potential of up to 70 V could be applied to the rear of the cell to direct ions to the detector

For all laser desorption measurements, indium foil was used as the sample. 1064 nm light for a Nd:YAG laser was introduced through a fiber optic and was incident on the sample with a laser fluence of 1×10^{8} W/cm^2, sufficient to promote plasma ignition conditions. All of the TOF profiles were generated as a summed average of 10 laser shots.

TOF OF TRAPPED LASER DESORBED IONS

The profiles in Figures 1 and 2 are for time-of-flight of In^+ trapped in the ICR cell for 10 ms and 10 s cooling times, respectively, with a 2 V trapping potential. In Figure 1a, ions trapped in the cell for 10 ms arrive at the detector in 700 µs, which corresponds to a kinetic energy of 2.4 eV. In Figure 2a, even after a 10 s cooling delay, a bimodal distribution is still observed even though the 1.7 ms flight time indicates ions have been cooled to 0.41 eV. Figures 1b and 2b include a +70 V pulse applied to the rear trap electrode to direct the ions to the detector. Similar profiles in both cases indicate that ions are retained in the trap and can be detected by TOF even when ion energies in the cell are insufficient to direct ions to the detector.

QE OF TRAPPED LASER DESORBED IONS

Presented in Figures 3 - 4 are TOF profiles for laser desorbed In^+ initially trapped in the ICR cell and subjected to various cooling delays. The profiles are for cooling delays of 100 ms and 1 s, respectively, in a 70 V trapping well. The signal is substantially degraded, likely due to an increase in the radial extent of the ion cloud due to magnetron effects. Figures 3b and 4b are

for conditions identical to those shown in Figures 3a and 4a, with the exception that a QE cooling delay replaces the simple cooling delay event. As the profiles indicate, QE serves two functions, both in reducing the axial extent of the ion cloud resulting in a narrower TOF profile in Figure 3b, and dramatically reducing the radial ion distribution, thus significantly increasing the intensity of the TOF profile in Figure 4b.

CONCLUSION

Although FTICR instruments have the ability to trap large ion populations, the resulting signal is not linear under high space charge conditions even at small trapping potentials. The use of FTICR/TOF alleviates this problem by detecting the ion signal on an external electron multiplier which has a large linear dynamic range thus allowing for the evaluation of different ion trapping techniques. It has been shown in these studies that quadrupolar excitation is a successful method for cooling of externally injected ions to the center of the trapped ion cell

In the future, an electron ionization (EI) source will be added which will provide more control over initial ion formation as well as allowing more quantitative measurements to be made.

Improved Ion Injection in a Single-Trap Electrode Cell for FTICR

J. S. Anderson*, T. A. Torres, V. H. Vartanian, Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, Texas 78712

A distinct advantage of the open geometry trapped-ion cell is the relative ease of external ion injection without complications arising from electrode charging and ion trajectory perturbations characteristic of the closed-cell geometry. Coupling this advantage with the inherent flexibility of open geometry construction leads to a unique trapped ion cell with a single trapping electrode at the cell center. Absent in this cell design is the presence of an electrostatic barrier predominant in both conventional closed and open cells. Instead, a potential depression is formed into which ions of any initial kinetic energy may descend and potentially be trapped. Previously employed for FTICR feasibility studies with electron ionization and low molecular weight compounds[1], the single trap electrode cell is used here to probe trapping mechanisms for externally generated laser-desorbed ions and contrast the results with similar experiments in conventional geometry cells.

Experiments were performed in a 3.0 Tesla superconducting magnet with a modified Extrel-FTMS dual cell assembly. This particular arrangement consisted of a 5.0 cm closed cubic cell and the single-trap electrode cell. Laser desorption experiments included MALDI of small proteins and IRLD to allow cation-attachment of similarly sized molecules. For the MALDI process, laser light from a nitrogen laser at 337 nm (Laser Science, Inc., Cambridge, MA) is focused into a 200 μm. all-silica fiber optic (General Fiber Optics, Inc., Fairfield, NJ) and directed onto a probe tip with matrix (2,5 Dihydroxybenzoic acid) and analyte. Laser experiments conducted with IR light employed a Nd:YAG Surelite 1 laser (Continuum, Santa Clara, CA) operating at 1064 nm.

The methodology of trapping externally generated ions is fundamentally different in the single-trap electrode cell from all conventional FTICR cells. As shown in Figure 1a, efficient introduction of ions in a two-trap electrode cell using accumulated trapping requires the ion to have translational kinetic energies sufficient to overcome the potential barrier projected at the front trap electrode. The distinction from conventional cells with terminal trap electrodes is that both gated and accumulated trapping mechanisms are represented simultaneously in the single-trap electrode cell. All ions, regardless of their kinetic energies, will be able to penetrate the trapping volume in the single-trap electrode cell. The same ion in Figure 1a will readily penetrate the negatively biased potential depression shown in Figure 1b, and potentially be trapped.

One theory behind cation-attachment of neutral molecules is that precursors, such as K_2Br^+, attach to neutral molecules, M, to form $(M+K)^+$. Overall, the trapping process is dependent on ion kinetic energy and the applied trap potential, with only certain ions being able to enter conventional cells at a fixed trap potential. In contrast, the single-trap electrode cell provides a different set of conditions for trapping $(M+K)^+$ ions. The combined nature of accumulated and gated trapping allows $(M+K)^+$ ions of low kinetic energies to enter the cell and be trapped. Consequently, as a first order approximation, this trapping process is integral in that all ions may enter the cell and be trapped without exclusion of lower kinetic energy ions.

Experimental results for trapping $(M+K)^+$ gramicidin S ions are shown in Figure 2. As discussed above, the single-trap electrode cell is shown to be efficient at trapping low energy ions with negligible ion loss. Demonstrated for the cubic cell is the derivative trapping characteristic of all conventional FTICR cells.

The conventional method for trapping MALDI/FTICR ions is gated trapping with a decelerating potential applied to the rear electrode[2]. Precise timing of the gated trapping event is required to prevent repulsion of ions by the applied decelerating potential. Trapping mechanisms in the single-trap electrode cell are inherently different from its conventional two-trap electrode counterpart. First, the possibility of accumulated trapping exists because of the absence of a potential barrier at the cell entrance. In addition, the injection period of MALDI ions is not limited by the presence of any decelerating potential as with conventional cells. Shown in Figure 3 is a comparison of injection profiles for both cubic and single-trap electrode cells where accumulated trapping occurs in the single-trap electrode cell. Alternative gated trapping schemes may also be employed in the single-trap electrode cell for MALDI generated ions. Shown in Figure 4a-d are three types of gated trapping along with accumulated trapping for external ions.

The integrative trapping, characteristic of combined accumulated and gated trapping, within the single-trap electrode cell exhibits novel trapping of externally generated laser desorbed ions. Low energy thermally desorbed ions, which experience kinetic energy discrimination in conventional two-trap electrode FTICR cells, can penetrate the potential depression formed by the single-trap electrode cell without energy discrimination. In addition, MALDI ions injected into the single-trap electrode cell do not experience the same electrostatic repulsion that occurs during conventional MALDI gated trapping. As a result, ions experience a longer injection duty cycle in the single-trap electrode cell. Lastly, unit mass resolution has been achieved in the single-trap electrode cell with small proteins such as gramicidin S.

Quadrupolar Excitation Efficiency in Non-Ideal FTICR Trapped Ion Cells

J.J. Drader, C.L. Hendrickson, J.M. Robinson and D.A. Laude, Jr.; Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712

Quadrupolar excitation is being used increasingly in FTICR-MS as a technique for improving the quality of the ion population stored in a trapped ion cell. As the name of the technique implies, the axialization of the ion cloud is optimally achieved in regions of the cell subject to a pure quadrupolar potential. Thus a potential problem with the technique is that in cells without hyperbolic geometry, the QE process will not be effective in cooling the ion cloud. Fortunately, the potential at the center of all trapped ion cells is to some degree quadrupolar.

The purpose of this poster is to determine to what extent QE and related procedures will work under non-ideal conditions. The premise will be that rather than construct a cell geometry that is optimized for QE at the expense of analytical utility, the applied fields can be modified. To perform the work, an elongated open cell which is ideally suited for external ion injection, but not optimized for QE, will be employed. A collection of cooling experiments will be investigated to determine the conditions under which axialization of the ion cloud is feasible.

The experiments were performed on a 3 Tesla concentric tube electrospray equipped with a 2.5 inch diameter open elongated cylindrical cell. Concentric tube pumping combined with a mechanical shutter reduced the pressures in the analyzer region to 1 x 10^{-9} Torr. Argon gas was pulsed in the cell at a pressure of 5 x 10^{-5} Torr during axialization. A switching circuit was employed to convert between dipolar and quadrupolar excitation modes. The data was collected and processed with use of an Odessey data station, however, it was necessary to employ a PC based data station to continuously output waveforms for broadband quadrupolar excitation.

Quadrupolar excitation is conventionally applied to two pair of opposed electrodes, however, it has been shown [1] that QE can be simplified by applying the excitation to only one pair of opposed electrodes. All of the following data has been collected with the two plate configuration.

One of the advantages of coupling electrospray ionization with FTICR is the ability to obtain isotopic resolution on large proteins. A difficulty that arises when collecting high resolution data is overcoming space charge effects associated with a large population of ions spread over a range of charge states. Following an initial excitation/detection of horse heart myoglobin (MW = 16,951 Da), QE was used to axialize the +14 charge state. A 40 second pump down delay allowed system pressures to reach 2 x 10^{-9} Torr. A high resolution spectrum was obtained by applying a second excitation followed by high resolution detection. The resulting charge state was isotopically resolved with a resolution of 300,000.

Typically, a perfect quadrupolar field is desired to facilitate ion axialization. However, in an actual ion trap the field deviates from a pure quadrupolar potential. Bollen et. al. [2] have shown that there can be a significant quadrupolar component associated with dipolar excitation. Following an initial scan of horse heart myoglobin, dipolar excitation was applied to selectively cool a charge state . The excitation profiles in Figure 1 illustrate the quadrupolar component of the dipolar field diminishes as the ions approach the cell center.

Bollen et. al. also predict that axialization should be facilitated by application of an octupolar field (twice the cyclotron frequency). Such a field should be present as a non-ideal component of the azimuthal quadrupolar field. This was confirmed by isolating one charge

state of horse heart myoglobin after applying such a frequency. The excitation profile in Figure 2 confirms that the octupolar component only exists significantly at the cell perimeter.

The ability to cool over an arbitrary mass range is essential in realizing the full analytical utility of axialization. The coupling of quadrupolar axialization with SWIFT excitation has been shown to be ideal in achieving this result [3]. As an example, Figure 3 shows a remeasurement of horse heart myoglobin after applying a 4 second SWIFT quadrupolar excitation. This remeasurment yielded a larger abundance than the original scan. It should be noted that remeasurement in the absence of axialization was unsuccessful at the large excitation radius used.

The selectivity afforded by the SWIFT technique is demonstrated by the spectra in Figure 4 which shows selective axialization. An overlay of the SWIFT waveform used for axialization shows the requested quadrupolar excitation amplitude.

Trapped ion cells typically used in FTICR experiments are incapable of producing perfect excitation fields and instead produce fields which are composed of a linear combination of higher order components. In this work these multipole components are evaluated in an open cylindrical cell. These results indicate that a pure azimuthal quadrupolar field is unnecessary for performing efficient ion axialization and that the higher order fields can also be used to cool ions to the cell center.

MALDI/FTICR Using Quadrupolar Excitation in a Single Trapped Ion Cell

J. S. Anderson*, and D. A. Laude, Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, Texas 78712

In recent years, MALDI ionization coupled with FTICR detection has demonstrated continued progress and versatility for many different experiments[1-3]. The recent development of quadrupolar excitation[4] (QE) for motional conversion and ion cooling has lead to still improved ion trapping and detection efficiency of MALDI generated ions. Many of these applications employ very homogeneous (100 ppm over the cell volume) high magnetic fields with dual cell arrangements or electrostatic ion guides for efficient ion transfer and optimum performance. In work presented here, we employ QE to facilitate high performance FTICR with a single trapped ion cell in a low homogeneity 7.2 Tesla magnet. Theoretical discussions are made concerning the deleterious effects of gradient (ΔB) magnetic fields on premature ion loss from the trapped ion cell. In addition, our results indicate that the analytical utility of a low homogeneity magnet relies on the use of quadrupolar excitation to help localize and entrain ions inside the cell.

Laser light employed for MALDI ionization is transferred by fiber optic through a probe interface to the matrix/analyte sample. A nitrogen laser using light of 337 nm (Laser Science, Inc., Cambridge, MA) transmits energy of 40-50 µJ through the fiber onto the sample surface. Various proteins are mixed with an abundance (1000-5000/1 molar ratio) of 2,5 dihydroxybenzoic acid for the final sample composition.
All MALDI experiments were controlled by Odyssey V3.1 (Extrel-FTMS, Madison, WI) software. Following the pulse gas and laser event, application of QE for a variable time period is followed by a cooling delay and subsequent dipolar excitation and detection. All experiments were done in a 1.00" closed cylindrical OFHC copper trapped-ion cell.

A major point of experimental concern is the effect of axial magnetic inhomogeneity on overall FTICR performance. In our particular magnet, the field homogeneity is 1 ppThousand over 1 cm DSV with 7.2 Tesla at the cell center and approximately 7.16 Tesla at the trap electrodes. Prior studies of magnetic field inhomogeneities have focused on cyclotron frequency shifts[5] and low energy ion injection[6] in regions of magnetic field gradient. In these studies, ions experience a much greater axial magnetic field inhomogeneity within the cell volume than previously used for high performance FTICR studies. These field gradients are detrimental for achieving high sensitivity and high mass resolution.
In a constant magnetic field, ions oscillate along the z-axis centerline with constant radius and velocity and cyclotron frequency are position invariant. In the curved magnetic field representation, the first order approximation of ion motion can be understood as follows[7]. Ion radius along the z-axis will change with axial position and radial velocity and cyclotron frequency are position dependent. Such inhomogeneity causes ion loss and deterioration in resolution.
In a homogeneous magnetic field, externally generated ions spiral around magnetic field lines and are focused directly along the z-axis centerline into the trapped-ion cell. This spatially defined packet of ions typically encounters negligible ΔB gradients in an FTICR cell. Ion loss usually occurs due to effects of electric field perturbations. In our case, MALDI ions injected through the initial mesh trap electrode are not confined radially along the z-axis and as a result are not adequately defined energetically or spatially. Such ions experience greater electric field inhomogeneities at the cell boundaries, greater ExB forces, and are prematurely lost from the cell.

Plots of normalized bovine insulin b chain ion abundance versus delay time between laser firing and quadrupolar excitation application are shown in Figure 1. In plot a) it is readily observed that ion signal decreases rapidly in the 7.2 Tesla magnet without immediate QE. The plot in b) represents an identical experiment in a homogeneous 3.0 Tesla system. Here, ΔB gradients are not a factor and retention of ions is not immediately dependent on QE application.

In prior experiments without application of QE, MALDI ions up to the mass of bovine insulin could be effectively trapped. However trapping times and ultimate mass resolution were severely limited ($m/\Delta m$=3000-4000 at m/z 1600). Employing QE, increased trapping time, a 75-100 fold increase in signal-to-noise, and mass resolution far above unit mass resolution for proteins up to bovine insulin b chain have been achieved. In Figure 2, the duration of QE application is shown to be important for resolving the sodium and potassium attached adducts of gramicidin D. In our experiments, application of QE for more than 3-4 seconds is needed for optimum resolution. In Figure 3, the QE selectivity is shown as the QE is adjusted to give both different isotopes and adducts of gramicidin D. In many cases, single isotopes can be selected for subsequent excitation/detection. Mass resolution for each of these spectra is approximately 15,000 for all isotopes and adducts. Maximum mass resolution to date for single isotopes is 30,000 for gramicidin D and 7,000 for bovine insulin b chain.

INTRODUCTION

Electrospray mass spectrometry (ESI/MS) is a fast, efficient and versatile method of obtaining information that the biochemist seeks: primary amino acid sequence and protein conformation, as well as determining the location of reactive sites along the peptide backbone. Structural characterization of proteins by mass spectrometry is often carried out using fragmentation processes, such as sustained off-resonance irradiation (SORI), collision cell or nozzle-skimmer dissociation. The purpose of this work is to evaluate how these techniques may be exploited further to provide conformational data, as well as identify and locate reactive amino acid residues along the peptide backbone.

Several approaches are explored. Energy-dependent fragmentation pathways are evaluated for the SORI fragmentation process. Fragmentation pattern is studied as a function of charge state as a means of evaluating protein conformation. Proteins are treated with site-specific reagents to produce covalently-bonded adducts, which are then fragmented to locate the site of reaction.

INSTRUMENTATION

All spectra were obtained with a 3.0T FTICR mass spectrometer with four differentially-pumped concentric vacuum chambers coupled to a Chait-type electrospray ionization source. The spectrometer included a 6" diameter bore magnet into which the vacuum chamber was inserted. Two-plate quadrupolar excitation (QE) was applied during the accumulated trapping event to exclusively trap ions at the m/z value of interest for further study. Once such ions had been isolated, a single frequency excite was applied 1500 Hz off-resonance for a period of 1.5 seconds. Peak-to-peak voltage was increased until sufficient energy was deposited to surpass the fragmentation threshold. Argon was pulsed into the cell at a pressure of 2 x 10-5 torr during the QE and SORI events.

ENERGY-DEPENDENT FRAGMENTATION PATHWAYS

Nozzle-skimmer dissociation has been used extensively to fragment biomolecules prior to mass analysis. It is well documented that proline residues are the predominant site of fragmentation due to their inherent rigidity. The proline bond strain results in direct cleavage when the molecule encounters the high-energy collisions of the nozzle-skimmer region. However, SORI provides a mechanism that favors low-energy dissociation pathways.

Yeast ubiquitin was fragmented using SORI to determine if proline residues would be the predominant site of fragmentation as in the case of nozzle-skimmer dissociation. Surprisingly, only one, low-abundance proline (Pro) cleavage was observed, whereas aspartates (Asp) and glutamates (Glu) appeared to be the dominant fragmentation sites. The dominance of acidic residue rearrangement over proline cleavage can be explained by evaluating the fragmentation pathway as a function of energy deposition. At lower energies the rearrangement process occurs but the cleavage does not. However, once the energy threshold for cleavage is achieved, the cleavage mechanism occurs at a faster rate than the rearrangement process. Angiotension II was chosen as a model compound because it has one aspartic acid and one proline residue. Figure 1 demonstrates the energy-dependence upon site of fragmentation. At low energies, no fragmentation occurs. In contrast, just above the fragmentation threshold, aspartic acid fragmentation is more abundant than proline cleavage. As the energy increases, the proline cleavage becomes more favorable until it becomes the dominant fragmentation pathway.

FRAGMENTATION PATTERN AS A FUNCTION OF CHARGE STATE

If all charge states fragmented alike, this would suggest that either all the charge states had an identical conformation or that the internal energy from SORI disrupts conformational interactions as well as peptide bonds. However, the spectra of melittin in Figure 2 indicate that charge states exhibit different fragmentation patterns. This change in location and abundance of fragmentation for different charge states may be due to coulombic repulsion effects or the dissociation of different gas-phase conformations. If Coulombic repulsion is the cause, then more fragmentation should occur as the number of charges on the molecule increases. However, this is not true for melittin; fragmentation decreases as charge state increases. Therefore, variations of gas-phase conformation with charge state may be responsible for the different fragmentation patterns.

EVALUATION OF SITE REACTIVITY AND LOCATION

The basic goal of protein chemistry is to relate specific structural features of biomolecules to their physical, chemical, and biological properties. Recently, "active-site-directed" reagents have been designed to react preferentially with only those parts of protein molecules that are physically in the vicinity of particular biochemically active sites. ESI/SORI/FTICR analysis of these chemically modified proteins would provide a quick and efficient method of determining the location of reactive residues along the peptide backbone.

To provide a simple demonstration of this technique, acetone was added to an aqueous solution of yeast ubiquitin, later followed by the addition of methanol and acetic acid. Reaction between the free amine sites of the protein and the carbonyl carbon of acetone produces a Schiff-base. The -C=N- bond formed is sufficiently strong to survive the ion dissociation process and each Schiff-base increases the molecular weight by 40.06 Da. Figure 3 presents the SORI analysis of the modified ubiquitin protein. Modified protein ions were selectively trapped using QE accumulated trapping. Figures 3a and 3b demonstrate how the relative abundance of modified to unmodified fragments can be used to elucidate site reactivity and location.

Three-Dimensional Collisionally Stabilized Motion in an Open Cell Applied to Remeasurement in FT-ICR

V. H. Vartanian and D. A. Laude, The University of Texas at Austin, Austin, Texas 78712-1167

Introduction: The first demonstration of dynamic motional stability of high amplitude trajectories of small organic ions in an open cell [1] using only a d. c. trapping field is applied to the FT-ICR remeasurement experiment [2]. Remeasurement efficiencies of more than 99.62% have been observed over 300 cycles for benzene using helium as the buffer gas. In the open cell, ions can penetrate axially past the physical boundaries of the trap electrodes into regions where the radial electric field actually becomes inward-directed. Since the radial electric field reverses orientation at increased axial displacement, it is possible to refocus ions back to the z-axis of the cell to reduce magnetron motion. The ability to maintain a constant magnetron radius even in the presence of a high pressure buffer gas can be immediately applied to the remeasurement experiment. The open cell axial position dependent radial electric field passively stabilizes collisionally destabilized ions. Ions are maintained in stable trajectories as long as they penetrate sufficiently far into the potential well where the radial electric field orientation shift occurs. A static pressure of a low mass buffer gas can be used to increase the ion axial amplitude similar to the mechanism observed for collision-induced axial excitation in the CID experiment [3].

Theory: The principal limitation in remeasurement is the inability to retain ions long enough to perform a sufficient number of remeasurements. Consecutive excitation events are performed in an outward-directed radial electric field which causes radial drift of the ion cloud, preventing the relaxation of the ion cloud to the original radius. The result is ion loss, and the limitation of remeasurement efficiency. Although the addition of a high-pressure buffer gas damps the cyclotron motion for subsequent reexcitation, the high collisional rate further destabilizes the magnetron motion and accelerates off-axis drift. As the ion mass decreases with respect to the buffer gas, the radial scattering angle increases. Remeasurement experiments without quadrupolar excitation (QE) have relied on minimizing the radial electric field in the cell.

Represented in Figure 1a is a SIMION plot of the radial electric field for the closed elongated cell as a function of z-axis position. An ion sustaining a collision with a neutral molecule anywhere in the cell would experience magnetron destabilization. However, the open cell intrinsically produces the required radial stability for ion reaxialization. In the open cell illustrated in Figure 1b, the radial electric field is outward-directed near the center of the cell, but becomes increasingly inward-directed (negative) at increased axial displacement. An ion of low oscillation amplitude that sustains a collision experiences magnetron destabilization while an ion of large axial amplitude experiences radial stabilization in the inward-directed radial electric field. The reaxialization ions experience is a function of time spent in the stabilizing regions of the cell and ions undergoing large-amplitude oscillations experience greater stability. The dynamic effect of radial electric field focusing on radial ion trajectory in closed and open cells is shown in Figure 2a where a 0.02 eV ion in a closed elongated cell indicates that after only 220 us, the ion has collided with a cell electrode. In actuality, ion motion is radially stabilized by the Lorentz magnetic force. In contrast, Figure 2b indicates that a 0.73 eV ion in an open cell may remain trapped indefinitely.

If the ion trajectory following a collision results in increased axial amplitude allowing ions to experience the inward-directed radial electric field, then the radial expansion of the ion cloud can in principle be offset. In CID, high buffer gas pressure is used to affect fragmentation as ions are accelerated to several keV. As target neutral pressure and excitation power increase, axial ejection increases as the ion cloud expands axially. As the ion-to-neutral mass ratio decreases, axial ejection increases due to greater z-amplitude scattering. Ion loss decreases as trapping potential increases, in contrast to what is observed for radial ion diffusion. The same tendencies have been observed in the open cell remeasurement experiment.

Experimental: Remeasurement was performed in an open cell appended to the analyzer side of a dual cell assembly in a 3.0 Tesla magnet. Helium buffer gas was maintained at 2×10^{-4} Torr. Neutral benzene was maintained at a pressure of 6×10^{-6} Torr in the source side where it diffused through the conductance limit to a pressure of 1×10^{-8} Torr in the analyzer side. A remeasurement pulse sequence was used with the form $I\text{–}D_z\text{–}[Ex\text{–}A\text{–}D_{xy}]_n\text{–}Q$. The ionization event, I, using a 5μA, 5 msec, and -15 eV electron beam generated ions. A 1 second axialization delay, D_z, permitted collisional cooling of axial motion prior to excitation. Multiple applications (n) of the three event cycle $[Ex\text{–}A\text{–}D_{xy}]$ resulted in ion excitation (Ex) with a 100-μsec pulse. A pressure-dependent collisional cooling delay (D_{xy}) of varied duration facilitated

relaxation of the cyclotron motion prior to the next measurement. Parameters effecting remeasurement efficiency were altered including excitation power, relaxation time, and trap voltage.

Results and Discussion: Figure 3a depicts a plot of signal intensity as a function of excitation power, indicating that during eight remeasurements, maximum signal intensity occurs at 3.48 $V_{P\text{-}P}$, or at a radius at 13% of the cell radius. At greater excitation levels, ions encounter regions of the cell where relaxation is not as efficient or energies associated with increasing excitation radius may promote axial or radial ion scattering. In Figure 3b, a plot of abundance versus relaxation delay between successive excitation events involving eight excite-τ-excite cycles followed by detection indicates that maximum signal intensity occurs with a 500 ms relaxation delay. The effect of trap voltage on remeasurement as a function of excitation energy is shown in Figure 3c where increasing trap voltage increases radial drift, reducing signal.

Figure 4a is a plot of the summed signal intensity for benzene versus the number of remeasurement cycles. The top plot represents the theoretical performance expected for 100% remeasurement efficiency while the bottom plot represents the experimental 99.62% remeasurement efficiency. Because the chief motivation of remeasurement is S/N enhancement, Figure 4b illustrates S/N ratio of benzene versus number of measurements. The top plot represents the S/N enhancement for theoretical 100.0% efficiency where the signal should increase as the square root of n measurements (in this case there is no ion loss). The bottom plot represents experimental 99.62% remeasurement efficiency following 300 measurements.

Facile Implementation of Quadrupolar Axialization in FTMS

C. F. Ijames
Section on Analytical Biochemistry, National Institute of Mental Health, Bethesda, MD 20892

Quadrupolar excitation coupled with collisional damping of the resultant cyclotron motion is an important new tool in FTMS. As originally described, two waveforms, differing in phase by 180°, are applied to the plates parallel to the magnetic field of the trapped ion cell. Each waveform is applied to a parallel pair of plates. Irradiation at the cyclotron frequency effects periodic interconversion of magnetron and cyclotron motion, and by matching the interconversion rate to the collisional damping rate, ions can be spiraled back to the center of the cell. This reverses the natural growth of the magnetron radius with collisions, the primary limitation on ion storage time, and provides a much more localized ion packet for subsequent manipulations such as transfer to another cell or excitation and detection.[1]

Several limitations exist with this scheme, however. If the cell is also to be used for detection, then the cell plates must be disconnected from the excite amplifier and reconnected to the preamp inputs during the experiment sequence. This is very difficult to do with adequate shielding and without adding additional capacitance, both of which reduces the signal-to-noise ratio. Also, a popular high voltage excite amplifier used in commercial FTMS systems has severe constraints on the capacitive loading of its outputs, such that it is impossible to merely connect two cell leads directly to the amplifier output without causing oscillation and damage. While fast (millisecond) relays certainly can be used to switch the amplifier outputs, they require some care in use in the strong fringing field of typical superconducting magnets, and require the appropriate control and driving electronics.

Here we describe the implementation of quadrupolar excitation using an unbalanced mode, where only one waveform is applied to a parallel pair of cell plates, while the other pair is left grounded (or connected to the preamp inputs) This reduces the electric field by half, requiring twice the applied voltage or twice the interconversion time, but eliminates the problems of switching the preamp inputs. It also causes a modulation of the trap potential, but so long as the resonance at twice the trap frequency is avoided, causes no ill effects. Further, the high voltage excite amplifier is actually a dual amplifier, providing two independent differential outputs with well matched gain characteristics. By using the in-phase outputs of both channels and applying each channel to only one cell plate, the capacitive loading problems are eliminated. Finally, the dipolar excitation can be performed in an unbalanced mode as well. While this is less ideal than balanced dipolar excitation, increasing the susceptibility to space charge effects, reducing the observed signal slightly, and reducing the ultimate resolution by perhaps half, it does allow quadrupolar axialization to be implemented merely by interchanging two cables connecting the dual cells of a FTMS 2000 (Extrel FTMS, Madison, WI) to the high voltage excite amplifier. This permits both dipolar and quadrupolar excitation to be applied in the unbalanced mode to both cells, without disturbing the preamp inputs and without using relays to switch the amplifier-cell connections.

Also presented are four cell connection schemes of various complexity (numbers of relays required) to allow quadrupolar and dipolar excitation to be applied in the balanced and unbalanced modes (see Table 1). Scheme 1 is the most complete implementation, providing balanced quadrupolar excitation in cell 1 and balanced dipolar excitation in both cells, but requires five relays and switches the inputs of both preamps. If there is only one cell a dummy load must be connected to S+ and S- during non-quadrupolar excitation events. Scheme 2 is a simplified version of scheme 1, requiring only 2 relays, which

provides balanced quadrupolar excitation in cell 1 and balanced dipolar excitation in cell 2 but does not allow dipolar excitation/detection in cell 1. This is equivalent to the experimental arrangement utilized in previous dual-cell quadrupolar excitation reports, and does not switch the preamp inputs.[1] Rather than leave unused cell plates floating, a 1 megohm resistor can be connected between each plate and ground. Scheme 3 is the most efficient. It provides unbalanced quadrupolar excitation in both cells, balanced dipolar excitation in both cells, does not switch the preamp inputs, and requires only 2 relays. Scheme 4 provides unbalanced quadrupolar excitation and unbalanced dipolar excitation in both cells, and does not require any switching during an experiment, making it the simplest to implement.

Table 1. Possible Dual-Cell Connection Schemes for Extrel High-Power Excite Amplifier

		Quadrupolar Excitation									Dipolar Excitation/Detection

Electron Beam Enhancement of Laser Desorbed Ion Signals in FT-ICR

Easterling, Michael L.; Amster, I. Jonathan

Department of Chemistry, University of Georgia, Athens, GA 30602-2556

Laser desorption and matrix assisted laser desorption ionization are among the most powerful methods of generating ions of non volatile molecules. These modes are adept at ionization of large molecules and especially well suited for FT-ICR mass spectrometry. The major weakness in laser desorption for our experiments is the often oscillation of the ion signal intensity seen in successive shots on a given region of the sample. Also, the desorption parameters of laser irradiance and sample preparation must be meticulously adjusted to produce desired ions

In our lab, we have observed the application of a low energy electron beam applied along the magnetic axis of an FT-ICR mass spectrometer can significantly enhance the amplitude of the observed ion signal.. Experimentally, we use a 1 Tesla electromagnet with a cubic ICR cell. A filament placed just outside of a trapping plate provides the electron beam that propagates along the magnetic axis. An **IonSpec™** digital-analog controller modifies the potential of the filament, and can be programmed for microsecond resolution throughout the trapping sequence The laser beam path to the sample probe lies perpendicular to the magnetic axis.

Unlike normal modes of electron beam operation that use acceleration voltages of 60-70 eV, ion signal enhancement appears to be most efficient when the filament potential is near ground. The electrons are drawn out into the cell by the 3 V trapping potential used in this experiment. The beam is normally pulsed for 2-3 repetitions of 10-20 ms for a 2 second trapping sequence. As the acceleration voltage is low, ionization effects from the electron beam are not observed.

The ion signal enhancement varied as a function of filament current and was observed to have an optimal range of around 1.9 - 2.1 A. This corresponded to a measured emission current of 4-10 uA. Signal improvement was nominally 2-40 times that of the background signal In many cases, signals could be obtained from a sample that produced only noise under normal conditions. Also, low intensity ions that were not normally identifiable were detected with the electron beam enhancement.

Although a combination of sequences were used for the electron beam event, it was observed that the beam must not be active during the detect phase. Although transient signals last much longer in the presence of the electron beam, a current dependant mass shift will result. In extreme cases, this mass shift approached 10-12 m/z units If the electron beam is quenched prior to detection, mass shifting and resolution degredation is not observed.

EXPERIMENTAL STUDIES OF BROADBAND QUADRUPOLAR EXCITATION IN FT-ICR

C. C. Pitsenberger*, I. J Amster
Department of Chemistry, University of Georgia, Athens, Georgia 30602

Since its debut, quadrupolar excitation (QE) has attracted considerable attention for the enhancement it provides to FT-ICR performance [1-4] When combined with collisional damping, QE leads to axialization of ions. QE has been shown to provide unique capabilities for permitting ion remeasurement leading to high mass resolution and sensitivity Most published work has focused on single frequency excitation Axialization over a mass range has been reported,[4-6] in particular using SWIFT QE for transferring ions from source to analyzer in a dual cell ICR systems. Yet, the utility of this technique has not been fully developed for MS/MS studies or for ICR systems lacking SWIFT capabilities. For some time now, our group has been working on extending the capabilities of single frequency QE (in a single cubic cell) to a broadband axialization (in a single cubic cell). One of our principle goals for this research is to develop well characterized MS/MS experiments Our single analyzer cell and pulsed gas flexibilities will allow us multiple MS/MS with high resolution capabilities when used in conjunction with QE Here we describe some of the different methods used in pursuit of this goal, including repetitive chirp excitation and filtered noise excitation. The efficiency and applicability of broadband repetitive chirp excitation is presented and we introduce, specifically for the first time, the method feasibility and signal enhancement gained when using filtered white noise QE

Two plate quadrupolar excitation[7] was used in these experiments Both broadband repetitive chirp and filtered noise QE experiments were similar in sequence A 1-T electromagnet and 337 nm output of an excimer laser were used for laser desorption of the peptide (Val-Pro-Leu) studied. Both white noise and continuous frequency chirps originated from a Stanford Research Systems frequency synthesizer. White noise was passed through an active filter before amplified and applied to the cell plates. The bandpass could be adjusted to select the desired frequency range for excitation.

Both broadband repetitive chirp and filtered white noise quadrupolar excitation efficiently axialize ions in our instrument. Figure 1a illustrates MALDI of VPL in the absence of QE. Figure 1b Illustrates axialization of VPL ions in the presence of filtered noise QE This demonstrates the phase independence of QE.[5] Efficiencies are in excess of 98% for repetitive chirp excitation and greater than 99.5% for single frequency quadrupolar excitation (See Figure 2). Remeasurement efficiencies for filtered white noise QE were found to be much lower (80%), but this is in part attributed to the initial selection of the active filter. The active filter will next be modified to yield a flatter bandpass and sharper cutoffs. It is demonstrated that both repetitive chirp and filtered noise QE have potential to enable high resolution analysis. The duration of the transient signal increases by more that three orders of magnitude when either broadband QE method (chirp or noise) is used to axialize ions before the detection event. Remeasurement efficiencies and high resolution experiments should be more efficient using QE at higher magnetic field strength. The

ability to efficiently remeasure ions is obvious for MS/MS analysis of biopolymers and we have presented two techniques that hold great potential for this application

Quadrupole Excitation Trapping during Electron Beam Events in ICR Spectrometry

Joey Hatcher, John Bartmess*, Department of Chemistry, University of Tennessee, Knoxville TN 37996-1600

The generation of cations by electron ionization is straightforward above the ionization energy, all compounds form some cations, with only ca. two orders of magnitude variation in the ionization cross-section.

Formation of anions, however, is much more variable The cross-section varies over more than seven orders of magnitude, and in a non-monotonic fashion with electron energy. Few compounds fall in the high-cross-section end of the range. Relatively high pressures for many of the neutral precursors are thus required to yield reasonable signal intensities in negative ion EIMS.

For example, in ICR spectrometry, Cl^- from CCl_4 yields an intense signal with a partial pressure of CCl_4 at $1x10^{-8}$ torr, with a 10 msec, 1 microamp electron beam. In contrast, to produce a comparable amount of hydroxide from water at the appropriate E_{max} requires an H_2O pressure of ca. $5x10^{-6}$ torr.

Such high pressures result in signal broadening in ICR spectrometry, and leave little "pressure range" above that for other reactant gases. Although external ion sources can inject any ion into a low pressure reactive gas environment in ICR spectrometry, we seek a lower cost method.

Experiments were carried out on a home-built ICR mass spectrometer. Pumping was via a 100-l/s turbomolecular pump. This is normally throttled down considerably for the constant pressure experiments, to minimize pressure gradients. Quadrupole excitation was implemented essentially as described in the literature.[1] A General Products pulsed valve was overdriven at ca 70 V in a 1 msec pulse, to raise the pressure of the anion precursor to the 10^{-5} torr range. Backing pressure was the vapor pressure of water at 25^0C, 25 torr.

Typical optimized values for parameters include an quad rf level of ca. 150 mV (about 5 times theoretical value)[1] and a frequency several percent higher than theoretical ideal (at δ_c) The latter may be in part due to the electron beam being present in the cell, at the location to which the ions relax.

For development, benzene was used as the pulsed gas, with no constant pressure gas. The benzene radical cation was detected, when the electron beam event commenced at the start of the gas pulse. The gas pulse peaked at approximately mid 10^{-5} torr, and was below 10^{-6} torr at ca 700 msec Quadrupole excitation trapping was carried out from the start of the electron beam event, for 700 msec, then detection was performed staring at 900 msec.

In negative ion mode, water gave abundant HO^- under comparable conditions. With ethylbenzene present at $1x10^{-6}$ torr, it required quadrupole trapping at both 105^- and 17^- to obtain the 105^- signal

This is intriguing, in that the full chemical sequence is:

$H_2O + e^- \rightarrow H^- + HO^\cdot$

$H^- + H_2O \rightarrow HO^- + H_2$

$HO^- + PhCH_2CH_3 \rightarrow H_2O + PhCHCH_3$ (105^-)

and m/z 1, the primary ion, was not trapped via QE The second reaction must be far more rapid than ion loss.

At this point the pulsed valve developed an air leak, as evidenced by the 32^- signal becoming the base peak when trapping 17^-. Interestingly, we were not irradiating at the 32^- frequency; this may be due to exothermic electron transfer from HO^- to O_2 in the lower pressure latter stages of the experiment.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Studies of Individual Large Molecules by ESI-FTICR Mass Spectrometry

Ruidan Chen, James E. Bruce, Xueheng Cheng, Dale W. Mitchell, Steven A. Hofstadler, Gordon A. Anderson, and Richard D. Smith
Pacific Northwest Laboratory, Richland, Washington 99352

We have developed methods for molecular weight (MW) determination of megadalton molecules based on the measurements of individual ions by FTICR-MS. Stepwise charge state shifts of individual ions in reaction with selected reagents produce multiple peaks from the same ion, from which charge states and MW can be calculated.[1,2] Alternatively, the number of charges can be measured simultaneously with the mass-to-charge ratio to obtain the molecular weight of an individual ion, although with precision currently limited to 5 ~ 10%. For the case of very large molecules (>10 MDa), only the latter approach has been effective thus far.[3,4]

To extend the study of such large molecules, two efforts have been carried out. First, theoretical explanation of the mass-discrimination in FTMS during excitation for large ions was explored. We have previously observed that, for ions having similar m/z values but different masses, lighter ions are excited to larger radii than heavier ions. Several mechanisms may be involved, such as collisional damping that expands lighter ion's magnetron radius more rapidly than heavier ion's. The Coulombic interactions between large (heavier and more charge) and small (lighter and fewer charge) ions may constrain small ions move around the large ones which makes the smaller ones being ejected earlier. The so-called "centrifugal separation"[5] of different ionic species may also involved in such a process. Second, we studied theoretically the damping (or expansion) rate for large ions and our results showed that large ions (MW > 1,000,000 Da) have much slower damping (and magnetron expansion) rates, consistent with our previous observations. Furthermore, we acquired several long transients from Coliphage T4 DNA ions. Figure 1 shows a 1040 second transient (limited by the Odyssey Data system used in our experiments), much longer transients could be acquired when appropriate hardware and software were available.

Pacific Northwest Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy under Contract DE-AC06-76RLO 1830.

The selective accumulation from externally generated low ion currents in an FTICR mass spectrometer can be effectively accomplished.[1] The selective ion accumulation process can facilitate many types of studies, and is particularly effective in conjunction with continuous injection from an electrospray source. However, this technique also requires relative high background gas pressure ($\geq 10^{-5}$ Torr), which can limit the optimal performance for subsequent FTICR measurements at pressure of $\sim 10^{-8}$ Torr and below. To resolve these conflicting demands, we have designed a new dual cell-type of ion trap. The first cell is sealed in a box which is slightly larger than the cell itself. A gas inlet line is connected to the box, and collision gases are introduced directly into the first cell (see Figure 1). This reduces the gas load upon the vacuum chamber during selective ion accumulation by as many as 4 orders of magnitude. This feature allows greatly extended selective ion accumulation. After the selective ion accumulation, the accumulated ions can be transferred through a conductance limit into the second cell for further manipulation and detection, where pressure is $\sim 10^{-9}$ Torr. To increase the obtainable pressure difference beyond the two orders of magnitude typically achieved in dual cell designs, a "shutter" over the conductance limit has been incorporated, and which is only open during transport of ions between the cells. Thus, this new cell allows the combination of the continuous ion injection and selective accumulation in the first cell, the periodic sampling from the first cell, and high performance analysis by the second cell. In a control experiment, buffer gas is continuously leaked into the first cell by a leak valve for ion accumulation, while the selected ions are transferred to the second cell for detection.

To utilize this dual cell trap for the analysis of large complex biosystems, e.g., a mixture of a biotarget and a large inhibitor library, two more experiments are carried out: 1) Selectively accumulated ions can be transferred to the analyzer cell in a multistage transfer sequence (see Figure 2). The ion intensity (Ubiquitin, 1 mg/ml in 10 mM acetic acid) detected in the analyzer cell increases linearly with the number of ion transfers until the space charge limit is reached where frequency shift and/or peak distortion occur. 2) Accumulated ions can also be selectively transferred to the analyzer cell by using magnetron excitation and single frequency quadrupolar cooling. A dipolar magnetron excitation waveform can also be used to enlarge the ion magnetron radius in the first cell. Only those ions which are "cooled" by a quadrupolar cooling waveform can be transferred to the analyzer cell through the conductance limits (see Figure 3).

Fourier transform ion cyclotron resonance (FTICR) mass spectrometry is becoming a powerful technique for the investigation of large biomolecules. This evolution has been made possible with the advent of new ionization techniques, such as matrix assisted laser desorption-ionization (MALDI) and electrospray ionization (ESI). However, with this introduction of new methods of ionization has arisen a broad range of new challenges for detection. For example, the high ionization efficiency of ESI provides a basis for considerably surpassing the sensitivity and dynamic range of FTICR, and in fact, most mass spectrometers. The development of methods for the generation of large libraries of biomolecules, such as those employed in combinatorial studies, and the desire to apply ESI to the analysis of these types of mixtures further enhances the motivation for even greater sensitivity and dynamic range. We have developed the technique of selective-ion accumulation (SIA)[1] for the purposes of increasing both the sensitivity and dynamic range of FTICR mass spectrometers with the application of quadrupole excitation during the ion accumulation period. This process has been shown to provide many advantages, two of which are the accumulation over relatively long time periods and *m/z* selectivity of the accumulation process. These features both arise from the continuous reduction of magnetron orbits which would otherwise lead to ion loss. For example, the effective analysis of low concentration solutions is increased three orders of magnitude since the accumulation period can become arbitrarily long (at least as long as pumping allows), with the reduction of ion loss through magnetron motion that normally occurs due to the extended high pressure.[2] The dynamic range is enhanced by the removal of more intense species, simultaneous with the accumulation process, thus allowing longer accumulation events focused on the detection of less abundant ions. A possible limitation of this dynamic range expansion arises from the speed with which non-selected ions can be forced off axis by increased magnetron motion. The magnetron motion of these species has normally been increased through collisions with neutral buffer gas molecules. Under our normal operating conditions, non-selected ions can still be detected (although with reduced peak intensities and resolution) after several seconds of high pressure. In a continuation of our development of the SIA process, we report here the application of a dipolar excitation waveform simultaneous with the SIA event, similar to those previously reported for purposes of collisional activation during quadrupole excitation[3]. Here, however, dipolar excitation is applied at the magnetron frequency to *actively* increase the magnetron orbits of all ions and thus, provide faster separation of selected from non-selected ions

Figure 1 illustrates the application of magnetron excitation concurrent with the selected ion accumulation process. Figure 1 (a) shows the normal accumulation spectrum of bovine ubiquitin without the use of selected-ion accumulation or magnetron excitation. The largest peaks here are those of the 6+ charge state. Figure 1 (b) shows a spectrum acquired with a 1 second selected-ion accumulation of the 7+ charge state (and various adducts) followed by a 1 second continuation of the high pressure and quadrupole excitation to further move non-selected ions off axis. The largest peaks are those due to the 7+ charge state; however, those due to the 6+ charge state are still evident and will require at least an additional 4 seconds of extended high pressure to be completely removed from the spectrum under these conditions. Figure 1(c) illustrates the results obtained under the same experimental conditions as applied to produce the spectrum in 1(b) except this time with the application of magnetron excitation of 300 mV at 18 Hz. These data illustrate the increased removal of unwanted ions from the FTICR cell with SIA and

the use of magnetron excitation to provide increased speed of ion removal during selected-ion accumulation (by a factor of about 5). Greater magnetron excitation voltage levels can provide an even faster magnetron ejection and accumulation, but may also produce higher levels of collisionally activated dissociation since the selected ions can achieve greater magnetron orbits prior to interconversion.

In summary, active magnetron excitation has been shown to provide faster removal of the undesired ions for more efficient selected-ion accumulation. Modest gains in efficiency are reported and further gains are predicted, but require careful tuning of quadrupole and magnetron excitation amplitudes to balance CAD, magnetron expansion and cyclotron damping rates.

Stored Waveform Inverse Fourier transform (SWIFT) excitation, introduced in FT-ICR nearly ten years ago,[1] is the method of choice for selective ion excitation and isolation over an arbitrarily wide range in mass-to-charge ratio. Originally developed for dipolar radial excitation of ion cyclotron motion, the SWIFT technique may also be applied to broadband azimuthal quadrupolar excitation for axialization in FT-ICR MS.[2] The advantages of SWIFT excitation for one-dimensional experiments also carry over to new two-dimensional FT-ICR MS experiments.[3a] A SWIFT-based method can even excite relativistic ions whose cyclotron frequency changes during the excitation process.[3b] Finally, the SWIFT method has been adapted for selective ion axial dipolar excitation and ejection in a quadrupole ion trap.[4]

Full realization of SWIFT's advantages depends on optimal phase-encodement of a given frequency-domain excitation magnitude profile. Fig. 1 compares several phase modulation methods, where all of the waveforms are obtained from a smoothed square magnitude spectrum.[5] For linear phase encodement, the time-domain waveform has a very high peak amplitude due to the superposition of all the sinusoids at a particular instant. Pseudo-random phase encodement yields a waveform with very low peak amplitude, but with very non-uniform time-domain excitation magnitude. A "minimum" phase may be obtained by Hilbert transform of the magnitude spectrum to give a time-domain waveform with minimum group delay, but without much amplitude reduction. Optimal peak amplitude reduction is achieved by use of optimized phase[7] which distributes excitation power over a specified time segment.

Ion motion *along* the magnetic field in an ICR trap may also be selectively excited. Isolation of ions according to their linear axial motional frequencies is especially attractive for low-mass ions whose cyclotron frequencies may be too high for commonly available ICR electronics. Fig. 2 shows selective axial ejection of ions from a crude oil sample. Another advantage of ion axial ejection is its low kinetic energy requirement: ions need be excited to only a few eV axial kinetic energy for axial ejection whereas cyclotron (radial) ejection requires a few hundreds of eV. A Unified Description of Space Charge Effects in FT-ICR Mass Spectrometry

Dale W. Mitchell and Richard D. Smith
Pacific Northwest Laboratory, Richland, WA 99352

A deeper understanding of space charge effects is required in order to make further improvements in the FT-ICR method. Due to the Coulombic interaction between different m/Z ion clouds, the cyclotron trajectories of the ions are perturbed from circular orbits moving with the cyclotron frequency, resulting in a sometimes dramatic variation from the behavior predicted for a single ion. Phenomena arising from the Coulombic interaction due to interactions between different m/Z ion clouds, same m/Z ions, or image charge induced on the trap electrodes, are generically referred to as space charge effects Trap geometry as well as the shape of the ion cloud determine the maximum number of ions which can be confined in a Penning-like ion trap. We consider the two important cases of either spherically or cylindrically shaped ion clouds (i.e coherently moving ion ensembles with different m/Z). These models exhibit the most important space charge effects in Fourier transform ion cyclotron resonance mass spectrometry including frequency shifts, amplitude and phase modulation and phase-locking. Both positive and negative frequency shifts are possible for spherical ion clouds when their cyclotron radii differ Due to the Coulombic interaction between ion clouds, cyclotron radius and phase modulation occurs. This modulation increases inversely to the cyclotron frequency difference. Cyclotron phase-locking results when two ion clouds have similar mass to charge ratios and a sufficiently large ion population, at which point a mass spectrum shows only a single peak. Spherical ion clouds are usually more likely to phase-lock than cylindrically shaped clouds. The phase-locking threshold sets new limits to the maximum resolution, mass accuracy and dynamic range achievable by mass spectrometry. Numerical and analytical methods are applied to two related problems of immense importance to FT-ICR mass spectrometry [1]. The first studies the dynamics of an individual ion cloud in the presence of external perturbing forces which act to destroy cloud coherence. The second problem involves the dynamics of Coulombically interacting ion clouds

I. Stability of Individual Ion Clouds

When many ions are simultaneously confined within the trap, the single ion description breaks down due to Coulomb interactions and one is confronted with a complicated many body problem A mean field approach is employed to study the stability of coherent cyclotron and magnetron motion. That is we investigate the stability of a test ion located initially on the edge of the ion cloud which interacts with the space charge electric field arising from the ion cloud The total charge within the ion cloud is assumed to be much greater than the charge of the test ion, therefore, while the test ion is perturbed by the ion cloud, the ion cloud is assumed unaffected by the presence of the test ion. The space charge electric field arising from the ion cloud introduces a fourth fundamental ion motion in addition to the $\omega_{\pm}$ and ω_z harmonic oscillations; the spin rotation of the ion cloud about its own symmetry axis in the x-y plane at a frequency ω_r [2] The ion cloud spin originates form the **E x B** drift where **E** is due to the ion cloud's own space charge electric field. Therefore, if the ion cloud is moved off of the trap z-axis (e.g. given a coherent non-zero magnetron or cyclotron radius), the ion cloud still has spin at frequency ω_r about the cloud symmetry axis with coherent magnetron or cyclotron motion superimposed. The theory is applied to force gradients arising from trap imperfections, magnetic bottle and image charge.

II. The Cyclotron Motion of Coulombically Interacting Ion Clouds.

Coulomb induced frequency shifts, amplitude and phase modulation, and phase-locking are the most important space charge effects in FT-ICR. The Coulomb interaction between two different m/Z ion clouds excited to some cyclotron radius (not necessarily the same radius) modifies the radial electric field experienced by the ion clouds. The cyclotron frequencies are shifted from their unperturbed values as a result of this space charge induced radial electric field Since the distance between the ion clouds changes with periodicity $\approx \Delta\omega_c^{-1}$, where $\Delta\omega_c$ is the cyclotron frequency difference, the cyclotron phases are modulated. The cyclotron radii are modulated as well since the mutual **E x B** drift between the two ion clouds, where **E** is the space charge induced electric field, causes a variation in radius with time However, if $\Delta\omega_c$ is small compared to the **E x B** drift frequency, the two ion clouds may phase-lock, whereby both clouds revolve around one another as well as the trap center During phase-locking, a mass spectrum shows only a single peak, and not two peaks. Theoretical relations are derived for the phase-locking threshold [1]. Good agreement is found between our predictions, results of numerical simulations on two ion clouds, and previously published experimental data [3] Our theory differs quantitatively from a recent investigation [4]. We have also carried out numerical simulations on cyclotron phase-locking involving more than two ion clouds

III. Space Charge Limits in FT-ICR

i z-confinement: Space charge potential cannot exceed trapping well depth This sets a maximum total charge which can be contained in the trap

ii. radial-confinement: Force balance between the radial space charge electric field, Lorenz magnetic force and coriolis force sets a maximum number density called the Brillioun limit which can be achieved.

iii cloud stabilization: The **E x B** drift rotation due to the ion cloud's own space charge electric field acts to maintain coherence for sufficiently dense ion clouds The ion cloud is destroyed if force gradients across the cloud diameter exceed a critical value.

iv. phase-locking: Related to cloud stabilization Consider two different m/Z ion clouds. If the **E x B** space charge cloud dynamics dominates the relative cyclotron motion then the ion clouds likely phase-lock, i.e. have identical detected cyclotron frequencies. Excited pure magnetron modes are almost always phase-locked due to the near m/Z independence of the unperturbed magnetron frequencies.

Minimization of Frequency Shifts for Improved Mass Accuracy in FT-ICR MS

Kent Gillig, Brian Bluhm, David H. Russell
Laboratory for Biological Mass Spectrometry
Department of Chemistry, Texas A&M University
College Station, TX 77843

Matrix Assisted Laser Desorption Ionization (MALDI) is an excellent method for ionizing a wide variety of large biomolecules. Thus, there has been considerable interest in combining the high resolution and accurate mass measurement capabilities of FT-ICR mass spectrometry with MALDI. In this study, the performance of several ICR cell geometries are compared (cubic, field corrected, elongated cylindrical, wire ion guide[1]) in terms of trapping efficiency and observed trapping voltage frequency shifts. The most accurate mass measurements are obtained using a wire ion guide cell, which produced trapping frequency shifts of ~1.6 Hz/Volt. Results from SIMION suggest that the improved performance of the wire ion guide cell is due to a more homogeneous trapping potential inside the cell. Figure 1 contains a internally calibrated broadband spectra of bovine albumin. Using a linear calibration curve the experimental mass of Bovine Serum Albumin was less than 1% different from the actual value (using 3 point calibration with Gramicidin S, Melittin, Bovine Insulin) as shown in Figure 2. Using conventional ion cells we were unable to detect ions for each component of the mixture; however, using the WIG cell, the abundance of each component is comparable. This WIG cell has been coupled with high trapping voltages to investigate their combined effects on trapping efficiency. An increase in trapping efficiency has been noticed along with a decrease in observed frequency shifts. To further improve trapping efficiency the ion cell geometry has been modified to emulate an electrostatic Kingdon Trap[2]. By applying DC voltages to all six plates and the wire of the WIG cell a Modified Kingdon Trap has been integrated into a conventional FTICR experiment. This has been accomplished by the addition of a relay system to switch from DC trapping to rf excitation in a one section cell. Figure 3 contains a diagram of a standard electrostatic Kingdon Trap and a diagram of a Modified Kingdon Trap used in FTICR experiments. Simulations of ion trajectories in the x-y plane of a Modified Kingdon Trap and a Modified Kingdon Trap in a 7-tesla magnetic field are shown in figure 4 and figure 5, respectively.

The coupling of electrospray ionization (ESI) with FT-ICR MS provides unrivaled sensitivity, mass accuracy, and resolving power for large biological molecules. By use of SWIFT isolation of individual charge states and infrared multiphoton dissociation for gas-phase ion desolvation, unit mass resolution FT-ICR mass spectra of molecules as large as bovine serum albumin (66 kDA) may be obtained,[1] although a single-scan spectrum may have poor signal-to-noise ratio. Here, we demonstrate dramatic improvement in signal-to-noise ratio, without the loss of mass resolving power, by use of enhanced analysis routines which have been incorporated into a new high performance data system built at the National High Magnetic Field Laboratory.

Time-domain ICR data for ions generated by ESI from large biological molecules typically consist of narrow "beats", which are widely spaced due to the numerous isotopic peaks which are almost equally spaced in frequency.[2] The intervals between beats consist primarily of noise, so that FFT magnitude mode spectra (which are obtained from equally-spaced samples thorughout the time-domain data) are quite noisy (Figure 1, top). A (non-FFT) analysis that selectively extracts the signal from the beats while ignoring the noise between them, should thus produce dramatically improved signal-to-noise ratio.

One simple FT-based method for enhancing spectral quality is to set all data between the beats to zero-amplitude, thereby suppressing the low-signal data while preserving the "beats" which contain most of the signal. FFT of such a partly-zeroed data set remains computationally simple and produces modest improvement (Figure 1, center).

A standard algorithm for non-linearly sampled data[3] produces a dramatically enhanced spectrum (Figure 1, bottom), at the cost of significantly higher computational effort. This work was supported by NSF (CHE-93-22824), NIH (GM-31683), and the National High Magnetic Field Laboratory at Florida State University.

We are developing the first experimental attempt at optical detection of electron spin resonance (ESR) spectroscopy of gas-phase molecular ions which have been mass-selected by ion cyclotron resonance. The generally accepted detection limit for conventional power absorption-based ESR detection is ~10^9 spins for a single one-second scan at room temperature of a 1 cm^3 sample of 1 Gauss linewidth at 3 tesla (84 GHz electron Larmor frequency).[1]

Optically detected magnetic resonance (ODMR) on phosphorescent neutral (singlet ground-state) molecules in solids dates back to 1967.[2] Use of optical rather than microwave photons for the detection of magnetic resonance offers vastly improved sensitivity compared to microwave detected ESR, leading to the recent ODMR detection of magnetic resonance of a single molecule.[3] In a cubic ICR ion trap at 3.0 tesla, only ~10,000,000 mass-selected organic ions are easily confined, so that ODMR methods are needed. Although ODMR of atomic ions has been observed by several groups,[4] ODMR of organic ions is much more difficult due to additional relaxation mechanisms (leading to much shorter electron spin-lattice relaxation time, T_1, and thus higher required microwave power to saturate the ESR transitions).

The experimental apparatus is shown in Figure 1. We use an open-ended multi-section cylindrical Penning ion trap to collect electron-ionized organic molecular cations in the presence of continuous azimuthal quadrupolar excitation to cool, axialize, and mass-select the ions as they fill the trap.[5] We propose to start with simple molecular ions like hexafluorobenzene. which should form abundant doublet ground state molecular radical cations. We shall monitor visible fluorescent emission while scanning the microwave irradiation frequency until the microwave frequency matches the Zeeman splitting; electron spin resonance is then inferred from a change in the fluorescent emission intensity. Automated and calibrated control of the experiment will be provided by a PC running under LabWindows and interfaced to a Hewlett-Packard VXI bus, GPIB and R232.

This work was supported by the National Science Foundation (CHE-93-22824) and the National High Magnetic Field Laboratory at Florida State University.

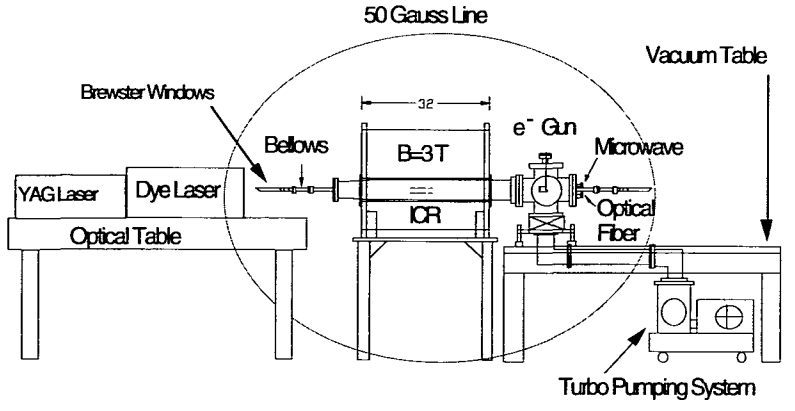

Figure 1. Apparatus for optically detected electron spin resonance of trapped, mass-selected molecular ions. The vacuum chamber is pumped to 10^{-9} torr by a turbomolecular pump (550 L/s). The solenoidal superconducting magnet is 3 tesla (Oxford Instruments) with 150 mm diameter bore for trapping ions. Two Brewster windows reduce the scattered light from the laser.

A Three-Section Quadrupole Ion Trap for FT-ICR Mass Spectrometry

Yulin Huang, Guozhong Li, Shenheng Guan*, and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State University, 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

* Department of Chemistry, Florida State University

We propose a novel three-section ion cyclotron resonance ion trap capable of high-pressure operation (Figure 1). Each section of the trap consists of four parallel circular cross-section rods. The middle section of four rods is held at ground potential. Axial confinement of ions along or opposed to the magnetic field direction is provided by applying the same d.c. potential to each set of "end cap" rods. Ions are trapped in the radial direction by the combination of a spatially homogeneous static magnetic field, B_0, and an azimuthal rf-inhomogeneous field produced by applying differential rf voltages to four rod electrodes parallel to the magnetic field axis. The overall effect is much like that of a quadrupole mass filter. When the rf frequency is high enough (several MHz), the azimuthal rf-inhomogeneous electric potential field forms an "effective" electrostatic potential (or "pseudopotential") well with a minimum at the center of the trap. Ion cyclotron frequency increases with the strength of the applied rf trapping field. Ion trajectories are stable even in the presence of ion-neutral collisions. Upper mass detection limit is dramatically increased by the addition of an rf electric potential. The trapping properties are revealed by construction of a "stability diagram".

Possible applications of this trap are as follows. First, for a given mass-to-charge ratio, m/q, we may adjust the rf amplitude to make the effective rf electric field, E_{rf}, equal in magnitude and opposite in direction to the regular dc trapping field, E_{dc}. In that limit, there is no magnetron motion (the magnetron frequency, ω_-, is zero); the "reduced" (observed) ICR frequency, ω_+, is unshifted by the electric field in the trap (for simplified mass calibration);

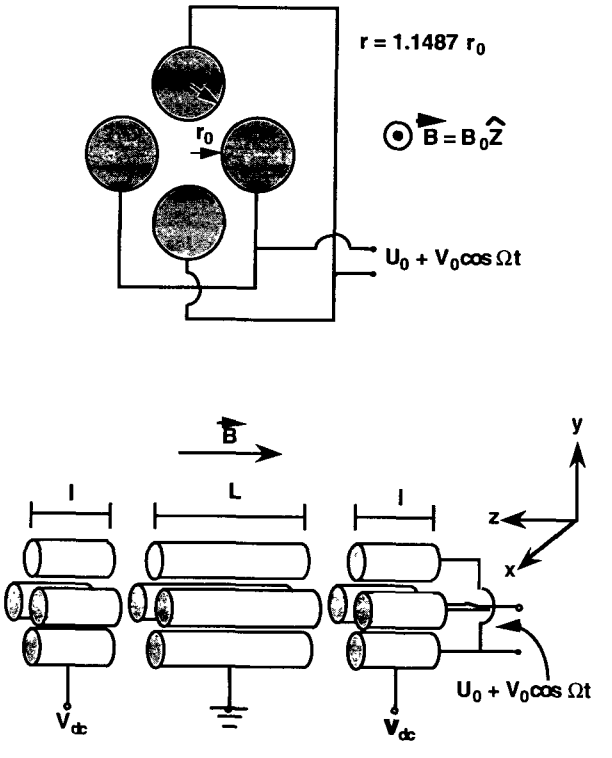
$$\omega_+ = \frac{qB_0}{m} = \omega_c$$

$$\omega_- = 0$$

and there is no upper mass instability limit. Second, the detectable upper mass limit may thus be extended to the theoretical limit for thermal motion, by setting the rf voltage amplitude, V_0 (see Fig. 1), such that $E_{rf} > E_{dc}$. For example, for V_{dc} = 1 V.

m/z	V_0(V)
1	2.2
10^3	69
10^5	690

Third, for all ions with mass less than the upper mass limit, ion motion is stable (i.e., the ion remains within the trap) even in the presence of collisions. Fourth, the effective magnetic field increases slightly on application of V_0.



U_0: dc voltage amplitude
V_0: rf voltage amplitude
V_{dc}: dc voltage in z-direction;
Ω: rf frequency;

[4]Gesellschaft fur Schwerionenforschung, D-64220 Darmstadt, Germany

The evaporation of neutrals is one possible decay channel of excited metal clusters. The time scale on which this process takes place is mainly determined by the statistical distribution of the excitation energy over the internal degrees of freedom of the cluster and the probability to locate a sufficient amount of energy on one degree suitable for dissociation [1] Investigations of the dynamics of the cluster fragmentation via beam experiments allows the observation of the decay only during short time windows determined by the length of the drift section of the apparatus, typically several hundred microseconds [2] The use of an ion trap for the storage of cluster ions extends the observation of the dynamics of fragmentation processes from microseconds to several seconds The experiments we report have been performed on gold and silver cluster ions of size n = 9 and 21 The clusters were excited via photons in the energy range between 3.7 eV and 4.4 eV

The cluster ions are produced by laser evaporation/ionization of a metal wire into a helium gas pulse which is expanded adiabatically into the vacuum [3]. They are transferred and injected into a Penning trap where they are stored in a 5T magnetic field. Specific cluster sizes are selected by resonant ejection of all unwanted ions. The mass selected cluster ions are centered by a combination of buffer gas cooling and quadrupolar rf excitation in the middle of the trap to obtain an optimal geometric overlap between clusters and laser beam. The beam of a Nd·YAG pumped Dye laser, whose output is frequency doubled (covering the wavelength range from 840 nm to 210 nm), is focused along the flight path of the ions into the center of the trap After the interaction the reaction products are identified via mass analysis using a two-stage time-of-flight mass spectrometer

Varying the delay between laser pulse and detection of the reaction products over a range of a few microseconds to hundreds of milliseconds the temporal development of the fragment pattern is observed Figure 1 shows on the upper part the signals of the precursor Ag_{21}^+ and its fragments at several times after the selected cluster Ag_{21}^+ has been excited. While the intensities of the precursor and all clusters with n≤18 stay constant, the Ag_{20}^+ ions decay to Ag_{19}^+ in the time range of about 2 ms The fragmentation behavior can be understood by considering the number of photons absorbed by the selected Ag_{21}^+ cluster Some will not absorb any photon and do not fragment Others absorb more than one photon and therefore decay fast to small cluster sizes n ≤ 18 Finally, the precursors Ag_{21}^+ that absorb just one photon decay to the next smaller cluster size "spontaneously", i.e in a period short compared to the duration of extraction from the Penning trap (about 20 μs). These primary fragment products, Ag_{20}^+, continue to decay to Ag_{19}^+ The time constant of this decay is a function of the photon energy and varies from 1 ms to 20 μs for photon energies from 3.7 eV to 4 4 eV

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Analogous studies on Au_{21}^+ show a different behavior. The creation of the fragment Au_{20}^+ and Au_{19}^+ is observed on different time scales Au_{19}^+ is created spontaneously, while the time constants for the appearance of the fragment Au_{20}^+ (fig. 1 lower part) at photon energies from 3.8 eV to 4 4 eV vary from 1,3 ms to 50 μs.

In this case similar conclusions can be drawn about the absorption of photons as above for the fragmentation of Ag_{21}^+. The slow development of the fragment Au_{20}^+ is due to the absorption of one photon by the precursor. The fragments n≤19 appear quasi-spontaneously and are the result of the absorption of at least two photons by Au_{21}^+. This explanation is also supported by the photon flux dependence at long (40ms) and short (12μs) decay times of the decay of Au_{21}^+ One finds a linear slope for the former case whereas the latter shows quadratic behavior and a lower fragment abundance (see also the contribution of C Walther et al.). The data are currently further evaluated and binding energies of the cluster ions will be extracted by use of RRK - models

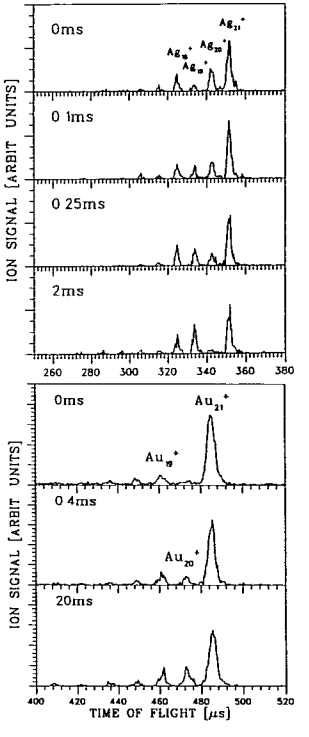

Figure 1. Time-of-flight mass spectra after photoexcitation of size-selected gold and silver clusters (delay periods between excitation and detection as indicated) Top· Ag_{21}^+ at a photon energy of 3.8 eV (time constant for the decay of Ag_{20}^+ and the appearance of Ag_{19}^+ 460 μs) Bottom Au_{21}^+ at a photon energy of 3.9 eV (time constant for the decay of Au_{21}^+ and the appearance of Au_{20}^+: 860 μs)

Instabilities of Ion Motions in Ion Cyclotron Resonance Traps

L. Schweikhard[1], J. Ziegler[1], H. Bopp[1], and K Lützenkirchen[2]

[1]Inst. f. Physik, Johannes Gutenberg-Universität, D-55099 Mainz, Germany
[2]Inst. f. Kernchemie, Johannes Gutenberg-Universität, D-55099 Mainz, Germany

Ion cyclotron resonance (ICR) traps (as used e.g. for Fourier Transform-ICR) store charged particles via a superposition of static magnetic and electric fields. In dependence of these fields ions of a very broad range up to a maximum mass-over-charge ratio $(m/q)_{crit}$ (the so-called critical mass) can be trapped. This theoretical mass limit for an ideal ICR trap (Penning trap) has been compared with experimental results

The measurements were performed by use of gold cluster ions and a Penning trap at a magnetic field of $B = 5\ T$ After production in an external source and transfer to the trap the ions were captured and size-selected at a low trapping voltage The trapping voltage was then varied to probe the maximum value possible, the critical trapping voltage U_{crit} (in analogy to $(m/q)_{crit}$ to which it can easily be transformed). Ion detection was achieved by axial ejection into a time-of-flight section. The setup has been constructed for the study of the properties of metal cluster ions by various mass spectrometical and laser spectroscopical methods as described in a recent review [1].

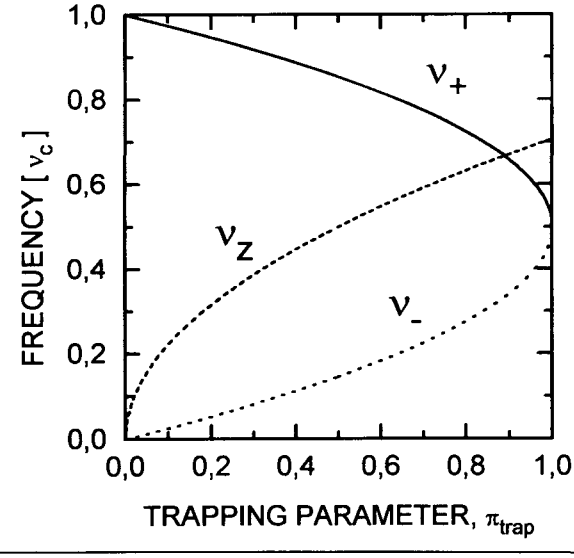

Figure 1. Eigenfrequencies of ion motion ω_+, ω_z, and ω_- (normalized to the cyclotron frequency) as a function of the trapping parameter π_{trap}.

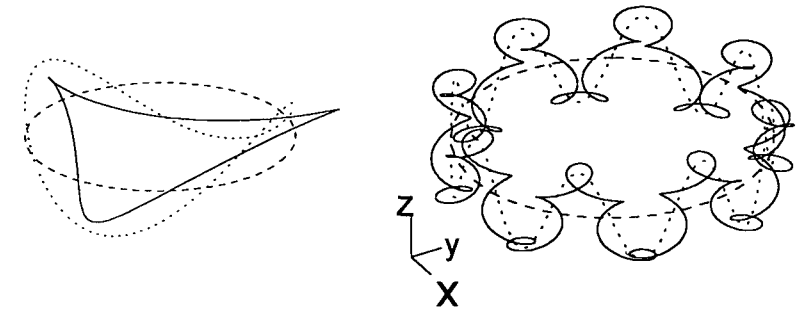

Figure 2. Ion motion in a Penning trap Dashed line. magnetron motion only, dotted line· combined magnetron and trapping motion; solid line full ion motion, i e combined magnetron, cyclotron, and trapping motion Left: $\omega_+ = \omega_z = 2\omega_-$. Right $\omega_+ = 4\omega_z$, $\omega_z = 8\omega_-$

In order to describe the trapping conditions with respect to the critical mass a generalized trapping parameter can be introduced [2]·

$$\pi_{trap} = 2\frac{\omega_z^2}{\omega_c^2} = \frac{U}{U_{crit}} = \frac{m/q}{(m/q)_{crit}} = \frac{2U}{d^2B^2}\frac{m}{q} \qquad (1)$$

$\pi_{trap} = 1$ corresponds to the critical condition ω_z and ω_c denote the trapping and cyclotron (in the absence of the electric field) frequency, respectively and d gives the dimension of the trap electrodes By use of the single parameter π_{trap} all ratios of the eigenfrequencies of the ion motion (ω_z, as well as the reduced cyclotron frequency, ω_z, and the magnetron frequency, ω_-), and their relation to ω_c (Figure 1) may be described simultaneously

The prediction of eq. 1 is in good agreement with the experimental results [2]. In addition to the well-known motional instability of ions exceeding the critical mass a new instability has been found at trap parameters that have so far not been considered to be 'critical' It appears at $\pi_{trap} = 8/9$. This means that the ratio of eigenfrequencies is $\omega_+ = \omega_z = 2\omega_-$. The ions' motion is a simple closed loop (Fig. 2 left) as compared to motions where the ions sample a larger part of the trap (Fig 2 right) Therefore the reduction in trapping efficiency may be understood by considering the repeated influence of perturbations of the ion motion from deviations of the actual trapping fields with respect to those of a perfect Penning trap [2].

Gold cluster ions (containing n = 3 to 23 atoms) are produced by laserevaporation of a metal wire into a helium gas pulse which is expanded adiabatically into the vacuum [1]. They are transferred and injected into a Penning trap where they are stored in a 5T magnetic field Specific cluster sizes are selected by resonant ejection of all unwanted ions. The mass selected cluster ions are centered in the middle of the trap by a combination of buffer gas cooling and quadrupolar rf excitation.

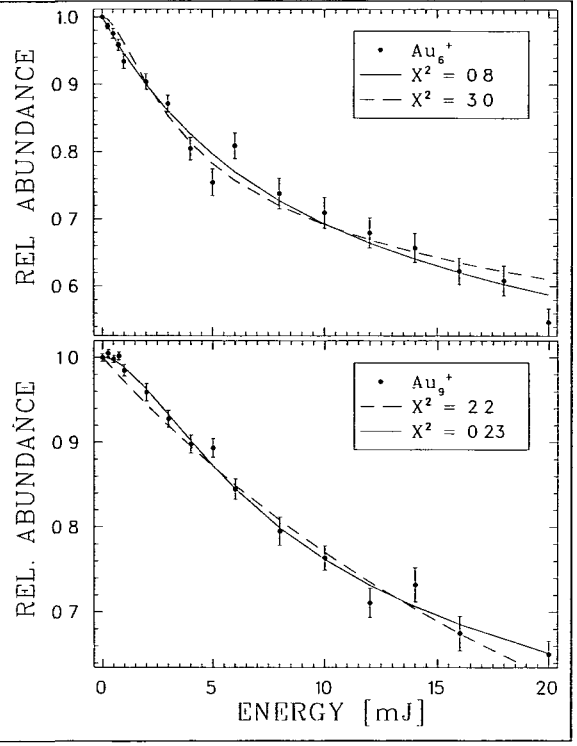

Figure 1. Photofragmentation of Au_n^+ using the second harmonic of a Nd:YAG laser (2 3eV). Top. Fragmentation of Au_6^+ The flux dependence shows a linear slope at low intensities indicating a one-photon process.
Bottom· Fragmentation of Au_9^+. A quadratic behavior is observed corresponding to a two-photon transition.

The second, third, and fourth harmonic of a Nd:YAG laser (wavelengths of λ = 532 nm, 355 nm, and 266 nm, respectively) is focused axially into the trap. In addition the output of a Nd YAG pumped dye-laser can be frequency doubled covering the wavelength range from 840 nm to 210 nm. The selected clusters and their reaction products are identified by mass analysis using a two-stage time-of-flight mass spectrometer. The experiments are an extension of previous work where the stored clusters have been collided with a buffer gas to induce dissociation [2].

The observed fragmentation patterns show a preferred production of odd cluster sizes, indicating that those clusters (containing an even number of atomic valence electrons) are more stable than even ones Clusters with an even number of atoms always evaporate monomers. For low laser intensities at 532 nm and 355 nm we found small odd clusters to prefer the evaporation of neutral dimers whereas at 266 nm the emission of single atoms was as likely This can be understood as follows: For photon energies near the fragmentation threshold only the energetically most favorable channel is populated. At photon energies considerably above the monomer evaporation becomes equally probable.

Using one fixed photon energy (2 3 eV) a cluster may need one or two photons to fragment, depending on its binding energy. In the former case one observes a linear increase of fragments with rising photon flux density as shown in the top of Fig 1. The latter results in a quadratic slope for low laser pulse energies (see bottom of Fig. 1). By use of the χ^2-values of the corresponding fits one can distinguish the two possibilities very well. (However, it is nontrivial to deduce the binding energies from these data.

For a given cluster size a transition from one to two photon fragmentation is achieved when the photon energy is lowered stepwise. Again, the transition energy is not identical with the fragmentation threshold but significantly higher. In the case of Au_{21}^+ the binding energy was found to be 2.0 (1) eV although for energies up to 4.0 eV (311 nm) 2-photon fragmentation is observed This difference increases, the more atoms the cluster consists of.

The fragmentation is understood as a statistical process. The excitation energy absorbed by the electrons of the cluster is transferred very rapidly into vibrations of the ionic core. Because of the finite temperature of the cluster before excitation, thermal energy (corresponding to room temperature in our case) has to be added. For an evaporation to take place it is necessary to accumulate an amount of energy exceeding the binding energy into one degree of freedom Especially if the excitation energy exceeds the binding energy only by a small amount this can take times up to tens of milliseconds. In contrast to beam experiments trapping the ions enables us to measure decay constants in this time domain. Being limited to short time scales may lead to an incomplete observation of fragments as the following example may illustrate· For Au_{21}^+ and a photon energy of 4 3 eV the time constant of the monomer evaporation (i.e. buildup of Au_{20}^+) is 50 (10) µs. But a certain amount of Au_{20}^+ appears quasi-spontaneous on the time scales accessible with our apparatus (faster than 10µs) Investigating the photon flux dependence at long (40 ms) and short (12 µs) delay times yields a linear slope for the former case whereas the latter shows quadratic behavior and a lower fragment abundance. This indicates the absorption of two photons and thus a higher excitation energy. Binding energies may be extracted by use of a RRK - model (see also M. Lindinger et al.).

Analysis of the substituent distribution in *O*-methyl celluloses by MALDI-FT-ICR-MS

C.G. de Koster, M.C. Duursma, P.W. Arisz, R.M.A. Heeren and J.J. Boon

FOM institute for Atomic and Molecular Physics, Kruislaan 407, 1098 SJ Amsterdam, The Netherlands

Methyl celluloses are heterogeneous mixtures of cellulose *O*-methyl ethers with a variable degree of substitution at different sites of the constituing monomers. Both the degree of substitution and the substituent distribution along the backbone determine the thermogelation temperature of the compounds. The *O*-Me substituent distribution along the cellulose backbone has been investigated by GC of their monomers and by FAB-MS with a sector instrument of perdeuteromethylated oligomers prepared by partial hydrolysis of the samples [1]. The distribution of the methyl groups in the perdeuteromethyl-*O*-methyl-cellotriose is derived from the peak intensities of the sodiated molecules in the FAB-MS spectrum. FAB-MS analysis of larger oligomers is hampered, due to the upper limit of mass resolution of the sector instrument, by the interference of fragment ions originating from sodiated oligomers with a higher degree of polymerization. Another complication in this context is the presence of FAB matrix cluster and fragment ions as a chemical background in the mass spectra.

FT-ICR-MS analysis of MALDI ionized perdeuteromethylated partial hydrolysates of methyl celluloses is a potentially highly advantageous method for the determination of the *O*-methyl substituent distribution in oligomers with a higher degree of polymerization than that of cellotriose. The external ion source FT-ICR-MS used in this work was a modified Bruker Spectrospin APEX 70e, 7T FT-ICR-MS with a home built ion source. MALDI of derivatized partial hydrolysates mixed with 2,5-dihydroxybenzoic acid (DHB) in a 1 : 1000 analyte / matrix molar ratio (sample size: a few ng on the target) produces sodium cationized molecules with a sufficient yield to detect the ions in the ICR cell. In a typical broad band experiment resolutions of 12,000 $(m/dm)_{50\%}$ were obtained with a S/N ratio of 30 at m/z 906 (tetramers). The perdeuteromethyl-*O*-methyl-cellotriose, -cellotetrose and -cellopentose pseudomolecular ion distributions were determined in heterodyne mode.

The MALDI-FT-ICR mass spectrum (heterodyne mode) of the perdeuteromethylated pentasaccharide obtained from a methyl cellulose hydrolysate is shown as a typical example in Fig. 1. The mass spectrum covers the entire methyl substituent distribution of perdeuteromethylated/methylated compounds CD_3O-(nCH_3O / (15-n)CD_3O-cellopentose)-CD_3 beginning with [CD_3O-(15CH_3O-cellopentose)-CD_3 + Na]$^+$ at m/z 1095.57 unto the CD_3O-(15CD_3O-cellopentose)-CD_3 + Na]$^+$ cations at m/z 1140.85. MALDI ionization of the derivatized cellopentose produces predominantly sodiated molecules giving peaks at equidistant intervals of 3 Dalton. No signals from potassiated or protonated species are observed. The resolution $(m/dm)_{50\%}$ is approximately 55,300 with a signal to noise ratio of 210 at m/z 1110.67 [CD_3O-(10CH_3 / 5CD_3O-cellopentose)-CD_3 + Na]$^+$ for a sample amount of a few ng on the target. Two ion series coincide with the mass range of the perdeutero/methyl cellopentoses. The series of peaks at the low mass end of the spectrum differs 17 Dalton with the corresponding [M+Na]$^+$ ions from the cellopentoses. These lower mass ions originate most likely from glycosidic

bond fragmentations of higher oligomers with charge retention on the reducing end [2]. The resolving power which is required to separate these fragment ions from the sodiated perdeuteromethyl/methyl cellopentose molecules is 30,000. The origin of the series of peaks at the high mass end of the spectrum is less obvious. However, both series of peaks do not interfer with the pseudomolecular ion distribution of the perdeutero/methyl cellopentose molecules. Therefore, the resolution of 55,000 $(m/dm)_{50\%}$ in heterodyne mode is sufficient to mass resolve interfering fragment ions and pseudomolecular ions, enabling the estimation of the O-methyl distribution along the backbone of methyl cellopentose.

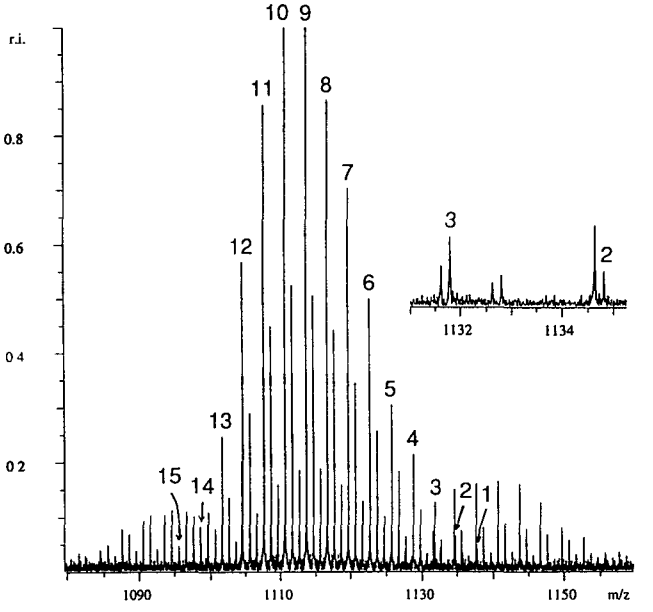

Fig.1 MALDI-FT-ICR mass spectrum of the cellopentose fraction in a perdeuteriomethylated partial hydrolysate of methyl cellulose. The peaks are labelled by the number of CH_3 groups (n) in the CD_3O-(nCH_3O / (15-n)CD_3O-cellopentose)-CD_3 compounds.

Characterisation of Electrosprayed polymers with MALDI-FT-ICR-MS

Ron M.A. Heeren, G.J. van Rooij, Marc C. Duursma, Chris G. de Koster and Jaap J. Boon.
FOM-Institute for Atomic and Molecular Physics,
Kruislaan 407, 1098 SJ Amsterdam, The Netherlands.

The combination of an ionisation technique like Matrix Assisted Laser Desorption Ionisation (MALDI) with mass spectrometry has already proven to be a valuable technique to characterise the molecular weight distribution and the dispersity of synthetic polymers. In this paper we have used the unequivocally high resolution of Fourier Transform Ion Cyclotron Mass Spectrometry (FT-ICR-MS) to additionally identify the elemental composition of the monomer and endgroup of several (homo)polymers. The information thus obtained provides insight in both initiation and termination of the polymerisation reaction cycle, as parts of the reactants are found back as structural components in the end-groups. In all experiments, MALDI performed in a homebuild external ion source [1] was used as ionisation technique. Sample preparation turned out to be critical for the succes of this method. In the following sections we will discuss a new sample preparation method which we found to yield very strong and reproducable MALDI-FT-ICR-MS signals of polymeric compounds.

All experiments in this paper were performed on a Bruker-Spectrospin APEX 70e, 7T FT-ICR-MS equipped with an in house designed MALDI ion source. The instrument is equipped with a Bruker Infinity™Cell for improved sensitivity. A differential pressure of 5 orders of magnitude between the ICR-cell region and the source can be maintained, with a three stage differential pumping scheme, without using cryopumps. The vacuum system used was described in previous publications [1,2] and enabled us to perform helium collisional cooling experiments when required. The source was interfaced with a nitrogen gas discharge laser (Photon Technology International, Model PL2300), which delivered a 600 ps, 0.5 mJ pulse of 337 nm to the target probe inside the ion source. By means of a simple telescope the beam was transported from the laser to the ion source, and focussed through a quartz window to a 1.5x3 mm spot size. The ions formed in the source are transported by means of an electrostatic ion guide to the ICR cell, where they are subsequently analysed.

In the course of our MALDI experiments, we evaluated two sample deposition methods, a dried droplet method and a new, electrospray sample deposition method. In the second method, the analyte-matrix solution was nebulised in a 4 kV/cm electric field. The stainless steel sample probe was the ground electrode in this homebuild electrospray set-up, and was positioned approximately 1 cm away from the tip of a 180 um i.d steel capillary. We found that this method yields superior shot-to-shot reproducebility and signal-to-noise ratio. We attribute this improvement to the quick formation of small crystals over a large surface area. This method gives us excellent control over deposition area, deposition speed and sample thickness. The method also eliminates the time consuming search for a good crystal on the probe, and the ability to use thick sample layers ensures a long lasting signal from one particular probe position. Typically we obtain 1000 reproducible shots from one position in a PEG1000-2,5-DHB mixture. NaI, LiI and KI were added to the analyte-matrix solution to promote sodium cationisation.

The broadband MALDI-FTMS mass spectrum of native PEG1000 is shown in figure 1. Note that the front and back trap electrode of our ICR cell were biased at 2.5 and 3.5 V respectively during this experiment.

This uncommonly low trapping voltage could be used by the virtue of the external ion source. Also no pulsed gas was applied to the cell to enhance the trapping efficency. The cell pressure during these experiments was $1.3*10^{-10}$ mbar. This resulted in a broadband resolution of 30000 $(m/dm)_{50\%}$ with a S/N of 100 at m/z 965 for the $[M_{21} + Na]^+$ monoisotopic peak. This resoltution enables us to perform linear regression analysis on the measured masses for each monoisotopic peak as a function of the corresponding degree of polymerisation. An example of such a plot is given in figure 2, were the measured masses of both native and per-deutero methylated PEG1000 with different cation adducts has been plotted versus their degree of polymerisation. The intercept of the fitted line yields the residual endgroup mass of the polymer. Its slope yields the mass of the repeating unit in the polymer. This value can also be deduced from the equidistant (m/z 44) peaks in the molecular weigth distribution, and subsequently be used as fixed coefficient for the linear regression analysis. This will result in a slightly more accurate endgroup mass.

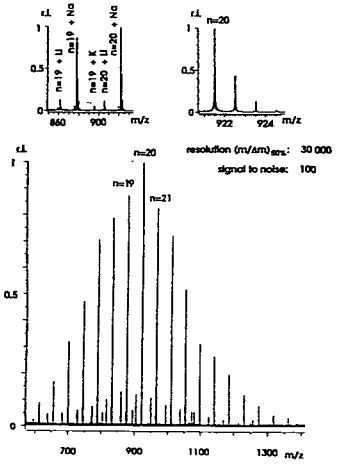

Figure 1 A broadband MALDI-FT-ICR-MS spectrum of a native PEG1000.

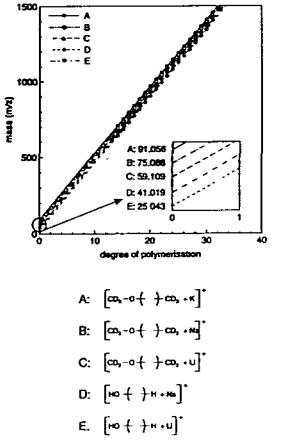

Figure 2. Linear regression analysis of native and per-deutero methylated PEG1000 with different cation adducts.

Similar experiments were perfomed on a PEG4000, where the error in endgroup analysis was appr. two orders of magnitude larger due to the larger extrapolation error. However, the accuracy was still more than sufficient to positively identify the distal part of the polymer. Using isotopically resolved peaks containing 2 ^{13}C isotopes, we were able to distinguish a PEG4000 with a di-propyl end group from a PEG4000 with a di-acetyl endgroup, both having nominally identical masses.

FT/MS Analysis of Block and Random Polyester-Urethane Polymers

Paul Souchek, James DeFelippis, Yvonne Berry-Walker and *Robert Ludicky, Morton International, 1275 Lake Avenue, Woodstock IL 60098

Introduction

Polyester-urethanes are utilized in a wide range of adhesives and coatings. These polymers can be either mixes or blocks of polymers tied together. Block copolymerization allows the synthesis of copolymers which can be tailored for a wide variety of physical properties. This tailoring process, however, also means that the final performance of the copolymer will depend on both monomer composition and exactly how the polymer is assembled. Traditional polymer analysis, by techniques such as pyrolysis, hydrolysis and NMR can easily determine a polymer's composition. These same techniques, however, are very weak at determining whether the composition of a polyester-urethane is random or block. In this day of specialized step polymerized polymers, monomer composition is no longer sufficient for block copolymer characterization.

Experimental

Two different sets of block and random polyester-urethanes were analyzed by negative ion carbon dioxide laser desorption FT/MS. Each set consists of a random and block polyester-urethane of identical monomeric composition. The only differences between members of a set relates to the number of polyesters utilized to produce each member. The compositions of the four polyester-urethanes are given below:

Polyester-Urethane 1		Polyester-Urethane 2	
Prepared from DEG-NPG-AA +MDI		Prepared from DEG-AA, NPG-AA +MDI	
MDI	11.07 %	MDI	11.44 %
DEG	24.58 %	DEG	24.60 %
NPG	23.37 %	NPG	23.35 %
AA	40.96 %	AA	40.60 %

Polyester-Urethane 3		Polyester-Urethane 4	
Prepared from DEG-NPG-IPA-AA +MDI		Prepared from DEG-IPA-AA, NPG-IPA-AA +MDI	
MDI	9.15 %	MDI	11.44 %
DEG	25.30 %	DEG	23.96 %
NPG	22.57 %	NPG	23.57 %
IPA	21.48 %	IPA	20.65 %
AA	21.48 %	AA	20.65 %

All the percentages given in the preceding table are mole percents. The following abbreviations were utilized to name the polyester-urethane components: Methylene Diisocyanate (MDI), Diethylene Glycol (DEG), Neopentyl Glycol (NPG), Adipic Acid (AA) and Isophthalic Acid (IPA).

Discussion

The negative ion laser desorption spectra of the random and block polyester-urethanes of nearly identical monomeric composition, urethanes 1 and 2 and urethanes 3 and 4, were quite different from one another. The block copolymers, urethanes 2 and 4, gave two repeating ion series. The random polyester-urethanes 1 and 3 gave only one set of ions apiece. The differences in the number of sets of ions appears to be directly related to the number of polyesters utilized to produce a particular urethane. The mass spectra of all four urethanes were very similar to those obtained from their base polyesters. For the block copolymers, the mass spectra of urethanes 2 and 4 appear as if the two polyesters utilized to produce these urethanes were mixed without MDI. This fact makes identification of the base polyesters relatively easy. This fact, however, also raises a question about how the polyester-urethanes can be ionized and fragmented without showing the presence of MDI.

There appears to be two possible explanations for the unusual mass spectral behavior discussed above: Massive fragmentation which results in selective ionization of polyester fragments or laser desorption of residual polyesters. The NMR spectra of the polyester-urethanes does not show any detectable hydroxyl functionality but does show free isocyanate groups. FT/MS experiments carried out with short time delays also are shifted to higher mass. These two pieces of data tend to support the massive fragmentation hypothesis and oppose the residual polyester hypothesis. Regardless of the mechanism, it appears that FT/MS can quickly and easily distinguish between random and block polyester-urethanes of very similar monomeric composition. In this day of tailored polymers, where monomer analysis by itself if often not sufficient, this type of information may be crucial to understanding how a polymer performs.

Analysis of Urban Air Particulates, SRM 1649, by Negative Ion FT-ICR MS and GC/NCI MS

Ming Xu, Hyun Sik Kim,* Shenheng Guan,* Alan G. Marshall,* Ralph C. Dougherty

Department of Chemistry, Florida State University, Tallahassee, FL 32306-3006

*Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State University, 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

Urban air particulates are composed mostly of inorganic components, e.g. ammonium sulfate. A large number of organic chemicals are adsorbed on the inorganic matrix at ultra-trace to ppm levels. The organic chemicals come from surface sources and are often modified in the atmosphere.[1] Some of the chemicals are mutagens and/or carcinogens.[2] High electron affinity, in the gas-phase or in solution, correlates with mutagenicity,[3] suggesting that negative ion screening might be a productive approach to evaluation of hazards in air particulates. We have applied this approach to ambient urban air particulates, National Institute of Standards and Technology Standard Reference Material (SRM) 1649 by use of negative ion laser desorption/ionization FT-ICR MS and GC/NCI MS.

Dichlorophene, an artifact from the SRM collection, dominated the negative ion spectra of extract SRM 1649.[4] This compound produced peaks corresponding to $(M+O-2H)^-$ and $(M-4H)^-$, in addition to the $(M-H)^-$ anion when it was subjected to laser desorption/ionization. The product ions correspond to dichloro-dihydroxybenzophenone ($C_{13}H_8O_3Cl_2$) and dichloroxanthone ($C_{13}H_6O_2Cl_2$), respectively. The relative signal magnitude increased after axialization of the ions in the ICR ion trap. The reactions that lead to dichlorodihydroxybenzophenone from dichlorophene are similar to the formation of $(M+14)^-$ reported by Buchanan *et al.*[5] Dichloroxanthone arises from dehydration of dichlorodihydroxybenzophenone.

Product ions from dichlorophene corresponding to the dimer anion, $C_{14}H_{10}O_2{}^{35}Cl_2$ (m/z 280) of 4-chloro-1,2-quinomethane ($C_7H_5O^{35}Cl$, m/z 140) were observed by use of 7 eV ionization, and detection at 10^{-9} torr in the analyzer of a dual cubic trap. An anion at m/z 407 ($C_{20}H_{14}O_3{}^{35}Cl_3$) that corresponds to an adduct of the deprotonated molecule and the 4-chloro-1,2-quinomethane was also prominent in the spectrum. Positive electron ionization (EI, 70 eV) of dichlorophene resulted in product ions corresponding to protonated 4-chloro-1,2-quinomethane ($C_7H_6O^{35}Cl$, m/z 141) and 4-chlorophenol ($C_6H_5O^{35}Cl$, m/z 128) in addition to the molecule ion ($C_{13}H_{10}O_2Cl_2$, m/z 268). Dichlorodihydroxybenzophenone was confirmed by GC/NCI MS of a standard sample of dichlorophene.

A small sample (0.1 g) of SRM1649 was Soxhlet-extracted with methylene chloride. The extract was partitioned by 10% aqueous sodium hydroxide into acidic and neutral fractions. The basic solution was neutralized (HCl) and the organic components were back-extracted with methylene chloride. Solvent was removed using a Kuderna-Danish followed by a stream of high purity nitrogen.

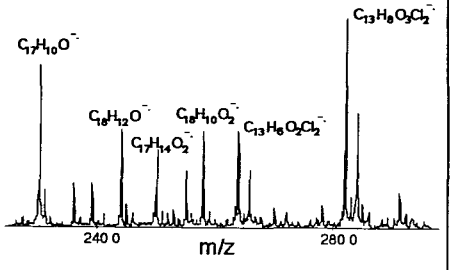

Figure 2. Gold film-assisted laser desorption/ionization negative ion FT-ICR mass spectrum of the neutral fraction of SRM 1649 extract.

Figure 1 illustrates the negative ion spectrum of the acid fraction obtained by gold film assisted laser desorption/ionization. Components that apparently arose from addition of dichlorophene to the collection filter included dichlorodihydroxy-benzophenone (m/z 281.9791), dichlorophene (m/z 267.0015), and monobrominated dichlorophene ($C_{13}H_9O_2BrCl_2$, m/z 346.9274). The presence of all of these components in the sample was confirmed by GC/NCI MS.

The negative ion spectrum of the neutral fraction obtained by gold film assisted laser desorption and ionization is shown in Figure 2. Dichloroxanthone ($C_{13}H_6O_2{}^{35}Cl_2$, m/z 263.9824) and dichlorodihydroxy- benzophenone (m/z 281.9832) were present in this fraction with relatively high abundance. Of oxy-polynuclear aromatic hydrocarbons, the spectrum shows the molecule anions for benzanthrone isomers ($C_{17}H_{10}O$, m/z 230.0715), benzanthracene-dione isomers ($C_{18}H_{10}O_2$, m/z 258.0677), hydroxybenzanthracene/methyl benzanthrone isomers ($C_{18}H_{12}O$, m/z 244.0854) and a C_3-alkyl anthroquinone isomer ($C_{17}H_{14}O_2$, m/z 250.0983). With the exception of the hydroxybenzanthracene/methyl benzanthrone isomers the existence of these components in the mixture was confirmed by GC/NCI MS.

The correlation between mutagenicity and electron affinity[3] suggests that the new components of atmospheric air particulates that were revealed by this LD FT-ICR screening procedure should be examined toxicologically. Work supported by N.S.F. (CHE-94-13008) and the National High Magnetic Field Lab at Florida State Univ.

A New Approach for the Analysis of Volatiles in Complex Matrices

S.A Barshick, M V Buchanan, and M.R. Guerin
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120

Introduction: Analytical methods for the analysis of volatile organic compounds (VOCs) in water are well established in EPA methods. These methods, however, typically have limited applicability to the direct analysis of solid samples or complex media, falling short in the sample preparation and sampling areas. A novel off-line blender-purge and trap sampling device was developed to overcome some of the problems encountered in the analysis of VOCs in solids and/or complex matrices (1). The blender-purge and trap sampling device was designed to allow simultaneous or sequential homogenization and sampling of solids or complex media to be conducted in a closed system thereby minimizing loss of volatile analytes during the sample preparation steps This device offers several unique advantages for analyzing complex matrices including the ability to customize the homogenization and purge processes to accommodate sampling of any solid or liquid matrix and the ability to be used in a purge and trap mode (purge outlet is connected to a sorbent trap for GC/MS analysis) or in a direct sampling mode (purge outlet is connected directly to an ion trap MS)

Experimental: In this design, a commercial 1L stainless steel Waring blender with a 7 speed motor was modified. The original 1L blender container was replaced with a 50-250 mL capacity stainless steel mini-container. To obtain a closed system, a stainless steel lid was made and mounted to the blender container by welding a half inch wide rim to the top of the container and placing a neoprene gasket between the container and lid The lid was designed with 3 cajon fittings: a 1/16" fitting provided connection for the purge inlet line, a 1/4" fitting was used to connect to the purge outlet line, and a second 1/16" fitting served as an injection port through which water or internal standards could be added to the sample. An additional modification was the replacement of the original blending assembly with a special bearing cap and replaceable pressure seal that allowed the sample to be blended and purged without leaking.

Results and Discussion: The blender-purge & trap sampling device was developed as part of a GC/MS method for the quantitative determination of benzene in foods. To evaluate the blender-purge and trap method versus a more conventional purge and trap method, a series of studies were conducted to establish the detection limits, accuracy, and reproducibility of the two approaches. The results for the analysis of target foods were compared to a standard purge & trap GC/MS method based on EPA Method 624. Results are shown for the mean concentration of benzene found (ppb) ± 95% confidence interval as determined from linear regression analysis of standard addition data for triplicate analyses. Concentrations given in ( ) indicate that the quantitative results were not statistically different from zero. The results, shown in Tables 1 & 2, demonstrate several advantages of blender-purge & trap sampling over the conventional approach including: improved reproducibility (lower confidence intervals), the ability to quantitate both liquid and solid samples equally well with respect to accuracy and reproducibility, low ppb to ppt detection capabilities in complex matrices, and accuracy well within EPA QA acceptance criteria.

The ability to alter the types of volatile compounds sampled using the blender-purge & trap device also was investigated for qualitative GC/MS analysis In preliminary studies, the effects of various sampling treatments on the production of volatiles from reference cigarettes were investigated. The treatments included heat, aqueous extraction, and change in pH. Several observations can be made from these results, including: an increase abundance of hydrocarbons in the dry heated samples, the appearance of chlorinated hydrocarbons in the aqueous extracted samples, and a change in sensitivity for certain compounds (e.g. tetrahydrofuran & acetic acid ethyl ester) as a function of sample pH. These pilot studies demonstrated the ability to alter selectively the types of volatile compounds that can be observed by changing sample conditions.

Table 1: Comparison of Methods for the Determination of Benzene in Foods

Sample	Conventional Purge & Trap GC/MS	Blender-Purge & Trap GC/MS
Coffee	(0.07 ± 0.99)	0.10 ± 0.09
Tea	(0 16 ± 0.35)	0.11 ± 0.07
Cranberry juice	0 69 ± 0 66	0 55 ± 0.19
2% Milk	(0.00 ± 0.59)	(0.02 ± 0.05)
Orange juice	(0.00 ± 1.01)	(0.04 ± 0 05)
Raw Chicken	2 44 ± 0 87	(0.06 ± 0.12)
Cooked Chicken	(2.04 ± 2.83)	0.11 ± 0.02
Scrambled Eggs	(0 20 ± 0.50)	0.10 ± 0.07
Instant Oatmeal	(0 31 ± 3 80)	0.07 ± 0 05
Tomatoes	(0.36 ± 1 08)	(0.02 ± 0.02)

Table 2: Determination of Benzene in QA/QC Fortified Food Samples

Sample	Reported Conc. ± 95% C.L.	QA/QC Fortified Conc.	% Error
Chicken	0 47 ± 0.28	0 51	8%
2% milk	0 36 ± 0 16	0 31	16%
Tomato	0.22 ± 0.06	0.24	8%

Conclusions: A method for the analysis of volatiles in complex matrices was developed using a novel blender-purge & trap sampling device. Several significant advantages of this device compared to conventional methods for the analysis of VOCs were demonstrated including the ability to sample and analyze both liquid and solid samples with minimal loss of analyte, accuracy well within EPA QA acceptance criteria (for benzene: 37-151%), and low ppb to ppt detection limits in complex matrices, such as foods. Additionally, the use of this sampling device for qualitative & quantitative GC/MS analysis was demonstrated. Future work will involve the development of this device in conjunction with Direct Sampling Ion Trap Mass Spectrometry (DSITMS) as a screening method for VOCs in a variety of complex matrices.

EPA Method 8270 (Semivolatiles) using a GC/Ion Trap Spectrometer

S.A Barshick, S. Worthy, and W H. Griest
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120

Introduction· EPA method 8270 describes the analysis of over 70 semivolatile organic compounds (SVOCs) in groundwater, soils, and solid and mixed wastes. Estimated quantitation limits for this method using a quadrupole mass spectrometer are in the µg/L or µg/kg range. To achieve these concentrations levels, liter volumes of water or tens of grams of solid waste must be extracted and concentrated to 1-2 mL prior to GC/MS analysis. The inherent sensitivity of the ion trap mass spectrometer (ITS) and its compatibility with GC introduction makes GC/ITS ideal for use in EPA methods The goal of this work was to demonstrate the improvements possible in EPA protocols using an ion trap mass spectrometer. Method 8270 was chosen for this evaluation.

Experimental· Sample extracts were prepared and analyzed according to Method 8270 using both a quadrupole GC/MS and an ion trap GC/MS. The quadrupole GC/MS system used was a Hewlett Packard Mass Selective Detector (GC/MSD) GC/MSD analysis was performed by a certified laboratory (Analytical Services Organization, ORNL) following the standard EPA method 8270 conditions and procedures The ion trap GC/MS system used was a Finnigan MAT Magnum Ion Trap mass Spectrometer (GC/ITS) GC/ITS analysis was performed using EPA method 8270 as a guideline and the conditions shown in Table 1

Table 1. GC/MS Operating Parameters

Mass Range.	45 - 500 amu
Scan Rate:	1 sec/scan
Automatic Gain Control:	on
Filament Delay:	300 sec
Source Temperature:	220°C
Emission Current	50 µA
Transfer Line Temperature	290°C
Initial Column Temperature	40°C hold 4 minutes
Temperature Program	40-280°C @ 8°C/min
Injection mode·	on-column
Injection port temperature:	35 °C hold 0.1 min
Temperature program:	35-280°C @ 180°C
Column head pressure:	16 psi
Carrier gas:	helium @ 50 cm/s (@ 40°C)

Results and Discussion: Using the GC/ITS, quantitation limits in the ng/L range were possible compared to the µg/L quantitation limits listed in Method 8270 Initial calibrations were performed according to SW-846 Method 8270, however, the quantitation criteria required by the method could not be met using the GC/ITS and the splitless injection technique. All quantitation criteria, however, could be met using a programmable on-column injection system

Use of the temperature programmable injection method also resulted in improved resolution and increased sensitivity for the late eluting compounds compared to the splitless injection To validate the GC/ITS method, performance evaluation samples were analyzed by both instruments. Two one liter water samples (low and high level) were extracted and concentrated to a final volume of 1 mL. Half of the resulting extract was analyzed directly using the GC/MSD. The other half of the extract was used to prepare 1/1000 and 1/100 dilutions in methylene chloride. These dilutions were then analyzed using the GC/ITS Results for the low (10 to 50 µg/L) level sample compared well for the two instruments as shown in Table 2 To complete the method evaluation, both instruments were used to analyze several real sample extracts from various sources Results from those analyses demonstrated the ability of the GC/ITS to detect surrogates and analytes in samples with large hydrocarbon (oil) backgrounds, while the GC/MSD was unable to detect either

Table 2. Method Validation Results: APG Level 1

Compound Name	Reported GC/MSD	Reported GC/ITS 1/1000	1/100	All labs Mean	Acceptance Range
bis(2-chloroethyl)ether	54 8	49 8	62.8	74 1	39 0 - 109 2
hexachloroethane	13 9	16 5	17.7	18 8	5.6 - 32 0
2,4-dimethylphenol	13 5	**1.1**	7.2	14 6	3.2 - 26 0
2,4-dichlorophenol	22 8	**5.6**	21 8	32.2	13 6 - 50 8
naphthalene	23 9	22 4	25 8	32.8	15 8 - 49 8
hexachlorobutadiene	22.3	21.7	24.4	27.1	17 0 - 37 2
4-chloro-3-methylphenol	20 0	**10.2**	16 9	24.9	12.0 - 37 8
2,4,6-trichlorophenol	11 2	7.2	9.2	14.5	6.2 - 22.8
2,6-dinitrotoluene	16.2	13.4	19.6	19 7	10.7 - 28.7
acenaphthene	23.4	21.0	24.9	27.7	17.9 - 37.5
2,4-dinitrophenol	32 8	0 5	12.8	40 1	0 0 - 85 3
4-nitrophenol	37.0	1 7	22.6	31 5	0 0 - 72 0
2,4-dinitrotoluene	28 1	**8.5**	23 6	32.4	17 4 - 47 4
diethylphthalate	58 9	43 4	61 2	57.1	14 0 - 100.2
di-n-butyl phthalate	37 4	20.3	32.0	42.4	15.8 - 69 0
fluoranthene	20 6	15.9	22.1	23.5	12.4 - 34 6
bis(2-ethylhexyl) phthalat	24 8	**9.4**	13.7	23.6	10.4 - 36.8

Conclusions With the high sensitivity and dynamic range of the GC/ITS, regulatory limits for each analyte were met and exceeded The results for the method validation studies demonstrated the ability to accurately quantitate target compounds even in solutions that were 100 times or greater more dilute than those analyzed by the GC/MSD. This improvement in sensitivity equates to the ability to use smaller sample sizes and decrease solvent waste, to dilute out interferences or co-extracted radioactivity, and to increase sample throughput

FACTORS AFFECTING MEMBRANE INTRODUCTION MASS SPECTROMETRY

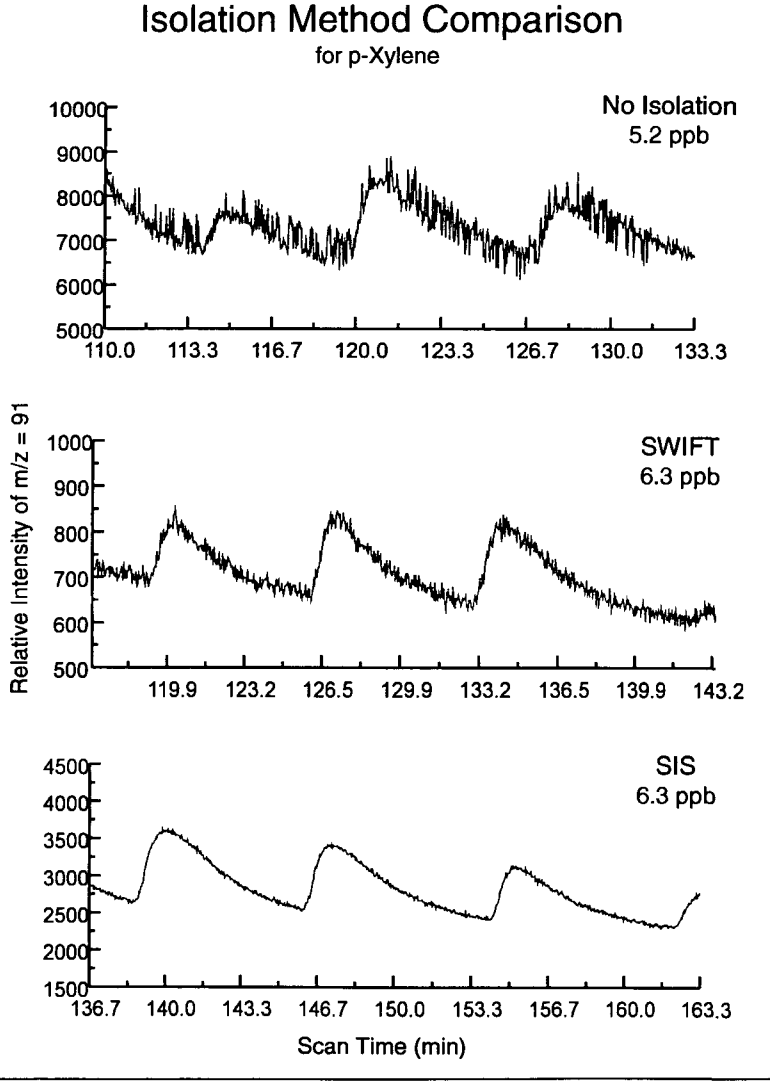
Susan Ohorodnik, John Callahan, Mark Anderson, and Steve McElvany
Naval Research Laboratory, Chemistry Division, Code 6113, Washington, DC 20375-5342

Membrane introduction mass spectrometry (MIMS) has been increasing in popularity as an environmental analysis technique for volatile organic compounds (VOCs) due to its ease of use and low detection limits. This research is concerned with developing a real-time, on-site MIMS analysis method for a wide range of volatile and semi-volatile organic compounds. Of particular interest is the modification and development of pervaporation membranes and mass spectrometer instrumentation to increase the selectivity and sensitivity of MIMS. The effects of membrane-mass spectrometer interface, selected ion storage techniques, and membrane composition on MIMS analysis for VOCs in aqueous solutions were reported.

Two membrane interfaces were investigated: a direct insertion probe inlet (MIMS Technology, Inc.) and a membrane/jet separator assembly. Both the DIP and membrane/jet separator inlets were configured to accept only membrane sheets. Detection limits for the DIP and membrane/jet separator systems were in the ppb and sub-ppb ranges, respectively. Lower detection limits were obtained with the membrane/jet separator system due to the removal of water from the system by the jet separator. The identification and quantification of VOCs in real environmental samples can be rather difficult requiring additional techniques such as MS/MS, selected ion storage methods, and ion-molecule reactions for accurate analyses.

In order to improve sensitivity by removal of unwanted background species and improve selectively for possible ion/molecule reactions, two ion monitoring methods were investigated: a user implemented SWIFT (stored waveform inverse Fourier transform) and (2) the commercially available selected ion storage (SIS) software package (Varian, Walnut Creek, CA). Dramatic improvement in S/N was observed when these methods were used for the isolation of 91 Da for p-xylene (Figure 1). SIS showed increased sensitivity, while SWIFT had detection limits similar to using no isolation. SIS outperformed SWIFT because it was capable of operating at longer ionization times. When SIS is operated at a fixed ionization time of 2.5 ms, the results were comparable to SWIFT results. Little improvement in sensitivity was observed when either SWIFT or SIS was employed with the jet separator assembly. Since the jet separator already efficiently lowers the water background, further improvements in sensitivity will require longer ionization times. Overall SIS and SWIFT are capable of giving comparable performance. SWIFT does have the advantage of allowing unlimited mass isolation ranges at varying isolation voltages while SIS currently only allows 5 mass ranges at a single isolation voltage.

Separation in MIMS is dependent on the differences in membrane permeability between the analyte compounds and feed solution. Silicone rubber (polydimethylsiloxane) has proven to be a very effective MIMS membrane. It is hydrophobic with high nonpolar organic permeability. However, its sensitivity tends to decrease and elution times increase for polar and semi-VOCS. Therefore, it is necessary to investigate or develop new membranes for selectivity and/or sensitivity toward these more difficult VOCs. The following membranes have been initially screened for MIMS analysis: cellulose ester, asymmetric polyvinylidene fluoride (PVDF), symmetric PVDF, styrene/butadiene copolymer, and acrylonitrile/butadiene copolymer. The copolymers appear to be the most promising once difficulties in casting the membranes are overcome.



DIRECT SAMPLING ION TRAP MASS SPECTROMETRY vs. GC/MS FOR MONITORING VOCs IN GROUNDWATER

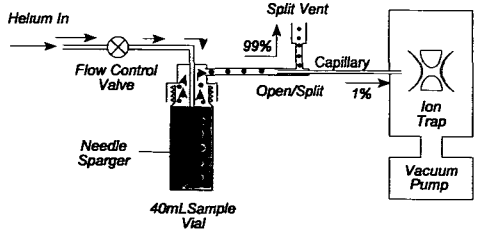
Marcus B. Wise, Roosevelt Merriweather, Michael R. Guerin
Chemical and Analytical Sciences Division, Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831-6120

Direct Sampling Ion Trap Mass Spectrometry (DSITMS) has been under refinement and demonstration by our laboratory for several years. The general technology is applicable to a wide range of problems which would benefit from high sample throughput, fast availability of results, and relatively low cost per sample analysis when compared with conventional analytical methods. At the present time, DSITMS can be used to determine targeted analytes in air, water, soil, and other media. This is accomplished by equipping an ion trap with a direct inlet system which consists of a splitter, capillary restrictor, and a set of sample inlet modules. The capillary restrictor provides the interface between atmosphere and the vacuum in the ion trap while the splitter enables sampling modules which require high gas flow rates to be used with the system. The sampling modules consist of a purge module for analyzing VOCs in water or soil, a direct air sampling module, and a thermal desorber. These modules are designed to be easily interchanged by means of quick connect fittings and a single electrical cable. In general, the DSITMS sample inlet system works equally well on all of the commercially available ion traps with which it has been tested including the Finnigan MAT ITMS, Finnigan MAT Magnum, Varian Saturn, and the Teledyne 3D-Q. Both the Magnum and 3D-Q instruments have been utilized for field applications as well as laboratory analysis.

The work presented here represents continued efforts to generate data necessary to gain acceptance of the DSITMS technology by regulatory agencies for routine use in environmental applications. Much of this effort is being devoted to the generation of comparative data between DSITMS and accepted standard methods in order to demonstrate equivalency with respect to data quality. This particular study is a comparison of DSITMS with a purge and trap GC/MS for compliance monitoring of VOCs in groundwater. The DSITMS method involves the direct purge of VOCs from water into the ion trap using helium as the purge gas at a flow rate of 100 mL/min. No sample preparation is required other than adding difluorobenzene to the sample as an internal standard. The ion trap is operated in a mode which provides alternating electron ionization and chemical ionization using water as the CI reagent. The EI mode provides spectra which are useful for the determination of halogenated hydrocarbons and alkanes. The CI mode provides enhanced sensitivity for aldehydes, ketones, and other water soluble compounds. Chemical ionization also produces pseudo-molecular ions for alkyl aromatics which are commonly found in the environment from fuel spills. Detection limits for most VOCs are in the range of 500 pptr to 5 ppb depending on the analyte. Additional sensitivity can be achieved by use of selective ion storage such as Filtered Noise Fie ld as with the Teledyne 3D-Q.

In this study, samples from over 100 groundwater wells were analyzed by DSITMS and by a certified laboratory using an approved Contract Laboratory GC/MS method. The primary contaminants which were found in the samples included dichloroethenes, chloroform, carbon tetrachloride, trichloroethylene, perchloroethylene, benzene, and gasoline constituents. Overall, nearly 70% of the samples analyzed were found to be blank by both methods. Those samples which were found to be contaminated had constituents which ranged in concentration from 1 ppb to 5 ppm. Quantitative agreement between the DSITMS results and the GC/MS results were generally very good. The DSITMS samples were typically analyzed in triplicate with the precision being less than 10% in most cases. In terms of cost per sample ($25-$50) and availability of results to the customer (same day), DSITMS has a significant advantage over GC/MS.

DIRECT PURGE APPARATUS



Comparison of DSITMS and GC/MS Results

Trichloroethylene in Groundwater

Well Number	DSITMS	GC/MS
1	3 ppb	3 ppb
2	89 ppb	81 ppb
3	5 ppb	3 ppb
4	1 ppb	0 ppb
5	3 ppb	0 ppb
6	11 ppb	8 ppb
7	28 ppb	19 ppb
8	90 ppb	56 ppb
9	72 ppb	76 ppb
10	5 ppb	2 ppb
11	7 ppb	7 ppb
12	1 ppb	1 ppb
13	61 ppb	53 ppb
14	4 ppb	4 ppb
15	40 ppb	49 ppb

Rapid Sampling for Rapid Analysis: A New Method for VOCs in Drinking Water

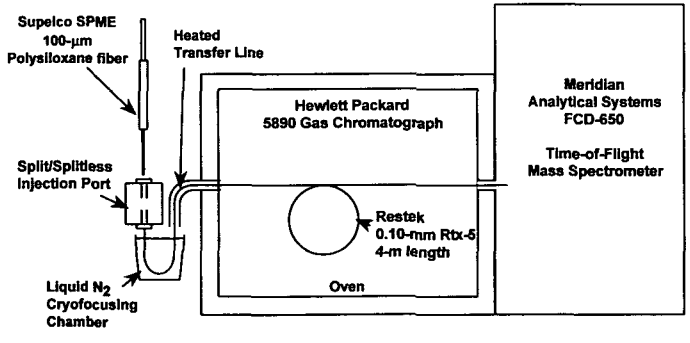
Ben D. Gardner[1], Jennifer A. Johnson[1], Viatcheslav B. Artaev[3]
O. David Sparkman[4], John F. Holland[2]
Departments of Chemistry[1] and Biochemistry[2], Michigan State University, East Lansing, MI 48824
Meridian Analytical Systems, Inc.[3], 2310 Science Parkway, Okemos, MI 48864
O.David Sparkman & Associates[4], 4045 Eagle Ridge Dr., Antioch, CA 94509

Until recently, there has been only moderate emphasis placed on the time consumption of the sampling process in many gas chromatography/mass spectrometry (GC/MS) analyses. Historically, the total analysis time has been primarily dependent upon the chromatographic separation and detection steps, and significant decreases in sample preparation time have had little impact on overall sample throughput. The recent maturation of gas chromatography/time-of-flight mass spectrometry (GC/TOFMS) using time array detection has decreased chromatographic separation and mass spectrometric detection times by factors of 10 or more, leaving the sampling process as a significant and often limiting factor in the total analysis time

Current methods for the analysis of volatile organic compounds (VOCs) in drinking water utilize headspace or purge and trap techniques requiring 20-30 minute sampling times to extract these compounds for analysis by GC/MS Solid-phase microextraction (SPME) has recently been presented as a viable alternative to the above methods. Sampling and desorption times of less than 10 minutes have been reported for part-per-billion levels of volatile organics in aqueous solution [1] These rapid times suggest a potential for combining SPME and GC/TOFMS technologies to create a methodology for high sample throughput.

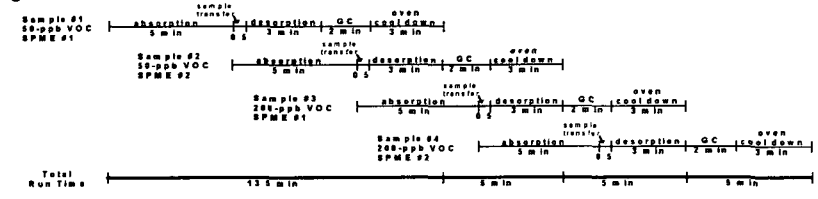
We have modified a GC/TOFMS system (Hewlett Packard 5890/Meridian Analytical Systems FCD-650) to accommodate external SPME sampling and cryotrapping as shown in Figure 1 The external cryotrap design allows simultaneous cryotrapping and chromatographic separation of alternate SPME samples Temperature and gas flow through the split/splitless injection port is controlled by the GC, with a 4-m 0.10-mm i.d. Rtx-5 capillary column used for chromatographic separation with a 9-cm loop at the beginning of the column placed in liquid nitrogen to accomplish cryotrapping. A heated transfer line into the GC minimizes the occurrence of cold spots.

Figure 1



To demonstrate this system, 50- and 200-ppb mixtures of aqueous VOC samples were prepared from a commercially available stock solution (Ultra Scientific) The headspace above 1-mL aliquots of these solutions in sealed vials was sampled for 5 minutes using a 100-µm polydimethylsiloxane fiber SPME device and constant stirring The SPME fiber was then transferred to a 260° injection port in splitless mode and desorbed for 3 minutes The desorbed analytes were cryotrapped on column using a removable container of liquid nitrogen Chromatographic separation was initiated by rapidly heating the cryofocus region of the column using a convective heat source The oven temperature was then ramped from 40°C to 140°C at 50°/minute. Mass spectral detection was performed over a range of *m/z* 40–290 at an acquisition rate of 50 spectra/second Desorption and cryotrapping of subsequent samples occurred during chromatographic separation of the previous sample. Using this system in multiplexed mode as illustrated in Figure 2, a steady state analysis rate of 5 minutes/sample was achieved

Figure 2



This combination of utilities illustrates the rapid analysis rates achievable when an appropriate sample introduction system is interfaced with GC/TOFMS for separation and detection. The utilization of *time compressed chromatography* where, using standard gas chromatographic equipment, gas flow rates and temperature ramps are maximized and column length is minimized, enables analyses to be performed in only a few minutes The use of high spectral acquisition rates and mass spectral deconvolution minimizes the chromatographic separation required for complete information recovery. A typical result is shown in Figure 3 illustrating the complexity of the sample and the time frame of the chromatographic analysis Library matchable spectra were obtained for each component of the mixture, deconvoluting where necessary

Figure 3

Monthly Variations of Haloacetic Acids in Drinking Water by GC/MS

Frank M. Benoit, David T Williams and Guy L. LeBel
Health Canada, Environmental Health Directorate, Tunney's Pasture, Ottawa, ON

Introduction. In a national survey of 53 drinking water plants in Canada, haloacetic acids (HAA) were identified as major disinfection by-products (DBPs) and were found in all the chlorinated drinking water supplies examined. The HAA levels were observed to vary with season (summer and winter), water treatment practice (chlorination, chloramination and ozonation) and distance from the treatment plant. In an effort to understand better the dynamics of HAA formation, three drinking water plants that used different disinfectant combinations (chlorine - chlorine, chlorine chloramine and ozone - chlorine) were studied each month (over a period of 1 year, 1994) at five locations within each supply system. Three HAA (mono- (MCAA), di- (DCAA) and tri-(TCAA) chloroacetic acids) were monitored in the present study, however, MCAA were consistently found at lower levels than DCAA and TCAA; only the DCAA and TCAA results are presented here.

Methods. Duplicate water samples (30 mL) were collected at the treatment plant (raw (R) and treated (T)) and at 3 locations within the distribution system at increasing distance (D1 3-4 km, D2 6-13 km and D3 15-20 km) from the treatment plant. The samples were extracted with diethyl ether and derivatized with diazomethane. The HAAs were analyzed as the methyl esters by selected ion monitoring of the [M - 59] ions. Response factors for the individual acids were obtained from the periodic analysis (replicate) of clean water samples that had been spiked with a suite of HAA standards of known concentration. 1- Bromo-4-chloro benzene was used as quantitation standard and 2-bromo-n-butyric acid was used as recovery standard. The accuracy of the method (ca 20 %) was estimated from the periodic analysis of water samples spiked with known levels of analyte. The minimum quantitation level was 0.01 μg/L.

Results. For chlorine - chlorine treated water (fig. 1), both DCAA and TCAA levels peak during the summer months. The DCAA annual variation (mean max/min = 3 ± 1) was less than the TCAA (mean max/min = 9 ± 5) annual variation. The DCAA levels ranged from 3 to 26 μg/L throughout the year (all samples) and TCAA levels range from 2 to 37 μg/L throughout the year (all samples). DCAA levels generally maximized at locations (T or DI) closer to the treatment plant than TCAA levels (D2). Both DCAA and TCAA are reduced at the furthest location (D3) from the treatment plant.

For chlorine - chloramine treated water (fig. 2), the chloramine residuals are known to mitigate the formation of organochlorines within the distribution system. DCAA (mean max/min 2 ± 0.4) and TCAA (mean max/min 5 ± 2) levels peaked twice but at different times during the year at most locations. D2 was located downstream from a reservoir; the low DCAA levels observed at D2 (fig 2) in the summer was attributed to the release of higher volumes of mature water from the reservoir into the distribution line as a result of high consumer demand. DCAA levels ranged from 2 to 25 μg/L (all samples) and TCAA levels ranged from 2 to 15 μg/L (all samples).

For ozone - chlorine treated water (fig 3), ozone treatment mitigates most organochlorine formation. DCAA peaked in the summer at T and in the fall at DI, D2, and D3. TCAA peaked in the summer at T, DI and D2 and in the fall at D3. In order to control algae which clog the filter media, an additional chlorine treatment is applied prior to ozonation; this resulted in elevated HAA levels in the summer and early fall. DCAA levels ranged from 3 to 13 μg/L (winter/spring) and from 3 to 53 μg/L (summer/fall). TCAA levels ranged from 1 to 13 μg/L (winter/spring) and from 2 to 22 μg/L (summer/fall).

Fig.1 Seasonal HAA Levels (μg/L) Chlorine-Chlorine Treated Water

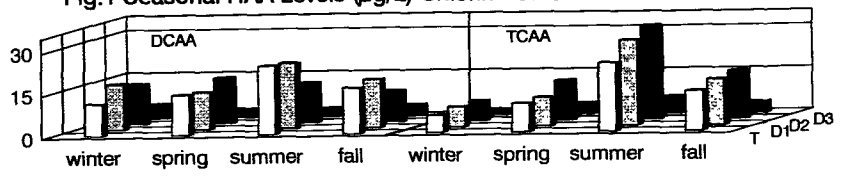

Fig.2 Seasonal HAA Levels (μg/L) Chlorine-Chloramine Treated Water

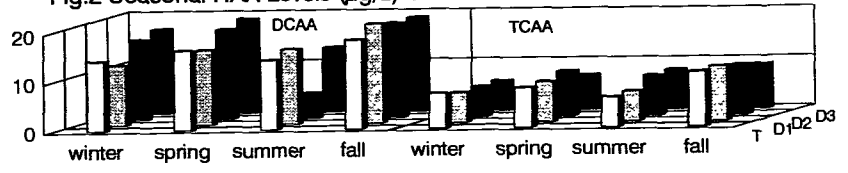

Fig.3 Seasonal HAA Levels (μg/L) Ozone-Chlorine Treated Water

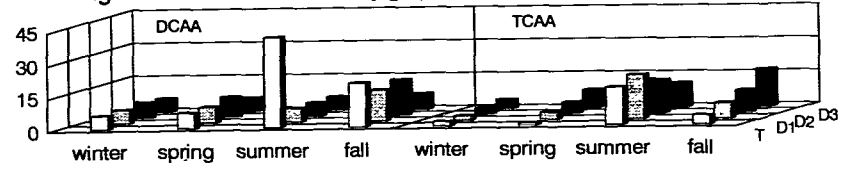

Conclusions. DCAA and TCAA were found in all treated water samples analyzed in the present study. The DCAA and TCAA showed significant variations as a function of month, location and treatment as illustrated in figs 1, 2 and 3. The HAA profiles for the three treatment processes are strikingly different. Of particular importance - no single sampling point gave simultaneous maximum concentrations for both HAAS. DCAA levels were similar for chlorine - chlorine and chlorine - chloramine treatments and slightly lower for ozone - chlorine treatment (except location T where the DCAA levels were considerably higher in the summer). TCAA levels were higher for chlorine -chlorine treatment than chlorine - chloramine and ozone - chlorine treatment (in summer and early fall TCAA levels were slightly higher at some locations). TCAA (and to a lesser extent, DCAA) levels minimized during the summer for chlorine-chloramine treatment whereas TCAA levels maximized during the same time period for chlorine - chlorine and ozone - chlorine treatments. The likely reason for this contrary behaviour is kinetic - HAAs are intermediate products and the measured values are dependent on the stage of the reaction for each individual HAA. In mature water, where the reaction time is sufficient to achieve completion, and in warm water, where the reaction is accelerated, the HAA levels will tend to be reduced.

Determination of Haloacetic Acids in Drinking Water by Electrospray LC/MS

David D. Kryak and Thomas D. Behymer
U.S. Environmental Protection Agency
Office of Research and Development
National Exposure Research Laboratory
26 W. Martin Luther King Drive, Cincinnati OH 45268

A number of studies have shown that haloacetic acids (HAAs), by-products of drinking water disinfection, are of concern to human health. Five compounds of this group, monochloro- (MCAA), monobromo- (MBAA), dichloro- (DCAA), dibromo- (DBAA) and trichloroacetic acid (TCAA), are proposed for regulation by the USEPA at a total maximum contamination level (MCL) of 60 μg/L in drinking water. Current methodology, such as EPA methods 552 and 552.1, utilizes gas chromatographic separation with electron capture detection (ECD). While these methods are capable of meeting this proposed MCL for haloacetic acids, they are complicated by the need for extraction and derivatization. In addition, identification of eluting analytes is dependent on retention times which may lead to misidentification when in the presence of coeluting ECD active compounds. Information obtained from mass spectrometry (MS) is generally more indicative of the eluting component(s) and is better suited for analysis of unknowns. With the development of electrospray ionization (ESI) techniques, a new approach has emerged for the analysis of small, nonvolatile, environmentally significant compounds without the need for derivatization.

ESI/MS and ESI/MS/MS was used with anion exchange high pressure liquid chromatography (LC) to identify and quantify the five HAAs proposed for regulation and bromochloroacetic acid (BCAA) after 20 fold concentration of fortified reagent water samples by lyophilization.

Chromatography was achieved using a Hewlett-Packard 1090 LC with solvents: A = 1 mM NH_4OH, B = acetonitrile, and C = 200 mM NH_4OH. Separation of 100 μL injections of an HAA mixture was achieved with a Dionex PAX 500 ion exchange column (4 x 50 mm) and a 0.5 ml/min flow rate with the following gradient: 81%A:19%B:0%C at 0 min,48%A:37%B:25%C at 15 min.

ESI/LC/MS measurements were achieved with a Finnigan MAT TSQ 700 triple quadrupole mass spectrometer equipped with a Finnigan ESI source. The ESI source conditions were: negative ion mode, 5 kV spray voltage, 200°C capillary temperature, 70 psi sheath gas (N_2) and rotameter setting of 30 for auxiliary gas (N_2). The mass spectrometer was scanned 90-300 amu in 1 s for full scan experiments. For all HAAs, $(M-H)^-$ was the base peak ion under negative ion conditions. For SRM experiments, the collision gas (Ar) was set at 2.5 mTorr and the collision offset was set at 15 v for all the HAAs except for TCAA which was set at 10 v. The most abundant daughter ion resulting from the collisionally induced dissociation of the $(M-H)^-$ was used as the quantitation ion. In the cases of the mono-halide compounds, the halide was the predominant daughter ion, while $(M-H-CO_2)^-$ was the predominant daughter ion in the cases of di- and tri-halide compounds.

Full scan and SRM instrument detection limits were determined at a signal to noise ratio of 3:1 as shown in Table 1. The instrument detection limit (IDL) by SRM was more than one hundred times lower than the IDLs by full scan for all HAAs studied here, except MCAA which was 25 times more sensitive by SRM.

Table 1. Estimated Instrument Detection Limits

Target Analyte	Full Scan ng	SRM ng
MCAA	1	0.040
MBAA	1	0.010
DCAA	1	0.010
BCAA	0.6	0.005
DBAA	5	0.010
TCAA	20	0.120

Quantitation was achieved using internal standard calibration. Bromopropionic acid which has similar chemical properties to the HAAs was chosen as the internal standard. Internal standard calibration plots showed good linearity from 0.1 to 25 ng. Daily instrument stability was determined by ESI/LC/MS analysis of 8 replicate analyses of 10 ng of each HAA. Relative standard deviations (RSDs) of less than 10% were obtained for all compounds.

Method detection limits (MDLs) were obtained by analyzing 7 replicate injections of 1 μg/L fortified reagent water which had been concentrated 20 fold by lyophilization. As shown in Table 2, recoveries were 86 to 135% with RSDs ranging from 8.6 to 16.9%. MDLs for all compounds are below 1 μg/L which exceeds the proposed MCL for the regulated HAAs.

Table 2. MDL data at 1 μg/L by ESI/LC/MS/MS using internal standard calibration

Analyte	Average Recovery %	RSD %	MDL μg/L
MCAA	113	8.6	0.31
MBAA	96	10.3	0.31
DCAA	86	14.0	0.38
BCAA	100	16.9	0.53
DBAA	100	10.7	0.33
TCAA	135	14.3	0.60

MDL = $t_{(n-1,1-alpha=0.99)}$ * Std. Dev., n = 7 replicates

Direct Analysis of Volatile Organic Compounds in Water at the Parts-per-Quadrillion (PPQ) Level using Membrane Introduction Mass Spectrometry (MIMS)

Scott Bauer, Jan Bauer, MIMS Technology Inc.

1900 S. Harbor City Blvd. Suite 115

Melbourne, FL 32901

Ion trap mass spectrometers have been used in membrane introduction mass spectrometry (MIMS) applications for years. The ion traps are very sensitive and perform exceptionally well in MIMS mode Typical detection limits for most volatile organic compounds in water are in the low parts-per-trillion range in ion traps. As sensitive as these ion traps are, the parts per quadrillion direct organic analysis barrier had never been crossed. The presentation describes experiments in population augmentation in the ion trap using stored waveform inverse fourier transform (SWIFT) to allow the direct analysis of organic compounds in water at the sub-parts-per-trillion level

A Finnigan Magnum ion trap configured for MIMS use was further modified through the addition of an analog switch, amplifier, balun, arbitrary waveform generator, and scan editing software to allow selected ion trapping in the spectrometer A scan function was produced with a 150 msec ionization time during which SWIFT pulses were applied to the end cap electrodes to destabilize all mass except m/z 96, the molecular ion for 1,2-dichloroethene. The long ionization time allowed the population of m/z 96 to grow large enough to detect the compound at sub parts-per-trillion levels while the SWIFT pulses removed enough of the unwanted ions to eliminate space charging conditions. Post acquisition data smoothing to enhance detection limits even further was also demonstrated. The 1,2-dichloroethene was detected at the parts-per-quadrillion level while in solution with other volatile organic compounds at much higher concentrations. The accompanying figure shows the mixture mass spectrum with the swift pulse on and off.

Introduction

European community directives dictate that the levels of pesticides in drinking waters should not exceed 100ng/l of each pesticide and 500ng/l total amount of pesticides. In order to comply with these regulations analysts require instrumentation which can achieve low levels of detection with high specificity and good linearity of response.

Several GC/MS and LC/MS methods have been developed for pesticide analysis. However, GC based methods are limited because of the thermal lability of many of these compounds and LC/MS methods have mainly used thermospray ionization which has suffered from poor reproducibility and fluctuating ion signals.

More recently, atmospheric pressure ionization techniques have been used for environmental monitoring with most methods employing atmospheric pressure chemical ionization (APCI) In view of the popularity of electrospray ionization for other LC/MS applications, we investigated the use of this technique for the analysis of phenyl urea and triazine herbicides in drinking water and field run off surface water samples

Results

The initial experiments concerned separating a mixture of 16 standard herbicides Full scan LC/MS gave excellent TIC signals and spectra at the 10ng level. Spectra for all of the 16 herbicides studied were dominated by protonated molecular ions [M+H]+. The 10ng level represents the detection limit quoted for thermospray techniques, however, this application of electrospray allowed full scan detection to at least 200pg on column for each of the standard herbicides (Fig 1)

At this stage, identification of the herbicides in solid phase extracted (SPE) surface water samples proved difficult due to the complex nature of the concentrated water matrix. As an alternative to more extensive sample clean-up, LC/MS/MS was employed for all further analyses of the herbicides in the environmental matrices (i.e surface water and the drinking water samples)

In order to investigate the potential for pesticide screening, an MS/MS library was created from the product ion spectra of 40 different pesticide standards The library was constructed from the collision induced dissociations (CID) of each pesticides' protonated molecular ion Fixed CID conditions of 20eV collision energy and an argon gas pressure of $2x10^{-3}$ mbar were maintained for each of the standard samples

Each product ion spectra from an LC/MS/MS analysis of the 16 herbicide mixture, at the level of 50pg per component, was then screened against the created library. All the standards were

correctly identified in the library as first hits From the studies conducted, 50pg on column was regarded as the limit of detection across the range of pesticides investigated These limits are of course restricted because of the need to maintain constant MS/MS conditions in order to screen unknown samples Using the same screening technique, 8 common herbicides were identified in each of the concentrated environmental samples. The product ion chromatograms for the drinking water sample is shown in Fig. 2

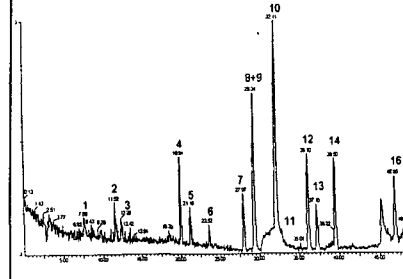

Fig. 1

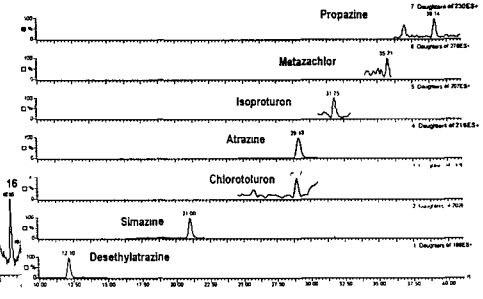

Fig. 2

Four of the most offending pesticides were quantitatively analysed in the three environmental samples using MRM scanning. The pesticides studied were simazine, atrazine, isoproturon and diuron. Calibration curves were constructed from concentrated standard solutions using a rapid LC separation. Linearity of response was observed from 10ng/l to 1µg/l, encompassing the European Community directive levels of 100ng/l for individual pesticides

(Values are in ng/l)	*Simazine*	*Atrazine*	*Isoproturon*	*Diuron*
Drinking water	138	249	16	146
Surface water 050	30	72	18	33
Surface water 110	167	134	16	99

The experiments confirmed some seasonal herbicide crop applications and the presence of 3 herbicides in the drinking water sample above the European Community regulatory levels. The higher concentration levels in the drinking water could be explained on the basis of the sample collection period All samples were collected in September, a period when herbicide application is low and hence the relatively low levels in the field run off samples It takes at least 8 weeks for the water from the fields to reach the reservoir for use as drinking water Therefore, the drinking water represents that which is derived from the summer season when herbicide application is high. This highlighted the need to recycle this drinking water before human consumption.

FORMATION OF ORGANOCHLORINE COMPOUNDS DURING WATER CHLORINATION

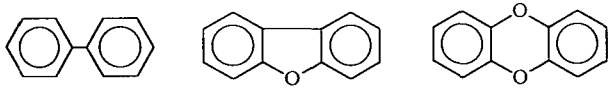
Lebedev A.T., Moshkarina N.A., Brodsky E.S., Klujev N.A., Petrosyan V.S.

Moscow State M.V.Lomonosov University, Organic Chemistry Department
119899 Moscow Russia

Chlorination has been used in water desinfection since the beginning of the 20th century. Being a very effective desinfectant chlorine is relatively inexpensive and stable enough to remain in water distribution systems for a long time. However, in the early 70th it was found that chlorination of drinking water led to the generation of undesirable organochlorine and other compounds which have been shown to be a serious chemical contamination of drinking water. A number of studies have confirmed that water chlorination was directly responsible for the formation of mutagenic chemicals in drinking water.

Until recently the attention was focused mainly on trihalomethanes $CHHal_3$, while natural humic material was shown to be the precursor of these compounds in drinking water. However, values for total organic halogenated compoundsformed in water exposed to chlorination were greater than could be accounted for by the amount of trihalomethanes formed. As a result a number of publications dealing with the identification of individual organochlorine compounds formed during water chlorination from humic material appeared.

Due to the complexity and variability of the composition and structures of natural humic substances it is extremely difficult to stady the detailed mechanism of their reactions with formation of organochlorine products, or to derive the pathways of their formation. This fact led to the wide use of simple model compounds comprising structural fragments of humic material in chlorination studies. A number of structural fragments of humic material were studied earlier, while this work deals with the water chlorination of diphenyl, dibenzofuran and dibenzodioxin.



These compounds may present individually in natural water or be structural fragments of humic or fulvic acids. The main interest to these particular compounds involves the fact that the organochlorine derivatives of these substrates are known to be extremely toxic pollutants while their presence in drinking water should be completely avoided.

The chlorination of the selected compounds was conducted in the dark at 20 C in 0.2M phosphate buffer solutions prepared from reagent grade potassium phosphate monobasic, sodium phosphate dibasic and distilled water (pH=7.2). Chlorine was used in water solution prepared by passing of gaseous chlorine through the distilled water at the Rublovo Water Treatment Station. Chlorine content was determined by iodometric

titration just before every chlorination procedure. In all the reactions substrate concentrations were 10^{-3} M while these of Cl_2 varied from 3.7 mg/l to 3.5g/l. Reaction time was 24 hrs.

Each sample was analysed with Varian-MAT 44S and Finnigan ITD 700 GC-MS systems using SE-54 (30m) and SPB-1 (30m) fused silica capillary columns. Interpretation of the qualitative and quantitative results (chromatograms and mass spectra) was performed manually using retention time information obtained by using model mixtures of chlorinated standards.

The most general equation for the reaction rate of the chlorination of an organic substrate may be presented as follows:

$$V = [S]^x \cdot [Cl_2]^y$$

Since chlorine concentration was up to 1000 times higher, while that of substrates at least 10^6 higher (comparing to the conditions of industrial water chlorination used) the rate of chlorination in laboratory was at least 10^9 times higher (x=y=1).

The most stable among the studied compounds surprisingly appeared to be dibenzodioxin, which even in the most strict conditions ($[S]/[Cl_2]$=1:50) gives only the traces of the monosubstituted product.

Diphenyl reacted with chlorine giving mostly two isomers of monochlorinated diphenyl and three isomers of dichlorodiphenyl. Therefore diphenyl underwent electrophilic substitution, although the reaction rates were not high. The products of the chlorination were identified as 2-chlorodiphenyl,4-chlorodiphenyl; 3,4-dichlorodiphenyl, 4,4'-dichlorodiphenyl and 2,4'-dichlorodiphenyl. No products of ring fission were observed.

Chlorination of dibenzofuran brought only to monochlorosubstituted derivatives while $[S]/[Cl_2]$ ratio was in the range from 1:1 to 1:10. However the subsequent increase of chlorine quantity ($[S]/[Cl_2]$=1:50) led to a sharp increase of the chlorination products. 3 Isomeric monochlorodibenzofurans 13 isomeric dichloro-, 27 isomeric trichloro- and 27 isomeric tetrachlorodibenzofurans were detected.The most toxic 2,3,7,8-TCDF may be among the reaction products, while the degree of conversion of the precursor dibenzofuran into this toxicant was about 10^{-3}%.

Therefore it is possible to carry on the following conclusions:

1. Only mono- and dichlorosubstituted diphenyls are recorded even under the most severe experimental conditions. The most toxic tetra-, penta- or hexachloro- congeners are not obtained at all. Thus there are no chance to get toxic polychlorinated diphenyls during industrial chlorination of natural water.
2. Only monochlorodibenzodioxins are recorded even under the most severe experimental conditions. The most toxic congeners are not obtained at all. Thus there are no chance to get toxic polychlorinated dibenzodioxins during industrial chlorination of natural water.
3. 2,3,7,8-Tetrachlorodibenzofuran was recorded among the other products of aqueous chlorination of dibenzofuran (degree of conversion 2 10^{-3}%). However due to the fact that the reaction rate in the experiment was at least 10^9 times higher than in real conditions it is possible to conclude that it is hardly possible to get this compound or its toxic congeners during industrial water chlorination.

Multispectral Identification of Ozonation By-products in Drinking Water

*Susan D. Richardson, Alfred D. Thruston, Jr., Timothy W. Collette,
U.S. Environmental Protection Agency, Athens, GA 30605.

Kathleen S. Patterson and Benjamin W. Lykins, Jr.,
U.S. Environmental Protection Agency, Cincinnati, OH 45268.

Because of concern over the presence of trihalomethanes (THMs) and other chlorinated by-products in chlorinated drinking water, alternative disinfection methods are being explored. One of the most popular alternative disinfectants is ozone. Ozone is more effective than chlorine for killing harmful microorganisms in drinking water and does not produce the high levels of THMs that chlorine does. It is also effective for taste and odor control. Although ozone has been used for more than 80 years to treat drinking water, very little is known about the identity of organic disinfection by-products (DBPs) that are produced.

Using multispectral identification techniques--gas chromatography coupled with low and high resolution GC/EI-MS, low resolution GC/CI-MS, and Fourier transform infrared spectroscopy (GC/FT-IR), we identified many ozonation by-products formed at a pilot drinking water plant in Jefferson Parish, LA. Rather than attempting to identify a few target by-products that are regulated for drinking water, our objective was to identify every compound that was detected in the sample extracts.

Experimental

Multispectral identification techniques included gas chromatography coupled with low and high resolution electron-impact mass spectrometry (GC/EI-MS), low resolution chemical ionization mass spectrometry (GC/CI-MS), and Fourier transform infrared spectroscopy (GC/FT-IR). CI-MS experiments utilized methane and 2% ammonia in methane gases. GC/MS analyses were performed on either a VG 70-SEQ high resolution hybrid mass spectrometer or a Finnigan 4500 quadrupole mass spectrometer. GC/FT-IR experiments were performed on a Hewlett Packard Model 5965B IRD.

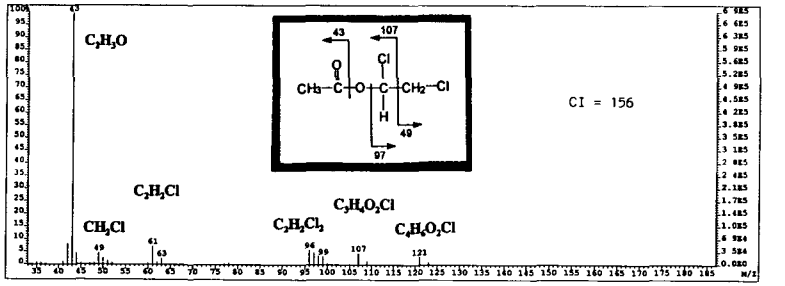
For this study, Mississippi River (Jefferson Parish, LA) raw water was treated at a pilot plant that uses ozone. Because ozone does not persist in water, an additional residual disinfectant, such as chlorine or chloramine, is required to maintain disinfection in the distribution system and to the home tap. As a result, the effect of residual chlorine and chloramine was also studied. All of these samples were concentrated onto XAD resins, eluted with ethyl acetate, and rotoevaporated to 1 ml. Half of the ethyl acetate eluents were reserved for diazomethane methylation reactions.

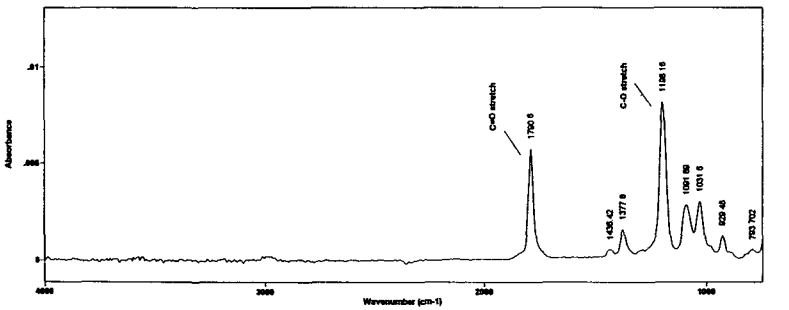
Results and Discussion

Numerous by-products were identified, many of which were not present in any spectral database and have never been identified before in drinking water. Many times, molecular ions were not present, necessitating the use of CI. High resolution data was essential for determining unknown structures, and GC/FT-IR was very useful for a few compounds where there was a choice of structures (based on mass spectral information). IR was definitive on the choice of functional group.

Ozone, by itself, produced a surprisingly small number of by-products, none of which

was chlorinated. The major DBPs produced were a series of aldehydes and carboxylic acids. The most concentrated by-product was heptanal, which was present at approximately 50 ppt (ng/L). Special derivatizations to extract highly polar aldehydes (e.g., glyoxal, methyl glyoxal) were not performed, so these previously observed aldehydes were not detected. However, because 1-chlorodimethyl glyoxal was detected in the ozonated water treated with residual chlorine, the presence of these aldehydes is suggested. 1-Chlorodimethyl glyoxal is likely a reaction product of chlorine and the ozonation by-product, dimethyl glyoxal. The levels of DBPs produced using ozone alone were much lower than what is typically found for chlorine. However, when residual chlorine was used, numerous chlorinated by-products were produced, among them some potentially hazardous halomethanes and haloacetic acids. The concentrations of these by-products ranged from approximately 5 to 300 ppt (ng/L). However, because volatile analyses were not done, it is likely that concentrations of the halomethanes were much higher than we observed. We used a semi-volatile method; volatiles would be lost in the concentration step. When chloramine was used as the residual disinfectant, fewer chlorinated by-products were produced (relative to chlorine), and no halomethanes were produced. One of the more interesting compounds identified was 1,2-dichloroethanol acetate, which was produced in both the residual chlorine and chloramine samples. Mass spectral and infrared data is shown below.





Identification of Brominated Organics in Ozonated Drinking Water

Alfred D. Thruston, Jr., Susan D. Richardson, and Timothy W. Collette
U.S. Environmental Protection Agency, Athens, GA 30605

Kathleen S. Patterson and Benjamin W. Lykins, Jr.
U.S. Environmental Protection Agency, Cincinnati, OH 45268

INTRODUCTION

The use of ozone for disinfection of drinking water is increasing as public utilities search for alternatives to the chlorination disinfection process, which produces trihalomethanes (THMs) as by-products. In drinking water treatment with ozone, the water is further treated with small amounts of chlorine or chloramine to maintain residual disinfection since ozone does not persist in water. However, little is known about the identity of the disinfection by-products (DBPs) that are formed in this treatment.

If bromide is present, as it would be in many coastal water supplies, it may be oxidized to hypobromous acid. This acid reacts with natural organic matter and residual chlorine or chloramine, producing brominated organic compounds.

We have identified a series of brominated compounds found in extracts of drinking water samples spiked with sodium bromide from a pilot drinking water treatment plant that uses ozone

EXPERIMENTAL

Identification techniques included gas chromatography coupled with low high resolution electron-impact mass spectrometry (GC/EI-MS), methane chemical ionization MS, and Fourier transform infrared spectroscopy (GC/FT-IR).

GC/MS were performed on a VG 70-SEQ high resolution hybrid mass spectrometer and a Finnigan 4500 Quadrupole mass spectrometer. GC/FT-IR analyses were performed on a Hewlett Packard Model 5965B IRD.

At the Jefferson Parish, LA, Pilot Treatment Plant, raw water from the Mississippi River was clarified by addition of coagulants and sand filtration. The water was spiked with 1ppm NaBr, a portion retained for background, and the rest was treated with ozone. The water disinfected with ozone was split, and one portion post-disinfected with chlorine (Cl_2) and the other with chloramine (NH_2Cl). All of these samples were concentrated onto XAD resins, eluted with ethyl acetate, and rotoevaporated to 1 ml.

Among the compounds found were bromohydrins, bromoalkanes, bromoacetonitriles, bromonitroalkanes, bromo acids, and bromophenols.

Multispectral techniques were used to identify most of the compounds. An unique example is the identification of **nitrodibromomethane**. The spectrum was not in MS spectral databases. Little structural information, other than the presence of bromine, could be gleaned from LR/EI/MS alone. Methane CI/MS showed no molecular ion. However, HR/EI/MS showed the m/z 43 to be $[CHNO]^+$, m/z 46 to be $[NO_2]^+$, and m/z 122 to be $[CHNOBr]^+$.

The IR spectrum is consistant with this structure. The O=N=O group gives 2 highly unique peaks, the antisymmetric and the symmetric stretching peaks at 1596 and 1326 cm-1, respectively. The C-Br stretching peak is observed at 794 cm-1. No features are present in this spectrum that are not consistant with this structure.

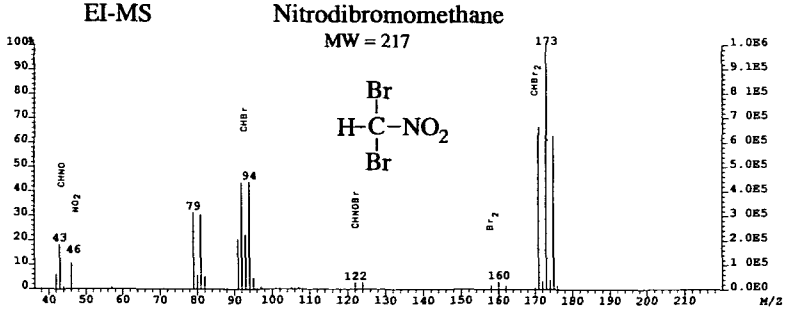
SUMMARY

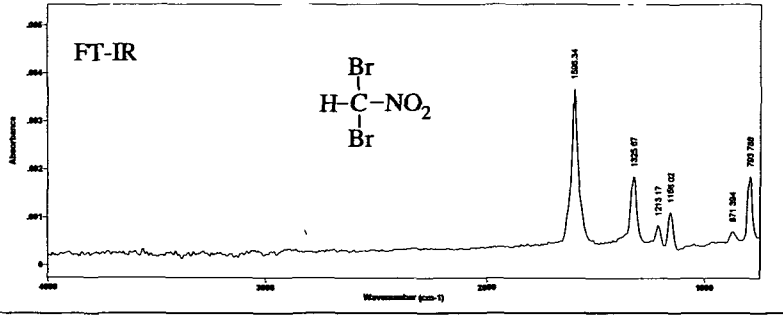
The halogenated disinfection by-products (DBPs) detected in the Br - spiked water concentrates, were mostly brominated and mixed bromochloro compounds.

A comparatively large amount of 2-bromoethanol (1ppb) was only found in the ozonated sample post-disinfected with NH_2Cl.

A comparatively large amount of bromoform (3 ppb) was found in the ozonated sample post-disinfected with Cl_2.

It is apparent that when Br - is present in raw water, ozone can oxidize Br - to produce HOBr, which, in turn combined with chlorine, or chloramine, reacts with naturally occurring organic matter to produce numerous brominated DBPs.





Isotope Ratio Monitoring for Stable Isotope Analysis on CH_4 and N_2O in Air

Brand, Willi A. and Seedorf, Ronald,
Finnigan MAT, Barkhausenstr.2, 28197 Bremen, Germany

It is a prominent disadvantage for isotopic monitoring of atmospheric trace gases that the required sample size using the traditional techniques is high. For CH_4-work for instance, typically more than 50 liters of air per sample are necessary (1). The idea to use the irm-GCMS (2-4) technique for high precision isotope analysis on trace gases like CH_4, CO or N_2O is obvious and suggests itself. For this purpose we have developed an automated pre-GC concentration device ("PreCon"). Its principle is outlined in **figure 1**:

For N_2O work, air samples of 100 ml size containing 1.4 nmol of analyte gas are driven through a H_2O and CO_2 scrubber tube using a Helium flow of ≈25 ml/min ("He-piston" technique). The CO_2 is withheld in the ascarite trap with an efficiency >0.999. A small amount of CO_2, all of the N_2O and most of the other air constituents escape the scrubber tube. The manual trap 1 downstream is not active, the combustion furnace is kept at ≈200°C, not being functional either. In trap 2 the condensibles are removed from the gas stream at -196°C. Trap 2 is made of a stainless steel tube (1 mm i.d.) filled with Ni wires for quantitative trapping. The automated trap is moving in and out of a LN_2 filled Dewar by means of an air actuated piston. It forms the loop of a 6-port valve (VALCO).
After sampling for 15-30 min the 6-port valve is rotated thus making the loop part of the injection system into the GC. Because of the size of the loop, the analyte components are transferred to a small diameter trap (0.5 mm i.d.) from where the GC analysis is started by removing the trap from the LN_2 container. Excellent GC resolution is mandatory for high precision results in N_2O isotope analysis.

For CH_4 work, the manual trap 1 is immersed in liquid nitrogen. Only compounds volatile at this temperature (N_2, O_2, Ar, CH_4, CO) pass the trap and enter the μ-combustion furnace at 1000°C. The latter is a vitreous alumina tube of 0.8 mm i.d., filled with 3 Ni wires (0.13mm). Before analysis the furnace was conditioned over night using clean O_2 (≈ 1ml/min) to burn off residual carbon or carbon containing compounds. The reaction products from CH_4 oxidation are frozen and transferred to the GC for further separation/purification in the same manner as described for N_2O.

Results:
The precision obtained for the trace gases in ambient air were:

N_2O: $\delta^{15}N$ = 0.155 ‰ (1σ) $\delta^{18}O$ = 0.20 ‰ (1σ)
CH_4: $\delta^{13}C$ = 0.16 ‰ (1σ)

Figure 2 demonstrates the ability of the method to monitor the changes of the isotopic composition of N_2O in ambient air over a period of 7 hours.

Evalution the Air Quality in Mass Spectrometry Laboratories by SPTD/GC/MS

Anren Hu and Jentaie Shiea*
Dept. of Chemistry, Natl Sun Yat-sen Univ., Kaohsiung, Taiwan 804

Mass spectrometer is one of the analytical instrument which need to be operated in the vacuum. If the mechanical pumps are set in the mass spectrometry laboratory, trace of volatile organic compound (VOC) originated from pump oil may leak to the air. Exposure in such contaminant environment for a long period of time will endanger workers' health especially in respiratory system. In this study, we examined the air quality of twelve mass spectrometry laboratories in Taiwan.

The air pollutant was adsorbed in Tenax-TA tube and a short path thermal desorption unit connecting to GC/MS was used for desorbing, separating and identifying the volatile pollutants. Figure 1 shows the result of analyzing 18 liters of indoor air sample from a mass spectrometry laboratory (#1) To ensure that the inside air not polluted by the exhaust from pump oil, the mechanical pumps are enclosed in a plastic box. The major component of the organic volatiles in the indoor air sample include a variety of aromatics such as toluene and xylenes and hydrocarbons characteristic of gasoline(Table1). The relative abundance of the aromatics with different molecular weight is as the following:

Toluene > Xylene > C3 benzene > Naphthalene.

By comparing the chromatogram of the outdoor air sample, it was found that the composition of pollutants in both air samples is nearly identical Obviously, the pollutants found in the mass spectrometry are originated from common air pollution especially from car engine exhaust. Except the difference in relative abundance, the type of volatile organics found inside the plastic box where the mechanical pumps are enclosed is nearly identical to those found outside the box and also outdoor (Figure 2). The order of the abundance of some aromatics is like:

Naphthalene > C3 benzene > Xylene > Toluene.

The most possible origin of the aromatics with higher molecular weight detected inside the box is from the pump oil. To testify such suggestion, a purge and trap sampling system equipped with a heater sleeves was used to collected the volatile organics from the pump oil. It was found that the volatile organics obtained from unheated pump oil is dominant with toluene and the GC chromatogram is nearly identical to those in Figure 1. However, once the pump oil is heated at 150°C, the volatile organics is dominant with xylene (Figure 3). Since the temperature of running mechanical pump itself is also extremely high at both inside and outside parts. This temperature effect will then make the evaporation of the aromatics with higher molecular weight become much easier and this is the reason why higher concentration of such compounds is detected

Figure 4 shows the GC chromatogram of one of the mass spectrometry laboratory (#2). As it can be seen, the concentration of xylene is greater than that of toluene After carefully examined the mass spectrometer, a series leakage at the joint of exhaust pipe to the body of the mechanical pump was found. According to the results shown here, the presence of unusually high concentration of xylene or C3 benzene in the air seems to be a good indication (marker) of air pollution by pump oil

Table 1. The identities of the volatiles in the air samples.

Peak	Compounds identified	Peak	Compounds identified	Peak	Compounds identified
1	Benzene	22	1,7,7-Trimethyl-bicyclo-2,2,1-hept-2-ene	43	2-Methyl-naphthalene
2	n-Heptane	23	Unknow	44	n-Tridecane
3	Toluene	24	1-Methyl-4(1-methylethyl)-benzene	45	1-Methyl-naphthalene
4	n-Octane	25	1-Ethyl-3,5-dimethyl-benzene	46	2,6-Dimethyl-naphthalene
5	Isobutyl acetate	26	1-Methyl-3-propyl-benzene	47	n-Tetradecane

Gas chromatography-tandem mass spectrometry a novel approach for monitoring the bacterial load in air.

M. KRAHMER*, K. FOX, and A. FOX. University of South Carolina, School of Medicine. Columbia, SC. 29208

Exposure to bacterial components can lead to pulmonary irritation and allergic reactions. Unfortunately, culture-based quantification of the bacteria present in airborne dust is inadequate for determination of the total bacterial load. The use of analytical microbiological techniques utilizing muramic acid (MA), as a marker for peptidoglycan allows comparisons of environments for overall contamination with culturable.

MA has been assayed in the past using a variety of methods. The earliest methods included spectrophotometry and later either gas or liquid chromatography. Recently mass spectrometry has increased selectivity while tandem mass spectrometry using multiple reaction monitoring has allowed dramatic improvements in specificity coupled with selectivity of detection.

METHODS AND MATERIALS

Culture:

Samples were collected in horse and hay barn using a single stage Anderson sampler with a flow rate of 18-20 liters per minute. Traditional colony counts were done for comparison to analytical methods to determine the percentage of nonculturable bacteria present in this specific environment. Profile evaluation of the culturable bacterial were determined using tryptic soy agar containing the fungal inhibitor cycloheximide TSA/H.

Sampling:

MA content present in dust samples was evaluated using teflon filters (air flows of 10-20 l/min) collected from the same environment over periods of 3-31 days.

Muramic acid analysis:

Samples were derivitized using the alditol acetate method. In brief, samples were sonicated, then hydrolyzed with 2N sulfuric acid for 3 h at 100°C Methylglucamine (2 µg) was added as an internal standard while rhamnose (1 mg) was added as a carrier to all samples Samples were neutralized with N,N-dioctylmethylamine:chloroform (50.50 vol/vol). The aqueous phase was passed through a C-18 column and reduced with 5 mg sodium borohydride. Methanol-acetic acid (200:1 vol/vol) evaporation was done under nitrogen to remove borate. The samples were dried and acetylated at 100°C overnight. Acetic anhydride was decomposed with water, then chloroform was added and the aqueous phase discarded. Ammonium hydroxide was added and the mixture passed through a Chem Elut column. The samples were evaporated to dryness and resuspended in 30 µl of chloroform.

The samples were analyzed using GC-MS-MS. The GC was a Fison:'s 8000 series equipped with an automatic sample injector (model A200S) and a SP-2330 fused-silica capillary column (Supelco, Bellefonte, PA). The MS-MS was a VG Quattro (Fisons, Boston, MA). Electron impact ionization and collision induced dissociation were performed.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

RESULTS AND DISCUSSION

Colony forming units/m^3 air were determined using TSA/H for isolation of viable bacterial load. Distribution of colony forming units (cfu) was highly variable between replicates and sampling times. Gram positive organisms were always predominant with Actinomycete-like bacteria generally a principal colony type. The study covered 5 months with 3 different representative sampling times and colony counts ranging from 51 to 375 cfu.

Concentrations of dust collected from the air varied from 9.1 to 40.3 μg/m^3 air with a mean and standard deviation of 20.3 $\pm$ 7.8. The MA concentration in the air sampled varied between 0.65 to 3.0 ng/m^3 with a mean and standard deviation of 1.4 $\pm$ 0.66. The MA values in airborne dust varied from 25.9 to 120.6 ng/mg with a mean of 76.8 $\pm$ 31.5.

Total viable and nonculturable bacteria were calculated from muramic acid values using two different methods, one which calculates the MA values based on the calculated average of MA content for a Gram positive population and the other which uses a calculated average of MA content for a Gram negative population. In both methods the weight of each cell was calculated assuming the density of a bacterial cell was approximately 1.0 and the cell dimensions taken from Bergey's Manual of Systematic Bacteriology. Four different genus of Gram positive and seven different Gram negatives were used.

Using the average weight of muramic acid per cell for either Gram positive or Gram negative bacteria and the muramic acid concentration of air (as determined by GC-MS-MS) the total viable and nonculturable bacterial concentration was calculated. The average MA concentration of various bacteria were used to determine the percent MA in a model bacterium. The percent dry weight MA of four Gram positive bacteria and seven Gram negative bacteria were used to calculate an average bacteriums' dry weight. For example, from Sept. 1-7, 1994 (1.2 ng/m^3) muramic acid values translated to 70,600 bacteria/m^3 air and from Sept.7- Oct. 8, 1994 (1.3 ng/m^3)there were 76,500 bacteria/m^3 air using the average Gram positive MA dry weight. While using the average dry weight MA for Gram negative bacteria the MA concentrations obtained on September 1-7, 1994 , and September 7-October 8, 1994 , the total bacterial load was respectively 120,000 cfu/m^3 and 130,000 cfu/m^3. The viable bacteria in this period was 1200 cfu/m^3 air.

The calculated cfu/m^3 obtained from the MA data does not correlate to the actual data obtained on culture. It is well established that the nonculturable population of bacteria contributes significantly to the overall bacterial load in diverse environments . Currently, few techniques are available to evaluate for this segment of the bacterial community. Using the Gram positive model as an indicator of the nonculturable population the calculated cfu/m^3 were increased sixty fold. However, the cfu/m^3 obtained using a model bacterium showed an increase of 2 orders of magnitude over actual culture.

This is the first attempt to evaluate the total bacterial load in airborne dust. The use of MA for detection of total bacteriological load in airborne dust provides an independent means to determine bacterial contamination without culture. Muramic acid values (as a measure of PG contamination) have the potential to become one of a battery of standard tests to aid the determination of bacterial biopollution in indoor air.

Effects of Transfer Line on MS Sampling and Analysis of VOCs in Air

Cyril V. Thompson, Marcus B. Wise, and Michael R. Guerin
Instrumentation/Chemical & Analytical Sciences Division,
Oak Ridge National Laboratory

The growing development of field analytical techniques for use in characterization of remediation sites, continuous emission monitoring of chemical processes, and locating sources for fugitive emissions has produced a variety of new methods and instrumentation for determination of volatile organic compounds (VOCs) in air and soil gas samples. Transfer lines are often used to convey these samples from remote sites, subsurface environments, or chemical reactors. The objective of this study was to determine the suitability of Silcosteel™ tubing for such applications.

Six compounds were used in the experiments, h-hexane, benzene, chloroform, toluene, trichloroethylene (TCE), and perchloroethylene (PCE). The experimental apparatus was designed so that an in-line air monitor sampled VOC-laden gas from a manifold, which could be switched so that sample was drawn through either the transfer line or a by-pass. The transfer line was maintained at a temperature of 57° F in a refrigerator during the experiments, as were the gas samples, to simulate physical conditions in subsurface environments. Experiments were conducted in triplicate at concentrations of 0.01, 0.1, 1, 10, 100, 1000, and 10,000 ppm. Gas samples were prepared by injecting methanolic solutions of the individual VOCs into Tedlar bags containing air at 90% RH (57° F), allowing the solution to evaporate, and placing the bags into the refrigerator to equilibrate at 57° F before sampling. The high humidity used to prepare the gas samples is typical of subsurface conditions in both arid and humid climates. Further experiments were conducted in which the transfer line was held at 35° F to simulate above-ground sampling in cold weather. Benzene and TCE were analyzed at 0.1 and 100 ppm and n-hexane and PCE were analyzed at 10,000 ppm under these conditions to provide both medium VOC exposure levels and high and low volatilities at high concentrations. Finally, experiments were conducted to determine the adsorption/desorption characteristics and clearance rates of the individual compounds from the Silcosteel transfer line. In these experiments, the transfer line was exposed to 10,000 ppm concentrations of the individual VOCs for a period of 30 minutes. The response for the compound was monitored after cessation of the

43rd ASMS Conference on Mass Spectrometry and Allied Topics

exposure for periods of up to 530 minutes to determine elapsed times to either 0.01 ppm or lowest achievable response from the transfer line.

Under the standard conditions of 57° F and 90% RH, the Silcosteel™ transfer line had only a minimal (7 - 9%) retentive effect on chloroform, TCE, and PCE, and then only at the 10 ppb level. n-Hexane, benzene, and toluene were unaffected by the transfer line at all concentrations. In the cold transfer line experiment with PCE at 10,000 ppm, the PCE apparently condensed in the transfer line. The response through the transfer line rose to only 54 % of the response through the by-pass. Also, the response for PCE, which would typically decline to baseline 30 seconds after exposure end, continued at near maximum levels for over 10 minutes. In all other experiments with the transfer line at 35° F, there was no effect on the air samples.

In the adsorption/desorption experiments, the Silcosteel tubing typically required 3 minutes or less to reach 10 ppm in the effluent from the transfer line after exposure to 10,000 ppm of the VOC had ceased. Sub-ppm effluent levels were reached in less than one hour in all cases. These times are quite favorable when compared with the tens of hours or even days to clear other types of tubing. Clearance times were generally correlated with the relative volatilities of the compounds.

In conclusion, Silcosteel™ transfer lines appear to be particularly well-suited for air sampling of in air, as they are much less adsorptive than other materials such as tubing of Nylon™, polyethylene, or even Teflon™. Response for VOCs through Silcosteel tubing is rapid, and quantitation is accurate, due to the low adsorptive properties of the tubing. Silcosteel tubing can also be resistively heated, further reducing its adsorption of VOCs, while polymer transfer lines must be wrapped in a heat tape or some such device to accomplish the same effect.

MONITORING TRACE CONTAMINANTS IN AIR VIA ION TRAP MASS SPECTROMETRY

P.T. Palmer, Dept. of Chemistry, SF State University, SF, CA
D. Karr, Teledyne Electronic Technologies, Mountain View, CA
R. Pearson, G. Valero, and C.M. Wong, NASA Ames Research Center, Moffett Field, CA

The ever-growing number of applications requiring fast, accurate, and reliable monitoring of trace-level contaminants in air is a major factor driving the development of new instrument technologies for in-situ, real-time analysis. The quadrupole ion trap is particularly well-suited to these applications due to its small size, high sensitivity, and programmable selectivity available through tandem mass spectrometry. A number of ongoing NASA investigations stand to benefit from the use of ion trap mass spectrometry for analysis of the Earth's atmosphere. These include monitoring various chlorofluorocarbon (CFCs) species regulated by the Montreal Protocol, determining baseline levels and emission profiles of volatile organic compounds (VOCs), and performing atmospheric assessments in support of the High Speed Research Program (advanced aircraft development).

Ambient concentrations of specific contaminants depend on the location, time, and many other parameters. Typical values for selected species are given in the table below.

compound	mean global concentration	urban concentration
carbon dioxide	350 ppm	200-1000 ppm
methane	1.7 ppm	1-5 ppm
trichlorofluoromethane (CFC11)	260 ppt	100-7000 ppt
dichlorodifluoromethane (CFC12)	260 ppt	200-3000 ppt
carbon tetrachloride	100 ppt	-
benzene	10 ppt	2-40 ppb
toluene	5 ppt	3-60 ppb

The purpose of this study is to evaluate commercial ion trap instruments for monitoring CFCs and VOCs in air. Our primary interest is in developing the capability to monitor **ambient** concentrations of these species in the atmosphere, which are typically orders of magnitude lower than those found in urban air samples.

These experiments were performed on Teledyne 3DQ and Finnigan ITS40 instruments. CFC and VOC gas standards were obtained from commercial sources or generated via a Environics gas dilution system. Three different sampling methods, direct sampling, gas chromatography (GC), and cryotrapping were evaluated. The direct sampling mode utilized a Valco 10-port valve configured in the gas sampling mode. This valve was equipped with an appropriately size sample loop, enclosed in a small oven heated to 100^0C, and connected to the ion trap via a short length of 0.25 mm ID capillary transfer line. Helium was employed to flush the air sample through the loop and into the ion trap at a flow of about 1 mL/min. The GC mode added a column in between the valve and transfer line. The cryotrapping mode added Tekmar Aerocan and Aerotrap interfaces to concentrate VOCs from large sample volumes.

Direct monitoring represents the simplest configuration of the ion trap for air analysis. Its biggest drawback is the relatively poor sensitivity which results from attempting to detect trace species against a large background of air. Although radiofrequency (RF) levels can be set to prevent ionization of background ions and Filtered Noise Fields (FNF) used to exclude unwanted ions, mass resolution is severely degraded as the "air slug" is flushed into the ion trap. As the offending neutral gas molecules are pumped away, mass resolution quickly returns to nominal levels. The cycle times (defined here as the

time difference between sample injection and completion of data acquisition) are approximately 10 seconds. Detection limits are on the order of 1 ppm for a 0.25 mL sample loop. Note that a number of investigators have utilized different implementations of direct sampling for ion traps and achieved detection limits ranging from ppm to ppb levels (1-4).

GC provides a means for separating air from the components of interest, thus avoiding the concomitant reduction in resolution and signal degradation. A DB-5 column provides complete separation of air, CFC12, CFC11, and carbon tetrachloride. Cycle times are approximately 5 minutes for an isothermal analysis at ambient temperatures. Detection limits depend on sample loop size. Injection of larger sample volumes results in broader peaks and less efficient chromatography. Detection limits on the order of 100 ppb for a 10 uL loop and 1 ppb for a 1 mL loop are easily achieved. Several groups have demonstated the use of transfer line GC on the ion trap to provide even faster cycle times and ppb-level detection limits (5-7). It should also be noted that atmospheric sampling glow discharge ionization and membrane introduction have provided comparable detection limits (8,9). Further reductions in detection limits are necessary before these techniques can be used to reliably monitor CFCs in "clean air" samples at high precision.

Cryotrapping addresses a number of problems including both air and water removal and enhanced sensitivity. It presents the most stringent requirements in terms of space, complexity, and materials (LN2). Moreover, the various steps in the sample processing (i.e.; evacuating, flushing, sampling, cryotrapping, desorbing, etc.) result in cycle times on the order of 50 minutes. Detection limits on the order of 1 ppt are easily achieved for a 1 L sample volume. For the purposes of our work, only cryotrapping was found to provide the ppt-level detection limits required for monitoring ambient levels of VOCs.

A detailed and rigorous intercomparison between MS and MS/MS modes of operation on the two instruments was not within the scope of this study. Our results indicated comparable detection limits between the ITS40 and 3DQ via both MS and MS/MS. The use of FNF to isolate the ions of interest showed improved signal-to-noise ratios versus conventional scanning on the 3DQ instrument.

We have rack-mounted and flight-qualified a system which incorporates a 3DQ instrument, a cryotrapping unit, and an atmospheric sampling unit that supplies constant sample pressures regardless of altitude. This system is currently being evaluated in flight experiments on NASA's DC-8 aircraft and will undergo further testing and flight deployments this summer.

Air Analysis for VOCS: Tenax Collection vs. On-Line Membrane Sampling

M. E. Cisper, C.G. Gill, P.H. Hemberger, Los Alamos National Laboratory, Los Alamos, NM 87545
G.L. Kok, National Center for Atmospheric Research, Boulder, CO

We have investigated two sampling methodologies for the analysis of volatile organic compounds in air. Both techniques employ a secondary jet separator stage for sample enrichment and ion trap mass spectrometry for detection.

The first method utilizes dual Tenax traps for continuous off-line adsorption and preconcentration of contaminants from a flowing air stream. As one Tenax trap is sampling, desorbed contaminants from the second trap are injected into a cryo-cooled injection loop. Subsequently, helium carrier gas sweeps VOCs from the heated injection loop to the on-line jet separator.

The second air sampling technique employs a pneumatically-assisted silicone membrane interface for on-line air analysis.(1) VOCs in air permeate through the outside of the tubular membrane into a coaxial helium flow in the membrane interior, which carries contaminants into the jet separator. Calibration and air sampling are accomplished using the flow injection process.

VOC transport efficiency through the membrane was estimated by using a Tenax trap to sample the air stream both before and after the membrane. The Tenax trap was then desorbed onto a gas chromatographic column. For the chlorinated and aromatic compounds we sampled, membrane transport efficiency ranged from 10 to 25% for concentrations ranging from 0.5 to 400 ppb in air.

Memory effects and interferences were studied for the membrane sampling system. Membrane response to a low level contaminant in air (70 parts-per-trillion toluene) was investigated under varying conditions. Neither the presence of a co-contaminant at 100 times the toluene concentration nor high toluene exposure appeared to significantly affect the reproducibility of low-level toluene response.

Chemical ionization (CI) can be readily implemented with the membrane introduction ion trap mass spectrometer. During air sampling, sufficient oxygen crosses the membrane to act as a charge exchange reagent with VOCs in the ion trap. Response to methyl ethyl ketone in air with the membrane sampling ion trap was improved by over two orders of magnitude using this method. For particular organic compounds, CI operation may prove a much more efficient ionization technique than conventional electron impact.

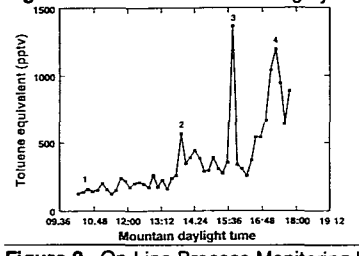
Both sampling methodologies have been successfully used in various air monitoring applications. Outdoor air was sampled during an eight-hour period using the off-line Tenax sampling technique. The results from that experiment are displayed in Figure 1. Detection of toluene in outdoor air could be readily correlated with uncontrolled events in the vicinity. On-line process monitoring of an air stream was accomplished with the membrane interface instrument. In one experiment, the plasma discharge breakdown of trichloroethene in air was observed over a one-hour period. Figure 2 displays fluctuations in TCE response which are readily associated with discharge events.

The two sampling methods are compared in Table 1. While Tenax collection offers greater sensitivity due to a higher flow rate and a longer, discrete sampling period, membrane introduction permits continuous air monitoring. A short membrane fiber (9.5 cm) has been

used to minimize response time; 90% of maximum peak height is attained within 60 seconds or less. Contaminants in air at the 20 parts-per-trillion by volume level have been detected following reductions in the membrane sampling interface volume.

Membrane introduction mass spectrometry provides rapid, near real-time assessment of air quality. Sample archiving and later verification by GC-MS can be achieved by adding the option of off-line air sample collection. Newly-designed circuitry which triggers off-line collection of air samples once a user-defined threshold is exceeded can be used to automate VOC collection on Tenax.

Figure 1. Outdoor Air Monitoring by Off-Line Tenax Collection



Outdoor air was sampled over an eight hour period. Events correspond to numbers as follows:
(1) Wind from south
(2) Delivery truck in parking lot; wind shifts to opposite direction
(3) Wind stagnant; response is spiked and erratic
(4) "Rush hour" starts

Figure 2. On-Line Process Monitoring by Membrane Introduction

CHARACTERIZATION OF VOLATILE ORGANIC COMPOUNDS BY THERMAL DESORPTION/GAS CHROMATOGRAPHY/MASS SPECTROMETRY

Cheng-Yu Ma, J. Todd Skeen, Amy B. Dindal, Cecil E. Higgins, and Roger A. Jenkins

Chemical and Analytical Sciences Division
Oak Ridge National Laboratory*

INTRODUCTION Carbonaceous triple sorbent traps (TSTs) have been widely used to collect and concentrate volatile organic compounds (VOCs) in vapor phase samples for subsequent GC/MS analysis. Recently, our laboratory has been involved in sampling and analyzing VOCs collected from various emission sources, including headspace samples from underground storage tanks at the Deparment of Energy's Hanford site, in Richland, Washington. In order to evaluate the sampling adequacy and to assess any health-related impact based on the analysis results, a validated method must be employed. Therefore, the main objective of this study was to develop a methology for thermal desorption/gas chromatography/mass spectrometry (TD/GC/MS) determination of VOCs in the vapor phase samples collected on Carbotrap C/Carbotrap/ Carbosieve S III triple sorbent traps. Techniques used in method validation included VOC standard generation, thermal desorption efficiency, reproducibility of spiking on and recovery from TST, use of internal standards, detection limits determination, linearity and reproducibility of calibration.

EXPERIMENTAL TD/GC/MS analysis was performed either on a Hewlett-Packard 5995 or 5972A GC/MS system. A modified injector port was installed to adopt an in-house manufactured short path desorber for transferring desorbate directly onto a cryofocusing loop in a splitless mode. A capillary fused silica column (Rtx-5, 0.32mm ID, 60m, 5u film thickness) was connected to a SS cryofocusing loop via a Valco 3-way ZDV switching valve. During the flash desorbing (400^0 C in 1.5 min) process, the carrier flow was increased to 50 ml/min by switching the valve to vent position.The oven temperature program (10^0 C for 10 min, 3^0 C/min to 230^0 C) was initiated immediately after the liquid nitrogen bath was removed from the cryofocusing bath. EI spectra were obtained with an electron energy of 70 eV. Mass spectral data were acquired with a scan rate of 1.2 scan/sec over a mass range of 29-300 amu. Positive CI mass spectra were obtained on a Hewlett-Packard 5985 GC/MS system using methane as reagent gas and the following instrument conditions: source temperature 200^0 C; electron energy 200 eV; emission current 300 uA; and source pressure 0.5 torr. VOC standards (target, internal, surrogate standards) used for method validation were generated using a method similar to the static dilution method described in EPA Methods TO-1. An aliquot of this standard was spiked onto TSTs with a gas tight syringe and 200 ml/min of helium purging through a preheated vapor injector.

RESULTS AND DISCUSSION The method delivered excellent results in terms of reproducibility, desorption effiency, stability of VOCs on TST, linearity, and method detection limit. The in-house manufactured short-path desorber and the cryofocusing system allowed us to perform flash thermal desorption in 5 minutes and to transfer desorbed VOCs directly and

quantitatively onto the GC column. Vapor phase standards generated from 4 internal standards, 3 surrogate standards and 23 target compounds (C_6 - C_{13} alkanes, alkyl alcohols, alkyl nitrile, alkyl ketones, and aromatic hydrocarbons) were used for method validation. A desorption efficiency of greater than 91% was obtained for all the standards studied, based on the ratio of MS response generated from TD/GC/MS to that generated from direct injection of the same standard followed by GC/MS analysis. In order to evaluate method reproducibility and to determine method detection limits for the entire procedure (including gas standard generation, spiking onto and desorbing from TSTs), triplicate TSTs spiked with gas standards at five concentration levels (5-200 ng/trap) were analyzed by TD/GC/MS in a random order over a two week period. The % RSD of the corrected area response (ratio of target compound response to internal standard response) was determined to be less than 10% for the TSTs spiked at 50 to 200 ng/trap level, and increased to less than 25% for the TSTs spiked at 5-10 ng/trap level. For twenty one target compounds, the method detection limit (MDL) was determined to be less than 10 ng. For the remaining two target compounds, the MDL was determined to be 15 and 20 ng. Thus, the higher level of %RSD were normally associated with TSTs spiked with gas standards at a level close to the MDL. Over a period of five months, four calibration curves were constructed at five concentration levels (20 to 700 ng/trap). The linear correlation coefficient (R^2) for all the target compounds falls in a range of 0.910 to 1.000. Additionally, the long-term reproducibility for selected target compounds has been evaluated by carrying out sixteen mid-level (180 ng/trap) calibrations on the same days when field samples were analyzed. In general, the response factor for the mid-level calibration deviated less than 16% from the average response factor generated from the five point calibration. The pre-analytical holding times or the practical reporting times (PRTs) for selected target compounds on TSTs were also determined as part of the QA/QC plans. Except for four target compounds (three alkanones and one alkanol), the PRTs are 30-84 days under refrigeration (2^0 C), as well as at ambient temperature (22^{0}C).

The validated method has been successfully applied to the characterization of VOCs collected from various emission sources in a diversified concentration range. For example, over an eighteen month period, about 150 headspace samples collected from 30 underground waste storage tanks at the DOE's Hanford site have been analyzed. The majority of VOCs were first tentatively identified based on their EI spectra, then were confirmed based on their chemical ionization mass spectra. In some cases, additional confirmation was carried out by GC retention time matching with authentic gas standards. The major VOCs present in those tanks are quite similar and represent a wide range of chemical classes and volatilities: alkanes, alkenes, alkylated cycloalkanes, alkyl nitriles, alkanones, alkanols, alkanoic acid esters, and alkyl phosphates and phosphonates. The recovery rates of three surrogate standards (spiked on TSTs prior to shipping to sampling sites and for process control) range from 87 to 98% with %RSD of 7 to 15%, indicating the spiking process as well as the analytical methodology are very reproducible, and the sample matrix has no or little effect on VOCs collected on TSTs. A relative standard deviation of less than 35% was generally obtained for the quantitation of target compounds. The higher %RSD for the entire process (sampling and analysis) presumably was due to the sampling process under less controllable conditions at the tank storage sites.

Analysis of Air Samples from Two Polypropylene Film Plants using Thermal Desorption/GC-MSD

C.W. Chuang; E.J. Arnold; T.A. Roy
Stonybrook Laboratories Inc. P.O. Box 1029, Princeton, NJ 08543

INTRODUCTION

Title III of the Clean Air Act Amendments (CAAA) of 1990, which is Hazardous Air Pollutants (HAPs), mandates that the US EPA address emissions of HAPs from both area and point source. In order to comply with Title III, industry must know what kind of materials are being emitted from the facilities. The availability of the speciation and quantitation of point- and area- specific emission data along with the risk information enables the industry to respond correctly to the regulatory agencies.

Ambient and stack air samples collected from two polypropylene (PP) film plants were analyzed for non-polar volatile organic compounds (VOC) using a thermal desorption unit interfaced with a gas chromatograph-mass selective detector (TDU/GC-MSD). The purpose of the study was to examine the VOC profile of both ambient and stack air inside the PP film plants.

EXPERIMENTAL

Air samples were collected on 6 mm o.d. x 20 cm Pyrex tubes containing 200 mg of Carbopack B and 350 mg of Carbosieve S-III (both from Supleco, Bellfonton, PA). Each tube was refurbished by thermal desorption at this laboratory prior to transport to the sampling sites. Air samples were collected from four stacks on a PP processing line and two ambient locations inside plant A and from three stacks on three separate PP processing lines and two ambient locations inside plant B.

Thermal desorption unit (TDU)--The TDU used was a UNACON 810 (Envirochem, Inc., Kembleville, PA). The sample sorbent tube is thermally desorbed in the tube desorber. The analytes are transferred to trap#1(2 mm i.d. x 20 cm) and then to trap#2 (<1 mm i.d. x 20 cm) before being swept out of trap#2 and cryotrapped at the head of GC column. The GC run is started at the beginning of the trap#2 desorption. After 1.5 minutes of GC acquisition, a liquid nitrogen cryofocus vessel is removed, the GC oven fan turned on and the GC run continued.

GC-MSD--A Hewlett-Packard 5890 gas chromatograph interfaced with a HP 5970B mass selective detector (MSD) was used for the sample analysis. The GC-MSD data system used for analysis was the Hewlett-Packard RTE-6 (Rev. F). The GC column used was a 0.25 mm i.d., 30 meter, 1.4 µm film thickness J&W (Folsom, CA) DB-624 fused silica capillary. The front portion (about 55 cm) of the column was looped and immersed in liquid nitrogen for cryofocusing during analyte transfer from trap #2 to the head of GC column.

Analytes were tentatively identified based on the retention window of C_6-C_{19} n-alkanes and a manual comparison of their mass spectra with the computer based mass spectra library search. Quantitation of compounds was based on the response factor of benzene (i.e., 5000 area count/ng). The method detection limit (MDL) was approximately one-part-billion (ppb) or 3.2 µg/m³ of benzene.

RESULTS & DISCUSSION

Non-polar volatile organic compounds were collected and analyzed following the general procedures outlined in the EPA Compendium of Methods for the Determination of Toxic Organic Compounds in Ambient Air (June 1988), Methods TO-1 and TO-2 [1].

The total non-polar VOC concentrations of stack air samples from the PP film plant A ranged from 0.1 to 7 mg/m^3. The majority of the individual components were tentatively identified as C_9-C_{14} alkanes/alkenes. The thermal and thermooxidative degradation of PP has been studied by Frostling et. al. [2] both in the laboratory and industrial setting. The profile of PP-derived thermal/thermooxidative products observed at the PP film plant A was very similar to those observed by Frostling and this laboratory. Most of the non-PP derived components were believed to originate from the terpene resin. The literature [3-5] shows that the basic terpene ring structure can undergo heat and acid-induced rearrangement, oxidation and condensation reactions to from numerous structural isomers and bicyclics, vinyl and aromatic derivatives and dimers. Compounds tentatively identified as $C_{10}H_{14}$, $C_{10}H_{16}$, and $C_{10}H_{18}$ appear to arise from unimolecular rearrangement and/or oxidation of terpenes. Compounds tentatively identified as terpene dimers are believed to originate from bimolecular rearrangement of terpenes.

The total non-polar VOC concentrations of stack air samples from the PP film plant B ranged from 0.006 to 7 mg/m^3. The majority of the individual components were tentatively identified as C_9-C_{16} alkanes. The profile of PP-derived thermal/thermooxidative products observed at this PP film plant was similar to that observed by Frostling. Additionally, compounds tentatively identified as semi-volatile non-polar organics (i.e., $>C_{12}$), which were not measured by Frostling, contributed significantly to the overall VOC emissions in the plant.

CONCLUSION

The qualitative profile of vapor phase compounds found at both sampling sites is consistent with that reported in the literature for pyrolysis/thermooxidative degradation of PP and terpenes.

VOLATILE ORGANIC COMPOUND (VOC) ANALYSIS IN BLOOD USING SPRAY EXTRACTION

F. St-Germain[1], B. Vachon[1], J. Brunet[1], O. Mamer[2], C. Des Rosiers[1] and J. Montgomery[1], [1]Dept. of Nutrition, Université de Montréal and [2]McGill University Biomedical Mass Spectrometry Unit, Montréal Québec, Canada.

The quantitation of volatile organic compounds (VOC) in gaseous or liquid media has important ramifications for identifying environmental and medical risks. Due to the volatile nature of these compounds, they are difficult to measure accurately. We describe here a new device (1,2) which extracts volatile and semi-volatile compounds from aqueous samples and transfers them to an ion trap mass spectrometer (MS) for analysis. Our inertial spray extraction interface (ISEI) consists of a nebulizer coupled to a chamber which is at room temperature. The sample is sprayed into the chamber thus facilitating the evaporation of VOCs from the aqueous sample. A continuous flow of helium transports the VOCs to the MS (Varian Saturn II ion trap). Depending on the compound analyzed, the ion trap is operated either in electron impact or in positive chemical ionization mode using methane as a reagent gas. Following injection of a 1 ml sample, less than five seconds are required to return to baseline conditions. Figure 1 presents an example of an injection of an aliquot of an aqueous solution of halothane, a common volatile anesthetic. The intensity of the ions of interest is proportional to sample concentration when normalized with an added internal standard. Detection limits are less than 10 parts per billion for many compounds including chloroform, acetaldehyde, and toluene and in the parts per trillion for others, for example benzene.

We present examples of analytical applications using ISEI. Blood samples from a pig anesthetized with halothane were analyzed both before and after induction of anesthesia (Figure 2). The mass spectrum obtained from the sample after anesthesia is dominated by the ions characteristic of halothane (Figure 1). The halothane signal was proportional to the dose administered and decreased rapidly when the anesthetic was withdrawn. In another experiment, human blood samples spiked with toluene and xylene were analyzed by both conventional headspace gas chromatographic assay and by our ISEI system. In another experiment, rats were exposed to air spiked with known concentrations of toluene and xylene and blood samples were analyzed by both methods. In both of these experiments, excellent correlation coefficients were obtained between the two methods. Analysis of VOCs in blood is possible in volumes as low as 0.2 ml, thus permitting blood sampling by finger-prick rather than venipuncture. ISEI coupled directly to an ion trap MS provides a quick, clean and reproducible way to analyze VOCs in aqueous samples. Unlike membrane introduction mass spectrometry, spray extraction avoids discrimination effects due to analyte solubility in the membrane. The ISEI has immediate use in the field of occupational health and coupled with MS/MS for compound verification would be applicable to other medical diagnostic procedures. (Financial support from Theratechnologies, Inc. and the Medical Research Council of Canada).

A Study of Semi-Volatile Organic Emissions of Polymer Combustion by GC/MS

The incineration of waste polymeric materials in air inevitably produces a large variety of hazardous organic emissions[1]. The organic emissions from the combustion of polystyrene, polyvinylchloride, polyethylene were evaluated by GC/MS. The evolved soot was retained on glass fiber filters and the semi-volatile organics were trapped on XAD-4 resin. The organics were removed with soxhlet extraction from both the glass fiber filters and XAD-4 with methylene chloride.

Methylene chloride was used to extract the organic compounds from both the filter paper and the XAD-4 resin. 100μg of d_8 naphthalene were added to the methylene chloride prior to soxhlet extraction and solvent reduction to provide a semi-quantitative indication of component amounts. 100μg of d_{10} anthracene was then added to the resulting 1ml of solution. The comparison of the peak areas of the deuterated naphthalene and anthracene in the total ion chromatogram (TIC) provided an indication of extraction efficiency. The combustion of the polymers was repeated if the TIC peak area for d_8 naphthalene was less than 40% of the peak area for d_{10} anthracene.

To account for the variablities in material handling, extraction efficiency, solvent concentration, and instrumental analysis, the data was normalized to the remaining d_8 naphthalene concentration. This procedure enables the relative comparison of semivolatile organic components generated in the combustion of polymers as a function of variations in combustion conditions, but does not provide an accurate quantitative analysis for the component concentration within a single sample analysis.

The filter paper that was placed over the XAD-4 resin physically trapped most of the soot that was generated during the combustion process. The comparative analysis of the soot/filter paper and the XAD-4 resin showed that all the semivolatile components observed on the filter paper extracts were also observed in the XAD-4 resin extracts. Despite some small differences in the ratios of some of the semivolatile components observed in the filter paper and the XAD-4, the data generated by the filter paper analysis provided no additional insight as to the identity and quantity of the semi-volatile components generated by the combustion process and therefore were not presented.

An empty combustion vessel was exposed to the combustion process to determine the identity and quantity of interferents resulting from the furnace, filter paper, XAD-4 resin, solvents and GC/MS instrument.

The GC/MS analysis of the semi-volatile organics emanating from the burning of polymeric wastes was conducted as a function of particle size, flame propagation, temperature, residence times and reaction rates. Organic emissions from horizontal furnaces at 900C typically produce high concentrations of polyaromatic hydrocarbons while polymers burned in laminar drop tube furnaces at 950-1250°C produce significantly reduced quantities of PAHs.

Polyvinylchloride (PVC). The largest number and quantities of polyaromatic hydrocarbons evolved from the combustion of PVC in a horizontal furnace. Similar levels of PAH's were observed when unsteady particle clouds (puffs) were combusted in the vertical furnace. No PAH's, with the possible exception of naphthalene, were observed in the vertical furnaces with

dilute particle aerosols at temperatures greater than 950°C. The largest component in the XAD-4 extracts resulted from the formation of benzoic acid.

Polystyrene (PS). Three major classes of combustion products were observed in the XAD-4 extracts in PS. Thermo-oxidative degradation of PS produced many low molecular weight oxygen containing species. The second class is low molecular weight polyaromatic hydrocarbons such as naphthalene, phenanthrene, anthracene, biphenyl and fluoranthene. The largest class consists of the compounds that are formed in "classical" type reactions of the styrene olefinic system, such as bibenzyl, stilbene, 1,4-diphenyl-1,3-butadiene.

Polyethylene (PE). The number of PAH's observed in the combustion of PE is remarkably reduced when compared to similar combustions of PS and PVC. The prevalent form of PAH were fused mulitple ring aromatics with the largest relative quantities of polyaromatic hydrocarbons for compounds with the chemical formulas $C_{12}H_8$, $C_{14}H_{10}$, $C_{16}H_{10}$, $C_{18}H_{10}$ and $C_{20}H_{12}$. A set of total ion chromatograms (TIC) are shown in Figure 1, with PAH's from the horizontal furnace (HF) shown in the back, while the temperature range of 950°C to 1250°C are shown for the vertical furnace (VF). PAHs were not observed with the higher temperature combustions. Peaks at about 10 minutes and 20 minutes represent d_8 napthalene and d_{10} anthracene respectively.

STRATEGIES FOR IDENTIFICATION OF VOLATILE ORGANIC COMPOUNDS OFFGASSED FROM MATERIALS AND ASSEMBLED ARTICLES

L. Yang*, H. Leano, M. Martin, T. Limero, and J. James[1]
Biomedical Operations and Research Branch and KRUG Life Sciences, Inc.,
[1]NASA-Johnson Space Center, Houston, TX 77058

Trace amounts of volatile organic compounds (VOC) offgassed from on-board equipment can degrade the respirable air in the closed environment of a spacecraft. Exposures to these chemicals may affect the health and performance of crewmembers. Consequently, NASA requires that all non-metallic materials and assembled articles present in the habitable areas of a spacecraft be assessed to ensure that the offgassed products meet established toxicological safety criteria. The offgassing test (OGT) object is enclosed in a test chamber in a zero-air test atmosphere at 1 atm., then heated to 50°C and held at this temperature for 72 hours. After cooling, a gas sample from the chamber is analyzed for its constituents[1]. The capillary column GC/MS combined with cryogenic preconcentration is the primary method we use to analyze the complex mixtures of VOCs released from OGT objects. The goal of our present research is to develop strategies for accurate and fast interpretation of GC/MS chromatograms, resulting in accurate and expeditious identification of VOCs in offgassed product mixtures. Ultimately, the goal is to efficiently provide quality analytical results to support toxicological assessments.

Offgassed products released from non-metallic materials or assembled articles are complex gas-phase mixtures of volatile organic compounds. A total ion chromatogram obtained from a typical offgassed product mixture is shown in Figure 1. Identification of OGT compounds is normally accomplished by searching the spectrum of each total ion chromatogram peak against commercial mass spectral libraries. The library search identification is confirmed by matching the spectrum and the retention time of a standard to the best library identification. For those spectra that have no match, manual deconvolution is attempted to identify any superimposed spectra. The deconvolution results are further confirmed by the comparison with GC/MS analytical results of standards. Figure 2 shows a no-library-match unknown spectrum extracted from an OGT total ion chromatogram peak. By means of manual deconvolution and standard confirmation, two compounds, nitroethane and tetrahydrofuran, were identified from this mass spectrum. Identification of isomers, such as acetaldehyde and ethylene oxide, is achieved by separating the mixture on a non-polar stationary phase capillary column before MS detection. The most difficult unknowns generated in OGTs are those that present the same mass spectrum in two different stationary phase capillary column GC/MS analyses, and the spectrum does not match any spectrum in commercial mass spectral libraries. In this case, typical mass spectral interpretation techniques are used to identify unknowns. The mass spectrum shown in Figure 3 is an example. The peak of ion 74 in the spectrum would be a common fragment ion of aliphatic nitrite, $ONOCH_2CH_2^+$[2]. The peak of ion 30 suggests the presence of NO^+, and the peaks of ions 39 to 43 for $C_3H_7^+$. Because the candidate standard, propyl nitrite, was not available in our laboratory, the GC retention times of 16.6 min., 18.0 min., and 25.6 min. on the same non-polar stationary phase column for methyl nitrite, ethyl nitrite, and butyl nitrite, respectively, were used to support the mass spectral interpretation of the unknown spectrum at retention time of 20.0 min.

The capillary column GC/MS system, interfaced with a preconcentration inlet system, is a powerful tool for identifying and quantifying volatile organic compounds in offgassed product mixtures. More than 400 VOCs have been identified using the strategies described above. These compounds include some long-term "unknowns". Those compounds positively identified are collected into the OGT-VOC library along with their GC retention time windows, mass spectra, and chemical properties. With this database, VOCs released from additional offgassing test objects can be accurately and expeditiously identified on the basis of their retention time windows and three major characteristic fragment ions or abundant base ions. In general, an offgassed product mixture of 60 VOCs can be identified in less than 4 hours. Some "tough" unknowns still have yet to be positively identified by use of the GC/MS method. Strategies based on a GC/MS/MS method are currently under development in our lab to better support toxicological assessments.

Electrospray Ionization and Tandem Mass Spectrometry of Dyes

Jennifer B. Fencl, Gary L. Glish and Robert D. Voyksner*
Department of Chemistry, University of North Carolina, Chapel Hill
Research Triangle Institute, RTP, North Carolina

Introduction

The identification of dyes and their components is a critical aspect of screening industrial waste streams. Because of their deleterious effects, a sensitive technique is needed for rapid identification of potentially harmful compounds. Thermospray ionization on a triple quadrupole has been previously utilized for this purpose.

As an alternative approach, we have investigated the use of electrospray ionization (ES) on a quadrupole ion trap. ES was tested on various dye classes to demonstrate its viability as a method of ionization for dyes. MS/MS and MS^3 experiments were performed to elucidate structural information. These results were compared to the data acquired using thermospray ionization on a triple quadrupole.

Experimental

Dyes were obtained from the Environmental Protection Agency, or purchased from Sigma. Stock solutions were prepared in ACN:H_2O:HOAc (50:50:1%) or CH_2Cl_2:ACN:TFA (50:50:1%) in millimolar concentrations. Aliquots of these solutions were diluted 10 to 100-fold and analyzed by the mass spectrometer to determine optimum ssample concentration. Flow rates were adjusted between 1 and 2 µl/min.

Five classes of dyes were analyzed using a quadrupole ion trap with a home built ES ionization source as shown in figure 1. Dyes were observed in the positive ion mode at a helium pressure of 1.1×10^{-3} torr.

Results

An example of the dyes studied using MS/MS is illustrated in figures 2 ,3 and 4. Figure 2 data is from a triple quadrupole, and and figures 3 and 4 are spectra from a quadrupole ion trap. Similar product ions appear in both spectra, but the quadrupole ion trap provides more information about the structure. MS^3 was performed on the product ion with the greatest intensity to obtain further structural information.

Discussion

It has been determined that data from the quadrupole ion trap provides as much or more information about the structure of various dyes. This is a result of two general factors. First of all, a quadrupole ion trap has a longer time window for fragmentation that favors low energy processes and facilitates detection of more low energy fragments. In addition, higher energy processes are also able to be viewed using MS^n because enough energy has been imparted to the ion(s) of interest from successive isolations and resonance excitation voltages.

Acknowledgement

This work was funded in part by the Environmental Protection Agency through cooperative agreement number CR-819555

Conclusion

An electrospray ionization source coupled with a quadrupole ion trap is a viable method for detection of dye compounds. Results indicate that fragmentation is more extensive in MS/MS and MS^3 experiments, providing greater structural elucidation than on a triple quadrupole. Both methods provide a complementary approach for detection and characterization of various dye classes.

ANALYSIS OF SURFACTANTS AND THEIR METABOLITES IN WASTEWATER BY HPLC-IS-MS AND MS-MS

by Andrea RAFFAELLI, Sergio PUCCI, Laura CAMPOLMI, Piero SALVADORI

Centro di Studio del CNR per le Macromolecole Stereordinate ed Otticamente Attive, Dipartimento di Chimica e Chimica Industriale, Università di Pisa, Via Risorgimento 35, 56126 PISA, Italy.

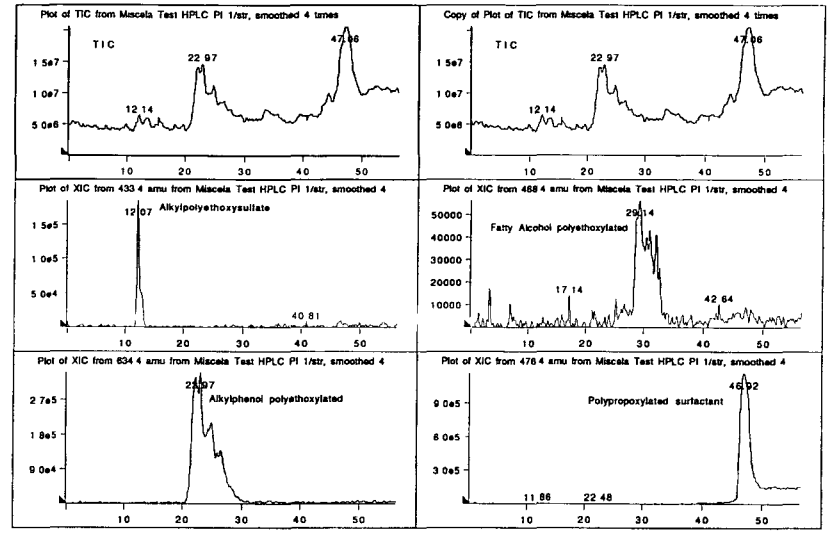
INTRODUCTION. The most common procedures for the analysis of cationic and anionic surfactants in wastewater are based on colorimetric methods. Although simple, these methods are neither very specific nor very sensitive. Moreover, they can completely fail on some metabolites, if the functional group responsible of the formation of the coloured adduct is not present anymore. Considering that sometimes the metabolites can be more toxic and stable with respect to the original surfactant molecule, this can be a real problem if a good control is required.
Mass spectrometry, owing to its high sensitivity and specificity, can be a very useful technique for the development of new analytical procedures, especially if hyphenated to suitable separation techniques. Due to the very low volatility of this class of analytes, liquid phase separation and ionization methods appear the right choice.
We present here a detailed study of different classes of detergent surfactants, as well as of opportune mixtures, by flow injection analysis (FIA) and high performance liquid chromatography (HPLC) coupled with Ionspray mass spectrometry and tandem mass spectrometry. Anionic, non ionic, cationic and anphoteric surfactants have been considered for this investigation. FIA-MS allowed to check the composition of different raw materials used for the preparation of final formulates. Reverse-phase HPLC has been used keeping in mind that the final target was the development of a universal analytical method for all different classes of tensides in water solutions. So we decided to look for a general gradient elution capable to separate at least the classes of compounds.
We are also studying some chemical degradation mixtures, obtained mainly by treating the above raw materials with oxidation agents. MS-MS will also be used in order to improve the method sensitivity and to elucidate the structure of unknown metabolites.

EXPERIMENTAL. A Perkin Elmer Sciex API-III Plus triple quadrupole mass spectrometer was used for Ionspray ionization MS and MS-MS measurements. A Harvard 22 syringe pump was used to provide a constant flow (infusion) of analyte at 5 µl/min into the source. FIA and HPLC were carried out using a Perkin Elmer Series 200 dual solvent delivery system, equipped with a loop-injector (20 ml). FIA eluent was a 10mM ammonium acetate water solution (50 µl/min). HPLC separations were performed on a Perkin Elmer C18 (3 µm particle size; 4.6 mm i.d. x 3 cm length) using ACN and FIA solvent in gradient elution (1 ml/min, split 1:40). Sample preparation involved diluting the raw materials in the FIA eluent.
Chemical degradation mixtures were obtained from Triton X-100 and sodium dodecylsulfate water solutions treated with H_2O_2 in presence of Fe^{2+} (Fenton's reagent). Order of addition and reagent ratios were varied in order to evaluate their relations with the nature of reaction products.

FIA-IS-MS RESULTS. We used ammonium acetate as an ionization aid in order to minimize the presence of alkali metal adducts that would decrease the sensitivity of the method by spreading the signal of each component into different ions of the spectrum. Moreover, alkali metal adducts are not

suitable to give significant product ion spectra in Tandem Mass Spectrometry.
Each surfactant raw material was analyzed both in the Positive (PI) and the Negative Ion mode (NI). Non ionic and cationic surfactants did not give relevant NI spectra. Different anionic oligomers of the same family showed very different response factors in PI with respect to NI.

HPLC-IS-MS RESULTS. The gradient elution method elaborated allows the elution of anionic and anphoteric surfactants first (8-13 min), whereas non ionic surfactants are more retained (25-40 min). We observed also a partial separation of ethoxylated oligomers. Cationic surfactants could not be eluted under these conditions. A sample chromatogram of a mixture of four different raw materials ir reported in the figure, showing the total ion current chromatogram (Top left and right traces) and the extracted ion current chromatogram for a single component of the four tensides (mid and bottom traces).



PRELIMINARY INVESTIGATION ON METABOLITES. Analysis by FIA-IS-MS of the oxidation reaction mixtures obtained by treating the surfactant of choice (Triton X-100 or sodium dodecyl sulfate in the experiments so far performed) with Fenton reagent showed the presence of higher as well as lower molecular weight products, in variable amounts depending on reaction conditions. The nature of the metabolites obtained in now under investigation. Separation by reverse phase HPLC was not achieved in the condition described above, as all components but the precursor eluted with the solvent, thus suggesting a very polar nature for these compounds.

The analysis of surfactants by lc and lc-ms.

SD Scullion, MR Clench and M Cooke

Division of Chemistry / Environmental Research Centre, School of Science, Sheffield Hallam University, Pond Street, Sheffield, UK. S1 1WB.

The determination of surfactants in drinking, surface and groundwater is currently a very "live" topic of analysis It is important to monitor the two most widely used forms of surfactant, i e. the non-ionic alkylphenol ethoxylates and the anionic alkylbenzene sulphonates. Recently it has been shown (1) that non-ionic surfactants of the alkylphenol ethoxylate type and their degradation products exhibit weak oestrogenic properties and may be implicated in the increase in male infertility in the western world.

The analysis of non-ionic surfactants of this type is made complex by the fact that they are formulated as a mixture of oligomers/homologues of a parent compound Non-ionic surfactants of the alkylphenol ethoxylate type are usually formulated so that the ethoxylate side chain varies from 1 to 30 units Analysis may be carried out by spectrophotometric or lc methods employing conventional detectors. However, neither of these techniques offers unambiguous identification of surfactant type and chain length Hence lc-ms has been investigated as a possible method of analysis

Particle beam lc-ms has been used in the determination of non-ionic surfactants in surface water(2) and drinking water(3) Clark et al(3) determined alkylphenol ethoxylates in drinking water after continuous liquid/liquid extraction of 500 litres of finished water The resulting extract was then analysed by pb-lc-ms (detection limits in the ng region were obtained) The method used by Clark(3) offers excellent sensitivity but is very time consuming. We have conducted experiments using lc-pb-ms and although reproducible TICs are readily obtainable poor sensitivity limits this method in terms of routine laboratory analysis Lc-APcI-ms offers robust and sensitivity means of analysis for the analysis of environmental samples containing surfactant mixtures.

We have investigated methods for the determination of surfactants by solid phase extraction C18 and SAX cartridges in series. Hplc separation of anionic and non-ionic surfactants on a C1(TMS) column has been achieved with detection via both fluorescence and liquid chromatography-mass spectrometry (atmospheric pressure chemical ionisation interface). Recoveries are approximately one hundred percent with detection limits of 50 ng on column for detection by fluorescence Alkylphenol ethoxylates have been detected in samples taken from the River Rother in South Yorkshire U.K at levels of 5.6 ppb

Kinetics and Pathways of Biodegradation by ES/APCI/MS and ^{14}C Labeling

S. W. Morrall, D. L. Lawrence, T. W. Federle
Environmental Science Department, Procter & Gamble Co., Cincinnati OH 45217

The environmental fate and ultimate effect that a water soluble compound will have in the environment is highly dependent on the complex process of biodegradation. Conventional evaluation of "biodegradation" is limited to removal of soluble organic carbon (SOC) and CO_2 production as metrics. These data are useful in screening compounds and setting criteria for "biodegradability", but have little diagnostic capability. The application of ESI/APCI/MS/MS has greatly improved the range and depth of information available concerning the biodegradation process.

METHODS

I - Biodegradation Test System

Two types of testing are typically used to determine the "biodegradability" of compounds disposed into waste water. A semi-continuos activated sludge (SCAS) experiment measures removal of soluble organic carbon (SOC). The amount of SOC attributed to the test material is determined by difference between the test compound and a control, which gives background SOC. Acclimated sludge from the SCAS unit can be used to inoculate another vessel where CO_2 emission is monitored. The outcome of this "mineralization" test is expressed as a percent of theoretical CO_2 evolved (based on total carbon contained in dose of test material) relative to a "background CO_2" control.

In order to have sufficient signal (SOC or CO_2) above the natural background, unrealistically high doses of the test material (~20 ppm) must be used. These high doses do not usually affect the judgment of whether a material is "inherently" biodegradable, but often induce a delay in the onset and decrease the rate of biodegradation. These effects are often attributed to the toxicity of the high dose and/or the time required for sufficient biomass growth to handle the high carbon loading

II - Radio Isotope Label (^{14}C)

Selective labeling of the test material with ^{14}C enables the biodegradation tests to be conducted at realistic concentrations (10-80 ppb) and provides a direct link between measured SOC/CO_2 and parent compound. Rad-TLC analysis of the test matrices provides additional data concerning primary degradation (loss of parent) and the presence and disappearance of intermediates. A carbon mass balance can be obtained for the test system However, the chemical structures of the intermediates and the pathways of the biodegradation process cannot be directly determined from the radio analytical experiments.

III - ESI/APCI/MS/MS

MS analyses (VG Quattro) of the SOC in the SCAS/CO_2 test system provides information about intermediate structures, biodegradation pathways, and any functional groups or components in the test material that is resistant to biotransformation. Analyses of extracts from the Rad-TLC plates directly links the ^{14}C kinetic data with intermediate structures. A variety of MS experiments are

used, depending on test material and matrix. Aqueous samples from the SCAS/CO_2 test are preserved and pre concentrated by SPE. Positive and negative ion modes are used with MS/MS confirmation of structures identified by mass of the molecular ion. Samples from the simpler matrices are often introduced by flow injection, with HPLC separation being used for the more complex samples.

RESULTS

I - Linear Alkyl Benzene Sulfonates (LAS)

LAS is a mixture of homologs (C_{9-13}) and isomers (branching and substitution on alkyl chain). Branched isomers (ABS) resist biodegradation, but are difficult to differentiate from LAS in environmental samples. ABS can be quantified using MS/MS (MRM) with appropriate standards.

A major biodegradation pathway is oxidation of the alkyl chain to form sulfophenyl carboxylates (SPC's). The doubly charged anions are useful for identification and quantitation of SPC's in complex matrices.

A lag phase of up to 10 days is seen between the high dose SCAS/CO_2 test relative to the more realistic ^{14}C die-away test (75 ppb, label in benzyl ring). However, biodegradation is complete at both concentrations without any evidence of persistent intermediates.

II - Alkyl Ethoxylates (AE's)

AE's are complex mixtures of several homologs (C_{9-18} and EO_{0-20}). Biodegradation can occur via several pathways with external cleavage of the EO chain being dominant in the SCAS/CO_2 test systems. Short chain PEG (Mw <600) is the primary intermediate.

H+ adducts were the dominant ions produced in APCI if an amino precolumn were used to separate inorganic cations (Na+) prior to ionization. ESI tended to produce both Na+ and H+ adducts (as well as NH_4+ if added). Quantitation was made difficult by a change in the relative abundance of the adducts as a function of EO chain length. The distribution can be easily shifted to all sodium adducts. However, H+ and NH_4+ adducts are more amenable to MS/MS analyses.

III - Nonylphenol Ethoxylates (NPE's)

NPE's are a mixture of ethoxylated homologs. Parent NPE degrades slowly, primarily via oxidation and cleavage of EO portion with limited oxidation of the highly branched alkyl chain. This degradation of EO portion produces a long lived intermediate (nonylphenol), which is more toxic than parent NPE

The pitfalls of nonspecific analyses being used to evaluate biodegradation are illustrated by a "commercial" NPE evolving a high level of CO_2 in a screening test. HPLC/ESI/MS experiments showed that a PEG contaminant was degrading, but the parent NPE was being biotransformed into nonylphenol.

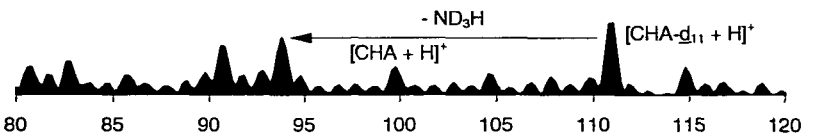
Detection of Atmospheric Contaminants Adsorbed on Surfaces Using Static SIMS

Gary S. Groenewold, Evan M. Harrison, James E. Delmore, Jani C. Ingram, Anthony D. Appelhans, David A. Dahl, Idaho National Engineering Laboratory, Idaho Falls, ID 83415-2208

The sensitivity of static secondary ion mass spectrometry (SIMS) to the detection of adsorbed atmospheric contaminants has long been recognized, but not exploited. Early in the history of static SIMS, Benninghoven noted that many of the ions observed in static SIMS spectra originated from contaminants which were probably of atmospheric origin.[1] Cooks and coworkers had attributed much of the observed hydrocarbon-type ion signal to pump oil present in the vacuum housing of most organic SIMS spectrometers.[2] In research conducted in our laboratories, it was noted that many compounds (e.g., tri-*n*-butyl phosphate[3]) may adsorb to a variety of surfaces, and are readily detectable using SIMS.

Analysis of cyclohexylamine (CHA) on soil. A compound which displays a particularly pronounced tendency to adsorb to SIMS samples and form abundant secondary ions is CHA. CHA is added to the boiler system of the author's laboratory in order to prevent scale build-up and corrosion. The blow-down from the boiler is used to humidify the laboratory, and typical indoor atmospheric concentrations in the winter months are in the 300 ppb range. CHA used in this fashion has been recognized as a potential chemical health concern, because even though it is not an acute toxin, it can be a sensitizer.[4]

When soil samples (aluminosilicate minerals) were exposed to the laboratory air and analyzed using static SIMS, an abundant ion at *m/z* 100^+ is observed, which corresponds to $[CHA + H]^+$. Other abundant ions are also observed, but these could not be ascribed to CHA because of hydrocarbon background originating from other organic surface contaminants. However, when the soil was exposed to CHA-d_{11}, rich fragmentation chemistry could be observed.



CHA-d_{11} was also used to estimate the amount of CHA on the soil surface. It was found that the exposure could be controlled by vaporizing a gravimetric quantity of CHA-d_{11} in a sealed glass jar containing the soil, and then allowing the jar to cool to room temperature. SIMS analysis of samples exposed in this manner showed that the abundance of the secondary ions was related to the level of exposure, expressed in monolayers. By comparing the abundance of $[CHA\text{-}d_{11} + H]^+$ to $[CHA + H]^+$, it was estimated that the concentration of adventitious CHA on a soil sample was approximately 0.3 monolayers. Sensitivity plots also show that CHA-d_{11} appears to facilitate the sputtering of CHA.

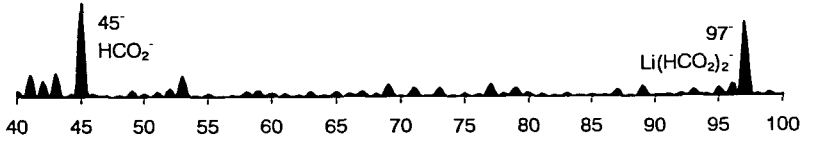
Analysis of small organic acids on basic surfaces. The observation of CHA on the soil samples led to experiments designed to see whether volatile acids would behave similarly. Samples in these experiments were exposed to gaseous acids by merely holding the sample proximate to the liquid acid for 20 sec. In fact, when soil samples were exposed to formic acid, low abundance ions corresponding to HCO_2^- were observed. The abundances of these (and related) ions were greatly enhanced when alkali metal (M) hydroxides were exposed to formic, acetic and propionic acids. The anion spectra showed ions corresponding to the conjugate base (CB^-), and the cluster ion $M(CB)_2^-$, and M_2CB^+ was observed in the cation spectra. An abundant ion corresponding to $M_3CO_3^+$ was also observed in all the spectra of the alkali metal hydroxides, which demonstrates the ability of these compounds to fix CO_2 from the atmosphere.



When the alkali metal hydroxides were compared, it was found that the abundances of the acid-derived ions were dependent on the cation M. Generally, the most abundant secondary ions were observed for Na^+ and K^+. This result is similar to the findings of Hand, et al. in working with perrhenate salts: K^+ resulted in the formation of the most abundant complex ions observable using ion bombardment.[5] A second interesting observation resulted when the acids were compared: the most abundant complexes involved formate, followed by acetate, and finally propionate.

INTRODUCTION

The 50th anniversary of the Hanford Site was celebrated in 1994. The Hanford reservation, a 560-square-mile site, is approximately 120 miles south of Spokane, Washington, and 220 miles southeast of Seattle, Washington. The Hanford Site was built by the Army Corps of Engineers and the Du Pont Corporation in 1943 to produce plutonium for nuclear weapons in support of the World War II effort. The facility was very successful; within two years after its formation, Hanford had supplied the plutonium (Pu) used for the bomb dropped on Nagasaki in World War II. As with all production operations, plutonium production created large quantities of (mixed) radioactive waste. Plutonium production continued after the war until January 1987 when the last production reactor ceased operation at the Hanford site. Reprocessing fuel from nine production reactors created a large quantity of radioactive mixed wastes, much of which was and continues to be stored in underground storage tanks. Three major reprocessing flowsheets (e.g., processes), the large scale recovery of enriched uranium (U), radioactive cesium (Cs) and strontium (Sr) recovery, and a variety of other waste management operations led to a variety of major chemical processing facilities and thus waste types. Both inorganic- and organic-containing waste was produced and is being stored at Hanford.

The wastes must be stabilized and isolated from the environment for thousands of years to ensure that radioactivity will decay to levels that pose no hazards to living organisms. The current treatment plan is to vitrify much of the waste, both low and high level, and send it to long term storage in a geological repository. The waste and by-products of nuclear production are primarily solid and aqueous solutions of ionic compounds in which acutely hazardous and/or radioactive compounds are present in relatively low concentrations. If advanced chemical separations could be implemented to remove the radionuclides without increasing the waste volume, treatment costs could be reduced significantly, and environmental acceptability would be improved. Materials derived from macrocyclic ligands such as crown ethers appear to be most promising, and their use in separations based on solvent extraction membranes are being investigated.

Crown ethers have attracted great attention primarily as specific ligands exhibiting high selectivity for nearly all kinds of cations. Unfortunately, the limited availability of crown ethers and especially a lack of experimental data for reprocessing of highly irradiated and concentrated aqueous solutions using crown ethers as extractants have somewhat inhibited the evaluation and recognition of crown ethers as new agents in the reprocessing of industrial nuclear fuel and radioactive waste. The most promising properties are related to dicyclohexano-18-crown-6 (DCH-6) and its derivatives. Mass spectrometry has been used to determine the relative radiation stability of the pure stereoisomers, cis-syn-cis-DCH-6 and cis-anti-cis-DCH-6.

EXPERIMENTAL

A Hewlett-Packard 5988A mass spectrometer was equipped with an HP 5980 gas chromatograph operated in the splittess mode. Separation was obtained with a DB-5 capillary column (30 m X 0.25 mm i.d., 0.25 µm-film thickness, J & W Scientific). The injector port was heated to 250°C, mass spectrometry interfaces 280°C, and source 200°C. The oven temperature was typically programmed in the following manner: 50°C for 1 min, 8°C/min to 300°C, and 300°C for 5 min. The mass spectrometer was scanned from 50 to 500 amu.

Fast atom bombardment experiments were performed with a JEOL SX-102/SX-102 double-focusing mass spectrometer equipped with a UNIX data system. The fast atom beam was generated from Xe ions, which were accelerated to 5 kV. The FAB gun emission current was 10 mA. The liquid matrix used was m-nitrobenzyl alcohol.

Pure samples of each DCH-6 isomer in glass vials were irradiated using a ^{60}Co gamma source. The dose rate was 3.0 Gy/s (1.08 x 10^6 R/h). The maximum total dose was 1.5 X 10^6 Gy (1.5 X 10^8 R).

RESULTS AND DISCUSSION

Figure 1 is a total ion chromatogram of non-irradiated DCH-6. Figure 2 is a total ion chromatogram of irradiated DCH-6.

The cis-syn-cis isomer of DCH-6 is more stable to gamma radiation than the cis-anti-cis isomer. The main components of radiation degradation products include monocyclohexyl polyethers (alcohols and aldehydes). Further studies are underway to examine the effect of radiation on the other isomers.

Pacific Northwest Laboratory*
Richland, WA 99352

INTRODUCTION

The end of the plutonium-production mission at the Hanford site (southcentral Washington state) left a legacy of environmental problems. One of the most prominent environmental and safety issues facing Hanford cleanup efforts is the radioactive wastes stored in the underground tanks. About 60 million gallons of high-level waste and 260 million curies of radioactivity are stored in 177 tanks. The long-term strategy is to reduce the volume of tank wastes, remove organic constituents, and separate remaining wastes into low and high level components for permanent isolation.

One task associated with the cleanup efforts is characterizing the vapors in the headspaces of high-level waste storage tanks. This is needed for three reasons: 1) to provide information in regards to potential worker health and safety hazards associated with the toxicity of the vapors, 2) to provide information about the flammability of the vapors in the tank, and 3) to provide screening information in regards to the actual waste in the tanks.

METHOD

Hanford vapor samples were collected with evacuated pre-cleaned SUMMA™ canisters. The SUMMA™ canister samples were analyzed by a modified version of U.S. Environmental Protection Agency compendium Method TO-14. The method uses an EnTech cryoconcentration system interfaced with a Hewlett Packard 5972 gas chromatograph/mass spectrometer (GC/MS). The EnTech concentrator was used to pull a metered volume of sample air from the SUMMA™ canister, cryogenically concentrate the air volume, then transfer the volume to the GC/MS for analysis. During analysis, the SUMMA™ canisters were heated to 120°C in specially constructed heating mantles to ensure recovery of polar and semivolatile compounds. Since 100-mL vapor samples were injected, water management was required. This was accomplished on the principal of a microscale purge-and-trap system. Using a cryogenically cooled glass-bead trap, sequentially followed by a Tenax adsorbent trap, this technique successfully reduced the water concentration in the sample while allowing relatively polar compounds such as ketones, alcohols, aldehydes, nitriles, and nitrates to be concentrated from the air volume and subsequently analyzed.

RESULTS/CONCLUSIONS

The sampling and analysis method described was applied to 25 different waste tanks representing 4 different tank farms. Over 200 organic compounds and several permanent gases have been identified and quantified in the tank-headspace samples analyzed to date. The chemical composition of tank headspaces is directly related to both recent and historical usage. Tanks in a particular farm have similar histories and therefore often share similarities in the composition of stored wastes. This appears to be especially true in the cases where tanks are linked together through cascading overflows. Tank vapors are generally comprised of varying concentrations of a homologous series of alkanes, alkenes, alcohols, aldehydes, ketones, and alkynitriles. We have observe that these series often extend from C3 to C10. It is possible that other homologues are also present, but not observed under current procedures.

The concentration of many organic compounds, especially the n-alkanes, can range over 4 orders of magnitude when comparing one tank to another. This can be explained by differences in the degree of venting, the amount of radioactivity in tank wastes changing the rate of waste aging, and the presence or absence of floating organic liquid layers. The semivolatile normal paraffinic hydrocarbons (NPH), ranging from C11 to C15, are examples of common extraction-process materials. The NPHs were constituents of diluents used with tributyl phosphate (TBP) to extract plutonium from spent uranium fuel. In several tanks, NPH as well as decahydronaphthalene and their radiolytic decomposition products have been found. Butanol, the main volatile decomposition product of TBP under alkaline conditions, is usually also found at relatively high concentrations.

Table 1. Concentration ranges (ppmv) of 2/3rds of the 25 high-level waste tank headspace samples analyzed to date.

Compound Class	Concentration (ppmv)
C_3-C_{10} n-Alkanes	0.01 to 5
C_3-C_{10} n-Alkenes	0.01 to 5
C_6-C_{10} branched-Alkanes/Alkenes	0.01 to 5
C_{11}-C_{15} n-Alkanes	0.01 to 50
C_{11}-C15 branched-Alkanes/Alkenes	0.01 to 5
C_3-C_{10} Ketones	0.01 to 5
C_3-C_{10} Aldehydes	0.01 to 0.1
C_3-C_{10} Alcohols	0.01 to 5
C_3-C_{10} Nitrles	0.005 to 0.1
C_1-C_6 Nitrates	0.005 to 0.05
C_1-C_5 Decahydronaphthalene (Decalin™)	0.005 to 0.5
C_1-C_5 Cyclohexanes	0.005 to 0.5
Hydrogen	*100 to 1000*
Nitrous oxide	*100 to 800*
Carbon dioxide	*200 to 700*

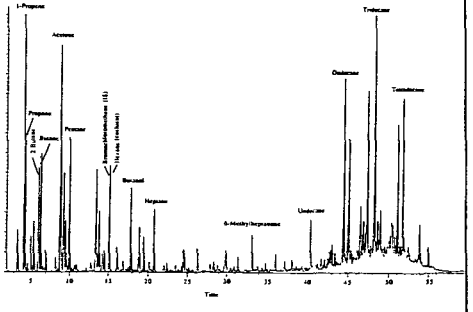

Figure 1. Selective GC/MS Chromatogram of Hanford Waste Tank BY-104 SUMMA™ Canister Tank Headspace Sample.

Our laboratory has successfully analyzed vapors from Hanford waste tanks; this has allowed flammability and toxicity issues to be resolved. The data from these analyses have also helped in classifying and evaluating the Hanford tanks, a small but significant step toward complete tank waste characterization.

MASS SPECTROMETRY ANALYSIS OF TANK WASTES AT THE HANFORD SITE

J.A. CAMPBELL, G.M. MONG, S.A. CLAUSS, AND R.B. LUCKE
PACIFIC NORTHWEST LABORATORY*
RICHLAND, WA 99352

INTRODUCTION

The Hanford Site in southeastern Washington is a 560-square-mile reservation built by the U.S. Army Corps of Engineers and the Du Pont Corporation in 1943 to produce plutonium (Pu) for nuclear weapons in support of the World War II effort. Major chemical processing facilities were constructed to reprocess fuel from nine production reactors and recover enriched uranium (U), radioactive cesium (Cs), and strontium (Sr). Reprocessing and other waste-management operations created a quantity of radioactive mixed wastes, much of which is stored in underground tanks. Three major processes led to a variety of chemical processing facilities and waste types. Both inorganic- and organic-containing wastes were produced and are being stored at Hanford.

Twenty-five of the 177 high-level waste storage tanks at the Hanford Site in southeastern Washington are being watched closely because of the possibility that flammable gas mixtures may be produced from the mixed wastes contained in the storage tanks. One tank in particular, Tank 241-SY-101 (Tank 101-SY), has exhibited episodic releases of flammable gas mixtures since its final filling in the early 1980s. It has been postulated that the organic compounds present in the waste may be precursors to the production of hydrogen. Mass spectrometry has proven to be an invaluable tool for the identification of organic components in wastes from Tank 101-SY and C-103. A suite of physical and chemical analyses has been performed in support of activities directed toward the resolution of an Unresolved Safety Question concerning the potential for a floating organic layer in Hanford Waste Tank 241-C-103 to sustain a pool fire. The aqueous layer underlying the floating organic material was also analyzed for organic components.

EXPERIMENTAL

The waste samples represented several segments of actual waste obtained by core drilling the waste in Tank 101-SY. This material was radioactive and contained a high concentration of nitrate and nitrite; the OH^- concentration was 2 M. A 5-g aliquot of the waste sample was weighed and then stirred with 10 mL of doubly distilled water overnight. The aqueous phase was filtered through a 0.45-µm filter. The filtrate was then passed through a cation exchange column (10 g, AG50W-X8 resin, Na^+ form) and then rinsed using an additional 10 mL of water to quantitatively remove the organic material from the resin. The resulting sample volume was 20 mL. After surveying the samples for radioactivity levels, the aqueous solution containing the organics was removed from the hot cell facilities. Aliquots (2 mL) of the sample were transferred to Teflon®-sealed vials, evaporated to dryness using nitrogen blow-down techniques, and derivatized with 2 mL of BF_3/methanol to produce methyl esters. The sample was heated to 100°C for 1 h. The reaction mixture was then quenched with a KH_2PO_4 solution and extracted with chloroform. The chloroform extract was then analyzed by gas chromatography/mass spectrometry (GC/MS).

The HP 5988 mass spectrometer was equipped with an HP 5980 GC operated in the splitless mode. A fused silica column (DB-5, 30 m X 0.25 mm i.d., 0.25-µm film thickness, J & W Scientific) was used. The oven temperature was typically programmed in the following manner: 50°C for 1 min, 8°C/min to 300°C, and 300°C for 5 min. The mass spectrometer was tuned daily with perfluorotributylamine. In these studies, the mass spectrometer was scanned from 50 to 500 amu and operated in the electron impact mode (70 eV). The source temperature was 200°C, the injector port temperature was 250°C, and the interfaces were also at 250°C.

Accurate mass measurements were performed using a JEOL SX-102/SX-102 double-focusing mass spectrometer equipped with an HP 5980 GC. Separation was obtained with a DB-5 fused silica column. The temperature program was the same as listed above.

RESULTS AND DISCUSSION

Six samples of core segments from Tank 101-SY, obtained during the window E core sampling, have been analyzed for organic constituents using derivatization GC/MS, liquid chromatography (LC), and LC/MS. Four of the samples were from the upper region, or convective layer, of the tank and two were from the lower, nonconvective layer. The combined techniques of derivatization GC/MS and LC have accounted for approximately 73 to 93% of the total organic carbon, depending on the sample.

The elemental compositions of 25 components in the derivatization GC/MS total ion chromatogram (Figure 1) have been determined using high resolution mass spectrometry. Several nitroso compounds were also unambiguously identified; however, thermospray LC/MS indicated the nitroso compounds were formed during the derivatization procedure. Thermospray LC/MS has been used to identify many of the small organic acids, including citric, acetic, formic, and glycolic. The total ion LC/MS chromatogram is illustrated in Figure 2.

Composition information of the floating organic layer in Tank C-103 was required to enable calculations to be made to estimate the lower flammability limit. Both normal paraffin hydrocarbon and tributyl phosphate were found to be the principal constituents of the organic layer. In addition to these components, branched alkanes and dibutyl butylphosphonate were also found in lesser quantities.

Mass spectrometry has proven to be an invaluable analytical tool for the analysis of organics in tank waste.

GC/MS METHOD DEVELOPMENT FOR THE CHEMICAL SPECIATION OF ARSENIC AND SELENIUM COMPOUNDS

Douglas Cameron, Tara Brozovich - Ford, Heath Watts, and Jin Wang
Chemistry and Geochemistry Dept., Montana Tech, Butte, Montana 59701-8997

INTRODUCTION Arsenic (As) and selenium (Se) are elements of economic value in a variety of industries. These elements are often naturally associated with minerals of economic value Consequently, these elements have multiple pathways into the environment As and Se can each exist in a number of inorganic and organic chemical forms The form of each element is dependent on its chemical, physical, and biological environment [1] The properties of these elements, such as mobility in the environment and toxicity to plants and animals, are dependent on the chemical form [2] Therefore, an understanding of the effects of Se or As in the environment requires a knowledge of both the chemical form and the concentration of the elements

A variety of chromatographic, spectroscopic, and hyphenated instrumental methods have been developed for the speciation of As and Se compounds [3,4] Hydride generation atomic absorption spectroscopy (HGAAS) is the most common method However, HGAAS does not determine most forms of As and Se directly, and the technique suffers from a variety of matrix effects. A technique, such as GC/MS, is needed that will determine all the chemical forms directly, at a reasonable cost, and at environmentally important concentrations

METHODS Aqueous solutions of the arsenic or selenium oxyanions were prepared using either the sodium salts or acid forms of the analytes For the liquid-liquid extraction experiments, optimal extraction efficiencies were obtained with an aqueous solution pH of 2 and cyclohexanone as the extraction solvent Extraction efficiencies were compared with and without the ion-pairing agent, tetrabutyl ammonium iodide Solid-phase extractions (SPE) were done using a variety of silica gel-based, bonded phase packings (Supelco). The extractions were vacuum assisted Cyclohexanone and N,N-dimethyl formamide were used as extraction solvents

HGAA was done using an Instrumentation Laboratory spectrophotometer with a homemade hydride generator Arsenate and selenate are reduced to arsenite and selenite for the analysis

GC/MS analyses were done using a Hewlett-Packard 5971 MSD A HP-5 30m column was used with a 0 25mm i.d and a 0 25 µm film thickness. An injection port temperature of 250°C and a detector temperature of 280°C were used Temperature programming from 50° to 300°C at 15 deg/min was used

RESULTS AND DISCUSSION We previously reported the results of our work on the GC/MS analysis of selenite, selenate and arsenate [5,6] After extraction into an organic solvent, these oxyanions are derivitized with N-(tert-butyldimethylsilyl)-N-(trifluoromethylacetamide). A t-butyl-dimethylsilyl group adds to each acidic oxygen. The mass spectra of these compounds matched those reported by Mawhinney[7] The mass spectra are characterized by no detectable molecular ion peak, a small peak for loss of CH_3 (M-15), an abundant peak for loss of the t-butyl group (M-57), and a variety of peaks for fragmentation of the remaining silyl groups However, we were not able to detect any derivatized arsenite (As^{3+}) as AsO^{3-} Since our initial report, we believe we have found arsenite in the meta form (AsO_2^-). The chromatogram of derivatized arsenite solution shows a peak not present in the blank (solvent and derivitizing agent) The peak is from a compound that elutes prior to derivitized arsenate, and the peak area is proportional to the amount of arsenite in the solution. Figure 1 is the EI mass spectrum of what **appears** to be the derivitized meta arsenite ($C_6H_{15}SiAsO_2$) The molecular weight of this compound is 222 The mass range about the molecular ion shows significant loss of multiple hydrogens. A disturbing feature is the over abundant peak at m/z 223. Approximately 20% of the 223 peak intensity is attributed to isotopic contributions from the 221 peak, Si (3 4%), O's (0.4%), and C's (0.2%) The peaks at m/z 206 and 164 represent losses of CH_3 and $C(CH_3)_3$ respectively from m/z 221 The low mass fragment peaks match those of derivatized arsenate

Quantitative analysis using our extraction and GC/MS method has proven difficult The oxidation or reduction of the analytes during extraction, storage, or derivitization has prevented quantitation The majority of selenate in a solution of N,N-dimethylformamide is reduced to selenite within 30 min This is contrary to the stability listed in the literature [7]

HGAAS has been used as our reference method for determining extraction efficiencies, however HGAAS is prone to matrix interference. Aqueous solutions of arsenic (as arsenite) at level of 8 49 µg/L range from 5-15 µg/L depending on what organic compound is added to the matrix The direction of these signal changes was always constant for a given matrix component but the magnitude of the change was not very reproducible Optimal liquid-liquid extraction efficiencies are approximated at 40-70% SPE efficiencies range from 0-100%, however elution efficiencies are currently unknown

CONCLUSION A GC/MS method using either liquid-liquid or solid-phase extraction has been demonstrated for the qualitative analysis of arsenite, arsenate, selenite, and selenate in aqueous solutions After extraction into an organic solvent and derivitization, arsenite appears to be in the meta form, AsO_2^- Several factors; including analyte stability, extraction and elution efficiencies, and arsenite composition, must be more thoroughly understood and controlled before the GC/MS method can be made quantitative Work must also be done on the methodology to analyze the environmentally important organic forms of arsenic and selenium

Organoarsenic and Organotin Speciation by Ionspray-MS-MS and LC-MS-MS

J.J. Corr[1] and K.W.M. Siu[2]
1: SCIEX, 71 Four Valley Drive, Concord, Ontario, L4K 4V8, Canada
2: National Research Council of Canada, Montreal Road, Ottawa, Ontario, Canada

The impact of trace metals on the environment has been the subject of extensive recent study by many groups. Since the toxicity and bioavailability of an element depends on its particular chemical form, it is no longer sufficient to employ total-element analysis. Hence the necessity for speciation anaylsis, which involves the determination of the exact chemical form of an element, whether it be an inorganic oxidation state or an organometallic compound.

In the present report ionspray (IS)-MS-MS has been employed to study synthetic and real samples containing arsenic and tin species. A selectable degree of declustering of solvent adducts or fragmentation of molecular ions in the differentially pumped interface (DPI) of the MS-MS system enabled the system to function as a molecular detector or as an elemental analyzer. In elemental analysis mode parameters were chosen such that maximum fragmentation of molecular species occurred, which promoted charge reduction and hence the observation of singly-charged bare elements.

Combining this declustering with an advanced collision cell allowed the detailed mapping of collision induced dissociation (CID) pathways for a number of organoarsenicals, including arsenobetaine (AsB) and arsenocholine (AsC). Both these species, and all others examined, were detected in fully intact molecular form at over 1e+6 cps per ppm, or could be fragmented in the DPI to bare As^+, or Sn^+, while retaining sensitivity. Two of the preferred CID pathways for these species were fragmentation to trimethylarsine for AsB or trimethylarsine + H for AsC, and loss of water. Another main CID channel for AsB was loss of CH_2CO, which resulted in a path through CH_3AsOH (m/z 107). Many of the CID channels involved the molecules CH_3AsCH (m/z 103) and CH_3AsH or AsO (m/z 91). For all organoarsenicals studied it was possible to observe bare As^+ through CID.

The liquid chromatographic retention of AsB was observed by combining this system with ion pairing LC. A C_{18} column with a mobile phase of 80:20 DIW-MeOH with 0.1 mM octanesulphonate and acetic acid, pH2.7-3.0, was employed to demonstrate the retention of AsB down to the level of 200 pg.

All the organotin species examined behaved somewhat similarly under DPI fragmentation and CID. For example, dissociation of the environmentally high profile species tributyltin (TBT) was primarily through loss of butyl groups. Since tin species do not readily form oxides in the ionization process, or in the interface, they are relatively easy to fragment in the DPI to bare Sn^+. The ease with which this system functioned in either analysis mode was indicated by flow injection analysis (FIA) of the NRC harbour sediment certified reference material PACS-1. Following extraction of TBT with 1-butanol and employing a carrier solution of methanol with 1 mM ammonium acetate, TBT was detected by single ion monitoring (SIM) of bare Sn^+ as

well as by selected reaction monitoring (SRM) of the dibutyltin product ion of tributyltin (see Figure 1).

The arsenic species examined in this work were arsenite, arsenate, monomethylarsonic acid (MMA), dimethylarsinic acid (DMA), tetramethylarsonium ion (TMA^+), AsB and AsC. TBT, triphenyltin (TPhT), tripropyltin (TProT), and dibutyltin (DBT) were the organotin species studied.

The dual mode capabilities of IS-MS-MS and the results of this study indicate that IS-MS-MS possesses great promise for speciation anaylsis.

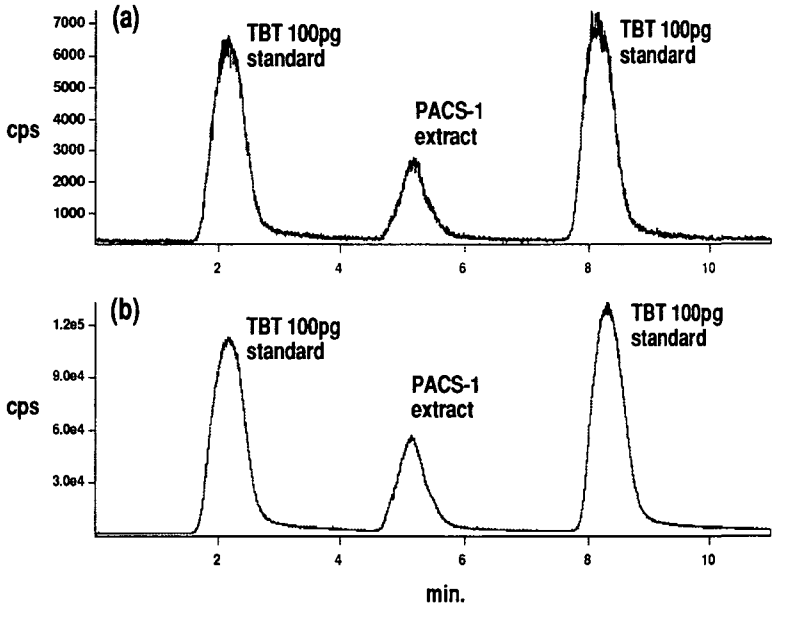

Figure 1. Flow injection analysis of an extract from PACS-1. Carrier solution: methanol with 1 mM ammonium acetate; 5 µL sample loop; 10 µL/min flow rate. Figure 1(a) displays molecular detection mode by SRM of m/z 291/235. Elemental analysis mode is indicated by SIM of bare Sn^+ (m/z 120) in Figure 1(b).

Quantitation of a CCK Ligand from Serum using LC / ESI / MS / MS on Ion Traps and Triple Quadrupoles,

Arthur Moseley*[1], Tim Tippin[1], Robert Hart[1], Tom Lloyd[1], Robert St. Claire III[1], Kathy Halm[1], Jae Schwartz[2], Adrian Land[2], and Ian Jardine[2],
[1]Department of Drug Metabolism, Glaxo Wellcome Research Institute, RTP, NC
[2]Finnigan MAT, San Jose, CA

The objective of this work was to evaluate the quantitative capabilities of the Finnigan LCQ ion trap mass spectrometer with both mobile phase standards and with "real world" rat serum samples from an in-vivo pharmacokinetic study. As a reference, the exact same samples were also analyzed on a triple quadrupole mass spectrometer using the same brand of autosampler. To permit high throughput sample analysis, we used a "fast" LC column (1x50 mm Hypersil BDS-C18 with 3 µm particles at 80µL/minute, retention time of 2.5 minutes, k' of 4) with selected reaction monitoring for detection of the analyte and internal standard. Prior to analysis the serum samples were cleaned up using an automated solid phase extraction procedure on a Zymark robot.

Mobile phase standards over the range of 1.22 to 5000 ng/mL were analyzed in triplicate, and spiked serum standards over the range of 1 to 7500 ng/mL were analyzed in duplicate (before and after the actual samples). Also note that in order to extend the dynamic range of the analysis the upper level standards were diluted.

A comparison of normal resolution (unit mass) and open resolution (4 m/z peak width at half height) conditions on the triple quadrupole showed a very significant increase in absolute signal, and a 4-fold improvement in the LOQ. Whenever possible, we use open resolution conditions for our LC/MS/MS quantitation on this triple quadrupole. Therefore, we used open resolution conditions to analyze the spiked serum samples on the triple quadrupole. Note that the use of open resolution conditions reduces the specificity of the analysis, so this approach must be used with caution. The ion trap was operated under unit mass resolution conditions at all times.

The triple quadrupole (under normal resolution conditions) and the ion trap gave an identical LOQ of 9.75 ng/mL (1/(x*x) weighting, r>0.990) with mobile phase standards (analyzed in triplicate). When open resolution conditions were used on the triple quadrupole, a four-fold lower LOQ was obtained. In contrast to the analysis of the mobile phase standards, the analysis of the spiked serum samples on the ion trap and on the triple quadrupole (under open resolution conditions) gave the same LOQ of 5 ng/mL (1/(x*x) weighting, r>0.990). Note that both data sets would meet GLP validation criteria.

Development of an LC/MS/MS assay for the concomitant detection of AGN 190168 and its metabolites from human urine

W. Luo[1], R. Matsumoto[1], D. Tang-Liu[1] and A. Breau[2]

[1]Department of Pharmacokinetics, Allergan Inc, Irvine, CA 92715
[2]The Perkin-Elmer Corporation, San Jose, CA 95131

AGN 190168 (tazarotene) is a synthetic retinoid currently being investigated for the topical treatment of acne and psoriasis. The concomitant detection of AGN 190168 and its metabolites, AGN 190299, AGN 190832, AGN 190844 (Fig. 1) from human urine following topical dosing with AGN 190168 gel was accomplished by atmosperic pressure chemical ionization (APCI) and multiple ion monitoring (MRM) on a PE-Sciex API III$^+$ triple quadruple mass spectrometer. Following liquid-liquid extraction and sample concentration, a 1 ng/ml level of quantitation was achieved for all four analytes. The assay methodology illustrates the versatility of atmosperic pressure ionization / tandem mass spectrometry, in conjunction with HPLC, for the separation and quantitation of drugs and their metabolites in the nanogram per mililitre range with acceptable precision and accuracy.

To 2 ml of human urine, 20 ng of ($^2H_7$)AGN 190168 and ($^2H_7$)AGN 190299 were added and mixed briefly. 2 ml of double distilled water, 200 µl of 1 N HCl and 4 ml of ethyl acetate:hexane (70:30) were then added. After rotary mixing for 5 min, the test tubes were centrifuged for 5 min to get better phase separation. The organic layer was decanted into another tube. Extracts were evaporated to dryness in a Turbo-Vap under nitrogen at 35-45°C. The residue was reconstituted in 200 µl of mobile phase A and 100 µl were injected onto the LC/MS/MS system.

A Sciex API III$^+$ triple quadrupole mass spectrometer equipped with an APCI interface was used for sample analysis. Processed samples were injected onto a Keystone ODS Hypersil (4.6 X 50 mm, 3 µm particle size) column for chromatographic separation. Mobile Phase A consisting 20 mM NH_4OAc and 5% AcOH. Mobile phase B consisting 20 mM NH_4OAc and 5% AcOH in methanol. The starting conditions were 53% A and 47% B with a curve 3 gradient to 10% A and 90% B in 6.3 minutes. After holding at 10% A and 90% B for 1.7 minutes, the column was re-equalibrated at initial condition. The flow rate was 1 ml/min.

The positive ion mode was used to detect all the analytes. The multiple reaction monitoring (MRM) was used, with a dwell time of 200 msec/channel. The analysis was divided into two periods. Period 1 included 340 to 280 (AGN 190844) and 368 to 280 (AGN 190832). Period 2 included 324 to 294 (AGN 190299), 331 to 297 ($^2H_7$-AGN 190299), 352 to 324 (AGN 190168) and 359 to 331 ($^2H_7$-AGN 190168). (Fig. 2)

A Sciex software MacQuan was used to construct the calibration curves for all the analytes. The dynamic range of the assay was 1 ng/ml to 100 ng/ml for all the analytes except AGN 190844 which had a dynamic range of 1 ng/ml to 50 ng/ml (Fig 3). The precision and accuracy of the standard curve read-back concentrations for all four analytes were all within the acceptable limits (±20%).The precision and accuracy of the 2 ng/ml, 10 ng/ml and 50 ng/ml quality control samples for all four analytes were all within acceptable limits (±20%).

Urine samples collected from two clinical trails conducted in the Department of Dermatology at Tokyo Women's College in Tokyo, Japan, were assayed for AGN 190168, AGN 190299, AGN 190832 and AGN 190844 using this validated LC/MS/MS method. Approximately 280 clinical urine samples were analyzed. The only detected analyte was AGN 190844. The highest measured concentration of AGN 190844 in any of the samples was 23.5 ng/ml, however, the majority of the measurable AGN 190844 concentrations were in the 1-10 ng/ml range.

Quantitative Analysis of Dofetilide and its N-desmethyl metabolite in Human Serum by Microbore High Performance Liquid Chromatography / Ionspray MS/MS.

R. P. Schneider and H. G. Fouda
Central Research Division, Pfizer Inc, Groton, CT 06340

Dofetilide is a selective and potent Potassium Channel Blocker useful for the treatment of re-entrant tachyarrhythmias. It acts by prolonging myocardial repolarizations with no effect on conduction parameters[1]. The pharmacokinetics and metabolism of dofetilide in animals and man have been described[2,3]. Following a single ^{14}C-dofetilide dose to human subjects, the parent drug was the main component in circulation. Only very low metabolite levels were detected in plasma [3].

Current assays for the determination of dofetilide concentrations in biological fluids include an HPLC/UV procedure with a lower limit of quantification of 2.5 ng/mL[4] and an RIA method with a lower limit of quantification of 0.05 ng/mL[5]. The development of an alternate specific method was desired. This report describes the development of a microbore HPLC / atmospheric pressure ionization MS/MS assay.

Control human serum was fortified with a structural analog internal standard and extracted with ethyl acetate under alkaline conditions. The organic layer was evaporated to dryness, and reconstituted in acetonitrile. Following a hexane wash, the acetonitrile was evaporated and the residues reconstituted in HPLC mobile phase. Samples were assayed by HPLC/MS/MS.

Validation parameters are shown in Tables 1 and 2. For dofetilide, intra-assay precision was better than 8.3% and the accuracy of the assay was within 2.6% of the nominal concentration. For the N-desmethyl metabolite, intra-assay precision was better than 9.6% and the accuracy of the assay was within 14.5% of the nominal concentration. The linear dynamic range of the assay was 0.05 to 3.0 ng/mL for dofetilide and 0.1 to 3.0 ng/mL for the N-desmethyl metabolite.

Measurement of CO_2 Exchange Rates in Transferrin by Mass Spectrometry

Todd Brown and Fred Hileman
Monsanto Corporate Research, 800 N. Lindbergh Blvd. St. Louis, MO 63167

Wes Harris
University of Missouri-St. Louis, Dept. of Chemistry, St. Louis, Mo 63121

There has been a long standing interest in the measurement of the exchange rate of carbonate with transferrin bound iron, especially in the presence of various anions. These measurements have typically been made with radiolabeled $^{14}CO_3^{2-}$ as a probe. This work involves the alternative use of $^{13}CO_3^{2-}$ as a probe combined with a purge and trap device and conventional mass spectrometry. Carbonate containing samples were placed in a specially designed purge and trap system (see Figure 1) in which acid was subsequently added to the sample to release the carbon dioxide. The evolved carbon dioxide was passed through a -20°C scrubber to remove the water and then cryogenically trapped on a short length of a Poraplot column maintained at -140°C. The trapped carbon dioxide was thermally desorbed into a conventional electron impact ionization mass spectrometer which used selective ion monitoring to quantitate both the native and labeled carbon dioxide.

Considerable care was taken to eliminate the background CO_2 in the system. Helium was used as the purge gas and it was necessary to remove any residual CO_2 from the helium prior to use. This was done by passing the helium through a liquid nitrogen trap and then through a molecular sieve 5A trap. Stainless tubing was used throughout the system to minimize the background.

To evaluate the system a standard curve was prepared. Solutions of 1 mM $NaHCO_3$ were made which contained 0, 25, 50, 75 and 100% $NaH^{13}CO_3$. All solutions were prepared in 50 mM HEPES buffer at pH 7.4. 100 uL aliquots of these solutions were introduced into the purge and trap device using the loop injector and were then acidified with 100 uL of 1N H_2SO_4 via a second loop injection. The released CO_2 was trapped and injected into the mass spectrometer where the $CO_2/^{13}CO_2$ ratio was determined. A plot of expected versus measured percent of CO_2 and $^{13}CO_2$ was then generated showing excellent linearity.

The experiments were carried out using 1 mM monoferric transferrin saturated with $^{13}CO_3^{2-}$ in 50 mM HEPES buffer at pH 7.4 containing 1 mM $NaHCO_3$. Perchlorate at various concentrations was introduced into the sample causing exchange of the carbonate between the protein and the buffer and the time course of this exchange was followed. Aliquots of the transferrin/carbonate/perchlorate solution were taken at specific time intervals. The supernatant of the aliquot was separated from protein via centrifugation through a membrane with a 10,000 dalton cutoff. A 100 uL sample of the supernatant was injected into the purge and trap system and the $CO_2/^{13}CO_2$ ratio was determined. The time course evaluation for a 100 mM perchlorate solution did not show any detectable exchange over a 4 hour period. When the experiment was repeated using 500 mM perchlorate the exchange shown in Figure 2 was observed. This illustrates the applicability of the technique and that it offers an alternative to the use of radioisotopes to follow this exchange.

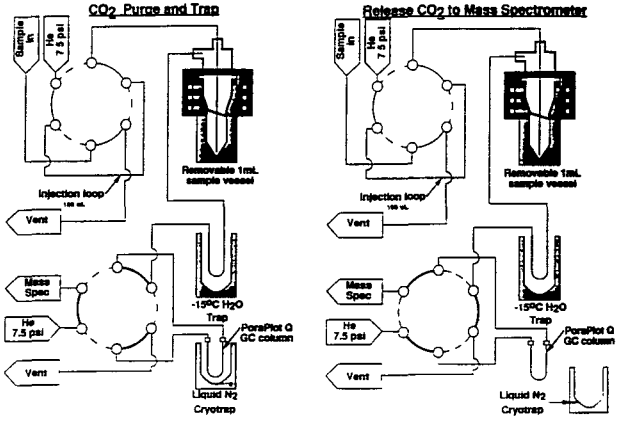

Figure 2. Exchange of carbonate in 1mM $^{13}CO_3^{2-}$ saturated monoferric transferrin with 1 mM $NaHCO_3$ in the presence of 500 mM $NaClO_4$

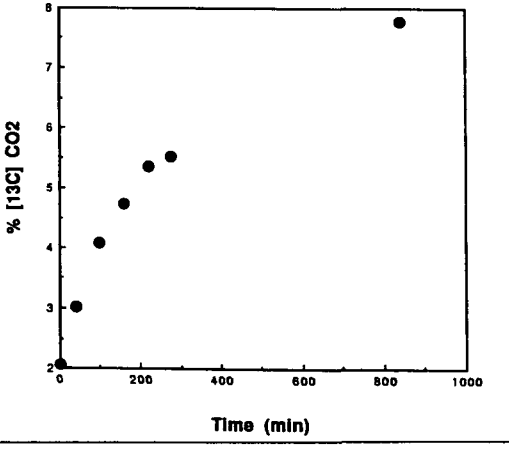

DETERMINATION OF 2-BUTOXYETHANOL AND METABOLITES IN HUMAN URINE USING GC/MS & ESI/MS

Dan A. Markham, M. J. Bartels and R. A. Corley, The Dow Chemical Company, Midland, MI 48674 & A. W. Rettenmeier, University of Tubingen, Germany

Industry and consumer cleaning product manufacturers use 2-butoxyethanol (BE) extensively due to it's versatile applications resulting from compatability in both hydrophilic and lipophilic systems [1]. The primarly metabolite of BE, butoxyacetic acid (BAA), has been shown to cause hemolysis in rats [2-4] and it's effect is being studied in humans. BAA is primarily eliminated via the urinary tract in humans [5], therefore an effective manner to calculate the exposure of BE is through monitoring the concentration of BAA in the urine. However, in a recent human exposure study, Rettenmeier, et al. [5], indicated that as much as 60% of BAA may be eliminated as the glutamine (primary) conjugate and to a lesser extent the glycine conjugate. To accurately determine the level of BE exposure both the unconjugated (free) and conjugated BAA must be determined. The accepted method to determine total (free + conjugated) BAA is to acid hydrolyze the urine samples prior to analysis [5,6]. This methodology will produce accurate total BAA determinations, however, due to possible BE exposure in everyday life it could be difficult to correlate the sources of BE exposure to the elimination of total BAA. This laboratory has observed background levels of BE ranging from 20 to 50 ppb in human urine. The stable isotope labelled analog ^{13}C-BE was therefore employed to distinguish between endogenous and dosed material and the related ^{13}C-metabolites. In addition, the possible elimination of BE metabolized as ethylene glycol (EG) was to be investigated.

A sensitive and selective chemical derivatization gas chromatography/methane negative chemical ionization/mass spectrometry (GC/NCI/MS) method has been developed to simultaneously quantitate 2-butoxyethanol (BE), 2-butoxyacetic acid (BAA see; Figure 1), and ethylene glycol (EG) in human urine. The BE and EG were derivatized using pentafluorobenzoyl chloride and the BAA using pentafluorobenzyl bromide. This method employs the use of both ^{13}C-labeled and deuterium-labeled analogs of each analyte as test materials and internal standards, respectively, to improve limits of quantitation and precision. The above method was also expanded to quantitate conjugated BE, BAA, and EG following acid hydrolysis of human urine. Calibration curves were generally linear over one order of magnitude, with limits of quantitation of 36 ng BE, 84 ng BAA, and 17 ng EG per gram of urine. In addition, a high performance liquid chromatography/ positive electrospray ionization/ mass spectrometry (HPLC/+ESI/MS) method was developed to confirm and quantitate N-butoxyacetylglutamine (NBGL see; Figure 2), the major urinary conjugate of BAA. Calibration curves were generally linear over one order of magnitude, with limits of quantitation of 204 ng NBGL per gram of urine. This poster will present the urinary results from a study in which six human male subjects were dermally exposed (single arm) to an atmosphere containing 50 ppm ^{13}C-BE to support the construction of a physiological based/ pharmacokinetic (PB/PK) model [7].

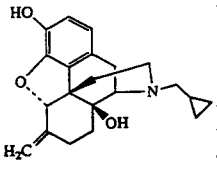
Evaluation of Nalmefene Metabolism in Rats and Dogs Using Thermospray LC/MS

C. Mathur, S. Murthy, L T Kvalo and J.A. Wilhelm
Ohmeda Pharmaceutical Products Division Inc., Murray Hill, NJ 07974



NALMEFENE

Nalmefene is a selective narcotic antagonist that is structurally similar to naloxone. Nalmefene's pharmacological activity is mediated via competitive inhibition of opioid receptor sites. It is indicated for the complete or partial reversal of opioid depression, including respiratory depression, and for the diagnosis and treatment of opioid overdose. For these indications, nalmefene will primarily be administered as an intravenous bolus

As part of a more comprehensive pre-clinical evaluation of nalmefene metabolism, *in vitro* and *in vivo* studies were performed in order to: 1)compare metabolite profiles generated from rat and dog liver microsome incubations to those obtained from rat and dog biological fluids (plasma, urine and feces), 2) positively identify the metabolites using co-chromatography of authentic standards and thermospray LC/MS, 3)further characterize the plasma concentration-time profile of nalmefene metabolites in the rat following intravenous bolus administration of nalmefene.

Metabolite Profiling and Identification: *In vitro* (rat and dog liver microsomal incubations) and *in vivo* (plasma, urine, feces samples from rats, n=3, and dog, n=1) metabolites were eluted with methanol from C-18 solid phase extraction (SPE) cartridges. Chromatographic separation was accomplished by HPLC using gradient elution (20-50% methanol in 0.05M ammonium acetate buffer, pH 4.5) with a flow rate of 1 ml/min and a Beckman C-18 Ultrasphere column (150 x 4.6 mm). *In vitro* studies indicated that the rat liver microsomes convert nalmefene to a phase I N-dealkylated metabolite, nornalmefene, while the dog liver microsomes did not produce nornalmefene to a significant extent. Comparative mass spectral profiles of urinary rat and dog nalmefene metabolites revealed the following metabolites: dog - nalmefene glucuronide and nalmefene diglucuronide; rat - nornalmefene, nalmefene glucuronide and nornalmefene glucuronide. Structural elucidation of the metabolites, based upon comparison of elution times and mass spectra, are provided.

Metabolite Pharmacokinetics: Rats (n=4) were surgically prepared and each rat received an iv bolus dose of 5 mg/kg nalmefene.HCl in saline. Metabolite plasma concentrations at 0, 5, 30, 60, 120, 180, 240 and 300 minutes were determined following SPE after the addition of the internal standard, naloxone. Mass spectral instrumentation conditions were: Finnigan MAT SSQ710 with thermospray interface, vaporizer temperature = 95°C, source temperature = 220°C, aerosol

temperature = 280 °C, electron multiplier =1500 volts, dynode = 15 Kvolts, discharge ionization = 0 volts and filament off. Plasma samples (0 2 ml) were assayed initially for free nalmefene and nornalmefene. Total nalmefene and nornalmefene (unconjugated and conjugated) were determined following overnight incubation with β-glucuronidase, SPE and LC/MS analysis. Chromatographic separation was achieved using a reversed phase system consisting of a Beckman C-18, Ultrasphere analytical column (150 x 4.6 mm) with isocratic mobile phase, methanol/ 0 05M ammonium acetate, pH 4.5 buffer, 30:70 (v v) at a flow of 1 ml/min. Detection and quantitation was accomplished in SIM mode. The data was processed and it generated plasma-concentration time profiles as shown above.

QUANTITATION OF RITALIN & RITALINIC ACID IN HUMAN PLASMA BY API LC/MS/MS

* Luca C. Matassa, Ken C. Cassidy
NOVAMANN (Ontario) Inc.
5540 McAdam Road, Mississauga, ON L4Z 1P1 CANADA

Ritalin (methylphenidate), Figure 1 is generally considered to be the drug of choice for the treatment of children with hyperactivity (ADD, Attention Deficit Disorder). It has been reported that about 80 % of such hyperactive children respond favourably when treated with methylphenidate 1. In humans, methylphenidate is metabolized primarily by de-esterification to ritalinc acid (Figure 1) which is therapeutically inactive.

Many methods for the quantitation of methylphenidate and ritalinic acid in plasma or urine have been described (GC/MS, HPLC) 2,3,4. Most of these methods require extensive extraction procedures and/or derivatization and lack the sensitivity required to characterize the pharmacokinetics of methylphenidate after an oral dose. Also most of these methods cannot extract both analytes together from the same samples. This is important with limited sample volume available for sample assay. Our objective was to develop an HPLC/MS/MS method for the detection and quantitation of 1 and 2 in human plasma which was sufficiently sensitive for analysis of clinical bioequivalence samples.

A reverse phase HPLC/MS/MS (Sciex API III - Plus, MRM mode, positive ion, IonSpray interface) method developed and validated at NOVAMANN (Ontario) Inc. for the quantitation of methylphenidate and ritalinic acid in human plasma is described. The extraction procedure involves solid-phase (C18) isolation of the analytes and internal standard (phenylalanine ethyl ester) after buffering the sample. Sample evaporation temperature was critical for the success of the assay. Plasma calibration curves extracted over 4 separate assay batches were linear from 1.0 to 60.0 ng/mL for methylphenidate and 10.0 to 600 ng/mL for ritalinic acid. Intra-batch and inter-batch precision and inaccuracy for methylphenidate and ritalinic acid over the 4 days was less than 15 %. Typical MRM chromatograms for a blank plasma sample extract and a plasma sample spiked with the analytes and the internal standard are given in Figure 2. Calibration curves are given in Figure 3. This method has been used to assay clinical bioequivalence samples.

INTRODUCTION

An electrospray tandem mass spectrometry (LC/ESI/MS/MS) method was developed, validated and used for the quantitative analysis of Sandoz compound SDZ CPI 975 in hundreds of human plasma samples on a routine basis in support of clinical pharmacokinetic studies. This phospholipid compound is a potential drug for the treatment of non-insulin dependent diabetes mellitus (NIDDM). It is not easily detected in biological fluids using conventional physicochemical detection (UV, Fluorescence) because it has no chromophore. Additionally, the compound is thermally labile making it incompatible with gas chromatography or thermospray mass spectrometry analysis.

EXPERIMENTAL

A stable isotope labeled analog of SDZ CPI 975 with twenty seven deuterium atoms was used as the internal standard. The sample preparation entailed the addition of this D_{27}-CPI 975 internal standard to 200 µL plasma standards or unknowns followed by protein precipitation with 400 µL of methanol. After waiting 30 minutes, the samples were centrifuged for 10 minutes and the supernatant filtered through a 0.45 µm Gelman filter. Reverse phase chromatography of 50 µL of the filtrate was performed on a Hewlett Packard Series II 1090M liquid chromatograph using a YMC Basic®C-8 column (2.0 x 100 mm, 5 µm) at a flow rate of 0.5 mL/min. Elution of the analyte and internal standard was performed at a temperature of 40°C using a gradient starting at 50% methanol and ending at 100% methanol over three minutes. Both SDZ CPI 975 and D_{27}-CPI 975 coeluted with a typical retention time of 3.5 minutes. To minimize contamination of the electrospray source, a post column divert valve was used so that non-retained (<3.2 min.) and late eluting (>4.0 min.) materials were diverted to waste. The column effluent containing SDZ CPI 975 and its internal standard was introduced into the Finnigan electrospray source without splitting in positive ion mode. The parent ion of SDZ CPI 975 and its deuterated internal standard at m/z 438.3 and 465.3 respectively were collisionally fragmented resulting in the same product ion at m/z 144. (see Figure 1).

RESULTS

The LOQ of the assay was 24.5 ng per mL of SDZ CPI 975 in plasma using relative response factors (RRF=conc./area ratio). A typical plot of RRF's is shown in Figure 2. No interferences from endogenous materials were observed.

CONCLUSION

The simple and rapid procedure described in this paper provides a highly sensitive and accurate method for the quantitation of SDZ CPI 975 in plasma by electrospray LC/MS/MS.

Introduction

GC/MS is the most widely accepted technique for the identification of drug metabolites. However, it has been generally unsuccessful for the determination of low volatility and thermally labile compounds such as reserpine. This basic drug is an ideal candidate for ionization techniques such as ion spray that do not require analyte volatility. Additionally, HPLC, the method of choice for separation of polar, low volatility drugs, is an ideal separation technique for these compounds with detection by ion spray mass spectrometry.

Reserpine is used for the treatment of hypertension and psychoses in humans, and as a tranquilizer in horses. Few data are available on the pharmacokinetic properties of reserpine because of the lack of an assay capable of detecting low concentrations of the drug or its metabolites. For clinical analyses where a high-volume of samples may need to be analyzed, rapid methods for sample preparation and analysis are needed.

Experimental

The goal of rapid, high-throughput analyses can be met by coupling good sample preparation and clean up with fast liquid chromatography with MS/MS as the final "separation" step. Isocratic conditions using an eluent of 80:20 acetonitrile:water, 5 mM ammonium acetate allow for a short analysis time. The use of a 1 mm column (Keystone Scientific Betasil C18 100 mm) combined with MS/MS in the selected reaction monitoring (SRM) mode provided a retention time of approximately three minutes for reserpine and the internal standard, rescinnamine. The ion spray interface on a Sciex TAGA 6000E triple quadrupole upgraded to an API III (operated at 4.6 kV in positive ion mode) received 50 μL/min from the column effluent with no post-column split.

A three step liquid/liquid extraction (1) was used to isolate reserpine and the internal standard, rescinnamine, from equine plasma. This extraction technique provides clean extracts with good recovery (60%) at low picogram levels. However, this method is very tedious and time consuming. We are continuing to develop improved alternative sample preparation procedures.

Results and Discussion

Calibration standards were prepared in duplicate by adding aliquots of reserpine and the internal standard, rescinnamine, to 2 mL of control equine plasma. The concentrations of the standard in the calibration curve were 10, 25, 50, 500, 2000, and 5000 pg/mL. The concentration of the internal standard in each standard curve sample was 1800 pg/mL.

Using liquid/liquid extraction, the lower limit of quantitation (LOQ) of reserpine in equine plasma is 50 pg/mL with a linear response up to at least 5000 pg/mL. The limit of detection (LOD) of reserpine in equine plasma is 10 pg/mL based on 2 mL aliquots. The accuracy from quality control (QC) samples (20, 200, 3000 pg/mL) was <15% for each QC level except at the lower limit of quantitation.

Lovastatin (LOV) (see figure 1) is a drug used for the treatment of high cholesterol. One of the metabolites of lovastatin, hydroxy-acid lovastatin (LOV-OH), is an active metabolite. Thus, a sensitive assay was needed for the determination of both lovastatin and LOV-OH in plasma.

The most sensitive assay that was found in the literature was a complicated multi-step GC-MS procedure. It was decided that the technique of HPLC combined with atmospheric pressure chemical ionization (APCI) tandem mass spectrometry (MS/MS) should provide the necessary sensitivity and selectivity to determine these two analytes at low levels.

Finnigan-MAT TSQ (7000 and 700) triple quadrupole mass spectrometers equipped with the Finnigan APCI source were used for the study. Dog plasma samples (1.0 ml) containing internal standards (simvastatin and simvastatin-OH) were subjected to solid-phase extraction. The dried extract was then resolvated and injected into the LC-APCI/MS/MS system. An HPLC system based on a reversed phase column (C-8) and a gradient elution provided a good chromatographic system for these compounds. The mobile phases (A & B) each contained 10 mM ammonium acetate. The MS analyses were performed using the selected reaction monitoring (SRM) technique. In each case, the $[M + NH_4]^+$ molecule was chosen as the precursor ion by MS1 (Q1) and a suitable product ion was selected for MS2 (Q3). Figure 2 shows a typical mass chromatogram for LOV spiked into dog plasma at 0.5 ng/ml, the limit of quantitation (LOQ) for this assay.

This assay has been validated and found to have an intra-day precision (%CV) of not more than 11% at the three quality control (QC) levels. The inter-day precision was not more than 13% at all three QC levels. In addition, LOV and LOV-OH were found to be stable in dog plasma stored at -70 °C for nine days or carried through three freeze-thaw cycles. The validated method was found to be linear over the range of 0.50 to 50 ng/ml plasma for lovastatin and 10 to 500 ng/ml for LOV-OH. The assay was found to be suitable for dogs dosed with lovastatin.

INTRODUCTION

The determination of Lovastatin (Lov) and its hydroxy acid (Lov-OH) metabolite in biological matrices has been reported using LC/UV[1] and GC/MS[2-4] techniques. Although the reported GC/MS methods showed good sensitivity for both compounds, time-consuming derivatization procedures were required for all analytes. In addition, the methods reported may not provide sufficient sensitivity for applications requiring plasma samples as small as 0.1 mL with trace level detection limits. We have developed an alternative method employing ion spray LC/MS/MS techniques that meets the needs of trace bioanalytical analysis.

A sensitive and novel analytical method was developed to simultaneously and directly quantitate Lovastatin and Lovastatin hydroxy acid in mouse and rat plasma without derivatization. This method employs a solid-phase extraction procedure to isolate Lovastatin and Lovastatin hydroxy acid from the biological matrix. Simvastatin (Sim) and Simvastatin hydroxy acid (Sim-OH) were used as internal standards for the respective compounds. Reconstituted extracts were analyzed by ion spray liquid chromatography/tandem mass spectrometry (LC/MS/MS).

EXPERIMENTAL

Bond Elut™ C8 SPE Cartridges were obtained from Varian/Sample Preparation Products, Harbor City, CA 90710. The liquid chromatography part of the system included a Hewlett-Packard Model 1090M pump, Hewlett-Packard, Avondale, PA 19311. Kromasil™ C18 columns, 2 x 50 mm, were obtained from Keystone Scientific, Inc., Bellefonte, PA 16823. The mass spectrometer was a PE-SCIEX API III+ from PE-SCIEX, Thornhill, Ontario. After solid-phase extraction, the reconstituted extracts were analyzed by ion spray LC/MS/MS. For each sample, the mass spectrometer was first operated in the negative ion mode for the detection of Lovastatin hydroxy acid, and then was switched to the positive ion mode for the detection of Lovastatin. The Kromasil™ C18 column was subjected to gradient elution with 1 mM ammonium acetate (pH 4.0) and acetonitrile.

RESULTS AND DISCUSSION

Figure 1 shows the full-scan product ion spectra of Lov and Lov-OH. The assay has a limit of quantitation (LOQ) of 500 pg/mL plasma for both Lov and Lov-OH based on 0.1 mL aliquots of mouse or rat plasma. Figure 2 presents the extracted ion current chromatograms of rat plasma extract at the LOQ level. The standard curves were linear from 0.5 ng/mL to 100 ng/mL for both Lov and Lov-OH. The intra- and inter-assay precision, calculated from QC samples, was less than 7% for Lov and less than 6% for Lov-OH in both matrices. The inter-assay accuracy as determined from QC samples was less than 6% for Lov and less than 8% for Lov-OH acid in both matrices. The overall recovery of Lov was 54% in mouse plasma and 55% in rat plasma, and the overall recovery of Lov-OH was 100% in mouse plasma and 67% in rat plasma. The recoveries of Lov and Lov-OH were not concentration dependent. Lov-OH was found to be stable in all experiments, while Lov was found to be unstable in plasma at ambient temperature for 4 hours and in the reconstitution buffer at ambient temperature for 24 hours. However, Lov did appear to be stable in the reconstitution buffer at 4 °C for 24 hours. Both analytes were also shown to be stable after three freeze(-70 °C)/thaw(4 °C) cycles in plasma and to be stable up to 4 days as dry extracts

43rd ASMS Conference on Mass Spectrometry and Allied Topics

at 4 °C. Since Lov is unstable in mouse and rat plasma at ambient temperature, sample preparation was carried out in an ice-water bath.

QUANTITATION OF LTE_4 IN HUMAN URINE BY ION SPRAY LC/MS/MS

Henry Y. Wu[1], Lily Y.-T. Li[1], Jack D. Henion[1] and George J. Krol[2].
[1]Advanced BioAnalytical Services, Inc., 15 Catherwood Rd., Ithaca, NY 14850;

INTRODUCTION

Leukotrienes (LTs) are biologically important compounds derived from arachidonic acid by the action of the enzyme 5-lipoxygenase. LTE_4 is a sulfidopeptide leukotriene that is difficult to quantitate because it is relatively unstable in the presence of metal ions and oxidants. Recently, the determination of LTE_4 in human and rabbit urine has been reported using solid-phase extraction (SPE)-HPLC-enzyme-immunoassay (EIA) and HPLC-UV, respectively.[1,2] However, the reported methods do not provide sufficient sensitivity for applications requiring trace level detection limits. A sufficiently sensitive but a rather complicated GC-MS procedure for the analysis of LTE_4 in urine has also been reported.[3]

We have developed a new sensitive and simple LC/MS/MS method to quantitate LTE_4 in human urine. This method employs a solid-phase extraction procedure using Empore™ extraction disks to isolate LTE_4 and the internal standard LTE_4-d_3 from the urine stabilized with 4-HO-TEMPO and EDTA.

EXPERIMENTAL

Empore™ C18 extraction disks were obtained from 3M Industrial and Consumer Sector, St. Paul, MN 55144. The liquid chromatography part of the system included a Hewlett-Packard Model 1090M pump, Hewlett-Packard, Avondale, PA 19311. Kromasil™ C8 columns, 2 x 50 mm, were from Keystone Scientific, Inc., Bellefonte, PA 16823. The mass spectrometer was a PE-SCIEX API III+ from PE-SCIEX, Thornhill, Ontario.

After solid-phase extraction, the reconstituted extracts were analyzed by liquid chromatography/tandem mass spectrometry (LC/MS/MS) operated in the negative ion mode using a TurboIonSpray™ interface. The Kromasil™ C8 column was eluted isocratically with methanol and aqueous ammonium acetate (pH 5.6) at a ratio of 70:30.

RESULTS AND DISCUSSION

The full-scan product ion spectrum of LTE_4 is shown in Figure 1. The assay has a lower limit of quantitation (LOQ) of 50 pg/mL of urine for LTE_4 based on 5 mL aliquots. The standard curves were linear from 0.05 ng/mL to 10 ng/mL by weighted (1/y) least squares regression of concentration versus peak area ratio of the analyte to the internal standard. Figure 2 presents the extracted ion current chromatograms for the control blank human urine extract and the urine extract at LOQ level. The intra- and inter-assay precision, calculated from QC samples, was less than 9% for LTE_4. The intra-assay precision was less than 11% for the LTE_4 standards. The intra and inter-assay accuracy was less than 14% and 8% for each QC level, respectively. The intra-assay accuracy was less than 14% for each standard level. LTE_4 was found to be stable in human urine (in the presence of 4-hydroxy TEMPO and EDTA) at -70 °C for at least 33 days, at ambient temperature up to 24 hours, and in the reconstitution buffer at 5 °C for 24 hours. LTE_4 was also shown to be stable after 3 freeze(-70 °C)/thaw cycles in human urine and to be stable for 2 days as dry extracts at -70 °C. The recovery of LTE_4 during solid-phase extraction was independent of LTE_4 concentration in human urine. The mean recovery of LTE_4 from human urine was found to be 72%. Several important parameters such as pH of the urine and pH of the wash solution need to be considered during the sample preparation.

Automation of Rapid, High Sensitivity Pharmacokinetics Assays by LC/MS/MS

Ken Stoney and Kerry Nugent, Michrom BioResources, Auburn, CA
Adrian Land, Mark Bier, Jae Schwartz and Kevin Wheeler
Finnigan MAT, San Jose, CA

Trace level detection and quantitation of pharmaceutical compounds and their metabolites in biological samples can be a very challenging analytical problem. During the development of a new drug candidate, researchers may be required to analyze thousands of samples to fully characterize the metabolism of the compound of interest in the target organism. Current methodology often requires extensive manual cleanup, including protein precipitation, liquid-liquid partition and/or solid phase extraction prior to analysis by HPLC or LC/MS. These techniques are often time consuming, and can lead to errors in quantitation from manual sample handling.

An automated LC/LC/MS/MS system has been developed which allows on line removal of high molecular weight compounds from physiological fluid samples by Gel Filtration (GFC) prior to analysis by RP-HPLC/MS/MS. These high molecular weight compounds are often the major problem in LC/MS studies, since they can rapidly contaminate HPLC columns and MS inlet systems. This automated LC/LC/MS/MS system allows overnight unattended analysis of up to 96 physiological fluid samples for trace level drugs and metabolites. Samples are loaded onto a GFC column to remove all of the high MW impurities (>2kD), then the small molecules are trapped, concentrated and desalted online, prior to final analysis. In this study, two tripeptides (MW 341 and 425) were used to characterize this system, and final analysis was done by LC/UV, LC/ESI/MS and LC/ESI/MS/MS.

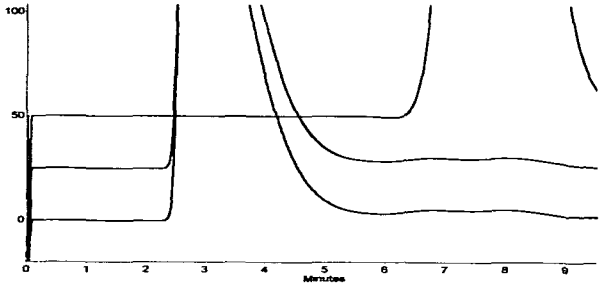
Figure 1

GFC of Plasma

500 ng Standard

100 ul Spike

100 ul Plasma



Although the automated GFC cleanup is not sufficient when using HPLC with UV detection, a mass spectrometer may be the ultimate detector for these rapid, automated pharmacokinetic assays. With a single quadrapole MS system, good sensitivity and selectivity can be obtained using the selected ion monitoring mode (SIM), where only the parent ions of the compounds of interest are monitored. With an instrument that has MS/MS capabilities (such as the TSQ 7000 Triple Quad and the LCQ Benchtop MS/MS systems used in this study), even greater sensitivity and selectivity can be achieved using the selected reaction monitoring mode (SRM).

Initial experiments run on the Michrom UMA Microbore HPLC / Finnigan TSQ 7000 Triple Quad MS/MS used a standard peptide column and mobile phase, but it was felt that the presence of TFA had an impact on the limit of detection. In the second set of runs using the Michrom UMA / Finnigan LCQ Benchtop MS/MS, a new column developed to allow good separation of peptides with acetic acid (HAc) in place of TFA was employed. Although the peptide peaks were slightly broader using HAc in place of TFA, the improvement in MS/MS sensitivity far outweighed the small loss of chromatographic resolution. The LCQ SRM runs allowed quantitation at the 0.5 ng/ml level, and the MS/MS spectra could be used at this level to positively identify the compounds of interest.

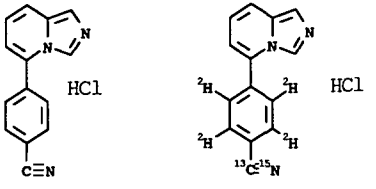
A Rapid Semi-automated Method for Quantitation of CGS 20286A in Rat Plasma Using Electrospray LC/MS/MS.

Michael J. Hayes, Jill C. Joshi, Steve F. Carlsen and Mark L. Powell, Ciba-Geigy Corp.,Pharmaceuticals Div., Research Dept., Summit NJ 07901

CGS 20286A ((+)-(5R)-4-(5,6,7,8-tetrahydroimidazo-(1,5-a) pyridin-5-yl) benzonitrile hydrochloride) is the (+) enantiomer of fadrozole. Fadrozole is a potent and highly selective non-steroidal aromatase inhibitor under investigation for treating estrogen-dependent diseases such as breast cancer, endometrial cancer, idiopathic oligospermia and endometriosis.
CGS 20286A is the pharmacologically inactive enantiomer of fadrozole and a method was needed to support a toxicokinetic study planned for the enantiomer in rats.

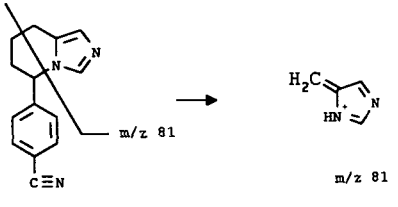


CGS 20286A **Internal standard**

Solid phase extraction was performed with a Gilson ASPEC XL sample processor The columns were 500 mg C8 extraction cartridges. One ml samples were applied to the columns, washed with 2 ml of 40% methanol in water and eluted with 2 ml of 80% methanol in water. A 10 ul aliquat of the eluent was taken for injection on the LC/MS/MS.

The instrumentation consisted of a Waters 590 pump with external mixing using a Lee TCMA 0120113 mixer. The column was an Inertsil 5 um ODS-2 column (150 x 2.0 mm). The mobile phase was 80% 0 05% acetic acid 20% acetonitrile at a flow rate of 0 25 ml/min. A CTC-200S Analytics autosampler with a 6-port Valco injection valve was used The mass spectrometer was a Finnigan TSQ 700, with the Finnigan electrospray source. Positive ion multiple reaction monitoring was utilized with argon collision gas at 2.5 mTorr and 35 eV energy. The parent ions were the $[M+H]^+$ ions at m/z 224 and 230 for the drug and internal standard respectively. Peak area measurement of both CGS 20286A and IS is done by monitoring the m/z 81 daughter ion. The scan time was 0.5 seconds and the capillary temperature was 200°C. The MS/MS fragmentation is shown in the diagram at right.

The calibration curve was from 5 to 10,000 ng/ml and the regression was log-log regression with y-correction ($Y = AX^B + C$) of peak area ratios. Standards were in duplicate at concentrations of 5, 10, 50, 200, 2000 and 10,000 ng/ml. Six replicate quality control samples were analyzed at concentrations of 5, 10, 200, and 10,000 ng/ml.



The method showed very high inherent sensitivity due to the high ionization efficiency of the compound. This is a result of the ease of protonating the imidazol nitrogen atoms and the resulting resonant stabilization of the daughter ion that is formed. The MS/MS spectrum is shown in Figure 2 The use of MS/MS provided very high selectivity eliminating interferences from the plasma matrix. Figure 2 shows a chromatogram of a 5 ng/ml rat plasma standard.

The method was applied to the analysis of rat plasma samples from a 13 week toxicokinetic study and provided rapid throughput with high accuracy and precision. The quality control samples showed a mean recovery of 95.2% with a CV of 8.5.

QUANTITATION OF CEFOXITIN IN TISSUES AND BIOLOGICAL FLUIDS BY NEGATIVE ION ELECTROSPRAY LC-MS

Jiri Zamecnik and Eugene Florio
Defence and Civil Institute of Environmental Medicine, North York, Ontario M3M 3B9, Canada

Sodium cefoxitin (3-[[(Amino carbonyl) oxy] methyl]-7-methoxy-8-oxo-7-[(2-thienylacetyl)amino]-5-thia-1-azabicyclo [4.2.0] oct-2-ene-2-carboxilic acid Sodium) is a semi-synthetic antibiotic from cephamycin C family, active against Gram-positive and Gram-negative bacteria. It is an important therapeutic agent because of its resistance to destruction by bacterial b-lactamase. It is commonly used for treatment of sepsis in Canadian Armed Forces. The high renal clearance limits the usefulness of this potent antibiotic. Our work involved studies of a liposome encapsulation of cefoxitin, to extend its 30-50 min. blood serum half life. For the study of pharmacokinetics and bioavailability we needed a sensitive and specific assay, which would allow us to look at the low concentration of this drug in small samples of various tissues, blood plasma and urine obtained from laboratory mice. The published methods deal with TLC, fluorometric assay and HPLC. None of these methods had the required sensitivity and specificity. We wish to report here a simple rugged quantitative assay of cefoxitin by HPLC with a mass spectral negative ion electrospray method of detection either using SIM or SRM. We have used cefuroxime as an internal standard. Cefoxitin and cefuroxime are structurally similar compounds.

Cefoxitin and cefuroxime were purchased from Sigma, St. Louis, MO. Fresh solutions were prepared from powdered drugs for every assay, since both antibiotics have a limited shelf life as aqueous solutions. Precautions were taken not to expose the solutions to strong light. Mouse blood plasma samples and aqueous tissue homogenates were extracted by a Bligh/Dyer method. Internal standard, cefuroxime (100 ng/10µL of saline) was added into 100 µL of plasma or tissue homogenates. Samples were then diluted with 210 µL of methanol, vortexed, 100 µL of chloroform was added, vortexed and spun for 5 min at 3000 rpm. Supernatant was diluted with 100 µL of chloroform, vortexed and again spun for 5 min. at 3000 rpm. The proportions of solvents is crucial for a proper phase separations. The organic layer was removed and water/methanol layer dried almost to completion under stream of N_2 at 40°C. Samples were dissolved in 100 µL of 1% formic acid, filtered using 4 mm, 0.47 mm Nylon syringe filters. Aliquots of the samples (10-20 µL) were injected onto LC-MS. The assay was done on Finnigan TSQ-700 equipped with Finnigan APCI/ESI LC-MS interface and Waters 600 HPLC with a WHISP autosampler. The HPLC conditions were as follows: 12.5 cm x 4.7 mm Whatman 5 mm PartiSphere C-18 reverse phase column fitted with a pre-column filter. Mobile phase methanol: 1% formic acid (40:60), flow rate 0.3 mL/min. The retention time of cefuroxime was 11 min. and cefoxitin 16 min. The mass spectrometer electrospray (ES) source spray set at 1500V gave a current around 1.5 mA. The capillary heater was set at 240°C, sheath gas N_2 pressure set at 40 psi. The skimmer pump pressure was 800 mtorr. The mass spectrometer was used in a negative ion mode, either :

- by scanning the first quadrupole sector from 422 amu to 427 amu in 5 sec. Areas under masses 423 m/z (cefuroxime) and 426 m/z (cefoxitin) were monitored.
- or by SRM, monitoring daughter ions 318 m/z and 336 m/z of cefuroxime parent 423 m/z and daughter 333 m/z of cefoxitin parent 426 m/z.

The manifold temperature was set to 80°C, the electron multiplier, equipped with 5 kV dynodes, was set at 1500V. The area ratios of cefoxitin / cefuroxime were plotted against a concentration of cefoxitin. The calibration curves were prepared by spiking 100 µL of blank mouse plasma with cefoxitin (0.01, 0.1, 1, 5, 10 µg/mL) and 100 ng of cefuroxime internal standard. The standards were processed identically to the samples. A least square fit was calculated using Excel spreadsheet resulting in a linear fit with a correlation coefficient greater than 0.999. Within assay coefficient of variation was <5% (n=10), between assay <10% (n=5).

Samples of mouse blood plasma, liver, spleen, kidney and lung were analyzed by this method. Positive ion electrospray yielded M^++1 ion and multiplicity of molecular ion+sodiums and molecular ion+potassiums adducts. The proportion of these adducts varied between assays and between samples within an assay. The attempts to stabilize these adducts were unsuccessful. The negative ion monitoring yielded mostly just ions of interest without any interference in SIM mode of operation. The selective ion monitoring (SRM) was not really necessary to obtain reliable results. The liposomal encapsulation of cefoxitin extended half-life of the drug several fold.

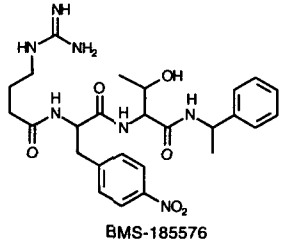
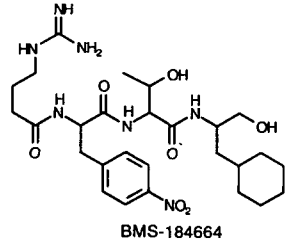
Detemination of Novel Thrombin Inhibitors in Animal Plasma by LC/API-MS.

Dineen J. White, John W. Russell and David Wang-Iverson
Bristol-Myers Squibb Pharmaceutical Research Institute
Princeton, New Jersey 08543-4500

The identification of a selective, orally active thrombin inhibitor with a long duration of activity has been an objective of the cardiovascular discovery program of the Bristol-Myers Squibb Pharmaceutical Research Institute. Preliminary pharmacokinetic data were required to evaluate first pass metabolism and oral absorption for a series of these compounds. The inhibitors in this series were administered to animals via three routes: oral, intravenous (iv) and intraportal (ipt, dogs only) or intraperitoneal (ip). Two of these inhibitors are presented in this work, BMS-184664, administered to rats, and BMS-185576, administered to dogs, rats and mice. Initial attempts to perform quantitative assays in plasma samples using HPLC with UV detection were unsuccessful due to insufficient sensitivity arising from the poor chromophore present in these analogs. LC/API-MS using pneumatically assisted electrospray as the interface was therefore selected for the analysis of these compounds. A sensitive, accurate and precise assay was developed for this series of thrombin inhibitors.



BMS-185576



BMS-184664

METHOD

Plasma samples (0.1 mL) were de-proteinized with three volumes of acetonitrile containing internal standard. The sample was vortexed, centrifuged and the clear supernate transferred to glass vials and dried under N_2. The dried extracts were reconstituted in 50 µL of loading buffer. The injection volume was 10 µL. The LC/MS system consisted of a Hewlett Packard 1090 HPLC and a Sciex API I mass spectrometer. The HPLC column was a Keystone Hypersil ODS 2 mm x 50 mm, with 3 µM particles, maintained at 60°C and a flow rate of 0.3 mL/min. The flow was split 1/6 prior to the ionspray source. The mobile phase containing H_2O, MeOH and 10 mM NH_4OAc utilized a 4 minute linear gradient from 30% to 90% MeOH. $(M+H)^+$ ions for both compounds were monitored. The standard curve range was 7.8 to 1000 ng/ml. Quality control (QC) sample concentrations were 20, 400, 800, and 4000 ng/ml. The 4000 ng/mL QC was diluted 1/10 with blank matrix prior to extraction.

RESULTS

QC samples in rat, mouse and dog plasma, as appropriate, were assayed on each of three separate days (n=6 for each level, each day). Accuracy and precision data for both compounds showed total assay variabilities of less than 15% at all QC levels. Average

deviations from nominal concentrations were also less than 15%. Dose-normalized areas under the curve (AUC) of each drug after ip or ipt administration were compared to those after iv administration to obtain an estimate of the first pass elimination of the drug. In the case of BMS-185576 in dogs, the extent of first pass elimination was estimated to be 17%. Similarly, a comparison of the dose-normalized AUCs after oral administration to that after iv administration provided an estimate of the oral bioavailability. After oral administration, C_{max} (651 ng/ml) occurred by 1 hr and the oral bioavailability was estimated to be 6%. The ratio of oral bioavailability to the ip (or ipt) bioavailability yielded an estimate of the extent of absorption of the drug, which was determined to be 7% for BMS-185576. This assay proved applicable for bioanalysis of other analogs in the series. Such pharmacokinetic results provided information to the chemists, aiding their synthetic strategies, as to whether first pass elimination and/or incomplete gastrointestinal absorption was the reason for a drug's poor oral activity.

LC/MS/MS METHOD FOR THE DETERMINATION OF NICOTINE AND COTININE IN HUMAN PLASMA

Allan Xu*, Jim Havel, Mary Petersen, John Fiene, James Hulse
Harris Laboratories, Lincoln, NE 68501

Cigarette smoking is the leading cause of preventable disease and death in the United States today. Several nicotine containing products have been introduced for the facilitation of smoking cessation. The current methodology for monitoring nicotine and its metabolite, cotinine, concentrations in human plasmas includs EIA (Elisa test, RIA), HPLC, GC and GC/MS. The disadventages of the above methods are lack of specificity, long sample preparation time, interfences and relatively long retention time (low throughput).

The purpose of this study is to develop and validate an LC/MS/MS with high sensitivity, specificity and throughput to support the on going pharmacokinetics investigations.

An LC/MS/MS method was validated for the determination of nicotine and its metabolite, cotinine, in human plasma using nicotine-methyl-d3 and cotinine-methyl-d3 as internal standards. Compounds were extracted from alkalinized human heparinized plasma with methylene chloride. Dried extracts are reconstituted with a solution of ammonium acetate/ methanol/ acetaonitrile and analyzed on a Keystone BDS Hepersil C18 column with a PE Sciex API III Plus MS/MS detecter operatd with APCI interface.

Figure 1.
Full scan spectrum of nicotine (A) shows m/z 163.2 as protonated molecular ion (MH+). The product spectrum of nicotine (B) has a base peak at m/z 84. Q1 full scan spectrum of cotinine (C) shows m/z 177.2 as the base peak (MH+). The product ion spectrum of cotinine (D) has a base peak at m/z 98. The above prarmeters were used to establish multiple reaction monitoring (MRM) condition for quantitative analysis.

Figure 2.
a)Extracted blank plasma sample with ISTD. Notice trace amount of nicotine (100-200pg/mL) present in non-smoker.b)Extracted 1ng/mL nicotine standard. Limit of quantitation is 1ng/mL for this assay.c)Extracted subject sample, nicotine concentration is 10.2ng/mL.e)Extracted blank plasma sample with ISTD.e)Extracted 10ng/mL cotinine standard, limit of quantitation is 10ng/mL for this assay.f)Extracted subject sample, cotinine concentration is 113.4ng/mL.

An LC/MS/MS method with APCI interface was developed and validated for the quantitative determination nicotine and its metabolite, cotinine, in human plasma. This method was successfully applied to several pharmacokinetic studies with more than six thousand clinical samples. The instrument parameters were optimized to obtain 1.0 minute run time with baseline separation of nicotine from cotinine. The method was validated over a range 1ng/mL to 50ng/mL for nicotine and 10ng/mL to 500ng/mL for cotinine, using 1 mL of plasma. The between-run precision and accuracy of the calibration standards were 1.7 to 3.9% C.V and -4.6 to +4.0% ralative error (RE). The within-run precision and accuracy of QC's (2.5, 15, 37.5ng/mL) were 4.3 to 5.9% CV and -2.9 to +1.2% RE. Stability of nicotine and cotinine in human plasma and processed samples has been established. The method was found to be easy, rugged, and suitable for pharmacokinetic studies of nicotine formulations used to aid smoking cessation.

The major advantage of this method is very short run time compared to HPLC or GC methds. At 1 minute per sample, we were able to analyze 400 clinical samples within 8 hr. When operated continuosly, we were able analyze 1000 samples within 24 hr. With this rapid turn around time, the investigator will be able to make decisions much faster.

Tetracyclines in Honey and Animal Tissues by ESI MS and MS/MS

Neil S. Snider and Greg P. Malis
Agriculture and Agri-Food Canada
Laboratory Services Division, Central Experimental Farm
Ottawa, Ontario, K1A 0C6, Canada

Introduction

Tetracycline antibiotics such as tetracycline (TC), oxytetracycline (OTC) and chlortetracycline (CTC) are widely used in modern agriculture. Human health and food safety concerns dictate regulatory antibiotic residue analysis to a 0 1 ppm level These antibiotics are most commonly analyzed by HPLC with UV or fluorescence detection and have produced false positives[1] In comparison, LC/MS offers a significant advantage of a more specific determination. FAB/MS has been the only MS technique applied to samples for residue analysis. TLC and LC/FAB/MS have been used for animal tissues and honey at the 0.1 ppm level[2,3]. The goal of this work was to develop a selective and sensitive ESI MS method for the qualitative and quantitative determination of tetracyclines in honey and animal tissues.

Methods

ESI/MS was carried out on a Fisons VG Quattro triple quadrupole mass spectrometer equipped with an electrospray interface. The source was kept at a temperature of 125 C For MS/MS analysis a pressure of 2.2 X 10^{-4} torr and an energy of 20 eV was used in the collision cell.

HPLC was carried out using three Fisons Phoenix 20 syringe pumps. The HPLC column was a Phenomenex Prodigy C 8, 2.0 X 100 mm, with 5 micron particle size. Two solvent systems were investigated at flow rated ranging from 75 to 150 ul/min The first utilized 0.005 M trifluoroacetic acid (TFA), acetonitrile (ACN) and Methanol (MeOH) A gradient from 90 % 0 005 M TFA, 5 % ACN, 5 % MeOH to 20 % 0 005 M TFA, 40 % ACN, 40 % MeOH in 10 minutes eluted the tetracyclines in approximately 7 minutes. A second solvent system used 0 02 N oxalic acid (OX), ACN and MeOH The gradient holds 90 % 0.02 N OX, 5 % ACN, 5% MeOH for 5 minutes, changing to 20 % 0.02 N OX, 40 % ACN, 40 % MeOH by 15 minutes This elutes the tetracyclines in approximately 9 minutes.

Results and Discussion

Positive electrospray results in a strong M+H ion for each of the tetracyclines An increase in the focus voltage (F), the potential difference between the electrospray capilliary and the skimmer lens increased the fragmentation observed for each of the tetracyclines At a focus voltage of F=30 V virtually no fragmentation is observed, at a focus voltage of F=60 V the three tetracyclines exhibit similar fragmentation each showing $[M+H-NH_3]^+$ and $[M+H-NH_3-H_2O]^+$ Figure 1 shows the MS/MS spectrum of tetracycline.

The daughter ion spectra of the [M+H] parent ions exhibit the same fragmentation observed at the higher focus voltage. For MS/MS conditions were optimized to give approximately equal intensities of each daughter ion thus giving two confirmatory ions for tetracycline identification. To achieve maximum sensitivity only the transitions of interest were monitored through multiple reaction monitoring (MRM)

When monitoring spiked sample extracts of honey and beef muscle using just the [M+H] ions of each tetracycline it became evident that there were to many interferences for positive identification In contrast figure 2 shows an MS/MS analysis of a beef muscle extract spiked at 1.0 ppm with each of the tetracyclines Virtually all interferences are removed by monitoring the daughter ions

Figure 2 also shows the present limit of detection for this method at 1.0 ppm for beef samples (1 0 g/mL) and 0.2 ppm for honey samples (5 0 g/mL) The injection volume is only 5 ul corresponding to 5 ng of each tetracycline being injected.

Conclusion

By utilizing LC/ESI/MS a selective and sensitive method for the determination of tetracycline residues in honey and animal tissues has been established Limits of detection are 1 0 ppm in beef muscle and 0.2 ppm in honey.

Future

By experimenting with larger injection volumes and by concentrating the extracts it is hoped that the limit of detection can be lowered to 0.1 ppm in both honey and animal tissue matrices.

Determination of a 4-Azasteroid in Serum Using Negative Ion APCI LC/MS

Kathy A. Halm, Thomas L. Lloyd and M. Lee Moss, Drug Metabolism Department, Glaxo Wellcome, Inc., Five Moore Drive, Research Triangle Park, NC 27709

INTRODUCTION

We report a bioanalytical method for the determination of a GI198745, a 4-azasteroid in rat serum. GI198745 is among a class of 5-α reductase inhibitors under development for the treatment of benign prostatic hyperplasia (BPH). Inhibition of the 5-α reductase enzyme prevents the conversion of testosterone to dihydrotestosterone, thereby decreasing the growth of the prostate in the male. The HPLC/UV method did not provide adequate sensitivity for the low dose pre-clinical studies, and therefore a high sensitivity LC/MS method was developed on a Finnigan TSQ-700 mass spectrometer. The analytical range was validated from 0.5 to 500 ng/ml.

SAMPLE PREPARATION

The serum samples (200 microliters) were prepared using an automated method developed on a Zymark robot. The internal standard (GI200402, a structural analogue) was dissolved in acetonitrile and added to the samples for protein precipitation. The automated sample preparation time was 10 minutes per sample. Samples were reconstituted manually and transferred to microvial inserts for LC/MS analysis.

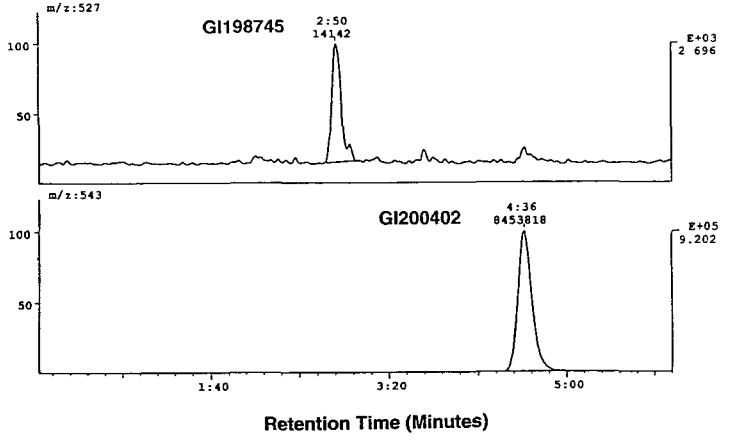
LC/MS ANALYSIS

The atmospheric pressure chemical ionization (APCI) source which accommodated conventional HPLC flow rates (1mL/minute) was used for the LC/MS analysis. Negative ion APCI MS provided high specificity and therefore selected ion monitoring (SIM), which showed greater sensitivity over selected reaction monitoring (SRM), could be used for detection. The mobile phase consisted of 40:60 (v/v) deionized water : acetonitrile. The separation was performed using a 4.6x50 mm BDS Hypersil C_{18} (3micron) column which reduced the analysis time while providing excellent resolution of GI198745 from the majority of endogenous serum components. Flow switching with a 6-port Valco switching valve minimized contamination of the APCI source. The retention times for GI198745 (m/z 527) and internal standard (m/z 543) were 2.9 and 4.7 minutes, respectively. The LC/MS analysis time was 6 minutes per sample.

RESULTS

Analytical method validation criteria were met for linearity, accuracy and precision. The intra-run precision of the quality control samples (1.5, 75, 360 ng/ml) ranged from 2.3 - 3.2% and accuracy was greater than 97%. The inter-run precision ranged from 3.0 - 6.8% and accuracy was greater than 98%. The extraction efficiency of the 4-azasteroid averaged 86.3% over the concentration range. The LC/MS method was cross-validated for serum from other species (mouse, dog, rabbit, marmoset and human).

SIM Chromatograms of GI198745 (LOQ, 0.5 ng/ml) and Internal Standard



CONCLUSIONS

The LC/MS method provided sensitivity, specificity and rugged, high sample throughput in support of pre-clinical studies over the range of 0.5 to 500 ng/ml extracted from 200 microliters of serum. The maximum number of samples analyzed by the LC/MS method in a single run was 117 samples over a period of 14 hours.

DETERMINATION OF 311C90, A 5-HT RECEPTOR AGONIST FOR THE TREATMENT OF MIGRAINE, IN HUMAN PLASMA BY LC-MS-MS.

I. J. FRASER, A.E. JONES, J.A. ALLANSON and S. PLEASANCE
GLAXO-WELLCOME, Group Development Operations, Department of Bioanalysis and Drug Metabolism, Beckenham, Kent, BR3 3BS, U.K.

Migraine, characterized by a throbbing headache which is usually unilateral and often associated with nausea, vomiting, photophobia and phonophobia, is a debilitating and recurrent disease affecting approximately 9-16% of the western population.

The neurotransmitter and vasoactive monoamine, 5-hydroxytryptamine (5-HT), that is widely distributed within both the CNS and the periphery, has been identified as having a central role in the pathophysiology of migraine [1], although its precise pathogenic role remains undefined. The novel compound 311C90 [(S)-4-[(3-(2-dimethylaminoethyl)-1H- indol-5-yl) methyl]-2-oxazolidinone] is an analogue of 5-HT displaying potent, selective agonist actions at the 5-HT$_{1D}$ receptor subtypes. The combination of high potency and an ability to act at central as well as peripheral elements of the trigemino-vascular system may offer a superior anti-migraine profile.

An HPLC method has been developed for the determination of 311C90 and its metabolites in human plasma to support early clinical development. The method employs automated solid-phase extraction (ASPEC) of plasma followed by HPLC using a TMS column (250 x 4.6 mm, Zorbax) and fluorescence (FLD) detection with excitation and emission wavelengths at 290 and 350 nm, respectively. The HPLC-FLD method provides a lower limit of quantitiation (LLOQ) for 311C90 and its metabolites of 2 ng/ml, sufficient to provide plasma concentration profiles for oral doses of 311C90 of 5 mg. Recent clinical studies have employed doses below 5 mg and consequently a more sensitive liquid chromatography tandem mass spectrometry (LC-MS-MS) based method using atmospheric pressure ionisation has been developed.

Both 311C90 and its desmethyl metabolite generate abundant protonated molecules under positive ion atmospheric pressure chemical ionisation (APCI) which subsequently give intense product ions during tandem mass spectrometry (see Figure) suitable for selected reaction monitoring (SRM). The increased selectivity and sensitivity offered by LC-MS-MS enables higher sample throughput since both the sample preparation time and the run time can be significantly reduced. The solid-phase extraction procedure used in the HPLC-FLD method was modified and a portion of the extract (20µL) is injected directly onto an SCX column (30 x 4.6 mm). A mobile phase of 30% 25mM ammonium formate (pH 5) 70% acetonitrile (v/v) at 1 mL/min resulted in an analysis time of approximately 4 minutes. Using a deuterated internal standard the LC-MS-MS method provides a LLOQ of 200 pg/mL with excellent precision and accuracy. In order to cross validate the LC-MS-MS method against the HPLC-FLD, quality control samples and plasma samples from clinical studies were analysed by both methods. A comparison of the data (see Figure) revealed the two method provided equivalent results across the overlapping ranges of quantitation. More recently the increased selectivity of the LC-MS-MS method has been successfully employed to support clinical interaction studies.

Quantitative Analysis of Tirilazad Mesylate (FREEDOX™) in Rat and Dog Plasma by Liquid Chromatography Atmospheric Pressure Chemical Ionization Tandem Mass Spectrometry.

Michael J. Hauer, Theresa A. Moore, Rick C. Steenwyk, Paul A. Bombardt, and Paul G Pearson.
Drug Metabolism Research, The Upjohn Company, Kalamazoo, Michigan

Tirilazad mesylate (FREEDOX™) is the first in a series of novel compounds that have been demonstrated to be potent inhibitors of membrane lipid peroxidation *in vitro*. Tirilazad has demonstrated efficacy in animal models for the prevention of neuronal damage due to head trauma, subarachnoid hemorrhage, spinal cord injury and ischemic stroke. As a consequence, tirilazad mesylate has the potential to improve the clinical prognosis in conditions where lipid peroxidation occurs secondary to traumatic tissue injury. A highly selective and sensitive atmospheric pressure chemical ionization tandem mass spectrometry (APCI-MS/MS) method for the quantitation of tirilazad in rat and dog plasma has been developed and validated. Mass spectrometric analysis was performed on a Finnigan-MAT TSQ 700 triple quadrupole mass spectrometer equipped with a Finnigan APCI source. The protonated molecular ion of tirilazad at m/z 625 underwent collisionally activated dissociation to afford a product ion at m/z 260 In a similar manner, the protonated molecular ion of [$^{13}C_3$,$^{15}N_2$]tirilazad (IS) at m/z 630 afforded a product ion at m/z 265. Selected reaction monitoring of the these transitions were used for quantitation. The method was refined to include an automated column switching device to eliminate carry-over of residual analyte following injection of high concentration samples Installation of a second HPLC pump and a custom valve switching device permitted the autosampler to be switched off-line during the analytical run. During this time, blank plasma samples were injected by the autosampler to facilitate elimination of residual analyte from the HPLC system; mobile phase flow to the analytical HPLC column was supplied by the second HPLC pump at the time of column bypass. Analytical separations were performed on a Kromasil 100-5C18 column (15 cm x 4 6 mm, 5 µm) using a mobile phase consisting of methanol:isopropanol:1 M ammonium acetate pH 4.5 (90:5.5) at a flow rate of 1 0 mL/min Under these conditions the retention time of the analyte and internal standard was 3.2 minutes. Aliquots (100 µl) of unknown plasma samples, standards of tirilazad in plasma (0.5 to 10000 ng/mL), and plasma controls (16 to 8000 ng/mL) were prepared for APCI-MS/MS analysis by precipitation of protein with acetonitrile containing IS. Unknown plasma samples were quantitated from the peak height ratio of the analyte to the internal standard using a weighted linear regression model. The limit of quantitation (LOQ) of tirilazad mesylate was approximately 0 5 ng/mL and the upper limit of quantitation (ULOQ) of tirilazad mesylate was approximately 10000 ng/mL

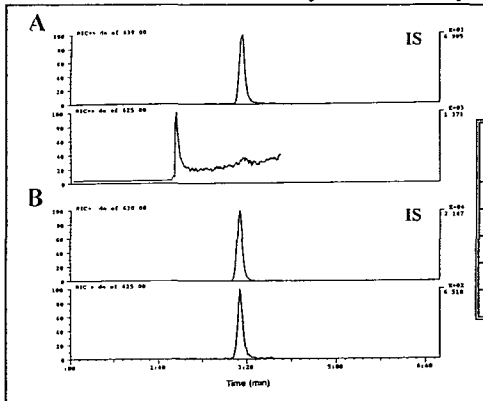

Figure 1
Representative chromatograms from multiple reaction monitoring of tirilazad mesylate and ^{13}C ^{15}N pyrimidine labelled tirilazad mesylate (IS), from dog plasma samples containing: (A) Blank plasma (B) 0.5 ng/mL standard (C). Tirilazad mesylate eluted at approximately 3.2 mins, allowing for analysis of over 100 samples in a single analytical run.

GC/MS AND LC/MS CONFIRMATION OF MALACHITE GREEN IN CATFISH

Sherri B. Turnipseed, José E. Roybal, Jeffrey A. Hurlbut, Austin R. Long
Animal Drugs Research Center, FDA, P.O. Box 25087, Denver, CO 80225-0087

Malachite green (MG) is a triphenylmethane dye used in aquaculture as a topical antiseptic to prevent fungal infections. Studies have indicated that these compounds can be carcinogenic and teratogenic, which makes monitoring of dye residues in some food products crucial. Determinative methods have been developed to quantitate the amount of MG and leucomalachite green (LMG), a reduced metabolite of MG, residues in fish tissue [1]. For complete analytical detection, mass spectral confirmatory methods are critical for the unambiguous identification of suspect residues found in the sample.

Confirmation of dye residue can be accomplished using particle beam LC/MS or GC/MS methods. The EI spectrum for LMG, obtained with the particle beam interface is shown (Fig 1). The most abundant fragment ions consist of m/z 330$[M]^+$;329 $[M-H]^+$; 253 $[M-Ph]^+$;210 $[M-C_6H_4N(CH_3)_2H]^+$; 165 M^{++}. The mass spectrum of MG is very similar with reduction of the cationic dye in the mass spectrometer leading to a large abundance for the ion corresponding to MH^+. An advantage of the LC/MS method is that the chromic and reduced forms of the dye can be confirmed simultaneously. However, the detection limits for the drugs in tissue are 20 ppb or higher and the relative abundances of the ions in the chromic dye vary due to reactions occurring in the mass spectrometer source. For catfish fortified at the 20 ppb level and incurred tissues (live catfish exposed to bath containing 1.0 µg MG/g water for 1 hr) after 24 depuration time, the LMG ion abundances(m/z 330, 329, 253, 210) are within 10% of that observed in the standard. For MG, however, the abundances vary more, 10-15% as compared to a standard. The ion at m/z 165 was also monitored as additional evidence for the drugs, but the relative abundance of this ion was not consistent.

Using GC/MS only the leuco form can be confirmed. However, this appears to be the marker residue for malachite green in catfish. The GC/MS method has been determined to be very sensitive (5 ppb) selective and rugged. The extracts from the HPLC/VIS determinative method [1] can be used with additional cleanup to isolate the leuco metabolite. The criteria for confirmation as described by Sphon [2] is met for LMG in all fortified and incurred tissue analyzed by GC/MS. Specifically, the retention time for LMG does not vary by more than 0.02 min (<1%) from that of LMG standard chromatographed the same day. In addition, the relative abundance of the five ions monitored varies by less than ±10% as compared to the same ratios calculated for a standard extract. Ion chromatograms for LMG in incurred catfish tissue (catfish exposed to bath containing 20 ng MG/g water for 1 hr, 24 depuration time) are shown in Figure 2. Validation of the GC/MS method was performed using fortified tissue and with several sets of incurred tissue with LMG concentration ranging from approximately 8 to 80 ng/g tissue.

National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson Street
Denver, CO 80206

INTRODUCTION

Free radical oxidation of glycerophospholipids is now recognized to yield a series of complex products including isoprostanes which have biological activity when hydrolyzed to the free carboxylic acid (1,2). The mechanism of formation of these doubly oxygenated products of arachidonic acid would suggest that other complex structures could also result, including compounds isomeric to another class of arachidonic acid metabolite having biological activity, namely the leukotrienes. Leukotrienes are formed by enzymatic oxidation of arachidonic acid by 5-lipoxygenase leading to formation of conjugated trienes including the 5,12-dihydroxyeicosatetraenoic acids such as LTB_4 (3). We have investigated the free radical oxidation of 1-hexadecanoyl-2-arachidonoyl-glycerophosphocholine using Fenton reaction conditions (4) to generate hydroxyl radical.

RESULTS

Oxidation of the precursor glycerophosphocholine containing arachidonic acid at the *sn*-2 resulted in a complex mixture of products, some of which absorbed ultraviolet light characteristic of conjugated trienes. These were detected by HPLC separation of the reaction products as shown in Figure 1A. The UV spectrum of one component in this complex mixture is shown in Figure 1B suggesting the presence of a conjugated triene as a structural feature of this metabolite. Electrospray ionization mass spectrometry of this HPLC fraction as well as fractions 46 and 47 resulted in abundant ion at 798.6, which upon collisional activation yielded the carboxylate anions at *m/z* 255 (hexadecanoic acid) and *m/z* 335 (arachidonic acid) plus two oxygen atoms (data not shown).

Following saponification of these glycerophospholipid metabolites, UV absorbing components were isolated by reverse phase HPLC which had the characteristic UV absorption maximum at 270 nm. Furthermore, testing of this biological extract using human neutrophils loaded with the fluorescent dye Indo-1 revealed each component to cause an increase in intracellular free calcium. This increase was blocked by a receptor antagonist to leukotriene B_4 suggesting this biological activity was mediated through the LTB_4 receptor.

Structural identification of the conjugated triene metabolites was carried out using ESI/MS/MS of *m/z* 335. Figure 2 and 3 show the CID spectra of the major triene metabolites in HPLC fractions 46 and 47 revealing formation of *m/z* 195 from *m/z* 335 characteristic of 5,12-dihydroxyeicosatetraenoic acids (5). Electron ionization mass spectrometry of the catalytically reduced, trimethylsilylated PFB esters produced major ions corresponding to α-cleavage adjacent to the hydroxyl groups at m/z 555, 215, 369, and 401 revealed both of these reduced metabolites to be 5,12-dihydroxyeicosanoic acids. Since a conjugated triene could only exist between the 5 and 12 positions and the additional double bond has been assigned at the 14-15 position as in the original arachidonic acid, these metabolites were identified as 5,12-dihydroxy-6,8,10-eicosatetraenoic acids. These two metabolites (Figures 2 and 3) as well as several other metabolites were found to have biological activity. These molecules are formed as intact phospholipids and represent a novel class of free radical products of lipid peroxidation.

LC-ESI-MS/MS OF POLYAMINES AND BASIC AMINO ACIDS.

Gottfried J. Feistner
Beckman Research Institute of the City of Hope, Duarte, California 91010

Recently, my interest in the biosynthesis of proferrioxamines prompted me to develop a method for the comprehensive profiling of basic amino acids and polyamines in microbial culture supernatants [1]. The method takes advantage of the complementary characteristics of dansylation and capillary reversed-phase chromatography - electrospray mass spectrometry (cLC-ESI-MS), and is characterized by convenience (no sample work-up required), good sensitivity and chromatographic resolution, and low solvent consumption. However, closely eluting isobaric compounds needed to be distinguished by co-chromatography. It was thus of interest to explore whether the specificity of the method could be improved by extending it to cLC-ESI-MS/MS. Without derivatization, the target compounds give rise to characteristic product ion spectra but are not amenable to RP-LC [1]. Whether the dansyl derivatives would give useful MS/MS spectra, was far from clear, since under EI conditions, the dansyl derivatives of biogenic amines have been reported to predominantly, and sometimes exclusively, give rise to dansyl group-related fragment ions [2], which are useless for structural characterization. This study therefore was initiated to explore whether the targeted dansyl derivatives give useful product ion spectra under LC-ESI-MS/MS conditions, whether isobaric derivatives can be distinguished in this way, and whether general fragmentation mechanisms can be deduced that may allow identification of related compounds in the absence of authentic reference compounds.

Figs. 1-3 show the product ion spectra of three pairs of isobaric compounds, namely Dns_2-diaminobutyric acid and Dns_2-2-hydroxycadaverine, Dns-acetylputrescine and Dns-agmatine, and didansyl N^1- and N^8-acetylspermidine, respectively. Clearly, the product ion spectra of these dansyl derivatives are structurally informative and readily allow to distinguish isobaric compounds. For example, $[M+H-H_2O]^+$ ions, which reportedly can be abundant for free basic amino acids under CI conditions [3], are not seen under ESI-MS/MS conditions (compare Fig. 1a), but are quite abundant for hydroxy derivatives (see Fig. 1b) Likewise, $[M+H-NH_3]^+$ ions appear to be characteristic for those target compounds that contain guanidino or urea moieties, obviously due to the fact that these groups are not amenable to dansylation (compare Fig. 2b). The two acetylspermidines, which are very difficult to distinguish chromatographically, fortunately also give sets of characteristic fragment ions; most notably a strong *m/z* 100 ion for N^1-acetylspermidine, which in all likelihood arises from the acetylaminopropyl moiety.

Establishing the entire fragmentation pathways in an unambiguous manner requires accurate product ion mass measurements, multistage tandem mass spectrometric analyses, and/or appropriate isotope-labeling experiments. Such rigorous analyses in turn require sophisticated instrumentation, such as four-sector or FT-ICR mass spectrometers, and/or considerable synthetic efforts, and could not yet be performed. Nevertheless, low-resolution tandem mass spectrometric analyses of a larger number of homologous or otherwise related amino acids and polyamines allowed to deduce rational fragmentation pathways. This in turn led to the identification of three unknown compounds in microbial culture supernatants as citrulline, acetylpropane, and diacetylspermine [4]. The identifications are, in part, based on the facts that Dns-acetylpropane and Dn_2-diacetylspermine both give rise to the characteristic *m/z* 100 ion, and that citrulline looses NH_3 from the molecular ion. Also, the MS/MS spectrum of suspected citrulline closely matched that of authentic citrulline.

INTRODUCTION

CP-0127 is a new potential drug for treatment of traumatic shock. CP-0127 (MW = 2805 Da) is a dimeric peptide with 6 arginines. ^{13}C-CP-0127 is used as an internal standard by replacing the $^{12}C_6$ ring of L-Phe, the $^{12}C_1$ of Leu, and the $^{12}C_1$ of Gly with ^{13}C to give a 16 Da increase in molecular weight. HPLC-UV and SIM LC/MS techniques are not selective or sensitive enough for quantifying CP-0127 in human plasma. The "stickiness" of this peptide causes considerable problems (e.g., poor recovery from a solid-phase extraction and carryover from a previous injection). Using solid-phase extraction followed by LC/MS/MS, an LOQ of 10 ng/mL can be achieved. The technique of LC/LC/MS/MS improves sensitivity to give an LOQ of 2 ng/mL in plasma. A series of subsequent HPLC solvent rinsing methods following an analytical HPLC method solved the carryover problem.

EXPERIMENTAL

Sample preparation involves protein precipitation with acetonitrile/ethanol followed by centrifugation, concentration to dryness by freeze-drying, and reconstitution in 0.1% TFA. These samples are then analyzed by column switching techniques which use three different column technologies. The first column is a Michrom BioResources protein removal cartridge (3 x 10 mm), the second column is a PerSeptive ID AD Sensor cartridge (2.1 x 30 mm) and the third analytical column is a Keystone Asahipak ODP C18 (2 x 50 mm). The total effluent from this column is directed to an ion spray LC/MS interface with TurboIonSpray-assistance to improve spray solvent volatilization. The PE Sciex API III ^{plus} tandem triple quadrupole mass spectrometer was operated in the selected reaction monitoring (SRM) mode.

RESULTS AND DISCUSSION

The protonated triply charged CP-0127 and ^{13}C-CP-0127 were monitored as precursor ions while corresponding structurally informative product ions were also monitored. From our earlier solid-phase extraction (SPE)-LC/MS/MS results (Figure 1), a limit of quantitation was determined at the 10 ng/ml level due to its "stickiness" resulting in poor recovery by SPE. After acetonitrile/ethanol protein precipitation followed by LC/LC/MS/MS, sensitivity was increased five-fold (Figure 1). On-line sample preparation eliminates sample loss that appears to occur with the solid-phase extraction. The "sticky" nature of this peptide also causes an HPLC injector carryover problem. Following a series of subsequent HPLC solvent rinsing methods, carryover was effectively reduced to less than 1% (33 counts, Figure 2) after a 400 ng/mL plasma standard (upper limit of quantitation) was injected (6308 counts, Figure 2). The technique of LC/LC/MS/MS provides not only the required selectivity but also improved sensitivity over the SPE-LC/MS/MS method.

DETECTION OF ENDOGENOUS NITRIC OXIDE GAS FROM LIVING ANIMALS BY MASS SPECTROMETRY

DELACOTTE J.M., FAYE T., *REGERT M., ROLANDO C. and SABLIER M.

Ecole Normale Supérieure, Dpt Chimie, CNRS-URA 1679, 24 rue Lhomond, 75231 Paris, FRANCE

Nitric oxide (NO) is an important mammalian intercellular messenger [1]. At present, the determination of NO gas solubilized in the effluents from tissues of a living animal, collected with a microdialysis probe would be of great interest.

Thus, pharmacologists are waiting for new methods for measuring NO that have at least three essential properties :

-A great sensitivity (to detect quantities less than or equal to 10^{-13}M) ;

-A small sample-test volume (few microliters) ;

-A great specificity.

In a first approach, we have adapted and simplified the determination of NO, as proposed by GUTZKI and al. [2]. But this method has a major disadvantage : The best purified waters contain nitrates. So the preparation of low level standard solutions is uncertain.

In a second approach, we intend to use the reactivity of nitric oxide towards diradicals [3] : The 1,2-bis(exoisopropylidene)cyclohexa-3,5-diene II comes from the decarbonylation of 1,1,3,3-tetramethyl-2-indanone I under ultraviolet irradiation [4]. In the presence of NO, the biradical/triplet state of II can react with the solubilized gas to form the 1,1,3,3-tetramethylisoindolin-2-yloxyl III [5].

In a preliminary experiment, we bubbled nitric oxide in a 15.6 mM deoxygenated solution of I in cyclohexane. This saturated solution of nitric oxide was exposed to UV irradiation during 20 mn.

The chromatogram (figure 1) of the resulting solution shows two compounds · The unchanged indanone I (scan 1916) and its already known photoproduct IV [6] (scan 1665). The nitroxide III is also detected (scan 2012) ; Calculated on the basis of peak areas, the conversion yield was approximatly 2%. The identity of III was confirmed by comparison with an authentic sample of 1,1,3,3-tetramethylisoindolin-2-yloxyl III.

MACROMOLECULE ISOTOPE-RATIO MEASUREMENTS WITH HPLC/CRIMS

Blaire L. Osborn and Fred P. Abramson, Department of Pharmacology,
George Washington University, Washington, D.C. 20037

The increased use of proteins as therapeutic agents intensifies the need for methods to study pharmacokinetics and metabolism of these macromolecules. These drugs are frequently used to augment endogenous protein in the body. To accurately perform pharmacokinetic and metabolism studies of therapeutic proteins, it is necessary to be able to distinguish between endogenous and exogenously administered protein. This study uses HPLC/CRIMS to determine the amount of stable-isotope labeled protein that can be detected against a background of unlabeled material.

Chemical reaction interface mass spectrometry (CRIMS), when combined with high performance liquid chromatography (HPLC/CRIMS), permits the study of nonvolatile species, such as intact proteins. The fundamental process of CRIMS involves a reaction chamber in which a microwave-induced plasma is generated that decomposes each analyte to its component elements. These elements then react with atoms from a second, reactant, gas to produce stable product species that can be detected by a conventional mass spectrometer using selected-ion monitoring. Since the products of the reaction are predictable, there is no need for hypotheses about metabolic products in order to detect them.

In this feasibility study, we have tested whether HPLC/CRIMS can detect a labeled protein against a background of unlabeled material. We chose an easily isolated macromolecule, phycocyanin (**P**), a chlorophyll-associated protein which is heavily expressed in cyanobacteria. Lyophilized algae (*Spirulina platensis*) grown under $^{13}CO_2$ as well as under a normal atmosphere were purchased, and **P** was isolated using ammonium sulfate precipitation. The **P**-containing solution was passed through an anion-exchange column, the deepest blue fractions were combined, dialyzed, lyophilized and stored at -20°C until used.

The mass spectrometer was set to obtain a minimum of twenty samples across the peaks. The reactant gas was SO_2, which oxidizes the elements of the analytes. The carbon in the protein was measured as CO_2, with $^{13}C^{16}O_2$ detected at mass 45, and the unlabeled carbons detected at mass 44 ($^{12}C^{16}O_2$). By integrating any HPLC peaks of interest for these two mass channels, calculating their ratio, and comparing this ratio to that for the naturally abundant species, one determines the isotopic enrichment of the sample. Studies were analyzed using a weighted ($1/y^2$) linear regression.

The initial experiments to evaluate purity used a 300Å pore, 30 mm x 4.6 mm Brownlee C4 column. Solvent A was 95% water: 5% methanol, and solvent B was 95% methanol:5% water. Both solvents contained 0.1% trifluroacetic acid. **P** was eluted from the C4 column using a gradient of 70-90% B and a flow rate of 1 mL·minute^{-1} over 10 minutes (Fig. 1). For the isotope-dilution experiments, a 2.1 x 30 mm Poros R1 perfusion column (PerSeptive Biosystems) was used for better resolution, sensitivity, and speed. Solvent A was 95% water:5% acetonitrile, solvent B was 95% acetonitrile:5% water, and both solvents contained 0.1% TFA. **P** was eluted from the column with a 30-60% gradient of B run over 2 minutes at flow rate of 1 mL·minute^{-1}. For the isotope dilution studies, labeled and unlabeled **P** were reconstituted in water. ^{13}C-labeled **P** was added to samples of unlabeled **P** to produce enrichments of up to 10%. Samples containing approximately 28 pmol, 110 pmol and 1100 pmol of unlabeled protein spiked with varying amounts of ^{13}C-labeled **P** were injected into the HPLC system using a 20 μL injection loop and eluted as described.

P isolated from the labeled Spirulina was highly enriched with ^{13}C. As shown in Figure 1, the predominant form of CO_2 was seen at m/z 45. With the C4 column, ^{13}C-**P** is separated into various subcomponents. The two large peaks presumably represent the α and β subunits of **P**. The third small peak could be a second type of α subunit called α_2, which is present in some species of **P**. When the areas of the two mass chromatograms are compared, the isotopic enrichment of ^{13}C-**P** is calculated as

75%. Other labeled peaks were not seen in the chromatogram.

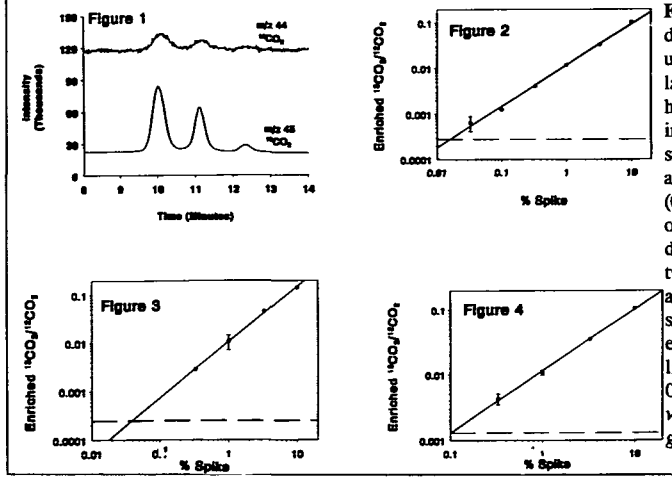
The isotope ratio of CO_2 from naturally-abundant **P** was 0.01300 ± 1.4x10^{-4} (mean ± SD, N = 4) as determined in the 1100 pmol experiment. The coefficient of variation was 1.1%. The isotope ratios obtained in the other two experiments were similar. The criterion for deciding whether enrichment was measurable was set to a value above the mean plus two standard deviations of the naturally-abundant protein. The dashed horizontal lines in Figures 2-4 represent this decision level.

As seen in Figure 2, using the largest amount of unlabeled protein, the lowest enrichment quantifiable at a background of 1100 pmol was 0.033 mole %, or about 330 femtomoles of ^{13}C-labeled protein. A similar level of detection was seen when starting with 110 pmol (Figure 3). Starting with 28 pmol of unlabeled **P**, a lower amount, 91 fmol, of ^{13}C-enriched protein was measured (Figure 4) but the limit of detectable enrichment was higher, 0.33 mole %. The limit of detection, as predicted from the intersection of the regression line and the dashed line, could be substantially lower (between 30 and 200 fmol) for all 3 experiments.

It is possible to detect femtomole amounts of labeled material against a 3000-fold background of unlabeled protein. When coupled with good HPLC separation, one should be able to obtain accurate information about labeled macromolecular species from biological matrices. These results support the hypothesis that HPLC/CRIMS will be a useful technique for obtaining pharmacokinetic and metabolic information on therapeutic proteins.

An additional experiment was conducted to estimate the ability of HPLC/CRIMS to perform material balance studies using stable isotopes. **P** was incubated with the enzyme Lys-C for several hours. At 0, 1, 2, and 4 hours 20 μL samples were injected into the HPLC/CRIMS system. The area under the multiple peaks produced by the degradation of the protein were 68-91% of the area of the single **P** peak at time 0. The addition of an internal standard should improve the accuracy of this study.

Figure 1. ^{13}C-**P** eluting from the C4 column. The amount of ^{13}C is enriched far above the natural abundance allowing the labeled protein to be detected at m/z 45 ($^{13}C^{16}O_2$) rather than at m/z 44 ($^{12}C^{16}O_2$).



Figures 2-4. Isotope dilution studies using unlabeled and ^{13}C-labeled **P**. These data have been transformed into ^{13}C enrichment by subtracting the naturally-abundant isotope ratio (0% spike) from the observed data. The dashed line represents two standard deviations above the 0% spike sample. All three experiments were highly linear with r^2 values of 0.994-0.999. *This work was supported by NSF grant BIR-9216935.*

QUANTITATIVE ASPECTS OF MASS SPECTROMETRIC IMMUNOASSAY

Randall W. Nelson, Jennifer R. Krone, J. Kathleen Lewis, Peter Williams
Department of Chemistry and Biochemistry
Arizona State University
Tempe AZ 85287-1604

INTRODUCTION

We have recently developed a method for the rapid and sensitive determination of antigenic species present in biological fluids. The technique has been termed mass spectrometric immunoassay (MSIA) [Nelson, R.W. *et al. Anal. Chem.* **67**, 1153 (1995)]. Briefly, MSIA combines the ability of immunoaffinity chromatography to selectively concentrate antigens with matrix-assisted laser desorption/ionization (MALDI) mass spectrometric detection. The assays are performed, however, in a manner much different than conventional chromatography/mass spectrometric methods; that is, the assays are performed with nanoliter volumes of reagent in a pipettor tip, rather than in columns with microliter volumes. This enables the assays to be performed quite rapidly, requiring on average ~ 15 minutes/assay, and with high sensitivity (picomolar concentrations).

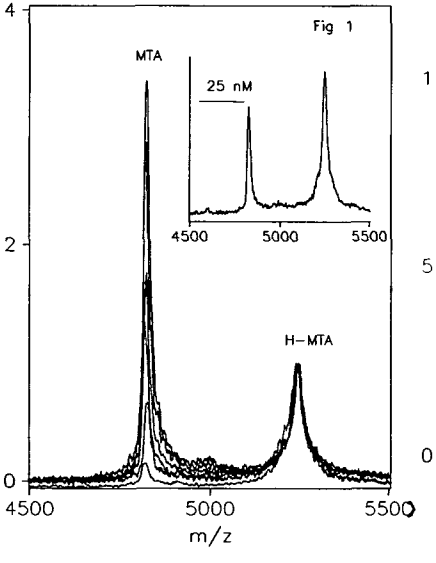
While the qualitative nature of the assay is obvious -- specific antigens are selectively retrieved from solution and identified in the mass spectrum at characteristic m/z values -- the quantitative nature of the assay is not. Considering that the criteria for successful quantitative MALDI analysis - the need to introduce an internal reference species (IRS) into the mass analysis in order to compensate for signal variations due to different laser irradiances and sample preparations [Nelson, R.W. *et al. Anal. Chem.* **66**, 1408 (1994)] - are further complicated by the sub-microliter volumes associated with the affinity isolation step, novel methods of IRS introduction are necessitated. These methods should be, within reason, fairly independent of both the volume of the analytical sample, and the volume of the affinity reagent. The most obvious approach is introduction in a manner analogous to that by which the analyte is retained, i.e., the internal reference species is introduced into solution to be retrieved by the affinity reagent. In this way, precise quantities of IRS can be delivered into the relatively large volumes of analytical sample (100's of microliters). Also, as long as the affinity reagent is not saturated by either the analyte or IRS, the approach becomes independent of the volume of affinity reagent used. Retrieval of the IRS can be accomplished by either; use of two antibody/antigen systems (the antigens being the analyte and the IRS), or, a single antibody/antigen system capable of retrieving the antigen and a modified variant of the antigen (used as an IRS). We have undertaken both approaches to quantitative MSIA and report here our findings on the latter; quantitative methods utilizing a single antibody system and modified variants of the antigen as IRSs.

RESULTS

Fig. 1 shows the results of a quantitative MSIA applied to the isolation of the toxin, myotoxin *a* (MTA, MW = 4,822), from human whole blood containing 0.002 mg/mL *C.v. viridis* venom. A version of the myotoxin *a* in which the lysines had been converted to homoarginine (H-MTA, MW = 5,242) was used as an internal reference species. Samples containing 10 - 100 nM of purified myotoxin *a* were used to generate a standard working curve **(overlay)** which was then used to quantify the toxin present in the venom-laced sample **(inset)**. A myotoxin *a* concentration of 25 nM was determined for the analytical sample. **Fig. 2** shows an alternate approach in which a series of modified variants of the antigen (MTA iodinated at the tyrosine residues) were introduced into the analytical sample to create an internal calibration "bargraph" for antigen quantification. Each species represents a particular concentration of the MTA **(inset)**. A myotoxin *a* concentration (for blood laced with 0.002 mg/mL venom) of between 20 and 30 nM is indicated.

CONCLUSION

Quantitative mass spectrometric immunoassays have been developed which use a single species of antibody covalently immobilized on a solid support to retrieve both the intrinsic antigen and modified variants of the antigen which have been introduced into the analytical system as internal reference species. A traditional working curve method has been employed and found to give reasonably accurate quantitative estimates (~ 10%) over at least an order of magnitude range of antigen concentration. Alternatively, the calibration scale can be built into the assay as a "bargraph" of multiple, mass-displaced variants of the antigen, each of an intensity indicative of a different antigen concentration. In this manner, antigen quantitation can be performed by simply equating antigen signals with those of the nearest concentration markers.



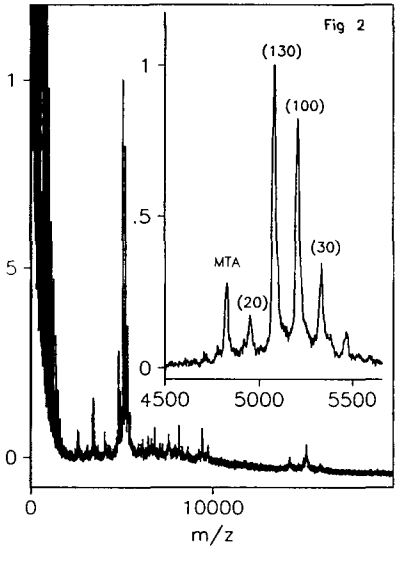


Fig. 1 Overlay of calibration spectra for MTA quantitative MSIA. The inset shows a MSIA spectrum of an analytical (blood) sample containing 0.002 mg/mL CVV venom.

Fig. 2 "Bargraph" method of quantitation in which the calibration curve is built into the MSIA spectrum. Iodinated MTA species were introduced into the analytical sample at levels to indicate 20, 130, 100, and 30 nM. The approximate concentration of MTA was then determined by equating the antigen signal with that of the nearest concentration markers. In this case, an antigen concentration of between 20 and 30 nM is indicated.

Analysis of Flunixin Residues in Animal Tissues by NICI-GC-MS

David Kwok, Pauline Chow, Larry Young and Brian Mori

Health Protection Branch, Health Canada
3155 Willingdon Green, Burnaby, B.C. Canada V6S 2J6

Introduction

Flunixin (Banamine®), 2-[[2-methyl-3(trifluoromethyl)phenyl]amino]-3-pyridinecarboxylic acid, (FLU) is a potent non-steroidal, anti-inflammatory and antipyretic veterinary drug which has been evaluated for the treatment of bovine respiratory disease and acute endotoxin-induced bovine mastitis in food-producing animals. FLU is currently not permitted for use in food-producing animals in Canada. Previous pharmacokinetic studies of the radiolabelled drug in cattle have suggested the persistence of tissue bound residues, creating concerns in the assessment of total residue depletion data.

To survey and determine the state of compliance of targeted food commodities with respect to veterinary drug residues, a SIM-NCI-GC/MS method has been developed for the confirmation and quantitation of FLU in pork and beef liver tissues with a limit of quantitation (LOQ) at 10 ppb.

Experimental

A HP Model 5988A mass spectrometer was interfaced to a Model 5890 GC under the control of a Model 59970C Pascal Chemstation for automated analysis. A DB-5ms, 30m x 0.25mm id x 0.25μm, capillary column was used with a temperature program and with helium as a carrier gas at a column head pressure of 12 psi (uncompensated). The injector and transfer line temperatures were at 250°C and 280°C, respectively. Mass spectral data were collected in the negative ion mode with a dwell time of 50 msec. Electron multiplier voltage was at 3000eV. Methane was used as a reagent gas with an ion source temperature and pressure at 180°C and 1.2 torr, respectively.

Beef and pork liver tissues were fortified with FLU. Niflumic acid (NFA) was used as an internal standard. An aliquot of 5.0±0.1g tissue was acidified with 2 ml of 6 M HCl followed by extraction with 100 ml of dichloromethane (DCM):acetone (1:1) by homogenization with a Polytron® in a 250 ml glass centrifuge bottle. The sample was centrifuged at 2000 xg and the solvent was decanted through a glasswool plug into a collection flask. The sample was likewise extracted with an additional 2 x 100 ml solvent. An aliquot of 75 ml of DCM was added to the pooled extract followed by passing the sample through a 100 g anhydrous sodium sulphate column. The solvent was removed by rotatory vacuum evaporation and the sample was reconstituted with 10 ml of DCM.

Sample purification was carried out using a 5g BondElut Florisil® solid-phase extraction cartridge, previously conditioned with 10 ml of DCM. Following sample loading, 10 ml of acetone was eluted through the cartridge and discarded. FLU was eluted by gravity with 50 ml of DCM:methanol (4:6). The solvent was removed by rotatory vacuum evaporation and the sample was reconstituted with 1 ml of acidified methanol. Methylation of FLU was carried out with 3 ml of freshly prepared ethereal diazomethane. The sample was subsequently evaporated to dryness under nitrogen in a 40°C block heater followed by reconstitution with 0.5 ml of iso-octane:acetone (9:1) for GC/MS analysis.

Results and Discussions:

Beef and pork liver samples were fortified with flunixin at 10, 50 and 100 ppb as quality control (QC) samples during method validation. Linear least square regression analysis was performed (without weighting) for the calibration samples on each analytical day. The calculated QC concentrations, expressed as percent deviation from the expected values (**Table 1**), were used to assess assay accuracy (% deviation), precision (%RSD) and overall assay bias.

Table 1. QC data for flunixin fortified in beef and pork liver at 10, 50 and 100 ppb.

	Beef			Pork		
ppb fortified	ppb calculated	% deviation from expected	%RSD	ppb calculated	% deviation from expected	%RSD
10	11.2	12.2		9.4	-5.8	
10	10.3	3.2		9.0	-10.1	
10	10.2	1.6		10.6	5.7	
10	10.6	5.9		10.0	0.4	
10	10.8	8.1		12.7	27.3	
10	10.3	3.0	3.6	11.3	13.2	12.9
50	48.9	-2.3		46.1	-7.8	
50	45.0	-10.0	5.9	48.4	-3.3	3.4
100	98.7	-1.3		100.9	0.9	
100	104	4.0	3.7	101.5	1.5	0.4
mean bias		2.4			2.2	

An assay LLOQ of 10 ppb was determined (n=6) with mean inter-day assay accuracy of 5.7% and 5.1% deviation from the expected concentration in beef and pork liver, respectively. An inter-day assay precision (%RSD) of 12.9 and 3.6 were obtained for beef and pork samples, respectively.

The mean (n=2 to 4) assay extraction recovery of FLU from beef liver fortified at 10, 50 and 100 ppb were found to be 70%, 69% and 98%, respectively. The mean (n=2 to 4) of FLU from pork liver over the same concentrations were determined to be 86%, 104% and 127%, respectively.

A representative selected-ion chromatogram and mass spectrum of FLU and NFA is shown in **Figure 1**. Mass spectral data acceptance criteria for the confirmation of FLU residues include i) GC chromatographic retention time established from the QC samples; ii) mass ion fragment ratio at m/z 310/280 and iii) isotope abundance ratio at m/z 310/311. This assay has been demonstrated to be a sensitive and reliable procedure for the routine confirmatory determination of FLU in beef and pork liver tissues.

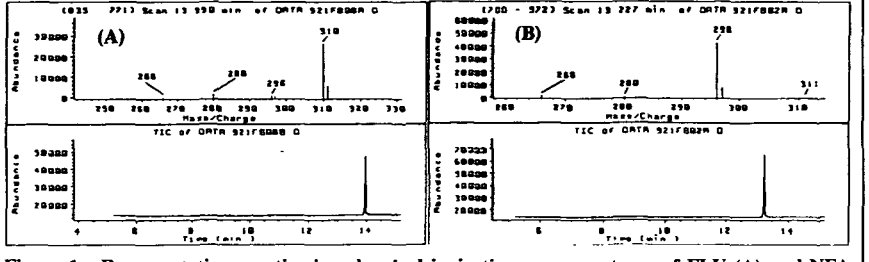

Figure 1. Representative negative ion chemical ionization mass spectrum of FLU (A) and NFA (B) as their methyl ester derivatives.

Metabolism of Perillyl Alcohol Following a Single Oral Dose in the Dog as Determined by Gas Chromatography/Mass Spectrometry

Limonene, a monocyclic terpene that is a major component in many citrus essential oils, inhibits post-translational isoprenylation of 21-26 kDa cellular proteins implicated in cell proliferation [1]. Perillyl alcohol was found to be one of the most potent compounds among a group of 24 limonene-related monoterpenoids tested for antitumor activity *in vitro* [2]. Our efforts focussed on characterizing the disposition of perillyl alcohol and identifying its principal circulating metabolites.

Sample Preparation and Analysis. Briefly, plasma samples (50 μl) were mixed with 50 μl of an aqueous solution 0.2 M in phosphoric acid and 1 M in potassium chloride, and then 100 μl of *tert*-butyl methyl ether containing the internal standard (perillyl hexyl ether) was added. Following mixing and centrifugation, the upper organic phase was transferred to a silanized borosilicate vial and analyzed by GC/MS, which was performed using a 5890 Series II GC in combination with a 5971A mass selective detector controlled by a DOS series MS ChemStation (Hewlett-Packard). Detection (EI, 70 eV) was performed by selected ion monitoring, measuring ions at *m/z* 121 and *m/z* 122 sequentially, utilizing a 75 ms dwell time. Standard curves were constructed by plotting the peak area ratio of each analyte to the internal standard against the respective concentration of the analyte. Linear least squares regression was performed using a weighting factor of $1/Y_{obs}$, without inclusion of the origin. Analyte concentrations in unknown samples were calculated using results of the regression analysis. The lowest concentration of analyte quantified with acceptable reproducibility in 50 μl of plasma was 0.25 μg/ml. The GC/MS assay was linear over the range of 0.25 to 7.5 μg/ml. Coefficients of variation for the mean predicted analyte concentration of each of the seven plasma standards were less than 10% within this concentration range for 12 standard curves prepared independently and assayed over a 4 week period.

Results. Plasma samples acquired from a beagle dog following oral administration of 250 mg/kg perillyl alcohol were analyzed by GC/MS using mass scanning detection. Mass spectra (EI) and retention times of the chromatographic peaks observed in plasma samples were compared to authentic standards of the potential phase I metabolites. Results of these analyses indicated the presence of only perillic acid and dihydroperillic acid (as a *cis-trans* mixture), representing the major and minor metabolites, respectively. The isomers of dihydroperillic acid could be distinguished on the basis of their mass spectra.

The plasma concentration of perillyl alcohol remained below the limit of detection (about 1.5 μM by selected ion monitoring) at all times after dosing. Peak plasma concentrations of perillic acid and dihydroperillic acid were 0.90 and 0.036 mM, occurring at 2.5 and 5.0 hr, respectively. Plasma levels of perillic acid could be monitored for 24 hr after dosing, whereas dihydroperillic acid was only detectable for 12 hr. The area under the plasma concentration-time profile of perillic acid (14.23 mM·hr) was 21-times greater than for dihydroperillic acid (0.69 mM·hr).

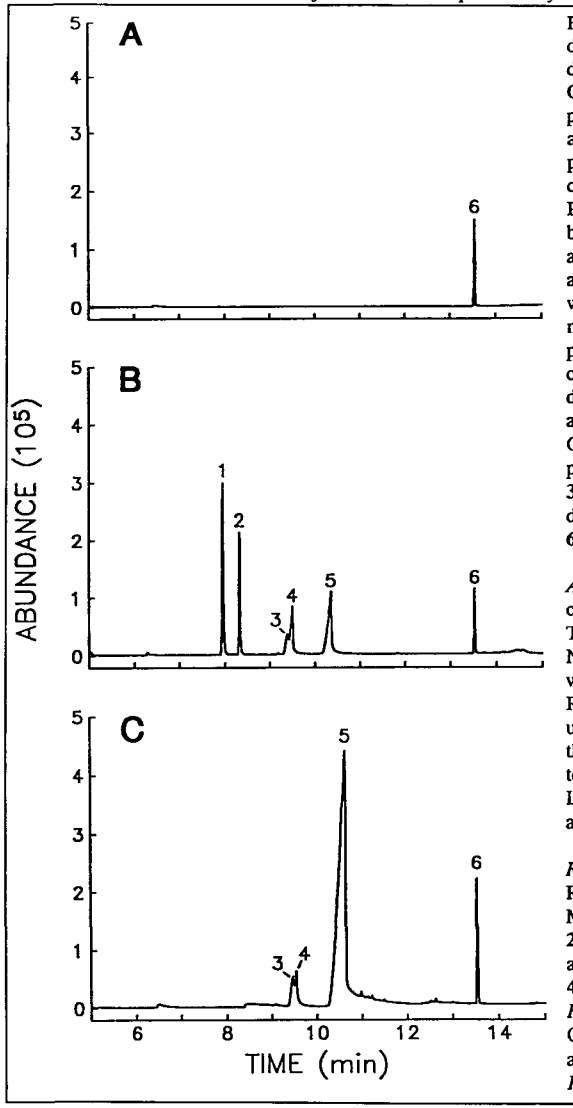

Figure 1. Gas chromatograms determined with mass selective detection at *m/z* 121 and 122. **A**, Chromatogram of drug-free dog plasma. **B**, Plasma to which perillyl alcohol and authentic samples of its potential metabolites were added at a concentration of 0.1 mM. **C**, Plasma acquired from a female beagle dog 8 hr after the administration of 250 mg/kg perillyl alcohol po. The sample was assayed without dilution, which resulted in minor distortion of the perillic acid peak due to column overloading, to clearly demonstrate the absence of drug-related peaks other than perillic acid and dihydroperillic acid. Chromatographic peaks: **1**, perillaldehyde; **2**, perillyl alcohol; **3**, *cis*-dihydroperillic acid; **4**, *trans*-dihydroperillic acid; **5**, perillic acid; **6**, IS (perillyl hexyl ether).

Acknowledgments. This study was conducted in cooperation with the Toxicology Branch, DTP, DCT, NCI. Dosing and sample collection were performed at the Midwest Research Institute (Kansas City, MO) under contract NO1-CM-37836 from the NCI (Bethesda, MD). We wish to thank Tyra L. House and Tracy L. Wolfe for their expert technical assistance in analyzing the samples.

Positive chemical ionisation GC-MS analysis of nicotine and cotinine.

Dalene M.[2], Loftus, N J.[1], Skarping G.[2], Speakman A.[1]
[1]Fisons Instruments, VG Organic, Crewe Road, Wythenshawe, Manchester, UK.
[2]University Hospital, Lund, Sweden.

Introduction.
Tobacco is one of the most widely used stimulants with recognised adverse health effects. In spite of the recognised adverse health effects, the dependence upon nicotine is still high and the prevalence of smoking approaches almost a third of the western population.

The risk of developing chronic lung disease is not restricted to active smoking, environmental tobacco smoke [ETS] inhalation (often referred to as passive smoking) presents a health hazard to both adults and children It is quite possible that children may be at a greater risk given the incomplete development of the respiratory and immune systems. Risk assessment studies of ETS exposure with children has taken into account exposure measured by non-invasive techniques such as air sampling and biological monitoring. The latter approach can be used as a direct measure of nicotine intake, however to provide meaningful data there is a clear need for a sensitive and specific assay using an appropriate biomarker Measuring the major metabolite of nicotine, cotinine, has been shown to be the intake marker of choice. In this study urinary levels of both nicotine and cotinine were measured by GC-MS using positive chemical ionisation detection in assessing the extent of exposure to ETS in populations of children in Sweden aged between 7-9 years with smoking and non-smoking parents

Methods.
Nicotine and cotinine were extracted from urine [2mls] spiked with trideuterated internal standards into dichloromethane [3mls] following the addition of sodium hydroxide [0.5mls 5N NaOH]. The two phases were shaken for 20 minutes and the layers were separated after centrifugation at 1500g for 10 minutes Most of the aqueous layer was removed before being placed in a cooling solution of solid carbon dioxide and acetone to freeze the remaining portion of water. The solvent layer was then transferred to a clean new vial and blow to dryness under a gentle stream of nitrogen. For GC-MS analysis the sample was then reconstituted in toluene [1ml] and the components separated on a DB5-ms column [30m in length, 1 0μm film thickness, 0.22mm internal diameter] using a splitless injection.

The MD800 mass spectrometer (Fisons Instruments, VG Organic) was optimised for the positive chemical ionisation detection of nicotine and cotinine using a source temperature of 250°C, interface temperature 280°C, emission 300μA, and electron energy set to 70eV. Ammonia reagent gas pressure optimised for

the intensity of m/z 35 proved optimum for cotinine. Single ion recording acquisition monitoring ions for nicotine [m/z 163], cotinine [m/z 177]; together with the corresponding trideuterated internal standards monitored at m/z 166 and 180 respectively using a dwell time of 0.2 seconds, span 0 10 amu and an inter-scan delay of 0 02 seconds.

Results.

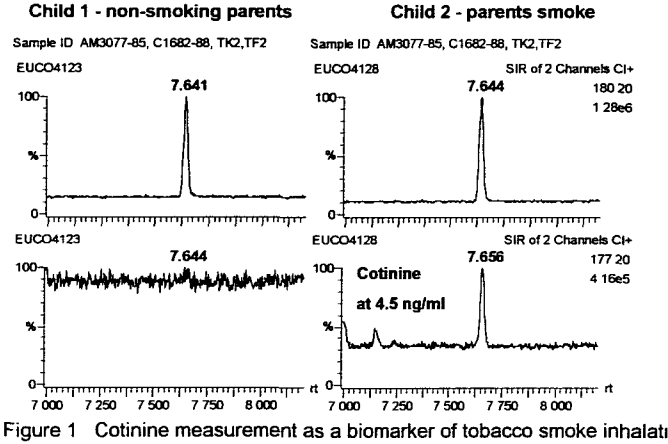

Figure 1 Cotinine measurement as a biomarker of tobacco smoke inhalation from passive smoking in children. The mass chromatograms of cotinine [m/z177] and the ($^2H_3$) internal standard [m/z180] in two urine samples

The results of the study show a clear relationship between tobacco smoke intake in children and parental smoking habits.

No. of children	130	12	23	21
Average	0.1	0.5	1.11	1.19
Minimum	0	0	0.2	0.1
Maximum	1 3	1.8	2 7	5 1
Median	0.04	0.24	0.81	0 88
	Neither	Father only	Mother only	Both

Conclusion.
Quantitative positive chemical ionisation has proved to be a precise and accurate means of measuring urinary levels of nicotine and cotinine [regression coefficients were typically r>0.9996; with a precision of 5.8% on absolute raw area, n=24 for the 20ng/ml standard, LOD at 0.1ng/ml]

Analysis of Anagrelide, in Human Plasma by GC / ECNCI MS.

Suresh N. Yeola[1], Sam A. Saleh[1], Stephanie C. Sanchez[1], Sara J. Kambouris[3], Ajai K. Chaudhary[1,2], Bruce H. Migdalof[4] and Ian A. Blair[1,3]

Department of Pharmacology[1], Biochemistry[2] and Chemistry[3], Vanderbilt University School of Medicine, Nashville, TN 37232
Roberts Pharmaceutical Corporation[4], Meridian Center III, 6 Industrial way west, Eatontown, NJ 07724

Anagrelide, (6,7-dichloro-1,5-dihydroimidazo-[2,1-b]-quinazolin-2(3H)-one monohydrochloride) is a potent inhibitor of agonist induced platelet aggregation. However, anagrelide was found to cause thrombocytopenia when given in high dosage to normal volunteers. This undesired side effect has been used to advantage for the treatment of myeloproliferative disorders such as thrombocythemia where there is increased platelet production. The present work represents a quantitative analysis of anagrelide (6,7-dichloro-1H-2,3,4,5-tetrahydroimidazo[2,1-b]quinazolin-2-one) in human plasma[1]. The assay is based on gas chromatography/electron capture negative chemical ionization mass spectrometry (GC/ECNCI MS). The internal standard used in the assay was a [^{13}C]labeled analog of anagrelide (2,3-[$^{13}C_2$]-6,7-dichloro-1H-2,3,4,5-tetrahydroimidazo[2,1-b]quinazolin-2-one). The synthesis[2] of an internal standard was performed as shown in Scheme 1. Separation of anagrelide and the internal standard from interfering substances was efficiently carried out by solvent extraction of the plasma. Anagrelide and the internal standard were then converted to their corresponding pentafluorobenzyl (PFB) derivatives for GC/ECNCI MS analysis. Full scan spectra typical of PFB derivatives were observed. The major negative ions for anagrelide corresponding to the molecular ions (M) - PFB appeared at *m/z* 254, *m/z* 256, and *m/z* 258 in the ratio of 9:6:1. These ions contained [$^{35}Cl_2$], [$^{35}Cl^{37}Cl$], and [$^{37}Cl_2$], respectively. Similarly, the [M-PFB]$^-$ ion for the internal standard appeared at *m/z* 256, *m/z* 258, and *m/z* 260 (Figure 1a, 1b).

The ions *m/z* 254 for anagrelide and *m/z* 258 for internal standard were monitored. Chromatography was carried out on a 30 m SPB-50 fused silica capillary column using a temperature programmed from 70 °C to 300 °C. The extraction procedure from plasma involved initial adjustment of the plasma to pH 9.2 and extraction into *tert*-butylmethyl ether (TBME)/ethyl acetate (4:1) with subsequent extraction from the organic solvent into dilute hydrochloric acid. This was followed by making the aqueous layer basic and back-extraction into TBME/ethyl acetate (9:1). Derivatization was carried out at room temperature by reaction with pentafluorobenzyl bromide dissolved in acetonitrile in the presence of diisopropylethylamine. Analyses were carried out using selected ion monitoring of *m/z* 254 (anagrelide) and *m/z* 258 (internal standard). Calibration curves obtained by plotting the peak height ratio of *m/z* 254 to *m/z* 258 against the amount added to the plasma, were non-linear (polynomial) in the range 0.083 ng to 8.248 ng using a weighted (1/concentration^2) non-linear regression analysis. Accuracy and precision studies were conducted and the method was found to be accurate and reproducible for anagrelide at the three concentrations that were tested. The lower limit of quantitation was 0.083 ng/mL.

A RAPID ANALYTICAL METHOD FOR THE QUANTITATIVE DETERMINATION OF ω-HYDROXY-TRIDECANOIC ACID DIMETHYLAMIDE IN HUMAN PLASMA

M. BRUDNY-KLOEPPEL, C. GUENTHER & C. WEISS
Institute of Pharmacokinetics
SCHERING AG, D-13342 Berlin, Germany

ω-Hydroxy-tridecanoic acid dimethylamide (ZK 118 372) is developed for the topical therapy of acne, because of its antimicrobial, comedolytic and anti-inflammatory properties. Prior to clinical studies, toxicological characterization was carried out with different animal species. In order to study the pharmacokinetics of the drug in man, ZK 118 372 was tested after intravenous and topical application. The evaluation of the experimental data required a sensitive and specific GC/MS method, which enables the quantification of the drug from the different biological matrices in a concentration range of 0.1 to 500 ng per ml serum or plasma.

The assay was developed and validated using rabbit serum as biological matrix. For the evaluation of clinical studies, the method was revalidated with human plasma. The drug and the internal standard ω-hydroxy-tridecanoic acid di-n-propylamide (ZK 135 704) were isolated from the biological matrix by a liquid-liquid-extraction using nanograde peroxide-free diethylether. The serum extracts were derivatized with 3,5-bis(trifluoromethyl) benzoyl chloride. For the separation a 30 m RTX®-5 Amine column with an internal diameter of 0.25 mm and a film thickness of 0.5 µm was used. The compounds were detected by means of NCI-GC/MS. The standard curve was linear in the range of 0.1 to 10 ng/ml and of 10 to 500 ng/ml (Fig. 1). The lower limit of quantification was 0.1 ng/ml with a precision of 14.2 %.

In order to assess the quality of the assay, six quality control samples with concentrations of 0.8, 8, 20, 80, 150 and 400 ng/ml plasma were included in the sample batch and were each analysed 5-fold. Nominal and measured concentrations (mean ± S.D.) as well as precisions (C.V.) and accuracies are presented in Tab. 1. During validation, revalidation and analysis of the clinical study, the intraassay precision of the lowest quality control sample was 5.3 %, 6.7 % and 3.7 %, respectively.

The method developed for the quantitative determination of ZK 118 372 from biological matrices is a rapid and precise analytical procedure. The assay is suitable for pharmacokinetic and bioavailability studies as well as for therapeutic drug monitoring.

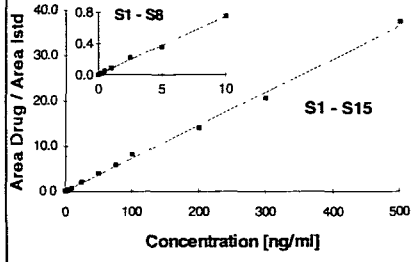

Fig. 1: Standard curve of ZK 118 372 in human plasma

Content [ng/ml]	Mean [ng/ml]	S.D. [ng/ml]	C.V. [%]	Accuracy [%]
0.8	0.77	0.03	3.7	96.3
8	7.68	0.20	2.6	96.0
20	18.8	1.1	5.9	93.8
80	78.6	2.5	3.1	98.2
150	153.3	3.4	2.2	102.2
400	417.6	23.7	5.7	104.4

Tab. 1: Quality criteria of the assay: nominal and measured concentration (mean ± S.D.), intraassay precision (C.V.) and accuracy

The plasma level-time course of ZK 118 372 was investigated in six healthy male volunteers over 50 years of age following intravenous and topical application. During intravenous infusion of 4.2 mg ZK 118 372, drug plasma levels increased rapidly to a maximum of 95 ng/ml at the end of the 10 min infusion period (Fig. 2). Postmaximum plasma levels decreased monoexponentially with a half life (t½) of ca. 2 min and were below the lower limit of quantitation (LLQ) of 0.1 ng/ml within 22 min after the end of infusion. The area under the plasma level-time curve (AUC) was 16 ng*h/ml. The clearance rate (Cl) was calculated to be 4.4 l/min, the apparent volume of distribution (Vc) was 11 l per individual.

After topical application of 50 mg ZK 118 372 as 10 % hydrogel to 100 cm² intact back skin (5 mg formulation per cm²), ZK 118 372 plasma levels did not exceed the LLQ of 0.1 ng/ml. After topical application of an identical dose to damaged skin, from which the stratum corneum was removed by multiple adhesive tape stripping, ZK 118 372 plasma levels exceeded the LLQ within 1 hour, and reached a maximum concentration of 3.1 ng/ml after 4 hours (Fig. 3). Postmaximum ZK 118 372 plasma levels decreased slowly reaching a concentration of 1.1 ng/ml after 24 hours. The $AUC_{(0\text{-}24h)}$-value after application to stripped skin was 44 ng*h/ml. The percutaneously absorbed dose (D) was 11.5 mg, corresponding to 23 % of the dose applied, resulting in a mean percutaneous flux of 4.8 $\mu g*cm^{-2}*h^{-1}$.

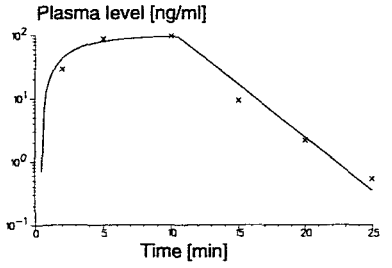

Fig. 2: Semilogarithmic plot of drug plasma level-time course after i.v. infusion

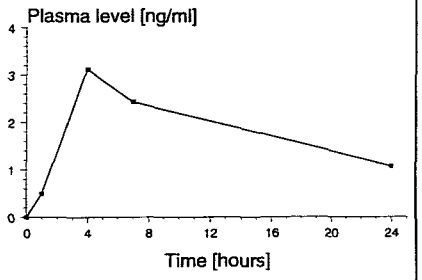

Fig. 3: Drug plasma level-time course after topical application to stripped skin

The basic pharmacokinetic properties of ZK 118 372 were determined after intravenous infusion. ZK 118 372 exhibited a limited distribution throughout the body and was very rapidly eliminated from the plasma. The drug was extensively metabolized as indicated by radio-HPLC[1] and the high clearance rate. The clearance rate exceeded distinctly the hepatic blood flow indicating additional extrahepatic metabolism. The very rapid elimination from plasma might be seen as an advantage for a topically applied drug, because the systemic drug load is reduced.

ZK 118 372 was released from the hydrogel formulation to the skin as was demonstrated following application to stripped skin. Only after adhesive tape stripping prior to the application, percutaneous absorption of ZK 118 372 was detectable. Thus, the stratum corneum has to be considered as the major skin diffusion barrier for ZK 118 372.

Quantitation of Odd-Numbered Long Chain Fatty Acids in Red Cell Membranes

Giordano G.*, Burlina A.B., Magarotto M., Edini C., Zacchello F.
Department of Pediatrics, University of Padova, Padova, Italy

INTRODUCTION

Patients with propionate metabolism disorders as propionic acidemia (PA) and methylmalonic acidemia (MMA) accumulate propionyl-CoA in large amount. Odd carbon number fatty acids (OLCFA) are precursors of propionyl-CoA but this metabolite can replace acetyl-CoA as a "primer" for de novo long chain fatty acids synthesis, leading to the formation of odd-numbered fatty acid.

Recently Wendel et al. (1) reported that the relative abundance of OLCFA (C15 and C17) in red cell membranes are elevated in patients with MMA and PA under catabolic conditions.

In order to evaluate if the levels of C15 and C17 OLCFA may represent an early biochemical parameter that can be used for long term assessment of these disorders we studied, in red cell membranes of 10 subjects affected by MMA (n=7) and PA (n=3), the OLCFA with a new quantitative method GC/CIMS in the positive ion mode with isobutane as the reagent gas.

MATERIALS

Blood sample of seven patients with methylmalonic acidemia B_{12} unresponsiveness and three patients with propionic acidemia were studied. All the subjects were diagnosed on the basis of clinical presentation and urinary metabolite excretion patterns In every patient, after an initial phase of induction of anabolism and/or toxin removal, treatment was started which consisted of restriction of dietary protein intake, supplementation of the diet with essential amino acids free of valine, isoleucine, methionine, and threonine, as well as carnitine and metronidazole.

In particular, one patient with severe form of MMA difficult to manage was weekly monitored for 8 months to better define the relationship among OLCFA urinary organic acids and different diet prescriptions. A group of patients with low protein diet, including PKU and urea cycle disorders, were also studied. For each patients lactate and ammonemia were also measured

METHODS

Red blood cells were isolated from heparinized sample using 154 mM NaCl and 0.23 mM butylated hydroxy toluene and stored at -20° C until analysis (2). Lipids were extracted from 0.1 ml of packed red cells twice with 4ml of isopropanol and 2 ml of chloroform. The extract was evaporated to dryness using nitrogen. Methyl esters were prepared using methanolic HCl for 45 min at 100° C, then neutralized with potassium carbonate. The methyl esters were extracted with hexane and concentrated to a volume of 100 µl. Chromatographic separation was performed on 25 m 0.2 mm i.d. H.P. SE-52 capillary columns using helium as the carrier gas. Quantitation of the fatty acid methyl esters was carried out using GC/CIMS (MD800 Fisons) in the positive ion mode with isobutane as the reagent gas. The data system was programmed to acquire at 70 eV, 300 mA emission, 0.08s dwell time, 0.02s interscan delay and 0.3 span. The abundances of $[M+H]^+$ positive ions of C15:0(m/z 257), C17:1(m/z 283), C17:0(m/z 285) and the internal standard C15:1(m/z 255) were recorded using selected ion monitoring technique.

Concentrations of OLFCA were expressed as µg/mg of membrane protein. They were measured from the erythrocyte membranes by a modified Bradford assay after wash with PBS, lyse with a lysing buffer and a centrifugation at 29.000xg at 4°C for ten min.(3)

RESULTS

1.There were no differences between the group on low protein diets and the normal subjects.The concentrations of $C_{15:0}$, $C_{17:1}$ and $C_{17:0}$ were in the range of 1-5, 1-2,2-4µg/mg respectively. (Table 1)

2.Two patients who were monitored during the course of acute episodes of decompensation showed significant increase in the concentrations of OLFCA immediately before clinical symptoms became apparent (Table 1). In one patient with a severe form of MMA, C15 and C17 concentrations increased dramatically following the decompensation episode (Figure 1). After one month of treatment, including overnight infusion, the same metabolite returned to asymptomatic levels.

3.We propose that the monitoring of OLFCA levels could represent a valuable tool in the management and follow up of patients with propionic and methylmalonic acidemia.

Analysis of Fadrozole Pseudoracemic Mixture in Human Plasma Using a Novel Approach for the Analysis of Nitrile Containing Compounds By GC/MS

Iannucci, Robert, M., Linberg, Leonid, F. and Powell, Mark, L.

Ciba Pharmaceuticals, Research Dept., Summit, NJ 07901

Fadrozole is as an orally active, non-steroidal aromatase inhibitor under clinical development for the treatment of estrogen-dependent mammary tumors. Fadrozole is a racemate The (-)-(S)-enantiomer (i.e., CGS 20 287A, eutomer) is responsible in-vitro and in-vivo for the inhibition of the aromatase enzyme system, while the (+)-(R)-enantiomer (i.e., CGS 20286A, distomer) is much less active towards this enzyme system. Fadrozole contains a nitrile group which makes it difficult to analyze by gas chromatography/mass spectrometry (GC/MS) because of its polarity and low volatility. Fadrozole also has a molecular weight of 223 which is coincident with the bleed peaks common to polysiloxane-based GC capillary columns and as a consequence, there is difficulty in attaining very low sensitivity in the EI mode. A previous analytical method utilizing GC/MS in the electron impact (EI) mode was developed by Ackermann and Kaiser to quantitate underivatized fadrozole in human plasma and urine with a limit of quantitation (LOQ) of 1.1 ng/mL [Biomed. Environ Mass Spec., 18 538 (1989)]. A new approach has been developed which involves reduction of the nitrile to the amine by lithium aluminum hydride. This is followed by derivatization of the amine with pentaflouroproprionic anhydride This method allows the use of the more sensitive negative chemical ionization (NCI) mode and shifts the monitored ions into a higher mass range free of bleed peaks and chemical noise. The method was validated with a LOQ of 0.25 ng/mL for both unlabeled and $[D_4]$-fadrozole. An M+6 stable isotope of fadrozole ([M+6]-fadrozole) was used as the internal standard.

This analytical method was used to determine the pharmacokinetics of the fadrozole enantiomers after administration of an 8-mg fadrozole HCl pseudoracemate dose containing a 1:1 molar mixture of unlabeled CGS 20286A and $[D_4]$-CGS 20287A to patients.

Mass spectrometry demonstrated the $[M-HF]^-$ ion derived from the perfluoroacyl derivative of fadrozole to be the major ion suitable for quantitation. For single ion monitoring analysis, the $[M-HF]^-$ions monitored were m/z 499, 503 and 505 for the unlabeled fadrozole, $[D_4]$-fadrozole and the internal standard ([M+6]-fadrozole), respectively.

Average correlation coefficients (r) of 0.9932 and 0.9909 were obtained for unlabeled fadrozole and $[D_4]$-fadrozole, respectively, indicating a good fit to the weighted linear regression model used. The overall accuracy, as indicated by the mean relative recovery for quality control samples was 105.3% for unlabeled fadrozole and 107.2% for $[D_4]$-fadrozole. The LOQ was 0 25 ng/mL and was defined as the lowest drug concentration for both unlabeled fadrozole and $[D_4]$-fadrozole, where acceptable accuracy was within 100 ± 15% and precision (CV) ≤ 20%.

Figure 1 shows the differences in the mean plasma concentrations of CGS 20286A and $[D_4]$-CGS 20287A. The pharmacokinetic behavior of the two enantiomers was significantly different. The (+)-R-enantiomer (CGS 20286A) showed significantly higher mean plasma concentrations than the (-)-S-enantiomer (CGS 20287A). CGS 20286A and $[D_4]$-CGS 20287A demonstrated mean(± SD) C_{max} values of 22.5(4.7) and 4.7(2.3) ng/mL, respectively CGS 20286A and $[D_4]$-CGS 20287A also demonstrated significantly different AUC(0-72) and $T_{1/2}$ values i.e., mean(± SD) AUC(0-72) values of 316 2(87 1) and 15.8(9 5) ng·hr/mL and mean(± SD) $T_{1/2}$ values of 13.0(4.1) and 2.0(0.6) h, respectively. In addition, CGS 20286A and $[D_4]$-CGS 20287A showed mean(± SD) T_{max} values of 1.6(0.4) and 1.0(0.3) h, respectively

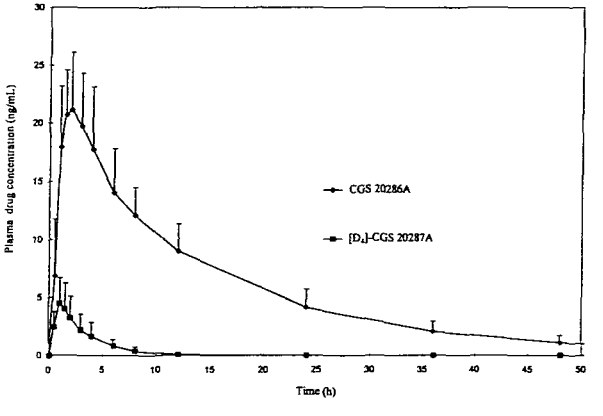
Mean plasma CGS 20286A and $[D_4]$-CGS 20287A concentrations in patients administered 8 mg fadrozole HCl pseudoracemate



Sonic Spray Ionization for API Mass Spectrometry

A. Hirabayashi, M. Sakairi, Y. Takada and H. Koizumi
Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo 185, Japan

We have developed a sonic spray ionization method in which a solution is sprayed from a fused-silica capillary with gas flow coaxial to the capillary. Protonated molecules produced from 1-μM solutions of molecules, regarded as neurotransmitters such as catecholamine, by this ionization method were analyzed with a quadrupole mass spectrometer. The S/N ratios for the protonated molecules in the mass spectra were nearly equal. Furthermore, protonated dopamine molecules were detected in a 10-nM solution.

Introduction

In the past few years, the science of the brain has developed significantly owing to a breakthrough in the functional magnetic-resonance imaging method.[1] For the next step, an understanding of the functional chemistry of the brain is important. A combination of mass spectrometry with on-line liquid-phase separation methods, such as capillary electrophoresis and liquid chromatography, is one candidate for analyzing neurotransmitters, such as catecholamine. The sensitivity of this method is, however, rather low in comparison with that of the electrochemical detection method. This is mainly because the current interfaces used in spray ionization methods, such as the atmospheric pressure chemical ionization[2] and electrospray (or ion spray)[3] methods, have low ion-production efficiencies for these molecules.

We previously developed a spray ionization method for the interfaces used in capillary electrophoresis/mass spectrometry (CE/MS) and liquid chromatography/mass spectrometry (LC/MS). In this "sonic spray" ionization method,[4] a solution introduced through the capillary is sprayed with gas flow coaxial to the capillary, and the ions are produced at atmospheric pressure. The ion intensity strongly depends on the gas velocity and reaches a maximum at a Mach number of about one: the sonic velocity.

Experimental Setup

The details of our experimental setup were described elsewhere,[4] so a brief account is given here. A solution was pumped by a syringe pump into the fused-silica capillary of an ion source at a flow rate of typically 30 μl/min. The fused-silica capillary tip was inserted into an orifice. The potential of the ion source was set to the ground level. Nitrogen gas was passed through the orifice to the atmosphere. A spray was thus generated in which droplets and free ions were produced. A quadrupole mass spectrometer was used to analyze the ions; the scan period was 4 s for m/z = 0 to 1000.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Results and Discussion

Typical mass spectra obtained from epinephrine and norepinephrine solutions in 50:50 methanol-water at concentrations of 1 μM are shown in Fig. 1. Protonated epinephrine and norepinephrine molecules were clearly detected at m/z = 184 and 170, respectively. Furthermore, protonated molecules of methanol, hydrated methanol, and methanol dimer were detected at m/z = 33, 51, and 65, respectively. The ion at m/z = 18 is the ammonium ion.

Solutions of dopamine, serotonin, γ-amino-butyric acid (GABA), and dopa with solution concentrations of 1 μM were also analyzed. The S/N ratios for the protonated molecules in the mass spectra were nearly equal. We also analyzed the dopamine solution at a concentration of 10 nM. The S/N ratio for the protonated dopamine molecule was about 20. Since the S/N ratio of the protonated dopamine molecule produced by the current ion spray ionization method from a 1 μM solution is about 20, the ion production efficiency of the sonic spray is two orders of magnitude higher than that of the ion spray. Note that a concentration of 10 nM is at about the detection limit of the electrochemical detector, which is connected to the capillary zone electrophoresis for analyzing the catecholamine.[6] With respect to the S/N ratio, the sensitivity of sonic spray mass spectrometry is an order of magnitude higher than that of electrochemical detection.

Electrospray LC/MS With Ion Trap TOFMS

Randy W. Purves and Liang Li*
Department of Chemistry, University of Alberta
Edmonton, Alberta, Canada T6G 2G2

Electrospray ionization (ESI) has become an increasingly important technique for ion generation in mass spectrometry. ESI is particularly useful for the analysis of polar and ionic species, including peptides and proteins. Since the solutions used for liquid chromatography (LC) are compatible with the ionic solutions used in ESI, these two techniques can be readily combined for on-line chemical identification and structural analysis. Presently, a quadrupole mass spectrometer is most commonly used for this type of analysis. However, for rapidly eluting species from an LC column, a time-of-flight mass spectrometer (TOFMS) possesses some inherent advantages, such as allowing for a high data acquisition rate over the entire mass range, and having a high detection sensitivity. Coupling of an ESI source to a TOFMS has been previously achieved either with the source orthogonal to the flight tube, or in a parallel configuration with an ion trap [1].

Reported here is the development of a linear TOFMS for the mass analysis of ions generated by ESI. Although this instrument was designed to be used either orthogonally, or with the ion trap, the work presented here is obtained exclusively with the ion trap present. A schematic of the instrumentation used in this study is illustrated in Figure 1. The sensitivity and resolution of this instrument are explored. With this linear TOFMS system, mass resolution values in the range of 600 to 950 fwhm are routinely obtained. Figure 2 represents a mass spectrum of equine cytochrome C in which the major peak, 16^+, has a mass resolution of 920 fwhm. This represents a marked improvement over previously reported optimal resolution values for linear TOFMS instruments. Shown in Figure 3A is an ion profile of an injection of 75 fmol of bradykinin, or 0.5 μL of a 125 nM solution. The ion profile is obtained by integrating the area of the major bradykinin peak, which corresponds to the 2^+ charge state, as a function of time. Figure 3B represents the complete mass spectrum that was obtained from this injection. Work on actual separations of protein mixtures using a micro-column LC system has been recently initiated.

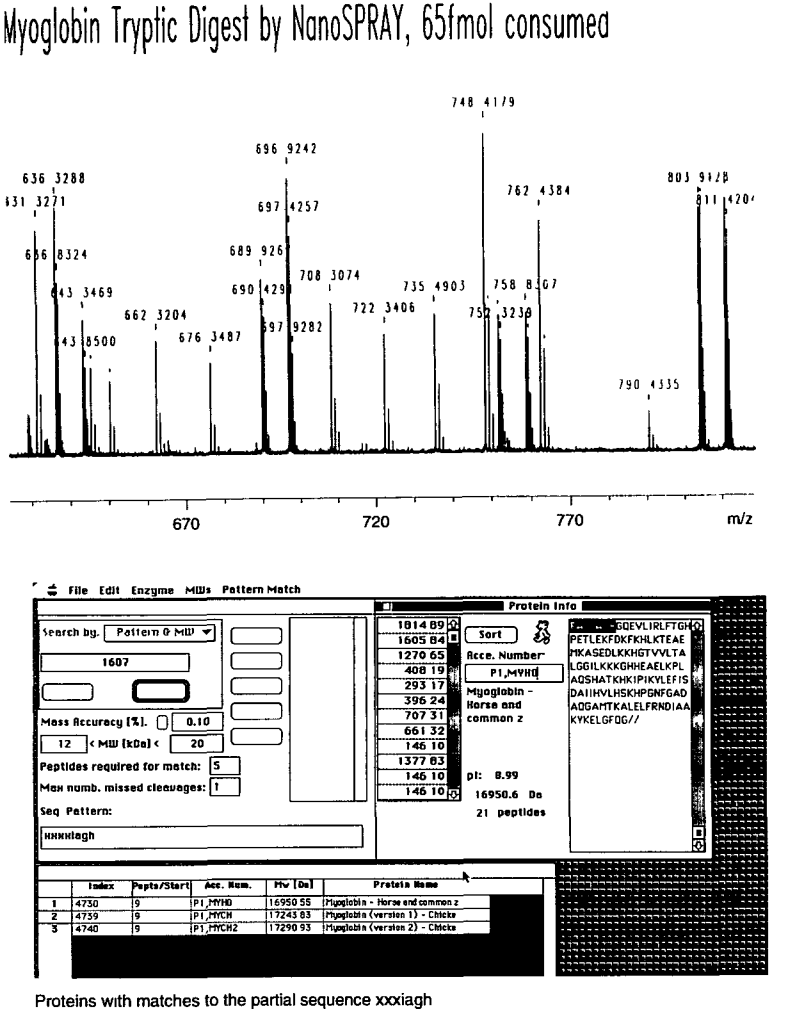
Current electrospray ion sources spray liquid from a needle at flow rates above 1µl/min. Optimization of conditions for high sensitivity MS/MS analysis may consume over 100 pmol of a sample. The use of a new small-scale "micro electrospray" or "NanoSPRAY" needle with an electrospray source permits the analysis of 1 µl or less of solution of low pmol/µl concentration at a flow rate of 25nl/min. Sensitivity enhancements result from more efficient ion evaporation from the smaller droplet and sampling a larger proportion of the ions produced by a combination of a smaller spray and a closer distance. Additionally, a wider variety of solvents, such as pure water or pure organics, can be sprayed without the use of sheath gas or nebulization since the effects of surface tension are less important with this design.

A sample of 2µl of myoglobin tryptic digest (40pmol) was applied to the NanoSPRAY needle. Identifiable peaks resulted from a single scan spectrum with a consumption of 4 fmol and an averaged spectrum using 65fmol is also shown (The presence of high levels of acids and salts in the digest sample results in lower sensitivity than expected from pure peptides in methanol/water/3% acid). The spectrum resulting from the analysis of the tryptic digest of myoglobin showed a number of ions. Charge state are easily determined from the isotopic spacing.

These masses were entered into PeptideSearch, allowing for only ppm errors in mass. Hits to myoglobins were found, with only horse myoglobin matching to 10 of the fragment masses

Using the same sample, one of the masses was isolated for SORI (Sustained Off-Resonance Irradiation) MS/MS. A partial sequence for the peptide resulted which can also be used for searching protein sequences. The CID spectrum was also obtained with fmol amounts of sample consumed. Two partial sequences could be determined from this spectrum as -HGAI/L- and -LV-. Without knowing if these ions are from b or y" series, the direction of the sequence is unknown

Searching for these patterns as either b or y" series also results in matches to myoglobin



Proteins with matches to the partial sequence xxxiagh

Characterization of *in vitro* Metabolites of Ziprasidone by HPLC/RAM/ESI/MS/MS

Amin Kamel*, and Chandra Prakash
Pfizer Central Research, Department of Drug Metabolism Groton, CT 06340.

Ziprasidone, 5-[2-{4-(1,2-benzisothiazole-3-yl)-1-piperazinyl}ethyl]-6-chloro-1,3-dihydro-2H-indole-2-one hydrochloride hydrate, is a potent and highly selective inhibitor of dopamine D2 and serotonin 5-HT2 receptors Ziprasidone demonstrates clinical efficacy against positive and negative symptoms of schizophrenia with reduced extra pyramidal symptoms *In vitro* Metabolism of CP-88,059 labeled with [^{3}H]-and [^{14}C] was investigated to predict the *in vivo* metabolism using hepatic microsomal preparation from phenobarbital (PB) induced rat liver microsomes The metabolites were separated on reversed phase HPLC using an YMC basic column A total of 12 radioactive peaks were detected by HPLC-RAM. Comparison of *in vitro* metabolism of ziprasidone using rat, dog, monkey and human liver microsomes indicated similarities in the major metabolites in all species.

Chemical structures of the metabolites were proposed based on ion spray LC/MS using a combination of Q1 scan, parent ion and product ion monitoring techniques Atmospheric pressure ion mass spectra of ziprasidone and its metabolites gave intense protonated molecular ions. Collision activated dissociation (CAD) product ion scans of protonated molecular ions provided the structurally informative fragment ions. The structures of 7 metabolites were confirmed unambiguously by co-elution on HPLC with the synthetic standards Five major metabolites were identified as the sulfoxide and sulfone of ziprasidone, and benzisothiazole and its sulfoxide and sulfone. The other metabolites were due to N-dealkylation of the benzisothiazole moiety and degradation of the piperazine ring, resulting in the formation of oxindole ethyl piperazine and ethylenediamine analog, respectively A scheme for the metabolism of ziprasidone is proposed

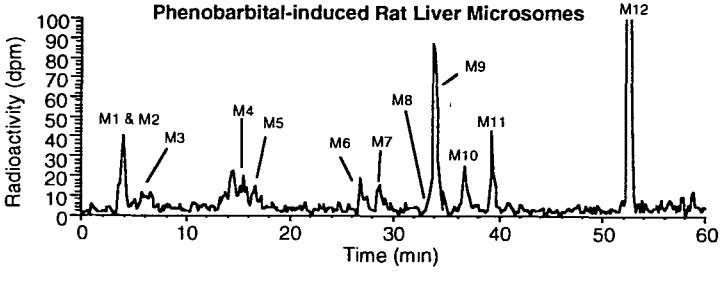


Figure 1. HPLC- Radiochromatograms of *in vitro* metabolites of ziprasidone

Reduction of Ambient Air Contaminants

Beat Aebi and Jack D. Henion
Analytical Toxicology, Diagnostic Laboratory, Cornell University,
927 Warren Drive, Ithaca, NY, 14850

To reduce the chemical noise on our Ion Spray - API Ion Trap mass spectrometer (ref 1-5), we have looked at the possible sources of contamination. The contaminants from the ambient air were found to be very important. As the heated shield uses heat for the desolvation of the analyte ions, plastic components were found to be gassing out elevated levels amounts of plasticizers and other substances. Ambient air penetrating the ionization region on this open interface appeared to produce a variety of background ions. Several experiments indicated that uncharged gaseous contaminants in the ionization region were ionized and entered the ion trap analyzer, producing different levels of chemical noise. We have modified the original, open heated shield interface to a plastic-free, closed type of interface with both bath and curtain gas to prevent any contaminants from entering the ionization region. Additionally, we have added a temperature controller to stabilize and hold the shield temperature at the desired level.
The closed shield interface was found to reduce chemical noise significantly and to produce a more stable ion current than the open shield interface. As a result, the scanned mass range could be expanded (from 100 or 200 Da to the full range of 10-650 Da) and the amount of substance detected in the extracted ion current could be lowered, yielding proper mass spectra without using signal averaging and backgound subtraction. The continuous removal of the ionization region atmosphere to allow new gas to enter and to purge solvent and contamination vapors could be the reason for the much better desolvation efficency and lower chemical noise.

The authors would like to thank the Eastman Kodak Company (Rochester, NY) and also the Varian Instrument Company for the generous support of this work . Special thanks go to Mr. Jerry Zweigenbaum from Eastman Kodak and Drs. B. Buttrill and B. Shaffer from Varian for invaluable assistance during this work.

Pulsed Electrospray and Selected Ions from Electrospray Ion Source by Ion Mobility Spectrometry*

#Guo-Zhong Li, Weimin Wang, Tamen Kim, R. B. Moore

Foster Radiation Laboratory
Department of Physics, McGill University
Montreal, Quebec, Canada, H3A 2B1

Electrospray as an Atmospheric Pressure Ion (API) source has been widely used in mass spectrometry because of it being an ideal interface between liquid chromatography and mass spectrometry, and because it can produce highly charged bimolecular ions. Ion Mobility Spectrometry (IMS) has been widely used for the detection of chemical weapons, drugs and explosive materials etc. [1], and even as a detector for liquid chromatography [2,3].

In this work we have investigated the pulsing of an electrospray source. There are several possible applications for such a source. One is to use a pulsed electrospray to replace the Bradbury-Nielson shutter-grid gate usually used for IMS. The advantage of this is the large ion current that can be delivered. Another is to use pulsed electrospray together with the Bradbury-Nielson shutter to enhance the selectivity of the IMS system. A third possibility is to use pulsed electrospray to replace the usual DC electrospray source for mass spectrometry. The advantage of this is to improve the efficiency of transferring ions from atmosphere into a vacuum by focusing the ions onto the vacuum orifice.

A schematic of the instrumentation used for pulsed electrospray and IMS is shown in fig. 1. High voltage pulses for the electrospray and the shutter were created by a high-voltage transistor switch from Belke Electronic. The voltage on the needle required for electrospray was less than 8 kV. At these voltages there was no corona and no sparking, the ions coming exclusively from the electrospray process. Polypropylene glycol with a molecular weight of 2000 Daltons was used as a sample, at a flow rate of 0.33 microliters/min. The IMS cell was at room temperature and the nitrogen gas flow rate through it was 300 microliter/s.

Figure 2 gives an example of the ion mobility spectrum without the Bradbury-Nielson shutter. We believe this to be the first use of a pulsed electrospray. Ions could be produced by a HV pulse of only one microsecond. However, for ionization efficiency and stability the pulse width used for the data of fig. 2 was chosen to be 4 ms. The ions could also be further selected by choosing the duration of the electrospray pulse and the delay time between the source pulse and the opening of the shutter. Figure 3 shows the result of using this combination.

Achieving High Sensitivity LC/MS with an API-Ion Trap Mass Spectrometer

Sohrab Habibi-Goudarzi and **Jack Henion,** Analytical Toxicology, Cornell University, 927 Warren Drive, Ithaca, NY 14850
Kevin L. Duffin and **Fred D. Hileman**, Analytical Sciences Center, Monsanto Co., 800 N. Lindbergh Blvd., St. Louis, MO 63167

Introduction:

An EI/CI Finnigan ion trap mass spectrometer has been extensively modified and equipped with a heated capillary type (1) atmospheric pressure ionization source. Our goal is to build upon the pioneering work of McLuckey, et al. at Oak Ridge National Laboratories (2) and the experience present in the Cornell laboratory (3) and construct an API-ITMS that is rugged, simple, reliable and that can be used with a number of on-line separation techniques with target sensitivity in the sub-femtomole range. We have achieved low femtomole sensitivity by on-line CE/MS and low picomole sensitivity by LC/MS.

Experimental:

Prior to every on-line experiment, the trap conditions were optimized by continuous infusion of a standard solution of the analyte(s) of interest. The trap typically is filled with ultra-pure Helium to a partial pressure of about one mTorr. Typical ion accumulation times of about 0.1 to 0.3 seconds were used at rf trapping voltage range of 496 to 958 volts (0-p) which corresponds to m/z cut-off at m/z 43 to 83. The total data acquisition time was adjusted to be suited for the width of the eluting peak.

The ion trap was coupled with a Hewlett-Packard ^{3D}CE via a sheath-flow interface. CE/MS experiments were carried out to analyze a mixture of eight β-Agonists. The fused-silica capillary column used had a 50 μm i.d and was 90 cm long and was maintained at 30 kV. The buffer was composed of 10 mM ammonium acetate and 0.1% acetic acid.

A waters 616 HPLC system was also coupled with the ion trap via an ion-spray interface. A Keystone Betasil C_{18}, 1 mm i.d. x 100, 5 μm particle size, column was used to analyze Reserpine from equine plasma extracts (through a three step liquid/liquid extraction). The HPLC separations were carried out under isocratic conditions using 80:20 acetonitrile : water and 5 mM ammonium acetate at 50 μL/min.

Results and Discussion:

The data were collected using our first version of the API-ITMS system. Many hardware changes were made which have increased the sensitivity. The most significant improvement took place by applying an improved ion-gating conditions. We still need to better understand the source of the chemical noise and reduce or eliminate it. Our goal is to be able to detect the presence of an analyte in the total ion current of a full-scan mass spectrum which is essential when analyzing ultra-trace level unknowns. We can now routinely observe low to sub-picomole levels of analytes from both standards (Figure 1) and "real" samples, e.g. reserpine in plasma extracts (Figure 2) in the TIC. The heated capillary inlet seems to work very efficiently, i.e. declustering in the trap via delay time is not needed. The capillary temperature can be lowered if the formation of clusters is desirable (e.g. in noncovalent interaction studies). At this time, the API-ITMS system provides quality data and the results are encouraging. However, we still need to improve the on-line sensitivity of the system by 100-1000 fold.

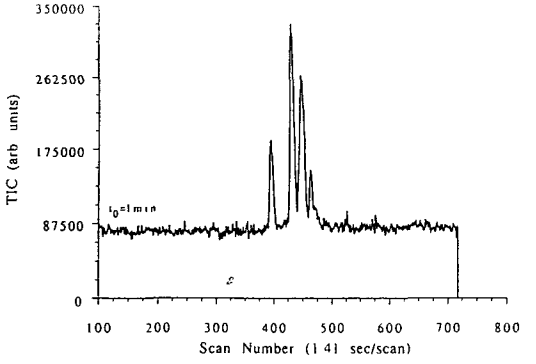

Figure 1: CE/MS of a mixture of eight β-Agonists. The amount of sample injected is one picomole. Scan range is m/z 40-640.

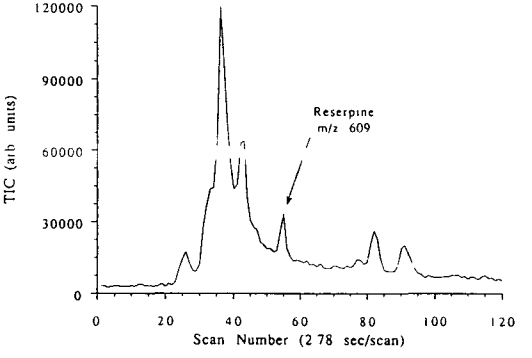

Figure 2: LC/MS determination of eight picomoles of Reserpine in an extract of spiked equine plasma. Scan range is m/z 80-640.

Acknowledgments:

Capillary, multicapillaries or porous tube for electrospray ion source

Claude Beaugrand#, Florence Charbonnier*, Christian Rolando*, Michel Sablier* and Florence Saru*

(#) AIRND, 35 rue Victor Hugo, 78230 Le Pecq, France
(*) Ecole Normale Supérieure, Département de Chimie, URA 1679, Procesus d'Activation Moléculaire
24 rue Lhomond, 75231 Paris Cedex 05

A major problem in electrospray ion sources is the transfar of ions from atmospheric pressure to vacuum. Most of the actual designs use a heated capillary tube (1). Using the three stages design, whith an RF only transfer quadrupole, we described last year (2), we have investigated how to improve the transfer of ions.

Various capillary tubes from 0.25 to 1.5 mm diameter have been tested, keeping the same pressure in the expansion area. This led us to use pumping speeds up to 80 cubic meters per hour. In all cases, electrospray ions can be obtained. Surprisingly, with large capillary diameter, results are not the best: total intensity is not higher and clusters intensity rises.

Desolvatation problems are due to a high velocity sampling flow in the capillary, which depletes the electrospray Taylor cone, or/and to low heat transfer to the bulk flow. Our best compromise is a 0.5 mm diameter capillary (as in most instruments). The pressure distribution is then : P_1 ca 1 Torr, $P_2 = 8x10^{-2}$ Torr, $P_3 = 7x\ 10^{-5}$ Torr. One way to solve those problems is to increase the flow but whitout enlarging the flow speed. This can be done by using several capillaries of smaller diameter.

We made a tube composed of seven small tubes welded together (Figure 1). The external diameter of each tube is 0.8 mm and the external diameter of the bunch is 1/8 inch. By closing one or several tubes we can modify the collecting surface.

Another approach is to create a flow speed gradient inside the tube. This can be achieved by exchanging the capillary tube by a porous metal one, of the same length but pumped separately by a mechanical pump.

The spray current of a solution of 10^{-5} mol.l^{-1} of TDA recorded after mass selection is given in the table below:

Number of tubes	1	5	5**	7
Current*	1	1.75	1.5	3.5

* relative values ** whithout center tube

TDA: (tris[2-(2-methoxymethylethoxy)ethyl]amine

The current we can obtain in the mass analyzer is not proportional to the sampling surface of the capillary. The position of the sampling surface in front of the needle plays a role. There are other problems in the limitation of the useful spray current than the maximum flow admitted to the system.

Transport of Electrospray Particles through the Interfaces

P.V. Bondarenko and R.D. Macfarlane
Department of Chemistry, Texas A&M University, College Station, Texas 77843

A stainless steel capillary, a teflon tube and a flat orifice were tested as atmospheric pressure/vacuum interfaces for electrospray particles. A solution of red Rhodamine B dye was employed to facilitate the quantitative measurements of transport efficiency using spectrophotometric analysis. The optimal transport efficiency was obtained where the 100 µm o.d. fused-silica electrospray capillary was positioned 1 mm from the 250 µm i.d. flat orifice. In that case, more than 99% of the electric current and dye component were transported into the vacuum.

The electrostatic deflection of the particles in vacuum allowed us to calculate an energy-to-charge ratio (E/z). The mean E/z ratio is 5000 eV/e. Assuming that the velocity of a typical particle is equal to the velocity of an air jet entering vacuum (velocity of sound), one can estimate the m/z ratio of the particles to be in the order of 10^7 u/e. From the electrospray flow rate of 0.5 µl/min and electrospray current of 40 nA used in our experiment, the m/z ratio of typical parent droplets was found to be equal to $2x10^7$ u/e. Those two m/z ratios are similar. Hence, the particles behind the orifice are predominantly parent charged droplets. The mass of those droplets is much larger than the mass of air molecules in the entering jet. Due to this fact, the charged droplets are directed strictly perpendicular to the orifice plane, with narrow angular distribution.

In the second stage of our investigation, the electrospray particles were introduced into a high vacuum chamber ($4x10^{-5}$ Torr) through the two additional pumped regions separated by two conical skimmers (Figure 1). The electrostatic deflection study showed that the particles keep their m/z ratio close to m/z ratio of the parent charged droplets. More than 30% of electrosprayed sample was transported into the vacuum through the orifice and the skimmers. Those droplets are requiring further evaporation to produce ions for mass spectrometry.

Evaporation in high vacuum is a difficult problem, because collisions with residual molecules of air are very rare. The charged droplets "freeze" in high vacuum and require an input of energy for evaporation and ion formation. At that point of our study, we introduced a Heated Electrostatic Particle Guide (HEPG) between the electrospray source and a mass analyzer (Figure 2).

The HEPG serves two purposes. First, it emits infrared and visible radiation. This radiation provides energy which is required for the evaporation and ion formation from the charged droplets (Figure 2). Second, as a component of the ion optics, it transports the droplets and ions through the vacuum chamber and focuses them onto the entrance of the mass analyzer. SIMION calculations (Figure 3) show that ions emitted from the droplets at the distance of a few millimeters from the wire will be captured by the field, transported along the rest of the guide and focused into the entrance of the mass analyzer. The HEPG-focusing electrode assembly was built according to the SIMION calculations and tested. It allowed us to focus the particles into a 7 mm dia. spot at the entrance plane of the mass analyzer.

Recently, we have built a time-of-flight mass analyzer which is the final step in the development of our mass spectrometer (Figure 1). With this analyzer, we plan to determine the m/z ratio of the final particles and observe the influence of the heating of the droplets on the ion formation and fragmentation.

Electrospray Ion Distributions and Efficiency of Transferring Ions from Atmosphere into Vacuum*

#Guo-Zhong Li, Weimin Wang, Tamen Kim, R. B. Moore

Foster Radiation Laboratory
Department of Physics, McGill University
Montreal, Quebec, Canada, H3A 2B1

The mechanism of electrospray has been extensively studied during the past several years. In its application to high resolution mass spectrometry an important aspect of such a source is the efficient transport of its ions through an orifice into a vacuum. In this paper we present results of a study of the ion distribution near a vacuum orifice and the efficiency of transferring ions through the orifice. The motion of electrospray ions from a source into a vacuum is determined by four effects, the spatial distribution of the ionization, the electric field from the voltage on the needle, Coulomb interaction between the ions and the gas dynamics near the orifice. The ions are usually produced in a small volume near the needle and in their early motion follow the electric field lines from the needle according to their mobilities. However, as the field drops rapidly away from the needle the ion speed considerably diminishes and Coulomb interactions between the ions become important, pushing them away from the axis of the transport system. Finally, as the ions approach the orifice, the electric field becomes relatively unimportant and gas dynamics become the overriding consideration, causing the ions to speed up again as they pass through the orifice and exceed the speed of sound.

A schematic of the instrumentation to study this motion is shown in fig. 1. Two samples were used in the study; 2-Propanol and polypropylene glycol of molecular weight 2000 Daltons. The orifice flow was attained by a Roots blower (Alcatel model MIV 350) with 116L/s pumping speed. The vacuum interface was made of a printed circuit board with copper rings concentric to a 0.6 mm orifice. Currents on the rings and the detector were measured by current meters. The total electrical current to the needle was measured by a current to voltage amplifier specially made to be floated at high voltage.

When there was no pumping, the ion intensity distributions were as shown in fig. 2. At high voltages on the needle the distributions were seen to have a ring shape with a depression at the axis of the system. With pumping so that the pressure on the vacuum side of the orifice became 0.57 Torr the distribution was as shown in fig. 3. In this case the current through the orifice was found to be always proportional to the current on the inner ring and that the efficiency of transfer of the ions through the 0.6 mm orifice could be as large as 6%. This indicates that with such a relatively large orifice the transfer efficiency can be made to be largely determined by the gas dynamics at the orifice.

Stability Of A Liquid Jet Emerging From An Electrospray Cone-Jet

Edward W Sheehan and Ross C Willoughby
Chem-Space Associates, 75 Chapel Ridge Place, Pittsburgh, PA 15238

In a continuing effort to understand the underlying mechanism of electrospray we present here an argument for the formation of an electrospray cone-jet based on the Rayleigh limit. When a liquid flows through a cylindrical capillary at low flow rates, spherical droplets emerge from the tip and are held by surface tension until gravity overcomes the adhesive forces; then the drops detach. When an electrical potential is applied to the capillary, the liquid is electrified. As the liquid is charged to a higher potential, the spherical liquid surface at the tip of the capillary deforms into a conical surface and a liquid jet emits from the apex of the cone. This liquid jet breaks up into droplets which undergo further deformation producing smaller droplets or ion clusters which eventually lead to gas-phase ions. The objective of the following study was to compare the Rayleigh limit for spheres and cylinders and observe the effects of density, surface tension, and viscosity of various solvents on the stability of liquid jets.

What is the Rayleigh Limit? Lord Rayleigh[1] described the stability of liquid surfaces as the balance of two forces, an inward pressure due to surface tension and an outward pressure due to charge repulsion. He formulated this as follows:

$$p^2 = n(n-1)/\rho r_s^3 \{(n+2)\gamma - (q^2/8\pi r_s^3)\} \quad (1)$$

where $(n+2)\gamma$ represents the surface energy component and $q^2/8\pi r_s^3$ the electrostatic component. For a spherical droplet, if the surface energy is greater than the electrostatic component ($p^2 > 0$) the spherical form is stable for all deformations When the charge density (q/r_s) is great ($p^2 < 0$), electrostatic forces dominate and the spherical form becomes unstable. Under these conditions the liquid droplet deforms, a cone forms, and liquid is thrown out in a fine jet (a cylinder).

Charge Limit for a Sphere and a Cylinder. The maximal allowable charge on a spherical droplet is:

$$q_s = 8\pi\varepsilon_0^{1/2} \gamma^{1/2} r_s^{3/2} \quad (2)$$

while the maximum allowable charge on a cylinder is:

$$q_c = 6^{1/2} \pi\varepsilon_0^{1/2} \gamma^{1/2} l_c r_c^{1/2} \quad (3)$$

where γ = surface tension; ε_0=permittivity constant; r_s is the radius of a drop; and l_c and r_c are the length and radius of a cylinder, respectively.

Ratio of the Maximal Allowable Charge of a Sphere and a Cylinder. Comparing the charge limits of a sphere and a cylinder (q_s/q_c) results in:

$$q_s/q_c = 0.94 \quad (4)$$

The fact that the ratio is not 1 or greater implies (1) that cylinders can hold more charge than a sphere of the same mass; (2) the 6% excess charge on the jet surface at the charge limit must be dissipated in droplet, cluster or ion formation process(es); (3) as a sphere reaches its charge limit it can relieve the electrostatic forces on it by forming a jet to carry away the excess charge; and (4) the transformation from a sphere to a jet is a cone.

Current Onset for Various Solvents. The onset of a stable cone/jet was observed for various solvents, such as water, methanol, ethanol, isopropanol, acetonitrile, and hexane. Figure 1 shows the variation in current with applied voltage for water and isopropanol (IPA). Two things were noted (1) for water: there was no observed stable cone/jet and the collected current was due to the discharge of the air surrounding the needle; (2) for isopropanol (and the rest of the solvents, not shown): a stable cone/jet was observed but in addition, as the applied voltage was increased the jet for IPA narrowed and took on a cone-like appearance before the jet broke up. This narrowing of the jet was not observed for less viscous solvents, such as methanol, ethanol, acetonitrile, and hexane. From these observations it was concluded that (1) for liquids with high surface tension (such as water), the gases surrounding the needle will discharge before the charge density on the surface of the liquid is high enough to form a cone/jet; and (2) viscosity may play an important role in the stability of a jet. Viscosity was not considered in the original treatment of the stability of electrified liquids by Lord Rayleigh and therefore to gain a more complete understanding of jet stability and the eventual production of gas-phase ions, viscosity warrants further investigation and inclusion in any theoretical treatment of cone/jet electrospray.

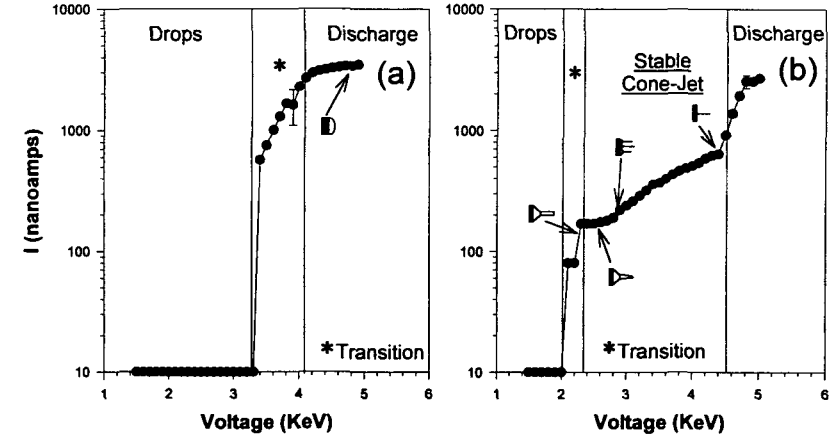

Figure 1. Variation of current with applied voltage by electrospraying water (a) and isopropanol (b) in air. The appearance of the cone/jet is also indicated on the figure. The distance between the needle tip and the grounded plate was ~ 2 cm. The current was determined by directing the droplets at the grounded plate and measuring the current between the plate and ground with a microampmeter. The needle, the electrospray cone, and liquid jet were observed through a microscope. Deionized water and pesticide grade isopropanol were used. Flow 1μL/min.

Secondary Droplet and Ion Formation in Electrospray: The Teardrop Model

Sheehan, Edward, and Willoughby, Ross
Chem-Space Associates, 75 Chapel Ridge Place, Pittsburgh, PA 15238

Experimental evidence has shown that at least one mechanism for secondary droplet and ion cluster formation in electrospray is through conical deformation of a charge saturated primary droplet. Photographic evidence has been produce from droplet electrospray[1], liquid droplets[2], and particle residues[3].

These results show that spherical droplets deform under the influence of high field. The high field is produced as a result of evaporation of droplets past there Rayleigh limit.[4] The deformation results in the observed "teardrop" geometry which can be evaluated for energy, charge, and mass balance as the deformation occurs. Any deformation of the droplet will result in a potential difference across the deformation and a net decrease in the potential of the droplet. If the system loses charge and moves matter, the potential energy of the system must be reduced.

Another important observation from the particle residue photographs was the consistency of the geometry in the particle. We conclude from these data that the teardrop process of secondary droplet and ion cluster ejection is a sustainable process; at least under conditions of high evaporation rate in these experiments. Few spherical geometries were observed.

The surface of a teardrop shaped droplet can be described by,

$$A_t = 2\pi r_s^2 (1 + \sin\theta + 0.5 (\cos\theta \cot\theta))$$

$$A_t = A_s (0.5 + 0.5 \sin\theta + 0.25 (\cos\theta \cot\theta))$$

where A_t = surface area of the teardrop, A_s = surface area of the sphere, r_s = radius of the sphere, and θ = angle of conical deformation.

The volume of a teardrop shaped droplet can be described by,

$$V_t = (4/3)\pi r_s^3 (0.25 \cos^2\theta - 0.25 \cos^2\theta \sin\theta - 0.75 \sin^2\theta + 0.25 \sin^3\theta))$$

$$V_t = V_s (0.25 \cos^2\theta - 0.25 \cos^2\theta \sin\theta - 0.75 \sin^2\theta + 0.25 \sin^3\theta))$$

where V_t = volume of the teardrop, V_s = volume of the sphere, r_s = radius of the sphere, and θ = angle of conical deformation.

The radius of a teardrop shaped droplet can be described by,

$$r_t = r_s (0.25 \cos^2\theta - 0.25 \cos^2\theta \sin\theta - 0.75 \sin^2\theta + 0.25 \sin^3\theta)^{1/3}$$

where r_t = radius of the teardrop and r_s = radius of an undeformed sphere.

The potential for a teardrop as a function of radius and angle of deformation can be described by,

$$V(r,\theta) = (1/4\pi\varepsilon_o)\ (q_s/r_t)$$

$$V(r,\theta) = (1/4\pi\varepsilon_o)\ (q_s/\ r_s\ (0.25 \cos^2\theta - 0.25 \cos^2\theta \sin\theta - 0.75 \sin^2\theta + 0.25 \sin^3\theta)^{-1/3})$$

Figure 1 is a graph of the potential of a droplet as a function of a teardrop deformation. This calculated decrease in potential may be used to evaluate the energy balance associated with the teardrop mechanism of secondary droplet and ion formation.

Future studies are intended to more fully characterize this model for the partitioning of energy in a similar manner to the needle cone-jet deformation process previously described.[5]

ROLE OF PEPTIDE STRUCTURE IN THE PRODUCTION OF IONS FROM CHARGED DROPLETS*

Kevin M. Downard and Klaus Biemann
Department of Chemistry, Massachusetts Institute of Technology
Cambridge, MA 02139-4307 U.S.A.

To date, there remains at a best a superficial understanding of the component mechanisms involved in the electrospray ionization process. This is due in large part to the complexity of the ionization event where analyte molecules dissolved in an electrostatically-sprayed solution are transferred to the gas-phase as a distribution of multiply-charged ions. The upper and lower charge state limits are influenced by a variety of experimental factors including the analyte's primary and higher order structure. Despite numerous investigations in several laboratories, the precise role an analyte's structure has on its charging behavior is poorly understood. Here we investigate the relationship between the structure of an analyte and the number and position of charge-carrying protons it supports by studying a series of specifically constructed arginine-rich peptides which differ in the length of the peptide chain and the number and proximity of the arginine residues.

The peptides studied are shown in Table 1 together with the maximum, and average (based on the ion intensities), charge state for each peptide. Note that although peptide $(RG)_3$ supports a maximum of three charge-carrying equal to the number of arginine residues it contains, this is not the case for the larger $(RG)_n$ peptides (n=6,10,15) where the extent of protonation of the arginine residues decreases with increasing n. The CID spectrum of the $[M + 3H]^{3+}$ ion of $(RG)_3$ (Figure 1) is consistent with protons localized on each arginine side chain in a high proportion of the precursors, commensurate with our previous observations that protons remain highly localized in singly and multiply-charged ions of basic peptides [1,2], even during their dissociation at high (keV) collision energies.

The reduced protonation of the larger peptides is not a consequence of a lack of charge-bearing protons available per analyte molecule, since identical results were obtained as the peptide concentration in solution was decreased by two orders of magnitude, and as the pH of the solution was lowered (to 2). Furthermore, conformational effects are unlikely to contribute substantially to their reduced protonation (relative the number of arginine residues) since a similar charging behavior is observed for isomeric peptides $(RG)_6$, $(RRGG)_3$ and (R_6G_6) (Table 1). This is also the case for peptide pairs $(RG)_n$ and $(R\bar{A})_{n-1}R$ (n=10,15) despite the fact that the peptide backbone has increased in length by almost 50%, and the arginine residues are further separated in peptides $(R\bar{A})_9R$ (where $\bar{A}$ = Ava = ε-amino valeric acid).

In the context of a reported mechanism for the electrospray ionization process [3], the results of this study suggest that the larger peptides leave the droplets as gas phase ions much sooner than peptide $(RG)_3$. This is the case irrespective of the conformation of peptides $(RG)_n$ and $(R\bar{A})_{n-1}R$ (n=10,15) since their size is sufficiently large that most (if not all) of the arginine side chains would be protonated if their ions were released at the same time as those of $(RG)_3$. If, as the model suggests, the charge-carrying species are equidistant at any time during the evaporation event [3], then the protons should be evenly distributed along the peptide backbone in the larger peptides provided they remain localized during ionization and dissociation. In accord, all of the major product ions of the CID spectrum of the $[M + 5H]^{5+}$ ions of $(RG)_{10}$ (shown partially in Figure 2) can be accounted for if their charges are well-separated and their dissociation reactions proceed through charge-remote fragmentation pathways.

Figure 1

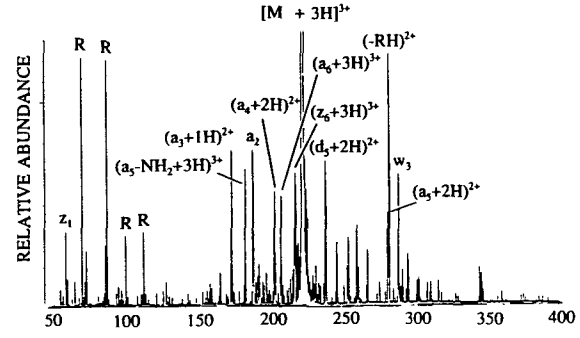

Table 1

Peptide	# backbone bonds	Max. z observed	Av. z observed	% R protonated
$(RG)_3$	20	3	2.8	95
$(RG)_6$	38	5	4.6	77
$(RRGG)_3$	38	5	4.0	67
(R_6G_6)	38	4	4.0	67
R_6	20	4	3.9	65
$(RG)_{10}$	62	5	4.0	40
$(R\bar{A})_9R$	86	6	4.7	47
$(RG)_{15}$	92	9	7.0	53
$(R\bar{A})_{14}R$	131	10	8.3	55

$\bar{A}$ = ε-aminovaleric acid

TUNING PARAMETERS: A CRITICAL DETERMINANT OF RELATIVE ION INTENSITIES IN ELECTROSRAY IONIZATION MASS SPECTROMETRY

John B. Cunniff and Paul Vouros. Barnett Institute and Chemistry Dept, Northeastern University, Boston, MA 02115

Ion intensities observed within the electrospray spectrum are a function of several parameters and may be expressed as:

$$I \sim N_o B_1 B_2 T_1 T_2 \qquad [1]$$

Whereby:

- I is the intensity of a specific ion peak [e.g.$(M+H)^+$,$(M+nH)^{n+}$,$(M-H)^-$,$(M-nH)^{n-}$]
- N_o is the number of sample molecules introduced into the ion source
- B_1 is the efficiency of producing the ion within the liquid phase
- B_2 is the efficiency of extracting the ion from the liquid phase into the gas phase
- T_1 is the transmission efficiency of the ions within the source
- T_2 is the transmission efficiency of the ions in the mass spectrometer

Much research has focused on the degree of contribution of the factors which influence ion intensity. Although the determination of I and N_o is rather straightforward, the quantitation of the remaining terms (B_1,B_2,T_1 and T_2) is not such a facile task.

Figure 1 illustrates that, for substance P, a large shift in relative ion intensities of the $[M+H]^+$ ion relative to the $[M+H]^{2+}$ is the direct result of changing a single lens voltage. Similarly, Tuning conditions were also shown to demonstrate a strong effect on the ion profile of an apo-myoglobin solution. Finally, by performing an "auto-tune on an m/z calculated to be a myoglobin/biotin complex (on a myoglobin/biotin solution for which no complex ion was initially detected), a new spectrum (Figure 2) was generated which indicates the presence of biotin complexes/adducts.

Small variations in lens voltages or tuning parameters have dramatic effects on relative ion intensities. The results indicate that relative ion intensities may be manipulated to an extreme degree by small tuning alterations. The results indicate that the typically observed ion profile is strongly a function of tuning parameters regardless of solution conditions. The results also indicate that nonspecific noncovalent complex ions can be detected with the simple manipulation of tuning parameters. Furthermore, because relative ion intensities are strongly a function of lens voltages, these nonspecific noncovalent complexes may be indistinguishable from any specific noncovalent complexes based on any given ion stoichiometry. Finally, the fact that different instruments and laboratories detect varying relative ion intensities may be attributed to the lack of any universal **intensity** calibrant for ESI mass spectrometers.

Characterization of m/z Deviates in Electrospray MS Data and Molecular Mass Measurement Uncertainty

Paul L. Juneau[1], Anne B. Giordani[2] and David A. Pyne[1]
Departments of Biometrics[1] and Chemistry[2]
Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company
2800 Plymouth Road, Ann Arbor MI 48105

A unique feature of electrospray (ES) mass spectra is that single spectra can provide multiple molecular mass estimates and hence the potential to estimate the mass measurement uncertainty without the burdensome task of conducting multiple determinations. Evaluation of the uncertainty of mass measurement by ES-MS is important to establish the quality of molecular mass determinations.

It is common practice to report the mean of the values calculated from each peak in the spectrum as an estimate of molecular mass. When a measure of the uncertainty is reported, the standard deviation of the molecular mass values calculated from each peak in the spectrum is typically used. The underlying assumption in using the standard deviation as a measure of the uncertainty in an ES mass spectrum is that each peak in an ES spectrum provides an independent measure of molecular mass.

In our poster from last year, we showed that the assumption that each peak in an ES spectrum provides an independent measure of molecular mass is not always valid because the m/z measurements may be autocorrelated[1]. If there is a positive autocorrelation and it is not addressed in molecular mass calculations, the derived uncertainty may underestimate the true uncertainty of the molecular mass measurement[2].

In terms of mathematical statistical theory, do other features of m/z measurements have the potential to affect molecular mass uncertainty estimates or even the molecular mass estimates themselves? Are these features consistent with the existence of autocorrelation in the m/z data? Do these properties vary with charge, and if so, does a simple model explain the relationship?

One property of ES m/z data is its *deviance*. The *deviance* of a measurement is the difference between its empirical value and the predicted value. For a known compound, m/z values can be predicted; thus, the measured m/z values can be compared to the predicted m/z values at every peak.

The arithmetic difference between an empirically derived (measured) m/z value and a predicted m/z value for a known compound may be viewed as a *deviate*. If there are at least three replicate determinations of a spectrum, the distribution of deviates can be constructed at each of the peaks. The deviates can be used to assess measurement bias. If the central tendency of the deviates between adjacent peaks is non-zero, a bias in the m/z measurement method may exist.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

A second property of m/z data that can affect uncertainty measurements is its *dispersion* or the spread in measured values at each peak. Peaks which have similar dispersion are said to be *homoscedastic*; those with differing dispersion *heteroscedastic*. Both inaccurate molecular mass estimates and underestimation of the true uncertainty can result from data which are heteroscedastic.[3] The m/z data dispersion may be compared by an examination of the deviate distributions.

This poster examines the statistical properties of deviance and dispersion in ES-MS data.

Conclusions

- An evaluation of the deviance in ES m/z data revealed evidence of bias. The pattern is consistent with positively autocorrelated data, which can lead to underestimation of mass measurement uncertainty.

- An evaluation of the dispersion in ES m/z data revealed evidence of heteroscedasticity, which can lead to both poor molecular mass estimates and poor estimates of the molecular mass measurement uncertainty.

- The relationship between the mean m/z deviates and charge cannot be readily explained in terms of a simple linear model.

Chemical Redox Reactions in ES-MS: Study of Electrode Reactions

Feimeng Zhou and Gary J. Van Berkel
Chemical and Anlytical Sciences Division, Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831-6365

We have previously demonstrated that chemical redox reactions can be used to ionize neutral compounds for electrospray mass spectrometric (ES-MS) detection[1]. The same approach can also be used, in conjunction with some electrochemical technique such as cyclic voltammetry(CV), to study electrode reactions. It has long been recognized that MS can be a powerful technique to provide molecular weight and structural information regarding the intermediate/products generated in electron-transfer reactions[2-3]. Although the principle behind using chemical redox reactions on-line with ES-MS for the study of electrode reactions is much the same as that behind using electrochemistry on-line with MS (EC/MS), a major advantage of the former approach is that the possible suppression of analyte signal by the added electrolyte used in excess in conventional electrochemical experiments is eliminated. This suppression effect and means to overcome it are discussed in greater detail in poster #222 which is related to the combination of electrochemistry on-line with ES-MS (EC/ES-MS).

Two different compounds, viz, $C_{60}F_{48}$ and β-carotene were used to demonstrate the utility of chemical redox reactions on-line with ES-MS for the elucidation of mechanisms of complicated electron-transfer reactions[4] and for the kinetic study of electrode reactions in which relatively short-lived intermediates are involved[5].

(1) Elucidation of Mechanisms of Complicated Electron-Transfer Processes:

Cyclic voltammetry reveals that $C_{60}F_{48}$ can be reduced in CH_2Cl_2 to its dianion which undergoes a fast follow-up chemical reaction (Figure 1a). A flow injection experiment employing a CH_2Cl_2 carrier solution containing ferrocene as the oxidant yielded a peak in the ES-mass spectrum (Figure 1b) whose *m/z* value corresponds to $C_{60}F_{47}^-$. Thus the chemical redox reaction between ferrocene and $C_{60}F_{48}$ suggests that the product from the follow-up reaction of $C_{60}F_{48}^{2-}$ should be $C_{60}F_{47}^-$. $C_{60}F_{47}^-$ can be further reduced to $C_{60}F_{47}^{3-}$ in the same solvent system and the CV (Figure 1c) indicates that $C_{60}F_{47}^{3-}$ also undergoes a fast chemical follow-up reaction. Another flow injection experiment is carried out with decamethylferrocene as the oxidant. The ES-mass spectrum, shown in Figure 2d, again provides information about the product of the follow-up reaction. Similar to $C_{60}F_{48}^{2-}$, $C_{60}F_{47}^{3-}$ also has a strong tendency to lose a F-.

On the basis of the CV behavior and the ES-MS mass spectra of $C_{60}F_{48}$ obtained using different chemical redox reagents, the following mechanism was proposed.

$C_{60}F_{48} + e^- \rightleftharpoons C_{60}F_{48}^{\cdot-}$	Electron-transfer, E
$C_{60}F_{48}^{\cdot-} + e^- \rightleftharpoons C_{60}F_{48}^{2-}$	Electron-transfer, E
$C_{60}F_{48}^{2-} \rightarrow C_{60}F_{47}^- + F^-$	Chemical Reaction, C
$C_{60}F_{47}^- + e^- \rightleftharpoons C_{60}F_{47}^{2-}$	Electron-transfer, E
$C_{60}F_{47}^{2-} + e^- \rightleftharpoons C_{60}F_{47}^{3-}$	Electron-transfer, E
$C_{60}F_{47}^{3-} \rightarrow C_{60}F_{48}^{2-} + F^-$	Chemical Reaction, C

(2) Kinetic Study of Electrode Reactions:

CV (solid curve in Figure 2a) and other electrochemical studies suggest the oxidation reaction of β-carotene in CH_2Cl_2 to be a simple two-electron transfer reaction forming the dication. The dication undergoes a follow-up reaction (EEC mechanism). A simulation based on the EEC mechanism using the same experimental parameters (dotted curve in Figure 2b) yields a rate constant for the first-order chemical reaction of 0.3 s^{-1}, or 2.7 s for the half-life of the dicationof β-carotene.

A flow-injection experiment using CH_2Cl_2/0.1% trifluoroacetic acid (v/v) as the carrier solution on-line with ES-MS shows two major peaks at *m/z* values expected for the dication of β-carotene, M^{2+},

43rd ASMS Conference on Mass Spectrometry and Allied Topics

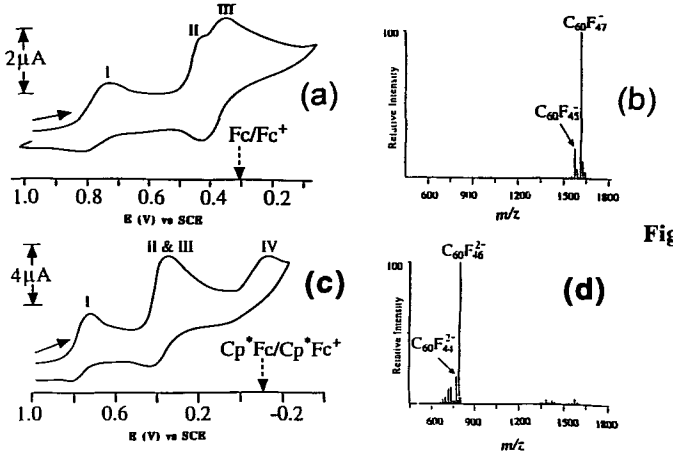

Figure 1

and at the *m/z* value corresponding in mass to $(M-1)^+$, respectively (Figure 2b). The peak at $(M-1)^+$ was assigned to the product of the follow-up reaction generated in the following reaction,

$$M^{2+} \rightarrow (M^{2+}-H^+)^+ + H^+$$

The relative abundances of the β-carotene dication and the species $(M^{2+}-H^+)^+$ were plotted as a function of flow rates. The linear plot yields a slope of 0.11 s^{-1} which is the rate constant of the above chemical reaction. Therefore, the solution lifetime of the β-carotene dication is determined to be 6.3 s by the flow injection experiment. This value is in good agreement with what is estimated from the simulation of β-carotene CV.

ELECTROCHEMISTRY ON-LINE WITH ELECTROSPRAY MASS SPECTROMETRY

Gary J. Van Berkel and Feimeng Zhou
Chemical and Analytical Sciences Division, Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831-6365

We have found electrospray (ES) to be a suitable interface for coupling electrochemistry (EC) on-line with mass spectrometry (MS) [1-4]. In contrast to many of the ionization methods/interfaces that have been used to couple EC and MS, ES involves no heating of the solvent systems, gas-phase reactions of the analyte/products are minimal, and a wide variety of solvent systems, ranging from water to nonpolar organic solvents like methylene chloride, can be used. Figure 1 is a *schematic representation of the electrochemical flow cells used on-line with ES-MS, viz., (a) thin-*layer, (b) dual-tube, and (c) coulometric. As shown in Figure 2, a decoupled mode (potentiostat control) (a) or a floated mode (b) (constant-current (c) or constant-potential (d) control) were used to connect the electrochemical flow cells on-line. In terms of carrying out on-line EC/ES-MS, selected applications showed that when either controlled-current electrolysis (CCE) or controlled-potential electrolysis (CPE) can be used, the CCE mode of operation offers several advantages. These advantages include, (1) the simple circuitry for CCE that can be easily floated at the high ES voltage, (2) the fact that CCE is easier to perform in resistive solutions than CPE (i.e., minimal electrolyte is needed which benefits ES-MS), (3) a reference electrode is not needed in CCE, and (4) the problem of potential drift that plagues two-electrode CPE is avoided in CCE. In terms of response time for gas-phase detection, the floated mode is most advantageous since a long transfer line from the cell to the ES source is avoided. The 50-100 mM concentration of nonvolatile electrolyte normally used in electrochemical experiments causes problems with plugging and degraded performance of the ES atmospheric sampling interface Even more significant is suppression of the analyte gas-phase ion signal that can result from this high electrolyte concentration. The most commonly used electrolytes (e.g., quaternary ammonium salts) have a very large propensity for gas-phase ion formation and concentrations even as low as ten to a few hundred micromolar can lead to significant signal suppression. Fortunately, less commonly used, but no less functional electrolytes, such as alkali metal salts, e.g., lithium triflate and lithium hexafluorophosphate, have a much lower suppression effect, which enabled their use in the present studies at concentrations as high as a few millimolar.

We carried out three selected applications which demonstrated the utility and versatility of the EC/ES-MS combination. These were the ionization of neutral analytes for detection by ES-MS, the study of the products of electrode reactions, including those or relatively short-lived species (i.e., half-life < 1.0 s) and the enhanced determination of metals achieved by coupling anodic stripping voltammetry [5] on-line with ES-MS. As an example, nickel(II) octaethylporphyrin ($Ni^{II}OEP$) was used to demonstrate the utility of EC/ES-MS for the detection of electrochemically generated species via stepwise electron-transfer reactions. $Ni^{II}OEP$ undergoes two reversible one-electron oxidation reactions (*E,E,* mechanism) in a variety of nonaqueous solvents. Because the products are stable, and therefore, do not require rapid detection, this work was carried out with the coulometric cell in the decoupled, three-electrode operational mode. The mass spectrometric hydrodynamic voltammograms in Figure 3 clearly indicate that the mono- and dication are formed at two different electrode potentials, the difference in these electrode "appearance potentials" being 0.50 V, which is in good agreement with the peak potential difference measured from the CV (i.e., 0.53 V).

Formation of Protonated Ions from Acidic Species at High pH in Electrospray.

Richard W Smith
Department of Chemistry, McMaster University, 1280 Main St W, Hamilton, ON, L8S 4M1, CANADA

Electrospray (ES) analysis of the anti-arthritic drug myochrysine in the negative ion mode abundantly yielded the $(M-H)^-$, $(M-2H)^{2-}$ and $(M-3H)^{3-}$ species when the sample was dissolved in CH_3CN/H_2O containing NH_4OH. In the positive ion mode, ions were observed which were identified as the $(M+NH_4)^+$ and $(M+H)^+$ species Remarkably, these positive ion species persisted even at pH 9.9 although at a much reduced intensity Considering that myochrysine contains eight carboxyl groups, this observation is difficult to explain in terms of acid/base equilibrium calculations in solution (1) To probe the mechanism of positive ion formation from myochrysine, we have studied the ESI and ammonia chemical ionization (NH_3 CI) characteristics of several model compounds including the three isomeric phthalic acids, maleic acid (cis) and fumaric acid (trans)

Pneumatically assisted electrospray ionization (ESI) was performed with 50/50 CH_3CN/H_2O as the mobile phase at a flow rate of 15µl/min employing a Brownlee Microgradient syringe pump Samples were introduced by flow injection at a concentration of 0 01M + 0 001M of base unless otherwise stated. The pH of these solutions ranged from 2.6 to 4.4 Full scan ESI experiments were performed with a Fisons Platform quadrupole instrument and the MS/MS data were generated with a Fisons Quattro II triple quadrupole instrument. All data was acquired in MCA mode (10 scans) A cone voltage of 35V was employed in all ESI experiments (unless otherwise stated) All NH_3 CI experiments were performed with a VG Analytical ZAB-E mass spectrometer The samples employed in this study were used as supplied by the manufacturer

The +ESI and NH_3 CI mass spectra of 1,2-phthalic acid (Figure 1) and maleic acid exhibit a number of intense ions characterised as $(M+NH_4)^+$, $(M+H)^+$ and $(MH-H_2O)^+$ In contrast, the corresponding ESI mass spectra of the 1,3- , 1,4- isomers and fumaric acid yield some of these ions at very low intensity (approximately a 50 fold decrease) This indicates that the facile formation of $(M+NH_4)^+$ adduct ions requires the presence of adjacent carboxyl groups. In ESI, the ratio of these ions is highly dependent on the cone voltage employed At low cone voltages (10V), 1,2-phthalic acid and maleic acid exhibit $(M+NH_4)^+$ and $(M+H)^+$ ions, which results in an ESI mass spectra very similar to the NH_3 CI mass spectrum shown in Figure 1 As the cone voltage is increased from 20V to 100V, the $(M+NH_4)^+$ and $(M+H)^+$ ions decrease in intensity and the $(MH-H_2O)^+$ species dominates This indicates a collisional activation component to the ESI mass spectra, which explains the significant intensity differences between the ions observed in the ESI and NH_3 CI mass spectra shown in Figure 1 Part of the $(M+NH_4)^+$ ions lose (i) NH_3 to yield the $(M+H)^+$, and (ii) NH_3 + H_2O, to yield the $(MH-H_2O)^+$ ion as established by MS/MS as well as D and $^{15}NH_4^+$ labelling

In an ESI study of 1,2-phthalic acid, where the pH was varied from 2 9 to 9 9 with conc NH_4OH, the intensity of the positive ions decreased by a factor of 20 however, the $(M+NH_4)^+$, $(M+H)^+$ and $(MH-H_2O)^+$ ions were always observed. At pH 9.9, 1,2-phthalic acid would be almost completely dissociated in solution (pKa = 5 51) yielding the $(M-H)^-$ and $(M-H-CO_2)^-$ species. The summed negative ion intensities were approximately 10 times greater than the positive ion yield across the same pH range, increasing to a maximum at the pKa of the first carboxyl group and then slowly decreasing. It is possible that the decrease in +ESI response may reflect the extent of dissociation in solution but may in part be due to ion suppression because of the high electrolyte concentration (2). However, positive ion formation must occur somewhat independent of solution pH indicating that gas-phase reactions may play an important role in the ESI generation of the $(M+NH_4)^+$ and $(M+H)^+$ ions

The observation of a +ESI mass spectrum from acidic species employing NH_4OH to effect ionization is interesting however, it is of little analytical use because a mobile phase containing 0.01% NH_4OH (pH > 9) would dissolve silica based HPLC columns A study was undertaken to discover whether other bases

(including NH_4OAc) cause ionization and if a correlation exists between the observed positive ion species and the proton affinities (PA) or the pKas of the bases The results indicate that there is little correlation with either PA or pKa For example, aniline and $(NH_2)_2(CH_2)_4$ with 1,2-phthalic acid The bases have very different PAs (209 5 and 237 6 respectively) and pKas (4 63 and 11.15/9 71 respectively) however, the resulting ESI mass spectra and relative responses (summed intensities for the ions observed) are very similar Indeed, all of the bases studied yielded similar ESI mass spectra although the relative responses vary by a factor of 3 The 1,3-, 1,4- phthalic acid isomers and fumaric acid yielded very low intensity +ESI mass spectra (if at all) although a good +ESI response was seen for 1,3-phthalic acid with $(NH_2)_2(CH_2)_2$ and $(NH_2)_2(CH_2)_4$ Consequently, it is proposed that two criteria must be satisfied in order that an intense +ESI response be observed from acidic species eluting in base Namely, (i) formation of a BH^+/sample complex (where B is the base used) and (ii) stabilization of this complex by dicarboxylic acids that contain adjacent, cis or interacting carboxylates

It has been reported that the favoured site for gas-phase protonation in carboxylic acids is the carbonyl oxygen (3) and that the loss of H_2O from protonated carboxylic acids with adjacent or cis carboxylates, such as 1,2-phthalic acid and maleic acid, is enhanced when compared to carboxylates that can not interact This behaviour is similar to the +ESI behaviour reported here The loss of H_2O from species such as protonated 1,3-, 1,4-phthalic acid and fumaric acid requires a 1,3- H shift which is symmetry forbidden and has a large energy barrier (4). This 1,3- H shift is obviated in species with a second interacting carboxyl group and the elimination of H_2O is favoured by the formation of the stable protonated anhydride, the m/z 149 ion in the +ESI mass spectra of 1,2-phthalic acid (Figure 1) Consequently, the formation of the $(M+NH_4)^+$, $(M+H)^+$ and $(MH-H_2O)^+$ ions in the ESI mass spectra of 1,2-phthalic acid, maleic acid and by analogy, myochrysine may involve reactions occurring in the gas-phase.

Modeling the Maximum Charge State and Proton Transfer Reactivity of Electrosprayed Ions

Paul D. Schnier, Deborah S. Gross, Evan R. Williams
Department of Chemistry, University of California, Berkeley, Ca, 94720

Electrospray ionization (ESI) mass spectrometry has become a powerful method for the analysis of large biomolecules. Multiply charged ions formed by electrospray are destabilized by electrostatic forces, resulting in greatly enhanced rates of reactivity and dissociation. We have recently developed a model which quantitatively accounts for the energetics of gas-phase proton transfer reactions. Here we describe the application of this model for calculating the maximum charge state of ions formed by ESI.

For a multiply protonated ion, the apparent gas-phase basicity (GB^{app}) can be calculated from estimates of the intrinsic proton transfer reactivity of the sites of protonation ($GB_{Intrinsic,\,t}$) and point charge Coulomb interactions experienced by the charge sites (equation 1)

$$GB^{app} = GB_{Intrinsic,t} - \sum_{i=1}^{n} \frac{q^2}{(4\pi\varepsilon_o)\varepsilon_r r_{i,t}} \qquad (1)$$

where ε_r is the effective shielding between charges in these ions. To calculate GB^{app} for a protein, the location of charges in the ion must be known. To determine the most energetically favorable location of charges for a given charge state, a pseudo random-walk algorithm is used.[1] This algorithm places charges at specific residues in a protein initially in a random configuration, and moves the protons such that equation 2 is minimized and the lowest energy charge configurations are found.

$$\sum_{\substack{i,j \\ i>j}}^{n} \frac{q^2}{(4\pi\varepsilon_o)\varepsilon_r r_{i,j}} - \sum_{i=1}^{n} GB_{Intrinsic,i} \qquad (2)$$

Typically, numerous charge configurations with a GB^{app} within 3 kcal/mol of the lowest energy structure are found. Some fraction of all of these configurations should be present near thermal conditions. We approximate this distribution by assigning the GB^{app} of the charge state as an average of all charge configurations within 3 kcal/mol of the lowest energy structure.

Peptides and proteins electrosprayed from denaturing solutions are modeled as elongated "strings" with residues separated by 3.8 Å. Proteins containing disulfide bonds, or electrosprayed from solutions in which they have a native conformation, are modeled using X-ray crystal coordinates. For proteins, $\varepsilon_r = 2.0$ is used in the calculations based on the experimentally determined effective ε_r of gas-phase cytochrome *c* ions.[2] The $GB_{Intrinsic}$ values are obtained from GB measurements of small peptides containing one basic residue.

Our calculated maximum charge state is obtained by comparing the calculated GB^{app} of a charge state to the GB of the solvent from which the ion is formed. The first charge state with GB^{app} < GB(solvent) is the predicted maximum charge state. Higher charge state ions should undergo proton transfer to gas-phase solvent molecules. The calculated GB^{app} as a function of charge for nine proteins is shown in Figure 1. The maximum experimental charge state reported in the literature for each molecule, electrosprayed from a methanol containing solution is circled. For these molecules, the calculated GB^{app} of the maximum charge states is close to the

2 Schnier, P. D ; Gross, D. S , Williams E R., *J. Am. Chem Soc.*, in press

GB of methanol (GB = 174.1 kcal/mol). For 15 commonly electrosprayed proteins, our calculated maximum charge state is within 6% of the experimental value. For these same proteins, the sum of basic residues (Arg, Lys, His, and N-terminus) differs from the experimental value by an average of 20%. Thus, the maximum charge state of electrosprayed ions is determined by gas-phase proton transfer reactions. Similar results are obtained for peptides with many basic sites ($\varepsilon_r = 1.3$). In contrast, the maximum charge state of a peptide with few basic sites appears to correlate with the charge state in solution.

This model has been extended to explain the formation of specific fragment ions upon ion dissociation. For a given charge state of an ion, the Coulomb strain on each bond is calculated for all lowest energy ion configurations. Primary sites of fragmentation are predicted to occur in regions where Coulomb repulsion is greatest. Due to the large number of charge configurations that can occur for some charge states, the predicted fragmentation must occur in at least 25% of these structures. For example, we calculate the greatest Coulomb strain for the 9+ charge state of ubiquitin to be between residues 33-42, 42-48, 42-54, and 54-63. These calculations are consistent with the y_{18}, y_{24}, and y_{37} fragments observed experimentally from multiphoton dissociation data of McLafferty and co-workers.[3] Figure 2 shows the calculated frequency of protonating residues in denatured ubiquitin as a function of charge state. For the 9+ to 12+ charge states of ubiquitin, our calculations are consistent with 83% of the experimentally assigned fragments in the multiphoton dissociation data.[3]

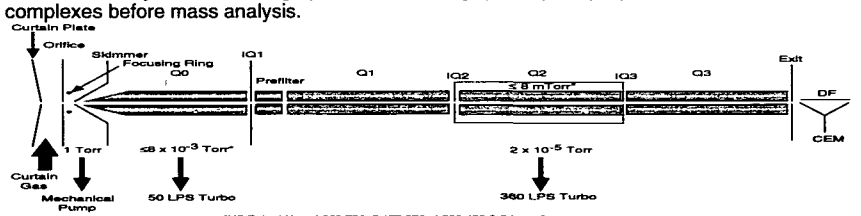
Protein Cations from Basic Solutions with an API III and an API 300

J.C.Yves Le Blanc(1), K.W.Michael Siu(2), Roger Guevremont(2) and Bori Shushan(1)
(1) Sciex, 71 Four Valley Drive, Concord (Ontario) Canada L4K 4V8; (2) National Research Council, IERT, Montreal Road, Ottawa (Ontario) Canada K1A 0R6.

In previous work, we proposed a model based on aqueous solution equilibrium to explain observed ion distributions of proteins in electrospray mass spectrometry (ES-MS)[1,2]. This model was successfully applied to both positive ions produced from acidic solutions[1] and negative ions electrosprayed from basic solutions[2]. One of the well accepted facts among users of ES-MS is that ions observed in the mass spectrum are pre-formed in solutions. The model we proposed also suggested that strong correlation between solution phase and the observed ion distribution. Kelly et al.[3] demonstrated that both positive and negative protein ions could be observed from acidic solutions (pH 3). Similarly, protein ions of both polarity could be observed from basic solutions (pH 10). Since proteins are "expected" to be anions in basic solutions and cation in acidic solutions, these observations were rather puzzling. Based on observations where gramicidin s was electrosprayed from nitrogen base solutions we concluded that the formation of doubly charged gramicidin ion at high pH involves two steps[4]. The first step is the formation [M+xB+nH]+2 ions in solution, where B represents the nitrogen base used to adjust the solution pH and M represents gramicidin s (x=0-2 and n=2). The second step involves the breakdown of the complex to form [M+nH+]+2 or [M+(n-1)H+]+ from collision induced dissociation processes that occur in the sampling orifice region of the mass spectrometer. In other words, the observation of multiply protonated species from high pH solution may only be rationalized by combining solution phase chemistry and gas phase chemistry phenomena. Since a gas phase processes appear to play a role in the observed ES ion distribution of multiply charged species, we investigated the formation of multiply charged protein cations from basic solutions on an API III and the new API 300 bench top mass spectrometer.

Instruments - Experiments were carried on three different systems: a TAGA 6000e, an API II and an API 300. Bot h the TAGA and the API II are equipped with cryogenic pumping and the analyzer region is separated from atmosphere by a nitrogen curtain gas. The API 300 is equipped with turbo-molecular pumps and the first analyzer is separated from atmosphere by both a nitrogen curtain gas and a differentially pumped region (Figure below). The API 300 interface offers a few advantages over that of the other two instruments. First, the differentially pumped region could be used to produce more energetic collisions when the ions are sampled for mass spectrometric analysis. Second, a larger orifice allows to introduce more analyte for better sensitivity. Third, the high pressure focusing quadrupole (Q0) serves to stabilize weak complexes before mass analysis.



*US Patent Nos. 4,963,736 5,179 278, 4,328,420 & 5,248 875

Results - Myoglobin was electrosprayed from a water:methanol (25:75) with 0.1M NH4OH with the API III and API 300. In both cases, the spectrum shows the apparently protonated myoglobin ions and the ion distribution ranges from +6 to +19 protons. From sequence information, apomyoglobin has 21 acidic groups and 33 basic amino groups. Even if all the amino sites retained the proton from the hydrogen-bonded ammonium ion after the CID process, the protein would have a net charge of +12 if one assumes that all carboxylic groups are deprotonated in a pH 10.1 solution. However, protonated carboxylic groups can be created in the lens region if some of the carboxylate anions were complexed with ammonium ions in solution. The formation of carboxylate-ammonium ion pairs in solution could then yield cations having charges higher than +12 after the CID process in the lens region. It is important to note that even though ammonium ions and myoglobin ions are desorbed into the gas phase during electrospray, proton transfer from ammonium ion to carboxylate anion in the gas phase cannot occur because of the overall charge of the myoglobin ion is positive. Ammonium ion can only approach a myoglobin cation in a medium of high dielectric constant (i.e. a solution) where electrostatic shielding is effective.

Even though the API 300 interface may be used to produce more energetic CID processes in the interface region, it may also be used to observe protein-amine complexes by lowering the potential difference between the orifice and the skimmer and/or the skimmer and Q0. Figure 1 shows the effect of reducing the potential difference between the skimmer and Q0 when an insulin/butylamine solution is electrosprayed. Insulin-butylamine complexes can easily be observed under mild sampling condition. At higher potential skimmer-Q0 potential difference we observe only the protonated insulin species.

Conclusion - The results strongly suggest that positive protein ions emerging from basic solutions are actually sampled as a ions of the form (M+nH+xB)z+ , where M represents the protein, n the number of protons in excess, x the number of nitrogen base attached to the protein either by hydrogen-bonded complexes with amino basic sites or by ion pairing with carboxylate anion sites and z represents the net charge of the ion sampled in the early stage of the ES process. The values of n and x for the original ions will more likely depend on the type of base used as well as the structure of the protein in solution. The API 300 sampling interface certainly offers the ability to sample both protein-amine cations and protein cations provided that the potentials across the sampling orifice-skimmer-Q0 are carefully selected

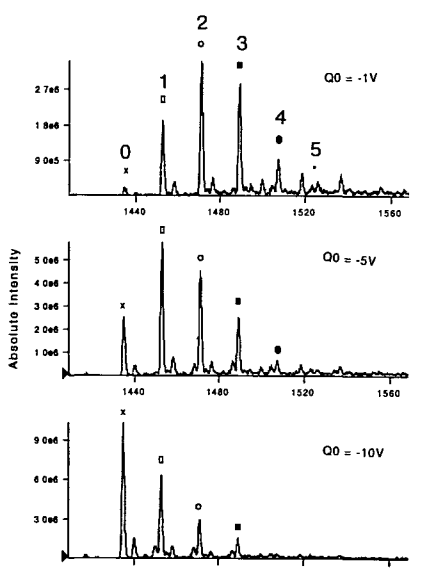


Figure 1: ES-MS of insulin in DDW:MeOH(25:75) 0.1M Butylamine. The values indicate the number of butylamine attached to the protein. All ions have 4 charges

Effect of Organic Solvents on Aerosol MALDI Ion Signal

Michelle D. Beeson, Xiaona Wei, and David H. Russell,

Laboratory for Biological Mass Spectrometry, Department of Chemistry

Texas A&M University, College Station, TX 77843

The effect of solvent on surface MALDI ion signal has been investigated by several groups.[1-7] Rapid evaporation of solvent produces a homogeneous sample surface consisting of small crystals. Surfaces composed of small crystals produce a more uniform ion signal over the sample surface as well as increased ion yield.[1] Improved sensitivity and mass resolution from surfaces composed of small crystals have also been reported.[2] Rapid solvent evaporation has also been achieved through the use of a flow of ambient or heated air,[3,4] dry nitrogen,[5] heat lamps,[6] or vacuum drying.[6] Other laboratories have prepared samples by spraying the solution of matrix and analyte onto the probe surface.[7] These sample spray methods promote solvent evaporation due to the large surface area to volume ratio of the aerosol particles of which the spray is composed.

In our previous work, we noted that solvent evaporation rates are important for aerosol MALDI: drier aerosol particles appear to produce larger ion signal.[8,9] In fact, aerosol MALDI ion signal was obtained with the present apparatus only after a 25 cm long heated drying tube was added between the nebulizer and TOF ion source region. Based on these observations, it seems reasonable to postulate that the more volatile solutions would yield drier aerosol particles resulting in improved MALDI ion signal.

Using the aerosol MALDI technique, the matrix and analyte-containing solution is delivered using a syringe pump to a pneumatic aerosol generator and sprayed into the mass spectrometer as an aerosol. The aerosol first passes through a heated drying tube at 500 C to remove solvent and then ionization is performed at 355 nm using a frequency tripled Nd:YAG pulsed laser. The ions are orthogonally accelerated at 10 kV, mass separated in a 1.1 m flight tube, and are detected with a microchannel plate particle multiplier. The mass spectra are collected by a digital oscilloscope and downloaded to a microcomputer for analysis.[8,9]

In addition to solvent volatility, matrix-analyte interactions are an important consideration in both solid and aerosol MALDI. For example, Beavis and Bridson proposed that hydrophobic interactions between the matrix and analyte lead to inclusion of the analyte into matrix crystals, thereby enhancing the ion yield.[10] Both hydrophobic and hydrophilic interactions between matrix and analyte molecules are undoubtedly affected by the solvent and the concentration of the matrix and analyte. It is probable the solvent can alter matrix-analyte interactions, and thus influence the aerosol MALDI ion signal. For example, we observed that optimum matrix to analyte ratios for aerosol MALDI are lower than for surface MALDI,[9] typically 10-100:1, as opposed to 100-1000:1 for surface MALDI.[1-7] We postulated that solvent/matrix/analyte interactions are responsible for this difference.

In previous work, we observed that drier aerosol particles produce larger aerosol MALDI ion signal.[8,9] Thus it might be expected that the most volatile solvent that dissolved the matrix and analyte would produce the largest aerosol MALDI ion signal. The volatility of the solvents used in this work is methanol > ethanol > isopropanol ≈ acetonitrile. The data presented in Figure

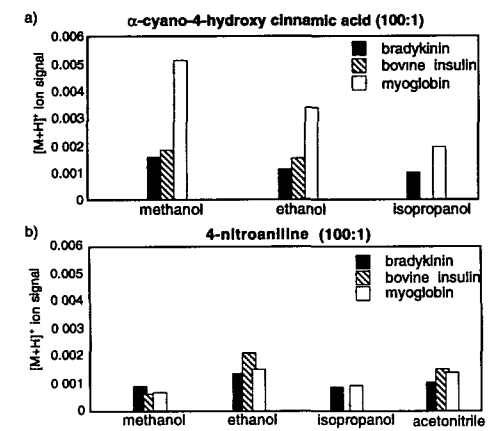

Figure 1. Bar graphs showing the aerosol MALDI ion signals in 100% organic solvents using the matrices **a)** α-cyano-4-hydroxycinnamic acid and **b)** 4-nitroaniline. The laser energy used was 13 mJ/pulse.

show that the aerosol MALDI ion signal is not directly related to solvent volatility For example, the ion signals obtained with 4-nitroaniline are nearly the same in all neat solvents, regardless of volatility. For more than 80 % of the analyte-matrix-solvent combinations examined the aerosol MALDI ion yield is greatest in organic/water mixtures even though the volatility of the organic/water mixtures is lower than that of the neat organic solvents. Thus the data indicate that aerosol MALDI ion yield is not strongly dependent on solvent volatility, but that the chemical interactions between the matrix and analyte are solvent dependent. Thus the choice of solvent in aerosol MALDI plays a key role in obtaining optimum ion signal.

"Analyzing Thermally Labile Compounds in Electrospray Sources using Heated Capillaries"

Brent L. Kleintop, H. K. Lim, Thomas D. Oglesby[1], Kelvin W. Chan, and Samuel F. Sisenwine
Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543-8000
[1]Taylor Technology, 107 College Rd. East, Princeton, NJ 08540

Introduction

The recent development of atmospheric pressure ionization (API) sources as LC/MS interfaces has led to the development of several different commercially available API sources. One design incorporates a metal-clad heated capillary to facilitate desolvation to allow the use of LC flow rates ranging from 1-1000 ml/min. A potential problem of this design is that some compounds may thermally decompose or form adducts while passing through the heated capillary. Although this is not always the case, we have seen examples of compounds decomposing in the ion source under "normal" operating conditions (*i.e.* higher capillary temperatures at higher flow rates). Intact molecular ions are essential in metabolite identification studies because thermal decomposition products or adducts may be incorrectly assigned as metabolites. Intact molecular ions are also important in quantitative analyses using stable isotope labeled internal standards. Thermal decomposition may result in the loss of the stable isotope label; the decomposition products for both the analyte and internal standard would be identical. This type of decomposition would require the use of a different stable isotope labelled compound. Finally, the heated capillary may affect the detection of non-covalently bound complexes, an exciting potential ESI/MS application.

This presentation addressed considerations for operating API sources with heated capillaries to minimize thermal decomposition to promote the formation of intact molecular ions. These effects were illustrated by the ESI spectra of some low molecular weight pharmaceutical compounds which readily decompose in the heated capillary under "normal" operating conditions. The mass spectra of a non-covalently bound complex obtained on two different source designs was also compared.

Experimental

Mass spectra were acquired using a Finnigan MAT TSQ-7000 and Finnigan API source. A schematic of the source is shown in Figure 1. Samples were infused at a flow rate of 5 ul/min into a 350 ml/min mobile phase flow resulting in a total flow rate of 355 ul/min into the ESI source. Mass spectra were acquired after performing signal averaging for 30 seconds. A Vancomycin-DALAA (non-covalent complex) mass spectrum was acquired by infusing the sample into the instrument at a flow rate of 5 ul/min and signal averaging for 30 seconds (10 scans). The mass spectrum of Vancomycin-DALAA was also acquired using a PE Sciex API III. The sample was infused into the instrument at a flow rate of 5 ul/min. The mass spectrum shown is the sum of 10 scans.

Results

The effect of capillary temperature and tube lens voltage on mass spectra of ACA-147 is illustrated in Figures 2a and 2b below. At the flow rate used for these experiments, we would normally use a capillary temperature of 225 C to produce efficient desolvation. However, at this temperature a significant amount of decomposition was observed (Figure 2a). Reducing the heated capillary temperature yielded poor desolvation which produced mass spectra which contained predominately solvent ion clusters. One method to overcome the loss of desolvating power at low capillary temperatures is by using in-source CAD to promote solvent declustering in the capillary/skimmer region of the interface. The higher voltages applied to the tube lens or capillary are more likely due to the need to decluster solvent ions rather than focus ions through the skimmmer. The mass spectra of Figures 2b demonstrate a significant increase in molecular ion production using lower capillary temperatures (125 C) with higher tube lens voltages (+190 V). At these conditions, stable molecular ion signal was observed for 10 minutes.

Another method to affect desolvation is the use of high flows of auxiliary gas. The effects of the auxiliary gas flow rate are illustrated in the mass spectra of ACA-147 shown in Figures 3a - 3b. These

mass spectra demonstrate that the use of higher flows of nitrogen auxillary gas helped to promote desolvation and greatly reduce the amount of methanol solvent clusters observed at temperatures. lower capillary temperatures.

The mass spectra of the non-covalently bound complex of Vancomycin and Diacetyl-Lys-Ala-Ala obtained using both an ESI source which incorporates a heated capillary and another design which doesn't incorporate heat were also compared. Both mass spectra showed detection of the Vancomycin-DALAA complex. However a much larger abundance of singly charged complex and free Vancomycin was observed in the heated capillary source. This may be a result of charge stripping caused by the heated capillary.

Conclusions

This presentation demonstrated that intact molecular ions of thermally labile compounds may be produced in ESI sources using heated capillaries at high flow rates (200-400 ul/min) and low capillary temperatures. The loss of desolvating power at low capillary temperatures may be overcome by using high tube lens voltages to promote solvent declustering via in-source CAD in the capillary/skimmer region of the interface. The use of higher flows of auxillary gas may also promote desolvation. Good molecular ion signal stability was observed when using low capillary temperatures at higher flow rates. Finally, non-covalently bound complexes can be detected using ESI sources of two different designs.

Peptide Mixture Analysis by Combining Electrospray-CID-MS and Chemometrics

William H. Cusworth, III and Frantisek Turecek
Dept. of Chemistry, BG-10, University of Washington, Seattle, WA 98195, USA

Introduction: Electrospray Ionization (ESI) has been shown to have wide applications in the analysis of peptides and other biomolecules. However, quantitative analysis of complex mixtures of peptides is often very difficult and usually requires a long separation step. Here a new analytical method for the analysis of peptide mixtures is evaluated. The method employs a novel second order mass spectral data collection scheme followed by second order chemometric analysis. The second order data is generated by collecting spectra produced under varying degrees of source-CID where fragmentation is induced in the interface region of the electrospray source. There are inherent advantages in second order data analysis. Unlike zero and first order methods, second order chemometric methods can offer a calibration that is not compromised by the introduction of unknown interferents such that calibration samples need only contain the target analytes (1).

Experimental: Two sets of experiments were conducted using mixtures of dipeptides as analytes to be quantitated and 100 μM solutions of the pure dipeptides as calibration standards. All samples used a solvent matrix of 80:20 MeOH:H_2O with 0.2% acetic acid.

The first set of experiments were carried out on a Hewlett-Packard 5971A bench top mass spectrometer which has been modified to support electrospray ionization using the transfer capillary design first published by Chait et. al. (2). Binary mixtures of the dipeptides Phe-Leu (FL) and Leu-Phe (LF) were chosen as a simple two-component model system for evaluation. FL and LF are isomers which give a parent ion at *m/z* 279. At higher collision energies, FL yields an *a*-type fragment ion at *m/z* 120 while LF yields an *a*-type fragment ion at *m/z* 86. The samples were injected using a simple FIA system at 5 μL/min. Ions exiting the transfer capillary are subject to CID by externally applying a voltage bias in the expansion region (1.2-1.4 torr) between the capillary and the skimmer. The quadrupole is scanned at low resolution in the selected ion monitoring mode (SIM) mode at 2 scans per minute for 30 preselected parent and fragment mass channels of importance. The voltage bias is applied in 25 V steps in one minute intervals to coincide with the scan of the quadrupole such that 9 discrete biases (18 scans) ranging from +125 V to +325 V are monitored. The data collected is combined into a 18 x 30 matrix. Figure 1(a) shows the second order spectra generated for the mixture of 80 μM FL and 40 μM LF.

The second set of experiments were carried out on a Finnigan TSQ 7000, a commercial tandem quadrupole mass spectrometer. Six-component mixtures of the dipeptides FL, LF, FG, GF, SL, and LS were made such that each component would have an *m/z* overlap of both its parent ion and the fragment ions. The components of these mixtures cannot be accurately quantitated by standard zero-order methods due to the absence of any unique peaks for calibration. Samples were infused from a syringe pump at 5 μL/min. Fragmentation was induced in the first octopole by ramping the voltage bias (software-controlled) in 1 V steps from +5 V to +34 V between the skimmer and analyzer assembly, which has the configuration: octopole-quadrupole-octopole-quadrupole. The first

quadrupole was operated in the RF-only mode while the second quadrupole was scanned from *m/z* 30 to 325 every 15 sec (1 scan for each voltage bias step). The resulting data matrix was reduced to a size of 30 x 50 by selecting 50 parent and fragment mass channels of importance. Figure 1(b) shows the second order spectra generated for the mixture of 40 μ M FL and 20 μM of the other 5 components.

Results: The second order data produced by the method described are non-bilinear in nature and were analyzed by Non-Bilinear Rank Annihilation (NBRA)(1), an extension of the Generalized Rank Annihilation Method (GRAM). Results of the NBRA (second-order) data analysis were compared to results of the standard zero-order method of predicting concentrations based on the ratio of the peak height of the parent or a fragment ion in the mixture to that in the standard. In the first set of experiments (binary mixtures on modified HP 5971A), it was found that the predictions using NBRA (using 1 principal component (PC) for FL, 2 PCs for LF) for most of the mixtures correlated well with predictions based on the ratio of unique fragment peak heights. As expected, predictions became worse as more mass channels containing primarily noise were included in the analysis. The six-component mixtures of dipeptides were unable to be analyzed due to the low signal of the in-house modified HP5971A, hence the use of the Finnigan TSQ 7000, which yields a greater than ten-fold better signal to noise ratio, in the second set of experiments. These experiments showed that concentration predictions based on peak heights of the parent ions were not in agreement with what one would expect based on the known isobaric overlaps. The signals for FL and LF appear to be enhanced in the mixtures while the other components are suppressed. The high total peptide concentrations ranging from 110 to 150 μM may account for the interaction between the analytes. The NBRA analysis (using 4 PCs) yielded predictions significantly closer to the actual values for FL, LF, and LS but not for FG and GF. Singular-Value Decomposition revealed that the matrices only had a rank of four, which means that at most four analytes can be quantitated successfully in this set of data.

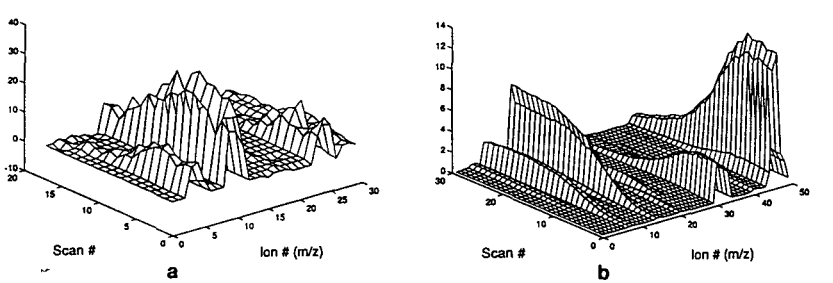

Figure 1. Second-Order Spectra of a) 80 μM FL & 40 μM LF on modified HP 5971A b) 40 μ M FL & 20 μM LF, FG, GF, SL, & LS on Finnigan TSQ 7000.

Ion Solvation in Electrospray Generated SDS Clusters

Q. Gao, A. C. Harms, J. Zhang, H. R. Udseth, A. L. Rockwood,
M. G. Sherman and R. D. Smith

Chemical Sciences Department
Pacific Northwest Laboratory, Richland, WA 99352

The investigation of ion solvation is important for understanding solution behavior. The extent of solvation of ions and molecules is not only a fundamental concern for elucidating reaction kinetics and thermodynamics, but also strongly influences molecular structure, stability and reactivity. In this research sodium ion solvation in the sodium dodecyl sulfate (SDS) surfactant clusters has been investigated using mass spectrometry.

Electrospray ionization was employed to generate gas phase ion clusters from SDS aqueous solutions. Gas phase sodium ions solvated by water were only observed for small singly charged clusters at low (100°C) capillary inlet temperatures (Fig. 1a). Larger size ion clusters $Na(SDS)_n^+$ ($n > 4$) preferentially associate SDS molecules (Fig. 1a). For multiply charged cation clusters (multiple sodium ion adduction) water solvation was not observed. This trend is opposite to that of metal halide salt clusters where greater solvation was reported for doubly charged ions than that for singly charged ions in a comparison experiment [1]. While the total number of associated water molecules with each sodium ion may depend on the kinetics of the desolvation process in the heated capillary, the preferential SDS attachment to large ions likely results from the higher thermodynamic stability for SDS association. This is confirmed from collision induced dissociation (CID) studies. The strength of association among SDS molecules is estimated to be a factor of 4 stronger than the association of water molecules to the SDS cation clusters. It is postulated, based on the CID results, that the SDS clusters are primarily bound by electrostatic forces rather than van der Waals forces.

For anion clusters (detachment of sodium ions), no solvation was observed at 100 °C capillary temperature (Fig. 1b), which may be attributed to the hydrophobicity of the hydrocarbon chain. Theoretical studies suggest that large halide anions would reside at the surface of water clusters, rather than being solvated internally by small water clusters [2]. This would lead to weaker water-anion interactions, hence, easier desolvation.

RAPID MOLECULAR WEIGHT DETERMINATION USING ELECTROSPRAY IONIZATION MASS SPECTROMETRY

Rich Gedamke, Gerald C. DiDonato, Mark E. Hail, and Mike S. Lee
Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton, NJ 08543

In the pharmaceutical industry, molecular weight characterization of synthetic organic compounds has been traditionally accomplished using probe techniques such as fast atom bombardment (FAB) and desorption chemical ionization (DCI). The choice of technique is usually determined by compound volatility and thermal stability, with DCI chosen for volatile compounds usually less than 700-800 Da. FAB is the technique of choice for peptides, salts, and intermediates with unstable protecting groups. Both techniques usually involve manual sample preparation and analysis.

The commercialization and availability of electrospray ionization (ESI) provides an additional method of sample characterization via mass spectrometry. ESI is capable of producing gas-phase ions from solution with little or no internal energy, resulting in simplified spectra often containing only a major ion associated with the molecular ion species. It would appear that ESI will have a significant role, complementary or perhaps exclusive, with respect to molecular weight characterization.

This poster describes our efforts to develop ESI conditions that would provide molecular weight information for the greatest percentage of all synthetically prepared samples submitted to our laboratory for molecular weight characterization. Amongst the parameters investigated were sample concentration, sample dissolution and preparation, LC eluent, pH, mobile phase flow rates, and instrument control.

EXPERIMENTAL

These studies were performed using a Finnigan TSQ700 mass spectrometer equipped with a Finnigan ESI source. The chromatographic system included a Waters Model 600MS LC and a Waters 717 autoinjector with 96 sample carousel under the control of the mass spectrometer data system.

RESULTS AND DISCUSSION

A small amount of sample is placed into a 1 mL autosampler vial. The sample amount is "eyeballed", but is generally in the range of a few hundred micrograms. In our initial studies samples were dissolved in the solvent indicated on the sample submission card as indicated by the submitting chemist. However, this procedure proved to be cumbersome and time consuming. In order to facilitate sample preparation, we sought the use of a single solvent system. A mixture of water, acetonitrile, methanol, and acetone was evaluated and is now routinely used since it can dissolve most of the compounds submitted for analysis. Typical exceptions to this are synthetic peptides which require dissolution in 0.1% TFA. Typically, 2 µL of this solution is injected, with the exception of peptides, in which 10 µL is injected. This results in injection quantities on the order of a few hundred nanograms.

Selection of an appropriate solvent system was central to the goal of developing automated flow injection ESI that could result in the successful analysis of the highest percentage of synthetic organic compounds. Our initial experiments with ESI involved the use of several

different mobile phase modifiers, including ammonium acetate, ammonium formate, formic acid, and TFA, in acetonitrile/water, in both positive and negative ion mode.

Both TFA and formic acid appeared to chemically cleave acid-sensitive protecting groups such as trityl and phenyl,di-tertiary butyl groups. Less degradation was noted when ammonium acetate or ammonium formate was used, however we were obtaining accurate molecular weight data on only 65% of submitted samples. Most successful analyses were those that yielded good positive ion data. We then evaluated several mobile phases in an effort to increase negative ion production and therefore increase the number of successful analyses. Several novel mobile phases were evaluated, including KOH in methanol, potassium-tert-butoxide in tertiary butanol, ethyl diisopropyl amine in methanol, and ammonium hydroxide. Both KOH/methanol and potassium-tert-butoxide/butanol were found to "salt out" of solution thus clogging the PEEK tubing and ESI manifold of the instrument. Ethyl diisopropyl amine in methanol was found to produce excellent negative ions for medium sized molecules with only one labile proton, including simple alcohols. Routine use of this solvent system was abandoned due to high background in positive ion mode. Ammonium hydroxide proved to be the most useful solvent for negative ion analysis across a wide range of structures. Further experimentation indicated that ammonium hydroxide could produce excellent positive ion data as well. Currently the method has been refined with a mobile phase consisting of 0.1% aqueous ammonium hydroxide/acetonitrile (50/50).

DATA REDUCTION AND INSTRUMENT CONTROL

Following the successful implementation of flow injection ESI it became apparent that the bottleneck in high-throughput automated analysis would be instrument control and data reduction. In order to facilitate these processes, an instrument control language (ICL) procedure, which we call pulsed positive ion negative ion electrospray ionization (PPINIESI), has been written which controls the Waters 600 MS HPLC and 717 autosampler and the TSQ700 mass spectrometer. Up to 96 samples can be loaded into the sample rack of the Waters autosampler. The operator simply appends the PPINIESI procedure with the list of compounds to be run. The instrument then acquires both positive and negative ion ESI data for each sample in the rack. Using a separate data system script, written in the UNIX C-shell environment, the raw data is automatically background subtracted and printed.

CONCLUSIONS

We have developed an automated flow injection ESI system capable of molecular weight characterization of over 85% of compounds received in our laboratory. Sample preparation is straightforward, requiring the use of a single dissolution solvent. Analysis of each sample in both positive and negative ion mode, using a single LC solvent, takes approximately 2 minutes per sample. Based upon our work it appears that ESI is a nearly all-encompassing molecular weight determination tool. ESI is very well suited to high-throughput molecular weight determinations. Future efforts with molecular weight characterization will almost certainly require the use of ESI sources on relatively simple quadrupole or ion trap mass spectrometers.

Adventures in the positive ion ESI/MS of acids and neutral molecules

Nikhil Shah and William L. Fitch
Affymax Research Institute, 3410 Central Expressway, Santa Clara, CA. 95051

Introduction

Electrospray ionization (ESI) has revolutionized the introduction of compounds for mass analysis. This simple technique can be used with ionics and non-ionics, with polar and reasonably non-polar compounds, with high and low molecular weights. As a general method for structure confirmation to a diverse population of small molecule and peptide chemists we utilize flow injection, positive ESI. Amines and quaternary ammonium compounds behave extremely well in ESI. Acidic and neutral compounds are not always so sweet.

Affymax is pioneering the automation of chemical synthesis and generating mixtures or "libraries" of compounds for drug discovery. One of our tasks is to develop MS methods for quality control of these mixtures. MS of a mixture is much more difficult when individual components of the mixture yield solvent adducts, oligomers, cation adducts or fragment ions.

Among the problems we are addressing:

Phthalate contamination, Solvent adducts and oligomers, Ion suppression by impurities and Artifacts from reactive solvents.

Conclusion

After one year of analyzing over 400 samples per month we are confident of our ability to obtain ESI molecular weights for 80-90% of the small molecules generated in a diversity chemistry lab.

Phthalates can arise from HPLC pump seals, impure water and impure acetic acid. We know how to avoid these problems.

Solvent adducts and oligomers arise from insufficient declustering in the heated capillary ESI interface. These artifacts can be lowered by adjusting ionization voltages and temperatures, by decreasing compound concentration and by doing low flow infusion instead of flow injection.

Suppression of ESI signal can occur when analyzing mixtures if different components have very different ionizabilities. LC/MS is the general solution to this phenomenon but not practical for routine analysis. We have shown that ion supression with the Dionex scrubber can be useful in some cases to remove the offending cations and allow the "hard to ionize neutral's" spectrum to come through. This phenomenon may be useful in mixture analysis.

INTRODUCTION

The characterization of noncovalent complexes from solution using electrospray ionization (ESI) constitutes a new capability for mass spectrometry (MS). Observation of many types of charged complexes has been reported. However detection of neutral, noncovalent complexes becomes difficult using ESI-MS when the molecules (complexes) do not have ionizable groups or when they are insoluble/unstable in the more typically used solvents. We will show that the use of organic-soluble charge carriers such as tetraphenylphosphonium chloride (Ph_4PCl) or tetraphenylboron sodium (Ph_4BNa) presents a new strategy to facilitate ionization for these neutral noncovalent systems. A family of self-assembled aggregates have been designed based on the cyanuric acid•melamine (CA•M) hydrogen-bonded lattice (Figures 1 and 2). These noncovalent complexes have been characterized using a variety of techniques and the results indicated the formation of tight complexes in non-polar organic solvents with a range of stoichiometries. Studies by vapor pressure osmometry suggested, however, that the molecular weights were 50-80% higher than those expected for these stoichiometries.

EXPERIMENTAL

A Finnigan MAT TSQ 7000 triple-quadrupole mass spectrometer with a home-built microspray emitter optimized for very low sample infusion rate (0.2-0.5 ul/min) was used. A solution containing 1-5 mM Ph_4PCl or Ph_4BNa and 1-5 mM analyte was prepared for the electrospray ionization by mixing appropriate amounts of each component in a 10 mM stock solution with the non-polar organic solvent. The solution was directly infused into the ion source of the mass spectrometer. In the collision-induced dissociation (CID) experiment, the precursor ion was selected using the first quadrupole with a window of ±5 *m/z* units, accelerated and collided with added argon gas in the second (rf only) quadrupole (E_{lab} = 35 eV, P_{Ar} = 1.58 mTorr). The product ions were detected using the third quadrupole with unit *m/z* resolution. For thermo-dissociation experiments, the desolvation capillary temperature was varied systematically while all other instrumental parameters were kept constant.

RESULTS

Successfully detection of several intact hydrogen-bonded supramolecular complexes using ESI-MS was made possible in non-polar organic solvents by attachment of small organic-soluble ions using reagents such as Ph_4PCl. These complexes have been observed using mass spectrometry for the first time and the accurate molecular weight measurements confirmed the stoichiometries inferred in solution. Figures 1 and 2 show the ESI-MS spectra for complex **4** and **7** using Ph_4PCl as charge donor. The Cl^--attached complex ions with expected stoichiometries were observed as the predominant species in these spectra. Additional structural features and relative stabilities of these complexes were revealed by thermally (Figures 3 and 4) and collisionally induced dissociation techniques. Complex **7** was shown to be more stable than complex **4**, consistent with results of solution studies. The dissociation of complex **4** produced predominately the individual components, demonstrating the highly cooperative nature of the subunit binding while complex **7** gave substantial amount of 1:1 complex in addition to the individual components. Successful detection of these complexes were also made using other organic soluble salts (such as Ph_4BNa) and solvent systems (such as CH_2Cl_2).

Electrospray Mass Spectra of Less Polar Compound Dissolved in n-Hexane

Wen-Shyang Wang, S-Wan Huang, and Jentaie Shiea*
Dept. of Chemistry, Natl Sun Yat-sen Univ., Kaohsiung, Taiwan 804

Electrospray ionization (ESI) has seldon been used in the anaslysis of less polar compound. This is because that the analyte has to be dissolved in nonpolar solvent and the electrospray of the nonpolar solvents has seldon been studied. In this study, it was found that good electrospray mass spectra of several less polar compounds such as long chain alcohols, acids, and esters dissolved in n-hexane were obtained. The ESI mass spectra were obtained by a PE Sciex API-1 mass spectrometer equipped with an ion spray source The sample solution was introduced by continuous infusion by a syringe pump at 5 ul/min through a fused-silica capillary column of 100 um i.d. The temperature of the electrospray interface chamber was held at 55 ± 1°C

Since the analyte such as long chain alcohols dissolved well both in n-hexane and methanol, the ESI mass spectra of the analyte obtained in both solvents were compared. Figure 1 and 2 show the ESI mass spectra of n-dodecanol ($C_{12}H_{25}OH$, 0.05 M) dissolved in mathanol and in n-hexane The required voltage for electrospray for n-dodecanol/methanol solution is 4200 V and the mass spectrum is dominant with sodium adduct ions such as MNa^+, M_2Na^+, M_3Na^+, and M_4Na^+ (Figure 1) The possible sources of the sodium ions are originated from trace impurities in the solvent or chemicals. The mass spectrum of n-dodecanol/n-hexane solution electrospraying at 5300 V is shown in Figure 2 The spectrum is dominant with the ions such as MH^+, $M(H_3O)^+$, M_2H^+, and M_3H^+ The results shown here indicate that the ions generated in n-hexane solution are dominant with protonated or hydronium-adduct ions which are different from those found in methanol.

Since very high voltage was applied during electrospray of n-hexane solution, it is possible that the moisture in the air will also be discharged. The formation of hydronium ions and the protonated water clusters by discharging become good sources to supply proton and hydronium ion to n-dodecanol. The protonated n-dodecanol can be formed by a series of ion-molecule reaction as those occurred in chemical ionization Since n-hexane is not involved in the process of ion formation, it is unnecessary for the mechanisms described above to be occurred only in n-hexane solution. At 5300 V, even in the methanol solution, the protonated (MH+) or hydronium adduct n-dodecanol ions ($M(H_2O)^+$) can be seen.

Low Temperature Electrospray Ionization Mass Spectra of Thermally Unstable Compound

Wen-Shyang Wang, Chin-Hsiung Wang, and Jentaie Shiea*
Dept of Chemistry, Natl Sun Yat-sen Univ., Kaohsiung, Taiwan 804

2,5-Dimethyl-2,5-dihydrothiophene is not only a very volatile but also a very reactive compound The compound is synthesized by the flash vacuum pyrolysis (FVP) at 600 C and 0.01 torr Once generated, the compound was collected in CH_2Cl_2 and the solution was then caped and stored in CH_2Cl_2/dry ice. The structural characterization of such compounds can only be done by low temperature NMR. So far, good mass spectra of such compound have never been reported This is because that none of the ionization techniques used in mass spectrometry can efficiently operate and generate ions at such low temperature. Since the freezing points of CH_2Cl_2 is - 95℃, a very low temperature ESI mass spectrum of the analyte in such solvent can be obtained. Here, we report the ESI mass spectra of both compounds by a home-built low temperature ESI source at - 78℃ (Figure 1)

To prevent the occurrence of decomposition and polymerization of the sample molecule, the temperature of the source is maintain at - 78℃ by putting it into a plastic box which is covered with fine dry ice powder The outside part of the box was then surrounded with a thick layer of foam to isothermally isolate it from environment The sample solution was introduced by continuous infusion. Since the glass syringe leaks at - 78℃, a special sample injection and storage unit was built for the analysis. About 0 3 ml of cold solution was rapidly transferred into one arm of a three-way tee. This was simply done by injecting the solution through a teflon tube by a 5 ml gas-tight plastic syringe. One arm of the tee was connected to a 50 ml air-tight plastic syringe. The sample solution in the tees will be delivered to the electrospraying needle by compressing the air in the syringe by a syringe pump. No nebulizing gas is used in this design. The high voltage required for electrospray was added through the stainless steel tube. The ion generated by the low temperature electrospray source was detected by a PE Sciex API 1 mass spectrometer. The operating parameters of mass spectrometer for the low temperature solution were similar to that at room temperature The temperature of the electrospray interface chamber in the mass spectrometer was held at 55 ± 1℃

Figure 2 shows the ESI mass spectrum of DMDHT (in CH_2Cl_2) at room temperature The required on set voltage of electrospray from pure CH_2Cl_2 at room temperature is about 5300 V. It can be seen that the intensity of MH^+ is low. Since the compound is very volatile, we speculate that most of the sample molecules evaporated during sample handling processes. Figure 3 shows ESI mass spectrum of DMDHT at -78℃. The peak from pseudomolecular ion of DMDHT (m/z 111) is the prominent peak on the spectrum. It was also found that the electrospray at such low temperature is more stable than that at room temperature. The required on set voltage of electrospray is nearly the same as that required at room temperature (i.e. ca. 5300 V). This imply that surface tension of CH_2Cl_2 does not increase too much when temperature drop from 25℃ to -78℃ As described before, the compound is very reactive, therefore, it is usually stored at low concentration condition to prevent the occurrence of polymerization Even at -78℃, polymerization still occurs for the solution with high concentration of the sample (Figure 4).

Multiple Channels Electrospray Ionization Source for Directly Coupling to HPLC

Ching--hsiung Wang and Jentaie Shiea*
Dept. of Chemistry, Natl Sun Yat-sen Univ., Kaohsiung, Taiwan 804

The problem of directly connecting HPLC to electrospray ionization (ESI) source is that good electrospray can not be generated under high flow of the HPLC eluent One way to solve the problem is to use multi-sprayer to take the high flow from HPLC[1]. Here, we report that two multi-channel electrosprayers which contains sixteen and seven sprayers respectively were built for this study. Figure 1 and 2 show schematic diagrams of the multi-channel electrosprayers. The ESI mass spectra were obtained by a PE Sciex API-1 mass spectrometer equipped with an ion spray source.

The electrospray source with sixteen sprayers was built for the purpose of directly connecting HPLC eluent to ESI/MS. Each sprayer is made by inserting a capillary column through a teflon tube which is held on an acrylic plate. The distance between two capillary column is about 3 mm To prevent the vibration of the sprayers during electrospray, the teflon tubes are glued together with epoxy No nebulizing gas is used in this design The required high voltage for electrospray (ca. 6-10 kV) is introduced into the solution through a thin stainless steel electrode inserted at one arm of the three way tee. The solution is delivered by a HPLC pump at a flow rate of 0 3 ml/min. Since the C-18 stationary phase in HPLC packing can not efficiently separate the analytes, each sample is introduced into the system by flow injection at one minute interval. Figure 3 shows that good mass chromatograms of five biomolecules can be obtained at the LC flow up to 0.3 ml/min. For higher HPLC flow, a source with more sprayers is required.

With the help of electrospray, the study of the gas phase chemistry of macromolecule become possible In this study, it was found that the multi-sprayer can also be used in this kind of study. The electrospray source is comprised of two syringe pumps which are used to deliver the solution with different composition (see Figure 2). The solution which contain myoglobin dissolved in 1% acetic acid solution was passed through the one of the spraying channel located at central position of the source The solution flowing through the rest of six channels is comprised of diethanol amine. DEA is known for its high basicity in the gas phase and can grabe proton from the denatured myoglobin ion in the gas phase. Figure 4 shows the ESI mass spectra of deprotonated myoglobin by DEA in the gas phase. As the concentration of DEA increasing the effect of deprotonation becomes more clear and the number of the charge on the myoglobin shift to lower number.

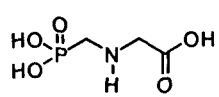
Negative-Ion ESI/MS Mechanism of TFA/TFE Derivatives of Glyphosate and AMPA

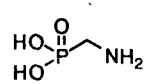
Hideji Fujiwara, Rajendra K. Singh, Ronn G. Nadeau, Robert C. Chott

Monsanto Co, Life Sciences Research Center, 700 Chesterfield Parkway North, St. Louis, Missouri 63198

Glyphosate, N-(phosphonomethyl) glycine (Glyph) **1**, is a widely used herbicide effective on a very broad spectrum of plant species and is registered for agricultural as well as residential uses. The most common metabolite of glyphosate in plants, animals or soil environments is aminomethylphosphonic acid (AMPA) **2**. These compounds are very polar and nonvolatile.



Glyphosate
1



AMPA
2

We recently found that trifluoroacetyl/trifluoroethanol (TFAA/TFE) derivatives of Glyph and AMPA demonstrated dramatically improved sensitivity during negative-ion electrospray ionization / mass spectrometric (ESI/MS) analysis and gave rise to abundant molecular ions. ESI/MS analysis of TFAA/TFE derivatives made possible the detection of nonvolatile products.

The formation of the derivatives and their ionization mechanisms were also investigated by analyses of the derivatives of various deuterium labeled Glyph as well as non-deuterated AMPA analogs.

MAtrix Assisted Laser Desorption/Ionization of Non-Covalently Bound Compounds.

A.S. Woods, J.C. Buchsbaum, J.M. Berg and R.J. Cotter. Johns Hopkins Medical School, Baltimore, MD 21205.

Proteins are biopolymers made of amino acid subunits joined head to tail by a peptide bond (a **Covalent** bond) between the carboxylic acid group of one amino acid and the amino group of the next. Although the amino acid sequence determines the information content of a protein, to use the information depends on much weaker **non-covalent** bonds. As the environment of a folded protein is altered by changing pH, temperature, or pressure, its physical properties do not change gradually. Instead it usually exhibit no change until a point is reached, at which there is sudden drastic change and a loss of biological function. This phenomenon is known as **denaturation**. Denaturation leads to disruption of non-covalent bonds, which lead to loss of tertiary structure and thus of protein function.

In matrix assisted laser desorption ionization (MALDI) mass spectrometric analysis, protein samples are usually dissolved in an aqueous solution of 0.1% TFA 20% or more CH_3CN, pH < 2.0. The matrix of choice is saturated 3,5-dimethoxy-4-hydroxy-cinnamic acid in 1:1 CH_3CN or C_2H_5OH:H_2O pH < 1.5. These highly acidic conditions are denaturing to proteins and peptides, thus making the study of non-covalently bound compounds impossible.

In this study we show that if the harsh acidic conditions present in MALDI MS are changed by using conditions that preserve the tertiary structure of the protein or peptide (pH 4 to 8), we can use this method to study: non-covalent complexes such as zinc finger peptides or enzyme substrate complexes. Mass spectra were obtained on a Kratos (Manchester, England) KOMPACT MALDI III.

a. Zinc Finger Peptides: Two zinc finger peptides were used CP MW 2962.2 PYKCPGCGKSFSGKSDLVKHNRTHTG and CP_{V22} which differs by substitution of a Val for an Arg at position 22. The matrix was a saturated solution of α-cyano-4-hydroxy-cinnamic acid in 1:1 1M NH_4HCO_3:C_2H_5OH. Solutions of CP and CP_{V22} (11pmoles/ul) with and without Zn or Co added were made using a 1M NH_4HCO_3 pH 8.5 buffer. In order to distinguish the different affinities of the Cys_2-His_2 motif for Zn and CO, we prepared a set of peptide samples with 0.5, 1, 5 and 100 equivalents of Zn or Co. All sample spotting on the sample slide were made in an anaerobic chamber. ZFP are small independently folded motifs, that model the multiple zing finger domains found in many DNA-binding proteins. The use of a 1M NH_4HCO_3 pH 8.5 buffer to prepare the peptide solution, as well as the matrix, resulted in a sample-matrix mixture with a pH of 7.2. The peptides used CP and CP_{V22} correspond to consensus sequences developed from earlier zinc finger data base. In this paper we show the first example of a coordinate-covalent metal complex using MALDI mass spectrometry. We also have on a crude scale distinguished between the affinities for binding of a zinc finger domain to two different metals, by "titrating" with equivalents of metal ions. We compared The spectrum of

CP+1.0 equivalent of Zn under anaerobic conditions, to the spectrum of the same sample after exposure to air and found a significant decrease in the MH^+ of ZFP+ Zn. ZFT are highly sensitive to oxydation and will oxidize on exposure to room air. The resulting disulfide bonds that are formed between the two cysteines, as well as other oxidative products involving cysteine preclude the formation of coordinate-covalent complexes between metal ions and Cys or His residues. Mass spectra of CP_{V22}+1.0 equivalent of Zn shows a more prominent $(M+Zn-H)^+$ than that of CP_{V22}+0.5 equivalent of Zn, while the $(M+Co-H)^+$ is barely visible when one equivalent of Co is added.

b. Enzyme-Substrate Complexes: Aminopeptidase I and growth hormone releasing factor (GH) MW 5107.8 were purchased from Sigma. GH solution was made in 1M ammonium citrate pH 6.0 (10pmoles/ul). The matrix was a saturated solution of 3,5-dimethoxy-4-hydroxy-cinnamic acid in 1:1 1M ammonium citrate:C_2H_5OH. Enzyme-substrate complexes have been extensively studied using a variety of methods. Most of these methods, however, require large quantities of enzymes which are not always available. MALDI MS could be an alternative method to the study of enzyme-substrate complexes. MALDI MS has the distinct advantage of requiring picomolar concentrations of protein to give the same information as more well-established methods.

We combined aminopeptidase I with the substrate (GH) and quenched the reaction by matrix addition. The mass spectrum of GH + aminopeptidase, shows MH^+ at 5108.8 amu (GH), 29970.9 amu (aminopeptidase I) and at 35117.5 amu (Enzyme-Substrate complex). The detected masses are well within the 0.1% margin of error typical of MALDI TOF spectra.

These results suggest that by avoiding denaturation of proteins and peptides MALDI TOF could be used as an effective tool to study various types of non-covalent bonding. Non-Covalent complexes have been more easily observed using ESI (1, 2 and 3). However the above results suggest that the effect of the matrix (which usually has an acidic pH) on the tertiary structure of proteins and peptides, rather than the laser desorption/ionization process itself, may limit the observation of non-covalent complexes. Thus, we expect that careful attention to the effect of the UV-absorbing matrices will improve the capabilities for observing the weaker interactions involved in non-covalent complexes.

Primary Structures of Proteins Characterised by Proteinase K Digestion and MALDI Mass Spectrometrry

Houjun Yang, Matthias Amft, Johann M. Grundwürmer, Xiaoling Li
and Jürgen Grotemeyer*
Institute of Physical Chemistry, Wuerzburg University, 97070 Wuerzburg, Germany

The advents of matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS) have enabled the determination of biomacromolecular mass with high sensitivity and accuracy. The technique finds many applications in solving problems encountered in biochemical and molecular biological research. A shortage of the technique is the production of the quasi-molecular ion with the absence of fragmentations, this is mostly a disadvantage in structural elucidation of biopolymers such as proteins The shortage of fragmentation can principally be improved by combining with enzymatic hydrolysis. The enzymes typically employed to completely hydrolyze proteins with high specificity into several lower-weight fragments which can then be sequenced are endopeptidases like trypsin. The less specific hydrolytic enzymes such as proteinase K has seldom been used for protein structure determination in combination with mass spectrometry However, the low specificity of proteinase K could be employed to advantage in hydrolyzing the substrate, since it can produce a series of peptide fragments somewhat like the sequence ions generated in mass spectrometry. Because proteinase K can hydrolyse the peptide bond adjacent to aliphatic or aromatic residues, it may act on every one of these peptide bonds in a protein exposed to proteolysis yielding a variety of fragments with different lengths, thus providing information about the primary structure of the protein. This is important especially in studying large molecules We have already been successful in investigating polypeptides with the method described above[1], it will be interesting to examine whether the method works for proteins which have high molecular weights

Insulin B-chain was first studied as a model compound with low molecular weight by incubating with proteinase K and subsequently being analysed with MALDI mass spectrometry. A series of peptide fragments were observed in the mass spectrum with reasonable intensities, and a careful calibration of the mass scale allows to identify each of the fragments (Table 1), thus providing reliable sequence information about the protein

Hen-egg white lysozyme and horse heart cytochrome C are well folded into globular in

their native state where many of the possible cleavage points are burried into the inner part and resistant to proteolysis. After unfolding in 3M guanidine hydrochloride abundant fragments can be produced from proteinase K digestion of the proteins, from which the primary structure of the proteins can be checked (see Table 2 for cytochrome C).

MALDI/TOF/MS AND RECOMBINANT HIV PROTEIN EXPRESSION

Carol E. Parker, Damon I. Papac, Kenneth B. Tomer

Laboratory of Molecular Biophysics
National Institute of Environmental Health Sciences
PO Box 12233
Research Triangle Park, NC 27709

We have been involved in a project to determine the epitope on recombinant HIV p24 that interacts with commercial antibodies. The method selected for this determination is proteolytic protection assays combined with MALDI/TOF/MS. As part of this project, we have used MALDI/TOF for verification of commercially-available recombinant p24. Because of the poor quality of the commercially available p24, and the low quantity available of p24 with the correct sequence, we have had to turn to expressing recombinant p24 in our laboratory

One of the most common methodologies for producing large amounts of proteins is by protein expression in genetically altered bacteria or yeast. The specific end-use of the recombinant protein can influence the exact expression strategy employed for protein production. Structural studies, in which the natural configuration is retained, are the most stringent end-uses of recombinant proteins in terms of the requirements for expression and purification This usually requires that the protein be made in a soluble form that does not require a denaturation/renaturation step in its purification. The protein must also be expressed in a system that minimizes proteolytic degradation In addition, the cloned gene is often introduced into the cell in combination with a gene that codes for a highly expressed carrier protein i e , as a fusion protein If chosen properly, the carrier protein can be exploited in protein purification

One example of a carrier protein is glutathione-S-transferase (GST) The recombinant protein is expressed as a fusion protein with the GST The fusion protein can be purified by affinity chromatography with an immobilized glutathione-agarose column In general, fusion proteins containing GST are soluble and can be purified under non-denaturing conditions. An additional gene is often incorporated into the fusion protein that expresses an amino acid sequence between the desired protein and the GST that can be cleaved by a site-specific protease, such as blood coagulation factor Xa. After the fusion protein is bound to the glutathione-agarose column and impurities removed by washing, the recombinant p26 can be cleaved from the GST while it remains bound to the affinity column. The cleavage of the recombinant protein is typically followed by SDS-PAGE.

We have expressed recombinant p26 (which contains the p24 protein along with several residues from flanking proteins) in *E. Coli* provided by Dr. I M. Jones (NERC Inst. Virology, Oxford, UK). During this procedure, we have noted that the use of MALDI/TOF to follow the purification and cleavage of the fusion protein through direct analysis of affinity bound analytes [Papac et al , *Protein Sci* (**1994**) *3* 1485] is much more facile than is the use of SDS-PAGE. We have also incorporated the use of HIV protease instead of Factor Xa to cleave the recombinant protein This enzyme cleaves p26 at two positions to give p24

The first figure is a bar graph of the time course of a Factor Xa cleavage of the fusion protein affinity bound to the glutathione column. This graph shows the absolute areas of the peaks due to starting material and to the product demonstrating a nearly steady and quantitative increase in product ions over time The second figure shows one time point in the HIV protease cleavage of the affinity bound fusion protein The spectrum shows the relative abundances of the ions for the starting material, intermediate products and final products. This spectrum can be obtained in minutes and demonstrate the ease, resolution, and utility of MALDI/TOF over SDS-PAGE.

MALDI-TOF Analysis of Peptide Digestion Mixtures with Detergents

Farzin Gharahdaghi, Joseph Fernandez, and Sheenah M. Mische
The Rockefeller University Protein/DNA Technology Center 1230 York Ave., N.Y, N.Y. 10021

Matrix-assisted laser desorption/ionization time-of-flight (MALDI/TOF) mass spectrometry, in combination with enzymatic digestion of proteins and peptide-mass database screening, provides a rapid means for tentative identification of known proteins at the subpicomole level (1-3). In general, regardless of whether the protein is "on-membrane" or "in-gel", the ideal digestion method would : 1) produce peptides in high yield. 2) produce longer species for Edman sequencing (important for unknown proteins, as more contiguous sequence data allows for better DNA probe design for subsequent screening of libraries). 3) recover peptides in an extraction buffer compatible with other microanalytical methods (i.e., RP-HPLC and MALDI-TOF MS). The inclusion of nonionic detergents has been shown to be essential for obtaining peptides in high yield, especially hydrophobic species and longer length peptides (4). Digestion methods employed for peptide-mass screening have not used detergents due to signal suppression effects (5,6). As a result, peptides recovered using these methods tend to be short, relatively hydrophilic and of low yield, suitable for peptide-mass database screening, but not ideal for the subsequent HPLC purification and Edman sequence analysis required for proteins not present in databases. Here we describe a one-step peptide preparation method that fulfills all three criteria. Utilizing a modified matrix solution of α-cyano-4-hydroxycinnamic acid containing 50% organic solvent, direct analysis of detergent/peptide mixtures by MALDI-TOF MS, mass spectra was obtained using *hydrogenated Triton X-100 (RTX-100), Octylglucopyranoside (OGP) or Tween-20.* Peptide-mass database searches were performed with 1-2% of peptide-detergent mixtures using the molecular weight search **(MOWSE)** fragment database and associated search and scoring algorithms (1). The results from peptide-mass profile search for human transferrin are summarized in **Table 1.** Peptide-mass database analysis provided rapid tentative identification of proteins in the database, and those not identified were subsequently characterized as unknown proteins by Edman sequencing of purified peptide, illustrating the utility of this approach for rapid protein identification of both known and unknown proteins using a one-step method for protein digestion.

Sample transferrin	RTX-100 / Tris	RTX-100 / NH4HCO3	OGP / Tris	OGP / NH4HCO3	Tween-20 / Tris	Tween-20 / NH4HCO3
50pmole	correct	correct	correct	correct	correct	false
25pmole	correct	correct	correct	correct	correct	false
12.5pmole	false	false	false	correct	false	false

Table 1: Search results for tentative identification of PVDF-bound protein by using 50%CH3CN in matrix solution (Error =+/- 2 daltons; *"Correct" designation =identified with highest rank (1)).*

Summary

I.) 50% CH3CN saturated matrix solution produced mass spectra from all detergent / peptide mixtures *(RTX-100, Tween-20* or *OGP)* with either Tris or ammonium bicarbonate buffer **II.)** Ammonium bicarbonate buffer provided the most sensitive direct analysis in combination with any of the detergents tested for direct analysis of detergent / peptide mixtures by MALDI-TOF MS using 50% CH3CN saturated matrix solution. **III.)** *OGP* is the preferred nonionic detergent, as it does not form clusters with buffer ions. **IV.)** 50% CH3CN saturated matrix solution in combination with 1% OGP / 25 mM NH4HCO3 buffer provided the most accurate peptide-mass profiles obtained from MALDI-TOF MS analysis of peptide-detergent mixtures from PVDF-bound proteins.

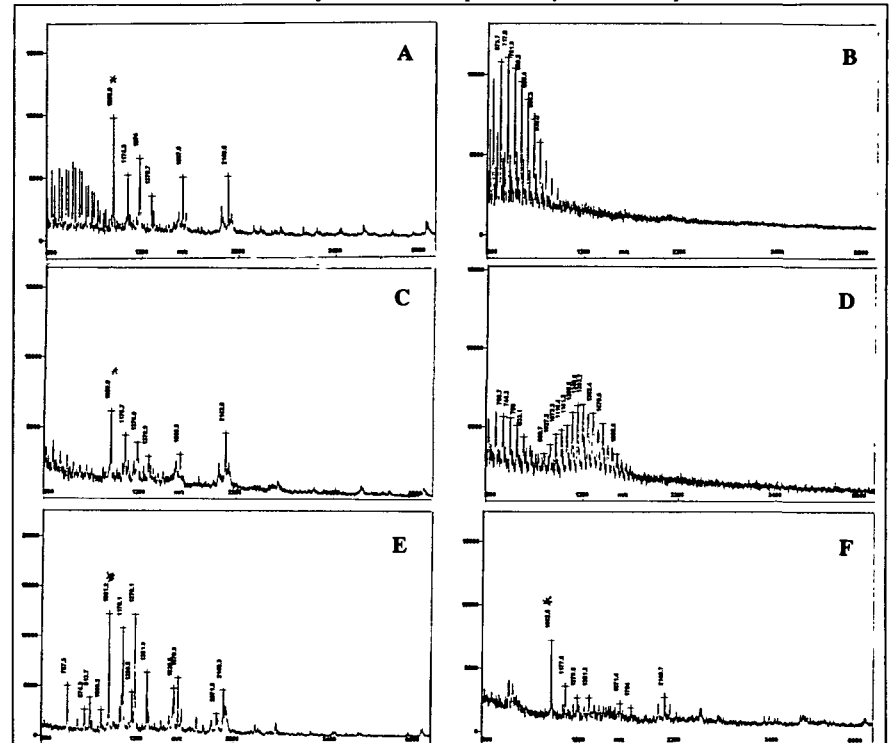

Figure 1 : PVDF-BOUND PROTEIN DIGESTED IN THE PRESENCE OF 1% OGP / 10% CH3CN/ 25 mM NH4HCO3 AND ANALYZED USING 50% CH3CN MATRIX SOLUTION IS THE PREFERRED METHOD FOR PEPTIDE-DETERGENT MALDI-TOF ANALYSIS. 50%CH3CN (A, C, E), or 30%CH3CN (B, D, F) matrix solutions were used for obtaining spectra from detergent/peptide mixtures performed with 25 mM NH4HCO3 . Digestion was performed in the presence of *RTX-100* (A, B), *Tween-20* (C, D) and *OGP* (E,F). Spectra represent 0.5% of the total digest mixture (125 fmol). Asterisks indicate internal standard (bradykinin).

Sample Preparation for Protein Fingerprinting of Bacteria Using MALDI MS

Xiaoli Liang, Teresa C. Cain, Jian Bai, Yan-Hui Liu and David M. Lubman
Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109-1055

Direct analysis of proteins from bacterial cell extracts has been proposed as a potential means for the identification of bacteria. This work demonstrates the differentiation of bacteria by mass spectrometry. Using MALDI TOF mass spectrometry, protein profiles of several bacterial species have been obtained (1). These profiles are distinctly different and allow differentiation of bacteria to the species level. The bacteria can be identified based on the presence of particular mass markers present in the protein profile. The identification of a mass marker(s) can be used to identify a single bacteria present in a mixture of bacteria. The protein profiles contain proteins in the mass range of 2,000 - 20,000 u.

The proteins were precipitated by the addition of water-miscible organic solvents, such as acetone and methanol. However, due to the complexity of the cell contents, extraction of proteins from the cell with organic solvents is selective, and often ineffective for removing the impurities from the crude extracts and for liberating the proteins from the cell membranes. Detergents are used most often for the extraction and purification of these membrane proteins. However, solubilized membrane proteins form mixed micelles with detergent such that the hydrophobic domain of the protein is shielded from contact with the aqueous buffer by detergent molecules. The use of SDS, in particular, can inhibit the precipitation with commonly used solvent systems The presence of impurities, particularly residual detergents can cause severe interferences with MALDI MS analysis, often resulting in the suppression of analyte signals, or reduced signal intensity.

Procedures involving the use of membranes and different organic solvent systems with the addition of detergents are evaluated for the extraction and purification of proteins from disrupted *E. coli* cells. The detergents used include sodium dodecylsulphate (SDS), Triton X-100, Tween 20, and Tween 80. The ether/ethanol system was used successfully for the precipitation of proteins from solutions containng nonionic detergents such as Triton X-100 and Tween 20 (Figure 1). Several poly(vinylidene

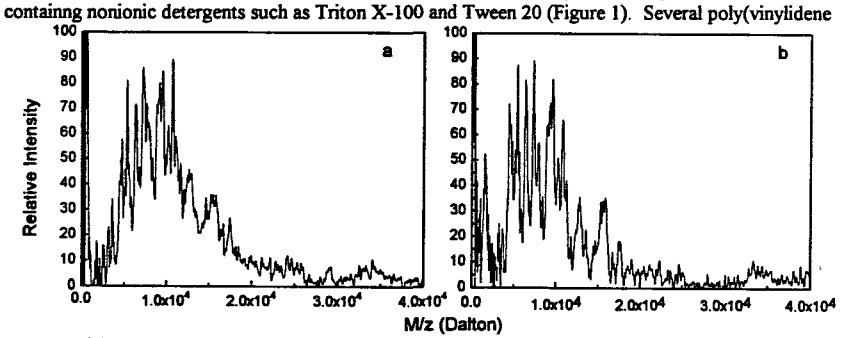

Figure 1. MALDI MS spectra of *E. coli* proteins precipitated by ether/ethanol (3:1) in the presence of (a) Triton X 100 and (b) Tween 20.

fluoride) (PVDF) based membranes are tested for the direct extraction of proteins from the bulk cell extract and for the removal of detergents (Figure 2). The results showed that the membranes can selectively absorb the proteins from complex mixtures. This may result from the competition between the protein/detergent and protein/membrane interactions. The membranes showed different selectivity toward the proteins. PVDF-CD was found to be the most useful one.

Another procedure tested was dot blotting, where the protein and detergent mixture was applied onto a NC membrane, and blotting was conducted in a semi-dry blotter. During the electroblotting, the proteins were transferred to the NC membrane, and were separated from the detergents. The NC membrane with the transferred proteins was washed to remove other unbound impurities, and the protein content was extracted from the NC for MALDI MS analysis (Figure 3).

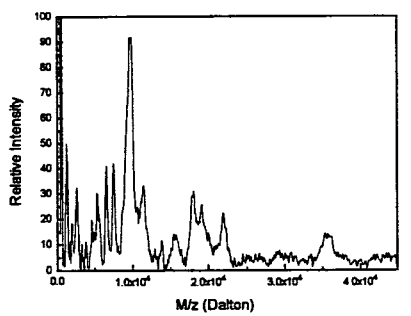

Figure 2. MALDI MS spectrum of *E. coli* proteins extracted by Immobilon-CD from a crude extract containing SDS.

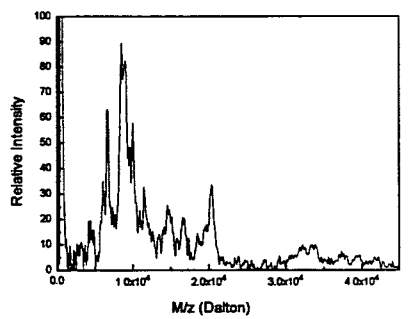

Figure 3. MALDI MS spectrum of *E. coli* proteins acquired by electroblotting from a SDS-containing mixture onto the NC and then extracted by the CHCA solution.

The use of membranes allows rapid extraction and purification of proteins in complex mixtures, particularly those that contain detergents. The purified proteins can be extracted and are found to be suitable for MALDI MS analysis for profiling purposes. Although the extraction and purification of proteins with membranes are used only for crude bacterial cell extracts, it may find potential applications in various biological systems.

Disulfide bonding plays an important role in the folding and unfolding of many proteins. Creighton pioneered the use of reduction/alkylation reaction chemistry for trapping disulfide-bond intermediates with iodoacetic acid, Figure 1. This method can also be adapted to mass spectrometry analysis as demonstrated by Morris et al.[1]. The objective of the study is to evaluate the use of MALDI-MS for performing detailed studies of disulfide bond reduction. MALDI is useful for such studies because it is an ionization process that forms ions of the intact protein. The strategy we have developed involves three steps, Step 1: The molecular weight of the protein is determined by MALDI-MS. Step 2: The protein is partially reduced by reaction with dithiothreitol (DTT) and alkylated with iodoacetamide. Step 3: The number of disulfides reduced is determined by measuring the MW of the alkylated protein; each disulfide adds two CH_2CONH_2 units (2 x 58 = 116 mass unit shift in MALDI-Mass spectra), Figure 2.

To determine which disulfide units of a multiple disulfide containing protein was reduced the following strategies were developed. Step 1: The partially reduced/alkylated protein is digested with chymotrypsin, and the MALDI-Mass spectra of the digest shown in Figure 3 is compared with the structure of bovine insulin to assign the fragments. The peaks at m/z 1892, 1910, and 1927 were assigned as fragments containing disulfide-linkage Cys-A20-Cys-B19 and the peaks at m/z 2450 and 2469 were assigned as fragments containing disulfide-linkage Cys-A7-Cys-B7. Step 2: The peak assignments of the fragments containing disulfide-linkages was confirmed by post-source decay. Figure 4 contains the post-source decay spectra of the m/z 1888 and 1911 ions.

The combination of MALDI-MS and partial reduction/complete alkylation of proteins is a useful probe of protein folding/unfolding. This study demonstrates the utility of MALDI-MS for monitoring chemical reaction of complex biomolecules. This work shows the sensitivity and efficiency of MALDI-MS for examining protein folding/unfolding as well as the utility of post-source decay experiments for unambiguously assigning the sequence of protein fragments.

CARBOXYL-TERMINAL LADDER SEQUENCING OF PEPTIDES AND PROTEINS

Rong Wang and Brian T. Chait
The Rockefeller University, New York, NY 10021

Facile, effective methods for carboxyl-terminal amino acid sequence determination have long been sought. None of the approaches developed to date rivals the effectiveness of amino-terminal sequence determination techniques based on the Edman degradation. One promising approach involves the use of carboxypeptidases in conjunction with mass spectrometry. However, the different rates of cleavage of carboxypeptidases for the different amino acids leads to gaps in the measured sequence. Here, we explore a new approach to C-terminal sequencing that addresses this problem.

Attachment of quasi-terminating groups to the C-terminal of polypeptide chains during the hydrolysis of polypeptides by carboxypeptidases can yield a peptide ladder that is free of gaps. In this approach, hydrolysis and aminolysis are set up as competing reactions catalyzed by the same carboxypeptidase. Hydrolysis removes terminal amino acid residues, while aminolysis adds the quasi-terminating group to the newly formed termini. Aminolysis is brought about by adding a large molar excess of amino amide to the peptide/enzyme solution. Terminal amino amides are quasi-terminating because they have a much slower rate of hydrolysis than terminal amino acids (1,2).

Carboxypeptidase Y was used in this study. Peptides (10 - 100 pmol) were dissolved in 10 μL of pH 7.3 buffer which consists of 100 mM Hepes and 10 mM EDTA. An enzyme-to-substrate molar ratio of 1:60 was used in this experiment. Lysinamide was used as the nucleophile and added into the reaction with the final concentration of 1 M. Digestion was carry out at 37 °C for 10 to 30 minutes. The reaction was stopped by adding 1 ul of 10% TFA. The resulting ladder sequence was read-out by matrix-assisted laser desorption mass spectrometry.

Renin substrate tetradecapeptide has sequence of DRVYIHPFHLLVYS (with one letter code for amino acid residues) and molecular weight of 1759.0 Da (Figure 1). The competitive carboxypeptidase Y sequencing reaction was carried out in the presence of excess amount of lysinamide (1 M) and the resulted sequencing spectrum is shown in Figure 2. This spectrum yields the carboxyl terminal sequence of the polypeptide up to six amino acid residues in a single operation. The first carboxyl terminal amino acid residue was determined by adding 127.2 Da (L-Lysinamide residue mass) to the mass of the intact molecular ion (1759 Da), followed by subtraction of the highest mass of lysinamide modified peptide peak (1799.0 Da). This calculation gives a mass difference of 87.2 Da, which corresponds to a serine residue. The remaining carboxyl terminal sequence can be read out from the mass differences between adjacent peaks in the spectrum. The mass difference of 127.1 Da between the peaks at m/z 1423.5 and 1296.4 corresponds to the lysinamide. The peaks on the lower mass side of the lysinamide residue correspond to the unmodified peptides and the peaks on the higher mass side of lysinamide corresponds to the lysinamide modified peptides. For comparison, the sample peptide was digested with carboxypeptidase Y in the absence of lysinamide. Figure 3 shows the sequencing spectra resulted by using 5, 10, 20, 100 ng of carboxypeptidase Y after 10 minutes reaction at 37 °C. Comparison of Fig. 2 and Fig. 3, show that the fast hydrolysis reactions has been balanced by the aminolysis reactions. The sequence gaps in the normal carboxypeptidase Y digestion (Figure 3) can be filled up by the lysinamide modifications.

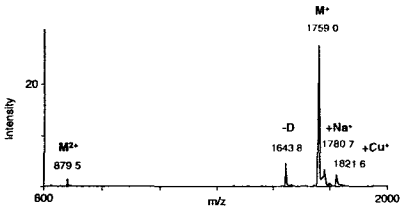

Figure 1 MALDI-MS spectrum of renin substrate decapeptide

Lysinamide functions as a nucleophilic reagent that competes with water for reaction with the newly generated peptide acyl-enzyme complex during the hydrolysis reaction. This competition results in the reduction of the overall hydrolysis reaction rate. The amide introduced by the lysinamide further slows down the hydrolysis of the modified peptide chain since the hydrolysis of the amino amide is far slower than that of the free C-terminal amino acid. These kinetic effects plus the positive effect of the lysinamide derivative on the mass spectrometric response make the application of carboxypeptidase for C-terminal sequencing much easier to control and read-out. This competitive reaction (or balanced reaction) strategy in C-terminal carboxypeptidases sequencing has the potential to be a easy and reliable method for protein and peptide C-terminal sequencing.

Protein Conformation, Hydrogen Bonding, and Energy Transfer in MALDI

Akos Bencsura[1] and Akos Vertes[2]
[1]Department of Chemistry, Catholic University of America, Washington, D.C. 20064
[2]Department of Chemistry, George Washington University, Washington, D.C. 20052

One of the critical steps in matrix-assisted laser desorption ionization (MALDI) mass spectrometry is sample preparation. The basis of the best established method is co-crystallization of matrix and analyte from their saturated solution [1]. A laser generated phase transition in the matrix crystals is believed to be at the core of the MALDI process [2].

Macromolecule folding in aqueous environment and macromolecule–water interactions are intensively studied and well described phenomena. Based on developments in molecular dynamics and semiempirical quantum chemical codes, conformation, hydrogen bonding, and phase transition characteristics can be calculated in relatively large protein–water systems.

Embedding of guest molecules into matrix crystals, and co-evaporation of matrix and guest molecules were studied using model systems. We wanted to explore peptide–matrix structures on the microscopic level and enhance our understanding of co-crystallization and co-evaporation in MALDI using molecular dynamics (MD) simulations.

Both the selected matrix (pyridine-3-carboxylic acid, nicotinic acid) and the analyte (leucine enkephalin, Tyr-Gly-Gly-Phe-Leu) were represented by their detailed molecular structure based on crystallographic data. The CHARMM (Chemistry at HARvard Molecular Mechanics) molecular dynamics code was used to model crystal dynamics upon laser excitation. Originally the program was developed to describe protein molecules in aqueous environment. An attractive feature of this code was that it accounted for the internal structure of molecules. The intermolecular potentials were calculated using *ab initio* (GAUSSIAN) and semi-empirical (AM1) quantum chemical codes.

In our simulation a ∅500 pm hemispherical volume of nicotinic acid molecules represented the matrix around a leucine enkephalin molecule. The validity of the model potentials was tested by comparing both the equilibrated nicotinic acid crystal structure to X-ray diffraction data, and the calculated heat of sublimation ($\Delta H_{calc.}$(sublimation)=101.5 kJ/mol) to the measured value (ΔH_{exp} (sublimation)=104.6 kJ/mol) for the matrix at 300 K. The peptide molecule showed hydrogen bonding to the matrix and preferential embedding along the layered structure of the host crystal [1].

Introduced by the laser pulse, an adiabatic temperature jump to 1500 K led to vigorous evaporation of the matrix molecules and to the desorption of the peptide. Detailed statistical analysis of the matrix structure showed dramatic changes in the pair distribution functions (PDF). At 300 K the N–O1 PDF between the pyridine N and the O in the carboxyl OH exhibited two sharp maxima at 300 pm and 410 pm, corresponding to the hydrogen bond and to the intramolecular correlation, respectively (Figure 1). At 1500 K a large part of the contribution from the hydrogen bond disappeared along with the long range order.

Due to the fast breakup of the crystal structure the energy corresponding to hydrogen bonds dropped, and in about 3 ps reached a new steady state value (Figure 2). It was interesting to note that a substantial part of the crystal did not evaporate and about half of the cohesive energy remained unchanged.

The fate of the peptide molecule was followed by recording the position of its center of mass relative to the matrix surface (Figure 3). Initially, the guest molecule was buried ~250 pm below the surface. In less than 1 ps the guest molecule emerged and lifted off the surface. The velocity of the neutral guest molecule showed exponential decay with a decay time of ~6 ps and a limiting value of ~155 m/s (Figure 4).

Mass Tracer Methods based on MALDI

Randy M. Whittal, David C. Schriemer, and Liang Li*
Department of Chemistry, University of Alberta
Edmonton, Alberta, Canada
T6G 2G2

The principle of mass tracing involves using the mass spectrometer to follow the fate of certain species carried through a particular process. As with any tracing method, it relies on the incorporation of a tag, however the tag does not have to provide the basis for detection, as this is supplied by the mass spectrometer. This principle has been applied previously to the MALDI experiment in the work of Hutchens and Yip [1].

Two other extensions of this principle to MALDI are currently being investigated in this laboratory. In one approach, the inherently low sensitivity of oligosaccharides can be improved with the incorporation of certain labels [2]. This allows for the detection of products of enzymes involved in oligosaccharide biosynthesis/degradation directly from crude serum. An illustration of this can be found in figure 1. The disaccharide αFuc(1→2)βGal-TMR$^+$, possessing the tetramethylrhodamine (TMR) label, receives a galactose residue from uridine diphosphogalactose (UDP-Gal) under the action of a blood group-B galactosyltransferase enzyme. The product of this reaction (B-TMR$^+$), though present in approximately 0.50 pmol/μL is easily detectable due to the sensitivity enhancement provided by the TMR label [3].

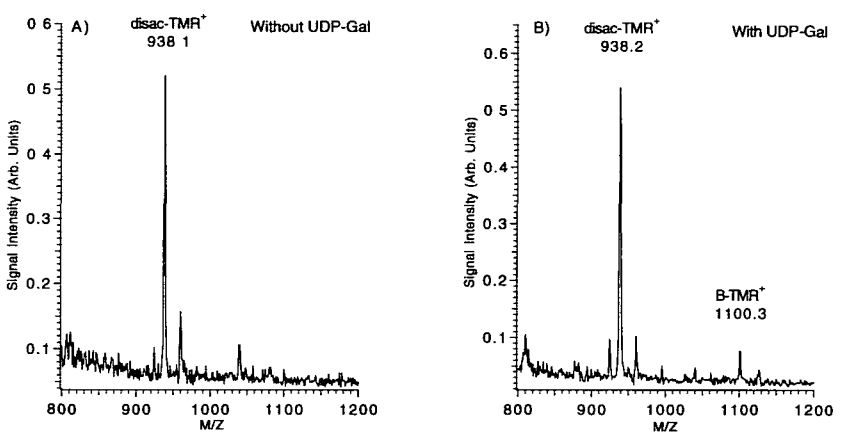

Figure 1

A second application is based on the selective binding of biotin by immobilized avidin, incorporated into a MALDI technique similar to the approach of Tomer et al [4]. A small quantity of immobilized avidin gel is added to a mixture containing a biotinylated compound. The gel is then washed to remove the unbound components of the mixture, whereupon the beads are directly analyzed by MALDI, for detection of the biotinylated compound. Sample preparation simply involves the deposition of a water slurry of the gel onto a thick layer of matrix. Figure 2 demonstrates this procedure on a synthetic mixture of the following species:

1. bradykinin
2. synthetic peptide
3. insulin chain B
4. insulin
5. insulin-biotin
6. insulin-(biotin)$_2$

MALDI-MS of Proteins Directly from Polyacrylamide Gels

R. R. Ogorzalek Loo†, T. I. Stevenson§, C. Mitchell†, J. A. Loo§, and P. C. Andrews†
†University of Michigan, Dept. of Biological Chemistry, 2560 MSRB II, Ann Arbor, MI 48109
§Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, Ann Arbor, MI 48105

A method for the analysis of proteins has been developed which takes advantage of the high sensitivity and mass range of matrix assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry and the high resolution separations attainable by electrophoretic methods, particularly isoelectric focusing (IEF). Previous methods involving electroblotted proteins and MALDI have been hampered by low resolution, poor mass accuracy, low sensitivity, or have required infrared lasers not widely used. We have obviated these problems by using ultrathin polyacrylamide gels which dry to thicknesses of 10 µm or less. Thin layer electrophoresis has the additional advantages of rapid preparation and run times. Proteins may be desorbed directly from dried gels or passively transferred to membranes, avoiding electroblotting. Spectra obtained by this method appear similar to analyses directly off the sample probe, including high sensitivity (sub-picomole), resolution, and mass accuracy. This method works well with IEF, native, and sodium dodecyl sulfate (SDS) polyacrylamide gels. The good quality mass spectra obtained directly from gels also makes it possible to run virtual 2-D gels in which proteins are resolved in the first dimension on the basis of their charge (i.e., IEF gels) while the second dimension is MALDI-MS instead of SDS gels electrophoresis. Virtual 2-D gels reduce the ambiguity in protein identification inherent in true 2-D gels by accurately determining mass. This method has been applied to the two- and three-dimensional analysis of complex mixtures with identification of component proteins by their isoelectric points, intact mass, and their CNBr fragment masses. When applied to non-denaturing gels, the method represents a very useful way to probe noncovalent complexes between proteins and a variety of ligands.

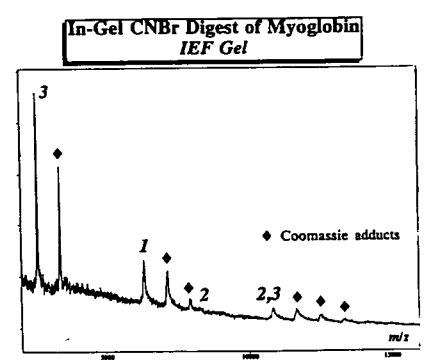
Thin layer IEF, native, and SDS polyacrylamide gel electrophoresis were performed under standard conditions. In some experiments, passive elution of the macromolecules from the gel to an appropriate membrane with subsequent analysis of the membrane-bound macromolecules by MALDI-MS was tested. MALDI mass spectra were acquired on a PerSeptive-Vestec (Houston, TX) LaserTec ResearcH™ time-of-flight mass spectrometer operating in the linear mode, employing a nitrogen laser (337 nm) for desorption.

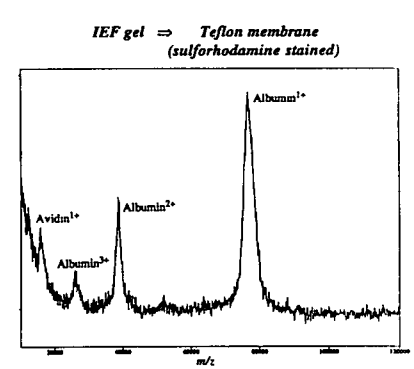
The thinness of the gels greatly enhance mass transport efficiencies relative to a conventional thicker gel, facilitating transfer and desorption. For SDS gels, the surfactant is present only in the buffer and the lower SDS concentrations can be reduced effectively by washing after electrophoresis. Spectra have been obtained for 60 pmole loadings of cytochrome *c* onto SDS gels. Spectra have also been obtained from IEF gels with 1 pmole myoglobin and 650 fmole hemoglobin loadings. Resolution is excellent for desorption from gels, we have achieved resolutions as high as 450 for myoglobin (17 kDa) desorbed from a native gel. Clearly, the sensitivity and mass resolution can be comparable to conventional desorption off the sample probe. By using calibration standards, good mass accuracy can be achieved. Solution containing internal standards can be applied directly to the band of interest or to the side of the band (0.1-0.2% accuracy). Standards should be spotted in several locations along a lane, because the calibration varies by 1-2% from top to bottom of a lane, if standards are not employed.

Although obtaining mass spectra directly off the gel has many advantages, the sensitivity, reproducibility, and mass accuracy for proteins larger than 20 kDa were found to be better in desorption from membranes. Protein bands were efficiently transferred from the gels to teflon or polyethylene membranes by diffusive transfer. Passive diffusion is most effective with ultrathin gels because transfer is simple and efficiency is quite good with relatively short transfer times. Spectra were obtained for bovine serum albumin (66 kDa) and bovine carbonic anhydrase (29 kDa) after passive diffusion from an IEF gel to which 11 and 14 pmol, respectively had been loaded.

Once the mass of an intact unknown protein is determined, additional structural information is required for identification. One method is to chemically or proteolytically digest the protein band (in-gel digest) and measure the masses of the resulting fragments (in-gel). This new information can then be used to mass search proteins in databases. The mass spectrum from an in-gel cyanogen bromide digest of horse heart myoglobin is shown in Figure 1. Approximately 60 pmol was loaded on the gel which was subsequently Coomassie blue-stained and CNBr digested. Coomassie blue adducts are apparent in the digest data obtained with sinapinic acid. All 3 complete cleavage products and one incomplete cleavage product were observed.

The combination of MALDI mass spectrometry and gel electrophoresis makes it possible to examine many noncovalently-bound systems because some gel electrophoresis methods can be run under non-denaturing conditions where many macromolecules maintain their native structures and thus their functions. Commonly used MALDI-MS methods destroy all evidence of noncovalent interactions. Avidin is a 64 kDa tetrameric glycoprotein with a high affinity for biotin and biotinylated-macromolecules. A gel loaded with 75 pmol biotinylated bovine albumin and 75 pmol of the avidin tetramer was run. The resulting bands were transferred by passive diffusion to a teflon membrane which was stained with sulforhodamine. The MALDI mass spectrum (Figure 2) shows molecular ions for both biotinylated-albumin (1+, 2+, and 3+ charges) and the avidin subunit (16 kDa), indicating that the avidin and biotinylated-albumin molecules migrated as a complex on the gel. Peaks are broad, indicating heterogeneous labeling with biotin and possible sulforhodamine adducts.





Evaluation of MALDI.MS For Agricultural Applications

[2]. Department of Medical Physics and Biophysics, University of Munster, Munster, Germany

In search for an analytical technique to study the structure of Ag biomolecules such as starch and its functional characteristics. We conducted several studies for specific starch fractions and other glycans using MALDI.MS. In addition, we evaluated the applications of the technology to investigate specific molecules which can be of special value for supporting AG discovery, biotechnology and formulation science. Among those molecules were enzymes, antibodies, natural products and formulated sulfonylurea.

Experimental and Sample Preparation

All data were generated on two instruments, a reflectron-type time of flight mass spectrometer (Lamma 1000, Leybold Heraeus) and a Finnigan Model Vision 2000. The Lamma instrument is equipped with a nitrogen laser at 337 nm and the Vision system was equipped by a Nd:YAG laser. The samples were dissolved in ultra-pure water at concentration of 1µg/µL. A one µL is pipetted on the stainless steel target (~0.5 inch diameter width). The target can be used to deposit up to seven sample spots in a time. One of the spots was always a standard mixture of known proteins which is used to check mass calibration and optimize the instrument parameters (melitin, insulin, cytochrome C and myoglobin, mass range 2000 to 18000 amu). Four microliters of the dihydroxy benzoic acid matrix were added to the sample spot and dried by blowing stream of hot air to the sample target while rotating the target.

Results and Discussion

Starch

Starch is a large and complicated molecule whose structure has not been well characterized. It is a mixture of two molecular entities, a linear fraction, amylose (α,1,4), and its branched counterpart, amylopectin with a branch point at the 1, 6 position . The basic building block is α-D-Glucose. All debranched starch samples were successfully ionized by MALDI by MALDI. On the other hand, the non-debranched fractions could not be ionized and no mass spectra were generated by MALDI. This can be explained due to the high mass and the nature of the starch crystal structure and intermolecular bonding. A typical MALDI mass spectra for a debranched starch fraction indicate an envelope of molecular ions in the range of 1000 amu to ~5000 amu with 162 mass unit difference between each two adjacent mass ions. The difference accounts for one glucose unit which is the monomer unit of starch. All detected ions were in the form of a sodium adducts. The degree of polymerization was calculated for the polymeric fractions to be 10 -30 dp. The debranched, *waxy (wx)* soluble and insoluble starch fractions indicated similar envelope but the spectra for the soluble fraction (Figure 1) indicated a baseline hump more apparent than the insoluble fraction.

The MALDI mass spectra for the debranched high *amylose* starch indicated a merged molecular ion hump with 14 mass ion difference. The detection of the 14 mass unit difference (baseline hump) was due to methylation. There is a correlation between numbers of long chains (amylose type) and susceptibility of the starches to methylation. In order to see if all the starch had been debranched, a further digestion of the debranched starches was completed with the enzyme, pullulanase. MALDI analysis of starch fractions during the course of the reaction with pullulanase indicated build up of ion signals at the 10,000 Da to >150,000 Da mass range These results indicate that further debranching can be carried out by selective enzymes. A combination of selective enzyme debranching, derivatization and MALDI analysis are the keys to unravel the starch molecules and relate it to functional performance.

Antibodies and enzymes

The antibodies and the enzymes were successfully ionized by MALDI The molecular weight for the antimethomyl antibody was detected at 147,828 amu which is the expected molecular weight range. The four enzymes were selected as a model for low pI enzymes which are more difficult to

ionize with current techniques. The enzymes samples included carbonic anhydrase, glucose oxidase, ß lactoglobulin and trypsin inhibitor. The MALDI mass spectra for each indicates the molecular ion M+, 2M+ and M2+.

The protein pellet from Klee and Rottannen honey

The MALDI mass spectra for the protein pellet from Klee and Rottannen honey.indicated the same component mass spectra of MW 52,763 amu protein. The peak shape and chromatographic behavior of the molecule with gel electrophoresis could indicate that the molecule is conjugated somehow and may be a glycoprotein. The results indicated that its structure is not related to the botanical origin of the feed. The two unifloral honey, Klee and Rottannen contain the same high-mass trace compound.

Formulated Sulfonylurea

Figures 2 shows the MALDI mass spectra of Ally® herbicide formulation at the sample spot rim and center. An interesting result was the difference in the spectral pattern observed within the sample spot. At the rim, the spectrum indicated mainly the specific ions for the active ingredient, metsulfuron methyl while the mass spectrum from the center of the sample spot indicated mainly the water soluble components as sugar. An explanation for this results is that the more water soluble compounds migrate with the water to the center as the spot has been dried off. The fragmentation pattern of sulfonylurea were informative and similar to the electrospray ionization using the source collision dissociation to induce fragmentation. The spectrum indicated a strong molecular ion adducts MH and M+Na in addition to 5-7 fragment ions.

Conclusion

MALDI is applicable to all the biomolecules we have selected and to study sample mixtures. It is a qualitative technique which can detect a large scope of compounds which could not be detected by other mass spec techniques. It handles mixture and matrices better than other techniques. Currently it is not a quantitative technique but could be in the future.

CID studies of MALDI generated peptide ions by RETOF MS

Holle, Armin, Köster, Claus
Bruker-Franzen Analytik GmbH, 28359 Bremen, Germany

Introduction

In recent years matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI TOF MS) [1] has grown rapidly in its importance in the analysis of biomolecules. As an additional tool, post source decay (PSD) measurements with reflectron time-of-flight mass spectrometers (RETOF) has become an established technique for obtaining structural information from picomol amounts of small peptides [2].
PSD is a collisionally activated dissociation technique. The activation step in this case occurs as: (1) multiple early collisions between the analyte ions and (neutral) matrix molecules during the plume expansion and ion acceleration, (2) from collision events with gas molecules in the field free path.
While in many cases it is possible to obtain useful sequence information for the peptides being analysed, one might frequently obtain more information if the activation step were more controlled
The control of the pressure of gas molecules in the field free region represents a means to obtain greater control of the activation step and thus the extend of ion fragmentation. For this reason, we have prepared and installed a special "collision cell" in a MALDI TOF mass spectrometer

Methods

The measurements were performed on a BRUKER REFLEX instrument equipped with a special "collision cell" This cell consists of a pulsed gas valve mounted about 10 cm downstream from the ion source The 1 mm aperture of the valve is directed orthogonal to the ion beam axis at a distance of 4 mm The advantage of this arrangement is to provide a high gas density along the beam axis without significant changes in the instrument background pressure (2 10^{-7} mbar without gas, 5 10^{-7} mbar with gas at 10 Hz repetion rate).
10 pmol of analyte were mixed with α-cyano-4-hydroxy-cinnamic acid as matrix (analyte/matrix = 1/5000)
Data were acquired using a 125 MHz digitizing rate The detector response of low-mass matrix ions was minimized by the application of a deflection voltage pulse. The total PSD-spectra are pasted from a set of 21 PSD-spectra where each spectrum represents the sum of 100 consecutive laser shots.

Results

In figure 1 is shown a comparison of PSD and PSD-CID measurements of angiotensin II in a low mass range which represents the behaviour of other investigated peptides like substance P, ACTH 18-39, bovine insulin b-chain or ubiquitin In the PSD-CID study almost every mass below 200 amu is occupied The signal-to-noise of pure PSD spectra in this low mass range is significantly reduced compared to the PSD-CID spectra This is especially true for increasing parent ion mass

Conclusion

High energy PSD-CID measurements show, besides fragment ions due to pure PSD, intense fragmentation in the low mass region. The most intense mass peaks can be assigned to immonium ions $(H_2N{=}CHR)^+$ or I-type ions which indicate the cleavage of the entire peptide backbone structure

Effective Methods for Characterization of Membrane Proteins by MALDI-MS

Bao-Jen Shyong, Charles Mitchell, and Philip C. Andrews
Protein & Carbohydrate Structure Facility, University of Michigan, MSRBII, Room 2560, 1150 W. Medical Center Drive, Ann Arbor, MI 48109-0674

Introduction:

The application of peptide mapping using laser desorption mass spectrometry (MALDI-MS) in conjunction with chemical and enzymatic digestion provides a fast and sensitive method for protein characterization(1). However, membrane proteins present a number of problems in purification and structure analysis compared with glycoproteins and cytosolic proteins. This type of protein is generally quite hydrophobic and is often contaminated with interfering substances used in the purification process (e.g. detergents) which must be removed for accurate mass analysis. Hydrophobic proteins tend to aggregate or precipitate and as a result are difficult to purify by HPLC. SDS-PAGE is an alternate technique for analytical separation and characterization of complex protein mixtures which is more suitable for hydrophobic proteins. The goal of this study is to develop a systematic protocol to characterize interesting membrane proteins by incorporating MALDI-MS with other chemical and separation technologies. Bacteriorhodopsin, a membrane protein, was used as a model to evaluate the protocol.

Experimental And Instrument:

Bacteriorhodpsin and glycophorin were purchased from Sigma and G protein (β-subunit) of bovine brain is a gift from Dr. Neubig (University of Michigan). The primary separation is performed as one dimensional SDS-PAGE on a Phast-Gel electrophoresis system (Pharmacia). After the separation and purification, the protein band(s) were directly subjected to CNBr or/and Lys C digestion(2). Pure proteins without the purification treatment were used as a control to determine the yield and suitability of the protocol.

For LD-MS analysis, the Lys C digested mixtures were desalted by HPLC with an isocratic gradient on a C4 column. The dry mixtures generated by CNBr or Lys C digestion were re-dissolved into 100 µl 0.1% $TFA_{(aq)}$ or 100% formic acid. An aliquot of peptide mixture (1 µl) was mixed with or without 1 µl of insulin (@ 0.5 pmol) as an internal standard and 1 µl of matrix solution (α-cyano-4-hydroxycinnamic acid @ 100 mM), loaded on stainless steel dowel pin, then air dried for MALDI-MS analysis. The mass spectrometer used in this work was a Vestec-2000 (Houston, TX), which is a LaserTec ResearcH laser desorption linear time-of-flight mass spectrometer, equipped with a 1.2 m flight tube, operated at 23 KV ion accelerating voltage and 3.5 KV multiplier voltage, a 337 nm VSL-337 ND nitrogen laser (Laser Science, Inc.) with a 3-ns pulse width. Spectra were summed from 15 to 20 laser shots.

Results And Discusions:

1. The Phast-gel electrophesis system provides a higher recovery yield for extraction than mini or regular gel systems. The thickness of this gel (SDS-PAGE) is 0.45 mm and the proteins are applied to the surface of the gel.
2. In general, protein(s) subjected to CNBr or Lys C digestion could supply reasonable lengths of peptides to avoid the matrix interference (<500 a.m.u.) of MALDI-MS and for other analytical methods. For unknown sequences of protein, the CNBr digestion might be a good first choice due to easy handling without further purification.
3. The MALDI-MS spectra obtained from 1-D SDS-PAGE are similar to those of the control. The intensity and number of species appearing in the spectra may vary due to the concentration of the mixture, suppression of the mixture, the interaction among components of the mixture, presence of an internal standard, and the matrix employed (See Fig. 1, 2, 3, and 4). For unknown protein, further separtion is necessary to obtain the internal seqence.

4. The flow chart for the characterization of membane proteins is shown as Schedule 1.

Assessment of Photoaffinity Crosslinking of Macromolecules by MALDI MS

Terry B. Farmer and Richard M. Caprioli
Department of Biochemistry and Molecular Biology and Analytical Chemistry Center, University of Texas-Houston Medical School, Houston, Tx 77225

Introduction

Chemical crosslinking reagents are dependent for their action on the groups available on the surface of the molecule for the crosslinking reaction to occur. Crosslinkers containing photoaffinity groups can be used to examine molecular interactions when reactive residues such as Lys are not available because the photoaffinity crosslinking reaction is nonspecific.

Experimental

Protein Crosslinking

Sulfosuccinimidyl-6-[4'-azido-2'-nitrophenylamino] hexanoate (sulfo-SANPAH), p-azidophenyl glyoxal (APG), and bis-[β(4-azidosalicylamido)ethyl] disulfide (BASED) (Pierce Chemical Co.) were used to examine crosslinking of equine alcohol dehydrogenase (eADH), lactate dehydrogenase (LDH), yeast alcohol dehydrogenase (yADH), glucose 6-phosphate dehydrogenase (G6PD) (Sigma Chemical Co.) and the chi and psi subunits of the DNA polymerase III holoenzyme (Dr. Charles McHenry). The crosslinkers **must** be handled in the dark until exposure to UV light for activation. APG and BASED, with limited solubility in aqueous solutions, are first dissolved in DMSO at a concentration of 200 μg/μl. BASED is then diluted to 6 μg/μl in DMSO and added to the buffered reaction solution so that the final reaction concentration is 1 mM in ≥ 10% DMSO. APG is first diluted to 6 μg/μl concentration in 50 mM ammonium bicarbonate (pH 8) when it precipitates out. To redissolve APG it is heated at < 100°C for less than 1 minute and added to the reaction for a final concentration of 5 mM. Sulfo-SANPAH is dissolved in 50 mM aqueous buffer with no primary amines (pH 8) at a concentration of 50 μg/μl and added to the reaction solution for a final concentration of 1 mM.

Protein concentrations were 10 pmol/μl. Protein solutions with added APG and sulfo-SANPAH were allowed to react in the dark for 45-60 minutes and then exposed to UV light at 365 nm (Spectroline E-Series, Spectronics Corp.) for 10 minutes on ice. BASED was added to the protein solution and after 5 minutes was exposed to UV light at 254 nm (Mineralight Lamp, UVP Inc.) for 10 minutes on ice. The reaction mixtures were then immediately washed with 6x volume of buffer using Ultrafree-MC 10,000 NMWL filtration units (Millipore).

MALDI TOF MS

Spectra were obtained using a PerSeptive Biosystems Voyager Elite MALDI TOF instrument with a N_2 laser and an acceleration voltage of 25 kV. Uncrosslinked and crosslinked proteins were analyzed with the same laser power and peak areas were determined using an integration algorithm in GRAMS386. Samples were prepared two ways: 1. Protein solution (0.5 μl) was added to 0.7 μl of saturated sinapinic (70% acetonitrile/30% 0.1% TFA) on the target. 2. Saturated sinapinic (2:1 water:acetonitrile) was pipetted onto the target and allowed to air dry. After drying, a glass slide was used to crush surface crystals and excess matrix was removed by gently brushing with a Kimwipe tissue. A 1:1 mixture of protein solution:saturated sinapinic (2:1 0.1% TFA:acetonitrile) was pipetted onto the first layer of matrix[1]. Both sample preparations were then allowed to air dry and were mass analyzed.

Results and Conclusions

In the present experiments the utility of photoaffinity crosslinkers was examined with proteins that have been analyzed both successfully and unsuccessfully by amine specific crosslinking reagents. Using glutaraldehyde, eADH, a dimer, showed addition to the monomer, but no multimer formation. However, using both APG and sulfo-SANPAH, an increase in the formation of dimer was seen from 4:1 monomer:dimer with no crosslinker to 1:1 monomer:dimer using these crosslinkers (Table 1). Gel filtration data indicates chi and psi subunits of the DNA polymerase III holoenzyme form a heterodimer[2]. Amine specific crosslinkers were ineffective for crosslinking because psi has one Lys residue. Crosslinking with APG and sulfo-SANPAH with subsequent mass analysis (Figure 1) showed formation of a heterodimer with some formation of higher oligomers. The results indicate that homo- and heterobifunctional photoaffinity crosslinkers can be used to examine intermolecular interactions. The efficiency of the crosslinkers (calculated by subtracting the % uncrosslinked multimer from the % crosslinked multimer) was 5-20% for APG, 0-10% for BASED, 10-40% for sulfo-SANPAH, while for an amine specific crosslinking reagent such as glutaraldehyde it was typically 50-80%. Low crosslinking yields for the photoaffinity crosslinking reagents may be due to limited aqueous solubility, especially in the case of APG and BASED. Work is currently in progress to analyze the chi and psi subunit interactions in the presence of the other gamma subunit components.

		Relative % Peak Area*

Micro-Concentration/Desalting/Matrix-Addition Procedure for High Sensitivity Analysis of Peptides by Matrix-assisted Laser Desorption Ionization Mass Spectrometry

Haiying Zhang, Per E. Andren, and Richard M. Caprioli

Department of Biochemistry and Molecular Biology and Analytical Chemistry Center, University of Texas Medical School, 6431 Fannin, Houston, TX 77225, USA

Matrix-assisted laser desorption / ionization mass spectrometry (MALDI MS) is rapidly becoming a standard analytical technique for measuring the molecular mass of polypeptides and proteins. Because of the trace concentration nature of some biological analytes, there has arisen a corresponding need for the development of concentration methodologies in conjuction with this ionization technique. Biological extracellular neurosubstances from microdialysates, for example, are usually present at amole per μL levels and in relatively large (μL) volumes containing high concentration of salts. Consideration of high detection sensitivity requires working with concentration techniques optimized for small sample spotting. In addition, salts which may interfere with MALDI analysis should be removed instead of being allowed to accumulate during the concentration procedure.

We have used a C-18 packed capillary as an integrated micro-concentration/desalting/ matrix-addition device for the analysis of trace level peptides in samples containing physiological salts. This methodology provides low fmole / high amole sensitivity for peptides in amole per μL concentrations. A fused silica capillary (50 μm i.d.) containing about 1 cm C-18 coated support was used. Samples were loaded onto the C-18 column via a 10 μL loop of an injector, and salts were washed off the C-18 column within five minutes using water containing 2% acetic acid at a flow rate of 0.3 μL/min. The purified samples were eluted by a solvent containing MALDI matrix in 75% acetonitrile (0.1 μL/min). Eluents were spotted onto the multi-well sample holder for MALDI MS analysis. Removal of salts and reduction of the sample volume from a few μL to about 5 nL led to a MALDI-sensitive spot area of less than 0.3 mm^2. A sensitivity of 200 amole was achieved for neurotensin (NT) from a 20 amol/μL solution containing 0.2 M phosphate buffer (Fig. 1). In contrast, samples in the same salt solution, without any purification, could not be detected using direct analysis. The quantitative reproducibility of this pretreatment procedure for MALDI MS determination of trace peptide levels in physiological salt solution is shown in Figure 2 for the analysis of substance P in a solution containing 0.2M NaCl and neurotensin as the internal standard. A linear intensity relationship was achieved down to 100 amol/μL level, which is two orders of magnitude lower than that from direct analysis of the sample. As an example to show the validity of the procedure developed here for real biological samples, the metabolic fragments of NT, including NT1-8, 1-10, 1-11, 1-12 and 9-13, were readily detected from an *in vivo* microdialysate after an infusion of 100 fmol/μL NT into rat brain (Fig. 3).

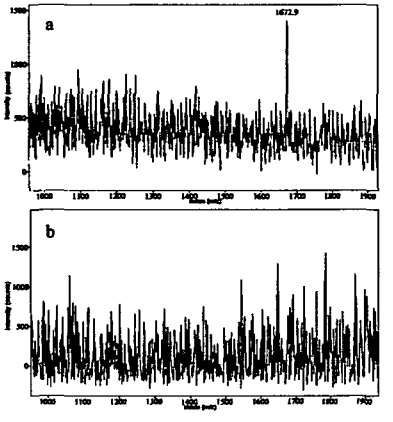

Figure 1. **(a)** MALDI mass spectrum obtained from C-18 packed capillary with 200 amole neurotensin loaded in 10 μL of 20 amol/μL solution containing 0.2 M phosphate (pH 7.0). **(b)** MALDI mass spectrum obtained from open capillary spotting with 100 fmole neurotensin from 1:1 mixture of 40 pmol/μL NT in 0.2M phosphate and MALDI matrix. In both cases, the volume spotted was 5nL.

Arizona State University, Tempe, AZ 85287-1604.

INTRODUCTION

Mass spectrometric immunoassay (MSIA) provides a degree of specificity beyond that of conventional immunoassays through the direct detection of antigens at defined and characteristic mass-to-charge (m/z) values [Nelson, R.W. Krone, J.R.; Bieber, A.L.; Williams, P. *Anal. Chem.* **67**, 1153 (1995)]. While mass-specific detection in principle eliminates ambiguous identification of antigens, practical limits arise from an inability to determine the absolute molecular weight of the antigen to within a given accuracy and/or the inability to resolve antigen ion signals from those of interferences. These limitations are especially pronounced during the MSIA analysis of systems which contain alternate forms of the same antigen. If the isoforms are retained during the immunoaffinity capture step of MSIA, and the mass difference between the versions is small, antigen determination becomes ambiguous. One way to resolve this problem is to use monoclonal antibodies specific to only the relevant variant of the antigen (a reagent which is not always available).

An alternative is to devise methods which enable a more specific mass spectrometric identification of the antigen. We have found enzymatic treatment - capable of creating characteristic peptide maps of MSIA-isolated species prior to mass spectrometry - to be a practical means with which to differentiate between antigenic species. Further, we have developed a series of "enzymatically-active" mass spectrometer probe tips in order to perform the assays in the most efficient manner possible. The probe tips derive their activity through the (covalent) surface immobilization of select enzymes (see **Fig. 1**). Antigen is eluted directly (from MSIA reagent) onto the reactive surface of the probe tips and time given for proteolytic digestion. The reactions are then terminated with the addition of a MALDI matrix (allowed to dry), the probe tip inserted into the mass spectrometer and mass analysis performed.

The "enzymatically-active" probe tips have been found a rapid, sensitive and convenient means for the routine characterization of proteins and peptides. Further, when used in combination with MSIA, the probe tips have allowed low specificity immunoaffinity reagents, such as antisera, to be incorporated into the assay without a sacrifice in specificity.

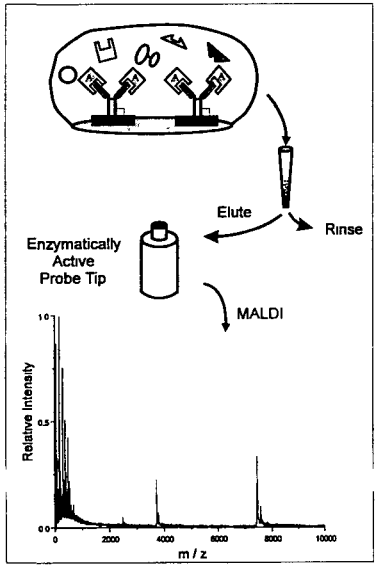
RESULTS

The MSIA/peptide map method has been used to the characterize antigens retained from the venom of the *N.n. siamensis* (**Fig. 2, top**). The MSIA procedure was as in Fig. 1 using an affinity reagent of immobilized anti-α-cobratoxin antisera. The first step of the assay indicates the successful retrieval of α-cobratoxin from the whole venom (**Fig. 2, center**). Digestion on a trypsin-active probe tip yields a digestion pattern consistent (**Fig. 2, bottom**) with the native form of the toxin (**inset**).

CONCLUSION

We have developed a rapid, sensitive and convenient method of mass spectrometric immunoassay which combines micro-scale immunoaffinity capture of antigens with enzymatic mapping and MALDI mass analysis. To execute the assays in the fastest and most sensitive manner possible, "enzymatically-active" mass spectrometer probe tips were constructed *with which* to

perform the digestion, i.e., the probe tips were the enzymatic reagent. The approach contributed an additional degree of selectivity to the assay (mass spectral peptide mapping) which allowed the use of low-specificity immunoaffinity reagents (such as antisera) for antigen isolation.



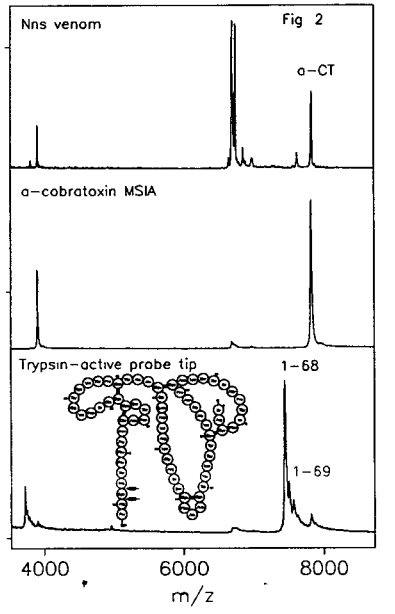


Fig. 1 General overview of the MSIA/peptide map process. Briefly, antigen retained during the MSIA process [1] is eluted onto an "enzymatically-active" probe tip where proteolytic digestion is allowed to occur. Digestion is terminated with the addition of a MALDI matrix

Fig. 2 Results of MSIA/peptide map process applied the whole venom of *N.s. siamensis*.**(top)** MALDI of whole venom. **(center)** MSIA using anti α-cobratoxin antisera as an affinity reagent. **(bottom)** Peptide map of MSIA isolated α-cobratoxin followed by proteolytic digest using a trypsin-active mass spectrometer probe tip. Peaks consistent with the native form of the toxin **(inset)** are observed.

Sequence Specific Fragmentation Generated by MALDI in Ion Trap/reTOF

Heewon Lee and David M. Lubman
Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109

MALDI is generally a soft ionization method and has been thought to produce little fragmentation for structural analysis. Although prompt fragmentation is not observed in the MALDI process on the time-of-flight (TOF) MS time scale, it has been shown that extensive metastable decay does occur as a function of time. In this study, sequence-specific fragmentation for structural analysis has been generated by activation of ions via MALDI in an ion trap storage/reflectron time-of-flight device. The key to this work is that ion decay can be induced by MALDI activation but requires an extended period of time to occur in large peptides. This extended decay period, which may be in excess of 20 ms, is provided in these experiments using the long storage times of the ion trap device. The ions are stored until decay is complete and then rapidly pulsed into a reflectron TOF for analysis. Since the ions decay within the trap, they ultimately appear as stable ions in the reTOF rather than as metastable decay peaks.

The wavelength of 355 nm of the Nd:YAG laser was employed with 2,5-dihydroxybenzoic acid (DHB) as a matrix for MALDI. The desorbed ions were stored by the quadrupole ion trap for a determined time which varied from 1μs to 90 ms before being extracted into the time-of-flight drift tube. Peptides used in this study include Leu-enkephalin, angiotensin I, II and III, bradykinin and substance P.

The fragmentation typically provides a, b, y and internal fragment ions. However, no charge-remote fragmentation, which was reported for high energy CAD, was observed. The fragmentation pattern was compared with that of other desorption/ionization and fragmentation methods such as FAB, LSIMS, MPI and CAD.

MALDI fragmentation spectrum of Leu-enkephalin is shown in figure 1. The fragmentation obtained was most similar to that observed in FAB-low energy CAD. The ion fragmentation was found to depend strongly on laser power and the RF voltage placed on the ring electrode of the trap. Figure 2 shows the dependence of the peak intensity ratio of a_4/b_4 of Leu-enkephalin on the trapping time and the laser power density.

It was reported that a peptide with a terminal arginine, which is the most basic residue among common amino acids, prevents obtaining informative sequence-specific fragment ion spectra for FAB-MS. To investigate this arginine effect in MALDI experiments, bradykinin fragment 2-7 and substance P fragment 2-11 (figure 3) were studied. The peptide without a terminal arginine residue showed far more sequence-specific fragmentation peaks.

In this work it is demonstrated that rapid peptide sequence information can be obtained using an ion trap/reTOF mass spectrometer via its ability to store ions for an extended time period so that the unimolecular decay of ions can be observed.

A Strategy to Locate Cysteine Residues by Specific Chemical Cleavage Followed by MALDI-TOF MS

Jiang Wu*, Douglas A. Gage and J. Throck Watson
Department of Biochemistry and Chemistry*, Michigan State University
East Lansing, MI 48824

Characterization of a protein requires a determination of the number and location of cysteine sulfhydryls and cystine disulfide bonds, due to the diverse roles they play in both protein structure and function. Classical approaches usually involve alkylation of the free sulfhydryls before and after reduction of the protein, enzymatic digestion , HPLC separation and Edman degradation of resulting peptides.

We are developing a simple method to characterize the number and location of cysteine and cystine groups in peptides and proteins, using chemical modification and MALDI-MS peptide mass mapping. This approach employs a specific reaction between free sulfhydryls and 2-nitro-5-thiocyanobenzoic acid (NTCB) to selctively cyanylate free cysteine thiols. The peptide bond on the N-terminal side of the modified cysteinyl residues can then be cleaved under alkaline conditions to form an amino-terminal free peptide and a series of blocked 2-iminothiazolidine-4-carboxyl peptides which can then be mass-mapped [1,2].

To determine the free sulfhydryl groups, the protein is first allowed to react with NTCB to cleave at free cysteine sites. The resulting disulfide bond-linked protein is then reduced by tris(2-carboxyethyl)phosphine (TCEP) to obtain a series of peptides whose number and mass are dependent on the number and position of free cysteine residues present in the protein. To determine the total cysteines, the protein is first denatured and allowed to react with TCEP to reduce disulfide bonds. NTCB is then added to modify all cysteines. MALDI mass mapping of the cleavage products indicates total cysteine groups in the protein.

The figures show the MALDI-TOF mass spectra of ovalbumin after being processed under the above two procedures. The protonated molecular weights for the predicted products and experimental data found by the use of external calibration are listed below:

TCEP/NTCB treatment			NTCB/TCEP treatment		
fragment	predicted	found	fragment	predicted	found
1-10	1011.1		1-10	1011.1

367-385*	2067.6	2066.9			

* incomplete cleavage and/or β-elimination products

Most of the proteolytic peptides can be detected directly by MALDI without the need for previous separation. However, the high mass fragments are often suppressed and not seen in the spectrum. Incomplete cleavage and β-elimination products may occur but these are never the major products. Although the NTCB reaction is specific for free sulfhydryls, high molar excess of NTCB and longer reaction times should be avoided because this can result in a side reaction with disulfide bonds. The reaction can be performed on a Zetabind membrane allowing the removal of MALDI contaminants and reagents and thereby reducing the required sample size for proteins to the low picomole level[3].

This developing methodology shows great promise for recognizing the location of the free cysteines and characterizing the distribution of disulfide bonds in proteins.

MALDI-MS of Proteins Electroblotted onto Membranes after 2D-PAGE-Separation

Kerstin Strupat, Christoph Eckerskorn*, Michael Karas, Friedrich Lottspeich*, Denis Hochstrasser§, Franz Hillenkamp,
Insitute for Medical Physics & Biophysics, University of Münster, 48149 Munster, FR Germany
* Max-Planck-Institute for Biochemistry, 82152 Martinsried, FR Germany
§ Medicine Department & Medical Computing Center, Geneva University Hospital, Geneva, Switzerland

It has been previously demonstrated that mass analysis of proteins immobilized onto polymer membranes is possible by MALDI-MS with IR-lasers (e.g Er-YAG-lasers) directly from the membrane.(1,2) It has been shown that proteins separated by SDS-PAGE with subsequent electroblotting of the separated proteins onto suitable blotting membranes and matrix incubation of the membrane in aqueous succinic acid solution for several minutes results in IR-MALDI-mass spectra of proteins taken directly from the immobilizing substrate

In continuation of this work, human plasma proteins were separated by (two-dimensional)-PAGE (2D-PAGE) according to Gorg *et al.* (3, 4) and Hughes *et al.*, respectively, and electrotransfered onto PVDF-membranes by a semi-dry procedure (Immobilon PSQ) The following matrix-incubation of the membrane was identical to the one found to be suitable for (one-dimensional) SDS-PAGE separated and electrotransfered proteins. One electroblot with 2D-separated plasma proteins was stained by Coomassie Blue and served as a reference blot, in order to locate the protein spots in the non-stained matrix-incubated blot. A home-built 1-stage reflectron time-of-flight mass spectrometer was used for this investigation An Er-YAG-laser at a wavelength of 2 94 µm and a pulse width of 100 ns was used to desorb the proteins.
Five protein spots were chosen in the mass range up to 20 kDa to demonstrate the feasibility of MALDI-MS to 2D-PAGE separated proteins Transthyretin (TTR, MW ca. 14 kDa) and the Haptoglobulins A, B, C (MW ca 16 kDa) of the α2-chain- differing in post-translational modifications - as well as an unknown spot D in close vicinity to the Haptoglobulin spot A were investigated by IR-MALDI-MS A MALDI-mass scan of the entire TTR-spot was performed in order to investigate the correspondence to the already known data of the laser densitometry of this spot

Figure 1 shows a MALDI-mass spectrum taken in the center of the TTR-spot. Its mass was determined to (13756±19) Da by external calibration using a 1D-separated Carbonic Anhydrase protein blotted onto PVDF-membrane as a reference protein on the same target. The standard deviation of this mass values results from 40 summed spectra of different locations, 10 single spectra were taken from each of the 40 different locations within the spot A comparison between the MALDI-mass data and the UV-laser densitometric data of the corresponding silver-stained TTR-spot in the gel shows excellent agreement with the local protein distribution. High MALDI-protein intensities are found in the center of the spot which decrease towards the edge.

Figure 2 shows MALDI-mass spectra of Haptoglobulin A-spot and its vicinity. Spot A has the lowest response in a silver-stained gel, among all investigated known proteins Its mass was determined to (16355±15) Da by external calibration The standard deviation of this mass values results from five summed spectra (10 single spectra) taken from five different positions in the spot. All spectra observed for the spots A, B and C of the Haptoglobins show a major component (slightly differing in their masses due to the post-translational modifications for the three Haptoglobulins) and a minor component

(shoulder) which is approximately 1240 Da lower in mass than the main component. The minor signal is found wherever the main component is found, its origin is not yet known. MALDI-mass analysis of areas in vicinity to spots A and C resulted in signals besides those from the Haptoglobin-modifications (see figure 2)

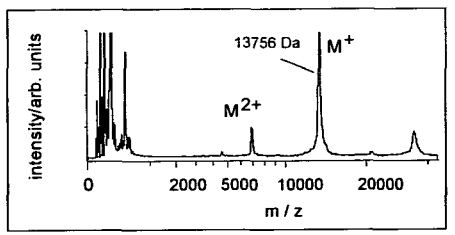

Fig. 1: MALDI-mass spectrum of the Transthyretin-spot taken in the center of the spot Membrane PVDF (Immobilon PSQ) Matrix succinic acid λ: 2 94 µm. Sum of 10 single spectra.
The mass of Transthyretin was determined to (13756±19) Da by external calibration using the protein carbon anhydrase (separated by SDS-PAGE) immobilized on PVDF-membrane From the literature the mass of the TTR-protein is 13762 Da.

Analysis of Oligonucleotide And Protein Samples Using Membranes And Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry

*Tracy I. Stevenson and Joseph A. Loo, Parke-Davis Pharmaceutical Research, Division of Warner-Lambert Company, 2800 Plymouth Road, Ann Arbor, MI 48105

INTRODUCTION One problem with matrix-assisted laser desorption/ionization (MALDI) mass spectrometry is that it is difficult to obtain accurate mass measurements for salt containing oligonucleotides and polypeptides due to adduct formation, causing broadening or skewing of the peaks, especially for samples over ~ 5 kDa. This problem can be minimized to some extent by sample cleanup and/or using an instrument with higher resolution capabilities to resolve the adducts, thereby allowing a more accurate mass determination. However, overall sensitivity is reduced because the ion signal is distributed over several ionic species.

Work has been performed in our laboratory to improve laser desorption and ionization of proteins and oligonucleotides while minimizing adduct formation and increasing resolution. Samples are applied to a specially prepared target plate membrane and allowed to dry. The samples are then washed to remove salts, which can form adducts, and then analyzed by MALDI time-of-flight (TOF) MS using an appropriate matrix for co-crystallization. The biological molecules bind to the membrane while the salts and buffers are washed away. Membranes tested to date include PVDF, Immobilon™-P, Immobilon™-CD, Nafion® 417, Nytran™, nitrocellulose, nylon 66, polyethylene, and Zitex®.

DISCUSSION Many biological samples are prepared or stored in buffer solutions which are very detrimental to obtaining high quality MALDI mass spectra. These buffer solutions can consist of mixtures of many species which mass spectrometrists have routinely avoided. An example of a typical mixture our laboratory receives is 50.0 mM HEPES + 10.0 mM CHAPS + 0.5 M NaCl + 10 % glycerol + 10.0 mM DTT. Some of the combinations are not a problem if sufficient protein is present in the solution enabling dilution, thereby lowering the concentration of the interfering species. However, others can cause problems even at extremely low levels such as sodium dodecylsulfate (SDS), which can completely suppress all ion signal at as low as 0.7 % (w/w) concentration.

To alleviate this problem, we investigated using membranes which have typically been used to bind proteins for sequencing, as well as some less traditional membranes. The sample containing membrane can be washed, removing the interfering species while retaining the analyte. To identify the best membrane for protein analysis, six different membranes were affixed to the sample plate and 10 pmol of bovine insulin applied to each membrane. The membranes were washed with copious amounts of deionized H_2O prior to the addition of matrix and MALDI analysis. PE (polyethylene) and Zitex® gave the strongest signals for the [M + H]+ ion of bovine insulin.

Figure 1 shows a very poor quality MALDI mass spectrum obtained for a HIV integrase sample in 20 mM HEPES + 10 mM CHAPS + 0.1 mM DPTA + 0.5 M NaCl and 20 % (w/w) glycerol (MW ~34,000 Da). The sample was cleaned-up by applying 2 µL of the protein solution to a PE membrane and washing away the buffer and salts with deionized H_2O. Once dry, 1.2 µL of sinapinic acid matrix was applied to the membrane and the sample was analyzed. The protein ion signal is now easily observed and its mass determined.

Oligonucleotides pose a similar problem for MALDI analysis. Salt adducts are very common and cause broadening of the ion peak which results in decreased mass accuracy and sensitivity. Figure 2 shows the negative ion mass spectra for oligothymidylic acid $d(pT)_8$ on Zitex® membrane. It can be seen in Figure 2b how Na+ adducts shift the mass of the oligonucleotide as well as cause a loss of resolution. However, after washing the membrane/sample with deionized H_2O, Na+ adduct formation has been greatly reduced and resolution restored, as shown in Figure 2c.

We have found in our laboratory that membranes can be used to quickly and efficiently clean-up peptide or protein samples which give no spectra or poor spectra due to contaminants present. This technique has proven to work well for samples ranging in molecular weights up to ~ 60,000 daltons. Polyethylene (PE) works best but is extremely fragile and difficult to work with in its presently available form (3M Disposable IR cards). Therefore, Zitex® is our membrane of choice due to its mechanical properties which make working with it very easy. Oligonucleotides have been much more difficult for our laboratory. We have not yet found a membrane for which we can obtain consistent results. DNA and RNA size appears to also play a crucial role in membrane selection and performance.

K. J. Matteson, and L. Y. Ch'ang

Oak Ridge National Laboratory
P. O. Box 2008, Bldg 5500, Oak Ridge, Tennessee 37831-6378

Since the discovery of matrix-assisted laser desorption (MALD) for protein detection by Hillenkamp and his co-workers, matrix-assisted laser desorption mass spectrometry has been successfully used to detect various kinds of proteins. Proteins with molecular weights higher than 300,000 amu have been detected. However, when MALD was applied to DNA, the success was limited to small DNA segments Recently, by using a custom designed time-of-flight mass spectrometer with high ion energy combined with specific mixtures of organic compounds as matrices, we succeeded in detecting oligonucleotides up to 500 base pairs in size. Experimental results are shown in Fig. 1. In addition, double-stranded DNA using polymerase chain reaction (PCR) and DNA segments produced from enzyme digestions were also successfully detected DNA sequence is shown in Fig. 2. Experimental results are in Fig. 3. Since large DNA segments can be detected, with good sensitivity, the applications for disease diagnosis becomes feasible.

Cystic fibrosis is the most common autosomal recessive genetic disease of Caucasians. The gene responsible for cystic fibrosis is composed of 27 exons spanning 250,000 base pairs and encodes a protein by 1480 amino acids named the cystic fibrosis transmembrane conductance regulator (CFTR). In the North American population, about 70% of the cystic fibrosis carriers have a 3-base pair deletion in exon 10, resulting in the loss of a phenylalanine residue at codon 508 (ΔF508). We succeeded in using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry to detect the codon 508 mutation in cystic fibrosis carriers and patients. Furthermore in a blind test, results from the normal and condon 508 mutation alleles in 30 clinical samples based on laser desorption mass spectrometry or the conventional gel electrophoresis of DNA were in total agreement.

In order to achieve MALDI for DNA sequencing, there are three critical requirements. They are (1) detection of large DNA segments, (2) detection sensitivity at a few femtomole region or better, and (3) resolution good enough to resolve DNA sizes of one nucleotide difference. Large DNA segments have been detected by MALDI with sensitivity at 100 femtomole. If the resolution can be improved, DNA sequencing by mass spectrometry should become feasible. Key factors to cause poor resolution of DNA segments by MALDI are (1) broad velocity spread, (2) chemical properties of matrices to cause fragmentation and adducts, (3) long ion production time and significant ionization volume, and (4) high laser fluence to cause ro-vibronic excited states that can lead to fragmentation. Major effort will be made to eliminate or reduce these factors.

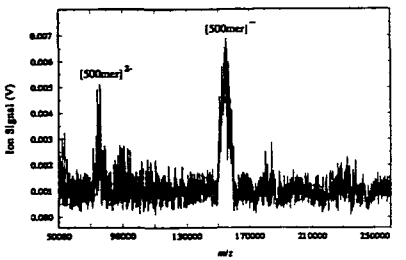

Figure 1. Negative ion spectrum of a 500-basepair DNA amplified from bacteriophage lambda genome. Total amount of DNA loaded was about 2.5 pmol. 2.4 μmol picolinic acid +0.3 μmol 3-HPA was used as a matrix. Laser wavelength was 266 nm and laser fluence was 200 mJ/cm². Both singly-charged and doubly-charged ions are observed.

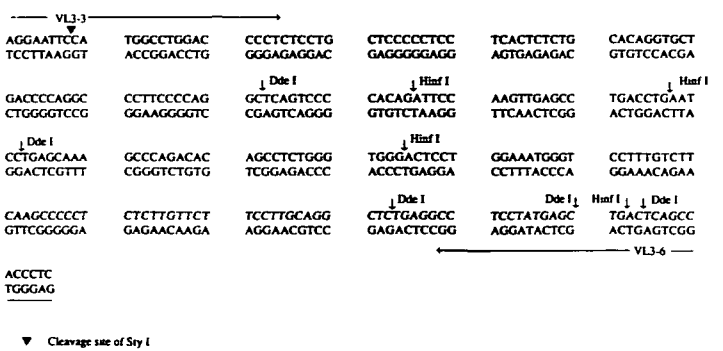

Figure 2. Sequence of DNA designated as pLB132. The sites for various enzymes to cut are also included.

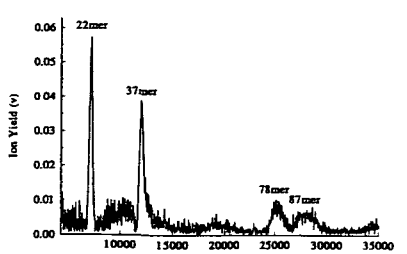

Figure 3. Negative-ion spectrum of DNA (LB132) cut with HinfI and StyI: 2 μL of DNA samples (~1-2 pmol of each fragment) were mixed with 2 μL of 3-hydroxypicolinic acid with a concentration of 0.3 M. The laser wavelength was 355 nm. The laser fluence was 70 mJ/cm². Data were obtained from the average of 20 laser shots.

MALDI MS for Rapid Screening of Genetic Polymorphisms Using Buccal Cell DNA

Yan-Hui Liu, Jian Bai, Xiaoli Liang, Mark G. Qian, and David M. Lubman, Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109-1055

INTRODUCTION. Rapid and cost-effect methods for detection of DNA polymorphisms are the basis of genetic diagnosis and linkage study. The development of such methods will play an increasingly important role in the field of molecular pathology/genetics. MALDI MS employing nitrocellulose (NC) film substrate as an on-probe purification scheme is applied in this work for rapid and accurate detection of human genetic polymorphisms using DNA extracted from buccal cells.

EXPERIMENTAL. NC film substrate was produced by application of ~1 μL of NC solution (~16 mg/mL in acetone) onto a stainless steel probe tip and air-dried. DNA sample was then added onto the NC film and air-dried before the application of the matrix. MALDI MS was performed on a linear TOF with a 355 nm Nd:YAG laser for desorption/ionization. DNA extracted from buccal cells collected on a cytology brush has been employed as the primary source for PCR amplification. PCR, including multiplex PCR and PCR primer mutagenesis were used for amplification of genes of carbonic anhydrase (CA) II & III and of cystic fibrosis transmembrane conductance regulator(CFTR) on exons 6a and 12. For restriction-length polymorphism (RFLP) study, a restriction enzyme was added directly to the cycled PCR reaction to simplify the digestion process.

RESULTS AND DISCUSSION.

MALDI MS of PCR products based on DNA extracted from buccal cells. Although PCR products obtained from buccal cell DNA on cytology brushes are less than those from some other DNA sources (1), they are sufficient to support the MALDI MS analysis in this work. 1/4 to 1/3 of a PCR reaction product, which was around subpicomole level (~ 400 femtomole assuming 100% recovery after purification), was used for each MALDI MS analysis. Figure 1 shows the spectra of genes of CA II and CFTR on exon 6a and 12 under normal PCR conditions Products of multiplex PCR amplification and PCR primer mutagenesis were also detected by the MALDI MS method in this work

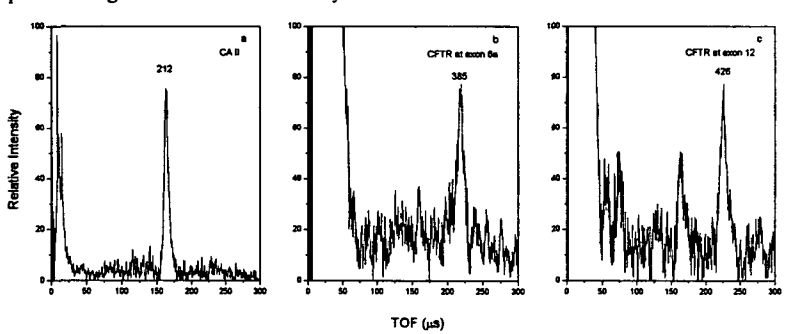

Figure 1. MALDI MS of PCR products of CA II (212 bp) and CFTR on exons 6a (385 bp) and 12 (426 bp)

Polymorphism study and disease diagnosis. RFLP of genes of CA II (Figure 2) and CFTR (Figure 3) on exon 6a and 12 was performed by direct digestion of PCR products with restriction enzymes followed by MALDI MS analysis.

MALDI MS of *BstN* I digest of CA II is shown in Figure 2. Individuals A and B are from homozygous population while individual C is form heterozygous population. Figure 3 shows an individual with both alleles normal for the CFTR genes on exon 6a and 12

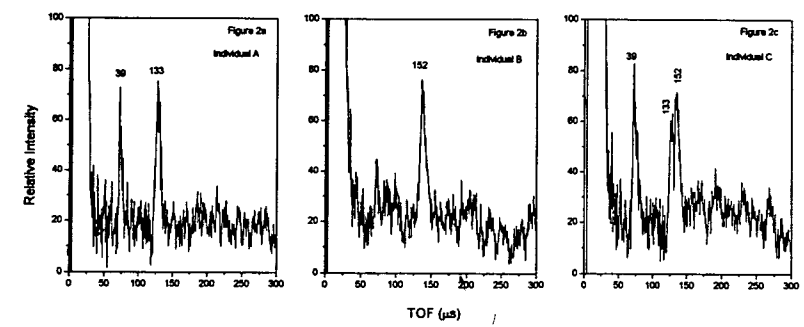

Figure 2 MALDI MS of *BstN* I digest of CA II gene

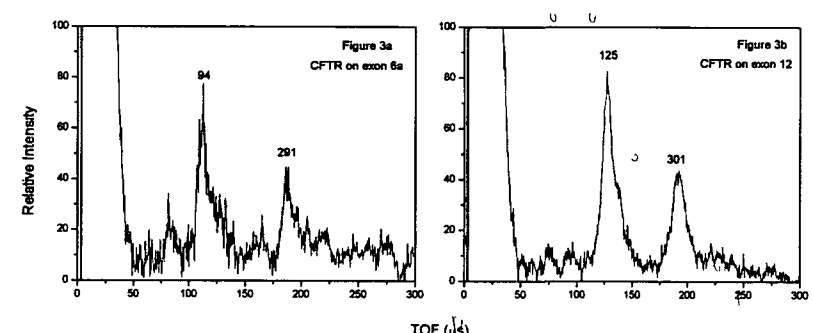

Figure 3 MALDI MS of (a) *Rsa* I digest of CFTR on exon 6a gene and (b) *Acc* I digest of CFTR on exon 12 gene.

CONCLUSION. MALDI MS with NC film substrate provides a fast, accurate and cost-effective method for detection of genetic polymorphisms following biological or clinical procedures. This method should also be readily extended to other areas which involve DNA mapping and screening

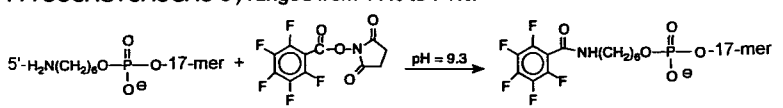
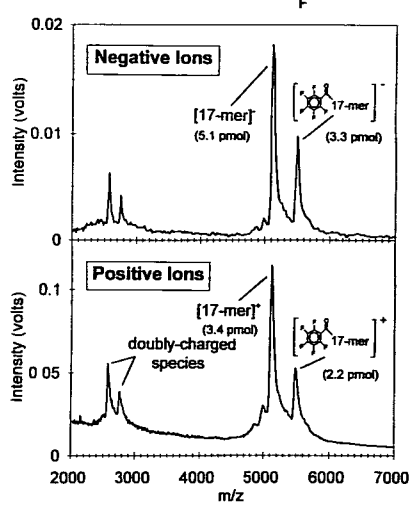
Synthesis and MALDI Characterization of Electrophore-Labeled DNA

Gregory B. Hurst, Phillip F. Britt, and Michelle V. Buchanan, Chemical and Analytical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37831-6365

To speed up sequencing and other DNA analyses that yield information encoded as a "ladder" of DNA segments of different sizes, MALDI-MS detection methods are being developed [1-4] to replace currently-used gel electrophoresis methods. Enzymatic sequencing with MS detection offers the possibilities of increased speed [1] and improved accuracy [4] over gels.

One challenge in applying MALDI-MS to DNA detection is that the sensitivity falls off drastically with increasing molecular weight [1], although progress in detecting higher-molecular-weight DNA has been reported [2]. Our approach is to enhance ionization efficiency by derivatizing DNA sequencing primers with an ***electrophore*** to allow formation of negative ions by electron capture. An electrophore-labeled primer would be incorporated into each DNA segment produced in a sequencing reaction. Methods have been described for the preparation of DNA and RNA oligomers with covalently attached labels for fluorescent, chromophoric, or chemiluminescent detection [5,6]. The reaction is shown below for one of the electrophores evaluated in this study [7]. Isolated yields of electrophore-labeled M13(-40) primers (5'-GTTTTCCCAGTCACGAC-3') ranged from 11% to 74%.





MALDI samples were prepared in the normal manner using a 3-hydroxypicolinic acid matrix, and analyzed using either a linear time-of-flight mass spectrometer [3] (Laser Photonics LN203C pulsed nitrogen laser) or an Extrel FTMS-2000 system [8] (3-Tesla magnet; Spectra Physics DCR-11 pulsed Nd:YAG laser, frequency-tripled line at 355 nm). The Figure shows positive- and negative-ion MALDI-TOF spectra of mixtures of the unlabeled and the pentafluorobenzoyl (PFB)-labeled M13(-40) primer. The measured m/z for the labeled primer is consistent with addition of one PFB group. Doubly-charged peaks appear in both positive and negative ion spectra for the labeled and unlabeled species. Similar results were obtained for the other electrophores studied (see Table 1.)

The electrophore-labeled primers retain the label during MALDI sample preparation and MALDI-TOF analysis, as demonstrated by spectra showing little or no fragmentation. As expected due to the longer time frame for the experiment [8], MALDI-FTMS of a PFB-labeled DNA tetramer (5'-ACTG-3') showed more extensive fragmentation to form sequence ions analogous to the unlabeled tetramer, although little loss of the label was observed. Because conditions for electron attachment by the labeled primer are not present in normal MALDI experiments, there is no enhancement in the signal due to the PFB-labeled primer in the Figure. We are modifying the MS measurement to improve conditions for electron capture by labeled DNA.

Compound	Calculated MW[a]	Observed m/z[b] (positve ions)	Observed m/z[b] (negative ions)
unlabeled 17-mer	5118.9	—	—
-17-mer	5476.9	5440±80	5464±35
-17-mer	5490.9	5493±18	5491±13
 -17-mer	5503.0	5504	5497±30
-17-mer	5446.0	5441	5437±75

[a]Calculated monoisotopic mass for the neutral molecule, assuming that all phosphates are paired with protons.

[b]Uncertainties are 95% confidence interval based on the least squares fit to the mass calibration equation. For values with no uncertainty listed, only two calibration points (the singly- and doubly-charged 5'-OH primer) were used.

Use of a Polymeric Substrate in MALDI MS for DNA Mapping and Screening

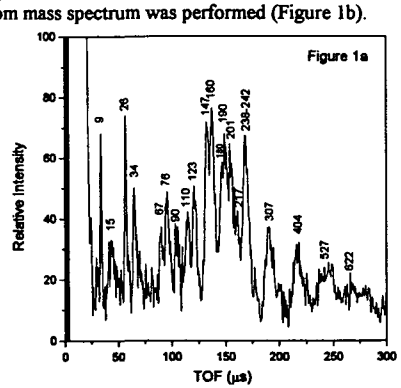
Yan-Hui Liu, Jian Bai, Xiaoli Liang, and David M. Lubman, Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109-1055

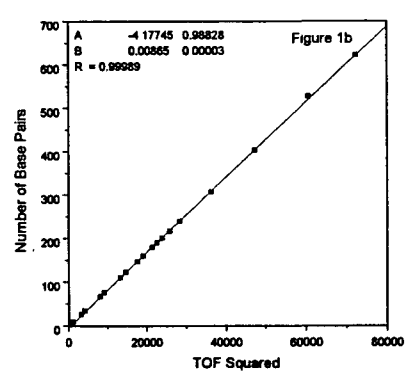
INTRODUCTION. One major issue concerning MALDI MS analysis of DNA is the presence of impurities in biological sample and the inhomogeneous desorption of all fragments in a mixture. In this work we present the use of a nitrocellulose (NC) film as a substrate which allows for effective on-probe elimination of the interfering effects of salts, buffers and other contaminants. This method has been successfully applied in the detection of DNA mixtures for DNA mapping and screening.

EXPERIMENTAL. NC film was produced by application of ~1 μL of NC solution (10 ~ 32 mg/mL in acetone) onto a stainless steel probe tip and air-dried. A thin and homogeneous layer of NC film is essential for the successful detection of DNA mixtures in this work. 2 μL of DNA sample was added to the hydrophobic surface followed by air-drying. 4 μL of matrix was then applied to the sample spot and air-dried before MALDI MS analysis. The matrix used in this work is the saturated solution of the mixture of 3-HPA and PA with molar ratio of 4 to 1 in a 36% acetonitrile in water. A linear TOF with postacceleration and a 355 nm Nd.YAG laser were used for MALDI MS

RESULTS AND DISCUSSION. The use of the NC film substrate greatly enhances the ion yields of DNA fragments, the reproducibility of the signal and the signal persistence. This may be explained by the fact that NC binds alkali metal ions through electrostatic interactions (1) and some other buffer impurities by hydrophobic adsorption, so they are partially excluded from the matrix/analyte during crystallization. It is also possible that NC acts as a crystallization moderator. With the use of a NC substrate a much more homogeneous crystallization of the matrix/sample was obtained compared with the use of a stainless steel probe tip.

Analysis of enzyme digests of ds-DNA. *Msp* I digests of ds-DNA pBR322 with fragments ranging from 9 to 622 bp were detected with NC film substrate (Figure 1a), while only fragments < 100 bp can be detected by using stainless steel probe. A new mass calibration scheme was established that linear regression of the number of base pairs of the fragments and the corresponding TOF squared measured from mass spectrum was performed (Figure 1b).





Polymorphism study. Variable number of tandem repeats (VNTR) polymorphism study of canine von Willeband's factor gene was performed by screening the PCR products directly by MALDI MS with NC film substrate. Figure 2a was from Siberian huskey which is homozygous with 9 repeats of AGGAAT on both alleles. Figure 2b was from a mixed breed dog which is heterozygous with 9 and 14 repeats of AGGAAT on each allele. Homogeneous and reproducible signal was obtained with the use of NC film substrate in MALDI MS analysis in this study.

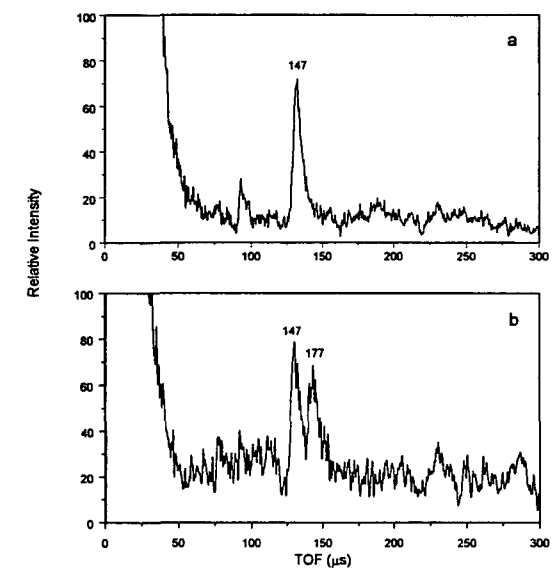


Figure 2. MALDI MS of PCR products of genes of (a) Siberian huskey and (b) mixed breed dog

CONCLUSION. The NC film substrate is demonstrated herein to enhance MALDI MS performance for DNA mixture analysis by effective elimination of impurities and by creation of a homogeneous crystallization of matrix/analytes. Desorption of all fragments in DNA mixtures were obtained by incorporating NC film substrate into MALDI process.

THE EFFECT OF IMPURITIES ON MALDI TOF MASS SPECTRA OF SINGLE-STRANDED OLIGODEOXYNUCLEOTIDES[1]

Thomas A. Shaler, Juanita N. Wickham, Kuang Jen Wu, Kristin A. Sannes, Joanna M. Hunter and Christopher H. Becker
Molecular Physics Laboratory, SRI International, Menlo Park, CA 94025

The effect of impurities on the matrix-assisted laser-desorption/ionization time-of-flight mass spectra of single-stranded DNA has been studied using the matrix 3-hydroxypicolinic acid and 355 nm pulsed light. The tolerance limits for impurities indicate that some preliminary purification of DNA is necessary to obtain good spectra. In addition, for some inpurities, the tolerance limits for DNA analysis differs significantly from the tolerance limits for protein analysis.[2]

By mixing the DNA oligomers with different concentrations of impurities and recording mass spectra, the tolerance limits are set for a given impurity in a sample. The tolerance limit for sodium chloride, sodium acetate, sodium fluoride, sodium dodecylsulfate (SDS), potassium chloride and manganese(II) chloride were found to be approximately 10 mM while the tolerance limit for magnesium (II) salts was found to be approximately 0.1mM (Table 1). In contrast, the tolerance limits of the organic compounds cyclohexane-N, N, N', N'-tetraacetic acid monohydrate (CDTA), ethylenediaminetetraacetic acid (EDTA) when present as its ammonium salt, dithiothreitol (DTT), glycerol, Tris(hydroxymethyl)aminomethane (Tris) and urea were 250-500 mM (Table 1). Given the significant degree of sample-to-sample variation, we estimate that these values are accurate to within about a factor of two.

Type I impurities (metal salts) degrade the signal by forming adducts with the DNA (Figure 1). Adduct formation causes a mass shift as well as a decrease in mass resolution. The simple *in situ* method of removing metal ions by adding chelating agents (i.e. EDTA and CDTA) did not improve the spectra significantly. Type II impurities (organic compounds) degrade the signal by disrupting the crystallization of the matrix and/or decreasing signal stability (Figure 2). For type I impurities, increasing the size of the DNA decreases the tolerance limit because the number of sites for adduct formation increases. For type II impurities, increasing the size of the DNA does not change the tolerance limit. For both type I and II impurities, changing the ion polarity does not change the tolerance limit.

ANALYSIS OF ENZYMATIC DNA SEQUENCING REACTIONS BY MATRIX-ASSISTED LASER-DESORPTION TIME OF FLIGHT MASS SPECTROMETRY

Thomas A. Shaler, Juanita N. Wickham, Kuang Jen Wu, and Christopher H. Becker
Molecular Physics Laboratory, SRI International, Menlo Park, CA 94025

The products from base-specific, chain-termination DNA sequencing reactions, catalyzed by the modified T7 DNA polymerase Sequenase Version 2.0 (USB), have been analyzed by the technique of matrix-assisted laser-desorption/ionization (MALDI) time of flight mass spectrometry. Preliminary experiments were performed to determine detection limits for a synthetic mixture of mixed-base single-stranded DNA which contained a 14-mer, a 21-mer, and a 41-mer. Acceptable spectra, showing peaks for each component, were obtainable for samples that contained as little as 5 fmol per component. A spectrum obtained from such a mixture is shown in Figure 1.

In separate experiments, we had found that a synthetic 40-mer could easily be resolved from a 41-mer under conditions of continuous extraction. Initial sequencing reactions were therefore carried out on 2-pmol amounts of a short synthetic template that was 45 nucleotides in length, employing a 12-mer as the primer strand. Figure 2 shows spectra obtained from the four different dideoxynucleotide-terminated sequencing reactions. Nearly unambiguous sequence information can be read from the spectra out to 19 bases past the primer. A single false-stop in the ddT reaction at the position of the 14-mer provides the only source of ambiguity, which is possibly due to the relatively short length of the primer. Further improvements and optimization should make sequencing of templates in the 50- to 60-mer range possible.

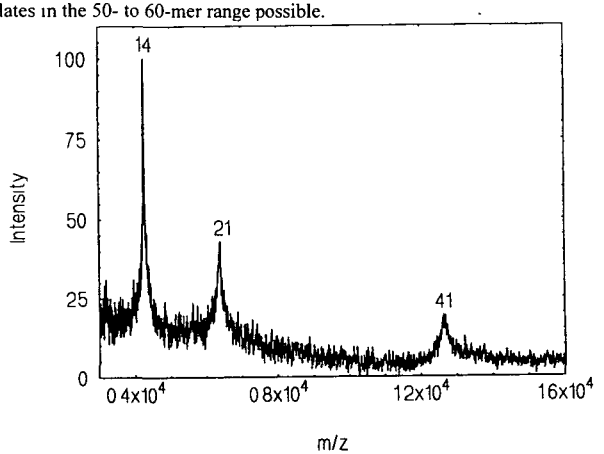

Figure 1. MALDI mass spectrum of a synthetic mixture of 14-, 21-, and 41-mer DNA containing 5 fmol each. The positive ion spectrum is the sum of 100 laser shots from 3-hydroxypicolinic acid matrix.

PROTOCOLS FOR IMPROVED LASER EJECTION/IONIZATION TOF-MS OF OLIGONUCLEOTIDES

Jannavi R. Srinivasan, Robert J. Levis
Department of Chemistry, Wayne State University
Detroit, MI-48202

Gas phase studies of biological molecules using laser mass spectrometry have provided new dimensions to the study of large molecules such as oligonucleotides. By replacing the gel electrophoresis step with mass spectrometry in the current sequencing methodology, enhanced sequencing rates may be obtained. For mass spectrometry to be a suitable substitute certain key factors such as the resolving power of the technique and the amount of material required for obtaining sequence information must be improved. This report deals with our efforts to improve laser ejection/ionization for oligonucleotide analysis.

The experiments are performed in a linear time of flight mass spectrometer as shown in Fig. 1 and a similar apparatus has been described in detail elsewhere(1). Oligonucleotide samples are prepared for laser analysis by premixing them with a UV absorbing matrix, 3-hydroxypicolinic acid(2). The substrates for laser ejection are 12mm quartz coverslips used in place of conventional metal substrates. The surface of the coverslips are chemically modified to provide a hydrophobic surface. The oligonucleotide/matrix sample is subject to a thermal processing step after being deposited on to the substrate. The resulting coverslip is mounted on one end of the sample rod that forms an integral part of the linear time of flight mass spectrometer. Laser ejection/ionization is performed by impinging a pulse of 355nm photons from a Spectra Physics GCR-11 Nd:YAG laser. The tripled output of the laser has a power density of 40mJ/cm^2 (unfocused, 2.7 ns) measured just before it enters the chamber. The ions formed during this event, both matrix and oligonucleotide, are extracted towards the detector by applying a potential of 5kV-8kV on the sample rod and maintaining a second grid (1.25 cm from sample) at ground. The positive ions are extracted into the field free time of flight region and detected by a hybrid detector placed 1.25m from the region of extraction. The current from the ions striking the detector is amplified and recorded by a LeCroy digital oscilloscope. The resulting data is then transferred to a 486 PC via GPIB.

The results reported here include investigations of the laser ejection process from glass substrates and improvements to the substrate surface to enhance key factors such as signal to noise ratios and detection limits. A unique detection system was tested for mixed base oligonucleotides of lengths greater than 50 bases. The sensitivity of the technique was determined for different oligonucleotide lengths. Fig. 2 is the laser ejection/ionization time of flight mass spectra recorded for a series of mixed base 32mer samples that were mounted on chemically modified glass and subjected

to thermal treatment prior to laser ejection. A detection level of 10 femtomol was achieved for this sample. This investigation was extended to the study of double stranded DNA that were obtained from a polymerase chain reaction. Fig. 3 is the laser ejection/ionization time of flight mass spectra of a 350mer (PCR product) comparing the effect of substrate treatment and detection system on the final data. The amount of DNA loaded on the substrate was 600 femtomol and 10 femtomol of the total sample was used to obtain the spectra shown here.

NON-COVALENT PROTEIN—OLIGONUCLEOTIDE INTERACTIONS MONITORED BY MATRIX-ASSISTED LASER DESORPTION IONIZATION MASS SPECTROMETRY

Xiaodong Tang[1], John H. Callahan[2], Ping Zhou[3], Joe Hayes[3], Akos Vertes[1]*
[1]Department of Chemistry, The George Washington University, Washington D.C. 20052
[2]Chemistry Division, Naval Research Laboratory, Washington D. C. 20375
[3]Cruachem, Inc., Dulles, VA 20166

The rapid development of new soft ionization techniques, such as matrix-assisted laser desorption ionization (MALDI), has made it possible to study the non-covalent protein oligonucleotide interactions by mass spectrometry. In this study our objective was to identify the amino acid and nucleotide residues involved in the interactions, and the matrix effects on the observation of protein-oligonucleotide complexes. The experiments were carried out on a linear time-of-flight mass spectrometer equipped with a nitrogen laser in positive ion mode.

Strong correlation was found between the presence of basic residues in proteins and the tendency to participate in complexation. Also, complex formation resulted in substantial improvement in mass resolution for DNA analysis. An example is shown in Figure 1, where MALDI-MS of $pd(T)_{10}$ and Arg-Lys—$pd(T)_{10}$ mixture are compared. When $pd(T)_{10}$ was measured alone, its molecular ion peak was broadened by the presence of sodium and potassium adducts (Fig. 1a). In the Arg-Lys—$pd(T)_{10}$ mixture, a large variety of complexes were produced containing up to six peptide units and four DNA units (Fig. 1b). The abundant $(1:1)^+$ complex was completely free from alkali adducts, leading to a trifold resolution improvement. In addition, $pd(T)_{10}$ formed complexes with other medium size proteins, including insulin, ubiquitin, lysozyme, ribonuclease A, and cytochrome C. It was demonstrated that Arg was distinguished from the other basic residues (Lys and His) by stronger interactions.

Further investigations proved the essential role of thymidylic acid in the DNA sequence for complex formation. We saw strong complex formation for the Arg-Lys—$pd(T)_{10}$ mixture (Figure 1b), whereas little or no interaction was observed between Arg-Lys and $pd(A)_9$, $pd(C)_{10}$, or $pd(G)_{10}$ homologues (Figure 2a, 2b, 2c). Under the same conditions, complexation occurred for Arg-Lys and a mixed DNA sequence, pd(AGCTCAGCTT) (Figure 2d). The interactions turned out to be specific to the properties of the base components and dependent on the pH value. In pH=1.7 DHB matrix solution, thymine stays in neutral form because an added positive charge can not be delocalized. The negative charge on phosphate group leads to strong ionic interactions with protonated sites on peptide molecules. Despite of the higher rigidity and spatial hinderance, extended chains of DNA can undergo similar ion pair formation with bulky proteins. On the other hand, positive charge attachment on adenine, guanine and cytosine is facilitated by delocalization. Therefore zwitterionic form is dominant in $pd(A)_n$, $pd(C)_n$, and $pd(G)_n$ systems, intermolecular ion pair formation is not feasible.

It was also found that the detection of complexes was strongly matrix dependent. The tested matrices included: 2,5-dihydroxybenzoic acid (DHB), sinapinic acid (SA), 3-hydroxypicolinic acid (3-HPA) and α-cyano-4-hydroxycinnamic acid (CHCA). The effects are shown in Figure 3 for lysozyme and $pd(T)_{10}$ mixture. In DHB matrix (Figure 3a), complex ions containing up to five $pd(T)_{10}$ and one lysozyme molecules were observed along with their doubly charged ions. In CHCA matrix, the mass spectrum was dominated by strong singly, doubly, and triply charged lysozyme ions, — no complex formation was found. Based on protein—oligonucleotide complex formation experiments the matrices can be divided into two groups: complex stabilizing (e.g., DHB and 3-HPA) and complex suppressing (e.g., CHCA and SA) matrices.

MALDI POST SOURCE DECAY OF OLIGONUCLEOTIDES

L.J. Deterding and K.B. Tomer

Laboratory of Molecular Biophysics
National Institute of Environmental Health Sciences
Research Triangle Park, NC 27709

Matrix-assisted laser desorption ionization (MALDI) mass spectrometry is rapidly becoming an integral part of the characterization of biological compounds. This technique has several advantages, including, detection of molecular species in excess of 100,000 Da, sub-picomole detection limits, and the use of a reflectron for metastable ion analysis. It has been demonstrated that, in MALDI, a large fraction of the analyte ions undergo fragmentation after full acceleration. This process is called post source decay (PSD) (1,2). The activation energy for the PSD reactions arises from collisions of the analyte ion with matrix molecules during the ion acceleration process and collisions of the analyte ions with residual gas molecules in the drift path. In a single stage TOF instrument, these fragment ions have the same velocity as their parents. This yields increased sensitivity but the structural information contained in the PSD ions is lost. In a reflectron-based TOF instrument, the ions undergo deceleration in the mirror to the point of being repelled back into the flight tube. The deceleration/reacceleration is mass dependent. Thus, the PSD ions will reach the detector at a time different from the parent ion. In this manner, the structural information contained in the PSD ions can be obtained. The sequencing of peptides has been demonstrated with the use of MALDI-PSD (1,2). Application of this technique to nucleic acids could be useful in DNA sequencing analyses. Structural characterization of normal and modified oligonucleotides is important not only for DNA sequencing but also for the determination of DNA modifications induced by toxic compounds. The applicability of mass spectral analyses to the structural characterization of oligonucleotides has been previously been limited in many cases by poor sensitivities and lack of complete structural information (3,4). In this paper we report the PSD results of some synthetic oligonucleotides and of the enzymatic fragments of a digest of an oligonucleotide and a protein. For the enzymatic digestions, the timed ion selector device was used. This device allows only ions of a selected mass to pass to the detector. This is beneficial when matrix ions or additional sample component ions can cause interferences in the PSD/MS/MS acquisitions.

The PSD/MS/MS data from the oligonucleotides show that any of the cleavages along the phosphodiester chain are possible. Ions arising from cleavages at every nucleic acid residue were observed in all cases. Prominent ions due to loss of a base from the backbone cleavage ions, e.g a3-G in the PSD/MS/MS spectrum of the $(M-H)^-$ ion of pd(GTTAAC) (Figure 1.), are also observed. Similar data were acquired for the digest fragments from the 5' to 3' degradation of d(TCTAGA) using phosphodiesterase II from calf spleen.

The PSD/MS/MS data from glucagon tryptic fragments show that the most common cleavage ions observed are the *a* and *b* ions, which result from the retention of the charge by the N-terminus, and *y* ions, which result from retention of the charge by the C-terminus. In addition, abundant ions resulting from the loss of 17 from the *a*, *b*, and *y* fragments are observed. Figure 2 shows the PSD/MS/MS spectrum of the (M+H)+ ion of T3,4 of glucagon. These data show that the sequence of the digest fragment can be determined using this technique.

New Instrumental Approaches to TOF Mass Spectrometry of DNA

David Dogruel, Randall W. Nelson, Peter Williams
Department of Chemistry and Biochemistry
Arizona State University, Tempe, AZ 85287-1604

Introduction

The matrix-assisted laser desorption/ionization (MALDI) process has proven capable of producing intact vapor phase polypeptide molecules with molecular weights up to 1 MDa. Most proteins are routinely analyzed using MALDI/TOF mass spectrometry, however, nucleic acids (DNA and RNA), have presented more of a challenge; spectra obtained during MALDI/TOF analysis of DNA do not exhibit the quality, sensitivity, or reproducibility of spectra obtained from proteins. This suggests that the matrix behaves differently in the two cases, i.e. fails in either desorption or ionization, or both, during nucleic acid analysis.

Methods capable of separating the duality of the matrices (desorption and ionization) are needed to gain a better understanding of the poor performances observed during nucleic acid analysis. Analytes which ionize via alternate channels (other than proton exchange with the matrix) are desired. Synthetic polymers which preferentially ionize via fortuitous cationization are such a class of analyte, making it possible to qualify the desorption event independent of ionization. Further, it is possible to gain greater insight into the limitations of the matrices (with respect to ionization) by incorporating polypeptide analytes into the analysis.

We have chosen for study the polar polymer, poly (methyl methacrylate) (PMMA) on the basis of its ability to provide unique neat and matrix-assisted mass spectra. By altering the pH and ionic composition of the matrix, we have been able to determine the practical limits for both desorption and ionization

Experimental

Sample Preparation

Poly (methyl methacrylate) (PMMA4K), nominal MW= 4100, was obtained from American Polymer Standards Corporation and dissolved in methanol to 200 pmol/uL. The protein α-cobratoxin (MW 7822) was dissolved in 0.1% aqueous trifluoracetic acid to 200 pmol/uL.

Titration of Matrix

A sample of .4133 g of 2,5-dihydroxybenzoic acid (DHB) in 25 mL of deionized water was titrated with a 0.01 M solution of sodium hydroxide, the pH being monitored with a glass electrode/pH meter. For the MALDI experiments, DHB in methanol was titrated with KOH, and aliquots of 200 uL were removed at intervals of approximately every 1 pH unit

Mass Spectrometry

Mass spectrometry was performed on a linear time-of-flight mass spectrometer equipped with a Nd:YAG laser, using the third harmonic output (355 nm). Positive ions were accelerated to 30 kV using a two-stage source. An electrostatic ion guide was used over the nominal 1.5 m flight path. Detection was accomplished with a hybrid, microchannel-plate/discrete-dynode multiplier. Ion signal was monitored on a sampling oscilloscope and signal averaged with a 500 MS/s transient recorder. Data were transferred to an IBM compatible 486 computer and analyzed with PC compatible software utilizing external calibration.

Results

The generation of qualitatively different polymer distributions from neat and matrix-assisted analysis makes PMMA ideal for evaluating the ability of a matrix to desorb large molecules.

Use of the proteins in combination with PMMA allows the total functionality of the matrix to be investigated. A series of spectra are shown in **Fig. 1** of a sample containing PMMA and the protein α-cobratoxin. Several features are important to note:

1) The matrix functions as a desorption and ionization vehicle for the protein only in the low pH buffer region, with the best functionality occurring at the intrinsic pH of the matrix and a progressive loss in the ability to protonate as the pH increases.
2) In the region where the pH is changing most rapidly (no buffer capacity), the matrix suppresses all analyte signal for both the polymer and the protein.
3) At a basic pH the matrix loses the ability to desorb (indicated by the neat PMMA distribution).

The ionization of PMMA was also studied as a function of the available cation by addition of alkali metal salts. **Fig. 2** shows the distribution centroid of cesiated PMMA being ~ 750 Da higher (~20%) than that observed for the sodiated; beyond that expected from the difference in mass between the two cations. This indicates a need for further understanding of the cationization processes.

Conclusions

The most important aspects of MALDI matrices are the ability to desorb and ionize the analyte. It has been shown that the matrix functions best as a proton donor at its intrinsic pH and progressively loses the ability to desorb with increasing pH.

The use of polymers, like PMMA, which serve as qualifiers for matrix-assisted laser desorption and ionization can lead to a better understanding of the roles of the two processes involved in DNA and biopolymer analysis. Also, the dependence of the PMMA mass distribution on the available cation has implications in the choice of substrate and matrix composition for polymer analysis.

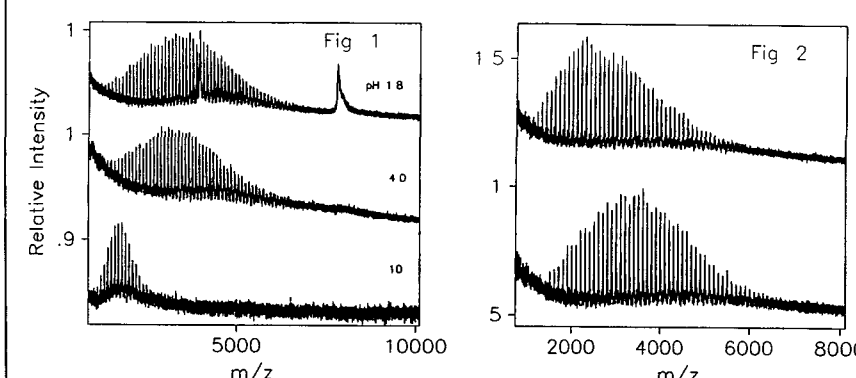

Figure 1: MALDI/TOF mass spectra of a mixture of PMMA and α-cobratoxin taken at different pH values
At the intrinsic matrix pH (1.8), strong protein signal is observed. As the pH increases, the ability of the matrix to ionize the protein via proton exchange is lost. At pH 10, the polymer distribution has reverted to neat desorption

Figure 2: PMMA molecular weight distributions obtained in the presence of different metal cations Top-Na^+ cationized PMMA, Bottom-Cs^+ cationized PMMA. The matrix DHB was used at its intrinsic pH (1.8) and the metal salts were doped into solution.

Progress in DNA Sequencing and Fundamental Studies Using MALDI-TOFMS

Chau-Wen Chou, Randall W. Nelson and Peter Williams
Department of Chemistry, Arizona State University, Tempe, AZ 85287-1604

A. The affinity cleaning-up of DNA sequencing fragments

MALDI has shown promise for a fast and accurate readout of DNA sequencing fragments. However, it seems probable that the final solution from the Sanger dideoxy method will be too much complex to be analyzed. Excess nucleotides, polymerase, buffers and other components may interfere with ablation or ionization. The impurities have to be removed rapidly and specifically.

The hybridization between two complementary strands is the most specific affinity force for DNA. Two experiments have been tried to select and separate the DNA fragments by using this feature:

(a). Agarose beads experiment. The complementary strand of primer is immobilized on the agarose beads. The fragments in the Sanger reaction solutions hybridize with the immobilized strand and can be separated by filtration.

(b). Biotin-streptavidin paramagnetic beads experiment. The complementary strand of the primer is labeled by biotin. It hybridizes with the fragments in the Sanger reaction solutions, and then is mixed with streptavidin paramagnetic beads. The strong affinity between biotin and streptavidin is used to select the biotinylated strand and then the fragments can be separated along with biotinylated strands.

The results showed that the hybridization yields between the DNA fragments and immobilized complementary strands on agarose beads were only about ~ 30%. It can be explained that the hybridization between solid and solution phase is not very efficient. On the other hand, the results from the biotin-streptavidin paramagnetic beads experiment were more encouraging. Fig.1 shows the spectra of DNA fragments (up to 52-mer) were captured from the solutions with possible impurities in the Sanger sequencing reaction. ~ 80% of DNA fragments can hybridize with biotinylated strands. After three washes and separations, only ~ 35% fragments were recovered. It indicates that the better protocols have to be developed to minimize the loss in the experiments.

B. The initial velocity measurements

The mechanism(s) of MALDI is (are) still not clear. Is it a thermal process or a photochemical process? The initial velocities of ablated matrix species and analytes may provide useful information on mechanisms. Here, the influence of laser wavelengths on the initial velocities of matrix have been studied carefully.

A modified Chait/Beavis [1] device was used to prevent field penetration derived the ground plate. Ions fly cross a 7.5 mm drift space mostly by their initial velocities. Small fields were applied to increase the signal intensity. We determined initial velocities and kinetic energies by comparing the flight time differences with flight time difference calculated for a range of initial energies of initial kinetic energies using the SIMION ion optics program.

Our results shows that the initial velocities of matrix ions are not affected by the small fields but vary due to the local conditions of sample spots. The results of anthranilic acid and co-matrix of nicotinic acid and anthranilic acid desorbed at 266 and 355 nm shows that initial velocities increase as the samples were desorbed by the photons with higher energy (Table 1). In addition, the laser desorption/ionization products of sinapinic acid are different at 266 and 355 nm. The wavelength discrimination is the characteristic of photochemical processes. It indicates that the photochemical processes play may more important roles than thermal processes in matrix-assisted laser desorption.

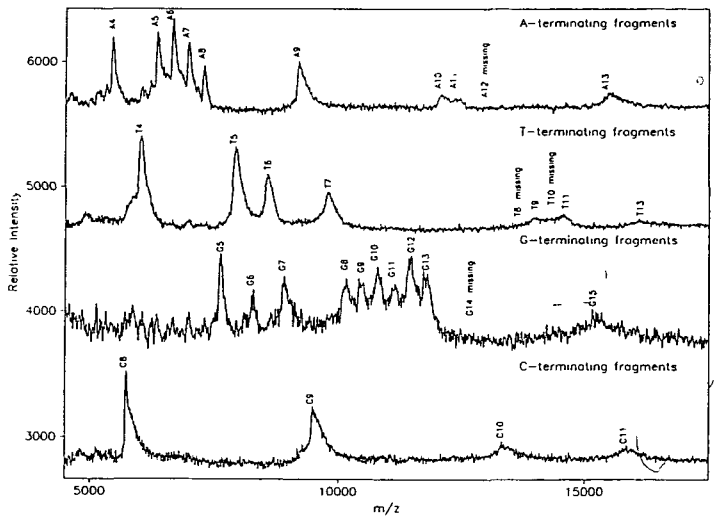

Table II Comparisons of initial energies of three different matrices at 266 and 355 nm

Anthranilic acid	
At 266 nm	At 355 nm
Average: ~1.9 eV ~ 1540 m/s	Average ~ 1.3 eV ~ 1370 m/s
Nicotinic acid and Anthranilic acid (1:1) mixture	
At 266 nm	At 355 nm
Average: ~ 1.3 eV ~ 1350 m/s	Average: ~ 0.7 eV ~ 970 m/s

MALDI of Drug Compounds from Intact Biological Tissue

*Christopher D. Reddick and Richard A. Yost
Department of Chemistry, University of Florida, Gainesville, FL 32611

Since its discovery in 1988 [1,2] matrix-assisted laser desorption ionization (MALDI) has played an increasingly important role in mass spectrometry. Most commonly, MALDI has been used to vaporize and ionize thermally labile and nonvolatile biomolecules, particularly peptides and proteins with masses between 1,000 and 50,000 Da. In our laboratory, we have investigated the potential of MALDI to detect smaller drug compounds (150 - 500 Da) from intact biological tissue. In this work, the MALDI process was optimized to enhance the production of analyte $(M+H)^+$ ions for the central nervous system (CNS) drug compounds, spiperone and ephedrine, in Matrigel model tissue. Experiments were also performed to evaluate the usefulness of MALDI for the detection of CNS drug compounds from actual biological tissue.

In all of the experiments performed, a Finnigan MAT™ Lasermat time-of-flight mass spectrometer was used. In the first optimization experiments, MALDI was performed on samples of spiperone and ephedrine in Matrigel using 2,5-dihydroxybenzoic acid (DHB) at analyte-to-DHB molar ratios of 1:100, 1:1,000, and 1:10,000 (*Figures 1 and 2*). For both compounds, increasing the concentration of the DHB matrix solution had the following effects: 1) ions from the Matrigel tissue were suppressed, 2) $(M+Na)^+$ and $(M+K)^+$ adduct ions were minimized, and 3) production of spiperone and ephedrine $(M+H)^+$ ions were improved. In the second set of optimization experiments, the effect of the MALDI matrix solvent polarity on the production of spiperone and ephedrine $(M+H)^+$ ions from Matrigel was investigated. The polarity of the matrix solvent was varied by using different mixtures of acetonitrile and water. Results of these experiments are shown in *Figures 3 and 4*. For both spiperone and ephedrine in Matrigel, production of the $(M+H)^+$ ion was improved by increasing the polarity of the MALDI matrix solvent. In the final optimization experiments with spiperone and ephedrine in Matrigel, the soak time of the MALDI matrix solution applied to the Matrigel samples was controlled by covering the Lasermat sample plate with a 2 mm thick Teflon disk. The disk was placed over the raised rim of the sample plate immediately after the MALDI matrix solution was applied, creating a miniature humidity chamber. Using this method, previously reported by Mock and co-workers (for MALDI of proteins adsorbed onto nitrocellulose membranes [3]), the matrix solution was prevented from crystallizing for intervals of 5-30 minutes From *Figure 5*, it can be seen that increasing the soak time from 1-10 minutes significantly increased the production of $(M+H)^+$ ions for both spiperone and ephedrine in Matrigel. At soak times beyond 15 minutes, no further increases were seen for either drug compound. These trends were attributed to the fact that at longer crystallization periods, the analyte was able to partition out of the Matrigel and into the MALDI matrix solution before it dried.

To evaluate the usefulness of MALDI for analytes in actual biological tissue, preliminary studies were performed with cerebral tissue from a male Spraige-Dawley rat. For analysis, thin slices of frozen cerebral tissue were incubated in a solution containing 100 ng of spiperone for 1 hr. MALDI was performed on the tissue samples by placing 1-2 µL of DHB matrix solution on top of the tissue *(Figure 6)*. These preliminary studies with rat cerebral tissue showed that MALDI was able to enhance the detection of spiperone from actual biological tissue.

The authors would like to thank Dr. Robert Perchalski for his helpful discussions pertaining to this work. Also, we would like to thank Dr. Robert Kennedy and the members of his research group for providing tissue samples for the final MALDI experiments. And finally, we would like to thank Bristol-Myers Squibb for their continued support and funding of this project.

Application of MADLI TOFMS for Quantitation

R.R. Hensel[1], R. King[2], K. G. Owens, Department of Chemistry, Drexel University, Philadelphia, PA 19104

The successful MALDI TOFMS experiment may be broken down into five distinct processes: ***sample preparation, application, desorption, ionization, and detection.*** This presentation focuses on the importance of the first two processes in obtaining quantitative results. We have found that electrospray application may greatly improve the reproducibility of the recorded MALDI mass spectra.

In MALDI TOFMS, analyte is mixed with an excess concentration of matrix in a suitable solvent. In the solution phase the mixture is homogeneous. However, when this sample is applied to the MS probe and air dried, analyte is incorporated into the matrix crystals to varying degrees and the sample may no longer be homogeneous. This is not surprising since crystallization is a simple means of purification. When sample is electrosprayed onto the MS probe, analyte and matrix seem to be much more evenly distributed.

The two methods of sample application may be compared in a number of ways: by measuring the peak height ratios of analyte to internal standard (IS) of a sample applied to a single probe tip; by measuring signal intensity as the laser sweeps across the sample; and by fluorescent microscopy.

Desamino-[8-D-arginine] vasopressin (DDAVP) and the structural analog, arginine vasopressin (AVP), suitable for use as an internal standard (IS), were selected for these experiments. 2,5-dihydroxybenzoic acid (DHB) was used as the matrix in all experiments because DDAVP and AVP were ***soluble*** in the solvent/DHB system used. Samples (10^{-11} to 10^{-13} moles loaded onto the MS probe) and matrix were dissolved in the same solvent. The solvent consisted of nine parts methanol and one part acetonitrile/water/0.1% TFA (30/70 v/v).

Electrospray was accomplished by introducing approximately 25 µL of sample into a small bore stainless steel capillary. A potential of approximately +5 KV was applied to the capillary while the MS sample probe tip was held at ground. A flow rate of 2-5 µL/min was applied by an infusion pump. Between 1 and 2 µL of any given sample was electrosprayed on a single MS probe tip.

Experiments were conducted to compare the within-tip reproducibility and the tip-to-tip reproducibility of air dried versus electrosprayed sample. Between 25 and 50 laser shots were accumulated per sample site for air dried samples (once analyte signal was detected). Between 50 and 100 laser shots were collected as the laser swept the sample for electrosprayed samples.

Comparison of Within Probe Tip Reproducibility

Method	% CV (n) of Analyte to IS Ratios
Air Dried	6.27 (3) 49.6 (3) 39.2 (5)
Electrosprayed	3.70 (4) 9.31 (5) 4.56 (4) 9.66 (4) 15.1 (4)

Air dried and electrosprayed samples were next scanned in ***chromatogram*** mode on a Shimadzu, Inc., Kratos Kompact MALDI 3 mass spectrometer. The signal intensity collected over the mass range of the protein sample of each laser shot was recorded. This resulted in a chromatogram of intensity versus laser position. The results show that air dried samples exhibit considerable area with no signal. Presumably this is an area devoid of analyte. Electrosprayed samples showed more consistent signal intensity across the entire sample, with no areas of zero signal intensity.

A fluorescent molecular weight marker, fluorescein isothiocyanate labeled -lactalbumin from Bovine milk, (14,200 Daltons, Sigma Chemical Co.) was added to matrix. Samples were air dried or electrosprayed. The images obtained at a magnification of 200x indicate that air drying creates large crystals of matrix which seem to contain variable amounts of fluorescently labeled protein. Discernible microcrystals are observed from the electrosprayed sample which shows fluorescence to be detected across the sample area.

It has been our observation that matrix/analyte solution components tend to partition during the solvent evaporation process. This component segregation yields an inhomogeneous sample surface, resulting in highly variable analyte ion production. Methods that increase the rate of solvent evaporation, such as the selection of volatile solvents and/or rapid evaporation under vacuum, reduce component segregation. The electrospray process is one sample application method which reduces the segregation occurring during solvent evaporation. The small droplets that are formed by this process improve the homogeneity of the sample surface. The presence of cation adducts demonstrates that solution components are less segregated when electrosprayed. This increase in sample homogeniety decreases the within and between probe tip variability, resulting in a decrease in %CV for the analytical results.The electrospray sample application process has resulted in a more objective analysis which will be easily automated.

The within tip reproducibility was approximately 15% or better. However, tip-to-tip reproducibility is of much greater importance in the overall development of a quantitative analytical method. The coefficient of variation was less than 17% for standards between 32 and 400 ng/50 µL (6.0 x 10^{-13} to 7.5 x 10^{-12} moles loaded).

The presence of salt adducts creates cationized interference especially when analyte and internal standard are close in mass. Experiments are in progress to overcome these challenges:

- selection of an IS with a greater mass difference
- use of more than one IS in the quantitative method
- use of ion exchanged matrix
- selection of matrix materials other than DHB
- mathematical deconvolution of overlapping peaks in the raw data

MALDI TOFMS has been used for the quantitative analysis of DDAVP, using AVP as internal standard, from human plasma after solid phase extraction. The range of quantitation (2.0 to 10 µg/mL) is of limited value for bioanalytical application. However, lower limits of quantitation have been demonstrated by the analysis of neat standards. The limitation with respect to bioanalytical application seems to be with the solid phase plasma extraction methods we have used to date and not necessarily the MALDI TOFMS process. Experiments are in progress to lower the limits of quantitation for analytes in human plasma and to demonstrate the application of quantitative MALDI TOFMS for higher mass analytes.

Analysis of Synthetic Polymers and Copolymers by MALDI-MS

Martin Schaer
Ciba-Geigy Ltd., CH-4002 Basle, Switzerland

The analysis of synthetic polymers is of high importance in industrial laboratories. This creates a demand for a fast and accurate problem solving system.
Matrix-assisted laser desorption/ionisation mass spectrometry (MALDI-MS) has become a powerful tool for the analysis of synthetic polymers and copolymers and is used on a routinely basis in the industrial lab.

Most polymers investigated in our laboratory have weight distributions < 10,000 Da. MALDI-MS was successfully applied to study the following problems:
- End group determination
- Absolute M_n- and M_w-values
- Oligomeric additives: Detection of different oligomeric series and improvement of product purity
- Copolymer analysis: Determination of composition with the aid of numerical simulations (Figures 1 and 2)

In spite of this success a problem often occurs: For the characterisation of polymers the molecular weight distributions M_n and M_w have to be determined. They are defined by:

$$M_n = \frac{\sum N_i M_i}{\sum N_i} \qquad M_w = \frac{\sum N_i M_i^2}{\sum N_i M_i}$$

It is often observed that these values obtained by MALDI-MS are significantly *lower* than Size Exclusion Chromatography (GPC)- or other conventional technique-values.

- M_n and M_w are in agreement for:
  - PEG
  - PPG
  - PMMA
  - PS

  with narrow size distributions.
- M_n and M_w are lower than GPC-values for:
  - Oligomeric additives
  - Polysiloxanes
  - Oligomer mixtures which have not narrow Poisson-like size distributions.

Several problems can lead to the GPC/MALDI-discrepancy:

- MALDI-MS:
  - Ionisation/desorption efficiency
  - Limited dynamic range
  - Detection
  - Resolution
  - Fragmentation?
- GPC:
  - Relative measurement dependent on external standards
  - Solvent
  - Detection

Nevertheless the amount and quality of information that is obtained by a MALDI-MS analysis is very high as can be seen in Figures 1 and 2.
M_n- and M_w-values hide this information. They are "chromatographic" values and should not be used for the representation of the results of a mass spectrometric analysis.

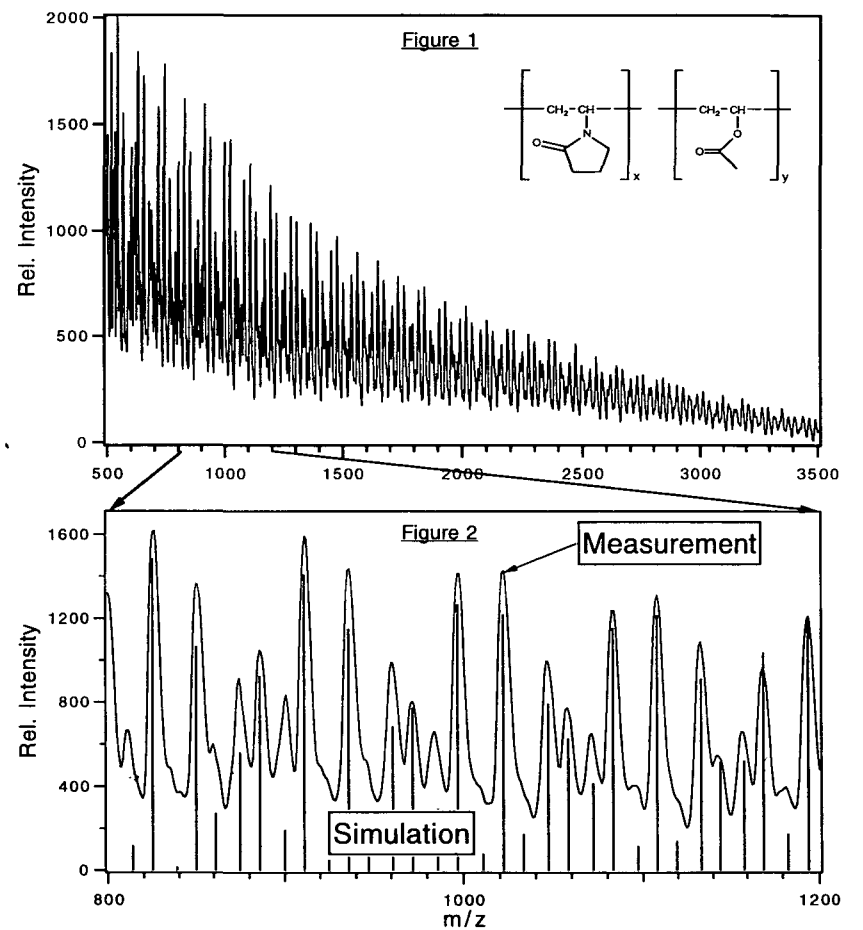

Figure 1: Positive ion mass spectrum of a copolymer consisting of N-vinylpyrrolidone and vinyl acetate.

Figure 2: The same mass spectrum in the range 800-1200 Da with a numerical simulation. A random sequence with x=0.2 and y=0.8 was assumed. Both, masses and ion signal intensities can be approximated with close agreement.

Characterization of Polyesters by Transesterification Using Matrix Assisted Laser Desorption Ionization Mass Spectrometry

John B. Williams, Arkady I. Gusev, and David M. Hercules
Department of Chemistry, University of Pittsburgh
Pittsburgh, Pennsylvania 15260

Introduction

Polyesters are a broad class of condensation polymers utilized in a variety of films, textiles, and, more recently, as thermoplastic molding material in the manufacture of blow molded containers. Knowledge of properties such as chemical structure, molecular weight distribution, and the presence of additives or impurities is crucial to the synthesis and performance of these materials. Matrix assisted laser desorption ionization time of flight mass spectrometry (MALDI-TOF-MS) has been applied to the analysis of many classes of synthetic and biological polymers. The method offers the advantages of generation of high mass ions (10^6 Da), high ion transmission through simultaneous monitoring of the entire mass range (multiplex advantage), ability to measure both mass and intensity, and production of spectra with limited fragmentation. These characteristics make MALDI-TOF-MS an ideal tool for analysis of synthetic polymers.

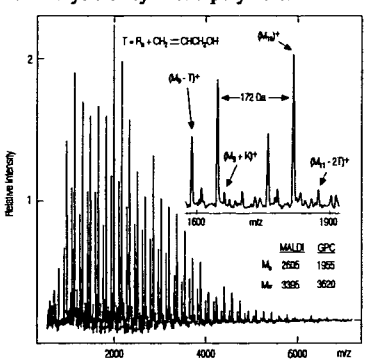

Figure 1. Oligomer distribution of poly(trimethylene glutarate) in IAA matrix.

The purpose of this research is to apply MALDI-TOF-MS to the characterization of polyesters. Molecular weight information can be obtained from the intensity and position of intact oligomers. Structural assessment is possible through evaluations of the position of oligomer and fragment peaks. Mechanisms of fragmentation may be investigated and compared to that seen in other mass spectrometric techniques. Tranesterification of these materials with trifluoroacetic acid (TFA) or chlorodifluoroacetic acid (CFA) will allow the acquisition of additional structural information from product oligomers and fragments as well as isotopic distribution. Transesterification also offers the potential for analysis of reaction products of intractable (insoluble, high molecular weight, or cross-linked) materials. Monitoring product formation with MALDI-TOF- MS should yield kinetic information on the transesterfication reaction.

Methods

The research was conducted on a LAMMA 1000 (Leybold-Heraeus Gmbh) modified with a Laser Science, Inc. nitrogen laser (VSL 337 ND). Matrices used are trans-3-indoleacrylic acid (IAA) and 2-cyano-5-phenyl-2,4-pentadienoic acid (CPPA). Mass calibration was achieved using poly(propylene glycol) (M_n = 440) as an internal standard.

Results

Figure 1 shows the oligomer distribution of poly(trimethylene glutarate) (PTG) in a crystalline IAA matrix. Intact sodium and potassium cationized oligomers, and corresponding sodium cationized fragments resulting from cleavage of the C-O bond are observed. Previous studies of fragmentation mechanisms using SIMS have suggested that C-O may be favored over C-C fracture.(1) This cleavage is accompanied by the transfer of hydrogen to form the acid terminated oligomers observed as fragments. Hydrogen migration has been shown by electron ionization mass spectrometric studies to occur by β-CH transfer (McLafferty rearrangement).(2) This mechanism may be responsible for the appearance of mono-, and sometimes di-, carboxylic acid fragments in the spectra of most compounds studied. Nuclear magnetic resonance (NMR) analysis of these materials indicated an absence of acid terminated impurities.

Transesterification results in formation diesters and diols of the reactant and TFA with a decrease in the molecular weight values of the material. Cleavage at the C-O bond also occurs in these products with fragments appearing at much higher intensity than corresponding product oligomers. Figure 2 allows observation of increase in intensity of a product fragment relative to the poly(butylene adipate) (PBA) oligomer in the 1400 to 2000 Da mass range from 15 minutes to 5 hours during transesterification with TFA. In addition to the possibility of obtaining kinetic data, the reaction also yields additional structural information for compounds, such as PBA, where fragmentation is not observed.

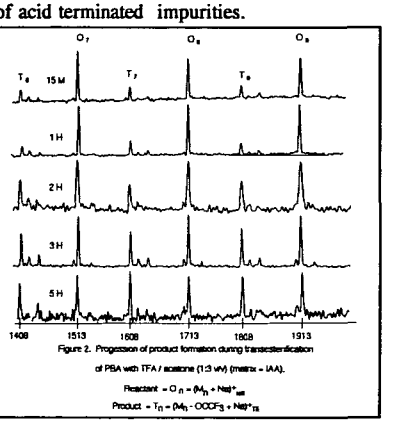

Figure 2. Progression of product formation during transesterification of PBA with TFA / acetone (1:3 v/v) (matrix = IAA).

Conclusions

MALDI spectra are useful for the determination of structure and molecular weight values for the seven experimental polyesters. Limited fragmentation, not observed in the MALDI analysis of many other polymer classes, occurs at the ester bond and is always accompanied by the transfer of a hydrogen to yield an acid terminated ion. Tranesterification of polyesters with TFA or CFA produces diesters that are readily identified as oligomers or fragments in MALDI spectra. These peaks, along with isotopic distribution pattern seen with CFA, yield additional structural information from the polyester. MALDI spectra can be used to monitor the growth of products in a reaction mixture. This ability encourages the implementation of more stringent controls to determine the feasibility of acquisition of quantitative kinetic information. The observed fragmentation of polyesters and derivatives arises from fracture of C-O bonds at unknown points in the polymer backbone. Experiments are being devised to determine if this cleavage is random or occurs at specific sites along the chain.

Accuracy of MALDI for Molecular Weight Characterisation of Synthetic Polymers

M. Koerner and R. Gerhards, Th. Goldschmidt AG, ZBF/Analytisches Labor, D-45127 Essen, Germany.
A. Keane, C. W. Sutton, and J. S. Cottrell, Finnigan MAT Ltd., Hemel Hempstead, Herts HP2 4TG, UK

Introduction: There is considerable interest in the use of mass spectrometry as an alternative to gel permeation chromatography (GPC) for the characterisation of synthetic polymers. The principal advantages of mass spectrometry for this application are speed of analysis, mass resolution, and the ability to measure accurate mass values. Using MALDI, the average molecular weight of a distribution can be measured without resolving individual oligomers. However, by resolving the distribution, not only is mass accuracy improved, but other characteristics such as the nature of the end group or groups can be determined. Using a reflectron instrument, such as the Vision 2000, mass measurement errors for individual, well resolved peaks of a few thousand daltons will generally be less than 200 ppm. However, the accuracy of the molecular weight of a distribution also depends on the accuracy with which the relative intensities of the peaks can be measured. This poster discusses the sources of error, both random and systematic, which affect such measurements.

Ionisation & Detection Efficiency: There are indications that systematic variations in ionisation efficiency across a distribution are relatively small, at least over a limited mass range. Good correlations have been obtained between GPC and MALDI data for samples with polydispersity values close to 1 by a number of groups [1; 2; 3]. However, there are also results which show discrepancies between GPC and MALDI data, particularly for polymers with large polydispersities [4; 5]. It is not clear to what extent this is attributable to variation in ionisation or detection efficiency with mass. Uniform detection efficiency across a wide mass range is largely a matter of having an adequate impact energy [6]. Since detector response should be largely independent of the chemical nature of the polymer, a detector response curve could be measured using standard mixtures and subsequently used to correct data from unknowns.

Peak Height or Peak Area?: Some investigators have taken mole fraction as corresponding to the intensity of a peak [4]. This may be a valid assumption if the time constant of the detector system is much longer than the true peak width. In general, the area under the peak would be expected to provide better precision. And, if individual oligomer peaks are not fully resolved, then molecular weights must be calculated by integrating across the entire distribution. To establish that mole fraction is indeed proportional to peak area, a series of mixtures of two polyethylene glycol standards were analysed. Aliquots of PEG1500 and PEG4600 solutions, which have negligible mass overlap, were mixed by volume in the ratios 3:1, 2:1, 1:1, 1:2, and 1:3. Graphs of peak area ratio versus composition yielded straight lines for both reflectron and linear mode, indicating that the proportionality between peak area and mole fraction holds, although the scatter on the measurements was quite large.

Sample Inhomogeneity: The variation in relative peak areas mentioned above can only be due to inhomogeneity in the deposit of matrix and sample. This is potentially a source of random errors, which will affect extended distributions most severely. If the sample is truly incorporated into the crystal lattice of the matrix , then it might be expected that some kind of sieving due to size exclusion processes would occur during crystallisation. The use of liquid matrices should avoid this problem [1] [7], but could

introduce artefacts due to variation in surface activity, (c.f. FAB). Clearly, more work is required to develop sample preparation methods which improve sample homogeneity. Possibly, the sample and matrix could be "frozen" into some kind of glassy solid solution, or electrosprayed onto the target so as to ensure rapid and uniform crystallisation.

Where's the Baseline?: One of the practical difficulties of integrating MALDI spectra of polymer distributions is knowing where to draw a representative baseline. Spectra of a series of polymethylmethacrylate (PMMA) standards illustrate this problem. A series of these standards was analysed using DHB matrix on a Vision 2000. The results are summarised below, together with data from GPC. Nevertheless, the agreement between the GPC and MALDI data is excellent, particularly above 10 kDa.

High Resolution MALDI Studies of Copolymers

David C. Schriemer, and Liang Li*
Department of Chemistry, University of Alberta
Edmonton, Alberta, Canada
T6G 2G2

Matrix assisted laser desorption ionization (MALDI) is finding increasing application in the area of polymer analysis. Success has been demonstrated in the determination of molecular weights and end-group analysis [1]. Polymers are arguably more difficult to analyze by MALDI than are biopolymers, due largely to their very diverse composition and chemistry.

Copolymer analysis by MALDI represents one of the more challenging applications. Proper matrix selection appears to be one of the most important parameters. In addition to commonly used matrices such as 2,5-dihydroxybenzoic acid and t-3-indoleacrylic acid, the following three matrices show promising general utility for a range of polymers:

1) 2-(4-hydroxyphenylazo)benzoic acid (HABA) [2]
   -for ether/hydroxyl containing polymers, allowing for alkali cationization

2) t,t-1,3-diphenylbutadiene (DPB) [3]
   -for unsaturated polymers, allowing for silver cationization

3) retinoic acid (all trans) [4]
   -useful for a wide range of polymer types, allowing for both alkali and silver cationization.

The MALDI experiments were carried out in a linear time-of-flight instrument, operated in time-lag focusing mode. This mode allows for routine achievement of an M/ΔM up to 3000, for lower molecular weight polymers. Two classes of copolymers were analyzed: alternating and block. Figure 1 displays the spectrum of the alternating copolymer poly[(o-cresyl glycidyl ether)-co-formaldehyde]. The spectrum was obtained from DPB in acetone with $AgNO_3$, and clearly demonstrates the mass of the repeat unit (176 amu). The secondary distribution arises from polymer with the loss of one epoxide. This is in keeping with the manufacturer's quote of 90% epoxide content.

Figure 2 contains an expansion of the spectrum of a block copolymer, poly(propylene glycol-b-ethylene glycol-b-propylene glycol)bis(2-aminopropyl ether). This spectrum was obtained from HABA in 1,4-dioxane doped with NaCl. This type of polymer places much greater demands on the resolution of the instrument, as any given number of the one monomer can have a distribution of the other, leading to overlap. In this mass range however, even isotope discrimination can be achieved, facilitating copolymer characterization.

Analysis of GPC Standards by Matrix-Assisted Laser Desorption/Ionization

Scott D. Hanton, David M. Parees and Brian F. Hanley,
Air Products and Chemicals, Inc., Allentown, PA 18195
Richard C. King and Kevin G. Owens,
Department of Chemistry, Drexel University, Philadelphia, PA 19104

The application of matrix-assisted laser desorption/ionization (MALD/I) time-of-flight mass spectrometry (TOFMS) to analyze synthetic polymers can provide important chemical structure and molecular weight information, including the number average molecular weight (M_n), the weight average molecular weight (M_w), and the polydispersity (PD). Molecular weight directly influences many polymer physical properties: tensile strength, elongation, brittleness, abrasion resistance, chemical resistance, viscosity, adhesion, and solubility.[1] We investigated a range of polymers: polystyrene (PS), polyethylene glycol (PEG), polymethylmethacrylate (PMMA), and polydimethylsiloxane (PDMS). The goal of this work is to investigate the accuracy of molecular weight values obtained by MALD/I in comparison with classical methods (osmometry and light scattering) and gel permeation chromatography (GPC).

A significant advantage of MALD/I TOFMS is the direct measurement of the sample mass. TOFMS measures ion flight times, and these flight times can be calibrated to ion mass independent of analyte chemistry. To calibrate the TOFMS for these higher molecular weight polymer materials, we generated individual mass calibrations for each polymer from spectra with resolved oligomers. Each of these individual mass calibrations were very similar. We applied an average of the four individual results as our instrument mass calibration.

In three cases (PS, PMMA and PEG), the manufacturers' specified molecular weights agreed well with the MALD/I results. We plot the measured MALD/I molecular weight versus the manufacturer's specified molecular weight. Figure 1 shows the relationship for PS. Ideally, the line relating the MALD/I molecular weight to the manufacturer's specified molecular weight should have a slope of 1.00 and an intercept of 0.0. For PS we obtain a slope of 0.907 and a intercept of 763.

MALD/I MW vs Specified MW
Polystyrene

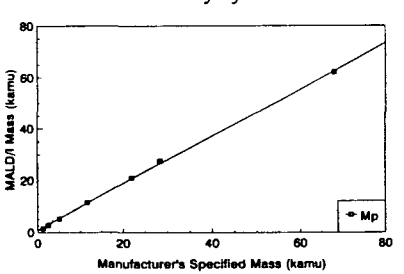

Figure 1

The PDMS MALD/I molecular weights appear to be approximately half of the manufacturer's specified molecular weights. In the plot of MALD/I molecular weight versus the manufacturer's specified molecular weight, we obtain a slope of 0.533 and an intercept of -286. Previous reports have indicated the ratio to be closer to one third.[2] In our MALD/I experiment, we employed a combination matrix consisting of 5-fluorosalicylic acid and an underlayer of trans-3-indoleacrylic acid. The use of the cooling underlayer is responsible for the larger (relative to the previous report) measured MALD/I molecular weights, which are in better agreement with NMR results.[2]

While most of the PMMA data show good agreement between the MALD/I, GPC and manufacturers' specified molecular weights, it appears that PMMA 9600 is considerably lower in mass than the specified value. Figure 2 shows a MALD/I mass spectrum of a mixture of PMMA 6300 and PMMA 9600. The two materials have very similar average molecular weights. We also observe longer GPC elution times than expected for PMMA 9600. While a lower MALD/I molecular weight has been previously reported for PMMA 9600,[3] it appears that the discrepancy may be due to a different end group, that may chemically affect the classical molecular weight measurements.

Structural Determination of Azo Dyes by Photoionisation Mass Spectrometry

Scott J. Wright, Michael J. Dale, Anita C. Jones and Patrick R. R. Langridge-Smith.
Department of Chemistry, The University of Edinburgh, King's Buildings, West Mains Road, Edinburgh, EH9 3JJ, UK.

Azo dyes are used extensively in industry as colourants for textiles, paper, leather and foodstuffs. The health hazards posed by their potential carcinogenicty mean that they are of significant environmental interest. Azo dyes have previously eluded routine mass spectrometric characterisation as a result of their thermal lability. Solid phase desorption/ionisation techniques, such as FAB and SIMS first enabled the analysis of such involatile species. However, fragmentation is difficult to control resulting in little or no molecular ion signal. Conversely, techniques such as thermospray ionisation generate essentially molecular weight information.

Laser desorption laser photoionisation time-of-flight mass spectrometry, L^2TOFMS, has been shown to be effective in the study of a wide range of thermally labile and involatile molecular species. This is due to separation of the desorption and ionisation events. An infra-red laser is used to desorb intact neutral species into the gas phase, which are then ionised by a UV laser and analysed in a reflectron time-of-flight mass spectrometer.

A series of azo dyes have been examined using two fixed ionisation wavelengths, 193 nm and 266 nm. A number of striking differences have been observed in the resulting mass spectra (see Figure 1).

Ionisation using 193 nm radiation generates predominantly molecular weight information via hydrogen and alkali metal adduct ions. The principal fragment ions observed correspond to cleavage of the C—N bonds adjacent to the azo functionality. Complementary structural information is obtained using 266 nm ionisation, where fragment ions corresponding to photolytic cleavage of the azo linkage dominate the mass spectra. This may be linked to trans-cis photoisomerism, in that both processes are thought to proceed via the same one photon excited intermediate state [1]. The results presented demonstrate that, using two ionisation wavelengths, it is possible to generate *both* molecular weight information *and* unambiguously determine the presence of an azo functionality.

It has also proved possible to differentiate between isomeric azo dyes. Two azo dyes, 4-[2-(amino) 4-(hydroxy) phenylazo] benzoic acid **(AHP)** and 3-[2-(hydroxy) 5-(amino)

phenylazo] benzoic acid **(HAP)**, have been investigated using 266 nm laser photoionisation. For **AHP**, the anticipated azo cleavage is observed. However, for **HAP** where the hydroxy group is ortho to the azo linkage, no azo cleavage products are detected. It is proposed that trans-cis isomerisation, and hence azo cleavage, is precluded by azo-hydrazone tautomerism. The resulting change in photochemistry allows for direct mass spectral differentiation between the two isomers using L^2TOFMS.

It has been further shown that the position of the carboxylic acid group, relative to the azo linkage, in isomers of methyl red can control the charge retaining fragment resulting from photolytic cleavage of the azo bond.

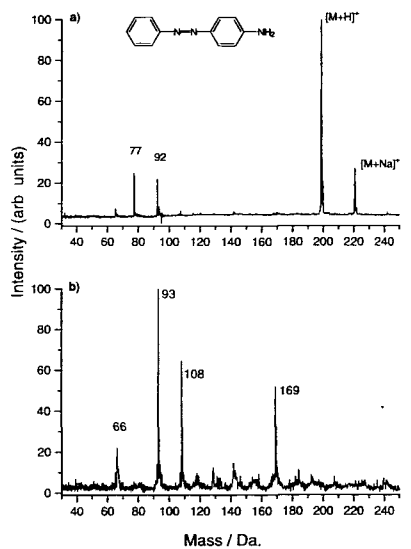

Figure 1: L^2TOF mass spectra of 4-phenylazoaniline using a) 193 nm and b) 266 nm ionising radiation.

TWO STEP LASER MASS SPECTROMETRY OF COPOLYMERISED INDOLE DERIVATIVES

J.Gordon Mackintosh, Scott J.Wright, Craig R.Redpath, Michael J.Dale, Andrew R.Mount and Patrick R.R.Langridge-Smith
Department of Chemistry, The University of Edinburgh, West Mains Road, Edinburgh, Scotland, United Kingdom. EH9 3JJ.

Over the last fifteen years there has been considerable interest in the electropolymerisation of heterocyclic molecules such as pyrroles and indoles to form electronically conducting polymers for a wealth of potential applications However the structural characterisation of these layers is made difficult by the fact they are generally insoluble and intractible The incorporation of solubilising functional groups into conducting polymers by the use of 5-substituted indole monomers, Figure 1, has been investigated.

Laser desorption laser photoionisation mass spectrometry (L2MS) has been used to investigate the products formed by the electropolymerisation of such substituted indoles[1,2] For each polymer studied to date, L2MS has revealed the presence of a trimeric species Further studies have shown that this trimeric species can be separated from other oligomers in the layer by differential solubility. The structure of species, Figure 2, has been elucidated using NMR spectroscopy[3] Electrochemical studies[4] have revealed that these trimer units, link together, to form polymer of linked trimer units.

Fig 1 where R=CN,COOH

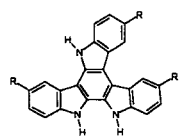

Fig 2 where R=CN or COOH

The copolymerisation of two different indole monomers would result in mixed functional trimers. If these trimers could be separated, polymers with mixed functional properties could be assembled from selected trimer units L2MS has been used to investigate the products of copolymerisation between an equimolar mixture of 5-cyanoindole (5CI) with indole-5-carboxylic acid (I5CA) It has also been used as a technique for monitoring the separation of these products

The polymer was grown on a platinum rotating disc electrode, and subsequently dissolved in dimethylformamide This solution was then cast onto a stainless steel rod and the solvent evaporated. An infrared laser was used to volatilise the neutral molecules, which were subsequently ionised using multiphoton ionisation and mass analysed using a reflectron time-of-flight mass spectrometer.

L2MS, Figure 3, reveals the presence of parent ions for 5CI and I5CA trimers, and also for two trimers of mixed functionality. This result confirms copolymerisation has taken place Extraction and separation of these four trimers was carried out by column chromatography This resulted in four fractions, the spectra of which are shown in Figures 4 to 7 Partial separation of the mixture is achieved. Fraction 1 shows mainly cyano trimer whilst fraction 4 shows mainly carboxy. Fractions 2 and 3 show a mixture although the relative proportion of each species does change These results were quantified by the spectrum shown in Figure 8, which results from an equimolar mixture of individually polymerised cyano trimer and carboxy trimer. Since, the trimers have similar ionisation efficiencies the relative abundance of each species can be estimated in the separated fractions It is clear from our work that L2MS is an invaluable tool for determining the structure of the products formed in this type of copolymerisation

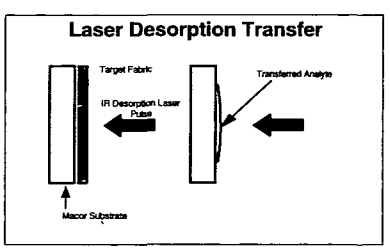
Molecular Analysis From Organic Substrates Using Laser Desorption Mass Spectrometry

Michael J. Dale, Patrick R. R. Langridge-Smith, Qiao Zhan* and Renato Zenobi*
Department of Chemistry, The University of Edinburgh, King's Buildings, West Mains Road, Edinburgh, EH9 3JJ, UK
*Laboratorium für Analytische Chemie, Universitätstr. 16, ETH Zentrum, CHN C59, CH-8092 Zürich, Switzerland

The analysis of dyes and pigments on textiles is a major industrial imperative. Such materials are often resistant to removal from their organic substrates making conventional mass spectrometry difficult. The purpose of the present study was to determine the feasibility of using laser desorption laser photoionisation mass spectrometry (L2MS) for the direct analysis of molecular adsorbates on a variety of textiles.

Infrared laser desorption is used to volatilise neutral molecules. These are then postionised using multiphoton ionisation (MPI) and mass analysed using a reflectron time-of-flight mass spectrometer. The principal advantage of the technique lies in the spatial and temporal separation of the desorption and ionisation processes. This methodology has enabled us to generate readily interpretable mass spectra of a variety of model systems, such as porphyrin pigments, azo and phthalocyanine dyestuffs, directly from their host substrates [1]. However, the analysis of "real" systems using this approach, e.g. dyes or stains on fabrics, has been restricted by insufficient detection sensitivities.

The timescale and yield of the desorption process for complex samples such as fabrics may be different to those observed when desorbing from a dielectric or metal substrate. For example, desorption may take place over an extended timescale. The 10 ns ionisation laser pulse would then sample only a fraction of the desorbed material. For these systems we have employed a different approach involving laser desorption transfer. This is a rapid and effective method of depositing and accumulating intact dyestuffs from organic substrates onto a substrate suitable for L2MS, such as MACOR.



43rd ASMS Conference on Mass Spectrometry and Allied Topics

The spectra below show the L2MS mass spectra obtained on analysis of polyester dyed with Disperse Blue 1 using (a) direct L2MS and (b) laser desorption transfer followed by L2MS. It can readily be seen that the use of laser desorption transfer confers a substantial signal enhancement. The selectivity inherent in MPI also means that the spectra are relatively free from background signals from the ablated polyester. From this preliminary study it is apparent that laser desorption transfer coupled with L2MS is a rapid and effective method of determining analytes on organic substrates.

WAVELENGTH DEPENDENT PHOTOIONIZATION OF SOME AMINES AT METAL SURFACES

Robert Goldschmidt* and Kevin G. Owens, Department of Chemistry, Drexel University, Philadelphia, PA 19104

In the course of doing some laser desorption experiments, we observed ion signal for aniline at both 337 nm and 351 nm when the laser beam was directed onto a metal surface. This was unexpected since aniline's ionization potential is 7.7 eV while two photons of 337 nm light equals 7.36 eV and two photons of 351 nm light equals 7.06 eV. We observe signal only when the beam is incident on a metal surface; when the beam is allowed to pass through the instrument without hitting any metal surface we observe no signal. The signal has an easily observable laser repetition rate dependence which also indicates that this is a surface influenced ionization and not a gas phase multiphoton ionization.[1]

The photoionization behavior of molecules near or adsorbed to surfaces may differ from their behavior in gas or bulk phases.[2] For example, the surface interaction may lead to a perturbation of the allowed states of an adsorbate or of a molecule close to the surface and so to differences in the electronic absorption spectrum.[3] The substrate-adsorbate interaction may also lead to charge transfer between the substrate and adsorbate. Also, the interaction of the photon field with the substrate may influence ionization through processes such as photoemission and second harmonic generation, as well as through thermal effects.

We tested various compounds, introduced as vapors into the mass spectrometer, with the 337 nm beam incident on a stainless steel surface. Only amines are observed to give ion signal at 337 nm; aromatic amines give the molecular ion with little or no fragmentation, while aliphatic amines give the protonated molecular ion with fragmentation that increases with the laser intensity. Similar results were observed for compounds tested using 351 nm and a stainless steel surface. To better characterize the nature of this ionization, we are investigating the wavelength dependence of the ion signal in more detail.

Scanning experiments have been performed with aniline and toluene over the range 277.5 nm to 292.5 nm using a stainless steel surface. Spectra were acquired at laser energies between 3 and 40 μJ, or approximately 5×10^5 to 7×10^6 W/cm^2. Under these conditions both the aniline and toluene signal show a laser repetition rate dependence and no ions are observed if the metal surface is removed. There is no observable wavelength dependence of the aniline molecular ion signal in this range, though the fragment peaks do show a wavelength dependence. Toluene gives signal past where might be expected from its UV-visible absorbance spectrum, though it is likely close to its long wavelength threshold at 290 nm. The results are consistent with ionization by

absorption of two photons if one allows for electronic perturbation and thermal effects.[4]

Results at 337 nm and 351 nm show an influence of the metal substrate on the ion signal. The laser intensity threshold for aniline when using a stainless steel surface is about ten times higher than at the shorter wavelength experiments described above. With a copper surface, the signal level from aniline and other amines is noticeably reduced when 351 nm is used instead of 337 nm; no such reduction is observed with a stainless steel surface. With a silver surface, only small signal is observed even at 337 nm.

Laser energy dependence experiments were performed for aniline at 290 nm and at 337 nm, and for tripentylamine at 337 nm. The data was tested against three models: a linear, one photon ionization model (signal level vs. laser energy); a multiphoton ionization model (log signal vs. log laser intensity); and a thermally activated model (log signal vs inverse laser intensity). Statistical analysis does not lead to rejection of any of the models, though the linear model appears to be a poor fit in all cases except for the 290 nm aniline molecular ion. For aniline at 290 nm the multiphoton model gives a slope of 1.50 with a standard deviation of 0.19 for the molecular ion, a slope of 3.10 with a standard deviation of 0.22 for the mass 54 fragment, and a slope of 2.91 with a standard deviation of 0.29 for the mass 28 fragment. This suggests a two photon ionization of aniline and absorption of an additional photon to produce the fragments. For aniline at 337 nm the multiphoton model gives a slope of 6.39 with a standard deviation of 0.41 for the molecular ion, which is the only ion observed. A six photon absorption by aniline seems unlikely here, and the thermally activated model is more in agreement with the substrate effect described above. Thus aniline exhibits different ionization mechanisms at 290 nm and at 337 nm. For tripentylamine at 337 nm the multiphoton model gives a slope of 2.79 with a standard deviation of 0.16 for the protonated molecular ion. Absorption of 337 nm photons by tripentylamine would be surprising, and the substrate effect described above makes the thermally activated model more appealing.

Enhanced Detection Limits for High Molecular Weight PAHs Using Direct LD-TOF MS

B. Soloveytchik, J.H. Miller, A. Vertes
Department of Chemistry, George Washington University, Washington, D.C. 20052

Materials like shale oil, coal liquid, petroleum, asphalt, fly ash, soot, and engine-derived particulates contain high levels of carcinogenic PAHs. These products, formed during combustion are generally identified by one or more of the following techniques: GC, HPLC, supercritical fluid extraction [1], thermal desorption GC-MS [2], or laser mass spectrometry with postionization [3]. The method outlined here –direct laser desorption time-of-flight mass spectrometry (LD-TOF MS)– has several advantages: minimum sample preparation, low detection limits, and simple instrumentation.

GC-MS maintains good reproducibility and sensitivity for the lower molecular weight PAHs whereas its detection limit increases with decreasing volatility and increasing analyte molecular mass. Another problem related to the application of GC-MS and HPLC is the dependence of analyte response on the matrix. Traditional MS detection methods show better sensitivity than GC and a response free from matrix effects.

Here we describe the direct LD-TOF MS measurement of PAH standards and soot extracts. Our 2 m time-of-flight mass spectrometer (TOF-101, Comstock Inc.) was equipped with a laser desorption ion source and dual channel plate detector. An excimer laser (LEXTRA 50, Lambda Physik GmbH) operating at 308 nm was used to pump the dye laser (LPD 3000, Lambda Physik GmbH). The selected Coumarin 540A dye (Exciton Co.) emitted in the 513-588 nm range. Frequency doubling was used to generate the tunable UV radiation. Spectra were captured by a transient recorder (TR8828D, LeCroy) and down-loaded to a PC for processing. Toluene based standard solutions were prepared in the concentration range 100 ppm to 1 ppt. The following PAHs were investigated: 2,6-dimethyl phenol, naphthalene, biphenyl, fluorene, phenanthrene, dibenzothiophene, anthracene, fluorantene, pyrene, perylene, benz[a]anthracene, and dibenz[a,h]anthracene. Four soot samples were collected from automobile exhaust systems. 3-4 mg portions of the samples were extracted for 24 hours with 100 ml of n-pentane in a Soxhlet apparatus. 10 μl aliquots of the obtained extracts were analyzed without any additional processing.

The efficiency of the laser desorption and the sensitivity of the method depended on a number of parameters, such as molecular weight, volatility, and molar absorptivity of the analytes and irradiance and wavelength of the laser. The optimum ionization conditions were found to be at λ=280 nm excitation, thus all measurements were performed at that wavelength. Other critical parameters were explored by choosing PAHs with different molecular weights and melting points. The melting point correlated with the molecular mass and could be viewed as a quantitative measure of volatility (phenanthrene: 178.2 amu, Mp=100°C; pyrene: 202.3 amu, Mp=150°C; benz[a]anthracene: 228.3 amu, Mp=160°C; dibenz[a,h]anthracene: 278.4 amu, Mp=266°C). The dependence of the detection limit on the molecular mass of analytes for GC-MS and LD-TOF MS is compared in Figure 1. The increase of molecular weight resulted in a decrease of the detection limit for direct LD-TOF MS, whereas the trend was just the opposite for GC-MS. The lowest detected concentration for LD-TOF MS, 0.01 ppb, was observed for the higher molecular weight PAHs, i.e., perylene and dibenz[a,h]anthracene (see Figure 2).

Figure 3 shows the spectrum of a soot extract. The peaks in the 200-300 amu area belong to PAHs, namely m/z 228 to pyrene and/or crysene, m/z 252 to benzo[a]pyrene, m/z 276 to dibenzanthracene, and m/z 300 to coronene. For identification of structural and quantitative information —very important aspects for environmental analysis— additional techniques can be used. The lack of structural information is a major disadvantage of the direct LD-TOF MS. Fragmentation induced by even shorter wavelength may provide the solution to this problem.

A significant drawback of the commonly used GC-MS is that it gives poor response in the case of larger nonvolatile and more carcinogenic PAHs. In contrast, direct LD-TOF MS demonstrates increasing sensitivity and reproducibility for higher molecular weight condensed aromatic systems. Another important advantage of the used method is the fact that no preliminary sample processing is necessary unlike in the case of chromatographic analysis. The simplicity of sample preparation and the short time of analysis make direct LD-TOF attractive for further development for the analysis of PAH mixtures.

REAL-TIME MONITORING OF AEROSOL REACTIONS

P.G. Carson, M.V. Johnston, Department of Chemistry and Biochemistry
A.S. Wexler, Department of Mechanical Engineering
University of Delaware Newark DE 19716

Rapid Single-Particle Mass Spectrometry has been used to monitor the reaction of ammonia and nitric acid vapor on sodium chloride aerosol particles. The reaction produces an ammonium nitrate surface layer. Sodium chloride particles (3.5μm dia.) were generated with a vibrating orifice aerosol generator and passed through a reaction chamber having constant partial pressure of nitric acid and ammonia. A portion of the particles leaving the reaction chamber were sampled directly into the mass spectrometer through a differentially pumped inlet. A particle beam was formed which then intercepted a continuous laser beam. The scattered radiation from each particle triggered an excimer laser which ablated the particle in flight. Ions produced by laser desorption/ionization were analyzed by time-of-flight mass spectrometry

In these experiments ammonia was the limiting reagent and its partial pressure determined the coating thickness. For a constant laser irradiance, increasing the partial pressure of ammonia caused a proportional increase in the ion signal intensities associated with the ammonium nitrate layer (O^-, OH^-, NO_2^- and NO_3^-). At the same time, the signal intensities of the ions associated with the sodium chloride core decreased (Cl^-, NaCl, $(NaCl)Cl^-$) Laser irradiance dependencies were used to probe the different layers of the coated particles A low laser irradiance preferentially formed ions from the ammonium nitrate surface layer while higher irradiances ablated a greater fraction of the particle and yielded a higher number of ions from the sodium chloride core.

To characterize the coating thickness, we plotted the signal intensity ratio of ions from the surface layer divided by the ions from the core as a function of the laser pulse energy (Figure 1). With a low laser pulse energy (0.2mJ), the spectra obtained from particles exposed to different partial pressures were indistinguishable within the experimental error. This result suggests that only the outer 50 nm of the particle is efficiently sampled by laser desorption/ionization. With pulse energies above 0.5mJ, a greater fraction of the particle is sampled and we can gain semi-quantitative information about the coating thickness from the NO_2^-/Cl^- signal intensity ratio. Figure 1 shows that this ratio increases with increasing coating thickness.

To accurately determine the average thickness of the ammonium nitrate coating, we collected the transformed particles on a teflon filter, removed them from the filter by dissolution in a phthalic acid solution and then determined the chloride to nitrate ratio by HPLC. Figure 2 results showed that the average coating thickness varied between 50 nm and 500 nm depending upon the ammonia partial pressure.

INTRODUCTION

The knowledge of polymer structure is important for understanding the chemical and physical properties of industrial polymers that are often manipulated via structural modifications. To analyze polymer structure by mass spectrometry, it is necessary to generate oligomer ions that are large enough to contain structural information by soft ionization techniques, such as laser desorption ionization (LDI). Using tandem mass spectrometry (MS/MS) and high resolution mass spectrometry (HRMS), one is able to obtain detailed chemical structures of homo- and co-polymers. For a copolymer, the relative abundance of oligomer ions provides useful information about its microstructure.

EXPERIMENTAL

Mass spectral data were collected by using an Extrel FTMS 2001 Fourier transform mass spectrometer equipped with a carbon dioxide laser (10.6 μm) probe. Two industrial polymers, poly(α-hydroxy acrylic acid sodium salt) (PHAS) and an ethylene oxide/propylene oxide (EO/PO) copolymer (Pluracol), were studied. PHAS was obtained from Nippon Peroxide Co. with an average molecular weight of 600 Daltons, as determined by gel permeation chromatography (GPC). Pluracol is a commercial product from BASF with an average molecular weight of 4000 Dalton (as determined by GPC). The EO/PO ratio of the polymer is 1.42 by NMR. PHAS was acidified by using HCl to pH≈3 prior to LDI/FTMS analysis. At the original pH, the sample showed no response to LDI. Pluracol was ionized directly by LDI without any matrix assistance.

RESULTS AND DISCUSSIONS

Structures of acidified PHAS by MS/MS and HRMS: Figure 1 shows the oligomer distribution of the acidified PHAS in negative ion mode. Direct examination of the spectrum reveals that there are at least three series of oligomers with a repeating mass of 70 amu, which appears to be consistent with CH_2=CH(COOH). The structure, however, was not confirmed by other analytical data. By using HRMS, we were able to determine that the elemental composition of one oligomer anion (m/z 261) to be $C_9H_9O_9$. Considering that no double bonds are present in the molecules (NMR), we can draw a lactone structure for the oligomer as shown in Figure 1. MS/MS further confirmed the lactone structure by examining a daughter ion spectrum of the oligomer. The combination of HRMS and MS/MS suggests that the acidified PHAS contains mostly polylactones. The repeating mass is 140 amu rather than 70 amu as suggested by the appearance of its mass distribution.

EO/PO copolymer microstructure by a Bernoullian model: The LDI mass spectrum of Pluracol shows oligomers with molecular weight much lower than that measured by GPC, suggesting that the observed species are either the low molecular weight oligomers or the thermal decomposition products of larger oligomers. A detailed examination of the mass spectral data using a multiple sorting procedure revealed the presence of two major oligomer series with molecular weight consistent with general formula (a) and (b).

CH_2=$CHCH_2$-(-OC_2H_4-)$_m$-(-OC_3H_6-)$_n$-OH (a) CH_2=$CHCH_2$-(-OC_2H_4-)$_m$-(-OC_3H_6-)$_n$-OCH_2COCH_3 (b)

The normalized oligomer intensities are compared with statistical calculation using a Bernoullian (random) model (Figure 2 (a)) under the assumptions that (a) the MS responses are uniform for all oligomer ions, (b) the distribution of EO and PO units are random and (c) the polymer dissociation is non-selective. The calculation matches with the experimental observation relatively well for the 11 and 12 mers but poorly for the 4 and 5 mers. To improve the fits for the small oligomers, a lower EO/PO ratio has to be assumed. Figure 2(b) shows that larger oligomers (N>9) have an EO/PO ratio close to the bulk ratio (1.42), implying that the copolymer indeed has a random distribution. The deviation increases as the oligomer size decreases suggesting that the EO/PO oligomer observed by LDI are from selective dissociation of larger oligomers.

The electronic spectroscopy of some *p*-alkylphenols and catechols

The University of Michigan, Department of Chemistry, 930 North University Avenue, Ann Arbor, Michigan 48109

Dopamine is a very important neurotransmitter whose biological function has been studied rather extensively. Nevertheless, many questions still exist concerning the physical properties that cause dopamine to manifest its interesting biological behavior. Investigation of the electronic spectroscopy of a molecule often yields insight regarding such properties. In these studies, it is useful to examine the spectroscopy of a set of simpler compounds that are structurally related to the compound of interest, and then to draw analogies among them. To this end, we have studied a set of *p*-alkylphenols and catechols by means of supersonic jet resonant two-photon ionization (R2PI) with mass-selective detection. This technique permits one to obtain a spectrum of the sample in the vapor phase, in which the electronic states of the molecule are not perturbed as they would be in solution. It also yields spectra in which transitions to individual excited states may be resolved. In addition, the mass-selective detection, as compared to other detection schemes, affords one much greater confidence that the observed spectrum arises from the molecule of interest and not, for example, from a cluster species or a contaminant.

Although many studies have been made of the ultraviolet spectroscopy of dopamine in solution, so far, no one has obtained a vapor-phase spectrum for dopamine. We have obtained R2PI spectra for several compounds that are closely related to dopamine. Despite considerable effort, however, we have not been able to obtain a spectrum for dopamine itself. In the course of our studies, we have found that certain catechols exhibit unusual behavior regarding the conditions under which they yield R2PI spectra. This behavior may offer clues as to why the vapor-phase electronic spectrum of dopamine has not yet been observed.

The molecules we studied were *p*-ethylphenol, *p*-isopropylphenol, tyramine, tyrosine, cathechol, 4-methylcatechol, 4-ethylcatechol, dopamine and 3-methoxytyramine (3-O-methyldopamine). We made R2PI assignments for all of these except for dopamine. To aid us in the R2PI assignments, we used infrared and Raman data to make correlations among the ground states of these molecules, and between the ground-state data and the R2PI data. The ground state for *p*-cresol is well known,[1] and was useful as a guide for the *p*-alkylphenol assignments. The well-known

catechol ground state[2] served as a guide for the catechol R2PI assignments. We assigned the 4-substituted catechols by analogy to existing assignments for other 1,2,4- trisubstituted benzenes.[3] 4-methyl- and 4-ethylcatechol yielded spectra only when the jet stagnation pressure was greatly reduced from the normal operating pressure (1atm absolute). An example of this behavior is shown in the accompanying panel.

R2PI spectra of 4-ethylcatechol with 90% neon/10% helium carrier gas at three different stagnation pressures

Laser Desorption/Ionization of Size Resolved Liquid Microdroplets

Bashir A. Mansoori* and Murray V Johnston, Department of Chemistry and Biochemistry
Anthony S. Wexler, Department of Mechanical Engineering
University of Delaware, Newark, DE 19716.

There is a continuing need for techniques that perform real time chemical characterization and quantitation of atmospheric aerosol particles Rapid single-particle mass spectrometry (RSMS) permits on-line analysis of aerosol particles by laser desorption/ionization. Particles are sampled directly into the source region of mass spectrometer where they are detected by light scattering from a continuous laser beam and then analyzed by laser desorption/ionization.

To understand the relationship between particle size and the resulting signal intensity, we have studied liquid microdroplets generated with a monodisperse aerosol generator. Liquid droplets have several advantages for quantitative work including well-defined morphology (spherical and homogenous), constant matrix composition surrounding the analyte, and straight forward preparation of calibration aerosol droplets having a known amount of analyte. The effects of droplet size, analyte concentration and laser irradiance on the signal intensity were systematically studied using two types of droplets glycerol droplets containing dissolved metal salts and 3-nitrobenzyl alcohol droplets containing the peptide leucine enkephalin.

For glycerol droplets containing inorganic cations and anions the threshold laser fluence for analyte ion detection is approximately 0.2 J/cm^2. With particles smaller than 5 µm diameter, the signal intensity is relatively invariant with increasing laser fluence Figure 1 shows plots of signal intensity vs. droplet diameter for glycerol droplets containing $FeCl_3$. This data was taken with a high laser fluence (3.4 J/cm)^2. As the droplet diameter increases, the signal intensity also increases but the relationship is nonlinear. However the signal intensity does increase linearly with volume. With low laser fluences and large (>5 µm) particles, the signal intensity correlates more closely with droplet surface area. Thus, high laser fluences appear to promote volume desorption, while low laser fluences appear to promote surface desorption. For a given particle size and laser fluence, the relationship between analyte peak area and analyte concentration is linear.

Matrix-assisted laser desorption/ionization (MALDI) can also be performed in liquid droplets For nitrobenzyl alcohol droplets containing leucine enkephalin the threshold for analyte signal detection is approximately 0.3 J/cm^2 Initially the peak area increases with laser fluence, but it reaches a plateau around 1 J/cm^2. Figure 2 shows the relationship between $(M+Na)^+$ peak area and concentration of leucine enkephalin in nitrobenzyl alcohol for 4.7 µm and 2.6 µm diameter droplets, respectively These plots indicate surface desorption and a surface preference for leucine enkephalin. The peak area increases with increasing concentration until a plateau is reached when monolayer coverage is achieved.

LASER DESORPTION IONIZATION T-O-F MASS SPECTROMETRY OF HYDROXY-NITROPAHs.

Dawit Bezabeh, and Peter B. Kelly, Department of Chemistry;
A. Daniel Jones, Facility for Advanced Instrumentation,
University of California, Davis CA 95616.

Introduction

Nitrated polycyclic aromatic hydrocarbons (NitroPAHs) are formed by reaction between PAHs and nitrogen oxides and/or nitric acids during incomplete combustion of organic matter. Analysis for nitroPAHs is complicated by the fact that their concentration are one to two orders of magnitude less than those of analogous unsubstituted PAHs. Our laboratory has been employing detection of negative ions for the purpose of selective detection of nitroPAHs over the large background of PAHs in environmental samples. In the environment, nitroPAHs are believe to further react with oxygen and/or hydroxyl radical to form hydroxy-nitroPAHs. Hydroxy-nitroPAHs, in general, are consider to be degradation products of nitroPAHs, hence we are investigating the negative ion laser desorption ionization of hydroxy-nitroPAHs.

Hydroxy-nitroPAHs are very difficult to analyze by other analytical methods, such as GC/MS, due to their acidity and polarity. Laser desorption ionization time-of-flight mass spectrometry has the potential to overcome the difficulty of analyzing polar hydroxy-nitroPAHs. The primary aim of the present study is to gain structural information about the photodegradation of hydroxy-nitroPAH and utilize these method to examine and investigate the chemistry of nitro-PAH photodegradation.

Experimental

Laser desorption ionization mass spectra were obtained using a custom-built time-of-flight mass spectrometry. A sample was prepared by depositing a small aliquot of the sample solution on a metal probe tip The sample was allowed to air-dry, forming a thin solid layer. Pulsed UV radiation at 266 nm was generated using the fourth harmonic of Quanta Ray DCR-3 ND:YAG laser with an 8 ns pulse width and focused in to the source region at a 45° angle of incidence on the surface of the sample. Spectra are obtained with a UV laser energy of 0.3 - 5 0 uJ/pulse

Results

Our initial work on the application of negative ion laser desorption ionization time-of-flight mass spectrometry of hydroxy-nitroPAHs yield structurally important peaks. The negative ion mass spectra of all hydroxy-nitroPAH standards gave $[M-H]^-$ as the most abundant peak. The hydroxyphenols show dimer and trimer anion formation with weak NO_2^- peak

As found in our earlier studies of nitroPAHs, characteristic CN^- and NO_2^- peaks were observed in the negative ion mass spectra of hydroxy-nitroPAHs with more than one benzene ring. The negative ion approach works well for analysis of mixtures of hydroxy-nitroPAHs. Good quantitative agreement between laser desorption ionization and electrospray ionization was found.

Infrared Spectroscopy of Methanol attached to Gold Cluster Ions

G. Dietrich[1], H.-J Kluge[2], K. Lutzenkirchen[1], L Schweikhard[3], C. Walther[3], and J Ziegler[3]

[1]Johannes Gutenberg-Universität, Institut für Kernchemie, D-55099 Mainz, Germany
[2]Gesellschaft für Schwerionenforschung, D-64220 Darmstadt, Germany
[3]Johannes Gutenberg-Universität, Institut für Physik, D-55099 Mainz, Germany

Infrared spectroscopy is one of the standard applications for structural elucidation of molecules It delivers information about the bonds inside the examined molecule via excitation of the vibrational states. For molecules attached to cluster ions in the gas phase, the absorption of IR photons results in the dissociation of the complex Both the number and the energy of the absorbed photons yield information about the bond strength and the vibrational frequency of the excited bond, respectively [1].

We report first results on infrared multi-photon dissociation (IR MPD) of cluster ions consisting of Au_4^+ and up to three methanol molecules attached. The gold clusters are produced by laser vaporization and transferred into a Penning trap. Methanol gas is added into the trap ($p \approx 1\times10^{-5}$ mbar) and adsorbed on the clusters. The products with either one, two, or three alcohol molecules attached are selected by radial ejection of all unwanted species. The beam of a line-tunable pulsed CO_2-laser (930-982 cm^{-1} and 1035-1086 cm^{-1}) is focused axially into the trap. In resonance, the absorption of photons leads to an evaporation of one or several methanol molecules. For identification, the dissociation product ions are ejected out of the trap and detected by time-of-flight mass spectrometry. For a detailed description of the experimental setup see ref. [2].

Figure 1 shows the resulting TOF-spectra of the experimental sequence. The distribution of $Au_4^+\cdot(CH_3OH)_{0\text{-}3}$ (fig. 1a) is obtained by the reaction of Au_4^+ with methanol for the storage period of 700 ms. In figure 1b the complex $Au_4^+\cdot(CH_3OH)_3$ is selected by radial ejection of all unwanted ions. The resulting spectrum of the IR MPD is shown in figure 1c. the ion dissociates up to three alcohol molecules after the interaction with the CO_2-laser beam at a frequency of 957.9 cm^{-1} and a power of 300 mJ. The dissociation process can be interpreted as the result of the excitation of the CO stretching vibration of the methanol molecules This leads to the breaking of the weak bond between the cluster and the attached alcohol molecule. No fragmentation of the gold cluster has been observed.

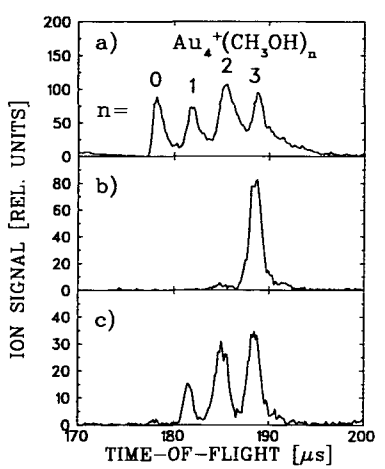

Fig. 1: Mass spectra showing the experimental sequence The reaction of the trapped Au_4^+ ions with methanol results in a distribution of attached alcohol molecules to the gold cluster ion (a) After selection of one of the ion-molecule complexes, e.g $Au_4^+\cdot(CH_4OH)_3$ (b), the dissociation of the complex is achieved by the exposure to the radiation of a CO_2 laser, e.g. 957.9 cm^{-1} (c).

In figure 2 the fragmentation yield of the IR MPD of $Au_4^+\cdot(CH_3OH)_{1\text{-}3}$ is plotted as a function of wavenumber. Compared to the frequency of the CO stretching vibration in the free methanol monomer at 1033.5 cm^{-1} [3] different red-shifts of the centers of the absorption bands for the three examined ions can be observed. The splitting of the bands for more than one methanol attached to the cluster can be explained by the formation of a hydrogen bonded methanol dimer on the surface of the cluster. The non-equivalent CO bonds absorb at different frequencies. A similar effect has been observed in a beam depletion spectroscopy experiment of size-selected methanol clusters [3]

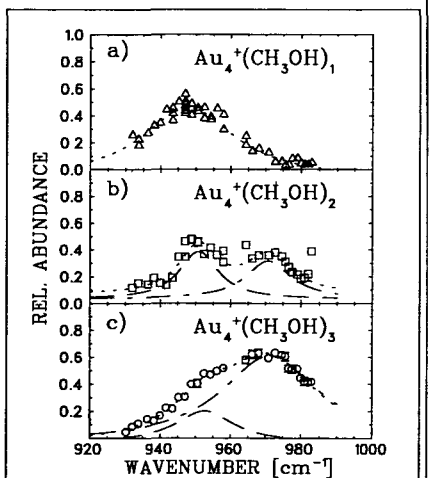

Fig. 2: Fragmentation yield as a function of the wavenumber of $Au_4^+\cdot(CH_4OH)_n$ (n = 1-3). The dashed lines are fitted Lorentzian curves, the dotted lines may guide the eye. The laser power was 472 mJ (n = 1) and 300 mJ (n=2,3)

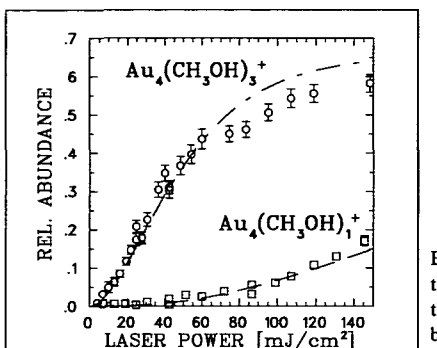

Fig. 3: Fragmentation yield as a function of the laser fluence of $Au_4^+\cdot(CH_4OH)_n$ (○ n = 3, ●: n = 1). The dashed lines represent processes due to 3 and 2 absorbed photons respectively.

By variing the laser power at a fixed wavenumber at the center of the depletion spectrum, the number of the absorbed photons required for fragmentation can be determined (fig 3). The data are fitted to multi-photon-fragmentation models [4] In the case of n = 2, 3 two photons were absorbed while for one adsorbed methanol molecules 3 photons were required. This indicates a larger bond strength for the $Au_4^+\cdot(CH_3OH)_1$ ion. Figure 3 shows the fragmentation yield depending on the laser power for n = 1, 3 In addition, the cross section of the photofragmentation could be determined to 2.3×10^{-19} cm^2 (n = 1, 947.0 cm^{-1}), 3.7×10^{-19} cm^2 (n = 2, 948.8 cm^{-1}) and 7.4×10^{-19} cm^2 (n = 3, 968 1 cm^{-1}).

Laser Desorption / Resonant Laser Ablation - Trace Analysis of Solid Matrices

C. G. Gill*, A. W. Garrett, W. L. Earl, N. S. Nogar and P. H. Hemberger
CST-1, MS J565, Los Alamos National Laboratory, Los Alamos, NM, 87545

Laser desorption (LD) and ablation (LA) have been recognized for some time as potentially useful methods for chemical analysis, in particular as methods for sample introduction for both organic and inorganic mass spectrometry (MS). Quadrupole ion trap MS is well suited to pulsed ionization sources, such as LD and LA, making it a suitable mass analyzer for this type of experiment. LD-MS frequently involves sample desorption from a matrix material or a solid sampling support [1], with the intent of providing quantitative and qualitative information about the content and structure of a sample. LA-MS typically ablates material from a native solid sample [2] in order to provide elemental or isotopic information from the analysis. Although most LA has utilized fixed frequency lasers operating at relatively high irradiance (~10^9 W·cm^{-2}), there has been some recent interest in the use of resonant laser ablation (RLA) [3] which typically uses modest intensity laser pulses tuned to a one- or two-photon resonant transition in the analyte to enhance the ionization yield. To obtain useful mass spectrometric information about trace analytes in solid analytical samples, the chemical form of the analyte must be considered. Our approach to trace MS analysis of solid samples uses LD to generate intact molecular ions for analytes on a solid support matrix, and RLA to create atomic species from solid materials, either of which can then be analyzed by quadrupole ion trap mass spectrometry.

The analysis of organics by LD-MS is presented for several solid support matrices. This work presents quantification for LD of pyrene as a linear calibration curve over four decades of concentration from ppb-ppm, demonstrating the utility of LD-MS for quantitative work. In addition, a complex PAH Standard mixture was analyzed utilizing Ambersorb as a sampling support, illustrating the use of a sampling sorbent with LD-MS for characterizing complex mixtures. Current research includes the investigation of chemically modified silica support matrices, sol-gels, zeolites, and carbon based adsorbents as solid sampling supports for LD-MS.

Resonant Laser Ablation (RLA) provides significant advances, which are presented by this work. RLA increases the ionization yield for target analytes by tuning the ablation laser to a resonant one- or two-photon transition. This selectivity is demonstrated by Figure 1, which shows two mass spectra, one for the Cu(2+1) resonance, and one off resonance. The striking appearance of the copper ions in the RLA mass spectrum illustrates the utility of the method, in that analytes can be selectively ionized in the presence of a bulk sample matrix. By tuning the laser wavelength to desired resonant transitions, target analyte signals can be enhanced manifold (up to 22,000X) over non-resonant laser ablation. The "2+1" optical spectrum for several analytes was determined using the method, and it was observed (for copper) that the transitions were laser linewith limited at 1.11cm^{-1}. Figure 2 shows the RLA optical spectrum for the Cu(2+1) resonance. This was obtained by analyzing a SRM664 steel sample, using 463.507 nm laser light to excite neutral Cu from $[3d^{10}4s]^2S_{1/2}$ --> $[3d^{10}5s]^2S_{1/2}$ (two photons), using a third photon to ionize the atom from this resonant energy level. The effect of linewidth for the RLA process was investigated, the result of which was an inverse relationship between selectivity and linewidth. The etch rate for the RLA process was measured by using thin films of copper on silicon as being 3X10^{-13} g/shot, facilitating the determination of meaningful absolute detection limits in the attogram range.

Lanthanide, Thorium, and Uranium Oxide Clusters Formed by DLV/FTICR

António Pires de Matos, Joaquim Marçalo, and João Paulo Leal
Departamento de Química, Instituto Tecnológico e Nuclear
P- 2686 Sacavém Codex, Portugal

In this work we report the formation of clusters of all the lanthanides (except promethium), thorium and uranium by direct laser vaporization (DLV) of surface oxidized metallic targets in a vacuum of about 2 x 10^{-8} Torr. The cluster ions were obtained using a Nd:YAG laser pulse (ca. 30 mJ at the fundamental 1064 nm wavelength) and the ions were stored in the trap of an Extrel (Waters) FTMS 2001-DT Fourier transform ion cyclotron resonance (FTICR) spectrometer.

We observed for all the lanthanides (Ln) that the clusters showed a sequential addition of Ln_2O_3 units in forming increasingly larger clusters, with two main series of the type $[Ln_mO_{(3m-1)/2}]^+$ (m odd) and $[Ln_mO_{(3m-2)/2}]^+$ (m even). Figure 1 shows the two series of oxide clusters for praseodymium. Work on lanthanide clusters has been reported by Gibson[1] using excimer laser abalation of lanthanide oxalates in a reflectron time of flight mass spectrometer, and by Kemp and Read [2], and Selbin et al [3,4] by fast atom bombardment (FAB) mass spectrometry of lanthanide salts. In some lanthanides, and due to the high resolution of the FTICR instrument, we could identify the two following clusters with hydrogen: $[Ln_2O_3H]^+$ and $[Ln_4O_6H]^+$ in which the fragment valence is 3 if H is present as OH. For Ce, with the 4 valence state accessible, we observed also clusters where the valence state is larger than 3, as for example in the series $[Ce_mO_{(3/2)m}]^+$.

For Eu, we observed clusters of the series of the type $[Eu_mO_{(3m-2)/2}]^+$ (m even), $[Eu_mO_{(3m-3)/2}]^+$ (m odd), $[Eu_mO_{(3m-4)1/2}]^+$ (m even), $[Eu_mO_{(3m-5)1/2}]^+$ (m odd), $[Eu_mO_{(3m-6)/2}]^+$ (m even) as previously reported by Gibson[1], but in addition we found clusters with hydrogen and in particular we mention here the clusters $[Eu_2O_2H]^+$, $[Eu_2O_3H_3]^+$ and $[Eu_3O_4H_3]^+$ in which all the Eu sites are in valence 2 if hydrogen is present as OH. Figure 2 shows the oxide clusters for europium.

For Th the clusters formed showed sequential addition of ThO_2, with the series $[Th_mO_{2m-1}]^+$ approaching a fragment valence 4 with increasing m. For U, five series of clusters were observed, $[U_mO_{2m}]^+$, $[U_mO_{2m-1}]^+$, $[U_mO_{3m-1}]^+$, $[U_mO_{3m-2}]^+$, and $[U_mO_{3m-3}]^+$, showing a sequential addition of UO_3 and UO_2, approaching fragment valences of 4 or 6, the most stable oxidation states in the case of uranium. While for U the largest cluster obtained was $[U_5O_{13}]^+$, for Th it was possible to obtain $[Th_{11}O_{21}]^+$. Figure 3 shows the oxide clusters obtained in this work for uranium. Thorium and uranium clusters have been previously obtained by Michiels and Gijbels (m = 1,2,3) using LAMMA [5] of oxides, and by Jennings et al [6], Tench et al [7], and Brown and Ismail [8] using FAB of thorium and uranium salts.

Summarizing, in all cases the cluster composition depends on the accessibility of the metal valence states, Ln(III) sites are dominant for the lanthanides, Ln(II) more easily accessible for Eu, M(IV) only for Ce, Th and U, and M(VI) for U.

Photolabalisation of Fe Bound Phosphine Ligands: Laser Desorption FT ICR MS.

Robin Aplin, Stephen Davies, Tom McCarthy and W Carl Watkins, The Dyson Perrins Laboratory, Oxford University, South Parks Road, Oxford, OX1 3QY, UK, Dwight Evard and Garry Krupper, Bruker Inst., Inc. Billerica, MA 01821, USA.

Contrary to the accepted dogma that Fe complexes containing both phosphine and carbon monoxide ligands preferentially lose the latter on photolysis. Davies *et al*,[1,2,3,4] have shown by a series of elegant but complex experiments that the primary photoreaction in a number of cases is the loss of the phosphine ligand. Nitrogen laser desorption **without** a matrix on a Bruker 4.7 BioApex MALDI FT ICR MS instrument has been used to study the photolabalisation of two different classes of iron phosphine complexes (1-3 and 4-6). Photolysis followed by FT ICR MS analysis showed that the complexes (1-3) decompose by cleavage of the phosphine- Fe bond to form predominently non-Fe containing species

(1) ------- *hv* ---- m/z 277, Ph_3P^+Me and m/z 339, Ph_4P^+.
(2) ------- *hv* ---- m/z 339, Ph_4P^+.
(3) ------- *hv* ---- m/z 319, p-tolyl$_3P^+$Me and m/z 395, p-tolyl$_4P^+$.

A similar analysis of tri-phenylphosphine and tri-p-tolylphosphine produced similar quaternary species:

Ph_3P ---- *hv* ---- m/z 339, Ph_4P^+.
p-tolyl$_3$P ---- *hv* ---- m/z 395, p-tolyl$_4P^+$.

Photolysis followed by FT ICR MS analysis of the complexes (4-6) showed that they decomposed by loss of CO to form predominently two Fe containing species.

(4) ------- *hv* ---- m/z 383, $Ph_3PFe^+C_5H_5$ and m/z 399, $Ph_3FeO^+C_5H_5$.
(5) ------- *hv* ---- m/z 383, $Ph_3PFe^+C_5H_5$ and m/z 399, $Ph_3FeO^+C_5H_5$.
(6) ------- *hv* ---- m/z 425, p-tolyl$_3PFe^+C_5H_5$ and m/z 441, p-tolyl$_3PFeO^+C_5H_5$

The quaternary phosphines detected from the complexes (1-3) were also observed as was expected from the known phototransformation of these Fe-COR and Fe-COAr complexes into the corresponding Fe-R and Fe-Ar complexes[4]. These investigations show that the nitroger laser photolysis followed by desorption and FT ICR MS provides a facile and rapid approach to the study of the photochemical decomposition of organometallic complexes.

Laser Ablation Mass Spectrometry of Sodium Penetrated Petroleum Cokes

Gary D. Willett, F. G. Hopwood and K. J. Fisher, School of Chemistry, The University of New South Wales, Sydney, NSW 2052, Australia
Paul G. Greenhill, Comalco Research Centre, 15 Edgars Road, Thomastown, VIC 3074, Australia

Introduction: Potassium and sodium modification of metallurgical cokes and carbon anodes and cathodes is of considerable interest to the aluminium industry as it can ultimately lead to the destruction of these materials. We have undertaken a laser ablation Fourier transform mass spectrometry study of a variety of carbon based materials including graphite, thermal black, carbon fibre, pitch coke, petroleum coke and glassy carbons in an effort to obtain information concerning the mechanism of sodium modification of these materials. A systematic analysis of a series petroleum cokes and sodium penetrated petroleum cokes which have been graphitised to different extents over the temperature range 800-2100°C have revealed noticeable differences in their respective negative-ion laser ablation FT-mass spectra.

Results and Discussion: Fig. 1 shows the effect of sodium modification of the graphitised petroleum coke on the negative-ion laser ablation (1064 nm) FT- mass spectra.

The striking results from the negative ion experiment are that:

(i) The sodium modification of the petroleum coke alters the production of the negative ions. Fig. 2 shows that the mass average of the carbon anion clusters decreases as the laser power increases. The corresponding sodium penetrated coke sample shows the opposite effect with a slight increase in carbon cluster mass average.
The carbon cluster mass average was calculated as $\frac{\Sigma mI}{\Sigma I}$ *where m = mass of carbon cluster and I = mass spectral intensity of carbon cluster.*

(ii) For the coke graphitised at 800°C, the anion production ceased at a laser power of 1,000 MW/cm^2 whereas for the sodium penetrated coke it ceased at 5,100 MW/cm^2.

(iii) The sodium penetrated cokes produce a greater abundance of the larger (C_n^- n>16) carbon cluster anions.

(iv) At low laser powers (1,000 MW/cm^2) there is significantly more hydrogenation of the carbon clusters produced with the sodium penetrated coke than is observed for the unpenetrated coke. There are generally two peaks associated with the odd-numbered clusters; C_n^- and C_nH^- whereas the even-numbered clusters exhibit three peaks C_n^-, C_nH^- and $C_nH_2^-$.

(v) In a separate experiment, *for which the mass spectral results are not shown here*, less graphitised carbon has a larger uptake of sodium and consequently a greater disruption of the carbon lattice which results in a larger carbon cluster mass average.

The positive-ion laser ablation mass spectra of the sodium penetrated carbons did not reveal any unusual features besides the presence of Na^+ and a range of hydrogenated carbon clusters. However, as Fig. 3 reveals, at low laser powers (~50 MW/cm^2) the raw petroleum coke readily produces a distribution of fullerene cations. At higher laser powers (~300 MW/cm2) the fullerene ions give way to smaller carbon cluster ions.

The addition of KCl to the petroleum coke shows that KCl enhances the production higher mass carbon cluster anions (m/z 200-500 dalton). The electron affinity of Cl is -3.63 eV which is very similar to that of many carbon cluster ions. For example, the electron affinities C_{13} and C_{17} are -3.60 eV. Presumably then, this increase in the number of carbon cluster anions due to the addition of KCl to the petroleum coke arises because of charge transfer between chloride based anions and the neutral carbon clusters.

Metal containing carbon clusters: There is no evidence in the laser ablation FT-mass spectra of the sodium penetrated carbons for carbon clusters which contain sodium. However, some of the carbons when doped with metal oxides readily form both fullerenes and metallofullerenes. Fig. 4 shows the cation LA/FT-mass spectra of a La_2O_3 / thermal black mixture.

Anion carbon cluster reactions with sulfides: The anion carbon clusters produced from the laser ablation of the petroleum cokes have revealed some unexpected reactions with sulfur based compounds. For example, Fig. 5 shows that the reaction of the odd-numbered C_9^- anion cluster produces a range of reaction products including HS^-, C_8H^-, $C_5S_2^-$, $C_8H_3S^-$, C_9HS^-, $C_9H_3S_2^-$. The reaction of $C_8H_x^-$ anions with H_2S produces only a $C_8H_x^-$.....H_2S adduct. We are currently studying the kinetics of these reactions.

LASER MASS SPECTROMETRY OF SYNTHETIC LINEAR AND DENDRITIC POLYMERS.

Ian A. Mowat, Robert J. Donovan, Morag Bruce and John J. Monaghan.
Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh, SCOTLAND, UK, EH9 3JJ.

(1) Introduction.

Laser mass spectrometry is an effective technique for the determination of the molecular weight distributions of a range of synthetic polymers (1-3). Previously this has been done using chromatographic methods such as Gel Permeation Chromatography or HPLC, or physical methods such as viscosity measurements. Unfortunately these methods require external calibration with a reference compound or significant information on the polymer's physical properties. Laser mass spectrometry enables large non-volatile molecules to be produced in the gas phase without significant decomposition or fragmentation. Time-of-flight analysis of the ions produced enables a complete mass spectrum to be obtained for all the ions produced in each laser pulse.

(2) Experimental.

A Nitrogen laser (337nm) was used to produce the ions, which were mass analyzed in a home built compact, linear, reflectron time-of-flight mass spectrometer (4). Spectra were acquired on a digital oscilloscope and transferred to a PC for storage and processing. Samples were prepared by a range of different methods, depending on the properties of the polymer being studied, e.g. either with or without a matrix, such as dithranol, or with or without added salts such as NaBr.

A wide range of polymers have been studied using this technique, including:- (i) Polar polymers and copolymers such as polyglycols, (ii) Non-polar polymers e.g. polystyrene, polyisoprene and polybutadiene; (iii) Polysiloxanes; (iv) Fluorinated polyethers e.g. Fomblin; (v) Mondisperse aryl ester dendrimers, and (vi) hyperbranched polyesters.

(3) Results.

Figure (1) illustrates the type of spectra obtained for an equimolar mixture of polyethylene glycol 1000 and 4600. Dithranol was used as the matrix and sodium bromide was used as the cationization agent. Spectra were acquired at a range of accelerating voltages from 400v to 20kV. This was to illustrate the vast change in sensitivity observed as the accelerating voltage (and hence the velocity) of the ions was increased. Information about the response factors of microchannel plates may also be obtained by this method.

The effect of increasing the accelerating voltage on the sensitivity of ion detection with respect to mass, can be illustrated such by taking the ratio of intensities of ions that were (a) far apart in terms of mass (i.e. the maximum peak of the PEG 1000 distribution, with several peaks in the PEG 4600 distribution; and (b) close together in terms of mass (i.e. several peaks in the PEG 4600 distribution).

It can be shown that for ions of similar masses, there is little change in relative sensitivity as the accelerating voltage is increased, i e. the ratio of peak intensities is fairly constant. However for ions that have different masses, there is a bias towards the detection of the faster, lighter ion at low accelerating voltages This bias decreases as the accelerating voltage is increased, and the difference in detection between low and high mass ions is reduced.

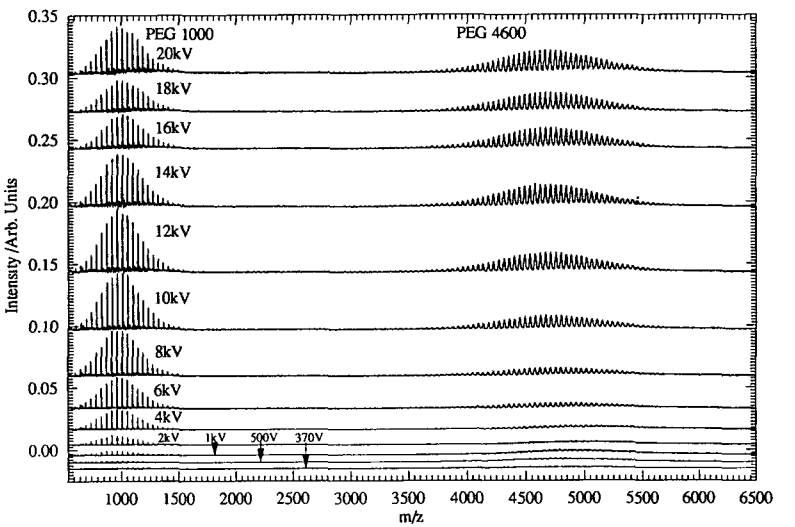

Figure (1) Equimolar mixture of PEG1000 and 4000, with a dithranol matrix and NaBr.

This work has been extended to a wide range of polymers, and experiments have been carried out to determine the important factors affecting the quality of MALDI spectra of synthetic polymers. Particularly useful compounds as an analytical probe of the MALDI process are dendritic polymers of a single molecular weight. These can then be used with a variety of different cationization agents to investigate the ionization process.

(4) Conclusions.

Laser desorption/ ionization mass spectrometry can quickly and successfully provide detailed information about synthetic polymers that is not otherwise available using other experimental techniques. However care must be taken in data interpretation as the behaviour of large molecules under laser desorption/ ionization conditions is not yet fully understood, and there are likely to be a range of properties which vary with molecular weight. This has important implications for the reliability of data obtained from the laser mass spectrometry of polymers.

Effects of Protonation on the Structure and Entropy of Bifunctional Molecules.

J.E. Szulejko, T.B. McMahon, Dept. of Chemistry, U. of Waterloo, Waterloo, Ont. N2L 3G1, **CANADA**
H. Audier and A. Milliet, DCMR, Ecole Polytechnique, Palaiseau, **FRANCE**

Protonation of acyclic bifunctional molecules, $X\text{-}(CH_2)_n\text{-}Y$ in the gas phase gives rise to the interesting possibility of *intramolecular* hydrogen bonding. The formation of an intramolecular hydrogen bond may (i) increase the proton affinity (PA) over that of similarly sized monofunctional molecules and (ii) induce a considerable loss of entropy due to the loss of internal rotors. In this pulsed electron beam High Pressure Mass Spectrometric (HPMS) study, X and Y were different groups in most cases, unlike previously reported work in the literature[1]. The functional groups investigated, mainly by equilibrium proton transfer HPMS experiments, ranged from -OH, $-OCH_3$, Phenyl, $H_2C{=}CH$- to methyl ketones. The thermochemical data derived from proton transfer van't Hoff plots are presented in TABLE 1.

The proton affinities (PA) of the methoxy-1-alkanols can be reasonably approximated by the PA of methyl propyl ether which is estimated by an additivity scheme to be 195.5 kcal mol^{-1}. The difference between the HPMS determined PA and 195.5 kcal mol^{-1} can then be used as a measure of the *intramolcular hydrogen bond strength* (IHBS), see Table 2. The IHBS is observed to increase in the order of 2-methoxy-1-ethanol < 3-methoxy-1-propanol < 4-methoxy-1-butanol viz, 4, 18 and 24 kcal mol^{-1}. An *ab initio* study[2] on protonated bifunctional molecules has shown that a ring size of 6 is most favoured. Smaller or larger ring sizes lead to non optimal bond angles. The IHBS for 2-methoxy-1-ethanol is the least, due to non-optimal bond lengths and angles.

The non intramolecular hydrogen bonded PA's for acetic anhydride and acetophenone can be estimated from an O 1s binding energy (BE) versus PA correlation[3] for carbonyl type compounds to be 183.8 and 203.3 kcal mol^{-1} respectively. However, the O 1s BE's are not known for phenyl or benzyl acetone. Their PA's can be approximated by that of 3-Pentanone (199.5 kcal mol^{-1})[3]. The IHBS increases in the order; acetophenone (~ 0), phenyl acetone (~ 3) and benzyl acetone (~ 7). In the case of protonated benzyl acetone, there appears to be a significant interaction energy between the π cloud of the phenyl ring with the protonated carbonyl site ≈7 kcal mol^{-1}

The half reaction entropy change for a protonation reaction, $\Delta S_{1/2}$ is defined as the entropy difference between the protonated base (BH^+) and neutral base (B). $\Delta S_{1/2}$ (est) can be approximated by the difference in entropies of the protonated forms (comparable sized methyl cycloalkanes) and methoxy-1-alkanols (comparable sized n-alkanols). The agreement between experiment, $\Delta S_{1/2}$ (expt) and $\Delta S_{1/2}$ (est) is excellent for 3-methoxy-1-propanol, fair for 4-methoxy-1-butanol and very poor for 2-methoxy-1-ethanol, see Table 2. On an empirical basis, $\Delta S_{1/2}$ is observed to decrease with increasing IHBS[1], reflecting favourable geometric conditions for the formation of a strong IHBS and the efficient loss of internal rotors. A similar trend is also noted for acetophenone, phenyl acetone and benzyl acetone.

DETECTION AND CHARACTERIZATION OF GAS PHASE CYCLODEXTRIN COMPLEXES

C. Dejsupa and David V. Dearden
Dept. of Chemistry and Biochemistry, Brigham Young University, Provo, Utah 84602

Cyclodextrins, which are cyclic polysaccharides having a truncated cone shape with all the glucopyranose units in substantially undistorted conformation (Figure 1), have been widely studied as models of host molecules for targeted complexation and delivery of guest drug molecules, or as catalysts in various stereoselective reactions.[1] This is mainly due to their unique structural features: a nonpolar cavity and a series of hydroxyl groups, acting as polar counterparts, cyclically arranged around the exterior of both ends of the toroid. Extensive work has been performed to gain better understanding of cyclodextrin reactions, but little has been done utilizing a mass spectrometer, and virtually nothing is known of the gas phase chemistry of these ions.

All experiments employed an APEX 47e (Bruker Instruments) FTICR-MS instrument equipped with a 4.7 T superconducting solenoid magnet. Equimolar concentrations (typically 0.1 mg/ml) of mixtures of α- and β-cyclodextrins were prepared in water:methanol:acetic acid in a ratio of 48.5:48.5:3. Electrospray ions were generated using a newly-designed electrospray source (Analytica, modified by Bruker Instruments) and then guided into the "Infinity" trapping cell by a series of electrostatic lens voltages. Neutral amines (n-butylamine, cyclohexylamine, L-methylbenzylamine, 1-naphthylmethylamine, diethylamine, and triethylamine) were introduced into the cell through precision leak valves. The pressure of the amine was typically in the 10^{-8} mbar range, as determined with an ionization gauge (Balzers). Postacquisition data analysis was done on a SPARC computer station (Sun Microsystems) with XMASS processing software (Bruker Instruments). Experiments were designed so that both cyclodextrins experienced identical amine pressures. The relative reaction rates of the protonated α- and β-cyclodextrin ions are therefore highly accurate (± 15%). Absolute rates (and absolute efficiencies) have considerably higher uncertainties.

Figure 2 shows the relative reaction efficiencies of a number of amines with the two protonated cyclodextrins. Notably, β forms complexes more efficiently than α for all the amines investigated. The linear alkylamines complex most efficiently, while the cycloalkyl and cycloaromatic amines are more than an order of magnitude slower. Complexation with 1-(cyclohexyl)ethylamine with either cyclodextrin (not shown) was too slow to measure accurately. The series n-butylamine, diethylamine, triethylamine compares primary, secondary, and tertiary amines. Interestingly, efficiency decreases in the order primary > secondary > tertiary, perhaps reflecting the decreasing number of hydrogen bond donor sites through the series. Size effects are more clearly evident in Figure 3, which shows the α/β efficiency ratio. In the same series, the difference between α and β becomes more pronounced as the amine becomes bulkier around the nitrogen. The smaller cyclodextrin is only slightly less efficiently than β for relatively unhindered primary amines such as cyclohexyl- or n-butylamine, while amines with steric constraints around their hydrogen bonding sites, such as methylbenzyl- or triethylamine, show the largest differences between the two cyclodextrins.

On the basis of semiempirical electronic structure calculations, we believe the cyclodextrins are protonated on their lower rims, suggesting this is where the hydrogen bonding interactions occur. While these complexes are clearly hydrogen-bonded electrostatic adducts, an important question arises as to whether or not the amines are bound within the cyclodextrin cavities to form inclusion complexes.[2] At present this question cannot be answered conclusively, but the data suggest that at least some of the amines may be binding inside. For example, some of the least efficient complexation is for aromatic amines such as methylbenzyl- and naphthylmethylamine, which are known to form inclusion complexes in solution, and with amines with bulky *R* groups such as cyclohexylamine and 1-(cyclohexyl)ethylamine, which intuitively would have steric problems accessing the interior. Curiously, reaction with the very bulky triethylamine is fairly efficient, suggesting it may bind on the exterior, but β is much more efficient than α for this amine.

We are grateful for the support of NSF, PRF, and Bruker Instruments, and for the assistance of Dr. Gary Kruppa.

Probing Hydrogen-Bonding Interactions in an Ion Trap

Jennifer S. Brodbelt, Brad Hall, Jim Shen, and Armando Colorado, Department of Chemistry, University of Texas, Austin, TX 78712

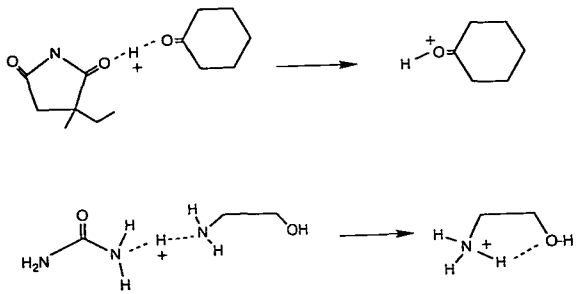
Hydrogen-bonds are important stabilizing interactions in many types of protonated molecules and other types of gas-phase complexes. We have undertaken a systematic evaluation of the factors which mediate the strengths of hydrogen-bonds in many types of organic molecules. The methods used to study these interactions include energy-resolved collisional activation to measure critical energies of dissociation and the ligand exchange method to determine orders of relative cation affinities. The systems of greatest interest include a series of polyether/ammonium ion complexes, quinone/borinium ion complexes, and a variety of proton-bound heterodimers and homodimers.

Experimental: All experiments were performed in a Finnigan quadrupole ion trap mass spectrometer operated in the mass-selective instability mode. Complexes were formed by ion-molecule reactions between an appropriate cation and organic neutral. Energy-resolved collisional activation was performed by application of an appropriate ac voltage across the end-caps during a 10 ms interval. The amplitude of the voltage was varied from 0 - 500 mV, and the observation of fragment ions was monitored as a function of the amplitude. The ligand exchange method was performed by introducing two compounds into the trap and monitoring the transfer of a particular cation, such as the proton or borinium ion, in both forward and reverse directions.

Results and Discussion:

The ion trap was calibrated by evaluating the threshold activation voltage needed to dissociate a series of proton-bound dimers and correlating the known critical energies with the activation amplitude. After a suitable correlation was developed, the dissociation of a series of proton-bound dimers was examined. The critical energies determined for the dissociation of listed below, with the fragmentation schemes shown for the heterodimers. As predicted, the critical energies for the homodimers are higher than those for the heterodimers because the proton-bridges in the homodimers are equally strong, whereas the bridges in the heterodimers are non-equivalent. The molecule with the higher gas-phase basicity engages in a stronger bond to the proton, and thus the other proton-bridge is weakened.

Complex	Critical Energy (+0.1 eV)	
(urea + H+ + urea)	1.5 eV	37 kcal/mol
(urea + H+ + 2-aminoethanol)	1.3 eV	30 kcal/mol
(cyclohexanone + H+ + cyclohexanone)	1.3 eV	30 kcal/mol
(cyclohexanone + H+ + ethosuximide)	1.0 eV	23 kcal/mol



The critical energies for a series of polyether/ammonium ion complexes were also measured, and some of the results are summarized in the table below. The critical energy depends on two factors: the difference in basicities of the polyether and amine, and the number of potential hydrogen-bonds formed between the polyether and amine. For example, pyridine has a substantially lower gas-phase basicity than 18-crown-6, and it does not possess numerous hydrogen-bonding sites. On the other hand, ammonia has a relatively low gas-phase basicity, but it can participate in numerous interactions within the cavity of 18-crown-6. 1,3-Diaminopropane has a higher gas-phase basicity than 18-crown-6, and thus the interactions with 18-crown-6 become somewhat non-equivalent. Thus, the critical energy of the 1,3-diaminopropane/18-crown-6 complex is reduced relative to that of the 2-aminoethanol/18-crown-6 complex.

Complex	Critical Energy (+0.1 eV)	
(18-crown-6 + H+ + Pyridine)	1.4 eV	32 kcal/mol
(18-crown-6 + H+ + NH3)	2.1 eV	49 kcal/mol
(18-crown-6 + H+ + 1,3-diaminopropane)	2.1 eV	49 kcal/mol
(18-crown-6 + H+ + 2-aminoethanol)	2.8 eV	65 kcal/mol

Photoinduced Proton Transfer of H-Bonded Clusters

Yong Huang and David H. Russell
Department of Chemistry
LABORATORY FOR BIOLOGICAL MASS SPECTROMETRY
Texas A&M University
College Station, TX 77843

Gas phase proton transfer is one of the most fundamental reactions in chemistry, and proton transfer is of fundamental importance in matrix assisted laser desorption/ionization (MALDI). We have developed a cluster beam apparatus to study proton transfer reactions between substituted aromatic compounds and model bases. The objective of this study is to probe the mechanism and energetics of proton transfer reactions in clusters.

Experimental: A gas mixture of ammonia and nitrogen or argon at 3 or 4 atm. is admitted into the apparatus through an R. M. Jordan Pulsed Valve. Ferulic acid is desorbed by a 337 nm nitrogen laser and entrained into the gas mixture. The clusters formed in the supersonic jet are ionized by 355 nm radiation from a Nd:YAG laser between high voltage plates. Ions are accelerated perpendicular to the jet and separated in a 1.1 m TOF mass spectrometer and detected by a dual MCP detector.

Results and Discussion: A typical spectrum of ferulic acid and ammonia shows $H(NH_3)_n^+$ (n=1 to 4) and $M(NH_3)_n^{+\cdot}$ clusters (M is ferulic acid, n=0 to >20). NH_4^+ and $M^{+\cdot}$ are always the most abundant ions in their respective series in the mass spectrum. The gas phase reactions involved are as follows[1]

$$M(NH_3)_n^* \xrightarrow{h\nu} M^*(NH_3)_n \quad (1)$$
$$M(NH_3)_n^* \xrightarrow{h\nu} M(NH_3)_n^{+\cdot} \quad (2)$$
$$M(NH_3)_n^* \rightarrow (M\text{-}H)^{-*}(NH_3)_nH^+ \quad (3)$$
$$(M\text{-}H)^{-*}(NH_3)_nH^+ \xrightarrow{h\nu} (M\text{-}H)^- + (NH_3)_nH^+ \quad (4)$$
$$(M\text{-}H)^{-*}(NH_3)_nH^+ \xrightarrow{h\nu} (M\text{-}H)^{*\cdot}(NH_3)_n^+ \quad (5)$$
$$(M\text{-}H)^*(NH_3)_nH^+ \xrightarrow{h\nu} (M\text{-}H)^\cdot + H(NH_3)_n^+ \quad (6)$$

and simple evaporation

$$H(NH_3)_n^+ \rightarrow H(NH_3)_{n-y}^+ + (NH_3)_y \quad (7)$$
$$M(NH_3)_n^+ \rightarrow M(NH_3)_{n-y}^+ + (NH_3)_y \quad (8)$$

The branching ratio between reactions (2) and (3) depends on the kinetics and energetics of proton transfer. The energy of intracluster proton transfer is highly cluster size dependent. The energetically favored structures of the base-solvated acid clusters are all with the base molecules attached to the acidic functional group. Hydrogen bonding to the O or N atom is energetically favorable over hydrogen bonding to the π ring. H-bonding to the π ring stabilizes the system by 2 to 3 kcal/mol,[3] whereas OH...O and NH...N bonding is 3 to 6 and 2 to 5 kcal/mol, respectively. But the geometric probability to form the conventional H-bonding may be less than that to form a H-π hydrogen bonding considering the large area of the π ring. The π solvation lowers the energy requirement for out-of-plane $^1(\pi,\pi^*)$ transition. In addition, the H-π hydrogen bond energy may be increased by as much as twofold for S_1 than for S_0 state.[4] The first few base molecules will occupy the positions above and below the π ring so that proton transfer is essentially blocked while the excitation of ferulic acid through the out-of-plane transition is

enhanced. As the number of base molecules increases, the probability for binding to the OH increases energetically resulting in formation of the precursor of the ion pair leading to proton transfer.

The laser power dependence of proton transfer is determined by plotting ion intensity (I) vs. laser energy (E). When E < 4 mJ, $I = aE^m$ is fitted with data points with R^2 value = 0.94 to 0.97, where m is the number of photons for the reaction to occur and a is the reaction cross section. For the $H(NH_3)_n^+$ series, m = 3.6, 3.0, 3.7 and 3.4 for n = 1 to 4, respectively. For the $M(NH_3)_n^{+\cdot}$ series, m = 2.2, 2.0, 1.7, 1.7, 1.7, 1.8 and 1.7 for n = 0 to 6, respectively. For $H(NH_3)_n^+$, the reason m = 3 or 4 is that reactions (1), (3), (5) and (6) may be the major path. If (3) requires another photon, m = 4. For $M(NH_3)_n^{+\cdot}$, m is close to 2 (reactions (1) and (2)). We estimate the ionization potential of ferulic acid to be 8 eV or even lower since cinnamic acid is ca. 9 eV and usually a OCH_3 and a OH substituent reduce IP 0.5 eV each. When E is higher, the I vs. E curve reaches a plateau around n=8 for NH_4^+, n=6 for $H(NH_3)_2^+$. For the $M(NH_3)_n^{+\cdot}$ series, the curve slope decreases but doesn't reach a plateau in the current experiment.

Future Studies: The goal of all these studies is to explore the mechanism of MALDI. NH_3 will be replaced by a nonvolatile biological sample. Clusters will be generated by seeding the carrier gas with the peptide volatilized by laser ablation.

Investigation of a Chirality Effect in Proton Bound Dimers of Dimethyltartrate

E.N. Nikolaev* and T.B. McMahon†
* The Institute of Energy Problems of Chemical Physics; Russian Academy of Sciences; 117829 Leninski Prospect 38; Moscow; Russia

In recent years, there has been a rapidly increasing interest in the influence of chirality on the biochemistry of chiral molecules. It has been found that the enantiomers of chiral bioactive molecules often differ in potency, toxicity, pharmacological actions, and metabolism[1]. It is also well known that important biopolymers are made up of monomer units having unique chiralities, with L-amino acid units in proteins and D-sugar units in DNA and RNA and chiral asymmetry is conserved in nature. The basis of this asymmetry conservation is chiral recognition. The molecular mechanism of recognition is not completely understood, however it is clear that it is based on enantioselective interactions of chiral molecules with monomers of a chiral matrix (stereoselective binding). A unique possibility now exists to investigate such chiral interactions in the gas phase.

Nikolaev and coworkers[2] have previously demonstrated a pronounced chirality effect in the unimolecular dissociation of proton bound dimers of dimethyl tartarate[2]. The present work extends the study of this chirality effect using high pressure mass spctrometry and using a high pressure ion source coupled to a FT ICR spectrometer. Additional chirality effects on unimolecular decomposition of the protonated dimethyltartrate (DMT) dimer as well as a hydrated proton bound dimethyltartarate dimer have been found.

Protonated monomers MH^+ and dimers M_2H^+ were produced by chemical ionization processes in methane. H_3O^+ adducts of tartarate monomers and dimers were produced from residual water and NH_4^+ adducts from ammonia which was added to the mixture in trace quantities. In order to distinguish L- and D- forms, the L- sample was deuterium labelled in each of the six hydrogen atoms of the ester methyl groups. To investigate the decomposition of dimers, they were isolated by ejection of all ions from the cell except the species of interest.

The protonated and hydrated dimer intensity distributions do not show a binomial distribution which would be expected for a statistical mixture of adducts. However the protonated ammonia adducts do exhibit such a statistical mixture. The pronounced deviation from a statistical intensity distribution is strong evidence of a substantial chirality effect. It can also be seen that nature of the chirality effect is strongly dependent on the adduct ion involved. In the case of the protonated dimers homochiral spicies dominate while in the case of the water adduct the heterochiral species is the most abundant.

This behaviour can be understood from the thermochemical data provided by high pressure mass spectrometric experiments. An analysis of the exchange of a ligand from the homochiral dimethyl tartarate dimer shows that the enthalpy change associated with replacement of a d,d ester by an l,l ester is +7.3 kcal/mole at temperatures below 60° C (Figure 1.). Thus the heterochiral species is of considerably lower stability and is disfavoured on thermodynamic grounds. A molecular modelling analysis shows that this lower stability likely arises from the opportunity to form a greater number of hydrogen bonds in the homochiral proton bound species (Figure 2.).

The thermochemical data then serve also to explain the kinetic data observed initially by Nikolaev et al. and in the current work using an external high pressure source to prepare the

various homo- and hetero- chiral dimers. By fitting the kinetic curves for the disappearance of the dimers to single exponential decay functions rate constants of k(DL)= 0.22 s^{-1} for heterochiral dimers and k(DD,LL)=0.027 s^{-1} for homochiral proton bound dimers are obtained. For water containing dimers the water loss rate constant and subsequent dimer decomposition into protonated monomers rate constant were found to be 2.0 s^{-1} and .05 s^{-1} for the homochiral dimers and 1.2 s^{-1} and .22 s^{-1} for the heterochiral species. These data then suggest that introduction of a water molecule into the proton bound dimers substantially alters the hydrogen bonding network.

In Search of Non-Classical Ethyl Cation Stabilized by Organic Molecules.

Dmitri V. Zagorevski and John L. Holmes

Chemistry Department, University of Ottawa, Ottawa, Ontario K1N 6N5 Canada.

Onium ions play an important role in organic chemistry. Ethyl-containing onium ions, $R_nX^+C_2H_5$ (X - heteroatom), are of a special interest because in the gas phase they potentially may exist in several isomeric forms, such as the classical structure **I** and the symmetrical proton-bound dimer **II** (Scheme 1). The aim of this presentation is to summarize results on the structure and unimolecular reactivity of a variety of halonium and oxonium ions published in the literature and recently studied by the authors [1-7]. The following problems are discussed: how to generate ethyl-containing onium ions in the gas phase, how to identify isomeric species, and does interconversion of isomers take place?

Ions of interest can be generated by ion-molecule reactions (IMR) and unimolecular dissociations. The experiments were carried out on a tandem mass spectrometer operating with a chemical ionization ion source. Some IMR were identified by using ion cyclotron resonance spectrometry. Examples of reactions are shown below. Formation of stable adducts between cations and neutral molecules was observed in some cases (reaction 1) The most common IMR involved elimination of a molecule or radical (reactions 2 and 3). The use of the molecular ion of ethyl iodide as the reactant was very effective. Many of these reactions involved the formation of ionized dimers, which dissociated directly giving rise to onium ions (reaction 4). Unimolecular dissociation of molecular ions of various organic compounds can be used to generate onium ions having a formal carbon-heteroatom double bond (reaction 5).

$$BrCH_2CH_2^+ + O(C_2H_5)_2 \;\text{--->}\; BrCH_2H_2O^+(C_2H_5)_2 \qquad (1)$$

$$(C_2H_5)_2O^+H + IC_2H_5 \;\text{--->}\; (C_2H_5)_2O\cdots H^+\cdots C_2H_4 + HI \qquad (2)$$

$$C_2H_5I^+ + O(C_2H_5)_2 \;\text{--->}\; (C_2H_5)_3O^+ + I \qquad (3)$$

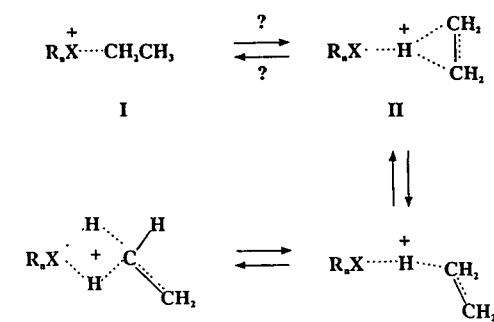
$$[C_2H_5I\ C_2H_5Br]^+ \;\text{--->}\; (C_2H_5)_2Br^+ + I^\cdot \qquad (4)$$

$$(CH_3)_3COC_2H_5^+ \;\text{--->}\; (CH_3)_2C{=}O^+C_2H_5 + CH_3^\cdot \qquad (5)$$

One of the most common arguments used in the identification of the non-classical structure **II** is the observation of hydrogen atom mixing prior to ethene loss. Isomer **II** is the key intermediate providing the exchange of hydrogen atoms between the carbon atoms of the ethyl

group. Non-symmetrical proton-bound isomers must also be introduced to complete the H-atom mixing (Scheme 1). The classical isomer may or may not be involved in this scheme.

Scheme 1.



Structures **I** and **II** can be identified by other dissociations. For example, the formation of a (non-classical) ethyl cation is usually associated with isomer **II**, whereas C_2H_5 and RH (or C_2H_6) losses are consistent with isomer **I**. The latter two reactions do <u>not</u> involve hydrogen atom mixing.

In some cases (protonated ethanol and diethyl ether, diethylchloronium ion) classical and non-classical isomers can be co-generated and they easily intercovert. The triethyloxonium ion is an example of the separate existence of isomers. The classical structure was produced by reaction 2 and no H-atom mixing was observed in these species. Reaction 5 resulted in a proton bound dimer. This ion showed hydrogen atom mixing in the ethyl group originally attached to the iodine atom.

Schistosome Surface Oligosaccharides Modulate Immune Response

Vernon N. Reinhold, Bruce B. Reinhold, Palanivel Velupillai, and Donald A. Harn
Boston University School of Medicine and Harvard School of Public Health

Successful parasites invade virtually every organ of their animal hosts, while evading nearly all of the host's immune defense responses. Why these parasites are successful is a question important not only to understanding and treating parasitic infections but also to other disease states in which the immune system is disabled or evaded. *Schistosoma mansoni,* appears to carry out this feat through carbohydrate signalling molecules on its egg's surface (1). Schistosomiasis is a chronic debilitating disease infecting 200-300 million people through out the world. In spite of the development of active and relatively safe drugs, prevention has remained a problem requiring repeat drug applications over a long period. Because of reinfection, there is a clear need for alternative control measures and in particular for an effective vaccine inducing significant levels of protection against the invasive stage of the parasite.

The most effective defense against schistosome parasites is considered to be the cell-mediated immune system, in which the macrophages are activated in response to the parasite and destroys the worms. But some worms survive which lay eggs that trigger an alteration of the lymphoid T-cell responses, shifting the immunity from cell-mediated to antibody-mediated (T-cell shifting), which is ineffective in combating the infection (2). In doing so they create their own environments in tissues and lay eggs where the worms hatch and thrive. In an effort to simulate this environment, Harn and colleagues (1) selected a battery of commercially available oligosaccharides, covalently bound them to human serum albumin and measured their lymphostimulatory effect. Lacto-N-fucopentaose III (LNFPIII), previously shown to be a stage specific antigen (3), stimulated splenic, non-T cells (B cells) to proliferate and produce IL-10 and prostaglandin E2 (PGE2), two mediators known to down-regulate CD4+ Th1 cells. This demonstrated a carbohydrate ligand dependent mechanism for cytokine production, and likely represents a novel mechanism for regulation of CD4+ T cell subsets. Other structurally related fucosylated, polylactosamine sugars appear to have similar lymphostimulatory properties as LNFPIII, and thus contribute to CD4+ T cell subset regulation.

To support this observation, we have isolated the egg surface enzyme (glutathione-S-transferase) from the *Schistosoma mansoni*. This glycoprotein gave rise to only O-linked glycans which were released by methylation and analyzed them by ES-MS (3). Within the distribution of glycoforms detected, fucosylation and Lewis X epitopes were detected by CID.

Human bone marrow transplants are performed as therapeutic treatment for severe aplastic anemia, leukemia, and immune deficiency disease. Even with the use of HLA matched siblings, aggressive pretransplant chemoradiotherapy, potent immunosuppressive drugs, and better antibiotics, bone marrow transplants can still result in 20-80% of cases of Graft-vs-Host Disease (1). It is believed that disparities for minor histocompatibility antigens between donor and recipient constitute a significant risk for graft failure, necessitating life long pharmacological immunosuppression of bone marrow transplant recipients. These minor antigens are peptides presented by the recipient on their HLA, and not the donor, due to slight differences in either protein sequence or antigen processing. Using electrospray tandem mass spectrometry, the first human minor antigen has been sequenced (2) This minor antigen was isolated from a patient suffering severe Graft-vs-Host Disease after a HLA identical bone marrow transplantation.

Peptides from B lymphocytes expressing this minor antigen were subjected to multi step fractionation beginning with immunoaffinity chromatography and then two dimensions of RP-HPLC. The single biologically active fraction obtained was then analyzed using a technique that allows for direct correlation of mass spectrometry and biological activity (3). The above approach reduced the number of peptide candidates from ~10,000 to only 5. Two peptides were then sequenced at the 25 fmol level using micro-capillary HPLC ESI tandem mass spectrometry on a Finnigan TSQ-7000. Only one of these peptides induced lysis by the minor antigen specific cytotoxic T-cell clone (see Fig. 1 CAD). The peptide sequenced was YXGEVXVSV. By co-elution, the Ile/Ile isoform was eliminated as the naturally processed peptide. The other three iosforms were tested for biological activity (see Fig. 2), and the Ile/Leu isoform was found to be more active by nearly two orders of magnitude (40 pM vs ~3 nM). This isoform was also the best binder to HLA-A2.1 with a 50% inhibition concentration of ~ 7 nM.

The naturally processed peptide was therefore determined to be YIGEVLVSV. This sequence was searched in protein and DNA databases. No 100% matches were found. However, thirteen proteins were similar with 6 matching 8 of 9 residues and 7 matching 7 of 9. The closest human sequence (YIGSVLISV), as well as the other twelve, are all from the same family of nonfilamentous class I myosins which are believed to be involved in cell and organelle locomotion. The strong homology between these sequences and the identified minor antigen provides strong evidence that the source protein is a member of this myosin family.

The minor antigen identified has potential as part of immunotherapy. This antigen is

restricted to the HLA-A2.1 population and has a frequency of 95%. Furthermore, It is tissue specific to hematopoietic, or white blood cell, including leukemic cells. In patients suffering from leukemia who express this antigen, cytotoxic T-cells raised against this minor antigen could be used to selectively rid the body of cancerous cells without damaging healthy tissue.

CE-MS AND MS-MS ANALYSES OF LIPOPOLYSACCHARIDES FROM *P.AERUGINOSA**

S. Auriola, P. Thibault, I. Sadovskaya[1], H. Masoud[1], E. Altman[1], J.C. Richards[1]
Institute for Marine Biosciences, National Research Council, 1411 Oxford St., Halifax, Nova Scotia, Canada, B3H 3Z1; [1]Institute for Biological Sciences, National Research Council, 100 Sussex Dr., Ottawa, Ontario, Canada, K1A 0R6.

Pseudomonas aeruginosa is a gram-negative bacterium recognised as an opportunistic pathogen among debilitated burn-wounded, and immunocompromised individuals. The major virulence factors of *P. aeruginosa* are associated with complex lipopolysaccharides (LPS) found on the outer surface of these bacteria. The LPS isolated from *P. aeruginosa* have been shown to contain a mixture of different polysaccharide lengths [1] and of different functionalities attached to the lipid A backbone [2]. At present, only partial or tentative structures of the core regions of these LPS are known, and detailed structural analysis including their heterogeneity is still fragmentary. Characterization of O-deacylated lipooligosaccharides (LOS) from core-deficient mutant strains of *P. aeruginosa* O6 was achieved using NMR spectroscopy [3], and provided for the first time a structural model for the complete core oligosaccharide of this serotype.

In order to investigate the sample heterogeneity often associated with substituents attached to the oligosaccharide backbone (i.e. fatty acids, phosphates, acetyl groups and substituted carbohydrate chains), the present investigation has focused on the development of on-line capillary zone electrophoresis coupled to electrospray mass spectrometry (CZE-ESMS). An example of a CZE-ESMS analysis is presented in Figure 1 for the injection of 20 ng of basic oligosaccharides arising from the complete deacylation and dephosphorylation of *P. aeruginosa* LPS. The total ion electropherogram is shown in Figure 1a, along with the two dimensional depiction of ion intensity as a function of both m/z and time (Figure 1b). The contour profile presented in Figure 1b clearly shows a series of at least five diagonal lines between 16 and 20 min, corresponding to doubly- and triply-protonated molecules. Members of series 4 consist of truncated core glycans, the highest member of which (oligosaccharide A) displays an $[M+2H]^{2+}$ ion at m/z 1017, and comprises a fully deacylated and dephosphorylated core having a glucosaminitol (GlcNol) at the reducing end. Diagonal lines of each series are formed of truncated glycans lacking alanine, rhamnose, and/or hexose residues. Series 1 differs from series 4 by the addition of a 3-hydroxy lauric acid on oligosaccharide A. Series 2 and 5 correspond to oligosaccharides of higher mobilities, lacking a side-chain KDO residue. The abstraction of an hexosamine residue from series 2 affords oligosaccharides of intermediate mobilities (series 3). Confirmation of individual oligosaccharide structures was facilitated using tandem mass spectrometry using either flow injection or on-line CZE-MS-MS analyses.

Combined CE-ESMS analyses also provided an efficient tool for monitoring the heterogeneity of substituents appended to either the O-chain (acetyl and formyl groups) or the core structure (phosphate and pyrophosphate groups) of LPS. Hydrophylic glycolipids arising from mild hydrazinolysis of *P. aeruginosa* LPS were successfully separated under anionic conditions using uncoated capillaries. The heterogeneity of the O-deacylated LPS arises mostly from substitution on the galactosamine residue of the O-chain, and from the number of phosphate groups appended to the core and lipid A structures. Based on electrophoretic measurements and MS-MS spectra, the incremental number of phosphate groups bonded to the core stucture was accounted for by the formation of pyrophosphate groups on the heptose residue. Further improvement in sample loadings was achieved using on-line capillary isotachophoresis (CITP) preconcentration prior to capillary zone electrophoresis, and enabled the on-column injection of up to 1 µL of O-deacylated LPS. An example of such application is shown in Figure 2 for the analysis of O-deacylated LOS from a core-deficient mutant of *P. aeruginosa*.

Killer T cells are part of the immune system that recognize peptide antigens derived from proteins expressed in tumor cells presented on the cell surface by major histocompatibility complex (MHC) class I molecules. The antigen processing mechanism involves protein synthesis and cytosolic proteolysis by the proteasome complex, followed by transport of peptides into the endoplasmic reticulum (ER) by the action of the transporter associated with antigen processing. In the ER, peptides are loaded into the MHC class I molecule and the resulting complex travels to the cell surface.

Most antigenic peptides have been predicted from a genetic sequence. Genomic libraries are generated from tumor cells and genetic fragments are transfected into cells that express the appropriate MHC molecule but not the tumor antigen. A combination of molecular subcloning and synthetic peptides based on the MHC binding motif and the proteins predicted sequence are used to identify the antigenic peptide.[1] Our approach is to isolate MHC class I associated peptides from the cell surface and then purify the mixture by multiple rounds of HPLC. A fraction containing peptide capable of reconstituting a T cell epitope is identified by ^{51}Cr release assays. Candidate peptides are identified and then sequenced by electrospray ionization tandem mass spectrometry (ESI-MS/MS).[2]

We identified a naturally occurring HLA-A2.1 associated peptide YMDGTMSQV in peptides extracted from melanoma cells. This peptide is identical to the antigenic peptide found using the genetic method except the amino acid residue at position three is an aspartic acid instead of an asparagine residue. Interestingly, the naturally occurring peptide YMDGTMSQV sensitized target cells for lysis at a 100 fold lower peptide concentration that the genetically encoded peptide YMNGTMSQV. The aspartic acid and the asparagine containing peptide bound to purified HLA-A2.1 molecules with similar affinity and therefore differences in binding affinity do not account for the differences in peptide recognition by the killer T cell clone.

We used mass spectrometry to determine whether the naturally occurring peptide epitope was a tyrosinase gene product that results from post-translational modification. HLA-A2.1 associated peptides extracted from the melanoma cell lines NA8mel, which does not express a tyrosinase gene, and NA8Mel+tyr, which has been transfected with a tyrosinase gene encoding the asparagine containing peptide were analyzed. Peptides were immunoaffinity isolated, concentrated, loaded onto a C18 micro capillary column (75 µm i.d. x 12 cm) and gradient eluted using acetonitrile and 0.1 M acetic acid with the concentration of acetonitrile increasing at 2%/minute into a Finnigan TSQ-7000 (San Jose, California) triple quadrupole mass spectrometer equipped with an electrospray ion source. Scans were acquired every 1.5 seconds over a mass range m/z 300-1400 and then plotted with intensities for m/z 1031 to 1032. Peptides YMNGTMSQV and YMDGTMSQV have molecular mass of 1031 and 1032 respectively. Analysis of the peptide mixture extracted from NA8mel failed to detect any species within the 1031 to 1032 mass window at greater than 0.2 fmol / 3 x 10^7 cells. The analysis of peptide extracts from NA8mel+tyr show one peptide within this mass window and was detected at a level of 200 fmol / 3 x 10^7. This peptide is therefore derived from the tyrosinase gene. When synthetic YMNGTMSQV was added to peptide extract from NA8mel+tyr two distinct peaks within this mass window were identified indicating that they do not have the same sequence. In contrast, when synthetic YMDGTMSQV was

[1] van der Bruggen, P., et al, Science, 254.1643-1647, 1991 December 13
[2] Cox, A. L.,et al., Science, 264·716-719, 1994 April 29.

added to the NA8mel+tyr extract the peptides co-elute suggesting that they are identical (Fig. 1). Proof for this conclusion was obtained by directly sequencing the naturally occurring tyrosinase peptide by mass spectrometry. To ensure that the conversion had not occurred during MHC purification and peptide extraction, HLA-A2.1+ T2 cells were pulsed with synthetic YMNGTMSQV prior to peptide extraction and purification and then analyzed (Fig. 3). These results establish that the peptide encoded by the tyrosinase gene has been post-translationally modified before presentation by HLA-A2.1 on the cell surface.

This is the first demonstration of a post-translational modification that results in the alteration of a peptides primary amino acid sequence. The alteration was directly identified by tandem quadrupole mass spectrometry and is relevant towards the identification and prediction of other peptide antigens. Further studies will investigate where the post-translational modification occurs within the cell and how this modification fits into the MHC class I antigen processing pathway.

Tandem Mass Spectrometry and Data Analysis of Immunological Peptide Mixtures

John R. Yates, Ashley McCormack, Jimmy Eng, Paul DeRoos[1], and Alexander Rudensky[1]
Department of Molecular Biotechnology and [1]Department of Immunology, University of Washington, Seattle, WA 98195

Micro-column liquid chromatography electrospray ionization provides a rapid and sensitive method for the mass analysis of complex mixtures of peptides and proteins. Coupling the resolving power of reverse phase HPLC with direct sequence analysis by tandem mass spectrometry (µLC/ESI/MS/MS) is a useful strategy for the determination of amino acid sequences of peptides in mixtures, such as the antigens isolated from class I and class II major histocompatibility complexes (MHC) (Hunt et al *Science* **255** 1261-1263 (1992)). Class II antigens are derived from extracellular proteins or peptides. These molecules are bound to receptors on the surface of antigen presenting cells and then ingested into the cell. Ingested proteins are processed to a set of peptides of 11-25 amino acids in length prior to loading in the binding pocket of class II MHC antigens. This processing occurs in a series of fractions enriched in each type that can be distinguished by their densities. By structurally characterizing the antigens contained in each type of vesicle an understanding of the events involved in processing can be obtained. We have applied µLC/ESI/MS/MS and database *searching to the studies of antigen processing.*

A sucrose gradient is used to separate the vesicles by density. The vesicles are then assayed to determine the homogeneity of each fraction. The vesicles are lysed and contents of the vesicles are passed through Centricon filters with 3,000 and 10,000 molecular weight cutoffs. The fraction of peptides under 3 kDa are subjected to automated LC/MS/MS. The resulting tandem mass spectra are then used in the database searching algorithm described by Eng et al. (J. Am. Soc. Mass Spectrom. **5**, 976 (1994), Yates et al *Analytical Chemistry* **67**, 1426 (1995)). The peptide sequence represented in the tandem mass spectrum is identified by correlation to it's protein sequence in the database. From the sequence of the peptide, information relevant to the specificity of the protease involved in antigen processing can be inferred. Spectra are analyzed using the OWL database version 24.0 (88,823 entries). OWL is a non-redundant database comprising protein sequences from the GenBank (Release 84.0, National Center for Biotechnology Information, Washington, DC), SWISS-PROT (Release 29, Swiss Institute of Technology), Protein Information Resource (Release 41, National Biology Resource Foundation, Georgetown, Washington, DC), and National Research Laboratory (Release 14, Brookhaven National Laboratory, Brookhaven, NY) databases. All searches were performed on a DecStation 3000/900 (Maynard, MA) (Figure 3). A detailed description of the methods used for data reduction, preliminary scoring, and final scoring used in the computer algorithm have been presented elsewhere (Eng et. al. *J. Am. Soc. Mass Spectrom.* **5**, 976 (1994), Yates et al *Analytical Chemistry* **67**, 1426 (1995)).

Tandem mass spectrometry is performed on a Finnigan MAT TSQ700 equipped with electrospray ionization. Product ion tandem mass spectra were acquired during an LC/MS analysis by using a computer program written in the TSQ 700's Instrument Control Language (ICL). At the start of the program the instrument was configured to scan the second mass analyzer (Q_3) from an m/z of 400 to 1400 at 1.5 seconds/scan. When the ion current for a particular *m/z* value was above a preset threshold value of 250,000 counts, the program switched the instrument to scan in the product ion MS/MS configuration. The *m/z* value measured in the main beam mode was used to set the precursor ion *m/z* value in the first mass analyzer. The mass range was set at 50 u to 2 times the precursor ion *m/z* value with a scan time of 1.5 sec during acquisition of product ion tandem mass spectra. Five scans were

acquired and the instrument returned to the main beam mode of scanning. All analyses were performed with the collision cell filled with argon to a pressure of 3.5 mtorr. The collision energy for product ion scans was set by dividing the *m/z* value of the precursor ion by a constant (-35). This process was repeated throughout the LC analysis.

Shown in Figure 1 is the LC/MS/MS analysis of a low molecular weight fraction of high density fraction. All spectra were subjected to searches of the OWL database. Shown in Table 1 is a list of the peptide sequences identified in both the high density and medium density fractions. The cleavage patterns to produce these peptides is consistent with proteolysis by the enzyme cathepsin. In both analyses approximately 25-35 tandem mass spectra were acquired over the course of a 35 minute reversed-phase HPLC analysis. This permits the acquisition of spectra with a high probability of identifying peptides from known sequences, thus leading to rapid identification of the spectra.

ES AND MALDI MS ANALYSIS OF GLYCOSYLATION-ENGINEERED α-1 ACID GLYCOPROTEIN

Mark F. Bean*, Michael J. Huddleston, Daniel J. O'Shannessy, and Steven A. Carr
SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19460.

Genetic engineering control of protein expression can be carried beyond amino acid sequence to include posttranslational modifications of proteins such as glycosylation. This is achieved by expressing the recombinant protein in a cell-line tailored to produce the desired modification. Traditionally, verification of the success of such glycosylation engineering has depended on antibody recognition of the modifications. We have explored the use of mass spectrometry for the same purpose and found it to be a much superior means of analysis in terms of its ability to characterize microheterogeneity within the oligosaccharide structures and to associate protein modifications to specific amino acid sites.

In the present study, glycosylation engineering of alpha-1 acid glycoprotein expressed in the mutant Chinese hamster ovary Lec-11 cell line produced a variant that specifically antagonizes E-selectin mediated adhesive events *in vitro*. E-selectin is an adhesion lectin involved in the recruitment of leukocytes to sites of inflammation. LC-ESMS of the engineered and natural glycoproteins after removal of neuraminic acids, reduction, pyridylethylation, and tryptic digestion clearly revealed that the engineering was successful in coating the protein oligosaccharides with the blood group determinant sialyl-Lewis X (sLe^X) as well as VIM-2 type sugar structures (NeuAc2-3Gal1-4[Fuc1-3]GlcNAc, and NeuAc2-3Gal1-4GlcNAc1-3Gal1-4[Fuc1-3]GlcNAc respectively). Moreover, it was possible to describe the heterogeneity in the glycoforms at each of the five N-glycosylation sites (for example see Figure 1a) and to show that this was site-dependent.

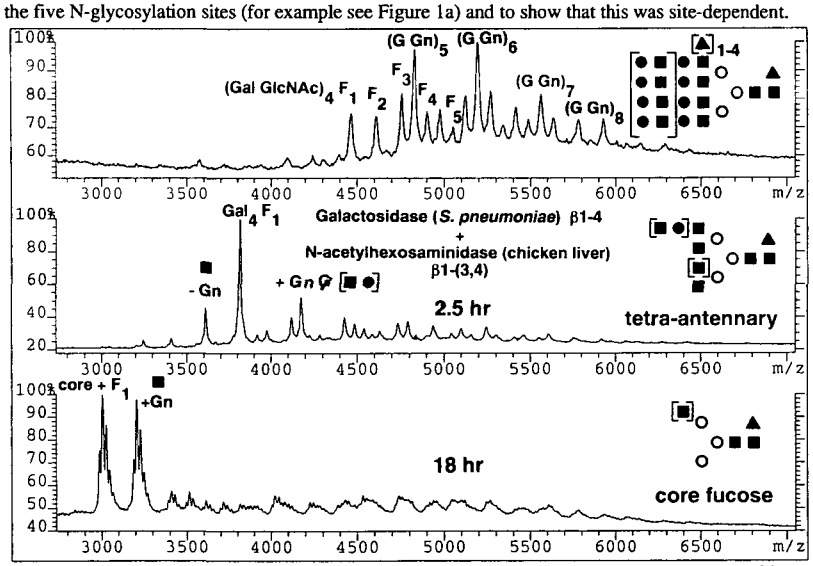

Figure 1. Time-course MALDI-MS of glycosidase treatment of a heterogeneous glycopeptide.

These particular oligosaccharide structures are of interest because they are the ones recognized by E-selectin in the inflammatory process. The natural human blood alpha-1 acid glycoprotein was shown by LC-ESMS to produce small amounts of multiply fucosylated and polylactosamine oligosaccharides, and thus probably has some sialyl-Lewis X constructs *in vivo*.

Through time-course MALDI MS analyses of glycosidase digests (galactosidase and N-acetyl glucosidaminidase) of one of the glycopeptides we were able to establish that the oligosaccharide was predominately tetra-antennary and that all of the other glycoforms possessed a core fucose unit (Figure 1, above). A further question was raised by the fact that two N-acetyl lactosamine units are isobaric with five fucoses (730 Da each). Certain peaks in the mass spectra thus had ambiguous structural assignments. One such spectral peak corresponded numerically either with a $(Gal\text{-}GlcNAc)_6\text{-}Man_3\text{-}GlcNAc_2\text{-}[Fuc]_1$-peptide or with a $(Gal\text{-}GlcNAc)_4\text{-}[Fuc]_5\text{-}Man_3\text{-}GlcNAc_2\text{-}[Fuc]_1$-peptide. This mass was selected for tandem ESMS fragmentation on a triple quadrupole using the new nanospray interface of M. Mann. The results are revealing (Figure 2); there can be no question that there are fucoses on some Gal-GlcNAc moieties (Lewis X constructs). Knowing also that all these oligosaccharides contained a core fucose, one is led to the unusual indication that some N-acetyl lactosamines are doubly fucosylated.

EPITOPE DETERMINATION BY MASS SPECTROMETRY: HIV p24

Kenneth B. Tomer, Damon I. Papac, Carol E. Parker

Laboratory of Molecular Biophysics
National Institute of Environmental Health Sciences
PO Box 12233
Research Triangle Park, NC 27709

Monoclonal antibodies are routinely used in vitro for diagnosis and in vivo for diagnosis and immunotherapy. The presence of specific monoclonal antibodies is also used to screen for the presence of the HIV virus in our nation's blood supply. Knowledge of the epitopes actually being screened for in these diagnostic kits is vital because sequence variations in the antigens being measured could lead to false negative results. This is particulary relevant with the HIV virus because the virus mutates constantly and, thus, avoids recognition by the host immune system.

One method for epitope determination is the proteolytic protection assay [Jemmerson et al , *Science* (**1986**) *232*:1001] in which the relative rates of enzymatic cleavage at specific residues are compared in the absence and presence of the antibody. Cleavages of the antigen occurring at residues involved in the binding with the antibody will occur at a slower rate in the bound state than in solution. Suckau et al. [*Proc. Natl. Acad. Sci. USA* (**1990**) *87*: 9848] incorporated the use of immobilized antibodies and PDMS product identification into this technique. We have recently developed a method to rapidly identify epitopes by using direct MALDI/MS analysis of the affinity bound proteolytic products [Papac et al., *Protein Sci.* (**1994**) *3*:1485]. A significant advantage the proteolytic protection assay has over other rapid approaches to epitope determination is that it is carried out under physiological conditions which permits the identification of conformationally and discontinuous epitopes.

The protein p24 is a core structural protein of the HIV virus It is a major target for antibody response, and antibodies to p24 are some of the first antibodies to appear during HIV infection. We have initiated a project to determine the epitope on recombinant p24 towards several monoclonal antibodies using the proteolytic protection assay combined with the direct analysis of products by MALDI/MS. The first step in this project involved the verification of the structure of several commercially available p24-based recombinant proteins. Several sources proved not to have molecular masses corresponding to the amino acid sequence provided for the sample. An authentic sample, however, was obtained from the NIH AIDS Research Resources Repository (donated by Dr. K. Steimer of Chiron Corp.) The binding of this material to three monoclonal antibodies under physiological conditions was then tested. One antibody did not bind the protein indicating that the antibody might be active towards denatured p24 (Fig. 1a). The other two antibodies did bind p24 (Fig. 1b). A LYS-C digest of the unbound p24 was analyzed by MALDI and all the expected fragments were found. This digest was then compared to a LYS-C digest of p24 affinity bound to a monoclonal antibody. The spectrum of the fragments from a LYS-C digest of p24 still affinity bound to one of the monoclonal antibodies is shown in Fig. 2. The presence of the ion at m/z3447 (L4 + 2H) suggests that the epitope may be discontinuous. These data show that mass spectrometry is useful for the determination of epitopes in their natural configuration.

Probing the protein-ligand interactions by affinity-selected mass spectrometry

Yingming Zhao[1], Ruud Steenvoorden[1], Tom W. Muir[2], Stephen B.H.Kent[2] and Brian T. Chait[1]

[1]The Rockefeller University, 1230 York Avenue, New York, NY 10021, USA

[2]The Scripps Research Institute, La Jolla, CA 92037

Highly specific interactions between biological molecules, often within complex arrays, are critical to many cellular processes such as signal transduction and gene regulation. A comprehensive understanding of these processes requires detailed information about such interactions at the molecular level, in particular, precise identification of the sites of molecular recognition on the protein protagonists.

The interactions between antibodies and antigens can be investigated by affinity-selected mass spectrometry, a method that uses affinity purification in combination with mass spectrometry. The method is demonstrated to be very rapid for the localization of linear epitopes against the monoclonal antibodies[1,2]. The epitope can be quickly located to 10-15 amino acid residue region by proteolytic digestion of antigenic protein and affinity-selected mass spectrometric analysis of the digested products. If required, the antigenic site can be completely defined using the synthesis and mass spectrometric analysis of synthetic peptide ladders covering the region of interest.

We have applied the approach to identified antigenic epitopes of proteins and small peptides with binding affinity between 10^{-6} to 10^{-9}. Affinity-mass spectrometry proves to be an effective technique for assaying the interactions between antibodies and small peptides. The epitopes against anti-bFGF Mab#11.1 and anti-Ad-2 Mab-Dav-1 were accurately defined by the synthesis of ladder peptides and assaying the binding of the peptides to the antibodies by affinity-selected mass spectrometry. The method can also provide relative binding affinity when assaying the interaction between antibodies and peptide ladders. Therefore,affinity-selected mass spectrometry provide an alternative to ELISA (enzyme-linked immunosorbent assay) to detect antigens and assay the interactions between antibodies and antigens.

The method can also be applied to study other molecule-molecule interactions (such as protein-DNA, protein-RNA, receptor-ligand, and protein-protein interactions). For these studies, one of the interaction molecule (Such as DNA, RNA or ligand) is covalently or non-covalently immobilized to solid phase (such as agarose beads). The resulted complex is then used to affinity-purify its binding peptide fragments from proteolytic digestion of its interaction protein. The identities of the binding peptide fragments can be determined by mass spectrometry.

Resonant Excitation of Injected Atomic Ions in an Ion Trap Mass Spectrometer

G. C. Eiden, C. J. Barinaga, and D. W. Koppenaal, Materials and Chemical Sciences Center, Pacific Northwest Laboratory, Richland, WA 99352

Resonant excitation of ion motion in an ion trap mass spectrometer (ITMS) is not a new idea [1,2]. Most previous reports have characterized the resonant absorption profile (loss of observed ion signal versus excitation frequency) with respect to space charge, and the amplitude (V_{ac}) and duration (T) of the excitation pulse. These reports have often focused on (single frequency) resonant excitation to effect collisionally induced dissociation for MS/MS. We report studies of single frequency and broadband resonant excitation applied to selective ion accumulation or ejection in elemental mass spectrometry. We are using the ITMS to sample ions from an inductively coupled plasma (ICP) ion source [3]. ITMS performance degrades rapidly with increasing trapped charge. We have measured the selectivity with which a chosen ion can be ejected from the trap as a function of most of the relevant operating parameters: q_{eject}, total space charge, buffer gas pressure, the amplitude (V_{ac}), duration (T), and frequency of the resonant excitation pulse, and the spectral content (single frequency or broadband) of the excitation waveform. The instrument consists of a commercial ICP ion source coupled to an ITMS [3]. Ions are injected into the ITMS and collisionally trapped and cooled at buffer gas (He) pressures between 0.07 and 0.3 millitorr (measured outside the trap; pressure inside the trap is higher). Dipolar resonant excitation is effected either by the ITMS frequency synthesizer or by a broadband excitation source (HST-1000, Teledyne Hitachi, San Jose, CA). We report results for sample solutions of the systems: Ag, Cd (Cd at 1-10 ppb; the Ag:Cd ratio at 100-1000); Sr, Y, Zr (Sr and Zr at ~1 ppb each; Y at 100 ppb); and Cd neat at 0.1-0.5 ppm. We have focussed on systems in which we resonantly eject an abundant ion at m/z M and measure the loss of ions at M ± 1 amu. This represents a worst case scenario in that resonant excitation of a large ion cloud in the trap will necessarily perturb other trapped ions, especially those closest in m/z to the resonantly excited ions. Real samples will often have matrix ion m/z values much further removed from the m/z of the ions of interest, e.g. analysis of actinides from an argon plasma.

The resonant ejection process has been characterized by variations in the shape of the absorption profile with parameters such as buffer gas pressure, V_{ac}, T, and spectral content of the excitation waveform. We have found that the ejection efficiency increases as the excitation amplitude or duration is increased, as expected [1]. The data presented in this paper give a more detailed view of the dynamics of the ejection process. For example, on the low frequency side of the absorption profile, the increase in ejection efficiency is a bi-linear function of the duration of the excitation pulse (Figure). On the high frequency side of the profile, the signal shows a smoother variation with tickle time. These observations are consistent with the increase in resonant frequency with increasing displacement from the center of a trap with substantial non-linear field components [2], as in the Finnigan Corp. ITMS used here. We have also observed a stronger pressure dependence on the low frequency side of the profile. The profiles broaden dramatically on the low frequency side for changes in pressure of a factor of ~2 (broader at lower pressure). This is due to weaker dampening of the ion motion

by He collisions. Also, at low pressure (0.1 mTorr), the signal versus tickle time curves show the sharp break in slope (and a slope of ~zero at longer tickle times) regardless of excitation frequency. This is in contrast to the data shown in the Figure which was taken at 0.2 mTorr. These and other characteristics of the excitation process, and a more detailed comparison with theory [2], will be addressed in the near future [5].

ION REMEASUREMENT IN THE RF QUADRUPOLE ION TRAP

Douglas E. Goeringer and Scott A. McLuckey
Chemical & Analytical Sciences Division, Oak Ridge National Laboratory

The development of the mass-selective instability mode of operation for the quadrupole ion trap has provided impetus for mass spectrometric applications of the device. In the technique, the amplitude of the confining rf voltage is increased linearly with time causing trajectories of stored ions to become unstable in the axial direction sequentially from low to high mass/charge. Ejected ions are subsequently detected by an external electron multiplier. Thus, the technique is straightforward but also destructive in nature; any further manipulations of the original ion packet are precluded by ion ejection and subsequent collision with the detector surface.

Trapped ions also can be detected by resonance absorption of energy from a supplementary excitation signal, and the varying, differential charge on the trap electrodes induced by resonantly excited, coherent ion motion produces fluctuating image currents detectable in an external circuit. Both of these *in situ* detection techniques have been used extensively in ion cyclotron resonance (ICR) mass spectrometry, although image current detection is now used almost exclusively due to its compatibility with Fourier transform signal processing. However, the first use of *in situ* ion detection in a mass spectrometry experiment was not made within the context of an ICR study but as part of the development of the rf quadrupole or Paul trap. Paul, Fischer, and Rettinghaus used such detection techniques in their early rf ion trap studies. In addition, image current detection and Fourier transform signal processing were later applied to ion trap mass spectrometry by Syka and Fies.

The nondestructive nature of image current detection was initially exploited for multiple remeasurement of ions[1] in FT-ICR mass spectrometry by Williams *et al.* Multiple excitation-detection-relaxation cycles were used to measure the **same** population of gramicidin D (*m/z* 1904) ions. With the remeasurement efficiency reaching up to 98%, signal averaging of spectra from 25 remeasurement cycles yielded a four-fold enhancement in signal-to-noise. The success with multiple remeasurement of ions in FT-ICR, along with the potential advantages of implementing the technique in the quadrupole ion trap, has led us to investigate adapting the method to the device.

We have modified a Teledyne 3DQ quadrupole ion trap mass spectrometer to allow for *in situ* detection and ion remeasurement via image current detection. Figure 1 is a block diagram of the signal processing configuration. A major obstacle to image current detection in the rf quadrupole ion trap, in contrast with the FT-ICR, is the trapping rf signal. This high voltage signal is coupled to the endcaps via the small ring-to-endcap capacitance producing a background signal level typically tens of volts in amplitude. Consequently, connecting the endcaps directly to the inputs of a differential amplifier, as is the normal practice in FT-ICR, is not practicable because the high background voltage overloads the inputs.

1. Williams, E.R.; Henry, K.D.; McLafferty, F.W. *J. Am. Chem. Soc.* **1990**, *112*, 6157-6162.

Thus, a center-tapped transformer was connected across the endcaps to circumvent the rf drive background. Coherent ion motion was induced by applying an excitation signal to the endcaps via the transformer; the excitation signal was tuned to the resonant frequency of the parallel LC circuit formed by the transformer and the endcaps. The signal voltage was generated by the resultant image current flow through the LC impedance. The signal LC circuit was connected to another reference LC circuit in a bridge configuration so that the excitation component of the overall signal could be nulled. Signals due to coherent ion motion were then low-pass filtered (cutoff frequency = 300 kHz) by an FET-preamplifier and processed by a lock-in amplifier which was phase-locked to the excitation signal generator. DC output signals from the lock-in were digitized and displayed by a digital sampling oscilloscope. Multiple image current measurements from a single population of trapped ions were performed by repeatedly ramping the trapping rf voltage. Figure 2 shows the signal corresponding to 24 remeasurement cycles for the m/z 131 ion of PFTBA. Analysis of the signal indicated the remeasurement efficiency was 99%.

Buffer Gas and q_{eject} Effects on the Performance of an Ion Trap

Lammert, S.A., Wells, J.M.
Oak Ridge National Laboratory, P.O. Box 2008, Oak Ridge, TN 37831-6120

The transformation of the ion trap from ion storage device to mass spectrometer was assisted in no small part by the discovery that the addition of a helium buffer gas greatly improved the mass resolution and sensitivity.[1] Ions formed in the ion trap are kinetically cooled to the center of the ion trap by collisions with the helium buffer gas. In the earliest form of the experiment, these ions were then ejected from the trap via a mass instability scan. It was later discovered that the application of a resonant ac voltage could further improve the performance of the ion trap by resonantly ejecting ions as they approached the stability boundary in a process that was named "axial modulation". Until recently, it has been widely held that the ion trap must operate using a helium buffer gas. The development by Bruker-Franzen[2] of the Chemical and Biological Mass Spectrometer (CBMS) and later the Generic Detector (GD) for the US Army has demonstrated that ion traps can be operated without helium, using only air as the buffer gas. Attempts, however, to operate ion traps from Finnigan-MAT using an air buffer gas have not been successful. This research examines the role of the helium buffer gas in an ion trap mass spectrometer and explores the possibility of substituting ambient air as the buffer gas.

The study examines the dependence of resolution and sensitivity on the type (air or helium), pressure, and method of introduction of the buffer gas, as well as on the q_{eject}, the mass, and the sample pressure. It is shown that resolution and intensity depend not only on the pressure of the buffer gas, but also on the q-value used for resonant ejection. Figures 1 and 2 show the results obtained by varying the buffer gas pressure (helium and air, respectively) and the q_{eject}-value on the resolution of m/z 69 from perfluorotributylamine (PFTBA). There is clearly visible in Figure 1, the known resolution valley at a helium buffer gas pressures of ca. 1 millitorr. There is, however a second valley at a q_{eject}-value of ca. 0.85 which shows a significant decrease in peak widths over those obtained at a q_{eject}-value of 0.906 (near the stability boundary). Concurrent with the resolution improvement (but not shown in this abstract) is an increased signal intensity (although the total peak area remains relatively unchanged). Figure 2 demonstrates that by substituting air for helium, similar resolution performance can be obtained although the optimum region of the pressure and q_{eject}-value minimum is much narrower. Signal intensities using both buffer gases were determined using krypton as the sample in order to ensure that the measured mass ion intensities were the result only of ion storage and not skewed to low mass by collisions with the larger air buffer target mass. It was observed that a 50% reduction in signal intensity for m/z 84 from krypton was obtained when substituting air for helium. At higher sample pressures as well as for masses > 200 da., both the improvement in resolution using helium at a q_{eject}-value of 0.85, and the ability to substitute air for helium without performance degradation is diminished.

Effect of Ion Population Upon MS/MS Parameters in a Quadrupole Ion Trap Mass Spectrometer

Timothy P. Griffin, Richard A. Yost
University of Florida, Department of Chemistry
Gainesville, FL 32711

Ion frequencies have been observed to change with ion population [1] in the quadrupole ion trap mass spectrometer which has an effect upon single frequency collision-induced dissociation and isolation techniques that employ the use of frequencies. The shifting of the ion frequencies for varying ion populations have made it impossible to accurately predict the ion frequency for a specific set of a_z, q_z (DC, RF voltage) values, thus making it difficult to use an ion trap for routine GC/MS/MS. The interdependence of ion frequency and ion population makes it difficult to know the actual frequency of the ions without performing extensive, time-consuming experiments. Therefore, further studies examining the effect that the storage parameters have upon the ion frequency need to be performed.

These experiments focused on examining the ion frequency for different q_z values along the a_z=0.00 line. To perform these experiments a modified Finnigan MAT ITS-40 quadrupole ion trap mass spectrometer with both software to write custom scan functions (MS/MS) and an instrument-controlled frequency synthesizer have been developed in our laboratory and used for all experiments. In addition, the software enable the automatic acquisition of profile data. The $C_4H_8^+$ ion (m/z 56) from butanol was used as an ion probe and introduced into the manifold via a Graville-Phillips valve to give an uncorrected gauge reading of 4×10^{-7}torr. Helium was introduced through a modified transfer line to give an uncorrected gauge reading of 5×10^{-5} torr. The frequency of the ion motion was determined by use of the scan function depicted in Figure 1 As can be seen, the q_z value (RF voltage) is changed only during the time that the auxiliary frequency is to be applied. In addition, to minimize ionization and storage effects constant ion populations were used instead of constant ionization times.

The effect of q_z and ion population upon the ion frequency can is shown in Figure 2. The solid line in the figure denotes the theoretically predicted frequencies. Ion populations of 1, 5, and 30 thousand counts were examined. Notice that the frequencies deviate from the theoretically predicted values by a larger amount than the deviations due to differences in ion population. In addition, the frequencies deviate more at larger q_z values. The frequency shifts have been theorized to be due to an effective DC voltage being induced upon the ion cloud. This affectively causes the a_z value to move or shift away from the theoretical values. The shifting of the a_z for different ion populations and at different q_z values is shown in Figure 3. The experiment again used ion populations of 1, 5, and 30 thousand counts. It is interesting to note that as the q_z value increases the deviation of the a_z value away from zero increases. The deviations of the a_z value from zero is markedly larger than that observed for the varying ion populations.

Fragmentation of Peptides by NanoES/Quadrupole Ion Storage (QUISTOR) MS

Roman Körner, Kenneth Morand, Matthias Wilm and Matthias Mann
Protein & Peptide Group – European Molecular Biology Laboratory
Meyerhofstr. 1, D-69012 Heidelberg, Germany

We have developed a nano electrospray (NanoES)/ion trap combination to allow long measurement times (>30minutes) on only 1µl of peptide solution. The long measurement time offers the possibility of time consuming experiments like MS/MS/MS and sequencing experiments on low amounts of digest mixtures .

The NanoES source features a finely drawn gold coated capillary, placed 1 to 2mm in front of the orifice (ref. 1,ref. 2). A differential pumped Analytica interface (Analytica of Branford, Inc.) transfers the ions to the ion trap (prototype of Esquire, Bruker-Franzen Analytic GmbH). Due to the short distance between the ion source and the orifice and the small size of the produced droplets it was possible to reduce the diameter of the orifice from 500µm (Analytica ES source) to 200µm resulting in an advantageous decrease of all pressures to about half the previous values.

On the ion trap it is difficult to obtain complete sequence information from a single collision induced MS/MS experiment.Firstly the internal energy of resonantly activated ions increases slowly via multiple collisions with He resulting in a cleavage of the weakest bonds of the ion before the internal energy for high energetic pathways is reached. MS/MS/MS can be helpful because less low energetic pathways are available for the second fragmentation .

The second reason is that to generate a sufficiently deep potential well for the fragmentation it is necessary to increase the RF amplitude resulting in the loss of fragment ions having masses below about one third of the parent ion mass. However,a subsequent fragmentation of a small fragment in a MS/MS/MS experiment often generates additional low mass fragments.

In the MS/MS/MS experiments the first fragmentation was performed in the interface region by increasing the potential difference between nozzle and skimmer. Stored Waveform Inverse Fourier Transformation (SWIFT, ref. 3) voltage pulses were applied during the injection time to accumulate a selected fragment in high intensity and good isolation in the trap for the resonance fragmentation.

As a model case the synthetic peptide HSIAGPPVPPR was fragmented. Due to the preferential cleavage on the N-terminal side of a proline the corresponding C-terminal peaks were not visible in the MS/MS spectrum, but the peptide could be sequenced completely by MS/MS/MS.

To examine the use of the ion trap for sequencing on peptide mixtures a tryptic digest of Cytochrome C was analyzed. A direct analysis of the digest yielded a sequence coverage of 64% (fig.1). This sequence coverage could be improved to 92% by selective storage of ions from approximately 150 Dalton broad mass windows using SWIFT pulses during the injection time. The ejection of ions outside this mass range permits increased accumulation of the required ions before space charge begins to negatively affect the spectrum. This leads to increased sensitivity. As an example fig. 2 shows that in the SWIFT selected mass range from 380 to 500 Dalton five additional tryptic peptides could be detected. The peptide (K73 K79)2+ was fragmented. A partial sequence of three amino acids could be determined from this MS/MS spectrum (fig. 3). Also in this case the peptide could be sequenced completely by MS/MS/MS (fig. 4) .

Peptide Sequencing Using Fast MS and MS/MS Scan Rates on a *uLC*/Quadrupole Ion Trap

Mark E. Bier*, Jae C. Schwartz, Joe Zhou, John E. P. Syka,
Dennis Taylor, Adrian P. Land, Mike James, and Bill Fies
Finnigan Corporation, 355 River Oaks Parkway, San Jose, CA 95134-1991

The quadrupole ion trap mass spectrometer may be operated at fast scan rates. The scan rate refers to the speed at which an amu is scanned out of the ion trap (amu/sec). Scan rates were first increased during the development of the prescan for variable ionization times. Years later at Purdue, the scan rate was increased by resonantly ejecting ions at a lower q_{ej}. (mass range extension) while maintaining the same Rf-amplitude scan rate . Fast scan rates can greatly improve detection limits because the ion current density over time is increased (i e. the signal height is increased), and the resulting shorter scan function allows for improved signal averaging.

Typically, the scan rate for ion trap mass spectrometers has been set at 5555-amu/sec (1X). In these experiments scan rates up to 177,778-amu/s, 32X the normal scan rate, have been tried, but we have primarily scanned at 16X the normal scan rate or less due to a data system limitation of the acquisition digital signal processor(DSP). In fact, to achieve these speeds the sampling rate was reduced from 10 at 1X to 4, 2, and 1 sample(s)/amu for the scan rate multipliers 4X, 8X, and 16X, respectively. The digital filter has been turned off at these higher scan rates to increase the bandpass. The q_{eject} was kept fixed at 0.83 for all scan speeds. A separate mass calibration file which included calibrated resonance ejection parameters was determined and loaded for each different scan rate. Initial investigations showed that a scan rate 16X the normal rate (i.e. 88880 Da/s) resulted in a resolution (m/Δm) reduction from 1100 to 250 at m/z=524.3 from MRFA and a signal height increase of *ca.* 6X. In one experiment it was possible to acquire 9 uscans at 16X the normal scan rate in the same time it would take to acquire 1 uscan at the normal scan rate from mass 80-1350 Da. In this case, the theoretical S/N ratio increases by 18 times over the normal scan rate data given there is no chemical noise. Chemical noise, however, will also increase in peak height with fast scan rates and will limit the S/N improvement to 3 times without background subtraction. Mass assignments at the faster rates, were found to be within an average of ca. ± 0.3 Da. Observations showed that there were reduced effects of space charge at higher scan rates. This suggests that a faster Rf scan rate allows for a larger number of ions to be ejected from the trap without causing a mass assignment increase.

Using capillary-LC(100um id x 15cm, POROS 10 R2 packing)(See Figure **1**), the low mass resolution MS/MS approach to peptide sequencing used by Hunt and coworkers at the University of Virginia, and fast Rf scan rates on a quadrupole ion trap we analyzed a mixture of five angiotensins: RVYVHPI, RVYVHPF, RVYIHPF, DRVYVHPFHL, and DRVYIHPFHL (Michrom Corp.). Both the MS (Figure **2**) and MS/MS scans were acquired to demonstrate the S/N enhancement. Background subtraction was also used to reduce the effects of chemical noise. Figure **3** shows the MS/MS spectrum of m/z 442.3^{+2} from RVYVHPI. We were able to acquire enhanced S/N spectra and make peptide fragment assignments at the 500 attomole level, however, unresolved adjacent mass peaks were given two fragment assignments. The (*) at m/z 385 in Figure **3** is believed to be a product ion from a coeluting parent.

Rapid scanning is limited by the acquisition rate of the processor, the degree of acceptable loss in mass resolution, the reduced S/N enhancement over slower rates as the duty cycle increases (i.e.

long ion times), and long scan functions such as MS^n that increases the time in which you are not looking at ions. The advantages of rapid scanning are: peaks have greater heights above non-chemical noise, signal averaging is improved, and space charge effects are reduced.

Practical Matrix-Assisted Laser Desorption/ Ionization Ion Trap Mass Spectrometry of Peptides

Jun Qin and Brian T. Chait
The Rockefeller University 1230 York Ave. New York NY 10021

Recent improvements in our understanding of the operation of the ion trap with an external matrix-assisted laser desorption/ ionization (MALDI) source have led to significant improvements in our ability to analyze peptides [J. Qin & B. T. Chait, paper in preparation]. A new excitation scheme [J. Qin & B. T. Chait, see companion paper at this conference.] allows for efficient collision-induced dissociation of peptide ions with m/z up to 3500. As a result of these improvements, MALDI/ITMS has become, in our laboratory, a routine and effective means for the sensitive characterization of proteins. We summarize here the performance of our MALDI/ITMS instrument and demonstrates its practicality through applications to a series of challenging biological problems.

The useful mass range (m/z) for peptides is up to 8 kDa. The resolution is both mass dependent and mass extension ratio dependent. For mass extension ratio of 10-15, the peak with (FWHM) is 2-5 Da for m/z < 3,500 and 5-7 Da for 3,500 < m/z < 8,000. Above m/z 8,000, the resolution deteriorates markedly. Single components as well as complex peptide mixtures (e.g. enzymatic digests; peptide ladders) can be mass analyzed with subpicomol sensitivity. Such mixtures can be readily analyzed without prior chromatographic separation. A mass accuracy of better than 200 ppm is routinely achieved with a simple three point external calibration over the whole mass range of interest.

MS/MS and sometimes MS/MS/MS can be performed with comparable sensitivity to single stage MS. Mass isolation is better than 3-5 Da for m/z < 3,000. MS/MS spectra (yielding useful sequence information) can be routinely obtained for all of the major proteolytic peptide fragments in a complex mixture without prior chromatographic separation using a loading of 0.5 pmol per component on the mass spectrometer probe. Such analysis was carried out for four different enzymatic digestions of E. Coli RecA protein (38 kDa).

In addition to its use as a sensitive tool for protein characterization, we have applied MALDI/ITMS to the identification of post-translational modifications, and have found the technique to be extremely useful for disulfide mapping and for the analysis of glycosylation and phosphorylation.

Inter-chain disulfide bonds dissociate spontaneously when disulfide-containing peptide ions are trapped. For a disulfide linked peptide composed of n (n >2) chains, a series of peptide ions containing n-i (i = 1, 2,..... n-1) disulfide bonds are observed in the positive ion spectra. In essence, this specific dissociation is equivalent to a controlled partial reduction of the disulfide bonds. This observation allows the disulfide connectivity to be defined. In disulfide mapping, intramolecular disulfide bonds are converted to interchain disulfide bonds by enzymatic or chemical cleavage of the peptide bonds between the cysteine residues. The unfractionated digestion is analyzed, and the disulfide linkages are determined. We have tested the strategy with synthetic C- terminal EGF-like domain in human blood coagulation factor XI, Iberiotoxin and αTGF. In addition, we have determined the disulfide linkages in earth worm hemoglobin linker chain L1(28 k Da), which contains a cystein-rich domain that has identical cysteine distribution pattern as that in the cystein-rich domain in the human LDL receptor.

In the ion trap, glycopeptides dissociate preferentially at the glycosidic bonds with charge retention on the peptide. These fragments allow a direct read-out of the composition (and sequence and branching in favorable cases) of the carbohydrate moiety. We have tested this strategy with synthetic glycopeptides and we have determined the sugar composition or sequence in some natural glycopeptides.

In the positive ion mode, we have observed that phosphopeptides lose ~ 98 Da upon trapping, providing an extremely convenient signature for phosphopeptides. Phosphoserine and phosphotyrosine are susceptible to this loss. Multiply phosphorylated peptides lose ~ 98 Da consecutively so that number of phosphate can be directly measured by the number of consecutive 98 Da losses. To determine the phosphorylation site within an enzymatic fragment(e.g., a tryptic fragment), the phosphoprotein is digested with the enzyme, then a peptide map is obtained by ITMS. The phosphopeptide is identified by the accurately measured mass, and further confirmed by the occurrence of ~ 98 Da loss. This method was tested with bovine β casein (23 k Da), a phosphoprotein containing 5 phosphates. We have determined the phosphorylation sites for bovine Synapsin I(74 k Da) as a substrate for the MAP kinase and CDC2 kinase (both are serine kinases). We have also determined the phosphorylation site for mouse lck (50 kDa) as a substrate for csk (a tyrosine kinase). In favorable cases, phosphorylation site can be determined to one amino acid by MS/MS if the phosphopeptide contains less than 15 amino acids. This capacity has been demonstrated with synthetic phosphopeptides.

In summary, we have developed a practical MALDI- ITMS instrument that can be used for the sensitive characterization of protein primary structures.

Analyzing Mixtures With a Hybrid Quadrupole/Ion Trap Mass Spectrometer

Karen R. Jonscher and John R. Yates, III
Dept. of Molecular Biotechnology, University of Washington, Seattle, WA 98195

Introduction: Tandem mass spectrometry has proven to be a versatile technique extending the mass spectrometry experiment to provide structural information for a number of different types of molecules. In this work we describe the construction of a hybrid quadrupole mass filter/quadrupole ion trap mass spectrometer interfaced to electron impact (EI), pulsed Cs^+ (LSIMS) and an electrospray ionization source (ESI) modified to incorporate a heated capillary. The goal of this work was to design a versatile instrument capable of analyzing complex mixtures of molecules.

Experimental: A quadrupole mass filter (mass range of 4,000 *m/z*), a focusing lens, a quadrupole ion trap mass spectrometer and a 20 kV collision dynode with an off-axis electron multiplier were aligned on a optical rail in the low pressure (~ 10^{-6}) region of a differentially pumped vacuum manifold. Operation of the ion trap was controlled by a PC interfaced to the ITMS™ (Finnigan MAT) electronics and operation of the quadrupole and vacuum system were controlled by a DECStation 2100 interfaced to a TSQ70 (Finnigan MAT). The mass analyzers were synchronized by triggering operation of the ion trap at the beginning of the quadrupole scan. The quadrupole was stepped through a given mass range in, typically, 10 u wide mass bins,and a scan window of 10 u was set in each mass bin. After triggering, the ITMS™ collected ions then a mass spectrum was acquired by resonant ejection at extended mass range. Data was displayed on a PC then ported to the DECStation 2100 for acquisition and data manipulation. Data porting time was on the order of 400 msec. The ITMS™ scan acquisition processor (SAP) board will not execute further instructions until the data porting is complete hence the duty cycle for the instrument is determined by the data porting time rather than by the ITMS™ scan time of ~ 120 - 220 msec. The minimum scan time for the quadrupole to scan in each mass bin was experimentally determined to be 0.57 sec, thus experiment scan times were typically on the order of 30 - 90 seconds to scan the quadrupole over a given mass range.

Results: Space-charge in the ion trap may limit the signal quality of ions present at low abundance in a mixture or in a matrix. Figure 1 provides an example of how the addition of the quadrupole mass filter, when scanned in small windows, significantly reduces space charge effects. Approximately 3 pmol of Glu-fibrinopeptide (MW 1571 u) were co-deposited onto a gold-plated probe tip with 1:1 glycerol:monothioglycerol and ionized by bombardment with 6 keV Cs^+ ions. Figure 1a shows suppression of the peptide in rf-only mode when all of the ions are being transmitted, while Figure 1b shows the reduction in space-charge effects obtained by scanning the quadrupole from 1450 *m/z* to 1650 *m/z*.

Electrospray ionization may be used to obtain LC-MS and LC-MS/MS information. Preliminary results are shown in Figures 2 and 3. Figure 2 illustrates the ion chromatograms resulting from electrospraying a mixture of angiotensin I (MW 1296 u) and ACTH 18-39 (MW 2466 u). Spectra obtained by summing scans under the peaks show excellent signal-to-noise obtained as well as some fragmentation upon injection into the ion trap. Figure 3 demonstrates the ability of this instrument to obtain fragmentation information "on-the-fly" for angiotensin I $(M+3H)^{+3}$. The capillary voltage is raised to promote source activation and the trap float voltage is decreased to increase the relative kinetic energy of the ions. Sufficient sequence information is obtained from the fragments to deduce the amino acid sequence for this peptide.

Conclusion: The hybrid instrument described in this work shows promise as a tool for the analysis of mixtures of molecules. The data porting time limiting the duty cycle may be eliminated by modification of the TSQ70 electronics to permit signal acquisition directly to the DECStation by way of the TSQ70 electrometer, bypassing the ITMS™ electronics. "On-the-fly" fragmentation may allow sequence information to be obtained for all ions in a mixture, reducing data loss due to co-elution during LC-MS.

A Portable Atmospheric Sampling QUISTOR/reTOF- MS for Air Monitoring

Louis I. Grace, David M. Chambers, Stan W. Thomas and Brian D.Andresen

University of California Lawrence Livermore National Lab. P.O. Box 808, Livermore, California 94551

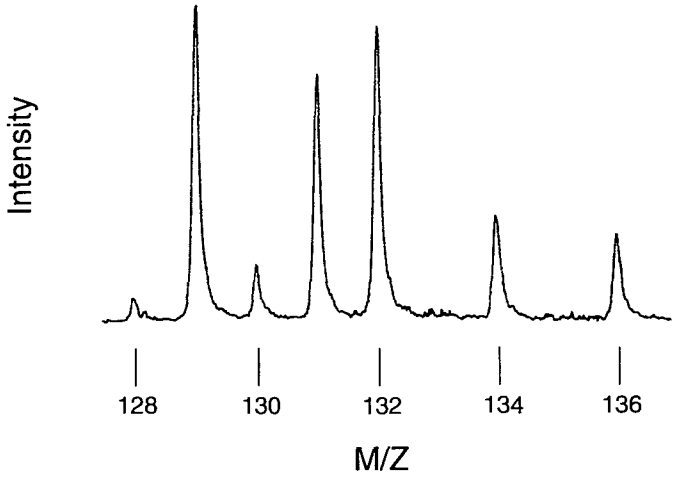
We are developing a portable mass spectrometer to detect volatile organic compounds in air. Given sufficiently low detection limits and high mass resolution, such an instrument will be useful in a wide array of air monitoring applications, for example, pollutant detection or plant maintenance and diagnostics. We chose a time-of-flight analyzer for its efficient ion transmission with virtually unlimited mass range. We use a quadrupole ion storage trap to create a pulsed source to provide a reference for ion flight times. Through its ion storage capability, the ion trap also lowers detection limits, enhances sensitivity and increases the duty cycle of the instrument. The flight tube houses a reflectron, which improves mass resolution by partially compensating for the kinetic energy spread of the ions. The ion trap is coupled to the flight tube via an einzel lens. An important feature of the new instrument is that the air sample is introduced directly. This eliminates the need for vacuum interlocks and various hardware associated with other types of sample inlet. Such a sampling system also reduces contact between the analyte and surfaces inside the instrument, thus greatly decreasing the loss of sample through adsorption onto the walls of the inlet, or through catalytic decomposition arising from such adsorption.

To aid the design of the portable instrument, we tested various features in a larger laboratory instrument. Based on these tests, we have chosen to use electron impact to ionize the sample. Also, we have designed an inlet which introduces the sample directly into the ion trap, so that the ions are formed within the trap instead of being injected externally. This may reduce the initial kinetic energy spread of the ions, and it offers lower detection limits. The various ion optics were modeled by means of the SIMION program and tested on the laboratory instrument. Then similar optics were designed for the portable instrument. To make the spectrometer portable, we have shortened the flight tube from 32in to 18in, and have made the ion trap envelope smaller.

For volatile organic compounds, the laboratory spectrometer has shown detection limits in the low to sub-ppb range (v/v) with mass resolution of 2000 or better (M/dM, FWHM). We are still making refinements to, and optimizing the tuning of, the portable instrument. At this point, the portable instrument shows detection limits of approximately 500ppb for a variety of volatile organic compounds. The mass resolution it achieves is routinely 1000 or better, and is often as high as 1250. The xenon spectrum in the accompanying figure is an example of the kind of data the new instrument yields. This spectrum shows a resolution of about 1000.

Xenon in Air

M/ΔM (FWHM) ≈ 1000, 100-ms ion accumulation time, average of 200 scans



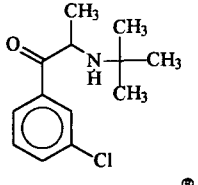
We find the performance of the portable instrument encouraging. Given the instrument's current capabilities, and based on our experience with the laboratory prototype, we expect to extend the detection limits of the new instrument into the part-per-trillion range and possibly also to improve the mass resolution.

This work was performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under contract W-7405-ENG-48.

IDENTIFICATION OF *IN VITRO* METABOLITES OF BUPROPION BY APCI LC-MS USING AN ION TRAP MASS SPECTROMETER.

Lester C.E. Taylor, Romi Singh, Sai Y. Chang, Robert L Johnson, Jae Schwartz‡.
Burroughs Wellcome Co , 3030 Cornwallis Road, R T P , NC 27709
‡Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

The drug bupropion (Wellbutrin®), Figure 1, *m*-chloro-a-*tert*-butyl-aminopropiophenone, shows activity as an anti-depressant (1) As part of continuing drug metabolism and structural characterization studies we have undertaken a series of mass experiments aimed at identifying the *in vitro* metabolites of bupropion



BUPROPION (WELLBUTRIN ®)

Mass spectrometry using atmospheric pressure ionization combined with triple quadrupole instruments has proven highly effective for identifying and quantitating drugs and drug metabolites in biological matrices such as plasma, urine and bile We report the use of APCI LC-MS for the identification of *in vitro* metabolites of bupropion using a quadrupole ion trap instrument fitted with an external atmospheric pressure ionization (API) source Preliminary experiments have shown that this instrument provides comparable sensitivity to conventional triple quadrupole instruments for metabolite identification while allowing further specificity for structural analysis by MS^n and is suitable for on-line coupling with HPLC

Ion Trap LC-MS

The quadrupole ion trap LC-MS system consisted of a Hewlett Packard HP1090 LC system using a Novapak C18 column. The column eluent was couple directly to a Finnigan APCI source operating at a nebulizer temperature of 500 °C, corona needle potential of approximately 4 kV A heated capillary interface to the mass spectrometer vacuum system was utilized operating at a capillary temperature of 150 oC and at a voltage of approximately 10 volts A linear gradient was run from 90% A to 60% A, where solvent A was a 50 mM ammonium acetate aqueous solution and solvent B was acetonitrile using a flow rate of 1 ml/min

The ion trap used for these studies was a prototype system configured especially for LC-MS applications. The ions exit the heated capillary and pass through a skimmer and are transferred by an RF only octopole which operates at a pressure of 1.3 x 10-3 torr through a 0.1 inch aperture lens into a second RF only octopole operating at a pressure of 2 x 10-5 torr This octopole transmits the ions into the ion trap through a 0 60 inch aperture in the entrance end cap of the ion trap The ion trap contains helium damping gas at a pressure of approximately 1 mtorr in order to trap injected ions and improve general performance of the trap The main components of the ion trap scan function consisted of ion injection times of between 5 to 1000 msec, single isolation using multifrequency waveforms applied for 15 msec per MS/MS stage, and spectrum generation using the mass selective instability mode with resonance ejection at a scan rate of 0 180 msec/amu. Total cycle times reached 1 5 sec/scan for MS^6 experiments The mass range of the ion trap is 2000 m/z and operates at a frequency of 760 kHz. A 15 kV conversion dynode along with a channeltron electron multiplier was utilized for optimum detection efficiency Being an early prototype, this system had several instrumental problems including a noisy dynode and some electronic instability which limited instrument performance for these studies

Results

We have followed the fragmentation pathways of several molecular ion species in a series of sequential $LC\text{-}MS^n$ experiments, extending as far as MS^6 with scan cycle times of less than 1 5 s Such experiments have provided insights into the structure of specific fragment ions. Bupropion was characterized in a series of MS^n experiments which established the fragmentation cascade of the parent compound This established the MS^6 pathway,(shown in Figure 1), MH^+ 240 to 184 to 166 to 131 to 130 to 103 The LC-MS analysis of human S9 incubation showed the presence of three isomeric monohydroxylated metabolites of bupropion These were further characterized in a series of MS/MS experiments which gave characteristic spectra for the three isomers. A minor dihydroxylated species (both hydroxyl groups located on the tertiary butyl group) was also identified in the human S9 sample and further characterized in a series of MS^n experiments Detailed structural information was generated by the use of on-line $LC\text{-}MS^n$ type experiments Additional metabolic products were identified in the rat liver microsome incubation sample

ANALYTICAL PROTOCOLS FOR ENVIRONMENTAL SUBSTANCES USING AN ION TRAP

J.B. Plomley, C.J. Koester, M. Lausevic, X. Jiang, F.A. Londry and R.E. March
Trent University, Department of chemistry, Peterborough, ON, Canada, K9J 7B8

The powerful capability of a capillary column for gas chromatographic separation of volatile organic compounds, complemented by the versatility of a mass-selective quadrupole ion trap detector operated in the tandem mass spectrometric mode, has been directed to the detection and identification of a variety of environmental pollutants. This GC/MS/MS combination with a choice of electron impact and chemical ionization offers both high sensitivity and high specificity. In order to establish an analytical protocol utilizing GC/MS/MS, it is necessary to ascertain ionization energies, proton affinities and the activation energy hierarchy of dissociation channels. With this information, one can then customize a scan function or functions wherein a molecular ion, protonated molecule or reagent ion is formed, stored preferentially, isolated, reacted, collisionally dissociated[1] and the fragment ions mass-analyzed.

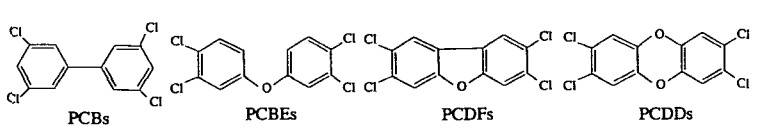
Instrument

The instrument used in this study was a modified Varian Saturn III GC/QISMS (Quadrupole Ion Storage Mass Spectrometer) equipped with a Varian waveform generator and a Varian 8200 autosampler. Saturn Revision C software was used for data acquisition; Saturn version 5.0 software was used to define GC retention-time windows while "Toolkit" was used to define ion preparation methods (or customized scan functions) for individual retention-time windows. The waveform generator could be employed during and after ionization.

Within a single GC run, a series of customized scan functions can be synchronized with retention time so as to determine the concentrations of many compounds in rapid succession. A modified Saturn I instrument was used for high mass-resolution studies.[2,3]

ANALYTICAL PROTOCOLS

A major effort in this laboratory is being directed to the establishment of analytical protocols for the determination of PCBs, PCBEs, PCDFs and PCDDs, for a total of 628 isomers not counting ^{13}C- and D-labelled compounds used as standards.



These compounds exhibit a range of toxicity from 1 - 10^{-13}. Toxicity correlates highly with both chlorine substitution and the absence of chlorine substitution in the *ortho* positions. The advent of the waveform generator, the development of software for multiple

43rd ASMS Conference on Mass Spectrometry and Allied Topics

scan functions, the loss of Cl and/or COCl upon dissociation and little variation of activation energies for dissociation among isomers combine to make us quite optimistic about the final outcome of this project.

Polychlorinated biphenyls (PCBs)

Two analytical protocols are being developed for PCB analysis; one is based on electron ionization (EI), the other on selected ion chemical ionization (SICI). The first protocol applies the EI method to congener-specific analysis using a customized scan function; the method is based on the difference between the fragmentation patterns of the highly toxic *(non* and *mono-ortho substituted)* congeners and those of the less toxic congeners.[4]

The second protocol applies the SICI method, using $C_2H_5^+$ reagent ions,[5] for the determination of total PCB content in a mixture and for differentiating between co-eluting congeners.

Polychlorinated biphenylethers (PCBEs)

The analytical protocol for PCBEs, which is under development, is based on the difference in fragmentation behaviour of *non* and *mono-ortho substituted* congeners and other congeners. All PCBEs exhibit loss of a chlorine atom from the molecular ion; *non* and *mono-ortho substituted* congeners exhibit also a characteristic loss of COCl.

Polychlorinated dibenzo-*p*-dioxins (PCDDs) and furans (PCDFs)

The analytical protocol for PCDDs[6] and PCDFs is now well developed. In this protocol, molecular ions formed by EI are isolated, dissociated resonantly, and daughter ions formed by the charateristic loss of COCl are mass analyzed. For a given degree of chlorine substitution, the apparent similarity of activation energy for loss of COCl among isomers is particularly fortunate given the complexity of rearrangement necessary. Switching of multiple scan functions permits determination of co-eluting dioxins, furans and their ^{13}C-isotopomers.

Time-of-Flight (TOF) Mass Spectrometry–Nearing the Half Century

K.G. Standing
Physics Dept., University of Manitoba,Winnipeg, MB Canada, R3T 2N2

It appears that the first published proposal for a TOF mass spectrometer was made by W.E. Stephens, a nuclear physicist at the University of Pennsylvania. The proposal was presented at a meeting of the American Physical Society in April 1946 [1], so it was probably submitted late in 1945; Fig. 1 shows the abstract. Thus we are about to celebrate the 50th anniversary of TOF mass spectrometry. In the present conference almost 10% of the presentations included TOF or TOF mass spectrometry in their keywords, so we may conclude that the field is flourishing. This is a pleasant contrast to the situation not too many years ago, when the TOF contingent at the ASMS meeting would have fit into a good-sized closet!

A few years passed before Stephens was able to report any measurements [2], and these showed "a peak width of two mass units at mass 40"-- not an impressive resolution compared to the values already obtained in sector instruments, but the spectrometer was expected to have other advantages, as pointed out in his abstract. Stephens' machine produced ions by a *pulsed* electron beam, then accelerated them across a *constant* potential difference, so it serves as the prototype for modern instruments using a simple DC accelerating voltage.

Soon afterwards Wiley and McLaren introduced a two-field source [3]. In their instrument, ions were produced in a field-free region, extracted by an accelerating *pulse*, then further accelerated across a constant potential difference. This was the basis of the Bendix TOF spectrometer, which dominated the field for many years. Wiley and McLaren gave a careful analysis of pulsed operation, including the effect of pulse delay, and their work still provides the foundation for instruments that employ pulsed extraction. They claimed a number of advantages for TOF spectrometers, including speed, ability to record the whole spectrum without scanning, and the absence of narrow slits. However, it is interesting to note that they did not mention the large m/z range of the instrument, a reflection of the inability of any existing technique to produce ions of high mass.

The first solution to the problem of producing large ions for TOF measurements was the dramatic discovery by Macfarlane and Torgerson that such ions could be desorbed from a solid surface by fission fragment bombardment [4]. In addition to a significant extension of mass range, their instrument introduced other important features; the ions were desorbed from a plane equipotential surface, thus providing small spatial dispersion, and modern (nsec) electronics were used, together with simple DC acceleration, which minimized stability problems. This was the basis for much of the TOF work in the next 10 or 15 years.

At the same time there were considerable improvements in TOF resolution as a result of the widespread adoption of various reflecting geometries, first proposed by Mamyrin [5]. A number of groups have reported values of $M/\Delta M_{FWHM}$>10,000 for simple inorganic compounds.

An even higher mass range became available with the discovery of matrix-assisted laser desorption/ionization (MALDI), the dominant TOF technique at present. Karas and Hillenkamp showed that the addition of a suitable organic matrix (initially nicotinic acid) to the sample made it possible to produce ions from a wide variety of biomolecules of masses up to 100,000 u and beyond with relative ease [6]. Since the lasers used are pulsed, the marriage with DC acceleration TOF is a natural one.

Electrospray ionization, the other new method for producing ions from high mass compounds, has only recently been coupled to TOF spectrometers, initially by Dodonov *et al* [7]. ESI/TOF instruments have a much larger m/z range than the quadrupole mass filters normally used with ESI, so they are particularly useful for examining interesting entities like non-covalent complexes [8]. They are also capable of giving spectra with considerably improved resolution, as illustrated by the spectrum of bovine insulin shown in Fig. 2.

Since ESI is a continuous method of ion production, it requires pulsed injection, so the ideas of Wiley and McLaren have acquired new relevance. If ES ions enter the spectrometer perpendicular to its axis ("orthogonal injection") [7], they can then be injected along a suitable flight path. It has recently been realized that pulsed methods can also give improved results for MALDI [8].

J1. A Pulsed Mass Spectrometer with Time Dispersion. W. E. STEPHENS, *University of Pennsylvania.*—Advances in electronics seem to make practical a type of mass spectrometer in which microsecond pulses of ions are selected every millisecond from an ordinary low voltage ion source. In travelling down the vacuum tube, ions of different M/e have different velocities and consequently separate into groups spread out in space. If the ions are collected in a fixed Faraday cage and the current amplified, then pulses of current corresponding to different ion M/e will be dispersed in time. If the amplified current pulses are put on the vertical plates of an oscillograph whose sweep is synchronized with the pulses, then an M/e spectrum of the ions will be exhibited. This type of mass spectrometer should offer many advantages over present types. The response time should be limited only by the repetition rate (milliseconds). The indication would be continuous and visual and easily photographed. Magnets and stabilization equipment would be eliminated. Resolution would not be limited by smallness of slits or alignment. Such a mass spectrometer should be well suited for gas composition control, rapid analysis, and portable use. A mass spectrometer of this type is being constructed

Organic Secondary Ion Imaging by Time-of-Flight Secondary Ion MS (TOF-SIMS)

Patricia M. Lindley[1] & Fraser Reich[2]

1. Charles Evans & Associates, 301 Chesapeake Dr., Redwood City, CA 94063
2. PHI Evans, 575 Chesapeake Dr. Redwood City, CA 94063

Time-of-Flight Secondary Ion Mass Spectrometry (TOF-SIMS) has now evolved to a state where commercial instrumentation is being used successfully in industries throughout the world for a variety of research and development projects, and also for powerful trouble-shooting of materials processing problems

In TOF-SIMS a pulsed, microfocused primary ion beam is scanned over a sample surface, generating secondary ions that are characteristic of that surface These secondary ions are created from the top few monolayers and are then extracted into a TOF spectrometer, where their masses are determined by precise measurment of their flight times to the detector. The resulting mass spectrum, however, is merely the starting point for the technique. The detector output is synchronized with the primary beam raster, so that secondary ion images may be obtained. Pulsed primary beams with probe sizes of 1000Å have recently been obtained using liquid metal ion guns (LMIG) While the experiment is running, the intensity of particular peaks in the mass spectrum may be monitored as a function of experiment time, and thus a 'time evolution of species' may also be obtained from the sample. Finally, secondary ion yields may be monitored as a function of depth for certain materials (inorganic), by sputter removal of material to reveal buried structures below the outer surface.

Although TOF-SIMS is capable of analyzing all vacuum-compatible solids, it is unique in its ability to characterize and image organic materials surfaces. This is due to the extremely high transmission and parallel detection capabilities of the TOF spectrometer Optimum use is made of the ionized material produced from the sample surface (>80% molecular ions created are transmitted to the detector), and a mass spectrum plus a full suite of secondary ion images may be acquired simultaneously before the top monolayer of material is consumed. This is extremely important for organic material analysis, since primary ion bombardment beyond this regime (known as the 'static SIMS' regime) results in the production of ever smaller fragment ions as the remaining surface becomes increasingly damaged by the incoming primary ions.

As the sample cannot be re-analyzed, it is important that maximum use be made of the information generated during the analysis, particularly if the analytical site is unique, as is often the case with defect analysis for instance. Accordingly, the TOF-SIMS technique has matured due to a combination of hardware and software interactions TOF-SIMS has seen the development of an interesting approach to data collection, in which the information concerning every secondary ion detected, its x, y position and time-of-flight (mass), can be saved to disk During the 'live' data acquisition, the analyst will examine the accumulating mass spectrum and initiate mapping of the species for which the lateral distributions need to be determined. Once the analysis is completed however, the 'raw' data set may be replayed any number of times off-line in order to finesse the data. This facility is surprisingly useful in a number of analytical situations Three examples serve to demonstrate this point:

(1) In the routine analysis of a homogeneous polymer film surface, a total positive ion image was acquired as a matter of course. At the end of the mass analysis and image acquisition, two small (1-2μm) particles were evident within the field of view. 'Regions of interest' mass spectra were acquired from the particles and a control area, by replay of the 'raw' data set Even after this stage however, the mass spectrum from the particles was not too dissimilar from the polymer sheet surface spectrum. Next, the two mass spectra were normalized, and the control spectrum was subtracted from the particles mass spectrum. Sole residuals after subtraction were identified as CF, CF_3, C_2F_4, C_3F_5 and so on, indicating that the particles were fluorocarbon-containing. A further replay, collecting an image from a combination of these species, then revealed locally intense signals of fluorocarbons from these small particles.

(2) A two layer paint on a wooden substrate was prepared in cross-section by microtoming, and analyzed in the TOF-SIMS instrument. The outer and inner layers were approximately 30μm and 60μm thick, respectively. Retrospective analysis permitted detailed investigation of the constituents and additives in the two layers of paint, that were not anticipated by the analyst from the outset. For instance, titanium (from a pigment) was found to be isolated within the top layer only, whereas sodium, although also present in this layer, had clearly diffused into the second layer When an image was acquired retrospectively from high mass fragments observed in the mass range 300-650 m/z, these species were all seen to be located in the lower paint layer, and are characteristic for a polymer paint additive. This mode of analysis is of great benefit to off-site clients, wishing to return with further questions concerning the original data so as to maximize the information from a single analysis.

(3) The mass resolution in the total mass spectrum acquired from a series of treated ceramic grains was severely degraded owing to the topography of the coarse crystals. Using the total ion image acquired during the analysis, individual grains approximately 10-75μm in diameter were easily identified. Mass spectra were then acquired retrospectively from individual grains whose surfaces were facing the analyzing beam at single, discrete heights in the secondary ion extraction region. The mass resolution following recalibration was seen to increase from approx 500 in the total surface spectrum to ~5000 (FWHM) in the spectra from individual grains For instance, a single peak at mass 43 was seen on individual grains to resolve into 3 peaks. This represents another example of how this type of off-line analysis permits the analyst to finesse the chemical information that is latent within these data sets

In conclusion, we have found that it is powerful to treat the TOF-SIMS data set as a very malleable entity which can be replayed and re-presented in a variety of ways to maximize the information available from the analysis. This is vital for samples which are unique and may be analyzed once only, and is very useful when it is not clear at the outset of analysis which species to map laterally on the sample.

Quantitative Analysis of Biomolecules by Time-of-Flight Secondary-Ion Mass Spectrometry: Fundamental Considerations

Static Time-of-Flight Secondary-Ion Mass Spectrometry (TOF-SIMS) has been applied to investigate an extensive assortment of analytical systems; from semiconductors to DNA sequencing. Recently, the TOF-SIMS method has been successfully applied to real biological systems [1,2]. This report focuses on some important aspects that must be taken into consideration when conducting measurements on biomaterials in order to observe the potential the TOF-SIMS method affords. The current data are presented using Cyclosporin A (CsA, 1202 Da) and cocaine (303 Da) as model compounds. CsA is observed in the TOF-SIMS mass spectrum predominately as a Ag-cationized species and cocaine as a protonated species; thus, they are complementary probe molecules.

Bioanalysis by TOF-SIMS is typically performed when the compound is supported on a chemically etched silver substrate resulting in a maximum secondary-ion (SI) yield. To obtain quantitative data for species requiring Ag-cationization, the Ag must be etched under identical conditions to avoid substrate variability introduced by the etching process (data not shown).

To define the dynamic range of the TOF-SIMS method, cocaine was used as a model compound due to its extraordinary SI yield. The TOF-SIMS detection system comprises a multi-stop TDC operating in the single-ion counting mode. The dynamic range of the TOF-SIMS method was limited using this detection configuration due to the probability of multiple ions arriving in a single primary ion pulse. Figure 1 shows the corrected standard curve for cocaine (using its deuterated analog as the internal standard) from 10 ng/mL - 100 μg/mL. Peak intensity corrections using a Poisson function (Eqn. 1)

$$I_{corr} = -n \times \ln\left(1 - \frac{I_{exp}}{n}\right) \quad (1)$$

where I_{corr} is the corrected intensity, n is the number of ion pulses and I_{exp} is the experimental peak area, extended the dynamic range of the TOF-SIMS method to over 4 orders of magnitude.

The therapeutic blood trough levels of CsA range from 25-2000 ng/mL; however, this is far from the maximum SI yield of CsA (*ca.* 500 μg/mL). Concentrating the sample has shown to decrease the SI yield which is attributed to an increase in the surface coverage (as a result of concentrating endogenous material present in the extract). Therefore, sample extracts must be of the highest purity prior to preconcentration and subsequent TOF-SIMS analysis to avoid an equal increase in coverage due to the presence of contaminants.

Enhancement of SI yield was observed utilizing a novel sample preparation technique. The initial observation was discovered when an allograft blood sample was analyzed on an etched Ag substrate that was soaking in a cocaine solution for *ca.* 2 months. The increase in SI yield was found to be over an order of magnitude (Figure 2). Attempts to reproduce the original experiment was done by applying 5 μL of a 20 μg/mL cocaine solution to an etched Ag substrate, allowing solvent evaporation, then applying either a CsA or polystyrene solution to the surface. These experiments resulted in about a 300% increase in SI yield. Taking into account the above mentioned results (except for the enhancement experiments), TOF-SIMS can provide quantitative information of drugs in real biological systems.

Peptide/Protein Sequencing by Exopeptidase Digestion Coupled with MALDI-TOF MS: Part of an Integrated Strategy

Dale H. Patterson, George E. Tarr, Fred E. Regnier and Stephen A. Martin
PerSeptive Biosystems, Framingham, MA 01701

Determination of the primary structure of peptides and proteins is critical as a support for molecular genetics, detection of secondary modifications, peptide/protein mapping, drug discovery and quality control Any single approach (instrumental or chemical) for deriving complete sequence information from all peptides and proteins is not viable as all methods possess inherent limitations. It is more advantageous to develop a number of integrated instrumental and chemical strategies that, when implemented as a whole, yield the desired structural information. MALDI-TOF is a tool around which these strategies can be built. Purely instrumental methods for deriving sequence information lie in MALDI-TOFs ability to deliver accurate molecular mass information over a wide mass range as well as MS/MS information in the form of post source decay (PSD). When coupled with enzymatically derived C- and N-terminal ladders, MALDI-TOF becomes a powerful tool to probe the primary structure of peptides as well as proteins.

Classical, solution-phase time-dependent carboxypeptidase Y (CPY) digestions have been performed on the ACTH 7-38 fragment and the resulting peptide ladders analyzed by MALDI-TOF. Optimization of this digestion has resulted in the sequencing of 19 amino acids from the C-terminus without gaps in 25 min. An improved strategy for performing the digestions was further developed wherein parallel CPY digestions of varying enzyme/substrate concentration ratios are carried out in the μL wells on the sample plate. This on-plate concentration-dependent strategy holds many advantages over the classical approach. Only sub-pmol amounts of total peptide are required; the manual labor of removing and quenching time aliquots is circumvented; and the total digestion time required is reduced to 10 min or less. Using the on-plate parallel digestion strategy has allowed the sequencing of numerous peptides of varying size, charge and polarity. Figure 1 shows the results for the ACTH 7-38 fragment.

To further the development of ladder sequencing, a strategy for applying statistical levels of confidence on residue assignments has been developed. The strategy involves the acquisition of multiple replicates, N, such that an experimental mean mass difference, x, with associated standard deviation, s, can be calculated. All possible assignments are used as the asserted mean mass, μ. Asserted means are deemed statistically improbable as calculated t-values for each μ are compared with a tabulated value for a desired confidence interval.

The integration of statistically accurate C- and N-terminal information via on-plate carboxypeptidase and aminopeptidase digestions offers a wealth of primary information from the termini of peptides. This approach often leaves the central portion of the peptide unexplored. Combining the terminal assignments with PSD data often proves sufficient for obtaining complete primary structural information. Figure 2 shows the results of on-plate carboxypeptidase Y and aminopeptidase 1 digestion coupled with PSD for the complete sequencing of renin substrate.

Delayed extraction (DE) MALDI-TOF has been shown to offer much improved resolution and mass accuracy due to its ability to significantly reduce the initial velocity distribution of extracted ions. DE MALDI-TOF holds advantages for the analyses of peptide ladders as its increased mass accuracy allows for a reduced number of replicates to be obtained in order to statistically deem improbable incorrect residue assignments. The much improved resolution of DE MALDI-TOF allows for the analysis of much larger ladders (*e.g* protein ladders) than does the continuous extraction technique. Figure 3 gives the DE MALDI-TOF analysis of an on-plate CPY digestion of pyridylethylated ribonuclease A, a 14,351 dalton protein.

MALDI Electrostatic Analyzer TOF Mass Spectrometry Studies of Biopolymers

K. J. Wu, E. P. Marsh and R. W. Odom

Charles Evans & Associates, 301 Chesapeake Drive, Redwood City, CA 94063

A new matrix-assisted laser desorption/ionization (MALDI) mass spectrometer has been constructed for biopolymer analysis. This new instrument is based on a mass spectrometer platform designed for time-of-flight secondary ion mass spectrometry (TOF-SIMS) applications. It features specialized stigmatic ion optics which extract and transport ions from the sample surface to the TOF mass analyzer. The time-of-flight mass analyzer consists of three 90° quasi-hemispherical electrostatic sector analyzers (ESA) in the ion flight path and a dual microchannel plate for ion detection. A schematic diagram of this apparatus is shown in Figure 1 These ESAs provide complete first order energy focusing of ion flight times. The design of the spectrometer corrects and compensates flight time variation due to kinetic energy aberration at the acceleration region as well as flight time differences arising from angular variances A fast sampling rate transient digitizer with speeds up to 500 psec/channel is used for ion signal acquisition.

A N_2 laser (λ=337 nm) with a pulse width of 600 psec is used for desorption/ionization. The laser beam is tightly focused onto the surface of the sample to ca 5 μm in diameter Such small desorption laser beam spots can in principle reduce the ionization volume which in turn would minimize the spatial distribution of MALDI ions and improve the mass resolution A micrometer controlled variable attenuator is employed for continuous adjustment of laser intensity.

The initial testing of the instrument included studies of known mass peptides, proteins, synthetic DNA oligomers and organic polymers. Detection sensitivity is comparable to the conventional MALDI-TOF apparatus, and typical amounts of analyte loaded for analysis are between 200 fmol to a few pmol The most improved feature of this instrument over conventional MALDI-TOFMS systems is its mass resolution and accuracy The routine mass resolution (M/ΔM, FWHM) has been demonstrated to be in the range of 5,000 - 7,000 for m/z up to ca 6,000. Resolution as high as 12,000 has been measured from bovine insulin on a single laser shot spectrum (Fig 2). Isotope distributions can not be definitively resolved for analyte compounds with mass over ~10,000 Da Instead, an envelop representing the isotopic distribution is measured and the mass resolution is determined by the width of the isotope profile The largest compound we tried and successfully measured was bovine trypsin (mw=23,311)

Mass accuracy measurements were carried out in two parts:
1) calibrate the mass constants of the instrument with four known mass standards 2,5-DHB (mw=154.1), leucine enkephalin (mw=555.6), substance P (mw=1347.7) and bovine insulin (mw=5733.5). The mass constants determined with these standards were kept unchanged throughout the following measurements
2) perform measurements on a mixture of three peptides: angiotensiongen (mw=1759 0), β-endorphin (mw=3465 4) and human growth hormone releasing factor (mw=5039 7) A total of 64 analyses over eight days were carried out in these measurements.

The mean of the measured molecular masses of these three analyte were compared with the calculated molecular masses The mass accuracy was determined to be ~ 40 ppm for analyzing compounds up to m/z = 6,000. Since this evaluation was performed with external calibration standards over extended period of time, it is expected that mass accuracy can be further improved with internal standards.

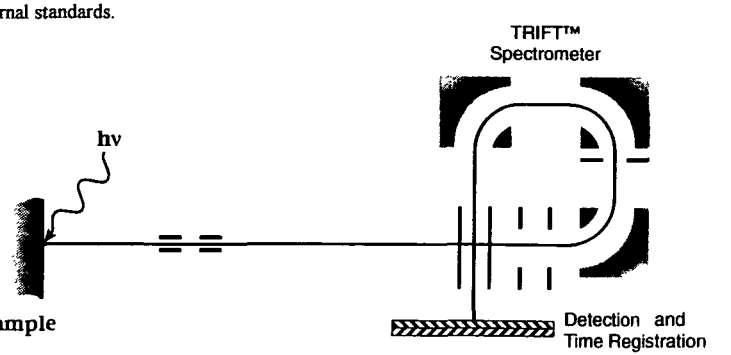

Fig. 1 - Schematic diagram of the MALDI triple ESA TOF mass spectrometer.

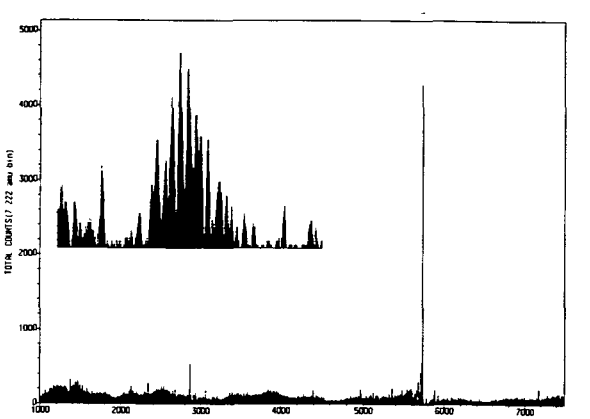

Fig. 2 - MALDI mass spectrum of bovine insulin with 2,5-DHB as matrix material. Spectrum was obtained with a single laser shot The insert shows isotopically resolved singly-charged mass peak distribution with a mass resolution of M/ΔM ~ 12,000 (FWHM).

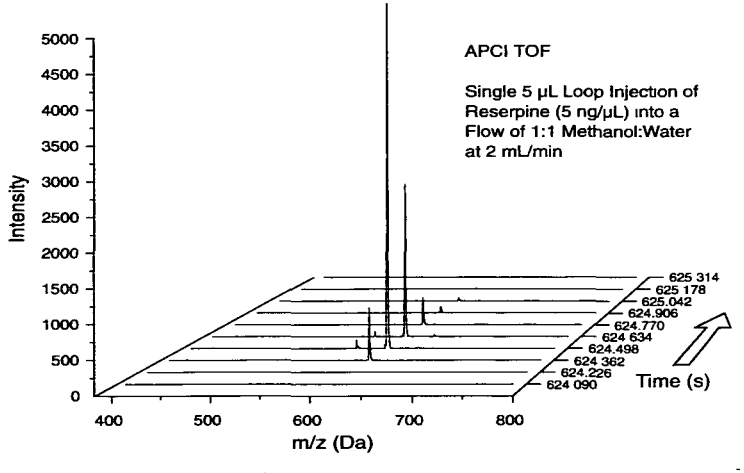
A Mass Analyzer for High Speed Liquid Chromatography

B. A. Andrien, J. F. Banks, J. G. Boyle, T. Dresch, P. J. Haren, and C. M. Whitehouse
Analytica of Branford, Inc., 29 Business Park Dr. , Branford, CT 06405

New fast liquid phase separation methods such as capillary electrophoresis allow complete separations to be performed in a few minutes with no loss in component resolution. Single constituent effluence peak widths of one second or even less have been demonstrated by optical detection methods. Conventional scanning mass spectrometers as detectors for chromatography are reaching their performance limits whenever a spectral mass range exceeding a few hundred amu has to be scanned at a rate exceeding one per second. On the contrary, time-of-flight mass spectrometry offers very high scan rates that can easily exceed 10^7 amu/s. It is therefore ideally suited as mass analyzer technology for the future high speed liquid phase chromatography.

The time-of-flight instrument developed in our laboratory is capable of recording more than 10 full mass range spectra per second with minimal dead time, each spectrum being the sum of multiple single scans. Orthogonal injection of the continuous ion beam from external atmospheric pressure ion sources and high repetition rates warrant high duty cycles and, hence, high sensitivity. Mass resolution of R(fwhm)=1000 has been achieved with a short linear configuration. When equipped with an ion mirror (reflectron) and an extended field free drift path of 130 cm total length, the instrument has a mass resolution of R(fwhm)=3000 .

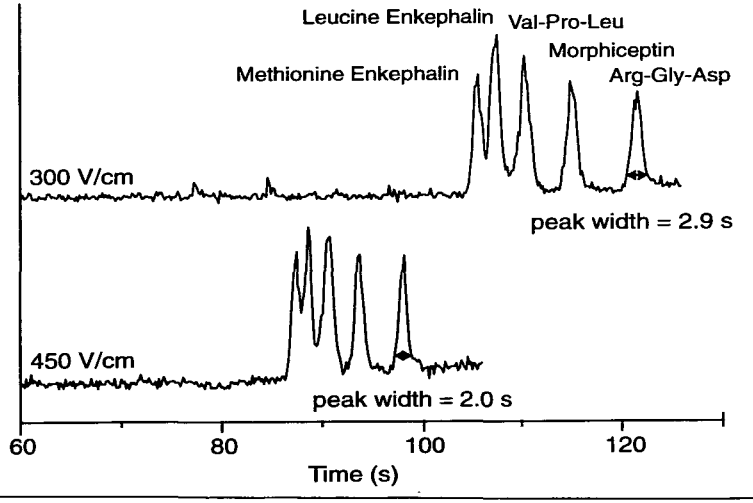
The high speed capabilities of the instrument were demonstrated using an atmospheric pressure chemical ionization (APCI) source. 5 µl of a sample solution of Reserpine (in metha-



nol-water, total analyte amount 25 ng) were injected into the continuous flow of buffer liquid (methanol-water). At a flow rate of 2 ml/min the sample elution peak is only 0.2 seconds wide (fwhm). The linear time-of-flight spectrometer was operated at a repetition rate of 4096 Hz; summing 512 consecutive scans to form an averaged spectrum results in an acquisition rate of 8 spectra per second. Spectra were recorded for the mass range 250-1200 amu. Figure 1 displays the ten mass spectra around the sample elution peak, showing that the sub second peak is captured reliably.

The mass spectrometer was then coupled to a capillary electrophoresis (CE) separation system. The CE column was interfaced to the electrospray ion source by means of the sheath flow mechanism introduced by R. D. Smith et al.; in this setup a sheath liquid makes the electrical contact to the CE buffer solution and at the same time provides for a stable electrospray process. Figure 2 shows a results obtained with an amine coated column of 75 µm i.d. and 66 cm length, at electrophoresis field strengths of 300 and 450 V/cm. The buffer solution was 0.01 M acetic acid. The sheath liquid was methanol at a flow rate of 4 µl/min. A sample mixture of peptides in aqueous solution elutes from the column in about 100 seconds with well separated components. Time-of-flight mass spectra were acquired at a rate of 8 spectra per second, each spectrum being the sum of 1024 single scans. The recorded mass range extended from 100 to 1700 amu.

The displayed curves are the total ion currents calculated in real time from the acquired mass spectra. At 450 V/cm the single peak width is 2 seconds at the base and 1 second at half peak height. Within the scope of this experiment it was found that the peak widths scale with the elution time. Shorter columns and higher field strengths will allow even faster separations to be carried out, while the recording speed of the time-of-flight mass spectrometer guarantees adequate analyzer response.



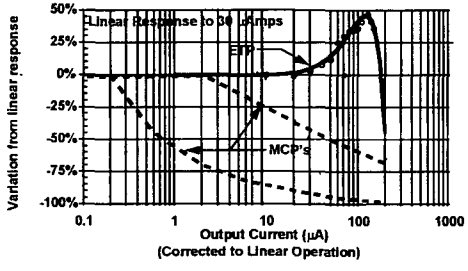
Achieving Linear Detector Response In TOF-MS

Dick Stresau and Kevin Hunter, ETP, Sydney, Australia
John Gray, ETP Scientific, Inc , Auburn, Ma., USA

Rapid development of Time-Of-Flight mass spectrometry is placing increased demands on detectors This challenge has been met using discrete-dynode electron multipliers designed specifically for TOF applications.

Our work has shown that three different issues are involved in achieving linear response in TOF detectors: linearity with large average output currents, linearity for large peaks, and gain recovery after a large peak. The flexibility of discrete-dynode technology allows us to achieve exceptional performance in each of these areas by adjusting and optimizing the ion and electron optics, individual dynode shapes, dynode voltage distribution, and inter-dynode capacitance. The result is a multiplier specifically tailored for TOF-MS applications

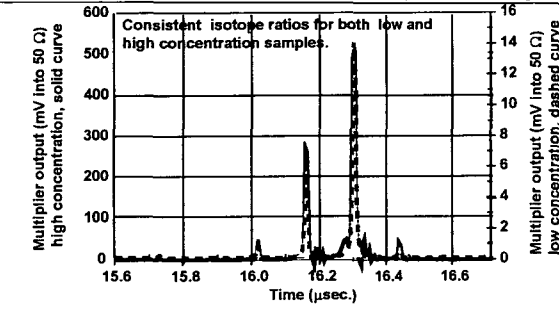
Linearity with large average output currents: Linear response for large output currents is similar to the considerations required in conventional mass spectrometry where one must be careful not to go beyond the linear limit for output current drawn from the multiplier



The above data is plotted as a percentage variation from linear response against the output current expected if things were perfectly linear. Notice that the **discrete-dynode multiplier is linear out to 30μA.** It is interesting to compare this to MCP performance. Even high current MCPs have only one tenth the current capacity of the new discrete-dynode TOF multipliers. Exceeding the linear limit will result in a loss of abundance calibration for the entire spectrum.

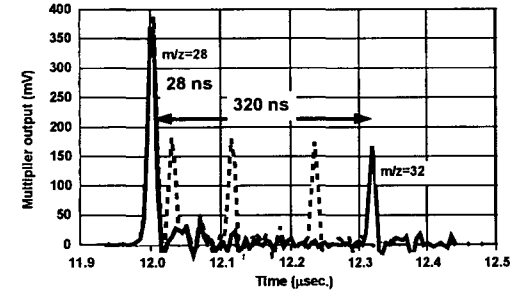
Linearity for large peaks: The linear limit for an individual peak in a TOF spectrum is several orders of magnitude greater than the average current limit. The new TOF multipliers exhibit linear operation with very large output pulses: 10^9 electrons or 500 mV (into 50 ohms, 10 nsec wide) Beyond this point space charge effects within the dynode structure begin to inhibit the flow of electrons between dynodes

Whereas excessive average-output-current affects the height of all peaks in a spectrum, an individual peak that exceeds the linear limit will be diminished without influencing the level of the smaller peaks This results in distorted abundance ratios



In the above figure two spectra are superimposed. The solid curve was taken with a very high concentration sample. The dashed curve is of the same compound but with 1/30th the concentration. The second spectrum is used as a "standard" to give an undistorted measure of abundance ratios. The two spectra are virtually identical. **The discrete-dynode multiplier shows no sign of non-linearity even with a 500 mV pulse!**

Gain recovery after a large peak: Achieving good linearity in a single pulse will have little advantage if the multiplier becomes saturated and effectively non-functional following the pulse Therefore it is important for a TOF detector to have very fast recovery after a large pulse.



To demonstrate large pulse recovery speed, we used a double pulse on an orthogonal gate TOF system This produced two overlapping spectra in the same TOF scan The time between the two gate pulses was adjusted, allowing adjustment between the mass 28 peak from one pulse and the mass 32 peak of the other Four measurements have been superimposed so that the pulse height consistency is easily seen Note how the height of the mass 32 peak remains unchanged as the time between peaks is decreased. **The large pulse recovery time is less than 30 nanoseconds!**

The newly developed multipliers excel in all of the areas which are important for achieving large dynamic range in TOF systems: **linear output current up to 30μA, linear response for pulses up to 500 mV, recovery time after large pulse of less than 30 nsec.**

A Time Focusing Equation and a Classical Uncertainty Relation in TOFMS

Ronald Stein, Applied Physics Laboratory, University of Washington, Seattle, WA 98105

A time focusing equation is developed in which time (of flight) is the central variable rather than a parameter. The one-dimensional form of this equation is used to develop a classical uncertainty relation. This relation is used in conjunction with Liouville's theorem on the incompressibility of particles in phase space to better understand the function of time of flight mass spectrometers.

Perfect space focusing with respect to time is defined as $\partial t/\partial x_o = 0$, where t is the time of flight of an ion and x_o is it's starting position. Perfect velocity focusing with respect to time is defined as $\partial t/\partial v_o = 0$, where v_o is the ion's initial starting velocity.

Consider an ion in a one-dimensional system. It's time of flight t is a function of initial position x_o and initial velocity v_o only if the fields are constant in time, i.e., if $t = f(x_o, v_o, T)$. The total derative of the time of flight with respect to clock time T is

$$\frac{dt}{dT} = \frac{\partial t}{\partial x}\frac{dx}{dT} + \frac{\partial t}{\partial v}\frac{dv}{dT} + \frac{\partial t}{\partial T} \tag{1}$$

Note that $dx_o/dT = v_o$, $dv_o/dT = F_o/m$, and T increases as t decreases; i.e., $T + t =$ a constant that gives $dt/dT = -1$. Also, changes in time of flight with the changes in time are zero when x_o and v_o are held constant or $\partial t/\partial T = 0$. Therefore

$$v_o\frac{\partial t}{\partial x_o} + \frac{F_o}{m}\frac{\partial t}{\partial v_o} + 1 = 0 \quad \text{(Time Focusing Equation)} \tag{2}$$

(which is readily generalized to a three dimensional system [1]). This equation connects space and velocity focusing independently of the forces on the ions as the ions move toward the collector. The equation shows that space and velocity focusing cannot be perfect simultaneously ($\partial t/\partial x_o = 0$ and $\partial t/\partial v_o = 0$ together). If $\partial t/\partial x_o$ or $\partial t/\partial v_o$ is known, then the other quantity can be found if the initial conditions on the ions are known.

Consider an ion starting at x_0 and v_0 in a TOFMS using a time-independent conservative field. The change in time of flight with respect to initial position and velocity is given by

$$dt = \frac{\partial t}{\partial x_o}dx_o + \frac{\partial t}{\partial v_o}dv_o \tag{3}$$

For a collection of ions in a "small" region where $\partial t/\partial x_o$ and $\partial t/\partial v_o$ are approximately constant and the initial positions and velocities of the various ions are not correlated ($\sum_{i=1}^{n} dx_{o_i} dv_{o_i} = 0$), we can write

$$\Delta t = \left[\sum_{i=1}^{n} dt_i^2\right] = \left[\sum_{i=1}^{n}\left[\frac{\partial t}{\partial x_o}dx_{o_i}\right]^2 + \left[\frac{\partial t}{\partial v_o}dv_{o_i}\right]^2\right]^{1/2} \tag{4}$$

Using the time focusing equation (1), we can eliminate $\partial t/\partial v_o$ from equation (4) and minimize Δt as we vary $\partial t/\partial x_o$;we then find

$$\Delta t \Delta E_o \geq \Delta x_o \Delta p_o \tag{5}$$

where $\Delta p_o = m\Delta v_o$ and where Δx_o, Δy_o, Δt, and ΔE_o are the initial rms dispersions in the ion cloud's

43rd ASMS Conference on Mass Spectrometry and Allied Topics

position, velocity, time, and energy, respectively.

$$\Delta E_o = (F_o^2\Delta x_o^2 + m^2 v_o^2 \Delta v_o^2)^{1/2} = (\Delta PE_o^2 + \Delta KE_o^2)^{1/2} \tag{6}$$

where ΔPE_o and ΔKE_o are the cloud's initial rms potential and kinetic energy dispersions, respectively. The inequality sign in equation (5) becomes an equal sign when the ion cloud is time focused in space or the ions again become uncorrelated in position and velocity and have the following specific expression for space and velocity focusing:

$$\frac{\partial t}{\partial x_o} = -\frac{\Delta KE_o \Delta p_o}{\Delta E_o^2} \quad \text{and} \quad \frac{\partial t}{\partial v_o} = -\frac{\Delta PE_o \Delta x_o}{\Delta E_o^2} \tag{7}$$

Liouville's theorem states that if the forces on a particle are derived from any potential (time varying or not), the volume in phase space (position and velocity space) of an ion cloud is constant ($\Delta x \Delta p =$ constant is the one-dimensional form.).

As a consequence of Liouville's theorem, we can drop the requirement of equation (5) that the fields be independent of time. Also, since the initial location can be any location where the phase volume is uncorrleated, we can drop the initial location subscripts and write

$$\Delta t \Delta E \geq \Delta x \Delta p = K \quad \text{(Classical Uncertainty Relation)} \tag{8}$$

where $\Delta x \Delta p$ is the initial uncorrelated phase volume K of an ion cloud and $\Delta t \Delta E$ is the time of flight and energy of dispersion at some later time. The inequality in equation (8) becomes an equality at the initial instant in time and at any later time when the ions become time focused or $\Delta x \Delta p$ is again an uncorrelated ion cloud.

Let us investigate some of the consequences of the Classical Uncertainty Relation so as to better understand how a higher quality time focus (smaller Δt) can be obtained. We assume that a time focus where $\Delta x_o \Delta p_o = \Delta E_o \Delta t$ is achieved, which assumes that $\partial t/\partial x_o$ and $\partial t/\partial v_o$ have been optimized. If the initial conditions of the ions in time-independent fields are fixed, $\Delta x_o \Delta v_o$ is constant, and the average initial velocity is fixed, then we must increase ΔE_o to reduce Δt. This can be done by increasing ΔPE_o, by increasing the initial force F_o, which reduces the turn-around time. In time-varying fields, one could increase ΔE after the flight of the ions has started, but a good time focus independent of mass would now be very difficult to achieve. One could make the ions in a smaller phase volume $\Delta x_o \Delta v_o$ initially, or one could select ions from a larger phase volume but this would reduce the TOFMS sensitivity. Finally, one could operate under circumstances where Liouville's theorem is no longer true and hence circumstances where the Classical Uncertainty Relation no longer applies by putting in forces which are not completely derivable from potentials. Examples of such forces are dissipative forces of friction, collision forces to transfer momentum to other particles, and radiation reaction forces due to energy loss by radiation. Ions could collide with a neutral gas to reduce their momentum to the thermal values of the neutrals (by using a quadrapole trap ion source with a high neutral gas pressure in the trap). Ions could be entrained in a supersonic jet to take advantage of the expansion cooling of the gas jet stream. Ions could be passed close to conductive surfaces and be slowed down by the resistive heating of the image charges flowing in the conductive surface.

The Time Focusing Equation and the Classical Uncertainty Relation are very useful tools to help in the optimization of TOFMS time resolution.

Analytical Form of Position Focusing in the Parabolic Electrostatic Field

Ronald Stein, Applied Physics Laboratory, University of Washington, Seattle, WA 98105

The parabolic electrostatic field can produce either perfect space or perfect velocity focusing in time (isochronous focusing). This well known result can be very desirable in a time of flight mass spectrometer to produce a quality time focus. The position (as opposed to the time) focusing properties of this field has been investigated by numerical methods for specific applications by others. Although some analytic results are in the literature [1, 2], the properties of this focusing are not generally well understood. Here, an analytical solution to the position focusing of charged particles in the parabolic electrostatic field is developed, with the solutions to the perfect space and perfect velocity focusing cases solved in some detail.

The only force field that will give perfect space and velocity focusing in one dimension over an extended region is one in which the force is attractive and directly proportional to the distance from the origin [3]. This force produces simple harmonic motion. For a charged particle q in an electric field E this force is given by $F_z=qE_z=-qAz$. The electrostatic potential V along the z axis is then given by $V=Az^2/2$ since $\vec{E}_z=-\partial V/\partial z$. If we have planar or cylindrical symmetry, and since $\nabla^2 V=0$, the potential in the neighborhood of the z axis is completely specified (see Fig. 1), or

$$V(z,x) = (V_o/L^2)(z^2-x^2/k) \tag{1}$$

where V_o is the potential on the hyperbolic surfaces shown and L is the distance form the origin to that surface along the z axis. In the planar case ($k=1$), the surfaces are hyperbolic rods perpendicular to the page. The same configuration is used in the quadrupole mass spectrometer. In the cylindrical case ($k=2$), the electrodes are hyperbolic surfaces of revolution which are used in the quadrupole trap. The parabolic potential can be generated by these electrode structures or with a wedge or cone along with one hyperbolic electrode to define a quarter space. The potential can be approximately produced along the z axis by a stack of coaxial parallel plates with the appropriate potentials on them and holes in their centers.

Since $\vec{E}=-\nabla V$, the electric fields are given by

$$E_z = -2(V_o/L^2)z \quad \text{and} \quad E_x = 2(1/k)(V_o/L^2)x \tag{2}$$

Since the force on the ions is given by $F=qE$ and F=ma, we have the equations of motion of $\ddot{z} = -\omega^2 z$, and $\ddot{x} = (1/k)\omega^2 x$, where $\omega=2qV_o/mL^2$. The forces in the z and x directions are independent. The ions are always forced away from the z axis (defocused) since E_x is always positive. The defocusing effect is twice as large in the planar case as in the cylindrical case.

Solving these equations of motion we find the position and velocity as

$$z = (z_o^2 + (\dot{z}/\omega)^2)^{1/2}\cos(\omega t-\phi) \quad \text{and} \quad \dot{z} = -\omega(z_o^2 + (\dot{z}/\omega)^2)^{1/2}\sin(\omega t-\phi) \tag{3}$$

$$x = x_o\cosh\omega' t + \dot{x}_o/\omega' \sinh\omega' t \quad \text{and} \quad \dot{x} = \omega' x_o \sinh\omega' t + \dot{x}_o \cosh\omega' t \tag{4}$$

where $\tan(\phi) = \dot{z}_o/\omega z$, $\omega'=\omega$ or $\omega/\sqrt{2}$ in the planar or cylindrical case, respectively, and at $t=0$ the initial distances and velocities are z_o, $\dot{z}_o$, x_o, and $\dot{x}_o$.

We now consider the two special cases where perfect space focusing ($\partial t/\partial z_o=0$) and perfect velocity focusing ($\partial t/\partial \dot{z}_o=0$) occur [4]. When ϕ is zero ($\dot{z}_o=0$) and the time t reaches $\omega t=\pi/2$, the z coordinate of the ion reaches zero independently of z_o (see Eq. (3)) and we have perfect space focusing for all z_o. Also, this time of flight is independent of x_o and $\dot{x}_o$. We analyze the special paraxial ray case where $\dot{x}_o=0$. The other initial conditions are $z_o=l$, $\dot{z}_o=0$, and $x_o=x_o$ (see Fig. 2). For the planar case at $\omega t=\pi/2$, we have $z=0$, $\dot{z}=-\omega l$, $x=x_o\cosh(\pi/2)=2.509x_o$, $\dot{x}=-\omega x_o\sinh(\pi/2)=-2.301\omega x_o$, and a focal length $F=l\coth(\pi/2)=1.090l$. In the cylindrical case we have $x=x_o\cosh(\pi/2\sqrt{2})=1.683x_o$, $\dot{x}=-(\omega/\sqrt{2})x_o\sinh(\pi/2\sqrt{2})=.975\omega x_o$, and a focal length of $\sqrt{2}\,l\coth(\pi/2\sqrt{2})=1.758l$. Referring to Fig. 2, the focal point is defined as the apparent point of origin of the ion if it's trajectory, on arriving at $z=0$, were extrapolated back in a straight line to the z axis. The focal length is independent of x_o.

To get perfect velocity focusing, we start an ion at $z_o=0$ and at some $\dot{z}_o=-\omega l$. Now $\phi=\pi/2$, and when the time t has gone from zero to $\omega t=\pi$, the ion has gone out to l and returned to $z=0$ with a velocity of $\dot{z}=-\omega l$. Since this time of flight is independent of $\dot{z}_o$, we have perfect velocity focusing. Also, t is independent of x_o and $\dot{x}_o$. We analyze the special paraxial ray case where $\dot{x}_o=0$. The other initial conditions are $z_o=0$, $\dot{z}_o=-\omega l$, and $x_o=x_o$ (see Fig. 3). For the planar case at $\omega t=\pi$, we have $z=0$, $\dot{z}=-\omega l$, $x=x_o\cosh(\pi)=11.592x_o$, $\dot{x}=-\omega x_o\sinh(\pi)=-11.549\omega x_o$, and a focal length $F=l\coth(\pi)=1.0037l$. In the cylindrical case, we have $x=x_o\cosh(\pi/\sqrt{2})=4.665x_o$, $\dot{x}=-(\omega/\sqrt{2})x_o\sinh(\pi/\sqrt{2})=3.222\omega x_o$, and a focal length of $F=\sqrt{2}\,l\coth(\pi/\sqrt{2})=1.448l$. Again, the focal length is independent of x_o.

A better understanding of the analytical form of the position focusing in the parabolic electric field should lead to improvements in time of flight mass spectrometer designs using this field.

SPACE-VELOCITY CORRELATION FOCUSSING

Steven Colby and James P. Reilly
Department of Chemistry, Indiana University, Bloomington, IN 47405

Since their earliest development, time-of-flight mass spectrometers have suffered from limited mass resolution. The initial ion temporal, spatial and velocity distributions are the primary factors that must be understood, eliminated or compensated for in order to achieve enhanced mass resolution [1]. Perhaps the most significant improvements to linear time-of-flight mass spectrometers were introduced by Wiley and McLaren in 1955 [2]. To limit the deleterious effects that ion spatial and velocity distributions have on TOF mass spectral peakwidths, they introduced the concepts of space and energy focussing. Each of these was found to play a role in TOF mass spectrometer optimization. However, Wiley and McLaren found that the two could not be accomplished simultaneously. They noted that a compromise between space and energy contributions to resolution must be achieved.

We recently demonstrated that under certain conditions, the spatial and velocity distributions of ions in the source region of a time-of-flight mass spectrometer are not independent [3,4]. In these circumstances, an ion's position and velocity can be related mathematically and it is possible to accomplish simultaneous space and velocity (i.e. energy) focussing. An important example that illustrates this case is the MALDI ionization source. MALDI TOF mass spectra recorded with linear mass analyzers generally display very poor resolution that has often been attributed to the broad velocity distribution with which macromolecules are desorbed [5,6]. Assuming that MALDI ions are formed close to the surface from which desorption occurs, their positions and velocities at times following the desorption pulse are linearly related. If an ion drawout electric field is applied at an optimal time after the desorption light pulse, then the spatial and velocity distributions of the ions at the time of the drawout pulse can be simultaneously focussed. The optimal ion drawout time can be derived using a computer program that calculates ion flight time dispersion for a certain range of initial ion velocities and then optimizes instrument parameters so as to minimize this dispersion. Demonstrating the significance of these concepts, Figure 1A displays the range of flight times expected for lysozyme ions (m/z 14306) in our laboratory's short (21 cm drift length) MALDI instrument for initial ion velocities between 0 and 1200 m/sec if we apply DC drawout voltages of 25 kV and 0 V to the first two ion acceleration grids. In contrast, Figure 1B displays the range of lysozyme flight times when we set our first three grids at 25 kV, 25 kV, 21.3 kV and apply a pulsed voltage of 1.82 kV to the first grid at an optimal time. The predicted improvement in flight time dispersion is evidently dramatic. Figure 2A displays lysozyme experimental data recorded with a DC drawout voltage of 30 kV. Figure 2B presents a positive ion lysozyme spectrum recorded using pulsed ion drawout under conditions optimized for space-velocity correlation focussing, with post acceleration between the ion drift tube and the detector. A sharp parent ion peak is evident along with a background pedestal that derives from metastable fragmentation. The latter can be discriminated against using an electric field in the postacceleration region, as displayed in Figure 2C. Although not shown, data can also be recorded without postacceleration. In addition to the tall parent ion peak, small features associated with matrix adducts appear in this

spectrum. Mass spectral resolution, m/Δm, of about 1500 has been obtained for lysozyme using this method.

Tandem Mass Spectrometry on a Triple ESA Time-of-Flight SIMS Instrument

M. J Kristo, R. W. Odom, and K. J. Wu
Charles Evans and Associates, 301 Chesapeake Drive, Redwood City, CA 94063

Time-of-Flight SIMS is useful in the analysis of bio-organic compounds due to its high sensitivity, high mass resolution (up to 10,000), excellent mass accuracy (ppm range), and ability to form images of mass selected ions emitted from solid surfaces in the sputtering process Most TOF-SIMS instruments form ion images by rastering a finely focused ion beam across the sample surface and correlating the detected secondary ions with the position of the primary ion beam.

The TRIFT™ (TRIple focusing Time-of-flight) spectrometer[1-2] can generate ion images not only through rastering, but direct ion imaging as well. In direct ion imaging, the spatial relationship of ions leaving the sample surface is maintained and magnified by the spectrometer. Therefore, by measuring the time and position of each ion's arrival with a spatially sensitive detector, one can build up images of ion emission from the sample surface as well as mass spectra Even for non-imaging applications, the TRIFT™ instrument provides several advantages: 1) proper time-of-flight compensation for large energy and angular spreads, 2) excellent transmission, and 3) low non-mass specific background -- even low intensity peaks are significant

Nevertheless, normal TOF-SIMS has several disadvantages for bio-organic analysis First, static SIMS provides variable and sometimes poor ion yield for large bio-organic molecules. Second, static SIMS is a relatively soft ionization technique producing predominately ions characteristic of intact molecules. At m/z above ~1000 Da, the mass resolution and mass accuracy of high performance TOF-SIMS instruments often cannot unambiguously identify molecular ions By coupling tandem mass spectrometry to TOF-SIMS, we can provide structural information about these ions which is an invaluable aid for identification. Third, the SIMS spectra generated from real biological matrices can be extremely complex. With MS/MS and the proper choice of precursor/product ion pairs, interferences are minimized when imaging bio-organic molecules in complex matrices -- resulting in high contrast images

We have generated MS/MS data on metastable ions from met-enkephalin and substance P using the TRIFT™ instrument. To obtain this data, molecular ions were formed under energetic (11 keV) Cs^+ primary ion bombardment TRIKES (Time Resolved Ion Kinetic Energy Spectrometry)[3-4] was used to identify the precursor/product ion masses. By placing an energy slit after the first ESA and scanning the three ESA's in unison, we can select product ions of a certain energy which represent a specific product ion to precursor ion mass ratio. By measuring the flight time of the product ions, we determine the precursor ion mass since the precursor ion and product ion have essentially equal velocities The product ion mass was calculated from the precursor ion mass and the product ion to precursor ion mass ratio

We generate TRIKES data essentially as MS/MS maps by scanning the ESA's (the energy range being transmitted) and acquiring a time-of-flight spectra for each energy setting Surprisingly, we have found metastable decay to be a highly probable process and have measured metastable efficiencies (defined as the intensity of all metastable ions divided by the intensity of all normal SIMS ions) of roughly 12% for met-enkephalin and 40-50% for substance P. Therefore, useful TRIKES spectra can be acquired using reasonable integration times (typically 1 minute integration times for each energy setting) Of course, the metastable ion intensity encompasses many different precursor and product ion masses Peaks from low abundance precursor ions or improbable precursor to product ion transitions will require longer integration

times. With the large energy pass of the TRIFT™ spectrometer, we can use energy steps of 1% (no energy slit) to generate a map without losing peaks. Thus, depending on the region of interest, up to 100 spectra would be needed to build a complete map For acquiring detailed precursor ion spectra, we use smaller energy steps (0 1%), so more spectra are needed to define the same region

Typical product ion mass resolutions are approximately 1000. Figure 1 shows a TRIKES spectrum of the YGG (278) to YG (221) transition for met-enkephalin (mass resolution of 960). Despite the energy release of the metastable decay, the product ion resolution is impressive for two reasons First, the spectrometer provides excellent compensation for energy spread at any given ESA setting Second, as the ESA is scanned, the flight time of the peak (and the apparent mass) shift as one would expect, but this shift is canceled by the change in the energy fraction (product ion mass/precursor ion mass). Therefore, the product ion mass (the precursor ion mass times the product ion mass/precursor ion mass ratio) does not shift. On the other hand, the parent ion resolution is limited by the energy release in the metastable fragmentation. Figure 2 shows the precursor ion spectrum for mass 221 in met-enkephalin (mass resolution of 56). This spectrum is extracted from TRIKES spectra obtained at energies of 0.787 to 0 802 times the accelerating energy. The mass resolution corresponds to an energy release of approximately 0.9 eV.

Mass Spectrometric Studies on Porphyrins and Geoporphyrins

*Quirke, J. Martin. E.[1]; Yost, Richard A.[2]; and Van Berkel, Gary J.[3]

2) Department of Chemistry, University of Florida, Gainesville, FL 32611-7200
3) Chemical and Analytical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831

Porphyrins are among the more important compound classes, playing significant roles in such diverse areas as medicine, material sciences, catalysis and the petroleum industry. The most valuable property of the porphyrin macrocycle is its ability to chelate with any metallic element. In organic geochemistry, geologically-occurring porphyrins, geoporphyrins, are of both academic and commercial consequence.

Geoporphyrins occur as complicated mixtures of nickel(II) and vanadyl(II) [VO(II)] complexes in a wide range of sedimentary environments. They are believed to be formed by transformation of the functional groups of biologically-occurring cyclic tetrapyrroles, especially chlorophyll a into alkyl or hydrogen substituents coupled with the oxidation of the chlorin (dihydroporphyin) to the porphyrinic system. This proposal, the Treibs' hypothesis, is the cornerstone of molecular organic geochemistry.[1] The precise composition of geoporphyrin mixtures varies from crude oil to crude oil. For this reason, analysis of geoporphyrin mixtures is a valuable tool for the correlation of crude oils with other oils and/or source rocks.[2] Less happily, the geoporphyrins, especially the vanadyl complexes, poison catalysts in cracking of crude oil and other industrial processes.[3] Mass spectrometry is perhaps the most valuable tool for analysis of geoporphyrin mixtures. Such analyses present the mass spectrometrist with several challenging problems. Geoporphyrin mixtures are composed of overlapping pseudohomologous series of at least nine skeletal types. Carbon number ranges of C_{28}-C_{50} are not uncommon. The upper limit of the carbon number range is still unclear.

In this study, four facets of mass spectrometric analyses of porphyrins and geoporphyrins will be presented. First, the value of electron ionization tandem mass spectrometry (MS/MS) for identification of the various skeletal types of cycloalkanoporphyrins (CAP's)—porphyrins bearing an exocyclic ring—will be demonstrated[4]. Careful analysis of the $[M-40]^+$ to $[M-45]^+$ region of the daughter ion spectra of the molecular ions of CAP porphyrins may be used to identify the size of the exocyclic ring. For example, a CAP porphyrin bearing a 5-membered ring shows an intense diagnostic daughter ion, $[M-44]^+$. Second, electron ionization tandem mass spectrometry provides the best analytical method for the analysis of high carbon number ($>C_{33}$) porphyrins in crude oils.[5] The commercial and academic importance of these largely unexplored compounds will be discussed. Third, electrospray mass spectrometric analyses of geoporphyrins will be described.[6] This technique shows great promise for determining the carbon number range, and relative abundances of the geoporphyrins in intact mixtures. Electron ionization mass spectrometry is not well-suited to this task because fragment ions can coincide with lower molecular weight components of the mixture. Fourth, recent tandem mass spectrometric studies on nitrated porphyrins will be outlined[7]. These compounds, which are in many cases highly distorted, display novel fragmentation patterns in which the expected β-cleavage of alkyl substituents is often suppressed. The potential role of distortion on the fragmentation patterns of porphyrins will be commented on.

Mass Spectrometry of Porphyrins: Ionization and Appearance Energies

*James A. Ferguson[1], J. Martin E. Quirke[2], Jodie, V. Johnson[1], and Richard A. Yost[1]
[1]Department of Chemistry, University of Florida, Gainesville, FL 32611
[2]Department of Chemistry, Florida International University, Miami FL 33199

Porphyrins are of importance in petroleum as geomarkers, molecules which allow the origin of the compound to be traced, and, unfortunately, as potential poisons for cracking catalysts. In addition porphyrins are employed medically in photodynamic therapy, as catalysts for epoxidation reactions, as models for biological systems, and have potential applications in materials science as molecular wires and molecular machines. Approximately 5000 papers dealing with porphyrins are published each year. Despite this high level of scientific output, there is still much fundamental information on porphyrin chemistry to be learned.

The planar geometry of a porphyrin's tetrapyrrolic ring and inherent aromaticity give it great stability. This stability is seen in the high number and abundance of doubly charged (and even triply charged in some cases) ions observed in their mass spectra. The planarity of the ring can be distorted by metalating the porphyrin or by or adding substituents on the *meso*-bridges of the ring (Figure 1). Such distortions can alter the energies required to ionize the molecule and to break the bonds. Monitoring ion intensities while varying the electron energy used in electron ionization (EI) mass spectrometry provides a means of determining the ionization and appearance energies (IE and AE's). The mass spectrometric results may be compared with theoretical calculations predicting ionization energies and bond strengths.

Compared with other methods available for determining ionization energy, EI on the TSQ-70 provides the advantages of requiring only small amounts of sample, rapid determination (on the time scale of minutes as opposed to hours) and automated, real-time computer control of experimental parameters. One disadvantage is the electron beam is not monoenergetic and the energy spread of the electron beam makes absolute determination of the IE's and AE's difficult. While absolute values for IE and AE's are not simple to determine from the data, relative values are readily obtained.

In order to minimize electrical field gradients which would alter the electron energy, the instrument was tuned with the collector (COLL) and first extraction lens (L11) set to instrumental ground rather than the +15V and -5 to -15V respectively to which they are typically set. The electron energy (ELEN) was incremented in 0.1 V intervals under real-time computer control using instrument control language programs. To improve signal-to-noise, ten scans per ELEN value were collected using selected ion monitoring at a 0.5 second per amu scan rate and averaged. The ionization and appearance energies of a series of divalent-metal complexes (including vanadyl – VO) of octaethylporphyrin were determined by varying the voltage on the EI filament in the TSQ-70 under automated instrument control and monitoring the energies at which the molecular ions (M^+ and M^{2+} – first and second ionization energies), and fragment ions, (e.g., $[M-CH_3]^+$ and $[M-2CH_3]^+$ – appearance energies) first appear in the mass spectrum. The first ionization energies of metalated and non-metalated *meso*-substituted (mononitrooctaethyl-, tetranitrooctaethyl-, and tetraphenyl-) porphryins were also obtained. Changes in the EI filament over time affect the absolute values of the IE's and AE's however relative values remain fairly

constant. Results are shown in Table 1. The first section of the table shows the effect of metalating the porphyrin. Addition of the metals tabulated causes only a small distortion to the ring, explaining the small differences in the ionization and appearance energies shown. The effect of addition of a one nitro group a *meso*-bridge carbon is shown in the second section (OEMNP = octaethylmononitroporphyrin). The addition of one nitro group leads to only a small distortion of the ring and only small changes in the first ionization energy were observed. The effect of substitution on all four *meso*-bridge carbons is shown in the third section. Results for tetraphenyl porphyrin (TPP) and octaethyltetranitroporpyhrin (OETNP) show that the increased distortion from the steric effect of tetrasubstitution lead to a larger change in the ionization and appearance energies.

This technique provides a rapid, automated method for determining the relative ionization energies of porphyrins and appearance energies for their fragments which may be of use in predicting the catalytic activity of porphyrins.

Resid is the nondistillable portion of crude oil, generally thought to consist largely of unsaturated molecules of considerable size and ring number. Such molecules must be upgraded to more saturated compounds if they are to be used as fuel sources. Current processing of resid is performed though coking, thermal and catalytic cracking, deasphalting and hydroprocessing. Thermal treatments, however, produce large quantities of low-value coke and hydroprocessing is expensive.

Asphaltenes comprise the most process resistant portion of the resid. They contain high concentrations of heteroatoms and a high degree of unsaturation. Because these undesirable characteristics are concentrated in asphaltenes, finding an improved method of upgrading asphaltenes is a prerequisite to improving the upgrading of whole resid to viable fuel. Asphaltenes have, at present, only an operational definition. They are insoluble in straight chain saturated hydrocarbons. Very little is known about the structure of compounds in asphaltenes. They are a highly diverse group of compounds that are resistant to analysis by conventional methods. Conclusions about the structures of asphaltenes tends to be speculative.

In this study desorption electron impact (HREIMS), chemical ionization high resolution mass spectrometry (HRCIMS), and laser desorption mass spectrometry (LD) have been applied to deasphalted oils (DAO) and asphaltenes derived from heavy Maya resid. LD data should yield information on the high molecular weight aromatic compounds, while HRMS can provide molecular characterization.

Experimental

The resid was obtained by vacuum distillation of an asphaltene rich Maya crude oil. The HREIMS and HRCIMS data were acquired with a Kratos MS50TA at 12K dynamic resolution at a scan rate of 10s/decade. The ionization energy was 70eV for the EI spectra. Isobutane was the reagent gas for the CI experiments. A DCI probe was used to vaporize the samples into the gas phase with a maximum temperature of 700°C and a source temperature of 200°C. The laser desorption data were acquired on both a time-of-flight mass spectrometer constructed in-house and a Kratos MALDI III time-of-flight mass spectrometer fitted with a reflectron.

Results

A comparison HRCIMS data of the resid asphaltene and resid DAO are shown in figure 1. The average molecular weight distribution of the DAO is on average higher that of the asphaltene. Hydrocarbon and heteroatom-containing distributions as a function of hydrogen deficiency are obtained by DEIHRMS. The results show that the distributions of sulfur- and nitrogen-containing compounds in asphaltenes are different from those in DAO. As expected, the asphaltenes show an increase in heteroatom content, while the DAO show more abundant distribution of hydrocarbon series. Monosulfur containing compounds in the asphaltene and DAO are different. Interestingly, the DAO shows a series of peaks separated by methylenes up to a ring+double bond equivalent of 20, indicating aromatic species that are highly alkylated with long carbon chains. Monosulfur compounds in the asphaltenes range between 10 and 25. The distribution of nitrogen containing ions as a function of degree of unsaturation in the asphaltene and DAO fractions is shown in figure 2. A difference in abundance is apparent, with most of the nitrogen ending up in the asphaltene fraction with degrees of unsaturation chiefly in the range from 6 to 26.

Laser desorption is used to provide molecular weight distributions of heavy aromatic vacuum resid asphaltenes. High molecular weight aromatic model compounds show that laser desorption is a viable technique for obtaining molecular weight information from highly aromatic fused-ring compounds. The lack of any appreciable ion intensity in the high mass region (>800 u) is a good indication that most molecules in the asphaltene are lower molecular weight species. However, data from LD for use in molecular weight distributions needs to be interpreted with great care due to wide variations in ion sensitivities. For example, volatile compounds are not observed and aliphatic compounds are ionized only under conditions where cation attachment can occur.

Although the mass spectra indicate low molecular weight distributions (300-1000 u), other techniques, such as vapor phase osmometry and gel permeation chromatography, support higher molecular weights (>2500) for the resid asphaltenes. Recent data from small-angle neutron scattering of resid asphaltenes supports a temperature dependent aggregation process. Thus, the conventional view of asphaltenes as large polycyclic aromatic ring systems is not supported by our results. Future studies will focus on LD of further separated asphaltenes to search for high molecular weight species and more detailed HRCIMS of the nitrogen containing compounds as a function of process conditions.

Richmond, CA 94802-0627

The requirement that all reformulated gasoline (RFG) sold in the United States be analyzed by GC/MS for aromatic content presents a unique challenge and opportunity for petroleum mass spectrometry. A brief overview will be presented on the specifics of the method and the current regulatory requirements it entails. Details of the proposed ASTM implementation of this method will be examined from a mass spectrometry point of view, with emphasis on accuracy and precision considerations as well as the challenges presented by moving this technique into a refinery setting.

A number of extensions and improvements on the current method are proposed A fast chromatography version of the method is introduced, decreasing analysis time from the proposed 90 minute method to 10 minutes The special advantages of micro-bore and mini-bore capillary GC columns for GC/MS quantitation is discussed, including their use to extend the dynamic range and cleanliness of the mass spectrometer Extensions of the method for quantitating oxygenates and individual toxics is evaluated, as well as a proposal for the future use of this method as a complete method for aromatics, benzene (currently only D3606 GC/GC method is acceptable for RFG), and oxygenates (approved method is an OFID method). Data from these methods and the EPA GC/MS method, both measured at the refinery, are compared to show the excellent precision and lack of bias inherent in the GC/MS procedure

Figure I. shows the agreement between the mandated oxygenates method and the GC/MS method using fast chromatography (9 minute GC/MS method). Figure II. shows a sample calibration curve for benzene from 0 1 to 5 weight percent using the small bore capillary column to increase mass spectrometer linear dynamic range.

ANALYSIS OF GASOLINE FOR AROMATIC HYDROCARBONS BY GC/MS AND BY LOW EV-HR/MS

Ronald D. Grigsby and Ted B. McWilliams

BDM-Oklahoma, Inc.
National Institute for Petroleum and Energy Research
P.O. Box 2565, Bartlesville, OK 74005

The United States Clean Air Act requires that finished gasoline be formulated to reduce ozone-reactive emissions and to lower gasoline toxicity Mandated changes in gasoline composition include limiting the concentrations of benzene and total aromatics, as well as other restrictions on composition and volatility. A set of guidelines published by the U.S. Environmental Protection Agency has specified GC/MS for determining total aromatics content Based on the EPA guidelines, the American Society for Testing and Materials has proposed a standard method for determining aromatics in gasoline by GC/MS [1]

In our laboratory, the ASTM gasoline samples have been analyzed by GC/MS in a magnetic-sector instrument equipped with a capillary column In addition, they have been analyzed by low eV-high resolution mass spectrometry with sample introduction through an all-glass expansion-volume inlet. Nominal 10 eV electron ionization was used in the low eV analysis and 70 eV electron ionization in the GC/MS analysis The high-resolution data were obtained at a resolving power of 10,000 For both methods, internal standards were included with the samples and calibration curves were calculated using least squares with a spreadsheet program. As a further check, liquid chromatography was used to analyze the samples for benzene and toluene.

Figure 1 shows the low eV calibration curve for benzene in standard mixture No. 1 The ratio of molecular-ion intensities, Ai/As, for benzene and the internal standard, chlorobenzene is plotted vs. the ratio of weights for the two compounds, Wi/Ws. Theoretically, a straight line passing through zero should be obtained By least squares analysis, the intercept is -0.0095 and the slope is 1 4642.

The GC/MS calibration curve for benzene in standard mixture No. 1 is shown in Figure 2 For this curve, Ai/As is the ratio of the areas under the GC peaks for benzene and chlorobenzene The least-squares intercept is -0.0439 and the slope is 1 6641. Slopes for the two calibration curves are different because the response factors for benzene and chlorobenzene are not the same under low eV and 70 eV ionization conditions.

Table 1 shows a comparison of the analytical results obtained for benzene and toluene in QC sample C1 by the low eV, GC/MS, and HPLC methods.

A comparison of the analytical results obtained for sample RFA by the low eV and GC/MS methods is shown in Table 2. Weight percents of isomers, such as the xylenes and ethylbenzene, are reported together as C2-alkylbenzenes although most of the isomers are actually separated by the capillary-column GC used in the analysis.

In comparison with the low eV method, the GC/MS method provides more detail on the identification and quantification of specific compounds. However, it also requires more time to acquire the data followed by a more complex procedure for data analysis. The low eV method cannot distinguish between isomers. Thus, only compounds having a single isomeric form, e g., benzene and toluene, can be unambiguously identified and quantified. This is not necessarily a disadvantage, though, if only a total percentage of a compound type, such as the C4-alkylbenzenes, is desired.

Hydrocarbon Analysis Using An Ion Trap/MS With External Ionization

Siu T Teng, Finnigan MAT
355 River Oaks Pkwy, San Jose, CA 95134.

Introduction

Hydrocarbon analysis by mass spectrometry in the past few decades was performed on beam type instruments such as magnetic sector or quadrupole mass spectrometers Only recently have a few works of hydrocarbon analysis utilizing a quadrupole ion trap devices been reported. However, until recently, commercial ion trap mass spectrometers were operated conventionally, where the ion trap device was simultaneously used as ion source and mass analyzer The present work was conducted on the GCQ, which decoupling the ion source from the ion trap device as mass analyzer. This external ionization technique offers the leverage of temperature controlling of the ion source independently from the ion trap manifold The ions generated in the ion source are injected into the ion trap via a lens system and controlled by radio frequency (RF) using the waveforms technique The ion population is controlled by instrument software.

Experimental

The GC/MS analysis of normal alkanes was conducted by injecting 0.2 µL, 100·1 dilution of a standard mixture (Supelco) into a DB5MS (J&W) column. For the GC/MS analysis of the gasoline refinery standards (AccuStandard) a DB1 (J&W), 0 1 mm ID,0 40 µmm film thickness, 20 meters column was used For the analysis of the high boiler additives in diesel the DB5HT (J&W) column was used.

Results and Discussion

Typically, the analysis of aliphatic hydrocarbons may be hampered by the virtual absence of molecular ions and excessive fragmentation This is especially true for the most ion trap instrumentations with internal ionization Phinney [1] showed that varying the thermal energy imparted to the analyte molecules in the ion trap manifold could reduce fragmentation of C10 to C28 alkanes and enhance the abundance of molecular ions However, the most crucial condition is a temperature controlled ion source, which is achieved by the external ionization Figure 1 shows C30 (triacontane) as example of the results of saturated straight chain hydrocarbons analysis The molecular ion is well detected The result exhibits the primary characteristic of saturated hydrocarbon mass spectra with a smooth envelop of relative intensity distribution formed by the odd numbered series of m/z (14n+1), termed A^+ ions, where n is the number of carbon atoms in the fragment The exessive fragmentation due to the α-cleavage of the adjacent carbon-carbon single bond was not observed. The series of the $(A-1)^+$ and $(A-2)^+$ ions also appear to be matching the conventional quadrupole mass spectra in its intensity distribution. Figure 2 shows examples of the five point curve calibration of toluene and naphthalene of a refinery standards mixture required for the proposed ASTM method (draft #5) for quantitative gasoline analysis Figure 3 shows an MS/MS product ion spectra of hexadecyl diphenylamine at 1 ppm in diesel fuel. This demonstrates the sensitivity and specificity using MS/MS technique to identify and confirm low level concentration components in complex matrices.

INDUSTRIAL APPLICATIONS OF FTMS: A PRESENT AND FUTURE PROSPECTUS

Joseph E. Campana, Extrel FTMS, Inc., 6416 Schroeder Road, Madison, WI 53711-2424

Petrochemicals include a wide variety of products from fuels, feedstocks derived from petroleum and natural gas, such as ethylene and butadiene; and large scale plastics and resins. We have reported how features of Fourier transform mass spectrometry (FT/MS), such as accurate mass determination (sub ppm) and ultra-high resolution can be applied to the analysis of hydrocarbons [1]. Figure 1 illustrates a relatively wide mass range (100 amu) ultra-high resolution (>200,000 resolving power) mass spectrum of a vacuum gas oil. The sub-ppm mass measurements were used to confirm the species identified in the inset. The mass errors for most peaks identified in Figure 1 are less than 1 mmu [1].

Other features of FT/MS include its compatibility with pulsed ionization techniques, such as laser desorption ionization (LDI) and matrix-assisted laser desorption; multistage mass spectrometry, high sensitivity, and compatibility with electrospray ionization, which will enable routine LC FT/MS. These features have application to the characterization of polymers and related materials, a necessity in today's petrochemicals industry.

LDI and MALDI FT/MS have been used to characterize many different classes of polymers ranging from polyols to glycol derivatives. Applications have been in structure determination, chemical composition, end-group identification, identifying variations in synthetic pathways, and average molecular weight determination. An example of MALDI FT/MS determination of average molecular weight with accurate mass measurement is illustrated in Figure 2 with polyoxyproplyenediamine, a product manufactured by a petrochemical company. There have been a wide variety of laser desorption FT/MS applications to polymer, plastics, and additives that have appeared in the chemical literature. Two recent review articles summarize such applications [2, 3].

These laser-based FT/MS techniques provide excellent molecular information and high sensitivity. High signal-to-noise ratio mass spectra can often be obtained in a single laser shot. This is very useful when a surface contaminant, a blemish, or impurity in a solid matrix has to be determined. The mass spectral results provide very high mass accuracy, and thus elemental compositions can be determined, unlike the results obtained on many time-of-flight mass spectrometers. Multistage mass spectrometry techniques can be applied if structural elucidation is necessary. Another important advantage of FT/MS is that high mass accuracy (less than 5 ppm error) can be routinely obtained without the use of an internal mass reference with laser desorption ionization. This is an advantage when probing solid and reactive materials where it is undesirable or at best, difficult to introduce an internal mass reference.

Advanced, state-of-the-art data acquisition hardware and software has improved the user friendliness of FT/MS for the non-specialist. It is also improving the performance and flexibility of the FT/MS technology as an analytical method. Expect to see further improvements in routine high mass measurement accuracy, higher resolution, the ability to perform ultra-high resolution accurate mass measurements over very wide mass ranges (1000 amu +) without internal mass references, and routine chomatography applications. These improvements will be a culmination of more powerful data stations and more people adopting FT/MS as the high-performance mass spectrometer of choice for analytical measurments.

The Identification of Zinc Dialkyldithiophosphates in Lubricating Oils by Electrospray Ionization Mass Spectrometry

Vincent P. Nero and Donald D. Drinkwater
Texaco R&D, PO Box 509 Beacon, NY 12508

Electrospray Ionization Mass Spectrometry (ESI) was used to characterize the Zinc Dialkyldithiophosphates (ZDDPs), which are usually found in finished commercial motor oils. ZDDPs are detergent-like molecules consisting of the polar heteroatomic organometalic core surrounded with highly alkylated side-chains to increase their solubility in the base oil The core contains a central zinc atom coordinated to two dithiophosphate esters Generally two alkylated side chains, ranging from three to thirteen carbons, will be on each ester. ZDDPs are low cost additives which form protective films to reduce engine wear and prevent metal seizures. ZDDPs also serve as oxidation inhibitors. Their concentrations typically vary between 1% and 4%

ESI procedures have been developed, which can quickly characterize ZDDPs even in a fully formulated lubricant. The technique uses both positive and negative ion modes, and sometimes daughter ion analysis was also used to further elucidate composition The molecular ion distribution of the various types of alkyl groups and information concerning the nature of dimeric forms of the ZDDPs is obtained
In the positive ion mode, ESI sodium adducts form with the ZDDP molecular ions. This provides excellent information for identifying and quantitating their alkyl distributions. Figure I illustrates the alkyl distribution patterns of a zinc propyl hexyl dithiophosphate. This figure also clearly shows the characteristic zinc isotopic distribution of the individual alkyl clusters Under atmospheric pressure chemical ionization (APCI) conditions, ZDDPs form both protonated adducts to the molecular ions and fragment ions, but unfortunately, these fragment ions dominate the spectrum. The primarily fragmentation arises from the extensive loss of alkenes. Figure II illustrates a typical APCI spectrum. The major ion cluster around 322.6 amu represents complete loss of alkyl groups.
The negative ESI mode also provides excellent information. Under these conditions, the dialkyl dithiophosphate anion dominates the mass spectrum. Figure III shows the anions produced by zinc butyl pentyl dithiophosphate. Again, the alkyl groups can be easily identified and their distribution can be easily quantitated

Sample Preparation: All samples were either commercial additive packages consisting of ZDDPs in base oils or completely formulated commercial lubrication oils 100 ppm solutions of the additive package or 1000 ppm of the lubrication oil were prepared in various mixtures of MeCl2 / MeOH / hexane Solutions were infused directly into the MS interface at 30 ul/min.

Instrument Parameters: Both APCI and ESI experiments were performed on a Finnigan MAT TSQ 7000 MS. ESI parameters were: 80 psi nitrogen as a sheath gas pressure, 10 ml/min auxiliary nitrogen flow, 5 kV ionization spray voltage in both positive and negative ion modes, 250 °C capillary temperature, 20 V on the tube lens, 65 V on the skimmer region, and -3 V on the octapole lens, generally with no CID offset voltage. APCI parameters were 40 psi sheath gas, 150 °C capillary temperature, and 3-6 kV corona discharge voltage. Scan times were 4 sec. in the profile mode. MS/MS spectra were obtained using 60 V argon collisions.

FLUID CATALYTIC CRACKING PRODUCTS CHARACTERIZED BY GCMS

Michael T. Cheng and James D. Hudson
Chevron Research and Technology Company
Richmond, California

Fluid catalytic cracking (FCC) products from the treatment of petroleum streams are important blending components for transportation fuels. There are many streams that can be the feedstocks to a FCC unit, therefore, FCC products are very complex and consist of many different types of compounds, such as alkanes, alkenes, cycloalkanes, and aromatic compounds. GCMS would be an ideal tool to characterize the FCC products, except that mass spectrometry is deficient as a tool to differentiate alkenes and cycloalkanes with same empirical formula, because they have very similar mass spectra. To fully characterize the FCC products, we describe in this report, a procedure in which the FCC products were analyzed before and after mild hydrogenation.

FCC products used in fuel blending are usually distilled, this sample was produced in the pilot plant and distilled at 343C. Initial GCMS run showed the presence of many peaks in the chromatogram. Most of the peaks can be identified unambiguously as alkanes (normal or branched C_5H_{10} to $C_{21}H_{44}$), or aromatic compounds, on the other hand, the alkenes and the cycloalkanes cannot be differentiated. Included in the aromatic compounds are alkylbenzenes, alkylindanes, alkylindenes, alkylnaphthalenes, alkylbiphenyls, and alkylphenanthrenes. The sample was then subjected to mild catalytic hydrogenation over 10% Pd on carbon at room temperature, and the hydrogen was supplied by a small party balloon. The hydrogenation was allowed to proceed until no hydrogen uptake was detected, however, the more definitive indication was by NMR. The proton NMR of the sample before hydrogenation showed olefinic protons and methyl groups attached to carbon-carbon double bonds, after hydrogenation the olefinic protons and the methyls attached to olefinic double bonds all disappeared, while the aromatic methyl groups are unchanged. This indicated that the olefinic double bonds were hydrogenated, while the aromatic double bonds were not changed.

This hydrogenated sample was then analyzed by GCMS. Many peaks present in the un-hydrogenated sample had disappeared upon hydrogenation, while no new peak was created upon hydrogenation. The disappearance of peaks was specially pronounce during the early part of the chromatogram, while the later part of the chromatogram was virtually unchanged. If a peak disappears upon hydrogenation, it then is an olefin; if it remains, a cycloalkane. Using this algorithm, all of the peaks in the un-hydrogenated sample can be identified. Using peak area from the total ion current trace, the following table summarizes the data.

	0-10 min	0-20 min	0-30 min	0-40 min	0-50 min	0-60 min
n-alkanes	8.8	5.3	3.9	3.6	4.0	4.5
branched alkanes	38.3	34.7	29.2	22.3	17.6	16.9
alkenes	49.2	32.5	19.9	13.7	10.8	10.4
cycloalkanes		17.7	19.0	13.0	10.3	9.9
cycloalkenes	3.7	2.8	1.9	1.2	1.0	1.0
dicycloalkanes			0.4	0.5	0.4	0.4
benzenes		6.9	24.4	28.1	23.0	22.1
indanes			1.0	12.8	11.6	11.2
indene			0.3	0.2	0.2	0.2
naphthalenes				4.4	17.1	16.8
biphenyls					4.0	5.6
anthracenes						0.9
total	100	99.9	100	99.8	100	99.9

Compounds with five or fewer carbons eluted in the 0-10 minute retention window, and in this window about 50% of the area was accounted for by the alkenes. In the 0-20 minute retention window, compounds with up to eight carbons elute; alkenes with five, six and seven carbon atoms account for about a third of the total area; cycloalkanes such as cyclopentanes and cyclohexanes, account for about 18% of the total; benzene and toluene are found in this window. In the 0-30 minute window, the benzenes account for about 25% of the total. Only small amount of alkenes with eight, nine, and ten carbons are found in the 20-30 retention window, the chromatograms for the sample before and after hydrogenation are very similar. From retention time of 30 minute until the end of the run, the TIC for before and after hydrogenation are essentially identical. In the 0-40 minute retention window, compounds with up to 13 carbon atoms are found. In the 0-50 minute window, compounds with up to 17 carbon atoms are found. And compounds with up to 21 carbon atoms are found in the last ten minute of the run.

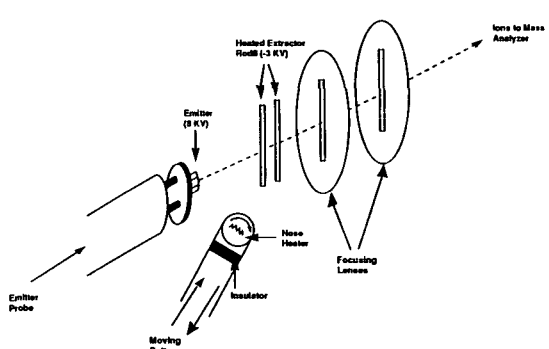
From the table, one can then conclude that, the alkenes formed in a FCC unit are small alkenes, five, six, or seven carbon atoms species account for most of the alkenes, and they constitute about 10% of the total; benzenes are the most abundant species, they constitute about 22% of the total. This strategy can be applied to many refinery streams where it is necessary to distinguish alkenes from the cycloalkanes.

Coupling Field Ionization Mass Spectrometry with Liquid Chromatography for the Characterization of Heavy Saturated Hydrocarbons

Z. Liang, C. S. Hsu* and P. B. Grosshans
Exxon Research and engineering Company
Annandale, New Jersey 08801

We have successfully re-configured a commercial field ionization (FI) source to accommodate the moving belt interface for on-line LC operations. This novel combination allows us to characterize saturates with maximum chromatographic resolution and minimal sample preparation. Optimum FI operating conditions are obtained by comparing the carbon number distribution of a synthetic wax mixture by FI with that measured by gas chromatographic distillation (GCD). We found that it is important to apply a flash current onto the emitter between scans to avoid the condensation of high boiling components. Otherwise, the signals of high boiling components would be enhanced, resulting in a distorted quantitative measurement of the components in the mixture.

A SIMPLIFIED VIEW OF MOVING BELT LC/MS WITH FI SOURCE



- EMITTER AND COUNTERELECTRODE - HIGH VOLTAGES

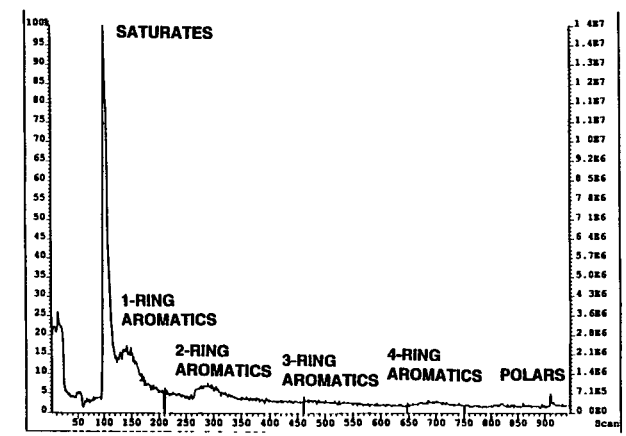
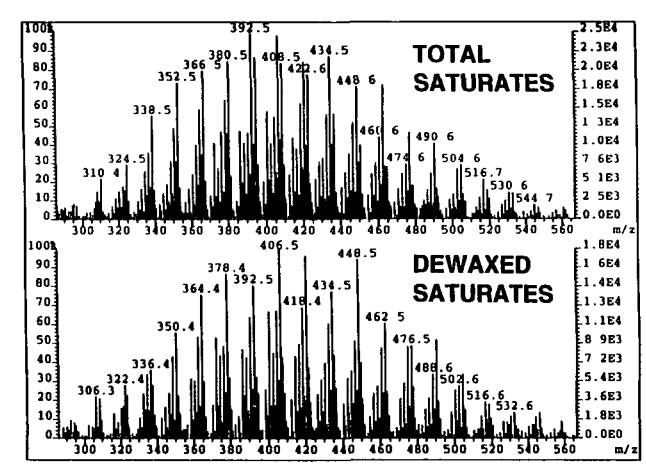
ON-LINE LC/MS ALLOW MAXIMUM CHROMATOGRAPHIC RESOLUTION AND MINIMAL SAMPLE PREPARATION



REMOVAL OF NORMAL PARAFFINS IS EVIDENT FROM THE FIMS MOLECULAR ION DISTRIBUTIONS



Why Do We Still Care about Dioxins?

Ronald A. Hites and Louis P. Brzuzy. School of Public and Environmental Affairs and Department of Chemistry, Indiana University, Bloomington, Indiana, USA, 47405.

Chlorinated dioxins and dibenzofurans (PCDD/F) are well-known environmental contaminants that have received prolonged attention by the scientific community and by environmental regulators. They enter the atmosphere primarily as byproducts from industrial combustion, waste incineration, metals production, and automobile emissions. PCDD/F are semivolatile, hydrophobic compounds; hence they accumulate in organic rich media such as soils, sediments, and biota .

In spite of our knowledge about the environmental behavior of PCDD/F, a significant problem remains: Deposition from the atmosphere is estimated to be roughly 10-25 times higher than estimated inputs from known sources.[1,2] There are three explanations for this mass balance discrepancy: **(a)** The depositional fluxes are overestimated because of sampling bias. **(b)** The input estimates are low because of unrecognized sources. **(c)** Both the sources are underestimated and the deposition is overestimated. We believe that depositional fluxes are overestimated because most PCDD/F measurements have been made in places of significant human industrial activity. Clearly, an expanded database of PCDD/F measurements from many geographical regions must be established before a realistic assessment of their mass balance can be made.

Measuring PCDD/F deposition directly is difficult, and there are few such measurements in the literature. Instead deposition is estimated from concentration measurements in other environmental matrices. For example, concentrations of PCDD/F in air and precipitation (usually rain) are used to estimate dry and wet deposition, respectively. Atmospheric deposition can also be estimated from PCDD/F concentrations in lake sediments. A sediment-derived estimate yields a sum of both wet and dry deposition.

Each of these techniques has practical limitations involving transporting and operating sampling equipment in rural and remote regions. To estimate fluxes on an expanded geographical scale, we have developed a technique using soils[3]. Soils are uniformly distributed, and they are relatively easy to collect and handle, providing a convenient matrix from which to estimate atmospheric deposition of PCDD/F.

Global Mass Balance for PCDD/F. We collected or had collected soil samples were collected from several areas of the world covering both the Northern and Southern Hemispheres. Over 300 samples were collected, and approximately 150 of these samples have been analyzed. From these data, fluxes have been estimated.

Atmospheric measurements of PCDD/F concentrations worldwide show that concentrations are within a fairly narrow range, between approximately 0.5 and 35 pg/m^3. This indicates that they are relatively mixed in the ambient atmosphere. Soil and sediment concentration values show greater variability. Sediment concentrations from the Great Lakes and Siskiwit Lake range

from 23 to 1500 pg/g. Literature values for background soil concentrations range from about 25 to 10000 pg/g.

Since PCDD/F are removed from the atmosphere by dry and wet deposition, then climatic factors that influence deposition might be controlling their concentrations in environmental sinks. We suggest that the deposition of PCDD/F from the atmosphere may exhibit some correlation to the various climatic zones of the world. If we consider these climatic zones as different depositional environments for atmospheric PCDD/F, we can estimate fluxes for each of these zones and revise the mass balance based on the flux and the geographical area of each zone.

Table 1. Area of the major climatic zones of the world, PCDD/F flux to, and estimated deposition to those areas.

Climate Zone	Area (10^{12} m^2)	Flux (ng/m^2 y)	Depostion (kg/yr)
Tropical Rainy	34.4	25	900
Dry	46.6	15	700
Humid Mesothermal NH	8.8	100	900
Humid Mesothermal SH	1.1	15	17
Humid Microthermal	16.4	70	1000
Polar	25.5	15	400
Undifferentialed Highlands	7.1	250	1800
Flux to Land			6000
Oceans	396 4	15	6000
Global Deposition			12000

Table 1 shows the major climatic zones of the world based on the designation of Trewartha[4], the areas of those zones, and the flux and the deposition of PCDD/F to those zones. Total deposition to these zones is about 6000 kg per year. However, this designation of climatic zones does not take into account the area of the global oceans. If we use a conservative depositional flux estimate of 15 ng/m^2 y, then the output rate to the global oceans is about another 6000 kg/yr. We estimate a total global deposition of PCDD/F at about 12,000 kg/yr, or about 12 kg/yr TEQ.

Based on current emission factor data from known combustion sources [5], we estimate global emissions of PCDD/F at about 5,000 kg/yr, which is about half of our estimate of deposition.

We conclude from this study that the global deposition of PCDD/F has been overestimated in the past. When deposition is estimated based on geographical regions, the mass balance between emissions and outputs improves. This indicates that most of the major sources of PCDD/F are known, and that PCDD/F contamination to the environment can be limited by controlling the emissions from these sources.

Ultra sensitive and Very Fast Analysis of Halogenated Toxicants

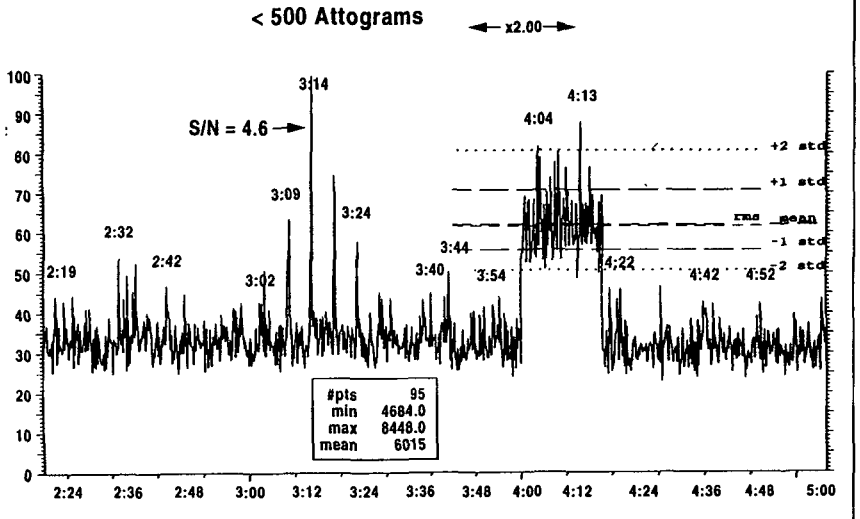
Donald G Patterson, Jr , Zaiyou Liu, John R. Barr, Vaughn E. Green

Centers for Disease Control and Prevention
4770 Buford Highway, NE, Atlanta, GA 30341

Current sample cleanup and mass spectral methods for halogenated environmental toxicant analysis have recently generated a large amount of human and environmental data The impact of this new human data on analytical needs will be discussed However, the high cost ($1000 to $2000 per sample) and slow sample throughput of these methods (3 unknown samples per day) limits the size and statistical power of epidemiologic studies designed to assess any potential human health effects from exposure to these compounds In order to reduce the cost of these analyses and increase the sample throughput, we have developed a high speed, ultra sensitive, comprehensive two-dimensional separation system with high resolution mass spectrometric detection

Comprehensive two-dimensional separations differ from conventional heart-cutting multidimensional separations in that all substances are subjected to both dimensions of the separation process The theoretical peak capacity obtained from an orthogonal two-dimensional separation process is the product of the peak capacities obtained on each dimension. The same number of theoretical plates necessary to resolve the analytes of interest can be generated in a much shorter time with a comprehensive two-dimensional separation scheme than with a single dimensional approach. We have developed a prototype comprehensive two-dimensional gas chromatographic (C2D/GC) system utilizing a two-stage thermally modulated interface. This system has been interfaced to a Fisons/VG AutoSpec mass spectrometer and the combined C2D/GC/HRMS system used to determine polychlorinated dibenzo-p-dioxins (PCDDs), halogenated pesticides, and other environmental toxicants in human sample extracts The C2D/GC system utilizes two capillary columns (DB-5 and OV-1701) with a two-stage thermal modulation interface The Autospec mass spectrometer is operated in the SIR mode at 3000 resolving power while monitoring several ions for the native compounds and several ions for the carbon-13 labeled internal standard. Each of the second-dimension GC peak widths are about 60 msec at half-height giving about 5 data points over each second-dimension peak The thermal modulation system also generates an increase in sensitivity For example, summing four second-dimension peaks gave a signal/noise ratio of 12 for 500 attograms of 2,3,7,8-tetrachlorodibenzo-p-dioxin injected (See Figure) These data demonstrate the high sensitivity and specificity of the C2D/GC-HRMS system

Comprehensive 2D/GC-HRMS (3000RP) of 2,3,7,8-TCDD



ACCUMULATIONS AND INVENTORIES OF ORGANOCHLORINES IN GREAT LAKES SEDIMENTS

D.L. Swackhamer, R.G. Pearson, University of Minnesota, Box 807 UMHC, Minneapolis, MN 55455; S.J. Eisenreich, Gray Freshwater Biological Institute, University of Minnesota, Navarre, MN 55392; D.T. Long, Geological Sciences, Michigan State University, E.Lansing, MI, 48108.

The Great Lakes are the largest reservoir of fresh water in the world They are home to more than 42 million people in the United States and Canada They also support an invaluable shipping industry, steel manufacturing, chemical industry, and commercial and sport fishery Unfortunately, they are also contaminated by more than 1000 chemicals The International Joint Commission has focused on 15 chemicals of concern, those that are persistent or have potential to bioaccumulate Included in this list of priorities are the pesticide toxaphene and the polychlorinated dibenzo-p-dioxins (PCDDs) and dibenzofurans (PCDFs) The state, provincial, and federal resource managers need to understand the history of these contaminants, and whether they are predominantly atmospheric or non-atmospheric, in order to best regulate the region

Toxaphene is a broad spectrum insecticide composed of hundreds of chlorinated bornanes and bornenes. Toxaphene was the replacement chemical for DDT, and was the most widely used organochlorine pesticide in North America It was mostly used in the southern U S., and was banned in the mid-1980's due to concerns of persistence and toxicity It is thought that toxaphene found in the Great Lakes is largely due to long range atmospheric transport from the south and atmospheric deposition into the lakes. The PCDDs and PCDFs are combustion products, and would be expected to have higher concentrations near urban and industrial regions.

Lake sediments accumulate over time, and particle-bound contaminants such as these will also accumulate over time in bottom sediments Thus sediments are useful to study in order to understand the history of inputs of contaminants to the Great Lakes We obtained several sediment cores from the Great Lakes, and used the data from them to determine current and past accumulations in the lakes, the time they first began to accumulate, the total integrated burden of contaminant in the lake, and evaluate the relative importance of atmospheric vs. non-atmospheric inputs. Cores were obtained from three sites in Lake Ontario in an east-west gradient, three sites in Lake Michigan in a north-south gradient; two sites in Lake Superior, one a depositional and one a non-depositional zone of the lake, and from two "control" lakes receiving only atmospheric deposition, one on Outer Island in the Apostle Islands, and Siskiwit Lake on the Bayfield penninsula Cores were sectioned in 1 cm or less intervals, and dated by ^{210}Pb. Sections were analyzed by Soxhlet extraction, silica gel and alumina cleanups, and gas chromatographic mass spectrometry in electron capture negative ion mode. Selected ions were monitored to quantitate homologs and total compound class

Accumulations of toxaphene in Lake Superior were two times greater than in the remote lakes (0.05 ng/cm2 yr), at all times. The homolog composition in the control lakes was constant throughout the cores and between cores, and showed a dominance of the heptachlorinated bornanes However, the composition in Lake Superior was significantly different, composed of mostly the octachlorinated bornanes. This composition more closely resembles the parent pesticide, while the control lakes are indicative of atmospherically weathered toxaphene. The inventories in Lake Superior are

approximately twice that of the control lakes. This evidence suggests that there has been and continues to be additional non-atmospheric inputs of toxaphene to Lake Superior.

Lake Michigan and Ontario accumulations are significantly greater than those in Lake Superior (5-10 times greater) The accumulations began in the 1940's, and maximized in Lake Michigan in 1980, except for the northern-most core In this core, the accumulations increased rapidly from the mid-1970's to the present Current accumulations here are higher than anywhere in the Great Lakes The homolog composition was similar for all three cores, however, and resembled the composition of parent toxaphene The inventories per unit area are 2-3 times greater than Lake Superior These data suggest that there has been a significant non-atmospheric source of toxaphene to Lake Michigan, and in particular there is a current source to the northern part of the lake

In contrast, accumulations in Lake Ontario increased to a maximum at about 1970 Accumulations increase from west to east in the lake The homolog compositions were similar in the western and central cores, having equal amounts of hexa-, hepta-, and octachlorinated bornanes, but the eastern-most core had a composition similar to parent toxaphene. Based on the hydraulics of Lake Ontario, this suggests an additional source of toxaphene from the New York side of the lake east of the Niagara River Inventories per unit area are slightly greater than those for Lake Michigan

PCDD and PCDF accumulations and inventories were similar in Lake Superior and the control lakes (1-3 pg/cm2yr), indicating that for these compounds, Lake Superior is an atmospherically-driven lake Accumulations were 5-10 times greater in Lake Michigan than in the control lakes, but they were not greater in the southern basin of the lake as was expected from the industrial and urbanized Milwaukee-Chicago-Gary corridor. Accumulations reached a maximum in the 1970's, except for the northern-most core which appears to have had constant accumulation since the 1970's The accumulations were another 3-5 times greater in Lake Ontario than in Lake Michigan, with a maximum in the 1970's.

The homolog composition of PCDDs was similar in all lakes and with depth The furan compositions were constant within a given lake and with depth, however, compositions differed among lakes In Lake Michigan and the control lakes, compositions were similar, and had a predominance of the less-chlorinated homologs (tetra- and penta-) In Lake Superior, the hepta-chloro homolog predominated The reason for the lack of agreement between Lake Superior and the control lakes is unclear In Lake Ontario, the furan composition was yet again different, having similar amounts of each of the homologs Furthermore, the relative proportion of furans to dioxins differed in Lake Ontario than in the other lakes, indicating a source of furans not linked to the source of dioxins

In summary, there are significant non-atmospheric sources of toxaphene to the Great Lakes, and current elevated accumulations in northern Lake Michigan. In general, accumulations maximized in the 1970's, but are still higher than in control lakes Lake Superior receives PCDDs and PCDFs almost entirely from the atmosphere, while much higher accumulations (order of magnitude) occur in Lake Michigan and Lake Ontario We do not see a sub-regional influence of PCDD and PCDFs on southern Lake Michigan as expected There appears to be an additional source of furans to Lake Ontario, decoupled from the sources of dioxins.

Characterization of Two Major Toxaphene Components in Lake Sediment.

Toxaphene, a complex mixture consisting primarily of chlorinated bornanes (CHB's), was once widely used as a insecticide and briefly used as a fish toxin during the late 1950's and 1960's in many North American Lakes. The technical material is thought to consist of between two and three hundred penta- to undecachlorobornanes and camphene/diene isomers[1,2]. It is well known, however, that toxaphene residues extracted from biotic and abiotic samples do not resemble the technical material as analysed by HRGC, but instead consists of a more limited number of hexa-, hepta-, octa- and nonachlorobornanes[3]. In previous work[4,5], we structurally identified the two major CHB congeners, T2 (2-*exo*,3-*endo*,5-*exo*,6-*endo*,8,8,10,10-Octachlorobornane) and T12 its nonachloro- analog (2-*exo*,3-*endo*,5-*exo*,6-*endo*,8,8,9,10,10-Nonachlorobornane) found in beluga blubber. We report here the isolation of two more environmentally significant toxaphene congeners, a hexa- and heptachlorobornane (Hx-Sed and Hp-Sed, respectively), from the sediment of two lakes located in Alberta Canada[6] and their structures as determined by mass spectrometry (GC-ECNIMS, high and low resolution EIMS and linked field scanning) and ^{1}H-NMR. In the early 1960's both lakes were treated by addition of toxaphene to the water column at low ug/L concentrations. Sediments were collected from these lakes by freeze-coring, dated using ^{210}Pb and by counting varves and extracted with DCM. Highest toxaphene concentrations (~500-1600 ng/g dry wt.) were found in sediments of both lakes in slices dated to the early 1960's. In these slices the chromatographic pattern resembled that of the toxaphene standard while in more recent slices, the number of CHB peaks was greatly reduced with the two most prominant peaks corresponding to Hx-Sed and Hp-Sed.

The EI positive ion mass spectra of Hx-Sed and Hp-Sed are shown in Figure 1. In the mass spectra of both compounds, a 110 Da neutral species is eliminated from $[M\text{-}HCl\text{-}Cl]^+$ (m/z 271 for Hx-Sed, 305 for Hp-Sed) to yield the m/z 161 ion in the mass spectrum of Hx-Sed and the m/z 195 ion in that of Hp-Sed The observation of these decompositions, verified for both compounds by linked field scanning, provides us with important structural information because the neutral species lost are comprised of the bridging carbon (C7) and its two substituents *i e.* $CH_2ClC{:}CH_2Cl$ Observed decompositions involving the loss of CH_2Cl in the mass spectra of both compounds and the absence of corresponding decompositions involving the loss of $CHCl_2$ further support the positioning of two monochloromethyl moieties on C7. The group of peaks starting at m/z 306 and 307 in the mass spectrum of Hx-Sed and at m/z 340 and 341 in the mass spectrum of Hp-Sed correspond to the ions $[M\text{-}Cl]^+$ and $[M\text{-}HCl]^+$, respectively. Verified by linked-field scanning, the neutral fragment $C_2H_2Cl_2$ is eliminated from the latter ion giving rise to the even mass odd-electron ion $[M\text{-}HCl\text{-}C_2H_2Cl_2]^+$ (m/z 210 for Hx-Sed, 244 for Hp-Sed). In the mass spectrum of Hx-Sed loss of C_2H_3Cl is also observed and gives rise to the even mass odd-electron ion $[M\text{-}HCl\text{-}C_2HCl_3]^+$ (m/z 244). Losses of both C_2H_3Cl and $C_2H_2Cl_2$ in the mass spectrum of Hx-Sed suggest that there are three chlorines on the ring, two on one side and one on the other. In the mass spectrum of Hp-Sed, loss of only $C_2H_2Cl_2$ and not C_2H_3Cl, C_2HCl_3, C_2H_4 or C_2Cl_4 suggest a total of four ring chlorines, two on each side.

In the mass spectra of T2 and T12, competitive losses of Cl and HCl from the molecular ion were observed while those of toxicants A and B (2,2,5-*endo*,6-*exo*,8,8,9,10,10/8,9,9,10-Octachlorobornane and 2,2,5-*endo*,6-*exo*,8,9,10-Heptachlorobornane, respectively) showed an enhance elimination Cl

from the molecular ion[5]. It was suggested that the enhanced HCl elimination from the molecular ions in T2 and T12 with respect to that of toxicants A and B was to be expected from the greater acidity of the 5-*endo* and 6-*exo* hydrogen of T2 and T12 relative to the 5-*exo* and *endo* hydrogens of toxicant A and B, due to the electron-withdrawing properties of the 5-*exo* and 6-*endo* chlorines. This competitive loss of HCl and Cl from the molecular ion is also observed in the mass spectrum of Hp-Sed. This result along with conclusions drawn by Hainzl[2] with regard to relevant structures of CHB's suggest that Hp-Sed, like T2 and T12, has a 2-*exo*,3-*endo*,5-*exo*,6-*endo* ring conformation. The postulated structure for Hp-Sed is thus, 2-*exo*,3-*endo*,5-*exo*,6-*endo*,8,9,10-heptachlorobornane and was varified using ^{1}H-NMR. Positioning of the three ring chlorines on Hx-Sed required the use of ^{1}H-NMR. Based on these results and the mass spectral results discussed above, the structure of Hx-Sed was determined to be 2-*exo*,3-*endo*,6-*exo*,8,9,10-hexachlorobornane. The enhanced elimination of Cl from the molecular ion relative to that of HCl loss may result from the reduced acidity of the 5-*exo* proton in absence of the electron-withdrawing properties of a 5-*endo* chlorine.

Department of Chemistry, Trent University
Peterborough, ON

Introduction: Polychlorinated dibenzo-*p*-dioxins and polychlorinated dibenzofurans are man-made compounds that have become widely distributed in the natural environment. These compounds are highly toxic to some species, exhibit a large inter-species variation in toxicity and have poorly characterized human toxicity. As a result, they are closely monitored in many jurisdictions.

Typical environmental levels for dioxins and furans range from parts-per-trillion and higher for soil and sediment samples to parts-per-quadrillion and lower for water samples. In many analytical methods ^{13}C-labelled surrogates are added to the samples for quantitation, necessitating the use of a detector more selective than low resolution mass spectrometry. In this laboratory we have employed both high resolution mass spectrometry (HRMS) using a sector mass spectrometer and tandem mass spectrometry (MS/MS) using a triple quadrupole mass spectrometer. These two types of instruments have comparable selectivity for dioxins and furans, but the HRMS instrument is approximately one order of magnitude more sensitive. HRMS and triple quadrupole MS/MS are also complementary with respect to interferences; an interfering compound observed by HRMS is rarely seen using MS/MS and vice versa.

We have recently begun analyzing dioxin and furan containing samples using an ion trap mass spectrometer equipped with a waveform generator to permit MS/MS operation. In MS/MS mode the parent ion is isolated in the trap, and collisionally activated dissociation (CAD) is performed by irradiating ions at their secular frequency. Ion trap MS/MS differs from triple quadrupole MS/MS in several respects that may influence the daughter ion spectra produced. For this reason we have conducted a comparison of the three instrumental techniques for dioxin/furan analysis.

Methods: All ion trap analyses were performed using: a Varian Saturn 4D system equipped with an rf waveform generator for MS/MS; Saturn version 5.0 and prototype "Toolkit" software. The ion trap was maintained at a temperature of 260°C. The GC flow rate was between 1.4 and 0.64 ml/min depending on GC column oven temperature. Only resonant irradiation techniques were examined in detail; non-resonant irradiation did not adequately fragment PCDD/Fs.

Three types of resonant excitation are possible using this instrument: single frequency irradiation (SFI), multi-frequency irradiation (MFI), and secular frequency modulation (SFM). Extensive optimization of all of these methods has been performed for PCDD/F; the details have been reported elsewhere.[1] Optimized irradiation conditions were used to produce all of the results discussed below.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Results and Discussion: We have compared the ion trap with HRMS and triple quadrupole MS/MS in three ways: CAD breakdown curves, isotope dilution quantitation and analysis of environmental field samples.

Breakdown Curves: Breakdown curves have been constructed for the three resonant irradiation modes of the ion trap and for the triple quadrupole using He collision gas. A comparison of the curves yields these observations: (1) the shape of the curves is similar for all irradiation modes of the trap. The irradiating voltage to produce a given product ion distribution varies with the mode. (2) The major product ions are the same for ion trap and triple quadrupole CAD, and are present in approximately the same proportions. (3) The onset of progeny ion production is much more rapid in ion trap CAD than in triple quadrupole CAD.

Isotope Dilution Quantitation: A set of calibration standards containing 17 native and 17 $^{13}C_{12}$-labelled PCDD/F at concentrations corresponding to USEPA Method 1613 were used to generate calibration curves using all three instruments. Typically, the HRMS and triple quadrupole instruments produce calibration curves with percent relative standard deviations (%RSD) of less than 20 percent for all 17 monitored congeners. On initial attempts, the ion trap produced %RSDs ranging from 16 to 80 percent. The worst results from the ion trap can be explained by poor chromatography caused by our use of a short GC column to decrease run times. Others, such as O_8CDD in the two most concentrated calibration solutions, produced poor results that appear to be concentration related. The ion trap produced a signal-to-noise ratio of 15:1 for 1 pg of 2,3,7,8-T_4CDD injected on the GC column.

Analysis of Environmental Field Samples: Several environmental samples of various matrices were examined. These samples were chosen because they contain multiple isomers in each congener group. The isomer pattern was similar for all congener groups in all of the samples examined. This indicates that the isomers have similar response relative to one another when examined using any of the three instruments. Some differences were observed in the ion trap chromatograms, but most of these are attributable to the lower resolution of the short GC column used on the ion trap. Quantitation of samples using the ion trap was not attempted, since not all of the required ions have been incorporated in the scan functions.

Conclusions and Future Work: In initial attempts, analysis of dioxins and furans by ion trap MS/MS produced results comparable to those obtained using HRMS and triple quadrupole MS/MS. The ion trap exhibits good sensitivity and selectivity. It appears that the CAD of dioxins and furans is similar in the ion trap and triple quadrupole. Calibration using isotope dilution quantitation standards was successful for several congeners, and poor calibration results for several others can be accounted for by chromatography. Future work will include: incorporation of additional ions in analytical scan functions; precise and accurate determination of isotope ratios; optimization of quantitation; and test stability of secular frequencies over time and with contaminated samples.

IONIZATION OF PCBs USING ION TRAP MASS SPECTROMETRY

M. Lausevic[1], X. Jiang[1], C.D. Metcalfe[2] and R.E. March[1]

[1]*Department of Chemistry, Trent University, Peterborough, ON, Canada K9J 7B8*
[2]*Environmental and Resource Studies Program, Trent University, Peterborough, ON, Canada K9J 7B8*

The toxicity of PCB mixtures is due principally to a small group of non-*ortho* and mono-*ortho* substituted congeners, usually present in environmental samples in lower concentrations than those of other congeners, thus the development of methods for toxic congener recognition is very important. The objectives of the present work were to compare quantitatively selected ion monitoring (SIM) of the electron impact (EI) mass spectra of PCBs with selected reagent ion chemical ionization (SRICI) mass spectra in terms of the detection limits achieved and to examine the possibility for distinguishing the more toxic congeners from those of lower toxicity. Since each ionization process determines the characteristics of the resulting mass spectrum, the task at hand was to identify from these mass spectra appropriate criteria for the determination of total PCB content and for differentiation of PCB congeners in order to determine the toxicity of PCB mixtures.

EXPERIMENTAL

The experiments were carried out with a modified Varian SATURN III Quadrupole Ion Storage Mass Spectrometer (QISMS™) coupled with a gas chromatograph and equipped with both a Varian waveform generator and a Varian 8200 autosampler SATURN revision C software was used for data acquisition in the EI and CI modes. The isolation of specific CI reagent ions, as well as isolation of molecular ions for resonant excitation experiments was achieved using a QISMS™ version 1.0 software package. A 30 m DB-5 chromatographic column was held at 38°C during the sample injection, than ramped to 260°C at 20°C/min and held at that temperature for 10 min.

RESULTS AND DISCUSSION

The relative responses of SIM of EI mass spectra and SRICI mass spectra of PCBs have been determined for some 60 PCBs contained in four standard mixtures.[1] The PCB congeners examined cover a wide range of toxicities. Average responses have been determined for PCBs as a function of the total number of chlorine substituents.

Relative responses and detection limits in CI and EI

In the CI mode, isolation of a specific CI reagent cation is carried out prior to protonation in order to ensure that a single reaction pathway predominates. In our previous study[2] it was shown that the reaction of PCBs with selected $C_2H_5^+$ ions isolated from methane yields CI mass spectra virtually free of contributions from charge exchange processes with the dominant product ion species being $[M+H]^+$. In addition, the enthalpy change for proton transfer is insufficient for fragmentation.

With selected $C_2H_5^+$ ions, the signal intensity per unit concentration decreases with increasing number of chlorine subsititutent atoms in the PCB molecule. The downward trend in average relative response in CI is due to the corresponding decrease in proton affinity (PA) with increased PCB electronegativity.

While the average relative response obtained in EI also shows a linear decrease with increasing number of chlorine atoms in the PCB molecule, the overall decrease observed with EI is much less pronounced than that observed with CI. The net decrease of the ionization efficiency is due to the corresponding increase in electronegativity of PCB isomers. Thus the increase in electronegativity with increasing degree of chlorination exerts a greater influence upon proton affinity than on ionization energy.

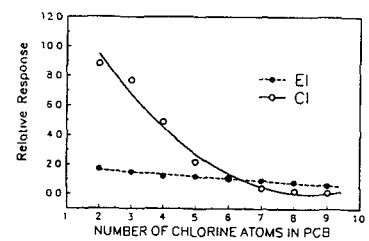

Fig. 1 The average responses of PCB isomers relative to hexa-chloro congener 153

The decreasing propensity for PCB ion formation (EI and CI) with molecular weight reflects the diminution of ionization efficiency for positive ion formation, and is opposite to that exhibited for electron affinity.

The detection limits for EI and CI were determined as the mass of congener 153 injected on column yielding a signal/noise ratio of 5:1. The detection limit with EI was found to be 0.8 pg; that with CI was found to be 30 pg. These detection limits reflect the efficiencies for positive ion (radical cation) formation and protonation, respectively.

An attempt to distinguish the more toxic congeners

An initial exploration has been carried out of the potential value of using a toxicity index.[3] Electron ionization, when combined with selected ion monitoring of both molecular and fragment ions, is the most sensitive mass-selective method for the determination of the most toxic PCB congeners. In our experiments, EI proved to be a reliable method for distinguishing between highly toxic non- and mono-*ortho* congeners and other PCBs. PCB ions with one or no chlorine atoms in the *ortho* position do not undergo one-chlorine atom loss from the molecular ion in EI. When there are two or more chlorine atoms in *ortho* positions, the loss of one chlorine atom is readily observed. Resonant excitation of isolated molecular ions suggests that losses of both one and two chlorine atoms can occur simultaneously and directly from the molecular ions. The typical fragmentation patterns can be recognised easily in selected ion chromatograms even when complex mixtures are analyzed.

Photoelectron Capture Negative Ion Mass Spectrometry of Organohalogens

Steven M. Colby, William A. Harris, Kent H. Hanser, and James P. Reilly
Dept. of Chemistry, Indiana University, Bloomington IN 47405

Photoelectrons, generated by directing a pulsed laser beam at a metal target, have recently been employed for electron impact ionization in time-of-flight mass spectrometry[1,2]. We have extended this concept to develop a new method in which laser induced photoemission is used as a source of electrons for electron capture negative ion mass spectrometry (ECNIMS)[3]. This technique has two principal advantages over conventional ECNIMS wherein electrons are generated from a heated filament. First, no mediating gas is required to thermalize the electrons. The electron energy is limited by the wavelength of the photons and the work function of the target material. It is therefore possible to select precisely the maximum electron energy. Some selectivity may even be achieved by tuning the electron energy to vibrational transitions of the analyte[4] This can dramatically increase the electron capture cross-section. The absence of a buffer gas eliminates several of the factors that can cause poor reproducibility and restrict the range of analytes. These include chemical reactions with the buffer gas and a strong temperature dependance on ion fragmentation patterns[5]. The absence of buffer gas also eliminates the pressure differential between the source region and the mass analyzer. This interface is responsible for a lack of reproducibility between instruments of differing design[5]. The second advantage to the generation of ions through photoemission is that electrons can be produced over a time period comparable to the laser pulse. This makes the method more easily adaptable to time-of-flight mass spectrometers. Because they are able to record an entire mass spectrum with each laser shot, these instruments are generally more sensitive than sector or quadrapole mass spectrometers.

The temporal duration of the emitted electron pulse depends on the mechanism of light interaction with the surface. Photoemitted electrons are produced only during the laser pulse while thermionic electrons, which require greater photon fluxes, may be observed for much longer periods. We have also found that it is possible for the laser light to be used for both electron generation and sample desorption. The technique can therefore be applied to samples whose vapor pressures are too low for conventional ECNIMS and Space-Velocity Correlation Focusing can be used to improve resolution[6,7].

It has previously been shown that a low energy electron beam may be used to generate negative ions from halogenated species[4]. However, this approach is limited by the low electron currents available. In contrast, laser induced photoemission may be quite efficient as has already been reported for Photoemission Electron Impact Ionization[1,2].

We have demonstrated Photoelectron Capture Negative Ion Mass Spectrometry with a number of halogenated organics. Figure 1 shows the mass spectrum of octafluoronaphthalene. The sample was introduced into the instrument through an effusive source and allowed to adsorb on a stainless steel surface within the source of the TOFMS. An ArF laser provided light to desorb the sample and generate electrons. By using the same surface for the trapping of analyte and as the laser target material we achieve good temporal and spacial overlaps between the molecules that are laser-desorbed and the generated photoelectrons. While parent ions are observed in Figure 1, extensive

fragmentation also occurs and the primary signal corresponds to halogen ions. This is in part due to the relatively high energy of the photoelectrons (up to 2.5 eV). When added to the electron affinity, this energy is sufficient to cause fragmentation. In future work we will attempt to reduce fragmentation by using longer wavelength lasers. We have also examined the sensitivity of this method by quantitatively introducing samples through a GC/MS interface. This interface, which is further described in another abstract at this conference[8], traps the GC effluent on a cryogenically cooled surface. Figure 2 shows a chromatogram of 10 ng of o-dichlorobenzene generated by monitoring the halogen atom signal. The width of the peak is due to a poorly heated valve between the chromatographic column and the GC-MS interface. This result is preliminary and further improvements in sensitivity are expected.

DETERMINATION OF PESTICIDES ON AGRICULTURAL SAMPLES BY STATIC SIMS ANALYSIS

J. C. Ingram, G S. Groenewold, A. D. Appelhans, D. L. Miller, J. E. Delmore
Idaho National Engineering Laboratory, P. O. Box 1625, Idaho Falls, ID 83415-2208

The development of methods to rapidly identify chemicals used in agriculture is important because detection is difficult using currently available technology Rapid screening of samples is needed in the areas of crop application, enforcement, food and environmental safety. SIMS instrumentation developed at the Idaho National Engineering Laboratory is demonstrating tremendous potential in this area through its ability to detect and identify chemicals of various types on environmental samples including vegetation, soil and rocks, stainless steel, glass, etc [i,ii,iii] SIMS is attractive as an analytical tool for application to agricultural and environmental problems due to the following· (a) no sample preparation is required, (b) no generation of waste, (c) rapid analysis (< 10 minutes), (d) amenable to almost any sample type, (e) ideal for involatile, ionic species (which can be difficult to detect by standard methods), (f) capable of "fingerprinting" (speciation), (g) non-destructive analysis allowing for additional analyses on the same sample Detection is achieved using a SIMS instrument equipped with a novel perrhenate primary ion gun, and pulsed extraction of secondary ions Together, these features allow analysis of insulating samples such as leaves and soils, which are not readily analyzed using conventional SIMS. Moreover, anion and cation spectra are acquired nearly simultaneously.

A scoping study was performed in order to evaluate the applicability of SIMS to detection of agrochemicals on various sample types. A matrix of 21 agrochemicals on four substrates were analyzed using a SIMS instrument utilizing a single quadrupole mass analyzer. These chemicals were applied to the samples at quantities approximating field usages (ca 5 $\mu g/cm^2$) Both the anion and cation SIMS spectra were collected for each sample. The results are summarized in the table. Strong detection indicates abundant quasi-molecular ions and/or abundant unique signature fragment ions. Medium detection indicates abundant signature fragment ions (no quasi-molecular ions). Weak detection indicates signature fragment ions observed in the SIMS spectrum at signal to noise values of 3 to 6. The results of this scoping study indicate that, in general, the more polar and less volatile agrochemicals are readily detected by SIMS. Additionally, in just over half the analyses, both the cation and anion SIMS spectra contained signature ions for the agrochemical analyzed.

Further elucidation of the SIMS spectra for selected agrochemicals was provided through utilization of an ion trap SIMS instrument with MS/MS capabilities. One example is diuron, a herbicide used mainly for roadside applications. The SIMS cation and anion spectra of diuron on a dandelion leaf recorded using a single stage quadrupole SIMS instrument is shown in Figure 1. Both the cation $[M+H]^+$ and anion $[M-H]^-$ quasimolecular ions are observed. In order to identify the fragment ions observed in Figure 1, MS^n was performed using a ion trap SIMS instrument capable of investigating both the anions and cations In the case of the anion MS, the following sequence was performed (Figure 2): a) MS of the $[M-H]^-$ ion (*m/z* 233) resulting in an anion at *m/z* 186 which is interpreted as a loss of $NH(CH_3)_2$, b) MS of the *m/z* 186 anion resulting in an anion at *m/z* 150 which is interpreted as a loss of HCl, c) MS of the *m/z* 150 anion resulting in an anion at *m/z* 122 which is interpreted as a loss of CO. In the case of the cations, MS of the $[M+H]^+$ ion (*m/z* 233) results in a cation at *m/z* 72 which is interpreted as a loss of $C_6H_3Cl_2NH_2$ (Figure 2).

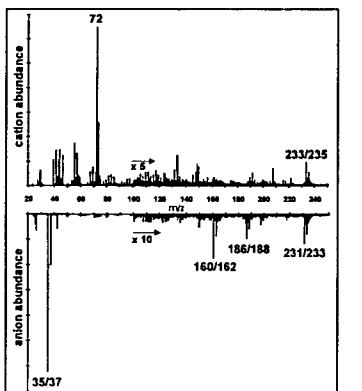

Figure 1

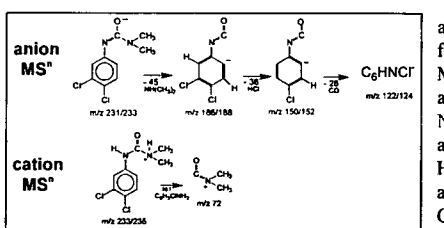

Figure 2

Comparing the ion trap results to the results recorded by the quadrupole SIMS instrument (Figure 1), it is clear that the anions at *m/z* 160/162 do not result from fragmentation of $[M-H]^-$ as this ion was not observed as a daughter ion during the ion trap (MS^n) experiments The *m/z* 160/162 ions are interpreted as originating from a cleavage of the N-C bond proximate to the aromatic ring of the neutral diuron molecule as illustrated in Figure 3 This interpretation together with the cation MS/MS results suggests that the cation at *m/z* 72 is a product of both fragmentation of the neutral diuron molecule and the $[M+H]^+$ quasimolecular ion The markedly abundant *m/z* 72 cation observed in Figure 1 is consistent with this explanation

[2]Pacific Northwest Laboratories
P.O. Box 999
Richland, Washington 99352

Real-time breath analysis offers a non-invasive method to detect exposure to toxic air pollutants. Breath measurements are useful in environmental exposure studies, and may provide evidence about previous long-term or repeated exposures in environments that are not easy to monitor. [1] If breath samples are collected during or immediately following a short term exposure, breath measurements can be used to predict the peak exposure. Previous breath sampling methodologies have been to collect repeated 1-minute breath samples at 5 minute intervals.[2] Although this method can aid in describing the rapid exponential emptying of the blood compartment that occurs following peak exposure, sampling 5 minute intervals still forces an approximation of the true shape of the clearance kinetics. We have developed a methodology to quantitively measure the concentration of exhaled volatile compounds in real-time using laboratory rats. Continously monitoring breath for a parent toxicant and its metaboloite(s) provides input into physiologically based pharmacokinetic (PBPK) models to describe the bio-kinetics of a chemical in the body. Real-time analyses are better than batch sampling methods because of the rapidly changing kinetics of elimination of some volatile chemicals from the body.

A Sciex TAGA 6000E MS/MS equipped with a low pressure chemical ionization source (LPCI), along with a Finnigan ITMS equipped with an atmospheric sampling glow discharge ionization source (ASGDI), and the Teledyne HST-1000 accessory kit (for filtered noise field (FNF) operation) were used for these experiments. The expired breath from 1 to 6 laboratory rats can be introduced separately into the two tandem mass spectrometers by way of a manifold. Figure 1 shows the schematic of the rat breath manifold. This device is a modification of a human breath interface patented by Battelle.[3] Carbon tetrachloride, its main metabolite, chloroform, and markers of lipid peroxidation; ethane and acetone, were simultaneously monitored in real-time, in the expired breath of the rats exposed to carbon tetrachloride. Figure 2 shows the results from the I.V. injection of a 0.6 mg/Kg dose of CCl_4. Figure 3 shows the results from a 25 mg/Kg dose of CCl_4 via oral gavage. The real-time concentration data was then input into a PBPK model to determine target tissue doses. The model accurately determined the dose of CCl_4 administered in each experiment. Since the methodology provides information on real-time metabolic processes and toxic responses, the implications for improving heath risk assessements are substantial.

TUNABLE ENERGY (0.03-60 eV) ELECTRON CAPTURE NEGATIVE ION SPECTROMETRY

J.A. Laramee, P. Mazurkiewicz, P.C.H. Eichinger, and Max L. Deinzer
Department of Agricultural Chemistry
Oregon State University, Corvallis, OR 97331

The presence of environmentally persistent chlorinated-hydrocarbons, the use of organophosphate pesticides, and the production, storage and testing of explosives is extensive. Consequently there is considerable concern about residue levels in human, animal, and plant tissue, as well as ground water and air. Most recent efforts to improve both the detection sensitivity and quantification of these residues have been made using Electron Capture Negative Ion Mass Spectrometry (ECNIMS) since the method generally provides greater sensitivity for electron-loving compounds than is achieved by positive ionization methods (Knighton, *et al.*, 1994).

ECNIMS *without buffer gas* to moderate electron energies to thermal levels has been achieved by using an electron monochromator (Laramee *et al.*, 1992). This device has the advantage of being simple yet reliable and practical for the analysis of electron-loving compounds such as explosives and polychloro compounds from Arctic trout (Laramee and Deinzer, 1994). The electron energy is tunable to give just the right energy for ionizing specific compounds or isomers, and because no chemical ionization plasma is present the plethora of radicals, cations, anions and high-energy electrons is eliminated along with spurious adduct ions that are largely responsible for irreproducible spectra from ion/molecule reactions.

This methodology has now been refined into a prototype ion source for use on a JEOL DX-303 mass spectrometer. Construction of the electron monochromator was guided from particle trajectory calculations corrected for space-charge, electron-optical aberrations, and interlens field penetrations. A rectilinear beam is formed from a ribbon filament using a Pierce element. But magnetic field confinement does not completely overcome beam widening caused by the anode aperture lens action since the radial velocity vectors cause electron spiraling to occur. Hence the beam shape is maintained via a unique dual anode lens configuration with zero net lens action that produces a parallel beam with few radial velocity vectors. Electrons are dispersed in a crossed electric (E) and magnetic (B) field with drift velocity of $(E \times B)/B^2$. 0.03 eV electrons were produced with the ion source floated at -3000 eV (Figure 1). This performance compares well with that of the archetype instrument (Figure 2). The fractional electron energy distribution was measured to be $\pm$ 0.34 eV using the negative ion resonance at 0.03 eV from hexafluorobenzene (Fenzlaff and Illenberger, 1984).

Electron energy is another analytical dimension of information that can be used to distinguish among structurally similar compounds. Three-dimensional spectra readily show distinguishing spectral features of the sixteen organophosphates surveyed. These 3-D spectra are expected to provide a potentially useful means for identifying environmental unknowns, for example parathion and paraoxon are readily distinguished by this molecular fingerprinting system (Figure 3). Rapid detection is possible since the complete electron energy spectrum can be recorded in 3 milliseconds (Laramee and Deinzer, 1994).

STRUCTURES AND ELECTRONIC PROPERTIES OF FULLERENE-RELATED COMPOUNDS*

Robert L. Hettich, Z. Charles Ying, and Robert N. Compton
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120

The synthesis and characterization of fullerene-related compounds has been the subject of active research both experimentally and theoretically since the discovery of C_{60} For example, endohedral fullerenes $M@C_n$ (carbon clusters containing a "trapped" atom M within their cage) can be generated for several different early transition metals and noble gases. The properties of these species have been modelled theoretically, and indicate that these species may have unusual applications. Likewise, the covalent attachment of hydrocarbon functional groups to a fullerene also alters its properties, opening up new applications as well The focus of this presentation is to describe how Fourier transform ion cyclotron resonance (FTICR) can be used not only for the detection and identification of fullerene-related compounds, but also the detailed structural interrogation of their properties. In particular, laser desorption FTICR was used to examine endohedral $La@C_n$ species and γ-radiolysis fullerene products Collisional dissociation and charge transfer processes were used to probe the structures and electronic properties of these nanoclusters in detail

Endohedral $La@C_n$ samples were generated by laser ablation of a lanthanum oxide-doped graphite rod in an argon atmosphere. The $La@C_n$ soot was deposited directly onto a stainless steel probe disk for subsequent examination by LD-FTICR LD-FTICR of the resulting samples revealed the presence of some C_{60} and C_{70}, although the most abundant species were $La@C_n^+$ for n = 60, 74, 82. Smaller peaks corresponding to $La@C_n^+$ for n = 70-100 were observed Three FTICR experiments were conducted to examine the $La@C_n^+$ species· 1) ion-molecule reactions with oxygen-containing species, 2) collision-induced dissociation reactions, and 3) charge exchange reactions to bracket the ionization potentials and electron affinities. The first two types of reactions were used to interrogate the structure of the $La@C_n^+$ species to verify that the metal atom was inside the cage (endohedral) and not attached to the outside of the cage (exohedral). No ion-molecule reactions were observed for $La@C_n^+$ and N_2O, and the collisional dissociation of $La@C_n^+$ for n = 60, 74, 82 revealed primarily sequential C_2 loss These results support the assumption that the La atoms are attached inside the fullerene cage. The third type of reaction (charge exchange) was used to bracket the ionization potentials of these endohedral species to ascertain the effect of the "trapped" heteroatom on the fullerene electronic structure $La@C_n^+$ was observed to charge exchange with decamethylferrocene (I P. = 5.8 ± 0.1 eV) and N,N,N,N-tetramethylphenylenediamine (I.P. =6 2 ± 0.05 eV), as shown in Figure 1 for $La@C_{60}^+$. Experimentally, this corresponded to a decrease in the $La@C_n^+$ signal and an increase in the ionized reagent with increasing reaction time $La@C_n^+$ is unreactive with ferrocene ((I.P. =6 75 ± 0 009 eV), implying that I.P. ($La@C_n$) < I.P. (ferrocene) Photoionization results of $La@C_n$ indicate that these species can be ionized with a ArF excimer laser, implying that I.P ($La@C_n$) < 6 4 eV. These experimental results imply that the I P. of $La@C_n$ is between 6.20 and 6.4 eV For comparison, the I.P (C_{60}) is 7 6 eV and the I P (La) is 5.577 eV Thus, the I P. of $La@C_n$ is between that of C_{60} and La. These measurements support the overall picture that the endohedral La atom transfers its three valence electrons to the lowest unoccupied molecular orbital (LUMO) of C_{60}. As a result, $La@C_n$ consists of a positively-charged La ion inside a negatively-charged C_{60} shell The molecular orbitals of C_{60} remain roughly the same, but are shifted downward in energy as a result of the Coulombic interactions between La^{3+} and C_{60}^{3-}.

Collaboration with Professor George Bakale (Case Western Reserve University) has been focused on identification of the γ-radiolysis product of C_{60} in cyclohexane Upon irradiation with γ-rays (1 42 krad/hr, total dose of 51 krad), the purple-colored C_{60} / cyclohexane solution turns muddy red. Positive ion LD-FTICR mass spectrometry (low laser power) of the resulting product reveals abundant ions in the m/z 1540-1560

region, shown in Figure 2a. Higher laser power densities reveal a series of fragment ions corresponding to loss of 82 Daltons from the ions stated above, shown in Figure 2b Accurate mass measurements and collisional dissociation experiments indicate that the radiolysis product consists of 10 cyclohexane groups attached to the C_{60}. This C_{60}(cyclohexane)$_{10}$ species fragments easily by sequential elimination of cyclohexene Apparently, the (C_6H_{11}) radicals formed by the gamma radiation of the cyclohexane solvent are efficiently captured by C_{60}, which is known to be a "radical sponge", until the terminal product of C_{60}(cyclohexane)$_{10}$ is generated Steric hindrance may prohibit attachment of more cyclohexyl groups to C_{60}.

Reactions of Fullerene Oxides in a Fourier-Transform Mass Spectrometer

Christopher Holliman and Stephen McElvany, Naval Research Laboratory, Code 6113, Washington, D.C. 20375-5342

High-intensity laser desorption of C_{60} fullerene results in the formation of larger fullerenes through coalescence. Fullerene coalescence appears to occur via the emission of small even-numbered carbon species. An understanding of the coalescence mechanism should provide insight into the fullerene growth process and may direct new synthetic routes to the macroscopic production of larger fullerenes.

The coalescence reactions of the fullerene oxides $C_{60}O_n$ (n = 1-3) proceed more efficiently and at a lower laser radiance than the coalescence of pure C_{60} [1]. The collisionally activated dissociation (CAD) spectra of CI-source produced $C_{60}O_n^-$ (n > 1) reveals that the loss of oxygen occurs exclusively with the disruption of the fullerene cage yielding odd- and even-numbered fullerene product ions [2]. The formation of similar product ions by laser irradiation or ozonolysis may be the first step in fullerene coalescence. The goal of this study is to produce possible fullerene coalescence precursors in the ion trap of a Fourier-Transform mass spectrometer. Once trapped, the structure and reactivity of the precursor can be probed via collisionally induced dissociation and ion-molecule reactions.

$C_{60}O_n$ neutrals are generated by bubbling ~6 % O_3 through a solution of C_{60} in toluene. The reaction mixture is separated by HPLC into five fractions (C_{60}, $C_{60}O$, $C_{60}O_2$, $C_{60}O_3$, $C_{60}O_{>3}$) using a Buckyclutcher column (Trident DNP).

The fullerene-oxide molecular anions are generated by MALDI from an acetylanthracene or dithranol matrix (~0.010 mg matrix / 1.0 mL THF) that is irradiated at the tripled-frequency (355nm) of a Nd-YAG laser. Ions are trapped in the source-side of a dual-cell FT-mass spectrometer and selectively focussed by quadrupolar axialization [3]. The ^{12}C isotopically pure ion is selected and submitted for CAD.

The MALDI-FTMS spectra of the $C_{60}O_2$ fraction that is obtained with the acetylanthracene matrix gives the expected isotopic abundances for $C_{60}O_2$. The CAD of $C_{60}O_2^-$ *m/z* 752 (Figure A) results in the loss of CO and the disruption of the fullerene cage. Further CAD of the product ion witf *m/z* 724 results in the loss of another CO unit and suggests that the C-O bonds of $C_{60}O_2$ are equivalent.

The CAD spectrum of the $C_{60}O_2^-$ ^{13}C isotopomer of *m/z* 753 (Figure B) reveals two new products corresponding to losses of 17 and 44u.

MALDI desorption of the $C_{60}O_2$ fraction from the dithranol matrix results in an increase in the abundance of *m/z* 753. Although the CAD spectrum of the dithranol-desorbed *m/z* of 752 is the same as that produced from the acetylanthracene matrix (Figure A), CAD of *m/z* 753 (Figure C) now produces abundant losses of 17u (OH) and 44u (CO_2). Figure C suggests the donation of a hydrogen atom from the dithranol matrix to produce $C_{60}O_2H^-$ *m/z* 753. Recall that the enol form of β-diketones are stabilized by intramolecular hydrogen bonding between the carbonyl oxygens. The product ion with *m/z* 736 loses oxygen upon further CAD indicating C-O bonding similar to that in $C_{60}O$ [2]. The product ion with *m/z* 753 loses a second CO unit upon further CAD indicating C-O bonding similar to that in $C_{60}O_2$.

The MALDI-FTMS spectra of the $C_{60}O_3$ fraction have been obtained. CAD of $C_{60}O_3^-$ *m/z* 768 results abundant losses of CO, CO_2 and C_2O_3 and the disruption of the fullerene cage.

$C_{60}O_n$ ions formed by CI and by MALDI of neutrals exhibit similiar CAD fragmentation. The addition of a second oxygen to the fullerene cage results in stronger C-O bonding than that observed in $C_{60}O$. The addition of hydrogen atom to $C_{60}O_2^-$ to form $C_{60}O_2H^-$ and the CAD spectra of both ions

support the proposed diketone structure of $C_{60}O_2$ MALD-FTMS followed by CAD is a viable route for the production and isolation of possible coalesenece precursors. Reactivity studies are now underway.

Collision experiments with fullerene ions and molecular target gases

Helen J. Cooper, Richard T. Gallagher and Peter J. Derrick

Warwick Institute of Mass Spectrometry and Department of Chemistry, University of Warwick, Coventry CV4 7AL, U.K.

Tore Vulpius

Department of General and Organic Chemistry, HC Orsted, University of Copenhagen, Copenhagen, Denmark.

Target capture is the process in tandem mass spectrometry in which the parent ion and the target gas do not separate following collision. It was predicted by Neumann *et al.* [1] and has been studied using Buckminster fullerene ions [2, 3, 4] and renin substrate ions [5].

The present study investigates the question of molecular target capture by $C_{60}^{+\cdot}$ ions. The gases employed were CH_4, CD_4, $^{13}CH_4$, N_2 and O_2. All of these gases form adducts with the $C_{60}^{+\cdot}$ ions and the mechanism of formation of these adducts has been studied by considering their translational energies.

Experiments were performed on a Kratos Analytical Concept IIHH four-sector mass spectrometer and a Jeol HX110A/HX110A four-sector mass spectrometer using EI ionisation and collision energies of 300-1000 eV. The gas pressure was sufficient to reduce the ion beam to 80% of its original intensity. Spectra were obtained by scanning the magnet of MS2.

At 1000 eV collision energy, the peak corresponding to $[M+13]^+$ is the most intense adduct for collisions of $C_{60}^{+\cdot}$ ions and methane. At 500 eV collision energy (figure 1), the $[M+14]^{+\cdot}$ peak is the most intense adduct. Also observed in this spectrum are peaks corresponding to $[M+1]^+$, $[M+12]^+$ and $[M+15]^+$. At 300 eV laboratory-frame collision energy the peaks $[M+14]^+$, $[M+15]^{+\cdot}$ and $[M+16]^+$ for $^{13}CH_4$ and $[M+14]^+$, $[M+16]^{+\cdot}$ and $[M+18]^+$ for CD_4 confirm that the adduct peaks with CH_4 are due to CHC_{60}^+, $CH_2C_{60}^{+\cdot}$ and $CH_3C_{60}^+$. At lower collision energies (ie less than 300 eV) no adduct peaks were observed.

Figure 2 shows the spectrum obtained with $C_{60}^{+\cdot}$ ions and nitrogen at a collision energy of 500 eV. A peak corresponding to $[M+28]^{+\cdot}$ is observed. This peak is also observed at 1000 eV collision energy. At 300 eV collision energy and below, no adduct peaks are observed. There is no evidence for the existence of an $[M+14]^+$ peak. Figure 3 shows the spectrum obtained with C_{60}^+ ions and oxygen at a collision energy of 500 eV. A peak corresponding to $[M+16]^+$ is observed. This peak is again observed at 300 eV although there is no evidence for its occurrence at higher collision energies (1000 eV). The full adduct $[M+32]^+$ is not observed.

The difference in translational energy between the parent ion and the adduct ion was measured and compared with predicted values. For the adducts $CH_2C_{60}^+$ and CHC_{60}^+, the measured and predicted values show good agreement. These adducts, therefore, may well be the result of fragmentation of a $CH_4C_{60}^+$ ion. A good correlation between predicted and measured values is also shown in the case of nitrogen. This is to be expected as the adduct ion observed was $[M+28]^+$ and could only be $N_2C_{60}^+$. The results obtained for oxygen are not consistent with the proposed mechanism i.e. $C_{60}O^+$ is not the result of fragmentation of $O_2C_{60}^{+\cdot}$.

Intermolecular Nitrile Oxide Transfer in Fullerene Isoxazolines

R. T. Pogue, M. S. Meier, C. Thomas, V. Majidi
Department of Chemistry, University of Kentucky,
Lexington, Ky, USA 40506

INTRODUCTION

Mass spectrometric analysis of fullerene derivatives often requires very different conditions and produces very different results than are expected when examining underivatized fullerenes. Frequently, mass spectra of derivatives have relatively small molecular ion peaks and are dominated by fullerene ion peak at high masses. The need for reliable mass spectrometric methods is increasing as new classes of fullerene derivatives are introduced. One such class of derivatives, the fullerene isoxazolines, is examined in this presentation.

Fullerene isoxazolines are produced via a 1,3 dipolar addition of a substituted nitrile oxide to either C_{60} (1) or C_{70} (2), and examples of both aliphatic and aromatic substituents have been isolated. Mass spectrometry of these materials indicates that they are stable to different types of ionization. In addition, these new compounds have some unusual chemical properties which can be seen under laser desorption conditions.

Laser desorption mass spectrometry (LD-MS) is typically considered a soft ionization technique which provides molecular ions for unstable and thermally labile analytes. Recently, however, we have witnessed condensed phase reactions on the LD probe which are initiated by the rapid deposition of laser energy into the sample. Such reactions were observed upon LD-MS analysis of fullerene isoxazoline samples containing fullerene internal standards.

METHODS

Fast-atom-bombardment mass spectra were acquired with a Kratos Concept 1H double focusing mass spectrometer using a Saddlefield FAB gun. Laser desorption profiles were collected using a time-of-flight mass analyzer built at the University of Kentucky.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

The third harmonic (355 nm) output of a Nd-YAG laser was used for desorption and ionization of the solid-phase samples.

RESULTS

Several of the isoxazolines studied were shown to undergo a fullerene-to-fullerene transfer of the entire derivative unit upon laser desorption of the isoxazoline with a fullerene internal standard. Subsequent fast-atom-bombardment (FAB) experiments, however, indicate that this reaction does not occur via a gas-phase recombination. Additional attempts at reproducing the reaction on the laboratory scale were unsuccessful. However by modifying the "trapping" material, it was possible to isolate nitrile oxide substituted materials not present in the original reaction mixture.

Thermogravimetric analysis (TGA) of several isoxazolines indicates that a mass loss occurs at 300-350°C which corresponds to the removal of the substituted nitrile oxide. This temperature may be similar to those temperatures which are present during the LD experiment (3). Additional heating to 900°C, in the TGA, causes loss of carbon from the fullerene cage.

Several authors have speculated that an "energy bottle neck" is responsible for the minimal fragmentation that is observed in laser desorption mass spectrometry. We believe that this bottle neck is useful in explaining the transfer of the in tact derivative moiety from one fullerene to another.

Ion Mobilities from FT-ICR Mass Spectrometry

Ljiljana Paša-Tolić, Shenheng Guan,* and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State University, 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

* Department of Chemistry, Florida State University

In an experiment conceptually similar to condensed-phase gel electrophoresis, Bowers and coworkers have shown that ion size and shape may be inferred from ion mobility, based on the (constant) rate of forced drift of ions through a collision gas chamber.[1] By analogy to condensed-phase diffusion, similar ion mobility information is in principle available from FT-ICR measurements. For example, mass-spectral peak width for unapodized data acquired for several time-domain damping periods is simply the momentum transfer collision frequency. Specifically, if collisions are considered to produce a frictional damping force proportional to ion veleocity, then the detected time-domain ICR signal decreases exponentially with time, with a frictional damping time constant which is related to ion size and shape.

Here we report preliminary results obtained for ions generated by matrix-assisted laser desorption/ionization (MALDI), i.e., polyethyleneglycols and peptides, by two experimental methods. Immediately after generation, ions are cooled and axialized[2] by azimuthal quadrupolar irradiation in the presence of argon collision gas in the source compartment of a dual cubic trap. In the first experimental scheme, ^{12}C ions are isolated by stored-waveform (SWIFT) excitation and then transferred to the analyzer compartment where they are excited and detected at high pressure ($0.2 - 5 \times 10^{-6}$ Torr of Ar). Initial data show that reduced collisional frequency (ν_r), i.e., FT-ICR frequency-spectral peak width decreases with ion mass, $\nu_r \propto m^{-4/3}$, as expected from a hard-sphere model for ion/neutral collisions. However, inital experiments also show that the quantification of data in order to obtain ion size and shape from collisional cross-section, σ, is not easy, because spectral line widths are affected by a number of other factors, and signal-to-noise ratio is typically low in these experiments. Thus, we developed a second experimental scheme that allows ν_r determination without line width measurement (Fig. 1). After axialization, ions are excited to small ICR radius (~ 5 mm) and, after variable collisional relaxation period, t, (at $\sim 2 \times 10^{-7}$ Torr of Ar), transferred, excited and detected in the low-pressure ($\sim 2 \times 10^{-9}$ Torr) analyzer trap. Relative abundances of ions with (significantly) different m/z values are directly related to the contraction of the ICR radius during collisional relaxation prior to the ion transfer, and (relative) reduced collisional frequencies, i.e., the time-domain exponential damping constants, may be determined from a plot of relative ion abundances vs. relaxation period. The results from this experimental procedure agree with those obtained using the first method, i.e., a damping constant which increases with ion mass. Our preliminary results thus show that ion mobility data may be obtained by FT-ICR techniques. Figure 1. Magnitude mode MALDI FT-ICR mass spectra of a mixture of substance P and insulin B-chain. After axialization and isolation in the source trap, molecular ions are excited to small ICR radius (~ 5 mm) and, after 50 ms (top), 100 ms (middle), and 1 s (bottom) collisional relaxation periods at $\sim 2 \times 10^{-7}$ Torr, transferred, excited and detected in the low-pressure analyzer trap. Note that relaxation time increases as m/z increases!

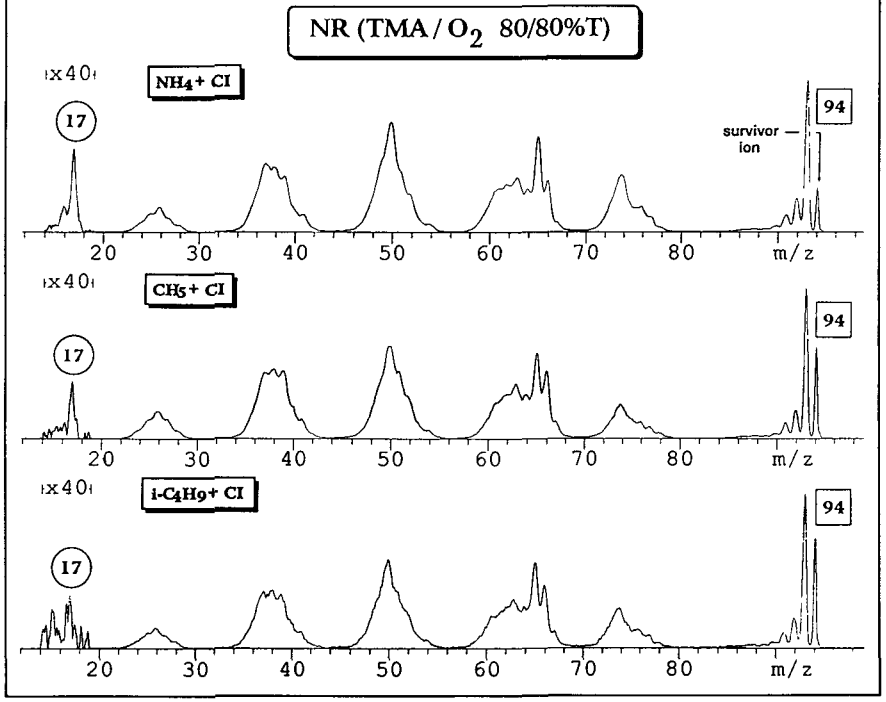
Gas Phase Protonation of Aniline

* Michael J. Nold and Chrys Wesdemiotis
Department of Chemistry, The University of Akron, Akron, OH 44325-3601

Neutralization reionization (NR) mass spectrometry has been employed for the structural elucidation of protonated aniline in the gas phase. Via this method, the structure of an ion can be deduced by examination of the stability and reactivity of the corresponding neutral.



43rd ASMS Conference on Mass Spectrometry and Allied Topics

N-protonation and ring-protonation of aniline generate ions (m/z 94) that can interconvert before dissociation making it impossible to determine the actual protonation site. However, the stability of the corresponding neutrals is quite different.

Neutralization of N-protonated aniline produces a hypervalent nitrogen site which should dissociate immediately, either by loss of a hydrogen radical or by loss of ammonia to yield aniline or the phenyl radical respectively. The latter process is revealed by an m/z 17 peak in the NR spectrum which cannot arise from aniline. Neutralization of ring-protonated aniline, on the other hand, produces a stable, bound radical. Following reionization, an intact MH^+ ("survivor ion") should be observed only for the ring-protonated form. Thus, from the relative abundance of MH^+ in the NR spectra, the extent of ring-protonation can be determined.

Based on the [m/z 94] to [m/z 17] ratio in the respective NR spectra, N-protonation decreases as the protonating reagent is changed from NH_4^+ to CH_5^+ to $(CH_3)_3C^+$. This order suggests that both steric effects and the gas phase acidity of the protonating reagent influence the site of protonation. The increased yield of N-protonated isomer with the reagent of lowest acidity (i.e. NH_4^+) points out that this isomer (i.e. the anilinium ion) is the thermodynamically more stable. Nevertheless, with the reagents used, the less stable C-protonated species (an immonium cation) is always coproduced.

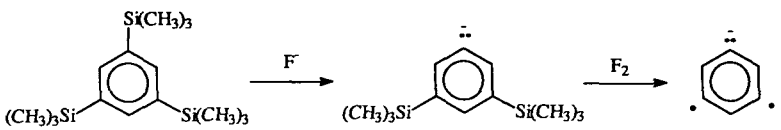
Synthesis and Characterization of 3,5-Dehydrophenyl Anion

Jun Hu and Robert R. Squires

Department of Chemistry, Purdue University, West Lafayette, IN47906

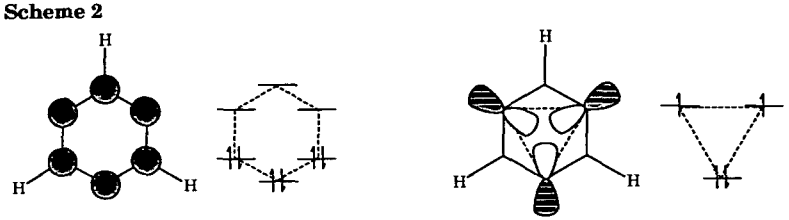
We have developed a general, regioselective method for producing biradical negative ions ("distonic" radical anions) in the gas phase, employing a flowing afterglow-triple quadrupole apparatus.[1] It involves reactions of trimethylsilyl substituted compounds with fluoride and molecular fluorine. During the reaction the trimethylsilyl groups are detached from the molecules and thus, radical anions are formed. Using this method we have synthesized the 3,5-dehydrophenyl anion as shown in Scheme 1.

Scheme 1



Simple molecular orbital theory predicts that this "triradical anion" will have an antiaromatic system for the three in-plane sigma orbitals, which are embedded in the 6π electron aromatic system of benzene. If the ion exists in a D_{3h} geometry, then it should be a ground-state triplet with a doubly degenerate HOMO(Scheme 2). While the synthesis of three-center 4π electron antiaromatic systems is a long-standing challenge in physical organic chemistry, there are no reports in the literature of previous attempts to synthesize sigma electron antiaromatic systems.

Scheme 2



6 Huckel orbitals

3 Walsh orbitals

The reactivity of this ion has been probed with a variety of neutral reagents such as CO_2, CS_2, NO, NO_2, SO_2, O_2, *t*-butyl alcohol and cyclopentadiene. The observed behavior is compared to that of the 2,3-dehydrophenyl and 3,4-dehydrophenyl anions, which are synthesized in a similar manner from 3-trimethylsilyl- and 4-trimethylsilylphenyl anions, respectively.

The differing reactivity of the three ions is consistent with the assigned structures. Radical-type reactions of the $C_6H_3^-$ ions are not observed, suggesting singlet ground states. The electronic structures of these ions have also been investigated with *ab initio* molecular orbital theory.

Reactions of Radical Anions with Formally Distinct Radical and Anion Sites

Joseph J. Grabowski and Daniel Owusu
Department of Chemistry
University of Pittsburgh, Pittsburgh, PA 15260

Distonic radical cations are now well established; these are species in which the radical and charged sites are localized on distinct atoms, and which require structural reorganization to be isomerized to their conventional isomers. While radical anions are well known, radical anions with (at least) formal separation of charged and radical sites are relatively uncharacterized.

We have examined the thermally-equilibrated (298K) ion-molecule reactions of some distonic radical anions, {$(M\text{-}2H)^{\bullet -}$} with typical probe reagents in the gas phase using the flowing afterglow technique. The radical anions studied were generated from the reaction of their neutral precursors with the atomic oxygen radical anion which is available from the DET of nitrous oxide. The reactions of the radical anion were compared with that of the corresponding closed shell anion (M-H). The probe reagents used include carbon disulfide and ground state triplet molecular oxygen.

Carbanions react with CS_2 to give products of three pathways: a) addition, $(M\text{-}H+CS_2)^-$ b) sulfur transfer, $(M\text{-}H+S)^-$ and c) electron transfer to carbon disulfide, CS_2^-. Sufficiently exothermic addition reactions may lead to fragmentation giving $(M\text{-}H+CS_2\text{-}H_2S)^-$ and ions with fewer carbons than $(M\text{-}H)^-$. It is also known that the more basic an anion, the more it reacts by sulfur transfer. Results for the reaction of CS_2 with $(M\text{-}H)^-$ and with $(M\text{-}2H)^{\bullet -}$ are shown in Table 1.

Table of Nu^- + CS_2 Reaction Products

Nu-H	$PA(Nu)^-$	CS_2^-	NuS^-	$(Nu+CS_2\text{-}H_2S)^-$	$NuCS_2^-$
	400 7		Exclusive		
	390 8	Significant		Significant	Significant
	385 7	Trace			Major
	385		Trace	Trace	Major
	381 1				Exclusive
	378 0		Minor		Major
	354 1				Trace @ v long time

Qualitative Yield Descriptors: Major (>50%); Significant (20-50%); Minor (5-20%); Trace (<5%).

Table of $(M\text{-}2H)^{\bullet -}$ + CS_2 Reaction Products

Nu-H	$PA(Nu)^-$	CS_2^-	NuS^-	$(Nu+CS_2\text{-}H_2S)^-$	$NuCS_2^-$
	400 7	Exclusive			
	390 8	$(C_3H_4)^{\bullet -}$ only formed in 6% yield; has not been studied			
	385 7	Data not yet available			
	385	Major	Significant	Significant	
	381 1				Exclusive
	378 0	Major	Minor	Trace	
	353 9	Major	Significant	Trace	Trace

Qualitative Yield Descriptors: Major (>50%); Significant (20-50%); Minor (5-20%); Trace (<5%).

Table 1 . A Comparison of the reactions of $(M\text{-}H)^-$ and $(M\text{-}2H)^{\bullet -}$ with CS_2

We find that whereas electron transfer product is minor or absent in $(M\text{-}H)^-$ reactions, it tends to be the dominant one for the corresponding radical anion. The increased electron transfer to CS_2 shows that the radical anions have a lower electron binding energy than their anion counterparts. Also the sulfur transfer product can become more important in the radical anion than in the $(M\text{-}H)^-$ reaction. The observation in classical anions that the more basic the anion the more it abstracts sulfur is not always found between corresponding $(M\text{-}H)^-$ and $(M\text{-}2H)^{\bullet -}$. The $(M\text{-}2H)^{\bullet -}$ of 2,3-dimethyl-1,3-butadiene is less basic than the corresponding $(M\text{-}H)^-$ yet afforded more sulfur transfer.

It is known that carbanions react with ground-state molecular oxygen by electron transfer, hydride transfer or addition to oxygen . All the $(M\text{-}2H)^{\bullet -}$ examined lost signal intensity on reaction with triplet oxygen but none of the products corresponding to the above reactions were detected (Table 2). The signal loss may again reflec lower electron binding energy in the radical anion precursor compared to that of $(M\text{-}H)^-$.

Table of Nu^- + O_2 Reaction Products

Nu-H	$PA(Nu^-)$	Observations
	400.7	Slow reaction. Oxygen atom abstraction (m/z = 93).*
	390 8	90% O_2^-; 1% $C_2H_3O^-$, 8% HO^- k_{obs} = 2.8 x 10^{-10} cm^3 $molecule^{-1}$ s^{-1} [1]
	385.7	Fast reaction, major products $C_4H_5O^-$, $C_3H_3^-$
	385	Fast reaction, major product: $C_5H_7O^-$.
	381 1	99% HO^- (+ RCHO), Slow with $^3O_2$ [2]
	378 0	No reaction.
	354 1	No reaction observed to very long times.

2. Schmidt *et al.*, *JACS*, 1979, *101*, 6443

Table of $(M\text{-}2H)^{\bullet -}$ + O_2 Products

M	$PA(M\text{-}2H)^-$	Observations
	371	Signal loss (*o*-quinone?). k_{obs} = 2.78 x 10^{-10} cm^3 $molecule^{-1}$ s^{-1}
		$(C_3H_4)^{\bullet -}$ only formed in 6% yield, has not been studied.
		Signal loss.
	385	Signal loss; rapid reaction.
		Signal loss, k_{obs} = 1 05 x 10^{-10} cm^3 $molecule^{-1}$ s^{-1}
		Signal loss, slow, no O_2 detected
	353.9	Signal loss, rapid reaction

Table 2. A Comparison of the reaction of $(M\text{-}H)^-$ and $(M\text{-}2H)^{\bullet -}$ with ground state triplet oxygen

The formation of adduct with nitric oxide may reveal the radical character of the radical anions. Such adducts were observed for some (e.g m-xylene radical anion) but not for others (e.g isoprene or benzene radical anion)

It is apparent from the above that the distonic radical anions are unique and their reactivity cannot be predicted simply by analogy to conventional anions. Experiments are under way to better characterize their radical behavior.

Photodetachment of Solvated Ions

*Y.J. Yang[1], D.M. Peiris[1], J. M. Riveros[2] and J.R. Eyler[1]
[1]Department of Chemistry, University of Florida, Gainesville, FL 32611
[2]Instituto de Quimica, University of São Paulo, São Paulo, Brasil.

Several methods have been used to measure the binding energies of solvated ions, including equilibrium measurements in both high pressure[1,2] and ICR[3] mass spectrometers and photodissociation measurements in a TOF mass spectrometer[4]. An alternate way to study ion/neutral binding energies (BE's) is photodetachment measurement with ICR mass spectrometry. By measuring the depletion of the parent ion as a function of photon energy, the threshold of photodetachment, related directly to the binding strength of solvated ions, can be determined. We have studied UV-visible photodetachment of alcohol solvated halides using the output of a doubled dye laser pumped by a Nd:YAG laser. The photodetachment thresholds of methanol solvates were determined and the BE's measured using photodetachment and thermal-equilibrium methods were compared.

The experiment was performed in a FT-ICR mass spectrometer equipped with a 3T superconducting magnet, vacuum system and an Ionspec data system. Laser power output was *ca.* 8-15 mJ/pulse and was kept constant for each spectrum. The solvated halides were formed by the ion-molecule reactions[5]:

$NF_3 + e^- \rightarrow F^- + NF_2$ or $CF_4 + e^- \rightarrow F^- + CF_3$
$F^- + HCOOCH_3 \rightarrow \mathbf{CH_3OHF^-} + CO$

$COCl_2 + e^- \rightarrow COCl^- + Cl$ or $ClCOOC_2H_5 + e^- \rightarrow COCl^- + C_2H_5O$
$COCl^- + CH_3OH \rightarrow \mathbf{CH_3OHCl^-} + CO$

$CH_3ONO + e^- \rightarrow CH_3O^- + NO$
$CH_3O^- + C_6H_5X/CH_3OH \rightarrow \mathbf{CH_3OHX^-} + C_6H_4$ where **X = Br, I**

where the pressure of NF_3, CO_2Cl_2, and CH_3ONO, were about 4.0-5.0x10^{-7} torr and the total pressure was maintained at 0.8-1.0x10^{-6} torr. Ions were formed using an electron beam pulse, followed by a period for ion-molecule reaction to form solvated ions as well as relaxation of internal energy before firing of the laser. The intensity of ions was measured before and after laser firing.

Figure 1 shows photodetachment spectra of CH_3OHF^-, CH_3OHCl^-, CH_3OBr^- and CH_3OHI^-. Four photodetachment thresholds, which were determined using linear extrapolation, for CH_3OHF^-, CH_3OHCl^-, CH_3OHBr^- and CH_3OHI^- were 279.5, 280.6, 309.2 and 337.0 nm respectively. So the differences between thresholds and EA's were 1.04, 0.81, 0.65 and 0.62 eV respectively (Table 1).

No increase in the intensity of halide ions was seen upon laser irradiation for solvates, which means either only the photodetachment channel occurred or photodetachment involved with photodissociation channel occurred. Correct interpretation of the data depends on whether vertical photodetachment occurs to a bound or repulsive state (Fig. 2). Based on work of D. Neumark[6] and J. Brauman[7] et. al., the structures which correlate with the known relative acidities of alcohols and HF are alcohol-solvated halides (ROH...F^-) since the proton affinity of CH_3O^- is 381.2 kcal/mol higher than that of F^- (371.4 kcal/mol). Therefore $ROHX^-$ underwent an adiabatic transition to a near transition state of the neutral complex with a small barrier. An upper limit of 0.05-0.1 eV can be placed on the differences between thresholds and EA's (Table 1).

Table 1 Data Results

	F⁻	Cl	Br	I
EA (eV)	3 399	3 615	3 364	3 061
Exp. threshold[a] (nm)	279 5	280 6	309 2	337 0

Advances in Applications of the Kinetic Method, G. Chen, C.D. Cleven, L. Horn, S. Ma, J.S. Patrick, S.S. Yang and R.G. Cooks, Department of Chemistry, Purude University, West Lafayette, IN USA 47907-1393

Since it's inception[1] the kinetic method has been used to obtain relative cation affinities for numerous compounds not easily studied by traditional methods.[2] These estimations are made based upon the relative extents of dissociation of an ion-bound dimer, such as a proton-bound dimer, of two compounds as is shown below.

$$B_1 + B_2H^+ \leftarrow [B_1\text{-}H^+\text{-}B_2] \rightarrow B_2 + B_1H^+$$

In the present work new applications and extensions of the kinetic method to unique classes of compounds are discussed. Studies using well-characterized dimer species such as the proton-bound dimer of n-propylamine and t-butylamine have provided insights into the mechanism of internal energy deposition during collision-induced dissociation (CID). Specifically, CID of this and other proton-bound dimer species with a variety of target gases has demonstrated a strong correlation between internal energy, measured as the effective temperature, and the center-of-mass collision energy. When the effective temperature is converted to a Boltzman energy, internal energy deposition is approximately 100% of center-of-mass, suggesting a collision complex or local collision effects in the CID mechanism.

Electron-bound dimer ions of polyaromatic hydrocarbons (PAHs) were formed under electron capture conditions using desorption chemical ioinization. The low energy collision-induced dissociation of these electron-bound dimer ions provides orderings and estimates of electron affinities for several PAHs ,including perylene (0.35 ± 0.1 eV), 1,2-benzanthracene (0.39 ± 0.1 eV), 1-methylanthracene (0.55 ± 0.1 eV), biphenylene (0.89 ± 0.1 eV) and benzo(ghi)perylene (0.42 ± 0.1 eV), whose values were previously unknown.[3] In addition, dissociations of electron bound dimer ions have been used to distinguish isomeric PAHs. For example, the isomeric PAHs 1,2-benzanthracene and triphenylene can be distinguished from the relative extents of dissociation of their respective electron-bound dimers with perylene.

The effects of steric hindrance have been investigated using the polyatomic $OCNCO^+$ cation as the binding ion in dimers of substituted and unsubstituted pyridines.[4] The relative extents of dissociation of proton- and $OCNCO^+$-bound dimer ions of substituted pyridines correlate well for meta- and para-substituted compounds. However, the relative dissociation of dimers containing ortho-substituted pyridines show substantial deviations from the behavior of the other pyridines. The plot of natural logarithm of the relative abundances from dissociation of $OCNCO^+$-bound dimer ions versus proton affinity shows this deviation.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

The degree of deviation from the straight line is related to the steric hindrance displayed by the ortho-substituted pyridines.[4]

Dissociation of proton-bound heterodimers of amino acids showed small differences in the relative product ion abundance when stereoisomers of isoleucine (Ile) were paired with those of alanine (Ala). The natural logarithm of the ratio of $AlaH^+$ to $IleH^+$ observed was 5.185 and 5.345 for the l-/l- and d-/l- isomer pairs, respectively. The observed differences are attributed to entropic factors related to the chirality of the amino acid monomers.

The gas-phase basicity (GB) of the zwitterion betaine has been estimated as 232.9 ± 0.8 kcal/mol using the kinetic method. By comparison the gas-phase acidity of N,N-dimethylglycine was estimated as 337.1 kcal/mol. The difference of 104-116 kcal/mol between the values for betaine and those of acetic acid and the N,N-dimethylglycine anion is attributed to coulombic effects and represents the largest substituent effect yet observed for proton affinities. The plot of natural logarithm of the relative product ion abundances versus GB indicates two lines having similar slopes. The GB value for betaine is consistent with the proton affinity value recently obtained.[5] This result suggests that two species are present during ionization. Estimation of the lower GB provides a value of 220.4 ± 0.5 kcal/mol, which is indistingishable from the value of 219.8 kcal/mol obtained by the kinetic method for authentic N,N-dimethylglycine methyl ester, a known rearrangement product of betaine.[6]

In experiments performed using membrane introduction and a benchtop ion trap mass spectrometer the proton affinity of bicyclo-[3.3.0] oct-1(5)-ene was estimated as 200 ± 2 kcal/mol.

The studies discussed above further demonstrate the capabilities of the kinetic method in making thermochemical estimates of unusual species or species in reaction mixtures.

Historically, a super acid has been defined as any acid which is stronger than sulfuric acid. The question: "what is the strongest neutral Bronsted super acid?" is difficult to answer in the condensed phase where solvation effects greatly affect the measured pK_as. This question can be answered by looking at intrinsic acidities in the gas phase.(1,2) We have used Cooks' kinetic method to study the relative acidities of sulfonic acids.(3) Dimer clusters with the general formula of $[RSO_3^- \cdots H^+ \cdots {}^-O_3SR']^-$ were formed via FAB (cesium ion gun operating at 25 kV, glycerol matrix) and then analyzed using unimolecular MIKES on a Fisons/VG (Manchester, UK) Autospec-Q instrument. The relative abundance of each sulfonate anion (RSO_3^- and $R'SO_3^-$) observed in the MIKE spectrum correlates with the relative acidities of RSO_3H and $R'SO_3H$.(3)

Based upon the experimental results, the following acidity scale is proposed (starting with the weakest acid): methane sulfonic acid, ethane sulfonic acid, methoxy sulfonic acid, sulfuric acid, m- and p-aminobenzene sulfonic acids, p-toluene sulfonic acid, benzene sulfonic acid, o-aminobenzene sulfonic acid, o-nitrobenzene sulfonic acid, cysteic acid, m- and p-nitrobenzene sulfonic acids, and triflic acid. This acidity ranking is similar to those of the analogous carboxylic acids except for the p-toluene and benzene sulfonic acids which show a reverse order.

In addition, *ab initio* studies on the acidities of the sulfonic acids RSO_3H (R = HO, CH_3, CF_3, F) have been performed up to the MP2(FC)/6-31+G*//HF/3-21+G* level of theory. The best correlation with the experimental literature values results from the HF6-31+G*//HF/3-21+G* level of theory, although the absolute ΔH°_{acid} *ab initio* values are poor. (1,2)

Using the same range of sulfonic acids, the fragmentation patterns of the monomer sulfonate anions (RSO_3^-) have been investigated via FAB/MS/MS techniques. CA/MIKES was performed using CAD (Ar gas) with attenuation of the parent ion beam by 70%. A general loss of R, resulting in the formation of radical anion of $SO_3^{\cdot -}$ is seen in all cases.(4) In agreement with Binkley et al, the loss of SO_2 is observed for those aromatic sulfonic acids bearing a H atom adjacent to the SO_3 group.(5) In those substituted aromatic sulfonate anions (when the substituent is either NH_2, CH_3, or NO_2) a general loss of the substituent at (NH_2, CH_3, or NO_2) to form the radical anion $C_6H_4SO_3^{\cdot -}$ was

observed. The ions $CH_3XSO_3^-$ (X = O and CH_2) also undergo loss of a $CH_3^\cdot$ radical. The fragmentation reactions of deprotonated cysteic acid and triflic acid are shown in equations 1 and 2.

BOND-SELECTIVE PHOTODISSOCIATION: MECHANISMS AND APPLICATIONS

Craig W. Bookwalter, David L. Zoller, Philip L. Ross, Murray V. Johnston
Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

Many small molecules are known to photodissociate directly from an excited electronic state Depending upon the nature of the excited state, preferential cleavage at the chromophore may be observed. If similar processes occur in large molecules, then site-selective bond cleavage may be achieved. Nonselective dissociation may not be practical for the structural analysis of large (> 10 kDa) precursor ions. If the product ion current is spread over many m/z peaks, then the signal-to-noise ratio will be low and the mass resolution may not be sufficient to separate adjacent peaks. In contrast, bond selective photodissociation limits the precursor ion to a few, specific dissociation channels.

In our laboratory, photodissociation-photoionization mass spectrometry is used to study such process. Neutral molecules are photodissociated with an excimer laser and the products are softly photoionized with coherent vacuum ultraviolet radiation. Recently, we have performed a systematic study of the photochemistry of simple aliphatic disulfides to gain insight on the structural information that may be obtained by photodissociation of larger analogs such as peptides containing disulfide linkages

The primary photodissociation reactions are shown below.

		ΔH (rxn)	
RSSR $\xrightarrow{h\nu}$	2 RS·	280 kJ/mole	(1)
RSSR $\xrightarrow{h\nu}$	R· + RSS·	235 kJ/mole	(2)

(R = CH_3, C_2H_5, C_3H_7, C_4H_9)

Figure 1 shows the 9 68 eV photoionization mass spectra of di-n-dipropyl disulfide photodissociated with 248 nm and 193 nm radiation. At 248 nm, the spectra are dominated by photoionized RS• radicals that are produced by S-S bond cleavage (reaction 1). At 193 nm, the spectra are much more complex and show products of several processes Photoionized RS• radicals indicate cleavage of the S-S bond (reaction 1). Photoionized RS_2• and R• radicals indicate cleavage of the C-S bond (reaction 2). Photoionized S_2 (m/z 64) is a secondary decomposition product of the RS_2• radical. Molecular rearrangements are also observed.

Table 1 shows the change in relative yield of S-S versus C-S bond cleavage when going from 193 nm to 248 nm. For any given compound, the yield is directly calculated from the peak areas of the respective ions in the photoionization mass spectrum. The values show that the branching ratio for S-S bond cleavage relative to C-S bond cleavage is typically one to two orders of magnitude higher at 248 nm than 193 nm.

The observed wavelength dependence cannot be readily explained by photodissociation from the ground state. The ground state S-S bond energy (280 kJ/mole) is much larger than the C-S bond energy (235 kJ/mole). If dissociation occurred from the ground state, decreasing the photon energy (i.e. going from 193 nm to 248 nm) would be expected to favor the lower energy process. The opposite effect is observed. Also, dissociation from the ground state would mimic thermal decomposition

pathways. However, for disulfides, these thermal pathways are nonselective, showing both C-S and S-S bond cleavage Therefore, the selective cleavage of the S-S bond with 248 nm radiation is consistent with excited state photochemistry.

COLLISION SPECTROSCOPY INVOLVING CHARGE PERMUTATION

Chrys Wesdemiotis, Sarka Beranova, Michael J. Polce, Yoojung Kim and Jody M. Talley

Chemistry Department, The University of Akron, Akron, OH 44325

A novel experimental approach for the study of gaseous ions and their decomposition mechanisms involves the use of neutralization-reionization mass spectrometry (NRMS).[1] With this method, which employs collisional charge permutation, it is possible to (i) identify the neutral fragments arising upon CAD of a mass-selected ion, (ii) determine ion structures and (iii) synthesize and characterize an ion's neutralized form, which can be an elusive neutral intermediate that is inaccessible by other means.

(i) Neutral losses are made detectable by collision-induced dissociative ionization (CIDI).[2] Their identification provides key insight on the dissociation mechanism of the precursor ion studied. This is demonstrated for $(CsI)_xCs^+$ and $(NaI)_xNa^+$ clusters (x = 2-4), whose CAD predominantly yields smaller cluster ions via evaporation of Cs_nI_n and Na_nI_n units ($n \leq x$), respectively, viz. eq 1 (illustrated with cesium). The identity of the evaporated neutrals has remained unknown.

$$(CsI)_xCs^+ \rightarrow (CsI)_{x-n}Cs^+ + Cs_nI_n \text{ [n times CsI, or } (CsI)_n \text{ multimer]} \quad (1)$$

Post-ionization of the neutral fragments from $(CsI)_3Cs^+$ to cations or anions gives rise to the neutral fragment-reionization ($^+N_fR^{+\cdot}$, $^-$) spectra of Figure 1. If the Cs_nI_n losses from this precursor ion (n = 1-3) exclusively consisted of CsI monomers, then the $^+N_fR^{+\cdot}$, $^-$ spectra should show no ions heavier than $CsI^{+\cdot}$ or $CsI^{-\cdot}$ (*m/z* 260). However, ions larger than $CsI^+/CsI^{-\cdot}$ do appear in both spectra. The product ions present in Figure 1 provide strong evidence that multimer moieties (i.e. smaller whole neutral clusters $(CsI)_n$) are evaporated in one step.[3] Note that, with the exception of $CsI^{+\cdot}/CsI^{-\cdot}$, radical ions are not observed in the $^+N_fR^{+\cdot}$, $^-$ spectra. Evidently, collisional ionization of $(CsI)_n$ preferentially yields closed-shell fragments $(CsI)_{n-y}Cs^+$ or $(CsI)_{n-y}I^-$ ($1 \leq y \leq n$). Analogous results are obtained for all other cesium and sodium iodide cluster ions investigated.

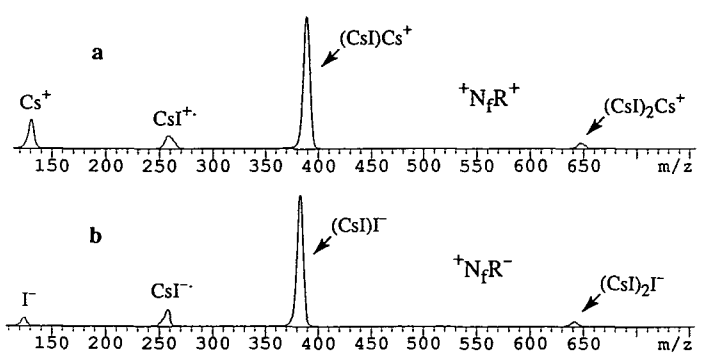

Figure 1. Neutral fragment-reionization ($^+N_fR^{+\cdot}$, $^-$) mass spectra of $(CsI)_3Cs^+$ precursor ions, acquired by subjecting $(CsI)_3Cs^+$ to CAD (with He) and later post-ionizing the so liberated neutral losses. (a) Post-ionization with O_2 to cations; (b) post-ionization with Xe to anions. The superscripts besides N and R denote the charges of precursor ion and ultimate product ions, respectively.

(ii) Neutralization-reionization (NR), a process entailing two successive charge changing collisions, offers an alternative means to study ion structures. This method is particularly useful whenever CAD induces rearrangement fragmentations, which may complicate structural assignments. For example, the CAD spectrum of $M^{+\cdot}$ from $CH_3OCH_2CH_2OH$ (2-methoxyethanol, ME) contains sizable fragments at *m/z* 47, $(CH_3)_2OH^+$,[4a] and 58, mainly $[CH_2OCH_2CH_2]^{+\cdot}$ [4b] (Figure 2a); such ions, which are also formed from metastable $ME^{+\cdot}$,[4] could imply that ionized 2-methoxyethanol has isomerized (at least partly) to the distonic isomers $CH_3(OH^+)CH_2CH_2O\cdot$ and $\cdot CH_2OCH_2CH_2OH_2^+$. The *m/z* 47 and 58 products are, however, suppressed in the corresponding $^+NR^+$ spectrum (Figure 2b). The dominant primary fragments in the latter are $CH_3OCH_2^+$ (*m/z* 45) and $^+CH_2OH$ (*m/z* 31), i.e. ions arising from structurally more diagnostic direct cleavages. The $^+NR^+$ spectrum of Figure 2b is consistent with retention of the original $ME^{+\cdot}$ structure and excludes any appreciable isomerization of (stable) $ME^{+\cdot}$ to distonic isomers.

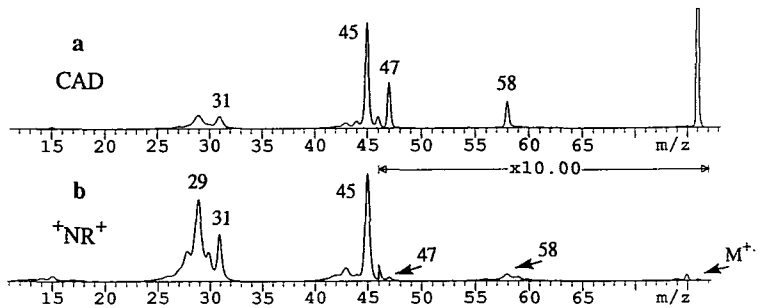

Figure 2. (a) CAD and (b) neutralization-reionization ($^+NR^+$) mass spectra of 2-methoxyethanol ion. Xe was used for neutralization and O_2 for CAD and reionization.

Rearrangements, which usually require lower critical energies than direct cleavages, are discriminated against upon neutralization-reionization because NR deposits higher average internal energies than CAD.[5] A large part of this energy originates in the reionization step, which involves collision-induced dissociative ionization (CIDI). This is shown to be true by comparison of the CAD and CIDI spectra of triethyl phosphate (TEP). The latter is measured by post-ionizing the TEP molecules eliminated from the proton-bound dimer TEP-H^+-TEP. The CIDI spectrum shows more direct fragmentations and more abundant lower mass fragments, pointing out that the nascent $\{TEP^+\}^*$ ions emerging from CIDI have gained higher average internal energies than the $\{TEP^{+\cdot}\}^*$ ions emerging from CAD.

(iii) The neutralization step also offers the potential to generate and study reactive neutral species from the corresponding cations or anions. Here, the carbene ion $HC-NH_2^{+\cdot}$ is used to prepare the elusive aminocarbene, $HC-NH_2$, a potential interstellar species. The $^+NR^+$ spectrum of $HC-NH_2^+$ includes an abundant molecular cation, indicating that the intermediate neutral, i.e. $HC-NH_2$, is stable towards dissociation. Moreover, the $^+NR^+$ spectrum is substantially different from that of the isomeric $H_2C{=}NH^+$ cation, indicating that the exothermic 1,2-H migration $HC-NH_2 \rightarrow H_2C{=}NH$ must surmount an appreciable barrier. Thus, aminocarbene must reside in an energy well and represents a bound molecule.

Collisionally Induced Emission Spectroscopy

Fred Wiedmann and Chrys Wesdemiotis
Department of Chemistry, University of Akron, Akron, OH 44325-3601

Collisionally Induced Emission (CIE) Spectra of small ions were first reported by Holmes et al. (J. L. Holmes, P. M. Mayer, and A. A. Mommers, JACS, 113, 9405 (1991)). Their results for $C_2H_4O^{+\cdot}$ and $C_2H_5^+$ isomers suggested that this method could become a viable alternative for structural analysis. Here we are continuing these studies.

The experiments are conducted with a VG Autospec EBE tandem mass spectrometer containing two collision cells between MS-1 (E1B) and MS-2 (E2). The tops of the cells and the cover of the instrument are equipped with quartz windows, permitting the detection of light emitted inside the cells. The light is measured by a photomultiplier tube that has been mounted onto the cover window. Cutoff filters can be placed between the PMT and the window to give a histogram. Early experiments used seven cutoff filters producing eight regions, while later experiments used ten cutoff filters producing eleven regions. The histograms have been corrected for the dark count, the ion abundance, and the filter transmittance, but not for the PMT response.

With this setup we have shown that the emission comes mainly from the projectile ion, its corresponding neutral, and any fragments. By looking at the emission spectra of a number of small ions, such as Cs^+, O_2^+, W^+, and Na^+, and comparing them to the published spectra of the ions and their neutralized forms, we know that the amount of emission from a projectile ion and its corresponding neutral change from one system to the next. For example, most of the emission from Na^+ appears in the region from 575-625 nm. This is the region that contains the Na lines at 589 and 590 nm, thus we see mainly emission from the sodium neutral. In contrast tungsten gives a dominant signal in the region from 200-300 nm. This corresponds well with the emission expected from W^+. The emission from Cs^+ also corresponds mostly to its ion, while the emission of O_2^+ is evenly distributed between the ion and its corresponding neutral.

As expected, the total emission is proportional to the total ion abundance. This is best seen with samples that decay relatively quickly. For example, the ion signal of $AlaH^+$(produced by FAB) decays over a period of about 20 minutes. The total emission spectrum is linearly related to the chromatogram. This relationship has been verified with several other ions.

While most of the emission comes from the projectile, both the choice of the target and its pressure effect the histogram. As expected, we have found that the total emission increases as the target pressure increases. The pressure of the target gas also has an effect on the relative intensity of the emission. For example, for Cs^+ projectiles and O_2 targets, the emission at 200 - 300 nm is very sensitive to pressure changes. This could be due to the fact that the O_2 target emits strongly in this region. Another explanation is that the more collisions the cesium ion has, the greater the probability that it is promoted to a highly excited state from which a higher energy UV photon is emitted upon the return to the ground state. Also, while different targets give the same peaks, each target gives a different relative intensity in a given band. These differences could be due to the emission of the target and/or the degree of projectile

excitation achievable with each target.

The total emission of several homologous ion series were measured under constant pressure. The results are summarized in the table below. The total ion counts have been normalized by the ion's abundance and are shown relative to the counts of the smallest ion in the homologous series. It was found that the total emission increases as the mass of projectile ion increases.

Ion	m/z	Total CIE	Ion	m/z	Total CIE
Na^+	23	1.0	Cs^+	133	1.0
Na_2I^+	173	1.2	Cs_2I^+	393	1.2
$Na_3I_2^+$	323	2.0	$Cs_3I_2^+$	653	2.7
$Na_4I_3^+$	473	2.9	$Cs_4I_3^+$	913	5.6
$Na_5I_4^+$	623	6.6			

Ion	m/z	Total CIE	Ion	m/z	Total CIE
$CuCl_2^-$	133	1.0	[Ala]H+	90	1.0
$Cu_2Cl_3^-$	231	0.9	$[Ala]_3H+$	232	4.3
$Cu_3Cl_4^-$	329	2.1	$[Ala]_5H^+$	374	8.7

A number of experiments have been run to determine the effect of different functional groups on the emission spectra. Below is a table listing the data for some of the molecules that were run. The total emission for each compound has been normalized to 100. At this time no definitive trends have been found. Several ions primarly (>65%) emit in the UV region, while others show significant near IR bands. There is very little or no emission found in the regions from 400-450 nm and from 575-625 nm.

MATRIX ISOLATION OF MASS-SELECTED IONS FOR ANALYSIS BY FTIR SPECTROSCOPY

John Allison, Thomas M. Halasinski, Jerry T. Godbout and George E. Leroi
Department of Chemistry, Michigan State University, East Lansing, MI 48824

Using matrix isolation techniques, scientists have been able to generate trapped ionic species for spectroscopic analysis, usually by photoionizing molecules in the matrix. We have demonstrated that mass-selected cations can be directly deposited into growing inert gas matrices at low temperatures.[1] For some ions, several hours of ion deposition results in a total number of ions sufficient for detection using FTIR spectroscopy, allowing for structures of ions of interest in mass spectrometry to be determined. While the ability to use conventional structural tools for the analysis of ions generated in a mass spectrometer is exciting, the experiment clearly should not work. If cations alone are trapped in an inert gas matrix, within milliseconds the matrix should achieve a potential that will prohibit additional ion accumulation. Some mechanism must exist to maintain electrical neutrality. We will address this topic here. For example, when CF_3Cl is ionized be electron impact in the ion source of a quadrupole mass spectrometer, the vibrational spectrum of CF_3^+ can be obtained after several hours of accumulation of this ion. Small amounts of neutral CF_3Cl are also present in the matrix. If a mechanism exists for the generation of counterions in the matrix, then one may expect them to be Cl^-, which would be the probable product of electron attachment to CF_3Cl. However, atomic anions have no vibrational spectrum. When the cation-containing matrix is vaporized, cationic *and* anionic species are expelled into the gas phase and can be detected. How are the anionic components of the matrix formed?

We report here the first direct observations of counterions in matrices formed during the codeposition of mass-selected cations and neon. We have discovered that the addition of carbon dioxide to the neon matrix gas during deposition of a mass-selected ion beam results in two unique advantages. The first advantage is that it enhances positive ion accumulation - detectable signals can be achieved in noticeably shorter times. The second advantage is that detectable quantities of CO_2^- are observed. Figure 1 shows the spectrum obtained when CF_3^+ is mass-selected and deposited, using a matrix gas with a molar Ne:CO_2 ratio of 2300:1. Absorbances due to both CF_3^+ and CO_2^- are observed and their intensities correlate.

The spectroscopic detection of a counterion provides a means for investigating mechanisms of counterion generation. While we cannot yet eliminate or substantiate all possible mechanisms, we present here evidence towards a "surface bombardment" mechanism. In this mechanism, the collision of incoming ions with metallic surfaces surrounding the CsI sample window region appear to generate electrons and negative ions which are subsequently attracted to the matrix. When an isolated metallic grid is placed on the CsI matrix window and a +80 V potential is applied during ion deposition, an absorption due to CO_2^+ is observed. Figure 2 illustrates this result from an ion deposition involving

$C_7H_7^+$. We attribute the appearance of CO_2^+ to ionization of neutral CO_2 molecules in the matrix by electrons that have been formed by cation bombardment of surfaces, and accelerated towards the matrix by the potential applied to the grid. Improvements in the measurement of charged species of both sign from the matrix as it is vaporized by applying potentials on the collectors is also presented. This technique is useful for determining the presence of positively and negatively charged species in the matrix when spectroscopic signals are not observed.

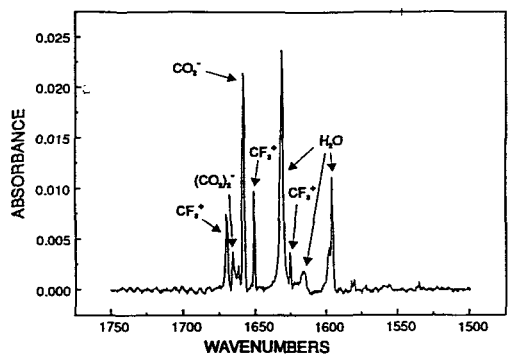

Figure 1. Infrared absorption spectrum of a 2300:1 Ne:CO_2 matrix in the 1750 - 1500 cm^{-1} region. 20 nA of CF_3^+ from EI of CF_3Cl was deposited for 13 hours.

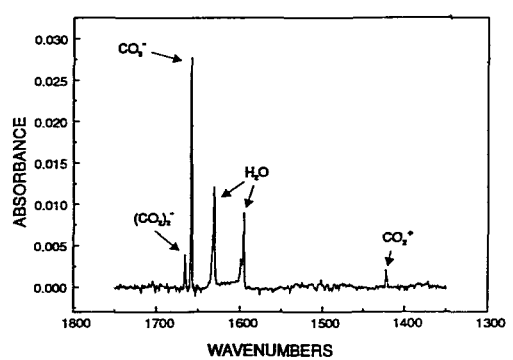

Figure 2. Infrared absorption spectrum of a 1500:1 NeCO_2 matrix in the 1750 - 1350 cm^{-1} region. 30 nA of $C_7H_7^+$ from EI of toluene was deposited for 18 hours. The copper grid on the CsI window was floated at a potential of +80 V during ion deposition.

SPECTROSCOPIC STUDIES OF THE ELECTRON RECOMBINATION OF SEVERAL SMALL IONS B. Lachele FOLEY, Nigel G. ADAMS, Lucia M. BABCOCK and Jeffery M. BUTLER, Chemistry Department, University of Georgia, Athens, GA 30602.

Dissociative electron-ion recombination is a critically important ionization loss process in many ionized gases including interstellar gas clouds and planetary ionospheres. Yet little data are available on this type of reaction and, in particular on the nature of the recombination products. To rectify this situation, we have used the chemical versatility of the flowing afterglow coupled with extensive spectroscopic facilities to identify recombination emissions from the recombination of H_3^+, HCO^+, N_2H^+, CO_2^+, CS_2^+, H_3O^+, NH_4^+ and CH_5^+. These emissions have been distinguished from those from other sources by adding a gas which rapidly attaches electrons (e.g., CCl_4, CH_3I or SF_6) upstream of the recombination region. Details of the technique have been discussed previously.[1]

For HCO^+ and N_2H^+, the electronic emissions CO(a→X) and N_2(B→A) have been observed and the individual vibrational bands have been separately identified. Using calculated Einstein A coefficients for the transitions, vibrational population distributions for the CO a and N_2 B states, resulting from recombination of HCO^+ and N_2H^+ respectively, have been determined. Comparison of these with the theoretical predictions of Bates,[2] for the *Impulse* and *Relic* mechanisms, has shown that the theory underestimates the degree of vibrational excitation. Further experimental studies with DCO^+ and N_2D^+ showed that there was little difference in the vibrational population distributions (≤10%) between the deuterated and undeuterated species whereas theory predicted a much greater effect.

For CO_2^+ and CS_2^+, CO (A→X), (a→X), (a'→a), (d→a) and CS (A→X) were observed. Note that the CO_2^+ recombination produces more emissions that CS_2^+ even though other states are energetically accessible in the latter case, presumably due to the availability of suitable curve crossings. The emission spectrum for the CO_2^+ recombination is remarkably similar to that observed from the Martian airglow[3], suggesting that this recombination should be considered as an emission source in addition to direct excitation by high energy electrons.

In the case of H_3^+ recombination, there has been controversy over the magnitude of the rate coefficient for the last ten years, the discrepancy being about an order of magnitude between the various workers. To try to determine the reason for this discrepancy, the emission spectrum of a recombining H_3^+/electron plasma was obtained over the available wavelength range (100 to 800 nm). The only significant emissions were in the range 110 to 170 nm with no emissions from H_3 Rydberg states[4] being observed. The observed emissions have been identified as H-atom Lyman α, H_2 (B→X) from v'=3 of the upper state to v"=9 to 11 of the lower state, and emissions from higher vibrational levels of the H_2 B state to the continuum of the X state.[5] None of there emissions are energetically possible with vibrationally relaxed H_3^+. Available potential curves for the H_3^+/H_3 system show that if the H_3^+ is excited to v~3 then curve crossings are available to produce H_2(X) + H(n=2) which emits L_α. Somewhat more excitation in the H_3^+ would be required to produce the H_2 B state emissions, however, potential curves for this are not presently available. A considerable effort was made to remove excitation in the H_3^+ by near resonant proton transfer with a large concentration of neutral H_2. Obviously, it is difficult to remove all of the excitation and this may be a contributor to the discrepancies

between the various measurements of the H_3^+ recombination coefficient. What is certain is that the recombination does not proceed via Rydberg states production followed by radiative decay, at least in the spectral range 100 to 800 nm.

Emissions have also been detected from recombining electron plasmas of H_3O^+, NH_4^+ and CH_5^+. For H_3O^+, no significant emissions were observed over the whole spectral range, even though several electronically excited states are energetically possible. Since the overall recombination coefficient is large (10^{-6} cm^3 s^{-1} [6]), and the OH X state is known to be a significant product (65% [7]), it appears that there are no suitable curve crossings to excited state products and that these crossings are inefficient compared with those to the ground state. For the other cases few emissions were observed, NH(A→X) for NH_4^+ and CH (A→X) and (B→X) for CH_5^+. A summary of the vibrational state distributions is given in the table below.

VIBRATIONAL STATE DISTRIBUTIONS OF DIATOMIC PRODUCTS OF ELECTRON-ION RECOMBINATION

Ab Initio Calculations of the $Ar{\bullet}CO_2^+$ Cluster Ion

Gregory I. Gellene
Department of Chemistry and Biochemistry
Texas Tech University, Lubbock, TX 79409-1061

Presently little detailed information is available on the structure of the $Ar{\bullet}CO_2^+$ cluster ion. In a photoionization study of $Ar{\bullet}CO_2$, Pratt and Dehmer[1] determined $D_0(Ar{\bullet}CO_2^+) = 0.26\pm0.03$ eV (2100 ± 320 cm^{-1}). They also concluded that the structure of $Ar{\bullet}CO_2^+$ involved major changes from the $Ar{\bullet}CO_2$ configuration which is known to be *T* shaped[2] with an Ar-C distance of 3.49Å.

Illies *et al.*[3] studied the photodissociation of $Ar{\bullet}CO_2^+$ and based on kinetic energy release measurements and the absence of rotational excitation in the CO_2^+ fragment concluded that the cluster ion was either linear or *T* shaped. Simple molecular orbital arguments were then presented in favor of a *T* shaped configuration.

Theoretically, the ion has been considered at the MP4(full)/G-31G*//MP2/6-31G* level of theory. Only linear and T shaped geometries were considered. It was found that the linear geometry was favored at the MP2 level while the T shaped geometry was favored at the MP4 level. However no frequencies were determined so the nature of the calculated stationary points is an open question.

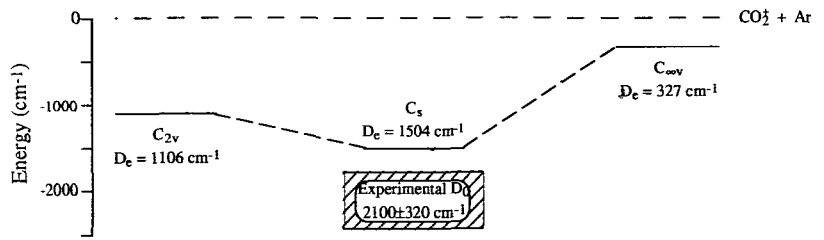
Recent studies in this laboratory of Symmetry Induced Kinetic Isotope Effects in the formation of $Ar{\bullet}CO_2^+$ have made it essential that the ground state geometry of the ion be established. Thus we have undertaken the following high level *ab initio* calculations.

Method. Calculations were performed using the cc-pVDZ and cc-pVTZ basis sets without diffuse function augmentation for oxygen and carbon and with diffuse function augmentation for argon. The diffuse functions were included to provide an accurate description of the polarizability of Ar. This property is particularly important for the description of $Ar{\bullet}CO_2^+$ where the charge remains largely localized on CO_2^+.

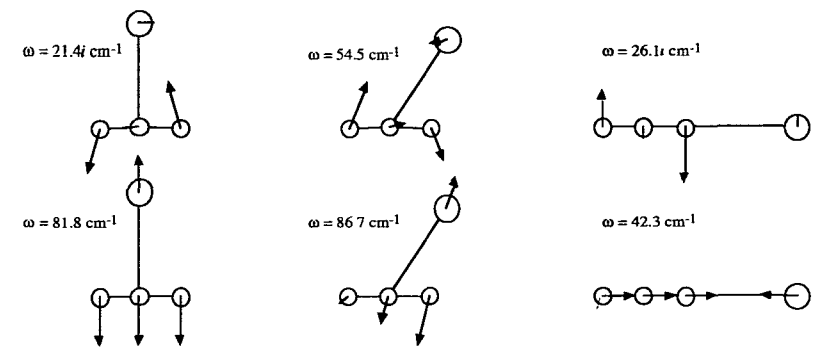
Electron correlation was included using QCISD and QCISD(T) theory because the availability of QCISD analytical gradients allowed efficient geometry optimization. Harmonic force constants were determined with the double zeta basis sets by numerical differentiation of analytical QCISD first derivatives. To ensure accurate characterization of the stationary points in the presence of low frequency van der Waals modes, geometry optimizations were continued until all residual forces were less than 10^{-6} au. Calculations were performed using the GAUSSIAN 92 suite of programs.

Results. The major results ar summarized on the following figure. The relative energies were obtained from QCISD(T) calculations performed QCISD optimized optimized geometries using cc-pVTZ basis sets for carbon and oxygen and aug-cc-pVTZ basis set for argon. The vibrational frequencies were obtained at the QCISD level of theory using cc-pVDZ basis sets for carbon and oxygen and aug-cc-pVDZ basis set for argon.

Stationary Points on the CO_2^+/Ar Potential Energy Surface



van der Waals Vibrational Modes



Conclusions

1. The $Ar{\bullet}CO_2^+$ cluster ion is neither *T* shaped nor linear but adopts an unsymmetrical C_s structure in its ground state.

2. It is interesting to consider whether thermal excitation and the double well nature of the potential energy well could give rise to the *T* shape-like photodissociation dynamics observed by Illies *et al.*

SYMMETRY BREAKING AND ELECTRON CORRELATION IN O_2^+, O_2, AND O_2^-

Charu A. Chandrasekher, Gregory I. Gellene

K.S. Griffith, Department of Chemistry and Geology, Mankato State University, Mankato, MN 56002

Coupled-cluster (CC) theory provides one of the most powerful approaches available for building electron correlation onto a single determinant reference wave function. Two particularly attractive characteristics of the approach are that all CC methods are size-extensive and the hierarchical structure of the theory causes methods to become increasingly accurate as more excitations are considered. Most of the dynamical correlation of a system is accounted for by the CCD approach which considers only the double excitation cluster operator. The addition of the single excitation cluster operator to CCD defines CCSD which is exact for a two electron system. However, it is known that triple excitations are required for the correct description of many molecules, and a number of approximate treatments of the effects of triple excitation operator have been developed. An alternative size-extensive approach called quadratic configuration interaction (QCI) was developed which in the single-double space (QCISD) is exact for a two electron system. QCISD has been shown to be equivalent to CCSD with a Hartree-Fock reference wave function where specific operators are omitted from the doubles equation and from the singles and doubles equation. Considering that QCISD is an approximation to CCSD, it might be thought that QCISD would be less accurate than CCSD. However both CCSD and QCISD are inexact and that numerical comparisons are required to assess their relative merits. CCSD(T) and QCISD(T) (both of which treat the inclusion of triple excitations perturbatively) have been compared in terms of eighth order Møller-Plesset perturbation theory. Although this demonstrated that CCSD(T) contains more triple excitation terms than QCISD(T), a higher number of contributions does not guarantee the superior performance of a method because some terms may be more important than others. Numerical comparisons of QCISD(T) and CCSD(T) are required to assess their relative merits.

Calculations were performed using Dunning's aug-cc-pVDZ (double zeta quality) and aug-cc-pVTZ (triple zeta quality) basis sets for oxygen. The two basis sets were used in symmetry constrained and symmetry relaxed unrestricted Hartree-Fock (UHF) calculations for eight internuclear separations (r) for each species. Electron correlation was built onto each of these UHF wave functions using CCSD, CCSD(T), QCISD, and QCISD(T) producing various point-wise defined potential energy curves for each of the three species. Continuous curves were obtained by fitting the calculated energies to a polynomial in r from which the value for a variety of spectroscopic constants were extracted. This investigation compares the accuracy of CCSD to QCISD and CCSD(T) to QCISD(T) in determining potential energy curves for $O_2^+(X^2\Pi_g)$, $O_2(X^3\Sigma_g^-)$, and $O_2^-(X^2\Pi_g)$. This series of molecules was chosen for the following five reasons: (1) The open shell electronic structure of these molecules is not well described by a single configuration making electron correlation important and the relative importance of excited configurations varies with internuclear separation. (2) The calculation of accurate ionization potentials (IP) and electron affinities (EA) requires treating electron correlation in the neutral and the charged species in a balanced manner, particularly where the correlation energy is in fact larger than the EA. (3) Each of these species is subject to inversion symmetry breaking, and recovering from this artifactual symmetry breaking is a challenging test of approximate treatments of electron correlation. (4) The size of the molecules is compatible with the use of large basis sets. (5) Accurate experimental information is available for comparison with the calculations.

For O_2^+, symmetry breaking was favored for all r studied, but O_2^- and O_2 favored symmetry breaking only for r > 1.40 Å and r > 1.25 Å, respectively. When symmetry breaking is favored, a symmetry constrained ($D_{\infty h}$) and a symmetry relaxed ($C_{\infty v}$) UHF reference determinant are available for post-Hartree-Fock calculations. Values for adiabatic IP and EA of O_2 at the various levels of theory were determined by taking the appropriate difference in the respective minimum energy of O_2 and that of O_2^+ and O_2^-. The strategy was to compare symmetry constrained results to experimental values for various spectroscopic constants to evaluate accuracy and to compare symmetry relaxed results to the corresponding symmetry constrained results to evaluate recovery from symmetry breaking. ***r_e*** and ***ω_e*** The r_e values show two general trends which have been identified previously for other systems: extension of the basis set tends to decrease r_e, and inclusion of triples excitations tends to increase r_e, while the ω_e values show trends which are the reverse: basis set extension tends to increase ω_e and inclusion of triples excitations tends to decrease ω_e. Because the symmetry breaking does not occur for O_2^- and O_2 at bond lengths equal to their respective r_e, the ability of the different methodologies to overcome the use of a symmetry broken reference function with respect to r_e is best addressed by the O_2^+ results. For both r_e and ω_e the best recovery from symmetry breaking is provided by the CCSD method. ***D_J***: The D_J values can be assessed only for O_2 and O_2^+. For these two molecules, the value of D_J calculated by QCI methods with a symmetry constrained reference function is more accurate than the corresponding CC result. Comparison of corresponding D_J values calculated with symmetry constrained and symmetry relaxed reference functions further emphasizes the general superiority of CCSD in recovering from symmetry breaking. ***IP, EA, and D_e***: The accuracy of the IP of O_2 calculated at the UHF level of theory is quite high, so there is little opportunity for the various correlated methods to distinguish themselves in this regard. However, the situation is very different with respect to the accuracy of the calculated EA of O_2 where UHF calculations fail to predict a bound species. The EA calculated with QCI methods is consistently superior to the corresponding CC results for all basis sets and correlation levels considered. Finally, with respect to D_e values, the results indicate that with symmetry constrained reference functions, the QCI results are superior the the corresponding CC results for the range of basis sets and correlation levels investigated. ***$\omega_e x_e$*** and ***α_e***: The results show that when symmetry constrained wave functions are used, the calculated values of cubic and quartic force constants (upon which $\omega_e x_e$ and α_e depend) are remarkably insensitive to the basis set, level of correlation (including no correlation), and correlation method. When symmetry relaxed UHF wave functions are used the calculated values of k_3 and k_4 show a significant dependence on the level of correlation and the correlation method employed. With respect to calculating higher derivatives of the potential, CC methods appear to be superior to QCI methods in recovering from a symmetry relaxed UHF wave function.

Thus, In agreement with previous results obtained for closed-shell species, basis set extension tends to decrease r_e and increase ω_e while inclusion of triples excitations tends to increase r_e and decrease ω_e. Comparison of corresponding symmetry constrained and symmetry relaxed calculations indicates that the CCSD method is generally superior to CCSD(T), QCISD, and QCISD(T) in recovering from a symmetry broken reference function.

ACCURATE IONIZATION ENERGIES AND HEATS OF FORMATION OF SIMPLE ENOLS

František Tureček and Christopher J. Cramer
Department of Chemistry, Box 351700, University of Washington, Seattle, WA 98195-1700
Department of Chemistry and Supercomputer Institute, University of Minnesota, Minneapolis

Enols cation-radicals represent important intermediates in gas-phase ion chemistry *(1-3)*. Enol ions are typically more stable than their keto or aldehyde isomers, while an opposite order of stabilities is found for the neutral systems. The thermochemistry of enol ions relies on appearance energy measurements, which in combination with thermochemical cycles provide estimates of the ion enthalpies of formation *(4-6)*. The latter, when combined with threshold ionization energies, are further used to estimate the enthalpies of formation of neutral enols *(6-8)*. Ab initio calculations at intermediate levels of theory have also been used to estimate the relative stabilities of enols and ketones or aldehydes for both ion and neutral systems *(9-11)*.

We report on a systematic ab initio study of the thermodynamics of simple neutral enols, $CH_2{=}CHOH$ (**1**), $CH_2{=}C(OH)CH_3$ (**2**), *(E)*-$CH_3CH{=}CHOH$ (**3**), and *(Z)*-$CH_3CH{=}CHOH$ (**4**), and their cation-radicals. The stable geometrical forms of these species, i.e., the *syn* and *anti* rotamers for **1-4** and $\mathbf{1}^{+\bullet}$ - $\mathbf{4}^{+\bullet}$, have been obtained by MP2(FULL)/6-31+G(d,p) calculations. Single-point energies were calculated at the effective QCISD(T)/6-311+G(3df,2p) level based on single-point QCISD(T)/6-311G(d,p) and MP2/6-311+(3df,2p) calculations. Isogyric and zero-point corrections to the calculated total energies yielded the Gaussian-2(MP2) energies. Enthalpies and entropies were also calculated for the 250-600 K temperature interval to elucidate the equilibrium concentrations of the rotamers. Isodesmic reactions were used to relate the enol relative enthalpies to the corresponding standard heats of formation, which are summarized in Table 1 and compared with experimental data.

Table 1. Heats of formation of enols and enol cation-radicals in kJ mol^{-1}.

Enol	ΔH_f (exp)	$\Delta H_{f,298}$	*Ion*	ΔH_f (exp)	$\Delta H_{f,298}$
syn-$CH_2{=}CHOH$	-128	-122	*syn*-$CH_2{=}CHOH^{+\bullet}$		772
anti-$CH_2{=}CHOH$		-118	*anti*-$CH_2{=}CHOH^{+\bullet}$	757,768	764
syn-$CH_2{=}C(OH)CH_2$	-170	-167	*syn*-$CH_2{=}C(OH)CH_2^{+\bullet}$		680
anti-$CH_2{=}C(OH)CH_2$		-161	*anti*-$CH_2{=}C(OH)CH_2^{+\bullet}$	661	676
(E)-syn-$CH_3CH{=}CHOH$	-169	-149	*(E)-syn*-$CH_3CH{=}CHOH^{+\bullet}$		689
(E)-anti-$CH_3CH{=}CHOH$		-145	*(E)-anti*-$CH_3CH{=}CHOH^{+\bullet}$	(665)[a]	681
(Z)-syn-$CH_3CH{=}CHOH$	-174	-149	*(Z)-syn*-$CH_3CH{=}CHOH^{+\bullet}$		691
(Z)-anti-$CH_3CH{=}CHOH$		-148	*(Z)-anti*-$CH_3CH{=}CHOH^{+\bullet}$	(665)[a]	681

[a]Isomers unresolved.

Neutral enols **1-3** prefer *syn*-geometries, while *anti*-**4** is slightly more stable than *syn*-**4**. All enol ions prefer *anti*-geometries by 4-10 kJ mol^{-1}. The calculated standard enthalpies of formation are in reasonable agreement with the experimental values for **1**, **2**, and $\mathbf{1}^{+\bullet}$. The calculated enthalpies of formation for **3**, **4**, and $\mathbf{2}^{+\bullet}$-$\mathbf{4}^{+\bullet}$ are systematically higher than the experimental estimates. By comparison, the calculations gave accurate enthalpies for isodesmic reactions involving acetaldehyde ($\pm$0.5 kJ mol^{-1}), acetaldehyde cation-radical ($\pm$0.1 kJ mol^{-1}), ethylene ($\pm$0.0 kJ mol^{-1}), and ethylene cation-radical ($\pm$3.0 kJ mol^{-1}). The discrepancy between the experimental and ab initio data for $\mathbf{2}^{+\bullet}$-$\mathbf{4}^{+\bullet}$ may be due to the unknown temperature of the enol ions formed at the dissociation threshold.

Adiabatic and vertical ionization energies (IE) of **1-4** have been calculated and compared with experimental data from threshold electron impact measurements and photoelectron spectra. The *syn*-isomers show adiabatic ionization energies (IE_a) which are 0.09-0.11 eV higher than those for the *anti*-isomers. The latter IE show good agreement with the experimental threshold values, e.g. 9.14 versus 9.14-9.17 eV for **1**, 8.68 versus 8.61-8.67 eV for **2**, 8.60 versus 8.64 eV for **3**, and 8.62 versus 8.70 eV for **4**. The calculated IE_a of *syn*-**1** (9.51 eV) agrees with the value from the photoelectron spectrum.

Vibrational analysis of *syn*- and *anti*-$\mathbf{1}^{+\bullet}$ allowed us to identify the modes which are likely to be excited upon vertical ionization of neutral **1**. These correspond to the C=C stretch (a'_1) and in-plane bends involving the hydroxyl hydrogen atom (a'_3, a'_4, and a'_5). The calculated harmonic vibrational frequencies allow one to reinterpret the fine structure of the first band in the photoelectron spectrum of **1**.

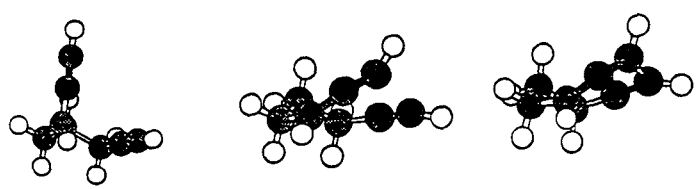
Theoretical Study of the Ring Closure of the 1,7-Octadiyne Cation.

* Ronny C. Robbins, James Jensen
U.S. Army
Aberdeen Proving Ground
Edgewood Area
APG, MD 21010-5423

The mass spectra of short chained alpha-omega diynes contain an intense ion at m/Z 91 and a minor peak at m/Z 45.5 indicating an aromatic type of structure for the m/Z 91 ion. Carbon-13 labeling experiments for 1,7-octadiyne, 1,8-nonadiyne and 1,9-decadiyne also indicate the formation of some type ring system before fragmentation. In table one, the mass spectrum of 1,7-octadiyne contains an intense peak at m/Z 91. This is a loss of a hydrogen followed by loss of a neutral CH_2. Also in table one, the mass spectrum of 1,2,7,8-^{13}C-1,7-octadiyne has a large m/Z 95 and a large m/Z 94 pointing to random carbon loss after ring formation.



REACTANT SADDLE POINT PRODUCT

Figure One: 1,7 Octadiyne Cation After Cyclization and in Lowest Energy Congifuration.

The ring closure of the 1,7-octadiyne cation is studied using the GAUSSIAN92 program. The open structure rearranges to form an eight membered ring. The ring structure is more stable by approximately 4-5 kcal/mol. Geometries and Mullikan populations for both the open and ring structures are presented.

The transition state geometry is presented and the activation barrier calculated. The calculations were done at the SCF and CASSCF levels of theory using 6-31g*, 8 in 8 basis set, and a total of 1764 configurant ions. The "Thru-Space" interaction of the pi systems on two alkyne fragments is examined.

The Presence of Hydrogen Trioxide H_2O_3 in the Gas Phase

Toshihiro Fujii[1] and Hiroshi Kishi[2]

1) National Institute for Environmental Studies, 16-2 Onogawa,Tsukuba, Ibaraki 305, Japan, e-mail; t-fujii@nies.go.jp 2) Oyama National College of Technology. Oyama 323, Tochigi

This report is concerned with the presence of H_2O_3 in the gas phase. During the studies on the identification of the principal species produced by the CH_4/O_2 microwave (MW) discharge, I have succeeded in determining the presence of hydrogen trioxides H_2O_3 in the gas phase. The Li^+-adduct mass spectra of the discharge plasma, obtained by Li^+ ion attachment technique, clearly show the peak m/z 57 ($H_2O_3Li^+$), giving the direct evidence that H_2O_3 is formed in the plasma environment and detected mass spectrometrically.

A literature search made it possible to understand the controversial hypothesis on the possibility of the existence of hydrogen polyoxides H_2O_3 and H_2O_4. According to the literature, a pioneer in this field was the French chemist M. Berthelot, who suggested the formation of a trioxide during the decomposition of hydrogen peroxide in 1880. Fifteen years later D. Mendeleev suggested another intermediate, the tetraoxide, H_2O_4, in the same reaction. In the late 1920' s, the next development came experimentally from the use of electric discharge. G. I. Lavin and F. B. Stewart found that when the discharge H_2O vapor stream is chilled quickly on a cold trap (about -190°C), a glassy, active solid is obtained, yielding some hydrogen peroxides on warming. This finding gave rise to many hypotheses. Then, many scientists tested this glassy solid using many methods, including structure analysis , such as X-ray diffraction , ESR, electron diffraction and molecular spectroscopy.

It seems that the most significant results were obtained by Giguere and his co-workers. In 1970, they succeeded in confirming the existence of the two higher oxides of hydrogen, H_2O_3 and H_2O_4 by the isotope shift technique of the IR and Raman spectroscopy. It is concluded that the two polyoxides of hydrogen can be made only at very low temperature. On warming from liquid air temperature, H_2O_4 begins to decompose at -100°C and H_2O_3 at about -55°C. As expected, these compounds have not been detected in the gas phase to date.

EXPERIMENTAL The apparatus is shown in Fig. 1. The apparatus was basically the same as used before in detecting the hydrocarbon free radicals. Briefly a Shimadzu atmospheric pressure ionization quadrupole mass spectrometer with a Li^+ ion attachment reaction chamber (RC) was used. A stream of reaction products from a quartz discharge flow tube is directed into the alkali-metal ion attachment reaction chamber. The RC has a glass bead (Li^+ emitter). By heating this bead, lithium ions are produced. These parent ions, in turn, ionize the chemical products (M) by adduct formation ($M+Li^+$). ($M+Li^+$) complexes are formed by termolecular association reaction. Parent-daughter ion pairs [$Li^+/(M+Li^+)$] are measured to detect the intermediate species and to identify their possible sources.

The Results and Discussion A number of runs were made to broadly establish the operating characteristics of the apparatus designed and to increase the intensities of ions at m/z 57, issuing through the Li^+ ion attachment reactions. Fig. 2 shows the display trace of the mass spectra over regions m/z 5-9, 38-42 and 54-58. These Li^+-adduct data taken with the discharge on have additional peaks in the spectrum, compared with the data taken with the discharge off. Thus the additional peaks, for instance, the m/z 57 peak in the upper stage are attributed to ion attachment to chemical species effusing from the plasma.

The presence of the chemical species, whose molecular weight is 50 amu, is denoted by an increase in the current of the Li^+-adduct ions (m/z 57). According to the CAS-ONLINE search, there are, surprisingly, only 43 chemical species which have 50 amu as the molecular weight. Table I lists all these compounds. Under the present experimental conditions, the possible compounds are either H_2O_3 or C_2H_3LiO. It is concluded from two candidates that the peak m/z 57, due to the Li^+-adduct ions, is assigned to that of $H_2O_3Li^+$, since the isotopic abundance consideration of the m/z 56 peak relative to the m/z 57 peak indicates containing one Li atom and hence, rules out the possibility of $C_2H_3LiOLi^+$.

In conclusion, the direct proof of the presence of H_2O_3 in the gas phase was provided by the recently developed ion attachment technique incorporated with quadrupole mass spectrometry.

Structure of Isomeric Gly-Pro b_2 Ions Calculated by Ab-initio Methods

Klaus Eckart, Max C. Holthausen§, Thomas Bräuninger§, Wolfram Koch§, and Joachim Spiess; Department of Molecular Neuroendocrinology, Max Planck Institute for Experimental Medicine, Hermann-Rein- Str. 3, D-37075 Goettingen; §Institute of Organic Chemistry, Technical University Berlin, Strasse des 17. Juni 135, D-10623 Berlin

INTRODUCTION

Acylium type dipeptide ions (b_2-ions) are expected to undergo cyclization to the corresponding protonated diketopiperazine. Recent investigations had shown that this expected process does not occur in the case of Gly-Gly (1) and Ala-Ala (2). More surprisingly, the cyclization could not be observed for the Gly-Pro b_2-ion, which should cyclize much easier due to the constraints introduced by the Pro pyrrolidine group (3). Furthermore, the amide bonds in the peptide backbone usually existing in the trans (Z) configuration do not possess a cis or trans preference for amide bonds involving the Pro pyrrolidine group as known from NMR data. Therefore, this sterical situation could not be responsible for the cyclization barrier.

It was speculated that this behavior depended on the structure of this particular dipeptide fragment ion, and some suggestions for the structures of the Gly-Pro dipeptide ion were made recently (3). These structures are based on the observed mass spectral fragmentation pattern, and it was therefore concluded, that the charged site must be localized on the pyrrolidine nitrogen. In the present work *ab-initio* molecular orbital calculations were performed in order to localize the most probable structure of this dipeptide fragment. The results will also be discussed with respect to production of b-ions in the course of peptide fragmentation. In addition different precursors to the Gly-Pro b_2 fragment ions are used to exclude a structural contribution from the neutral C-terminal leaving group.

METHODS

All mass spectral data were obtained on a VG Analytical AutoSpec-T tandem mass spectrometer equipped with a 3"-focal plane detector. Data were recorded and performed with the OPUS data system. Detailed experimental conditions were the same as reported earlier (3).

For the quantum chemical calculations the programs Spartan 3.0, Wavefunction, Inc. (semiempirical calculations) and DGauss 2.3, Cray Research, Inc. (DFT-calculations) were used. The global minimum in the conformational space of each respective isomer under investigation was located on the semiempirical (PM3) level. The geometry of each of the evolving structures has subsequently been optimized at the *ab initio* DFT level (BLYP, DZVP basis set employing a pseudopotential for the 1s electrons of C, O, N). The given relative energies refer to this correlated level of theory.

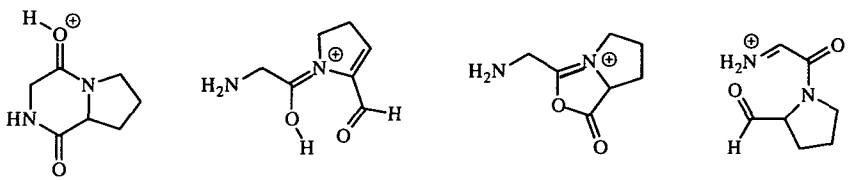
RESULTS AND DISCUSSION

The calculated relative energies of different isomeric Gly-Pro structures revealed a clear thermodynamic preference for the protonated diketopiperazine (Fig. 1). The small differences in the relative energies of **2**, **3**, and **4** suggested that these structures may contributed to the linear peptide fragment ion. Other alternative structures considered recently (3) exhibited relative energies above 100 kJ/mol. The Gly-Pro b_2-ions obtained through LSIMS induced fragmentation of Gly-Pro-β-naphthylamide and Gly-Pro-Gly were compared using high energy CAD. The resulting spectra demonstrated clearly that the C-terminal neutral leaving group does not significantly change the fragmentation pattern. Therefore, the structures of the investigated Gly-Pro b_2-ions may be almost identical.

The acylium ion type structure for the Gly-Pro b_2-ion could not be isolated as a global minimum. This localization ended up with the structure of **3**, which seemed to be the most likely

candidate. In this structure the positive charge is more effectively stabilized as in the acylium ion type structure. Furthermore, the constitution of **3** offers no structural possibility for forming the protonated diketopiperazine **1**. The same consideration appears for the alternative structure **2**.

Figure 1: Energies in kJ/mol from ab-initio MO calculations for the most stable Gly-Pro b_2 structures relative to protonated c[Gly-Pro].



1 $E_{rel}=0$ **2** $E_{rel}=72$ **3** $E_{rel}=66$ **4** $E_{rel}=72$

Structure **4**, which is stabilizing the positive charge at the N-terminal Gly residue, was also considered as a potential structural candidate based on the thermodynamical results. **4** is supposed to be the most likely precursor for the Gly immonium ion (m/z 30) in the high energy CAD mass spectrum of the Gly-Pro b_2-ion. The formation of **1** from **4** is prevented by the absence of nucleophilicity on the N-terminal amino group of **4**. High energy CAD which favors direct bond cleavage is better suited than low energy CAD to correlate stable ionic structures with mass spectral fragmentation patterns. This makes it possible to correlate the mass spectral fragmentation patterns with the structures obtained from *ab-initio* MO calculations (Fig 1)

The similarity of the high energy CAD mass spectra of the Gly-Pro b_2-ions obtained from different precursors suggested, that the structure of this b_2-ions was not significantly influenced by the C-terminal neutral leaving group and was therefore reflecting the molecular properties of the charged fragment. From these considerations it is obvious that stabilization of the positive charge on the pyrrolidine nitrogen as shown in Fig. 1 is the driving force for the cleavage of the amide bond C-terminal to Pro.

These results may also belong to the formation of b-ions from larger peptides. This can be demonstrated by the effect of selective amide nitrogen methylation as reported for the peptide Pyr-Phe-Phe-Gly-Leu-Met(NH_2) (4). The positive ion FAB mass spectra of the peptide methylated selectively on each Phe nitrogen, the Gly nitrogen, or the Leu nitrogen showed a significant enhancement of the corresponding C-terminal b-ion over the remaining b-ions when compared with the pattern of the non-methylated peptide. It should be mentioned that the Pyr nitrogen does not exhibit a significant basicity as the N-terminal amino group of non-protected peptides. Nevertheless, in positive ion mass spectra the above described effect is commonly known for Pro residues in peptides, which contain no residues with basic side chains.

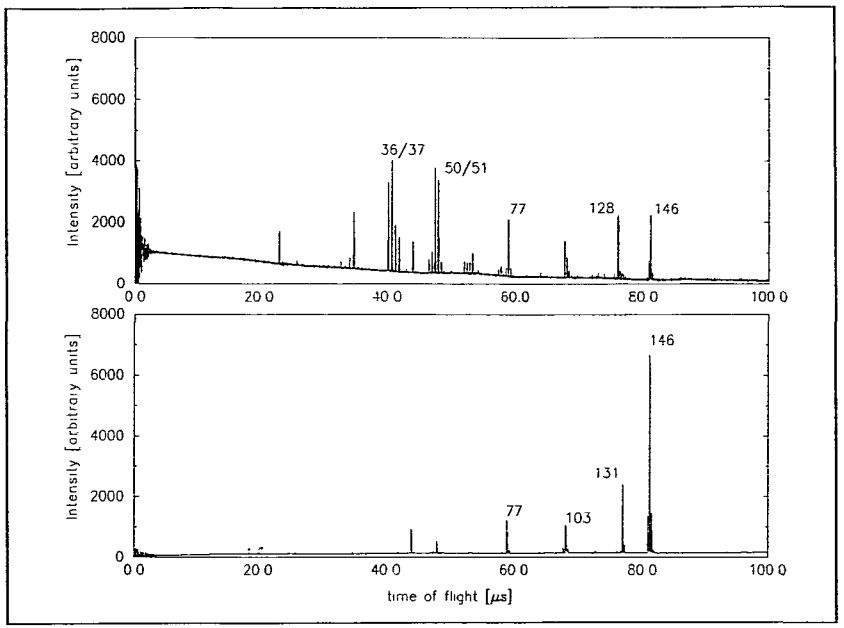
Fragmentation of Benzalacetones: Theory and Experiment

R. Heinicke, F. Moritz and J. Grotemeyer
Institut für Physikalische Chemie, Universität Würzburg
Marcusstr. 9-11, 97070 Würzburg, Germany

In order to understand the fragmentation reactions of cation radicals from certain organic compounds, cyclisation reactions via intramolecular substitution should be considered as a key step in the degradation of the molecular ions. This is important where the formation of an extended aromatic system is possible like in benzalacetones first observed by Williams et. al.[1]. In aromatic systems the facile loss of a hydrogen radical or another substituent from the aromatic ring of a molecular ion is unexpected in view of the strong bond of the sp^2 carbon atom to this atom/substituent. Thus it is reasonable to assume that there is at least a partial compensation of the energy needed for bond cleavage by bond formation via intramolecular aromatic substitution. Deuterium-labeling at the ortho position of the aromatic ring leads to a loss of hydrogen as well as deuterium. According to this results, there must be fast H-rearrangements prior to fragmentation in the aromatic ring. In further experiments Schaldach[2] und Grützmacher[3] investigated ortho-, meta- and para-substituted benzalacetones. In this paper we report some new results of the intramolecular aromatic substitution reaction of benzalacetones and substituted analogues. For investigation we used a Time-of-Flight-Mass-Spectrometer applying multi photon ionization (MUPI) with use of fs-laserpulses. Due to this ionization technique and the combination with supersonic beam the internal energies of the corresbonding molecular ions are comparatively well defined. Furthermore the fragmentation process yielding the loss of a hydrogen radical or in case of substituted benzalacetones the loss of the substituent leading to chromylium ions are studied.
Parallel to this experiments we performed semiempirical and ab initio calculations to determine the geometries and heat of formations of all structures and transition states taking part in the cyclyzation and fragmentation processes. The reaction dynamics are modelled with the help of RRKM-calculations.
The first efforts to ionize the molecule with ns-laserpulses failed. It was not possible to detect the molecular ion with reasonable intensities or to increase signal intensity by using different inlet systems. Using fs-laserpulses for ionization the signal intensity increased dramatically.

Figure 1 shows two spectra of unsubstituted benzalacetone obtained a) with ns-laserpulses (λ=255 nm, 20 μJ, pulse width 8 ns) and b) fs-ionization (λ~260 nm, 5.6 μJ, pulse width 500 fs).



For all substituted benzalacetones the specific peak at m/z=145 was observed resulting from the loss of the substituent independant from the position of the substituent. The different possibilities of the excited molecule are described to explain the differences between ns- and fs-ionization. Only fs-ionization is fast enough to compete with depopulation of the excited state - propably via intersystem crossing.

Formation of $[M+H]^+$, $[M+Na]^+$, $[M-H]^+$, and $[M-H]^-$ Ions of Methyl Octadecanoate under Electron Impact Ionization Conditions: Does Surface Ionization Occur ?

Mitsuo Takayama[1], Kenzo Hiraoka[2], and Hisao Nakata[3]

Introduction

Although the electron impact ionization (EI) behavior of methyl octadecanoate (**1**) has been extensively and intensively examined in connection with the McLafferty rearrangement (McR) reaction [1-3], here we report the formation of $[M+H]^+$, $[M+Na]^+$, $[M+K]^+$, $[M-H]^+$, and $[M-H]^-$ ions of **1** under low-impact energy EI (2~12 eV) conditions. Since the ionization energy (IE) of fatty acid esters lies in the range of 10~11 eV, this EI condition is unfavorable or critical for the formation of molecular ions M^+ and it could be expected that surface ionization (SI), thermal ionization (TI), and/or ion-pair formation from dimer M_2 under that EI conditions Our aims are to explain this strange ion formation and the following fragmentation behaviors

Experimental

Experiments were performed on a JEOL JMS-DX303 double focusing mass spectrometer equipped with a JMA DA5100 data system (JEOL, Tokyo, Japan). The sample was introduced into the ion source using a direct inlet probe with a glass sample tube of 16 mm x 2 mmø. The ionizing chamber temperature and ionizing current were 160 °C and 100 μA, respectively

Results and Discussion

The 2 eV/EI mass spectrum of **1** showed intense ion peaks of $[M+Na]^+$ at *m/z* 321, $[M+H]^+$ at *m/z* 299, $[M-H]^+$ at *m/z* 297, K^+ at *m/z* 39, and Na^+ at *m/z* 23, suggesting that the SI processes on the surface of a rhenium filament occur [4] (Fig.1). Generally speaking, the SI mass spectra of organic compounds show only few ion peaks together with intense $[M+H]^+$ and/or $[M-H]^+$ ions [5] On the other hand, the introduction of large amounts of the sample vapor into the ion source brought about the formation of preferential $[M+H]^+$ and abundant fragment ions in the vicinity of 8 to 15 eV impact energy though the spectral pattern fluctuated in intensity, while the M^+ ion disappeared at 10~11 eV when the small amounts of sample vapor. As shown in Fig.2a, positive-ion 12 eV/EI mass spectrum of **1** showed the McR ion at *m/z* 74 and related ions at *m/z* 75 and 87, but collision-induced dissociation (CID)

Fig.1 Positive-ion 2 eV/EI mass spectrum of 1.

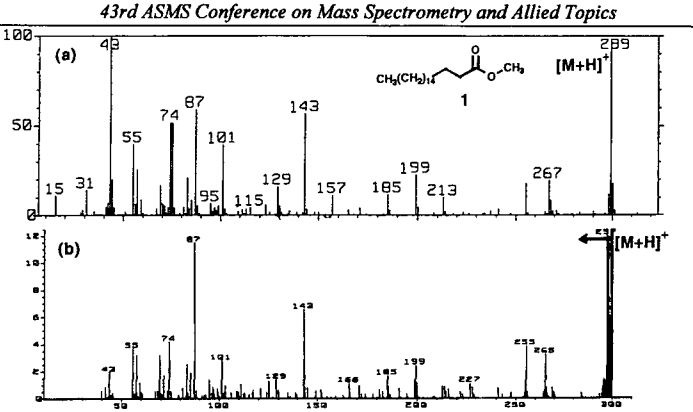

Fig.2 (a) Positive-ion 12 eV/EI mass spectrum of 1 and (b) collision-induced dissociation spectrum of the [M+H]+ ion produced under 12 eV/EI conditions.

spectrum (Fig 2b) of the $[M+H]^+$ ion did not show the peak of *m/z* 75 which may be originating from a hydrogen rearrangement like the McR reaction (Scheme 1)

It seems difficult to explain the formation of abundant fragment ions in the 12 eV/EI spectrum by the SI or a self-chemical ionization process. The resulted considerable fragmentation should be explained by the surface or thermal effect on the rhenium filament, or EI-induced fragmentation of the $[M+H]^+$ ions formed at 12 eV/EI conditions. Furthermore, negative-ion 8 eV/EI mass spectrum of **1** showed an intense peak of $[M-H]^-$ ion and it was almost independent of the impact energy (Fig.3).

Gas-Phase Decomposition of Dimethyl(hydroxy)silyl Radical

Viet Q. Nguyen,[1] Scott A. Shaffer,[1] Frantisek Turecek,[1] and Cornelis E C A. Hop[2]
[1]Department of Chemistry, University of Washington, Seattle, WA 98195-1700
[2]Department of Chemistry, university of Wisconsin, Madison, WI 53706

Silicon radicals play an important role in chemical processes ranging from organic synthesis to microprocessor manufacturing.[1] Despite that extensive studies, both experimental and theoretical, have been conducted on radicals derived from silanes, alkyl silanes and halogenides,[2] much less is known about oxygenated silicon radicals

In this work, dimethyl(hydroxy)silyl radical $(CH_3)_2Si^{\cdot}OH$ (**1**) is generated and detected using neutralization-reionization mass spectrometry ($^{+}NR^{+}$) with dimethyldisulfide and oxygen as neutralization and reionization reagents, respectively. The tandem quadrupole mass spectrometer employed for our study was described in detail elsewhere [3] The cationic precursor for **1**, $(CH_3)_2SiOH^+$ ($\mathbf{1}^+$), is prepared as a stable fragment from either $(CH_3)_3SiOCH_2CH_3^{+\cdot}$ or $(CH_3)_3SiOH^{+\cdot}$. $(CD_3)_2SiOH^+$ ($\mathbf{2}^+$) and $(CH_3)_2SiOD^+$ ($\mathbf{3}^+$) are also generated from $(CD_3)_3SiOCH_2CH_3^{+\cdot}$ and $(CH_3)_3SiOCD_2CD_3^{+\cdot}$, to yield $(CD_3)_2Si^{\cdot}OH$ (**2**) and $(CH_3)_2Si^{\cdot}OD$ (**3**) upon neutralization, respectively

Upon $^{+}NR^{+}$, dimethyl(hydroxy)silyl radical **1** and/ or $\mathbf{1}^+$ from $(CH_3)_3SiOCH_2CH_3^{+\cdot}$ dissociates extensively on the μs timescale As a result, almost no survivor ion is detected. The $^{+}NR^{+}$ spectrum contains fragments of $CH_3SiOH^{+\cdot}$ (m/z 60), $SiOH^+$ (m/z 45), $SiO^{+\cdot}$ (m/z 44), $Si^{+\cdot}$, and CH_3^+ By contrast, $^{+}NR^{+}$ spectrum of $\mathbf{1}^+$ derived from $(CH_3)_3SiOH^{+\cdot}$ shows a portion of **1** that survives (1 2 % of ΣI_{NR}) Significant survivor ions of **2** and **3** are also detected in $^{+}NR^{+}$ spectra of both $\mathbf{2}^+$ and $\mathbf{3}^+$ at 1.3 and 2.4 % ΣI_{NR}, respectively. Ab initio calculations show substantial differences between the optimized geometries between **1** and $\mathbf{1}^+$ predicting large Franck-Condon effects that result from vertical neutralization of ground state $\mathbf{1}^+$ It is argued that increasing the fraction of higher energy $\mathbf{1}^+$ would result in a larger fraction of stable **1** upon neutralization, as in the case of $\mathbf{1}^+$ from trimethylsilanol Kinetic isotope effects and the increased fraction of vibrationally excited $\mathbf{2}^+$ and $\mathbf{3}^+$ due to the lower vibrational frequencies in the deuterated ions can account for the survivor ions of **2** and **3** observed in the $^{+}NR^{+}$ spectra The $^{+}NR^{+}$ spectrum of $\mathbf{1}^+$ shows conspicuous absence of m/z 47 (loss of C_2H_4) and m/z 74 (loss of $H^{\cdot}$), which both appear in the CAD spectrum of $\mathbf{1}^+$ This can be explained by the lack of the competitive pathway to lose C_2H_4 from reionized $\mathbf{1}^+$ Also, thermochemical arguments indicate that silanone$^{+\cdot}$ (m/z 74) is formed with high internal energy and dissociates readily.

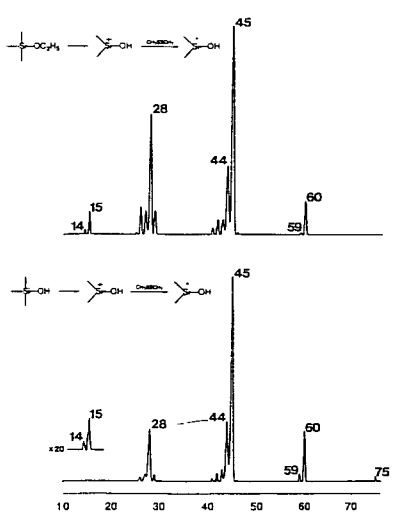
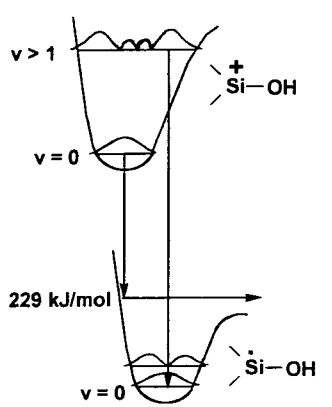
$^{+}NR^{+}$ (CH_3SSCH_3/O_2)



VERTICAL NEUTRALIZATION



Study of the evolution of the m/z 91/92 ratio during CAD of butylbenzene molecular cations under multiple collision conditions

Beaugrand#, C.; Leymarie*, N.; Rolando*, C.; Sablier*, M.
(#) AIRND 35, rue Victor Hugo - 78230 Le Pecq (France)
(*) Ecole Normale Supérieure, Processus d'Activation Moléculaire U.R.A. 1679
24, rue Lhomond - 75231 Paris cédex 05 (France)

Fragmentation of the butylbenzene molecular cation is one of the most studied topics in mass spectrometry (1). The ratio of m/z 91 ion to m/z 92 ion has been used as a "thermometer" for studying the internal energy of precursor ions in many different processes: electron impact ionisation, photoionisation, CAD at low, intermediate and high energy. A set of thermochemical data has been established for this decomposition using PEPICO experiment and RRKM calculation (2). In all these processes, the decomposition of the excited molecular ion is unimolecular, and the fragments are not allowed to collide with a neutral gas. More recently the same concept has been applied to CAD under multiple collisions such as those occurring in an ion trap. However, ions of mass 91 and mass 92 exhibit very different behaviour.

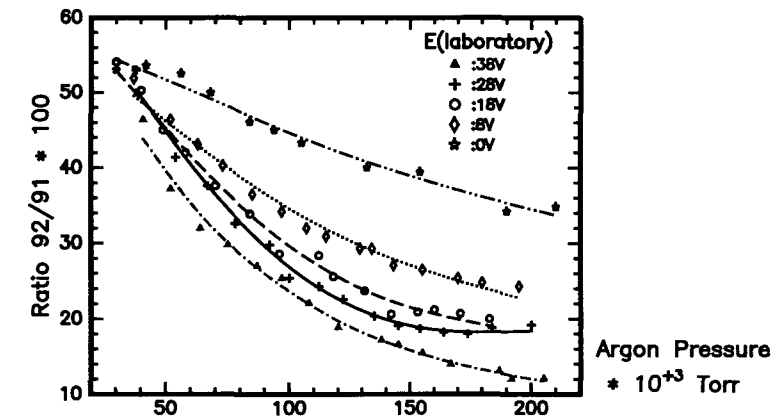
Using our MS/MS/MS multiquadrupole, we have been able to perform CAD in the first collision cell on the butylbenzene molecular cation, then select the m/z 91 ion, m/z 92 ion or both for purpose of studying their CAD under multiple collision condition in the second cell. Results for the unselected m/z 91 and m/z 92 ions, and for selected m/z 92 ion are presented on the figures below.

Under multiple collision conditions the two fragment ions exhibit strongly different behaviour :

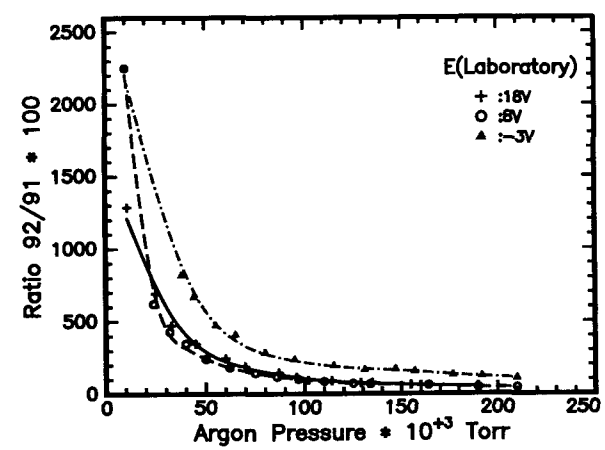
- the ion of mass 92 is more easily broken than that of mass 91 ion so the ratio m/z 91 to m/z 92 increases.
- One major breakdown pathway for the ion of mass 92 is the loss of hydrogen leading to m/z 91.

These two effects are cumulative, so the ratio of m/z 91 to m/z 92 ions is not constant and is very sensitive to additional collisions.

This ratio needs to be used carefully for estimating the transfer energy process to the precursor molecular ion under multiple collision conditions.



Variation of the m/z 92 to m/z 91 intensity ratio in function of the pressure of argon in the collision cell for various energy (laboratory frame) starting from a mixture of m/z 91 and m/z 92 ions :



Variation of the m/z 92 to m/z 91 intensity ratio in function of the pressure of argon in the collision cell for various energy (laboratory frame) starting from m/z 92 ion :

Can Protonated Peptides Fragment from Their Triplet States?

Árpád Somogyi, Vicki H. Wysocki
Department of Chemistry, Virginia Commonwealth University, Richmond VA 23284-2006, U.S.A.

István Mayer
Central Research Institute for Chemistry of the Hungarian Academy of Sciences, P. O. Box 17, H-1525 Budapest, Hungary.

Due to increasing numbers of experimental and theoretical studies, knowledge of peptide fragmentation is improving. Although there are some contradictory results and opinions, it is generally accepted that proton transfers within a protonated peptide can precede fragmentation. Our recent *ab intio* and MNDO bond order, as well as MNDO energy partitioning calculations[1,2] support this idea. Bond strength patterns (defined originally in Reference 2) show significant differences for different protonated forms of the same peptide. For example, in the energetically more stable amide oxygen protonated form, the strengthening of the amide bond indicates a non-fragmenting structure. In contrast, the energetically less favored amide nitrogen protonated form is a fragmenting structure, because the amide bond is significantly weakened. These results suggest that not all protonated forms undergo fragmentation and that thermodynamically less stable forms should also be considered in peptide fragmentation.

All the above conclusions were based on the assumption that protonated peptides fragment from their *ground (singlet) electronic* state. In the present study, *ab initio* (6-31G*) and MNDO bond orders and MNDO energy partitioning[3] values have been calculated and used to predict the bond strengths in protonated diglycines in their *triplet* states. For different protonated forms, several "triplet" UHF solutions were found that are close to each other in energy. This may indicate the existence of different close lying excited triplet states of these species. Comparisons with resent results for protonated peptides in *singlet* states show that the bond strength patterns are similar in singlet and triplet states in most cases. However, in one of the amide oxygen protonated triplets, the amide bond is predicted to be weakened; this could generate its easy cleavage (Figure 1). Nine different singlet → triplet excitations have been considered and characterized by using the MNDO energy partitioning method[3] for each of the protonated forms.

An energetic discussion based on MP2 6-31G*//6-31G* SCF total energies is also given for both singlet and triplet protonated diglycines. The formation of triplet protonated diglycines from the corresponding singlets requires an energy of 5.5-7.0 eV (Figure 2). The order of the relative stability of the singlet and triplet protonated forms is different; the most stable forms are the N-terminal protonated form for singlets, and the N-amide protonated form for the triplets (Figure 2). Although further experimental and theoretical evidence is necessary to prove (or exclude) the role of the triplet states in peptide fragmentation, the present results suggest that triplet states could be involved in the fragmentation of protonated peptides.

Elucidation of Mass Spectrometric Decomposition Mechanisms in the Compound 2,3-Difluoro-dimethyl-succinic Acid Diester

David M. Parees
Air Products and Chemicals, Inc., 7201 Hamilton Blvd., Allentown, PA 18195

The electron ionization spectrum of the title compound (Figure 1) contains a number of surprising ions and a significant number of the relatively intense ions obviously require rearrangements. This compound decomposes through interesting pathways, including losses of carbon dioxide, formaldehyde and methyl radicals. The molecular losses involve rearrangements of methyl (loss of carbon dioxide) and hydrogen (loss of formaldehyde) radicals. Succinic acid diesters have been studied before and a range of interesting losses and hydrogen and group migrations have been reported (1-4). In the present work, high resolution and exact mass analysis techniques defined the elemental composition of fragment ions. Low energy collision tandem mass spectrometry on a hybrid magnetic sector-quadrupole instrument provided data concerning the pathways of decomposition (see Figures 2, the precursors of m/z = 93, and 3, the progeny of m/z = 138).

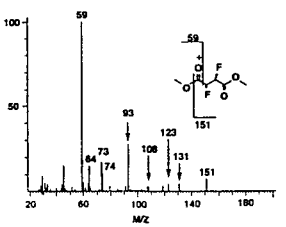

Figure 1

It appears that after initial loss of carbon dioxide, the ion at m/z = 138 (which is 0.15% relative to the base ion in the EI spectrum) can decompose with sequential losses of a methyl group (leading to the ion at m/z = 123) followed by loss of formaldehyde, to form the ion at m/z = 93. Similarly, these losses can occur in the reverse order, leading to the intermediate ion at m/z = 108. Analysis of a stable isotope labeled analog, in which all methyl hydrogens were replaced with deuterium, provided proof of radical movement from one part of the molecule to another. Shifts in the masses of some fragment ions, caused by the mass difference between hydrogen and deuterium, provided confirming evidence tracing migrations of hydrogen and methyl radicals. Exact mass analyses of some of these ions confirmed these rearrangements.

The ion at m/z = 74 was shown by exact mass measurement to not be a product of the decomposition of the ion at m/z = 93. The ion at m/z = 93 has two fluorine atoms and the ion at m/z = 74 has none. This decomposition pathway requires the shift of a methyl radical from one end of the molecule to the other, coupled with the loss of the middle portion of the molecule. The ion at m/z = 74 has the elemental composition $C_3H_6O_2$. This ion was examined by MS/MS and compared with the molecular ion of methyl acetate, which produced a significantly different spectrum.

Another fragment ion, containing only the fluorinated central portion of the molecule, was also surprising because of the required losses and its intensity in the spectrum.

Energy Resolved Mass Spectrometry of Organophosphonates

Michael W. Wensing, Brad E. Forch, Robert A. Fifer
U.S. Army Research Lab, Aberdeen Proving Ground, MD 21005
A. P. Snyder and C.S. Harden
U.S. Army, Edgewood Research Development and Engineering Center
Aberdeen Proving Ground, MD 21010

Organophosphonate compounds are a subgroup of the important organophosphorus compounds (OPCs). OPCs have been used in several applications including pesticides, plasticizers, pharmaceuticals, nerve gas agents, and lubricants. Their detection and differentiation is becoming a problem of increasing analytical importance. Detailed studies of the dissociation of OPCs can directly benefit the analyst who must detect and differentiate these compounds.

Energy resolved mass spectrometry (ERMS) is a very useful technique. Unlike MS/MS where collisions between a parent ion and an inert gas are usually carried out at a fixed parent ion energy, ERMS involved carrying out MS/MS at several parent ion energies. Parent ion energies are varied over a range which results in no dissociation of the parent ion to complete dissociation of the parent ion. The sequential nature of the dissociation of the parent ion is revealed directly in ERMS, but must be inferred in MS/MS. ERMS has been used to characterize the dissociation of odd electron molecular ions produced by electron ionization, however, ERMS has not been used extensively in characterizing the dissociation of even electron molecular ions produced by atmospheric pressure chemical ionization (APCI). Since very sensitive detection of OPCs is achieved by APCI due to the high proton affinity associated with these compounds, characterizing their dissociation pathways by APCI-ERMS has increased importance.

In this work, ERMS was used to characterize the dissociation pathways of two homologous series of phosphonate compounds. The first study involved the dissociation of diethyl alkyl phosphonates, specifically, diethyl methyl phosphonate (DEMP), diethyl ethyl phosphonate (DEEP), diethyl n-propyl phosphonate (DEPP), and diethyl n-butyl phosphonate (DEBP). All these compounds differ by the alkyl group which is directly attached to the phosphorus atom. The second study involve the dissociation of dialkyl methyl phosphonates, specifically, dimethyl methyl phosphonate (DMMP), diethyl methyl phosphonate (DEMP), diisopropyl methyl phosphonate (DIMP), and isopropyl methyl phosphonate (IMMP).

Neat samples of these compounds were analyzed via headspace analysis. Sample vapors were carried into the ion source aided by an exhaust motor and protonated via a corona discharge. The resultant parent ions traveled through a 2 mm orifice, a N_2 curtain gas region, a smaller orifice, and into the high vacuum region of a triple quadrupole mass spectrometer. The energy of the parent ions was increased by ramping the potential on the smaller orifice and keeping all the other lens elements at a fixed potential. Progeny ions were subsequently detected by scanning the first mass analyzer, Q1. The conventional collision cell, Q2, was not filled with Ar, and the third mass analyzer was operated in RF only mode.

The protonated parent ions of the diethyl alkyl phosphonates all undergo two sequential McLafferty rearrangements and produce two molecules of ethylene. The maximum intensity of the ion that is formed after the second McLafferty rearrangement is more intense than that of the ion that is formed after the first McLafferty rearrangement. This is consistent with what would be expected for two sequential and approximately equal, low energy pathways. The ion

resulting from the second McLafferty rearrangement further dissociates via either the loss of H_2O or the loss of R'OH where the R' group is the alkyl group that is directly attached to the phosphorus atom. The loss of H_2O is predominant at low parent ion energies for all compounds. This information is consistent with the more exothermic heat of formation of H_2O than the resulting alcohols. At higher parent ion energies the loss of R'OH becomes predominant for DEEP, DEPP, and DEBP.

The initial McLafferty rearrangement cannot be used to distinguish the dissociation of the parent ions of the diethyl alkyl phosphonates studied since all dissociate at similar energies. However, the ions that result from the second McLafferty rearrangement (protonated alkyl phosphonic acids) dissociate at resolvable energies. The protonated acid of DEBP is the most stable, dissociates least while the protonated acid of DEMP is the most stable and dissociates most. This leads to the conclusion that the R' group stabilizes the positive ion. The larger the R' group, the greater the electron-donating power and the more stable the ion.

Dialkyl methyl phosphonates where both alkyl groups are at least ethyl groups can be distinguished from their counterparts where the alkyl group attached to the phosphorus atom is larger than methyl. At high and low energies protonated methyl phosphonic acid which results from the CAD of DIMP and DEMP predominantly loses H_2O. At low energies, protonated alkyl phosphonic acids where the alkyl group is ethyl or larger predominantly lose water, while at high energies the these protonated acids predominantly lose R'OH.

DIMP and DEMP are distinguishable by ERMS. The McLafferty rearrangement that results in the loss of propylene occurs at a lower energy than the one the results in the loss of ethylene.

IMMP and DIMP are also distinguishable by ERMS. Both lose propylene via a McLafferty rearrangement, however, since IMMP cannot undergo another McLafferty rearrangement the intensity of its first generation product ion reaches a much larger maximum intensity than of the corresponding first generation product ion of DIMP.

DMMP is distinguishable from all the rest of the compounds studied in that it cannot undergo a McLafferty rearrangement. Therefore the protonated parent ion of DMMP is more stable than the protonated parent ion of any of the other compounds studied.

Energy Resolved Mass Spectrometry of Organophosphorus Esters

Michael W. Wensing, Brad E. Forch, Robert A. Fifer

A. P. Snyder and C. S. Harden
U.S. Army, Edgewood Research, Development and Engineering Center
Aberdeen Proving Ground, MD 21010

Organophosphonate compounds are a subgroup of the important organophosphorus compounds (OPCs). OPCs have been used in several applications including pesticides, plasticizers, pharmaceuticals, nerve gas agents, and lubricants. Their detection and differentiation is becoming a problem of increasing analytical importance. Detailed studies of the dissociation of OPCs can directly benefit the analyst who must detect and differentiate these compounds.

Energy resolved mass spectrometry (ERMS) is a very useful technique. Unlike MS/MS where collisions between a parent ion and an inert gas are usually carried out at a fixed parent ion energy, ERMS involved carrying out MS/MS at several parent ion energies. Parent ion energies are varied over a range which results in no dissociation of the parent ion to complete dissociation of the parent ion. The sequential nature of the dissociation of the parent ion is revealed directly in ERMS, but must be inferred in MS/MS. ERMS has been used to characterize the dissociation of odd electron molecular ions produced by electron ionization, however, ERMS has not been used extensively in characterizing the dissociation of even electron molecular ions produced by atmospheric pressure chemical ionization (APCI). Since very sensitive detection of OPCs is achieved by APCI due to the high proton affinity associated with these compounds, characterizing their dissociation pathways by APCI-ERMS has increased importance.

In this work, ERMS was used to characterize the dissociation pathways of two series of organophosphorus compounds. The first series include dimethyl methyl phosphonate (DMMP), trimethyl phosphate (TMP), trimethyl phosphite (TMPI), and dimethyl phosphite (DMPI). All of these compounds have similar structures and lose similar neutrals. The second series of compounds included four trialkyl phosphates, specifically, trimethyl phosphate (TMP), triethyl phosphate (TEP), tripropyl phosphate (TPP), and tributyl phosphate (TBP).

Neat samples of these compounds were analyzed via headspace analysis. Sample vapors were carried into the ion source aided by an exhaust motor and protonated via a corona discharge. The resultant parent ions traveled through a 2 mm orifice, a N_2 curtain gas region, a smaller orifice, and into the high vacuum region of a triple quadrupole mass spectrometer. The energy of the parent ions was increased by ramping the potential on the smaller orifice and keeping all the other lens elements at a fixed potential. Progeny ions were subsequently detected by scanning the first mass analyzer, Q1. The conventional collision cell, Q2, was not filled with Ar, and the third mass analyzer was operated in RF only mode.

The first series of compounds have similar losses. DMMP and TMP which both have a phosphoryl moiety lose CH_3OH predominantly. TMPI loses CH_3OCH_3 predominantly, but also loses CH_3OH. DMMP and TMP both have stronger alkoxy P-O bonds than TMPI. These bond strengths have been measured by others. This presumably does not allow much interaction between the adjacent methoxy groups which should be necessary to lose CH_3OCH_3. Therefore, the loss of CH_3OH is the predominant loss observed. TMP is observed to lose more CH_3OCH_3 than DMMP, which would be expected since statistics favor the loss of CH_3OCH_3 by 3:1 for

TMP assuming the P-CH_3 moiety is not involved. When TMPI is protonated a dipole is set up which attracts the neighboring methoxy group. This assists in the loss of CH_3OCH_3. TMP and TMPI have statistically the same probability of losing CH_3OCH_3, however, the weaker alkoxy P-O alkoxy bond of TMPI favors the dimethyl ether loss with respect to TMP.

DMPI predominantly loses CH_3OH. This is a very suprising result since the loss of H_2O would normally be expected. However, DMPI when it undergoes multiple collisions may isomerize to dimethyl hydrogen phosphonate, and then would not be expected to lose H_2O. This would explain the observed predominant loss of CH_3OH. The main conclusion reached is that the loss of CH_3OCH_3 does not predominate when a phosphoryl moiety is present.

The second series of compounds undergo similar decomposition mechanisms. Trialkyl phosphates where both alkyl groups are larger than ethyl, undergo three sequential McLafferty rearrangements. The ion which results from the third McLafferty rearrangement reaches the largest maximum intensity which is consistent with this low energy mechanism. This ion appears to be very stable and dissociates only to a small extent losing H_2O.

Effect of Multiple and Single Collision Conditions on the Reproducibility of FAB-MS/MS Spectra Obtained using the Calibration Point Method

Sharon W. Lemire and Kenneth L. Busch, School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400

The reproducibility of product ion spectra in MS/MS is dependent on instrumental parameters such as type and pressure of collision gas, collision energy and rf tuning. These parameters are difficult to reproduce from instrument-to-instrument, or even from day-to-day on the same instrument. To compare MS/MS spectra from different instruments, or to develop a library-quality database, instrument-independent spectra must be reproducibly acquired. Generation of reproducible MS/MS spectra requires a calibration method that is simple, reliable, applicable to a wide range of compounds, and independent of type of collision gas. Several researchers have proposed calibration methods, but so far no one has developed a method that is easily applied to all types of instruments and to a wide range of compounds. The calibration method presented here uses an empirically determined calibration point based on a variable collision energy at a set target thickness to acquire product ion spectra from precursor ions ionized by LSIMS. A similar protocol for EI-MS/MS produced data with spectral similarities of 80-90% between a VG70-SEQ and Finnigan MAT TSQ-70. Spectral similarities of 85% were obtained under both single (SC) and multiple collision (MC) conditions.

The experimental setup has been previously described.[1] Product ions were produced by collision-induced dissociation in an rf-only quadrupole collision cell with argon as the collision gas. The precursor ion was attenuated by approximately 80% for MC conditions, giving a reading of 2.3 x 10^{-5} mbar on the ion gauge nearest the cell, and by approximately 25% for SC conditions, giving a reading of 5.4 x 10^{-7} mbar. These readings were corrected for argon response. The collision energy ranged from 25 to 43 eV for MC and from 162 to 185 eV for SC. The rf voltage was set at 75V.

The calibration point compound, 2-butyl-triphenyl-phosphonium bromide (2-BTPP), was used because it is easy to handle and produces a stable, long-lived signal. *Meta*-nitrobenzyl alcohol (*m*-NBA) was selected as the matrix because it readily solubilizes 2-BTPP and it provides long ion lifetimes in the ion source. Model compounds used previously[1] were of a mass equal to or less than the mass of the calibration compound (m/z 319). To determine the useful mass range of this technique, compounds with masses of up to m/z 726 were added to the trial set. The following additional compounds were chosen to represent classes of compounds commonly analyzed by FAB/LSIMS: thiamine hydrochloride (Vitamin B1), acridine orange-10 nonyl bromide (A-1372), diphenyl 4-dodecoxyfluorophenylsulfonium antimony hexafluoride (New Sulf), 1,1'-didodecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate (D-383), 3,3'-dihexadecyloxacarbocyanine perchlorate (D-1125).

The calibration point, which has also been previously defined[1], was determined prior to each run, and then the product ion spectrum for each compound was acquired. For each MS/MS spectrum, the seven most abundant ions in the spectrum were chosen for statistical evaluation. After the ion intensities were renormalized to the most abundant product ion, a comparison of the spectra obtained under MC and SC conditions for each model compound was made using the mean relative intensities (mean RI). The mean RI of the seven selected product ions for both conditions are shown in Table 1. Except for a few product ions, the mean intensities under the two conditions are similar. Even when the mean intensity of a product ion differs significantly between MC and SC conditions, the same general pattern relative to the other product ions is maintained. This pattern similarity was shown previously for spectra obtained from day-to-day under the same conditions. For compounds with masses from 269 to 726, approximately 60% of the product ions fell within 30% of the mean RI under MC conditions. Under SC conditions, approximately 80% of the product ions from compounds with masses from 153 to 465, fell within 30% of the mean RI.

The reproducibility of spectra obtained from day-to-day under both MC and SC conditions was also assessed based on the similarity index for the seven selected product ions. Two MC and two SC runs were randomly selected for this evaluation. A similarity index expresses the percent run-to-run difference for each ion:

$$(|I_a - I_b|)/[(I_a + I_b)/2] \times 100\% \qquad \text{(Eq 1)}$$

where I refers to the percent contribution of each ion to the total intensity and the subscripts refer to two separate runs. As shown in Table 1, most of the spectra is more reproducible under SC conditions, but the two compounds of highest mass are more reproducible under MC conditions. Compounds with masses similar to the calibration point compound (C^+ = 319) show similar reproducibilities under both conditions. As the masses of the model compounds deviate in either direction from that of the calibration compound, the reproducibility under SC conditions deteriorates. Under MC conditions, reproducibility worsens as the masses of the model compounds decrease but remains constant as the masses increase. Overall spectral reproducibility was assessed based on the percentage of ions that possessed a similarity index of less than 30%. SC conditions produced data with spectral similarities of 85% or better for model compounds with masses from 227 to 465 Da and MC conditions produced data with spectral similarities of 85% or better for model compounds with masses from 319 to 726 Da. Spectral reproducibility assessed by comparing percent deviation from the mean relative intensity and by comparing similarity indices for MC and SC conditions produced similar results. Both methods show that, in general, spectral reproducibility is better for SC conditions, but over a narrower mass range. Thus the primary limitation of this technique seems to be the deterioration of spectral reproducibility at masses significantly different from the calibration compound. This limitation may be overcome by using more than one calibration compound to cover the necessary mass range.

"SUPRESSION" OF α-AMINO ACIDS SIGNALS IN COAXIAL CF/FAB

Francisco M. L. Amado*, Pedro M. N. Domingues, Cristina M.F.Barros, M. Graça O. Santana Marques and A. J. Ferrer Correia

Department of Chemistry, Mass Spec. Lab., University of Aveiro, 3800-Aveiro, Portugal

The variation of the relative abundances of the protonated ions from several amino acids, isolated and in binary mixtures, using coaxial CF/FAB, is discussed and a general supression mechanism is suggested.

Data presents two well-defined series. In the first series (hydrophobic/high volatility amino acids), the RA decreases with the increase of the B.B. index (Figure 1). In the second series (hydrophilic/low volatility amino acids) the RA decrease with the proton affinities (Figure 2). In this serie correlation with BB values is not apparent. These data shows that the abundances of the protonated amino acids depend on the ability of neutral species for changing from the liquid-phase to a gas-phase like, i.e. of its concentration in that phase. Once there, the relative abundances of protonated ions are the result of a competition process determined by the proton affinities of the amino acids.

There is no significant variation of the total ion current whenever an amino acid sample is introduced using coaxial CF-FAB. The increase of the ion current of the protonated molecular amino acid isolated or within a mixture (Figure 3) is compensated by the decrease of the protonated glycerol (and cluster glycerol ions). Results of binary mixtures of amino acids, compared with the relative abundances of protonated ions when isolated, show not only a decrease in the glycerol ion signal but also a decay of the ion current of each amino acid within the mixture. In face of these results its possible to assume that there is a limit for the number of ions that can be formed at a given moment in FAB, under the same experimental conditions.

PDMS Analysis of Frozen Cycloalkenes

R. L. Betts, E. F. da Silveira† and E. A. Schweikert

Center for Chemical Characterization, Texas A&M University, College Station, TX 77843-3144, USA

† Departamento de Física, Pontifícia Universidade Católica, C P 38071 Rio de Janeiro 22452-970, Brazil

In order to determine the influence of stoichiometry on desorption mass spectra, frozen cyclohexane, cyclohexene, 1,3-cyclohexadiene and benzene surfaces have been bombarded with ^{252}Cf fission fragments Secondary ions were accelerated over 3 5 mm by a 2 8 kV potential difference and analyzed by a 62 cm long time-of-flight spectrometer Samples were leaked into the analyzing chamber and condensed on a plate cooled to liquid nitrogen temperatures. In spite of a base pressure of 8 x 10^{-8} mbarr, water peaks (e.g , m/z = 18, 10 and 37) are seen in the spectra

We have found that the desorption yields of the $C_nH_m^+$ secondary ions follow certain general trends a) even-electron species are generally more abundant than odd-electron species; b) more saturated ions are more abundant than less saturated ions if the sample is a more saturated compound, and vice-versa, c) these trends are observed for all $C_nH_m^+$ groups except for the molecular ion group Trends a and c are illustrated in Fig 1, where the PDMS positive ion mass spectra, corresponding to the most saturated sample (cyclohexane) and the least saturated sample (benzene), are presented Even-electron species are known to be generally more stable than odd-electron species and, for them, a relative high abundance is expected Molecular or quasi-molecular peaks are also expected to be abundant because they are formed relatively far from the impact site and may easily gain or lose a few hydrogen atoms Trend b is better observed by calculating the ratio of the two spectra, i.e , by dividing the desorption yield distribution corresponding to the benzene sample by that one obtained from cyclohexane This ratio is presented in Fig 2a for the $C_nH_m^+$ groups (C_1 to C_5) lighter than the molecular peak group (C_6) In Fig. 2b this ratio is shown for the desorbed hydrogen group (H^+, H_2^+ and H_3^+), for the molecular peak group and two heavier ones (C_6, C_7 and C_8) Data corresponding to water dusters are not represented. One sees clearly a general decreasing of the desorption yield rates when the hydrogenation increases The light $C_nH_m^+$ group yield ratio exhibits roughly an exponential decay with hydrogenation, while the heavier groups are more sensitive to the sample molecular structure

It is interesting to note that similar results are obtained when one compares PDMS desorption yields of hexane and benzene [1] These observations suggest that stoichiometry effects, for the light groups, are more dominant than effects due to the initial molecular structure Such results are compatible with a plasma model formation for the low mass $C_nH_m^+$ desorbed ions Stoichiometry alters not only the ratio between C and H

atoms in the gas phase but also density, melting point and stopping power for the ^{252}Cf fission fragments These factors modify the plasma temperature and, as a consequence, the relative abundance of the formed species before the beginning of the free-expansion process Calculations assuming a quasi-equilibrium plasma indicate that temperatures of 5000 - 7000K are necessary to reproduce qualitatively the observed relative desorption yields The ratio between charged and neutral species is predicted to be 3 x 10^{-4}

CONCLUSION

PDMS mass spectra of frozen C_6 cyclohydrocarbons were obtained and compared A gradual and systematic influence due to their stoichiometry is observed in the desorption yield of $C_nH_m^+$ ions Abundances of highly saturated emitted species increases with increasing saturation of the sample For emitted species lighter than the quasi-molecular ion peaks, the memory of the sample molecule structure appears to be lost, increasing evidences for intense chemical interaction after the projectile impact

Taking into account that different stoichiometry also corresponds to different density, melting point and stopping power for the ^{252}Cf fission fragments, the observed relative desorption yields are compatible with the production of low mass ions in a plasma.

Biomolecular Cluster Formation in PDMS

P. Demirev, J.Eriksson, P.Håkansson, R.Papaléo, B.Sundqvist, R.Zubarev,
Division of Ion Physics, Department of Radiation Sciences,
Uppsala University, box 535, Uppsala S-75121, SWEDEN

Non-covalent cluster ions of biomolecules are often observed with various ionization techniques. In desorption ionization, e.g. FAB, PDMS and MALDI, it is still an open issue whether clusters are ejected as intact species, pre-existing on the surface, or they are formed during the desorption process. This question is directly coupled to the successes of MS as an emerging method for probing non-covalent interactions between biomolecules, including immunological response monitoring.

We have studied the formation of heteroclusters - dimers and trimers - in PDMS from targets containing mixtures of biomolecules. The targets included aminoacids - Ile (MW 131), and Phe (MW 165), and nucleosides - cytosine (dC, MW 227), adenine (dA, MW 251), and guanine (dG, MW 267). The targets were prepared by depositing sample solutions on thick Si backing (frontside desorption), or 2 μm aluminized Mylar foils (backside desorption). Evaporation resulted in microcrystalline films with submicron thickness. The aminoacid and the nucleotide mixtures were dissolved in glacial acetic acid and water, respectively. This target preparation technique was chosen in order to alleviate the influence on cluster formation of other target preparation techniques, employed in PDMS, such as electrospraying or adsorption to a nitrocellulose membrane. The "Diploma" reflectron TOF spectrometer, coupled to one of the beam-lines of the Uppsala Tandem accelerator [1], or a commercial "Bioion" spectrometer, also fitted with a reflectron, were used for PDMS. Swift iodine ions (72.3 MeV) or ^{252}Cf fission fragments were used as primary ions, incident at 45° from the front, or normally from the back side, respectively. Initial radial velocity distributions of ejected molecular, homo- , and heterocluster ions were determined on the "Diploma" spectrometer by measuring the ion yield as a function of deflection in radial direction according to already described procedures [2]. Typically 2.10^6 start events provided satisfactory secondary ion statistics.

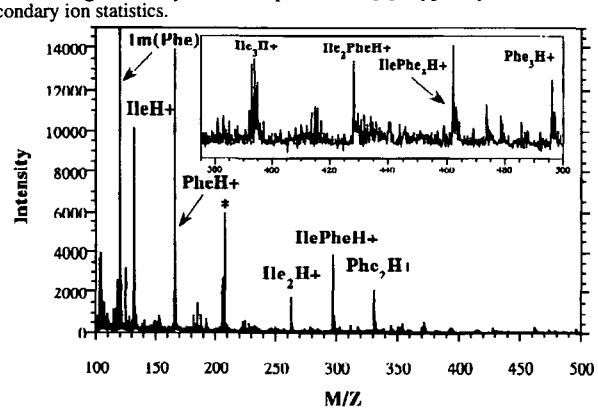

Fig. 1 PD mass spectrum from a Ile-Phe target;
inset : expanded view (m/z 370 to 500) of the trimer cluster region.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

A characteristic mass spectrum of the Ile-Phe mixture is presented on fig. 1. Peaks, corresponding to the respective homo- and hetero- dimer and trimer ions are clearly discerned. Interstingly, an intense peak (denoted with * on Fig. 1) coinciding in mass to the complex of the two immonium ions is also observed. The heterodimer peak in this and in other cases examined (Val+Leu, Phe+Trp, Tyr+His, Val+Cys, Ser+Phe) had similar intensity as the homodimer peaks. The PD spectrum of the nucleoside mixture (dC, dA, and dG) contains peaks corresponding to the complementary pair (dCdG), as well as to the homodimers: (dC)2, and (dG)2. No dA-containing clusters, either the homo- or hetero- dimer, have been observed.

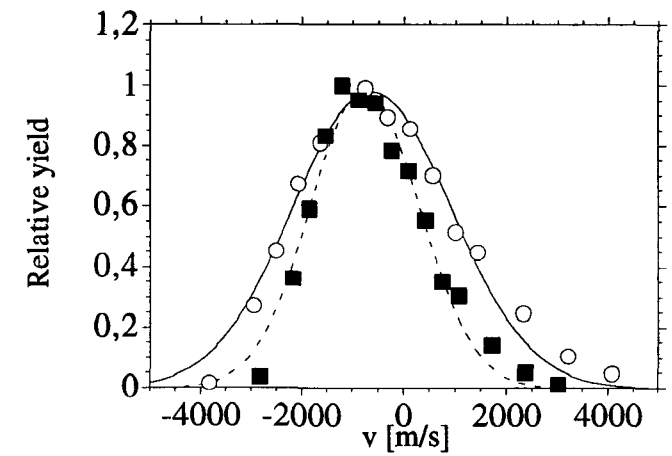

Fig. 2. Radial velocity distributions of dCH+ (o) and the mixed dCdGH+ cluster (■).

A comparison of the initial radial velocity distributions for the cluster and the monomer molecular ions reveals their remarkable similarity for both types of mixture samples studied - Fig 2. For instance, the respective values of $\langle v_x \rangle$ for IleH+, PheH+, Ile_2H+, IlePheH+, and Phe_2H+, are 578, 558, 559, 558, and 551 m/s. As typical for intact biomolecular ions both the homo- and the hetero-dimer clusters exhibit correlation with the direction of the incident MeV ion. The take-off angle of all these species is in a direction away from the trajectory of the impinging ion. In some favourable instances, e.g. for alkali cation attachment to peptides [3], initial radial velocity data can answer unequivocally the question whether cluster formation precedes or supersedes ion ejection. The data presented here, as well as data from coincidence experiments, cannot so far restore unambiguously the temporal (and spatial) sequence resulting in the observed cluster ions. Ejection of preexistent clusters as well as formation in the selvedge region are both plausible mechanisms, consistent with the current radial velocity data. Further experiments, including initial axial velocity determination and cluster formation specificity, may provide valuable additional clues.

The pyrazole derivatives are well-known for their analgesic and anti-inflammatory properties, specially the derivatives formed by replacing different functional groups in the C-5 position of pyrazole ring. A new series of eight 5-arylthio pirazole derivatives has been synthesized and analyzed through ^{252}Cf-PDMS and EI techniques. In this work the PDMS results are presented.

The PD mass spectra were obtained with a home-made time-of-flight spectrometer, having a 25 cm TOF tube and operated at 10 kV and - 7kV sample bias for positive and negative ions respectively. The spectrometer mass resolution is about 100. The samples were dissolved in acetone (around 7 μg/μl) and then electrosprayed on stainless steel electrodes. Data acquisition time was roughly 3 hours per sample.

The plane structure of the 5-arylthio derivatives is presented in figure 1. The positive and negative ion PD mass spectra for one of the compounds (R = H) are illustrated in figure 2.

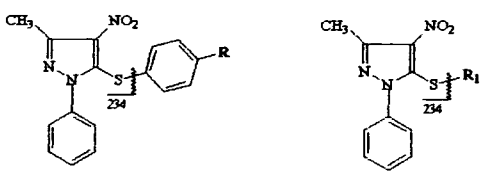

Fig. 1 - Plane structure of the compounds

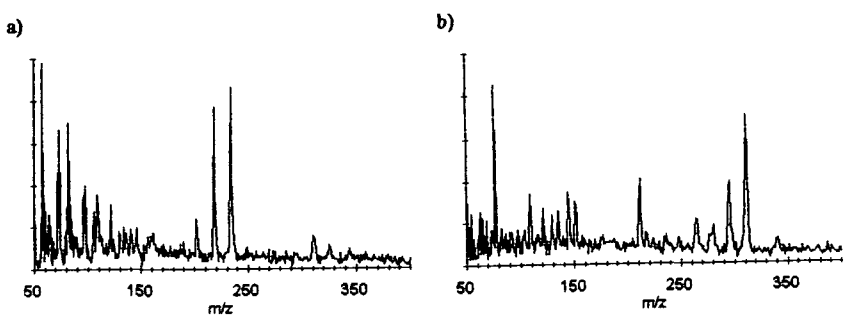

Fig 2 - a) negative and b) positive ion PDMS spectra of the compound (R = H)

In the **negative ion spectra** of the analyzed compounds, three peaks are always observed: m/z = 234, 218 and 202. The m/z = 234 peak may be attributed to the ion originated by the phenyl group loss bound to the sulfur atom, $[M - C_6H_5R]^-$ or $[M - R_1]^-$. Moreover, if this fragment loses either an oxygen atom or a sulfur atom, ions of m/z = 218 or 202 are formed.

The **positive ion spectra** show a pattern fragmentation characterized by the ions $[M - 17]^+$, $[M - 32]^+$, $[M - 46]^+$ and $[M - 100]^+$, attributed respectively to a loss of a hydroxyl group, a sulfur atom, a nitrogroup and a possible break across the pyrazole ring. Table I summarizes the percent desorption yield of those ions, normalized to the desorption yield of the molecular (or quasi molecular $[M + H]^+$) ion, corresponding to each R or R_1.

Table I - Desorption yield (%) normalized to the M^+ or $[M + H]^+$ peak

	R					R_1		
$[M - n]^+$ ions	H	OCH_3	Br	Cl	NO_2			
$[M - 17]^+$	53	53	67	77	42	33	48	19
$[M - 32]^+$	28	16	15	14	~ 0	~ 0	~ 0	8,6
$[M - 46]^+$	24	12	29	28	36	100	166	32
$[M - 100]^+$	27	2.5	43	62	25	26	37	4
MW =	311	341	389	345	356	312	313	352

Several observed trends can be noticed. The relative yield intensities for R = Br and R = Cl are very similar. Note that the yields of the $[M - 17]^+$ series are fairly constant and higher than those of the $[M - 32]^+$, probably because the loss of the sulfur atom requires the breaking of two bonds and a re-arrangement. In addition, the presence of nitrogen atom in R or R_1 substituent group stabilizes the bonding between carbon and sulfur resulting in the reduction of peak intensity of $[M - 32]^+$ and in the enhancement of the yield of $[M - 46]^+$ series. Thus, such observations give support to the proposed fragmentation pattern, i.e., the $[M - n]^-$ fragments are only differentiated by the substituent group (R or R_1).

A high mass resolution PDMS spectrum has been obtained only for the R = Br sample confirming the above results. It reveals a 3.6 ratio for the $[M(^{79}Br) + H]^+$ and $[M(^{79}Br)]^+$ peak yields.

Conclusion

The PDMS and EI measured mass spectra confirm the synthesis of the pyrazole derivatives. The molecular or quasi molecular peak of all the PDMS spectra are relatively more intense than the EI ones, showing that the latter process leads to a higher level of fragmentation. Positive and negative ion PDMS spectra of the different derivatives present a regular pattern corresponding the loss of the same fragments. This analysis illustrates PDMS as an useful method for structural determination of heterocyclic aromatic compounds.

Recent MALDI studies by Castoro and Wilkins have shown that the addition of pyrolyzable sugars increase the yield of certain analyte ions by decreasing the desorbed ions' internal energy [1]. To examine the matrix-related internal energy decrease in MALDI, Kinsel et al. used the fragmentation pattern of vitamin B_{12} to qualitatively study various MALDI matrices [2]. By determining the yield of $[M+H]^+$ with prominent analyte fragment ion yields such as $[972]^+$ and $[M\text{-}CN]^+$, they were able to compare the ability of certain UV-absorbing matrices to produce low internal energy quasimolecular ions. In a similar manner, we use PDMS to probe matrix-related internal energy effects by small, aliphatic molecules on the fragmentation of B_{12}.

Samples consisting of B_{12} (analyte), methyl cellulose (binder), and various small (i.e. < 400 m/z) matrix compounds were co-deposited onto stainless steel plates and dried. Matrices included dextrose, maltose, cellobiose, fructose, and valine, each with matrix:analyte molar ratios ranging from 1:1 to 1000:1.

Figure 1 shows PDMS spectra from B_{12} samples with differing amounts of dextrose. High matrix/analyte conditions significantly affect the yield of $[M\text{-}CN+H]^+$ while only producing a small effect in $[M+H]^+$ yield. The other matrices examined gave similar results. Compared with the results from dextrose, there was no apparent steric effects from either the increase in dextrose units (mono vs. disaccharide) or the respective alpha and beta linkages of

43rd ASMS Conference on Mass Spectrometry and Allied Topics

maltose and cellobiose. Similarly, the inability of fructose to form a hemiacetal also did not affect the relative increase in yields. Also, changing the class of the matrix (saccharide vs. amino acid) by the addition of valine, resulted in analogous results. These suggest that the isolation of the analyte within the matrix is responsible for the yield improvements of $[M\text{-}CN+H]^+$.

Texas A&M University, College Station, TX 77843-3144

For several years, plasma desorption mass spectrometry (PDMS) has been an effective tool for the characterization of large biomolecules. The use of PDMS has declined with the advent of matrix assisted laser desorption/ionization mass spectrometry (MALDI), which offers higher sensitivity and higher accessible mass range than PDMS. Both MALDI and PDMS involve deposition of energy via electronic excitation of the sample matrix. The excitation is converted to translational motion and the desorption of molecules. Because of the similarity in excitation, a few groups are now investigating the use of UV and visible absorbing matrices similar to those used in MALDI to improve the performance of PDMS [1,2].

We have recently shown that the photons and ions from individual ion impacts (keV and MeV energy) can be collected simultaneously [3] This project was begun to determine whether MALDI matrices will improve the yield of intact peptide ions in PDMS, in order that we might later probe the fundamental processes that follow electronic excitation of MALDI samples by examining correlated photon and ion emission Because the emission of photons occurs on a time scale an order of magnitude faster than secondary ions, these studies may provide important information about the energetics of the desorption and ionization of molecules in both PDMS and MALDI

We present here the results of the desorption of two peptides, bradykinin and angiotensin II, using MALDI type matrices and PDMS. In these experiments, peptide and matrix were co-deposited along with a methylcellulose (MC) binder to produce thin homogeneous films. The matrices included 4-nitrophenol, 4-hydroxy-3-iodo-5-nitrobenzoic acid (HINB), Sinapic acid, α-cyano-4-hydroxycinnamic acid and others. In most cases, the matrices improved the yield of the $(M+H)^+$ ion from both peptides above a peptide/MC blank sample. HINB provided the largest improvement for bradykinin (**figure 1**), while α-cyano-4-hydroxycinnamic acid was the best matrix for angiotensin II.

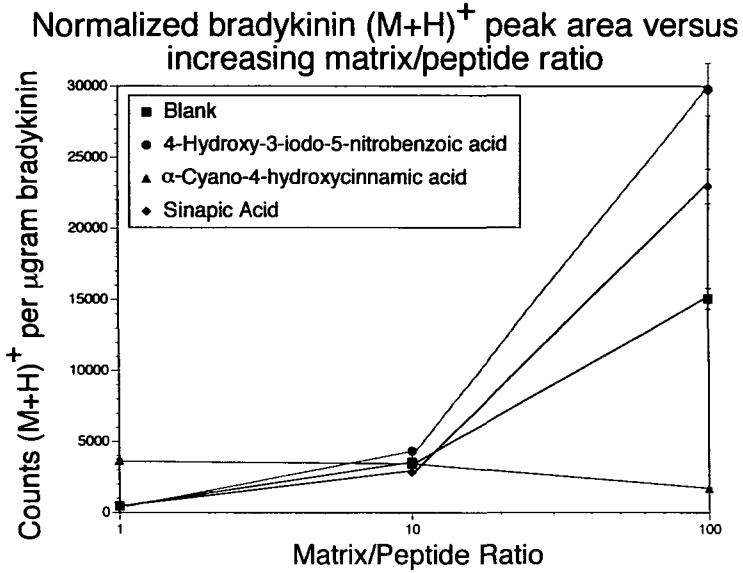

Figure 1

These results indicate that improved quasi-molecular ion yields in PDMS may be achieved by using acidic matrices. The positive influence of the MALDI matrices on ion yield in PDMS identifies a similarity in the ion formation process between the two techniques. Future experiments examining the ion and photon yields, and their relationship, should further the understanding of the chemistry and physics of ion formation for both methods of desorption.

Evaluation of Solvent Effects on MALDI Matrix Crystal Formation

Karen K. Campo, Ricky D. Edmondson, Lloyd W. Sumner, and David H. Russell
Laboratory for Biological Mass Spectrometry, Department of Chemistry, Texas A&M University, College Station, Texas 77843

The physical size and distribution of MALDI matrix crystals are dramatically effected by the solvent utilized in the preparation of matrix solutions. It is believed that smaller, more uniform crystals produce higher intensity MALDI ion signals and also improve mass resolution. Optimum reproducibility and surface homogeneity are directly linked to the solvent used in sample preparation.

In order to investigate these theories, the solvent, texture of the sample surface, and matrix were varied. The solvents used in this study were: acetone, 50/50 (v/v) acetonitrile and water, ethanol, methanol, and tetrahydrofuran. Alpha-cyano-4-hydroxycinnamic acid, 4-nitroaniline, and 3,5-dimethoxy-4-hydroxycinnamic acid (sinapic acid) were employed as matrices, with bovine insulin used as the analyte. The matrix/analyte samples were prepared on two stainless steel plates: one polished with 12000 grit sandpaper, the other polished with 1000 grit sandpaper. The dried droplet sample preparation method of a 50/50 (v/v) solution of both the analyte and matrix was used. The spectra were aquired at laser irradiances slightly above threshold, with the ion signal of each matrix/analyte/solvent being compared as to the solvent utilized. Each spectra were aquired at laser irradiances slightly above threshold. Three spectra were obtained from each sample spot. Three spots were obtained for each matrix/analyte/solvent. The crystal characteristics of each matrix/analyte/solvent sample were compared by using a Zeiss Auxiophot microscope.

From our results, ethanol used as the solvent in the matrix/analyte samples, gave the greatest ion signal in all three matrices, while methanol gave the lowest ion signal, as shown in Figure 1. Better sample-to-sample reproducibility was achieved on the more polished steel plate surface, as shown in Figure 2. Similar results have been obtained in aerosol MALDI experiments as well.[1]

Similar laser thresholds were seen for the three solvents, ethanol, methanol, and acetonitrile-water. Acetone had a lower threshold, while tetrahydrofuran had a higher laser threshold than the other solvents. Exact crystal size was undetermined due to the 800x magnification limit, yet, the crystal characterixtics could still be compared. In alpha-cyano-4-hydroxycinnamic acid, ethanol and methanol gave similar crystals, in 4-nitroaniline they did not. The same was true of acetone and tetrahydrofuran.

Infrared Matrix-Ass. Laser Des./Ion. (IR-MALDI) using a Free-Electron Laser

Cramer, Rainer, Haglund, Jr., Richard F., Hillenkamp, Franz
Department of Physics and Astronomy, Vanderbilt University, Nashville, TN 37235
Institute for Medical Physics and Biophysics, University of Muenster, Germany

At present a Free-Electron Laser (FEL) seems to be the most promising laser to help answer questions about the basic mechanisms of energy deposition, desorption or ionization in IR-MALDI. We use the Vanderbilt FEL for investigations in the 2-10 µm wavelength range and, along with an electro-optic switch, in the 100-5000 ns time regime of pulse duration.

Experimental: The mass spectrometer is a modified Comstock model TOF-101-MS with a microchannel plate detector. A high voltage (up to 30 kV extraction potential) ion source has been built allowing sample irradiation under 45 degree with both an UV-laser and the Vanderbilt FEL. By means of a dichroic mirror on the UV side, a video camera can be used for sample observation with a magnification of approximately 20. The IR side comprises a telescope optic to reduce the ~1 cm FEL beam diameter by a factor of 4 to an appropriate size for the aperture of the electro-optic switch, a broadband Pockels cell. The time structure of the FEL is shown in **Fig. 1**. Using the Pockels cell, the macropulse with a length of 2-5 µs can be continuously varied to achieve a pulse width between 100 and 5000 ns. In **Fig. 2** the wavelength range covered by the FEL is shown in comparison to other IR-lasers.

Measurements and Results: We were able to obtain spectra at wavelengths which were not used before in IR-MALDI (3.2 µm- 3.4 µm) and with different pulse lengths (100 ns - 2 µs). For the initial experiments shown here we only used succinic acid as matrix. **Fig. 3** shows the insulin peak of a single shot spectrum obtained by using a crystal as the sample. The wavelength is 3.25 µm, very close to the maximum absorption of the O-H stretch vibration of succinic acid. The insulin molecule ions could be detected for approximately the same period of time as the FEL macropulse, which was not shortened by the Pockels cell. **Fig. 4** shows a single shot spectrum of melittin. The laser parameters were the same as in **Fig. 3**. This time we used a standard MALDI sample preparation. The spectrum shows a melittin ion peak width slightly smaller than the FEL pulse width. It is noticeable that the maximum of the ion peak is reached earlier than in **Fig. 3**. **Fig. 5** shows a single shot spectrum of melittin obtained under basically the same conditions as in **Fig. 4** except the different FEL pulse length. In this case we used the Pockels cell to cut a 200 ns pulse out of the FEL macropulse. Compared to **Fig. 4** this spectrum has more background noise, less matrix ion signal intensity, the ion peak width is more than a factor of 3 smaller, and the mass resolution is increased by a factor of 3.

Discussion: Comparing **Fig. 3** and **Fig. 4** we note that the ion emission times are different. While in the first spectrum the insulin peak shape reflects the temporal FEL beam shape, in the latter the ion peak maximum is reached quite early and is followed by a decrease of the ion signal intensity. The most likely explanation for this disparity is based on the two different samples we used. When a crystal is used as in **Fig. 3**, within the laser spot the sample will not be totally desorbed by a 2 µs laser pulse whereas for the standard sample, which is at best 10-50 µm thick, almost all the sample will be gone. The pulse length we used in **Fig. 5** is close to pulse lengths of other IR-MALDI-lasers. Even if the quality of this spectrum is not state-of-the-art one can clearly see an improvement compared to the spectra with the longer pulse length.

Conclusions: Our first results with the Vanderbilt FEL support the assumption that the FEL is a promising laser to study IR-MALDI. Even with a macropulse of 2-5 µs we obtained IR-MALDI spectra. The substructure of the macropulse, the 1 ps micropulses, does not seem to be a problem. On the other hand it is quite rare to have all of the components (FEL, Pockels cell, TOF-MS) functioning at the same time. Therefore the FEL can be used as a research tool, but not as an IR-MALDI-laser for routine analysis. Once we know the parameters for best IR-MALDI performance one should rather develop an appropriate fixed-frequency laser or OPO.

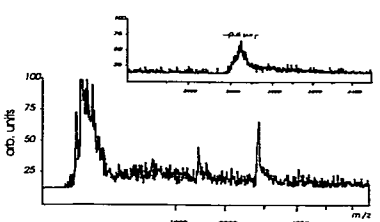

Fig. 5: Single shot spectrum of melittin from a standard sample with magnified analyte peak section indicating the peak width in time (wavelength: 3.25 µm, pulse length: ~ 200 ns)

Future Work: As the initial experiments indicate the FEL combined with our experimental set-up is suitable to carry out systematic investigations of fundamental aspects of the IR-MALDI.

We will study the correlation between sample absorption and desorption threshold as well as the effects of laser intensity and pulse duration on desorption and ionization.

Effect of Analyte Hydrophobicity on Beam-induced Dehalogenation in LSIMS.

R. Théberge* and M.J. Bertrand, Regional Center for Mass Spectrometry, Department of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7.

Dehalogenation reactions of organic compounds during their FAB/LSIMS analysis have been the object of several studies. The importance of these reactions lies in the fact that they can cause the presence of artefacts in the mass spectra. In a previous study[1] conducted in our laboratory, it was observed that the presence of an anionic surfactant additive can increase the extent of beam-induced dehalogenation of organic compounds. This observation was explained in terms of increased analyte surface concentration. In our continuing investigation of beam-induced dehalogenation, we have focused on how analyte surface activity (hydrophobicity) can affect the dehalogenation process through comparison of analogs of different surface activity. Mass spectral data were obtained using a VG Autospec-Q equipped with a caesium ion gun. The caesium ion beam energy and current were held constant at 22keV and 2μA, respectively. %Dehalogenation values were obtained from the first two minutes of analysis. Glycerol and 1,2,6-trihydroxyhexane were the matrices. The extent of dehalogenation was defined as

$$\%\text{Dehalogenation} = 100 \times [M_H H]^+ / [M_X H]^+ + [M_H H]^+ \qquad (1)$$

where $[M_X H]^+$ and $[M_H H]^+$ are the relative abundances of the protonated halogenated and dehalogenated species, respectively. In order to investigate the effect of analyte surface activity on dehalogenation, the analogous compound pairs 1-2 and 3-4 (**Fig. 1**) were used. The different surface activity of the analogs are based on the size of the alkyl side chain. For pre-formed ions, we can define analyte surface activity in terms of matrix surface coverage. As can be seen in **Fig. 2** and **3** from the intensity of the analyte ions with respect to the glycerol trimer $(gly)_3H^+$, the surface activity of compound 1 is much greater than 2. Compound 1 exhibits charge remote fragmentation which is characteristic of surfactants. The % dehalogenation for 1 is also greater than 2 (60 vs 44). A similar result was obtained for 3 and 4 (18 vs 24). These results *directly* support the contention that analyte surface activity can affect the observed extent of dehalogenation. This effect can be explained by the high concentration of beam-generated reductive species (thought to be electrons) near the surface. Hence, higher analyte surface concentration should result in an increased probability of reaction with beam-generated electrons and result in a greater % dehalogenation. The analyte surface concentration can also be affected by the surface tension of the matrix, particularly in the case of a surfactant such as 1. This hypothesis can be tested by using a matrix structurally analogous to glycerol with a lower surface tension such as trihydroxyhexane (THH). The relative abundance of analyte ions with respect to matrix ions as well as the extent of dehalogenation in THH (**Fig. 4**) is much smaller than in glycerol. The dependence of analyte signal strength on surface concentration is well known. Thus, analyte surface concentration is lower in THH and %dehalogenation is concomitantly lower (60 vs 45). It has recently been demonstrated that analyte signal increases with matrix surface tension[2]. It is understood that the LSIMS sensitivity (surface concentration) of a particular analyte is not governed solely by its surface activity and that other mechanisms, i.e. diffusion, may play an important role. It is also assumed that the beam-induced processes leading to dehalogenation occur to a comparable extent in glycerol and trihydroxyhexane.

An increase in analyte surface activity results in increased dehalogenation. The relationship between matrix surface tension and extent of dehalogenation was also established. These results support the hypothesis that analyte surface concentration can affect the extent of dehalogenation. It is proposed that this relationship might be applicable to other beam-induced reductions in FAB/LSIMS.

INVESTIGATION OF THE CLUSTERING PROCESSES OCCURRING IN LSIMS FOR A SERIES OF QUATERNARY ALKYL AMMONIUM SALTS

G. J. C. Paul[1], I. Marcotte[3], J. Anastassopoulou[1], T. Theophanides[1], M. Arkas[2], C. M. Paleos[2] and M. J. Bertrand[3],
[1]National Technical University of Athens, Chemical Engineering, Zografou 15780 and [2]NRC "Demokritos", 15310 Agia Paraskevi Attikis, Athens, Greece, [3]Regional Center for Mass Spectrometry, University of Montreal, Montreal, Canada, H3C 3J7.

The behaviour of quaternary alkyl ammonium salts in solution is of interest since they are amphiphilic molecules which are known to form micelles in solution. In this work, a series of quaternary alkyl dimethylammonium bromides, MBr, are studied by LSIMS. Pure glycerol was employed as the liquid matrix. The structures of these compounds are shown in Figure 1. Emphasis is placed on the clustering behaviour of these salts where the effect of structural changes is investigated.

A typical LSIMS mass spectrum for a quaternary alkyl dimethyl ammonium bromide is shown in Figure 2. The molecular ion, M^+, dominates the mass spectrum. The dimer, M_2Br^+, is the major cluster ion observed in LSIMS where X = H, CH_3 and CN. Negligible higher order clusters, $[M_xBr_{x-1}]^+$, where $x>2$, were detected in the analyte concentration range employed (0-0.35M). Different cluster ion formation of the general formula $[M_x-(x-1)H]^+$ where x = 1-4 is observed for X = COOH. Information on the clustering of these compounds in LSIMS was gained by investigating the relationship between the analyte concentration and the ion intensity ratio M_2Br^+/M^+ for X = H, CH_3 and CN. The plot for one of these ammonium salts is presented in Figure 3. At very low analyte concentrations, only M^+ is detected. Further addition of the analyte leads to dimerization where the M_2Br^+/M^+ ratio intensity increases until reaching a plateau where it remains constant. A similar trend was observed for X = COOH where the relation between $[M_2-H]^+$ and M^+ was investigated. The clustering behaviour of the quaternary alkyl dimethylammonium bromides in LSIMS with varying the analyte concentration can be explained in terms of equilibrium [1] for dimer formation and the corresponding equilibrium constant expression [1a]:

$$M^+ + MBr \rightarrow M_2Br^+ \qquad [1]$$
$$K = [M_2Br^+]/[M^+][MBr] \qquad [1a]$$

The plateau region of the plot where the M_2Br^+/M^+ ion intensity ratio remains constant is explained by the formation of an analyte monolayer at the liquid surface, where [MBr] remains constant and suggests a predominant sampling of ions originating from the surface in LSIMS. This explanation also holds for X = COOH compounds. The free energy of dimerization ($-\Delta G^\circ = RT\ln K$) can be related to the equilibrium constant expression by equation [2]:

$$-\Delta G^\circ = RT\ln [M_2Br^+]/[M^+][MBr] \qquad [2]$$

Consequently, values of M_2Br^+/M^+ for all the quaternary ammonium bromides provide relative dimer bond energies. Likewise, this can be performed for $[M_2-H]^+/M^+$ when X = COOH. These values are presented in Table 1. It can be seen from Table 1 that for m and X constant, increasing the alkyl chain length, n, decreases the M_2Br^+/M^+ (or $[M_2-H]^+/M^+$) intensity ratio. This

suggests that the hydrophobic interaction between alkyl chains in the dimer causes a destabilizing effect on the bond strength as n increases. It is also observed (Table 1) that for n and X constant, increasing the methylene spacer length, m, leads to a decrease in the dimer stability. This can be attributed to steric effects on the electrostatic interaction within M_2Br, as illustrated by the comparison of M_2Br^+/M^+ for X = CH_3 and X = H with n =12 and m = 0. Since H is a smaller substituent than CH_3, steric effects are lessened, permitting a stronger electrostatic interaction within the dimer. Comparing M_2Br^+/M^+ vs $[M_2-H]^+/M^+$ intensity ratios (Table 1) for X = COOH and X = CH_3, with n = 12 and m = 1, suggests stronger bonding energies for X = COOH Consistently, higher order clusters are observed for X = COOH. Formation of zwitterions for these ammonium salts is proposed through loss of proton from carboxylic acid, which forms stronger bonding than within M_2Br^+.

ORGANIC SECONDARY ION EMISSION FROM SOLIDS AND LIQUIDS

John McMahon, Peter J. Todd, Richard J. Caimi[§], J. Thomas Brenna[§]
Oak Ridge National Laboratory, Oak Ridge, Tennessee, and
[§]Cornell University, Division of Nutritional Sciences, Ithaca, NY

Microprobe analysis targeted at spatial localization of organic compounds in complex, real samples, depends on efficient production of organic secondary ions. Glycerol is rare among organic compounds because its SIMS spectrum does not change with primary dose and the secondary ion yield from liquid glycerol is high. The bulk of published data on organic secondary ion emission from liquid glycerol bombarded by high intensity fast atom beams at ambient temperature. However, analysis of some classes of samples, particularly biologicals, may require analysis at cryogenic temperatures and with low primary beam doses to minimize damage of the molecular solid. We wanted to identify the reason that secondary ion emission from liquid glycerol is so intense and persistent. We therefore set out to characterize emission of secondary ions from glycerol and a non-freezing solid, high molecular weight polyethylene glycol (PEG), as temperature is adjusted between room temperature and near liquid N_2 (LN2) temperature.

This work was carried out using an imaging SIMS instrument that enables imaging of secondary ions along with simultaneous visual recording of the sample surface using a video cassette recorder (VCR). The latter capability facilitates unambiguous determination of phase changes in order to relate them to changes in secondary ion emission. Cs^+ (10 keV) were the primary ions. The charge compensation device in this instrument is a filament that floods the surface with low energy electrons during short periods when the extraction optics are turned off. Charge compensation permits us to distinguish changes in emissivity due to changes in bulk electrical conductivity.

Secondary ion emission from a glycerol droplet is nearly unchanged as temperature is lowered from ambient to its freezing point. As glycerol freezes, there is an abrupt and dramatic drop in secondary ions emission from the center of the droplet, while emission continues from the periphery. This effect is easily reproduced as the temperature is cycled multiple times.

Emission from the PEG droplet decreases with temperature with no charge compensation. However, signal is fully recovered with the charge compensation, indicating that lower molecular mobility in cold PEG results in higher electrical resistance and charge build-up at the surface during sputtering. The independence of secondary ion emission from the glassy PEG suggests that the crystalline character of solid bulk glycerol is the critical factor reducing ion emission.

Based on a consideration of the instrument geometry, the anomalous emission from the periphery of the glycerol droplet compared to emission from the droplet's center is unlikely to be a topographic effect. We hypothesized that emission was related to the

thickness of glycerol droplet. We tested this hypothesis by preparing a thin glycerol smear and characterizing its secondary ion emission as it freezes and thaws. Our data show that emission continues through the phase transition, consistent with that at the droplet periphery, and similar to the waxy PEG. We conclude that the effect is related to thickness. These results explain conflicting literature reports on the attenuation of emission from glycerol due to freezing.

An effect of crystallinity on ion emission referred to as "channeling" is well known in inorganic secondary ion emission studies and is used for determining crystalline features. Briefly, a decreased sputtering rate is observed when crystal planes line up with the incident primary ion beam, since the probability of impact in the first few atomic layers drops. This effect may be operative here, although simple channeling phenomenon is unlikely since a) emission from thick solid glycerol is always very low, even though the solid surface is clearly rough, and b) thin solid glycerol emits strongly. Further study will be required to explain this effect.

We summarize our results as follows: 1) Thick solid glycerol emits molecular secondary ions at a rate orders of magnitude lower than liquid glycerol. 2) Thin solid glycerol emits molecular secondary ions at rate similar to liquid glycerol. 3) Glassy PEG does not show an abrupt drop in ion emission as its temperature is lowered when charge compensation is provided. 4) Crystallinity affects molecular secondary ion emission in a complex way not fully reconciled with well known results in elemental crystals.

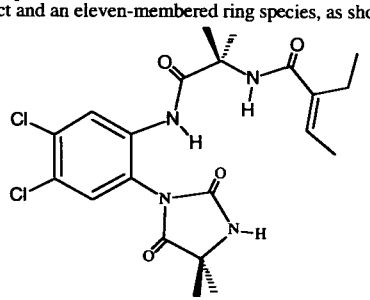
MECHANISTIC STUDIES OF HIGH VALENT IRON CATALYSTS

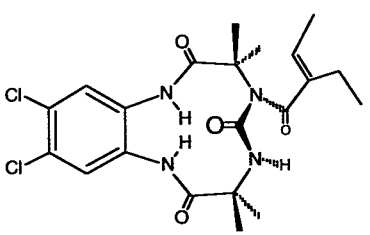
Susan T. Weintraub
The University of Texas Health Science Center at San Antonio
Michael J. Bartos, Scott Gordon-Wylie, James L. Wright and Terrence J. Collins
Carnegie Mellon University, Pittsburgh PA
Kathleen R. Noon
Michigan State University, East Lansing MI

Initial ESI/MS studies provided the key evidence for a novel chemical reaction that occurred when a model iron macrocyclic complex was exposed to an oxidant. Treatment of an iron(III) water complex with the oxidant *t*-butylhydroperoxide (TBHP) in acetonitrile yielded a product that could not be identified by traditional means. Through the use of ESI/MS it was ascertained that the nitrile solvent had been oxidized to release cyanide which was subsequently captured by the iron to give a deep blue iron(IV) cyanide complex. Although we were able to determine the structure of the product, two important questions remained. First, what was the origin of a significant infrared band at 1723 cm^{-1} that could not be attributed to any functionality in the iron(IV) cyanide complex? And second, what was the reaction mechanism for the C-H bond activation process?

After conducting extensive physicochemical analyses of the product exhibiting the 1723 cm^{-1} IR band, we concluded that a mixture must be present. But, we were unable to isolate a separate component responsible for the 1723 cm^{-1} IR band, using silica gel TLC with a variety of solvent systems. We found, however, that if the analogous tetraethyl-ammonium salt of the iron(III) water complex was employed in the reaction instead of the tetraphenylphosphonium salt, the product could be fractionated into two components: a blue compound that proved to be the purified iron(IV) cyanide complex (> 90% of the total mass) and a colorless compound that absorbed at 1723 cm^{-1} in the IR. We gave this compound the notation of **1723**.

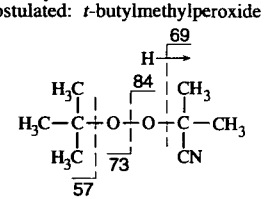
^1H and ^{13}C NMR analysis of **1723** revealed that the compound was diamagnetic; while **1723** had clearly retained many of the structural features of the original macrocyclic tetraamide, a new alkene signal could be seen by NMR. This new metal-free species appeared to be produced by alteration of the diethyl-substituted region of the macrocyclic backbone. Initial characterization of **1723** by FAB/MS indicated that the monoisotopic molecular mass was 468 Da, as evidenced by the moderately intense ions at m/z 469, 471 and 472, with the appropriate relative intensities for 2 chlorine atoms. The EI mass spectrum of **1723** exhibited a relatively weak molecular ion cluster (less than 1% of the base peak) at m/z 468, 470 and 472 with the appropriate pattern for 2 chlorine atoms. The base peak in the EI mass spectrum was at m/z 97. Chlorine-containing fragments roughly equal in intensity to the molecular ion were seen at m/z 411/413/415 and m/z 399/401/403, representing loss of 57 and 69 mass units, respectively. Other significant fragments were observed at m/z 287/289/291 and m/z 154, with less intense signals found at m/z 182, m/z 140, m/z 84, m/z 69 and m/z 58. On the basis of the NMR and mass spectral data, we were able to postulate two different but related structures for **1723**: a dimethylhydantoin ring containing product and an eleven-membered ring species, as shown below.





Examination of the hydantoin ring containing structure revealed that single bond cleavages along the enediamide chain could produce fragments with m/z values of 182, 154, 97 and 69. Formation of m/z 84, on the other hand, requires cleavage across the hydantoin ring in conjunction with hydrogen migration. The ion at m/z 140 is most likely produced by the loss of the elements of CH_2 from m/z 154. Inspection of the 11-membered ring containing product showed that it was also possible to generate the observed ions, although multiple bond cleavages, would be required. While these latter cleavages are decidedly less favorable than the ones associated with the hydantoin ring containing structure, the 11-membered ring product could not be ruled out on the basis of this evidence alone. Further evaluation by tandem MS and accurate mass analysis in addition to deuterium exchange studies were, therefore, conducted. In concert, the mass spectral analyses support the identity of **1723** as the product containing the hydantoin ring and rule out the 11-membered ring structure.

In an effort to determine the mechanism of formation of the cyanide ligand complex, mass balance analysis of the organic reaction products was undertaken. For these experiments, the oxidant was *t*-butyl-hydroperoxide and the solvent was isobutyronitrile. We suspected at the outset that free radical autoxidation might be involved in addition to metal-catalyzed processes and that these reactions might lead to thermally sensitive peroxide products. A technique was, therefore, devised to maintain component integrity in preparation for analysis. The TBHP-catalyzed reaction was allowed to proceed for 15 min and then the mixture was cooled to 0 °C. The organic products were vacuum-transferred to a liquid nitrogen cold trap, leaving behind the ligand-metal containing components as a solid residue in the reaction flask. The organic mixture was then analyzed by ^1H and ^{13}C NMR. After comparison with authentic standards, it was possible to unambiguously identify and quantify the following products: acetone, acetone cyanohydrin, *t*-butanol and di-*t*-butyl-peroxide. The identities of two additional products were also postulated: *t*-butylmethylperoxide and 2-*t*-butylperoxy-2-cyanopropane (termed the "mixed peroxide").



While assignment of the NMR signals for these latter products was straightforward, it was important to verify the structure of this unusual mixed peroxide. The structure of the mixed peroxide is shown to the left. From preliminary evaluation of standard di-*t*-butylperoxide and acetone cyanohydrin, appropriate conditions were found by which a 30 meter x 0.25 mm DB-1701 fused silica capillary column was able to resolve all of the components of interest. The mixed peroxide eluted from the GC in a sharp peak with a retention time of 6.9 min. Unlike di-*t*-butyl-peroxide which exhibits a molecular ion of modest intensity, no $[M]^+$ was detected for the mixed peroxide (M.W. 157 Da). The base peak in the EI mass spectrum of the mixed peroxide was m/z 57 ($[C_4H_9]^+$). Other structurally informative ions included m/z 73 (4% base peak) and m/z 84 (5%) representing the *t*-butanol and acetone cyanohydrin "halves" of the molecule; ions at m/z 69 (40%, $[(CH_3)_2CCN + H)]^+$), m/z 43 (42%) and m/z 125 (18%) were also observed. While the majority of the fragments could be readily interpreted on the basis of the proposed mixed peroxide structure, the peak at m/z 125 required further investigation. This ion represents the loss of 32 mass units from the molecular ion, and from inspection of the structure, this loss could only be a molecule of oxygen. Although there is precedent in the literature for loss of O_2 from organic peroxides, di-*t*-butylperoxide does not fragment in that way. Accurate mass analysis of the sample was, therefore, conducted. The high resolution mass of m/z 125 was found to be 125.1202, representing an elemental composition of $C_8H_{15}N$, with a difference of -0.3 mmu from the calculated value of 125.1205. The presence of oxygen in this ion was ruled out because the closest realistic oxygen-containing organic species ($C_7H_{11}NO$) has a mass of 125.0841, with a mass difference of 36 mmu that is greater than anticipated experimental error. The results also supported the assignment of m/z 73 as C_4H_9O (found, 73.0662; calculated, 73.0654; error, +0.8 mmu) and m/z 84 as C_4H_6NO (found, 84.0411; calculated, 84.0449; error, -3.8 mmu). In order to gain further insight into the mechanism by which these products were being formed, the reaction was then carried out in the presence of ^{18}O gas. It was quite surprising to find that while almost 50% of the acetone cyanohydrin molecules had become labelled, no more than 5% of the mixed peroxide was enriched in ^{18}O. Clearly, two different processes are involved in the formation of these products. Efforts are currently underway to elucidate these mechanisms.

New Axial Energy Analyzer for Secondary Ion Mass Spectrometry

Jian Wei and Richard A. Schaeffer
Extrel Corporation
575 Epsilon Drive, Pittsburgh, PA 15238

Introduction: Secondary Ion Mass Spectrometry (SIMS) has been widely used in depth profile analysis, surface contamination detection and the probing of the interactions between gas phase molecules and solid surfaces. Secondary ions are usually created by the bombardment of a substrate surface with a high energy primary ion beam and mass analysis of these ions will reveal some useful information about the chemical composition of the surface. However, the wide kinetic energy distribution in the secondary ions can severely degrade the resolution and abundance sensitivity of a quadrupole mass filter. In addition, both the high energy secondary ions and the neutral molecules generated by the ion bombardment on the surface will contribute significantly to the noises recorded by the spectrometer Thus, an energy analyzer with high transmission will be highly desirable in the SIMS applications.

Energy Analyzer Design and Working Principles: The energy analyzer reported here is coaxial with the quadrupole mass filter and can be used in tandem with a standard gas phase ionizer. There is a center stop in the analyzer to eliminate the high energy ions and the line-of-sight neutral molecules. Shown in Figure 1 is an example for the ion trajectories from SIMION simulations. The center stop inside the energy analyzer is omitted here for clarity. More detailed simulation results have demonstrated that the ions with energy outside a predetermined energy window will be rejected by the energy analyzer.

Experimental: The transmission of the tandem energy analyzer/ionizer was tested for both the RGA and SIMS applications using an Extrel 3/4" quadrupole mass at 2 1 MHz. The measurements were performed in a UHV chamber with the base pressure of 1.6×10^{-9} Torr. In the SIMS experiments, the energy of the primary Ar ions was 2 keV. The incident angle of on the samples is about 80° and the angle between the sample surface normal and the axis of the SIMS probe is about 10° Data acquisition was done through the INEL computer software.

Results and Conclusions: The RGA application to an Ar gas at $7\ 4\times10^{-7}$ Torr gave a sensitivity of 6 75 $\times10^{14}$ CPS/Torr (1.3×10^{-4} Amp/Torr) at the filament emission of 1.0 mA. This result from the new axial energy analyzer shows more than an order of magnitude improvement in transmission over the Bessel box energy analyzer. The detected background noise at this Ar pressure was 0.33 CPS, thus pushing the partial pressure detectability down to 1.0×10^{-15} Torr In the SIMS measurements, the new energy analyzer had also shown a 10X improvement in transmission. Figure 2 shows the spectrum from an unoxidized Al sample, where the Al^+ (27 amu) signal under the target current of 2 nA is 1.2 million counts per second. The band pass characteristics or the energy filtering effect of the energy analyzer can be seen through the low background noise and high abundance sensitivity in the SIMS spectrum. Figure 3 re-plots the data in Figure 2 to show this effect. The abundance sensitivity was measured to be better than 1×10^5 at 27 5 amu and the background noise was less than 1 CPS. Another application for the energy analyzer is to resolve the energy distribution of the ions being analyzed. The capability of the energy analyzer for fine energy scan is demonstrated in Figure 4

Quadrupole Mass Spectrometry Using the Second Mathieu Stability Region. Randall E. Pedder and Richard A. Schaeffer, Extrel Corporation, 575 Epsilon Drive, Pittsburgh, PA 15238

Introduction. The analysis of deuterium, tritium and helium for fusion applications requires extraordinary abundance sensitivity and mass resolution (900 FWHM for He^3 - HD, 3400 FWHM for HD-H_3) from a mass spectrometer, especially when the objective is to quantitate a very small relative concentration of one species in the presence of the others. Quadrupole mass spectrometers have been successfully applied to the analysis of hydrogen, helium and deuterium (1), with performance limited by the abundance sensitivity inherent in normal quadrupole operation (first stability region). More recently, the suitability of operation of a quadrupole in the second stability region for this application has been demonstrated.(2) In our laboratory, we have sought to characterize the operation of a quadrupole using the second stability region, specifically for high frequency operation with large diameter quadrupole rods (3/4", 19 mm) to yield extremely high resolution with excellent abundance sensitivity.

Experimental. Operation in the first stability region requires greater than 6:1 RF to DC voltage ratio (RF-only to unit-mass resolution). Operation in the second stability region requires an RF to DC voltage ratio slightly more than 2.1:1. This voltage ratio was effected through changing the gain resistor in the input buffer of the pole DC board by a factor of 2.9. The actual RF and DC voltages required to reach the high resolution tip of the second stability region are 4.6 and 13.4 times that required for the first stability region to reach the same mass. Experimental data was acquired using Extrel C-50 mass spectrometer electronics with an Extrel 150-QC quadrupole control electronics (300 Watt, 2.9 MHz), and a standard 3/4" quadrupole probe assembly with axial ionizer (Extrel 041-11) and analog electron multiplier.

Results and Discussion. Analysis of simulated ion trajectories reveals that the amplitudes of the higher harmonic frequencies in both the X and Y directions are much greater for the second stability region than the first, with a corresponding increase in ion velocity. This should translate into improved abundance sensitivity and resolution. Abundance sensitivity is a figure of merit of a mass spectrometer system which demonstrates the ability of a mass spectrometer to completely resolve adjacent peaks of widely varying intensities. For quadrupoles operated in the first stability region, it can be quite challenging to quantitate a low intensity peak which is adjacent to and at a lower mass than a very high intensity mass peak. This weakness is attributed to the weaker focusing of a quadrupole in the Y direction; the higher mass ions are not rejected effectively at the low frequency of ion motion boundary. Abundance sensitivity is demonstrated for the first and second stability regions in the figures to the right. Note that it is abundance sensitivity that limits quantitation in the first stability region. While high resolution (full width, half height FWHH) is demonstrated for the first stability region, the deuterium peak can be seen to leak over into the domain of the helium peak, making quantitation of low levels of helium in the presence of high concentrations of deuterium difficult. In contrast, the abundance sensitivity seen in the second stability region is limited only by system noise.

Ultra high resolution can be demonstrated using the second stability region, but as always, high resolution correlates with reduced transmission. The figure below represents typical resolution-transmission curves for deuterium for a quadrupole operated in the first and second stability regions. All resolutions are full width at half height. At the lowest resolution available for the second stability region the transmission is about forty percent that for equivalent resolution in the first region. At the lowest resolution available for the first stability region, the transmission is about eight times that of the highest transmission in the second region. At high resolution, the performance in the second stability region dominates, offering twice the ultimate resolving ability, with higher transmission than the first region at higher resolutions.

Conclusions. For applications requiring ultra-high resolution at very low mass with excellent abundance sensitivity, operation of a quadrupole in the second stability region offers clear advantages for maximum signal-to-noise. Operation in the second stability region allows for a factor of two or better usable resolution, higher transmission at extreme resolutions, and orders of magnitude better abundance sensitivity than operation in the first stability region. Indeed, abundance sensitivity measurements for the second stability region were immeasurable, effectively limited by system noise levels. One drawback of operation in the second stability region is the amount of DC voltage required (13.4 times as much as for the same mass in the first region). For the mass spectrometer configuration used, the mass range was limited from a standard sixty four amu to around eight amu.

Resolution and Transmission of Quadrupoles: RF-DC and RF-Only Operation. Randall E. Pedder and Richard A Schaeffer, Extrel Corporation, 575 Epsilon Drive, Pittsburgh, PA 15238

Introduction. The mass range of a quadrupole mass spectrometer is dependent upon the RF frequency, the RF and DC voltages available, and the rod radius (for round rods), as well as the mode of operation (RF-only, first stability region, second stability region...). There is a variety of combinations of RF frequency, voltage and rod radii which yield equivalent mass ranges for a given input power. The resolving RF-only mode of quadrupole operation was identified and refined in the 1970's using retarding potentials and specialized ion detectors.(1,2,3) In contrast with normal RF-DC quadrupole operation, RF-only operation relies on the strong focusing fields at the a=0, q=0.906 edge of the first stability region, requiring 9/7 times as much RF voltage to get to a given mass. We have demonstrated high performance operation of a quadrupole using a retarding exit lens potential in our standard ion detector hardware.

Experimental. All experiments were performed in this study using standard Extrel EXM series probe assemblies consisting of a flange mounted analog electron multiplier, quadrupole in a grounded housing with entrance and exit lenses, and an Extrel 041-11 axial ionizer. All quantitative experiments utilized an emission current of 5.0 mA, and a partial pressure of perfluorotributylamine of 5 X 10^{-6} torr. The ion energy for experiments in each quadrupole size was kept constant, with the rest of the tune elements optimized for best sensitivity and peak shape at each frequency. The same 3/4" quadrupole probe assembly was used for both the RF-only and the RF-DC experiments, changing only the tuning of the ionizer and quadrupole entrance and exit lenses and the presence or absence of the resolving DC voltage.

Results and Discussion. From Mathieu Phase Space analysis, the transmission of a quadrupole is predicted to scale with the square of the rod radius, and increase marginally with increases in RF frequency. Indeed transmission does follow this trend experimentally, with small increases in absolute and relative transmission with increases in frequency, but four-fold increase in sensitivity with a two-fold increase in rod radius. Relative transmission for the 3/4" quadrupole is better at all frequencies than relative transmission for the 3/8" quadrupole. The following table contains the experimental results of the measurement of absolute transmission (measured on a Faraday collector) of various quadrupoles operated at various RF frequencies. All currents are in picoAmps.

m/z	3/8" 880 kHz	3/8" 1.2 MHz	3/8" 1.7 MHz	3/4" 880 kHz	3/4" 1.2 MHz	3/4" 1.7 MHz	3/4" 2.9 MHz
50	17	17	14.6	55	82	90	
69	840	860	800	3416	4670	5650	6140
131	154	160	208	881	1290	1148	
219	137	94	157	676	905		
414	4	3.87	9 4	40.7	31		
502	5	2.7	7	52.3	28.2		

In high resolution RF-only quadrupole operation, the transition from high pass mass filter to high resolution is controlled through changes in the exit lens 'retarding' potential, as can be seen in the separation of 664 and 665 from perfluorotributylamine. Note that the transmission as a function of resolution for high resolution RF-only mode is better than normal RF-DC operation, but that abundance sensitivity is better for RF-DC except for the highest RF-only resolutions.

Conclusions. Bigger is Better! Transmission scales roughly with the square of the rod radius. Larger diameter quadrupole rods require lower (more power efficient) frequencies to yield the same mass range. By increasing the rod radius instead of frequency, the same magnitude of applied voltage yields dramatically better transmission and resolution. For a well collimated ion source emittance, an increase in RF frequency yields increased resolution and relative transmission with marginal increase in sensitivity. For high mass ions, RF-only operation with a retarding potential offers twice the ultimate resolution and higher transmission at all resolutions albeit at sacrificed abundance sensitivity for the lower resolutions. Dramatic improvements in sensitivity are predicted for higher mass range systems (smaller diameter quadrupoles, lower RF frequencies). Predicted applications include cluster analysis and deposition and the analysis of large bio-molecules.

Quadrupoles are dynamic mass analyzers which currently use a constant DC voltage and a variable AC voltage at fixed frequency. Mass scanning is accomplished by varying the AC voltage, keeping the ratio AC / DC voltage constant (1). For a quadrupole mass filter, the standard scanning mode is obtained by amplitude modulation of the voltages U and V applied to the rods, but keeping their ratio constant in order to get a constant peak width ΔM (1,2). The reason for this unic way to scan is due to the available technology at the time of discovery. As a result, the resolution is variable with the mass, the frequency of the R.F. voltage is fixed and the mass span is linear.

However, the basic equation governing the motion of ions in a quadrupole field leaves the possibility of an other mode of scanning based on the use of a fixed DC and a fixed AC voltage, but with a variable frequency f (frequency modulation). Modern electronic components allow the construction of such power supply (3).

In this new scanning mode, U and V are kept constant but the frequency f is modified with time. As a consequence, the position of masses is not linear but the resolution is constant over the full mass range.

The new power supply provides a variable R.F. frequency at an adjustable constant amplitude. A tuned transformer cannot be used (in comparison with a standard scanning device) and the R.F. high voltage is only limited by the electronic component used. Our maximum value is 400V with a frequency scanning from 400 kHz to 1 MHz (400 kHz to 2 MHz for a 100V DC voltage). The DC voltage is kept constant and is adjustable in order to control the resolution. Off setting is also possible and permits to apply a polarisation along the quadrupole axis.

The new R.F. power supply has been installed on a quadrupole filter from a Finnigan Mat 3200 OWA (diameter : 6.35 mm, length : 140 mm). The R.F. amplitude and frequency control is done through a function generator (Philips PM 5132). 4-bromotoluene is used as reference compound and is directly injected into the open EI source of the mass spectrometer.

As a result, mass spectra at 150V (f=0.875MHz) and 200V (f=1.08MHz) for the mass 170-172 of 4-bromotoluene molecular ions are presented below (figures 1 and 2 respectively). These mass spectra are obtained using a frequency modulation scanning. The employed R.F. voltage can be sinusoïdal or not, the mass span is varying with f^2, the mass range depends on the dimensions of the filter and is only limited by the R.F. voltage applied to the rods. The positions of the peaks are in accordance with calculations.

At the present time, the available resolution is at least as good as that obtained in the standard scanning mode and lays around a value of $M/\Delta M \approx 1000$.

As predicted from theoretical calculations, the resolution is shown to increase with the applied AC voltage. To improve the resolution of our device further, we are now working on a new R.F. generator capable of delivering an AC voltage greater than 5 kV.

24 rue Lhomond, 75231 Paris Cedex 05, FRANCE

Addition of a low frequency component (ca 10 kHz to 100 kHz) of small amplitude (one hundredth to one thousandth of the main voltage) to the standard RF frequency (ca 1 MHz) of a quadrupole mass analyzer, has a strong influence on resolution, peak shape and transmission of ions.

Experimentally, by using a sinusoidal voltage we observed "weak" optimum conditions, which allow an increase of ion transmission, a better resolution at high mass and a wider tolerance on ion beam energy spread.

The most efficient frequency is inversely proportional to m/z (Figure 1) whereas the optimum voltage is nearly proportional to m/z. Those parameters are close to the solution used on the device called "Resolver" which is fitted on instrument from Nermag company.

In order to try to understand these complex experimental results, we have performed numerical simulations of ion trajectories using a classical Runge-Kutta numerical integration of the Mathieu equation. Calculations have been performed on an IBM Risc 6000 320 H computer, using 10^7 steps per trajectory.

Figure 1: Optimal frequency of the added voltage for increasing resolution in function of the inverse of the mass.

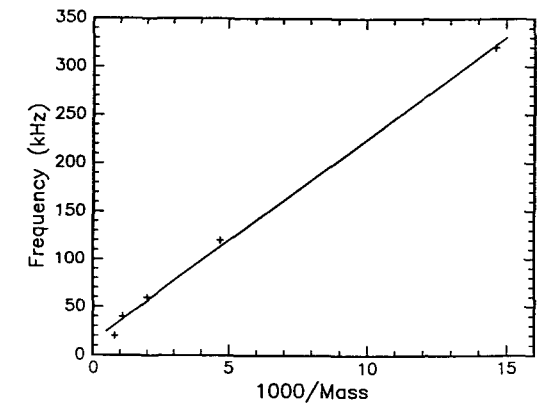

Figure 2: Numerical calculation of the stability diagram for a real quadrupole (r0=1", length 10", 1MHz), initial speed v=800 m.s^{-1}, perturbation q/1000, 10 kHz.

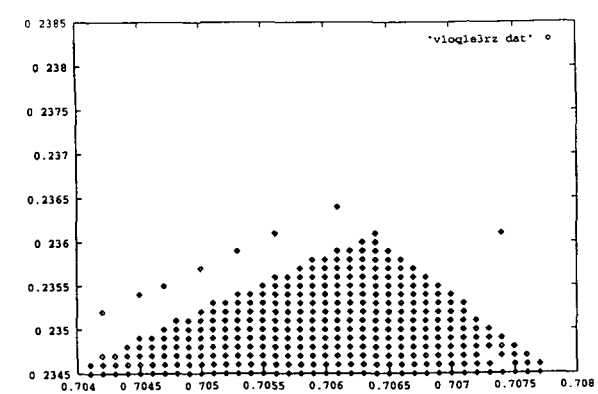

Numerical solutions are in good agreement with experimental results.

Preliminary analysis show that energy of ions (figure 2) and the finite dimensions of the quadrupole analyzer play a central role in the resolver effect.

CHARACTERISTICS OF A HIGH PRESSURE QUADRUPOLE COLLISION CELL#

P. Thibault[a], K. Whalen[b], R.K. Boyd[a], B. Shushan[c] and T. Sakuma[c]
a National Research Council, Halifax, Nova Scotia, Canada B3H 3Z1.
b Chemistry Dept., Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J3.
c SCIEX, 71 Four Valley Drive, Concord, Ontario, Canada L4K 4V8.

Recently (1-3) an RF-only quadrupole collision cell $\mathbf{q_2}$, of a new design, was described for triple-quadrupoles $\mathbf{Q_1q_2Q_3}$. This new cell can operate at collision gas pressures up to 10 mTorr, about 10 times higher than most cells of this type. At these higher pressures an entirely new operating regime is accessed, *e.g.* the transmission efficiency for precursor ions is *increased* over that observed in the absence of collision gas. The useable resolving power of $\mathbf{Q_3}$ is also increased, with no requirement for linking the offset potential of $\mathbf{Q_3}$ to its mass filter function. The increased transmission and resolving power were ascribed (1-3) to a collisional focussing effect analogous to that exploited in quadrupole ion traps, consistent with trends observed (2) on varying the molecular mass of the target gas (larger effect when the target mass is a small fraction of that of the precursor ion). This focussing effect restricts all ions emerging from $\mathbf{q_2}$ to trajectories close to the central axis thus increasing the transmission efficiency (all ions now fall within the phase space acceptance of $\mathbf{Q_3}$). The low energies of the exiting ions (<< 1eV) implies that the problem of matching the offset potential to the ion energies, difficult for conventional $\mathbf{q_2}$ cells, has been circumvented and good resolution is now possible across the entire mass range. These advantages are offset to some extent by longer transit times (10-20 msec) through $\mathbf{q_2}$.

The present work extends the characterization of this new cell to a study of the chemical reactions which can be induced. Charge-site-remote (CSR) fragmentations (4) were chosen for study since it is known (5) that it is difficult to observe these using conventional $\mathbf{q_2}$ cells. The ion $C_{16}H_{33}N^+(CH_3)_3$ was chosen for initial study, in the hope that its simple chemistry would permit investigation of the desired effects with a minimum of complications. Argon was chosen as initial collision gas, since it was shown (2) that it provides the best compromise between collisional focussing (increased transmission and resolving power) and available (centre-of-mass) collision energy (CID efficiency). Figure 1 shows the effect of initial collision energy at the entrance to $\mathbf{q_2}$, at a fixed pressure of argon. The characteristic CSR fragments can be observed at energies below 20 eV, although they become clearly observable only at energies above this value. This contrasts with the observations on the same ion-target combination using a conventional low-pressure cell (5), where collision energies of 200 eV were required. It seems likely that this difference reflects the much longer residence times (2) in the new cell. It is known (4) that CSR fragmentations are observable at low collision energies provided that reaction times are correspondingly long. However, it is still necessary to show that the observed fragments (Figure 1) are truly CSR reaction products, rather than the mixed mechanism products described by Tuinman *et al.* (6). Use of xenon rather than argon led to much poorer transmission and resolving power (mass ratio of target:ion too large for effective collisional focussing). Surprisingly, at lower energies and higher pressures of xenon the CSR fragments were suppressed, and replaced by what appeared to be $Xe^{+\cdot}$ ions. At the highest pressures used there was even evidence for formation of $Xe_2^{+\cdot}$. Clearly the new cell needs further characterization.

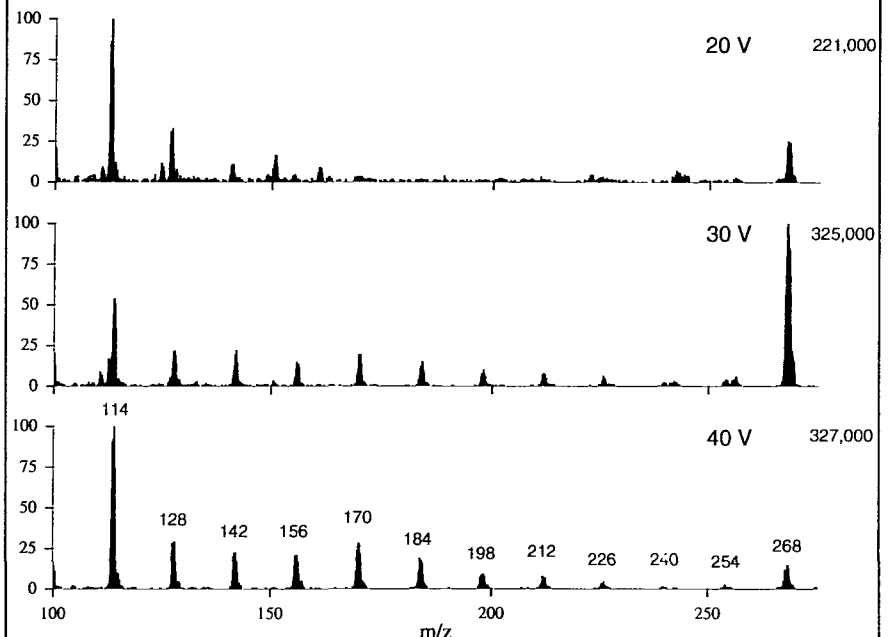
FIGURE 1. Hexadecyltrimethylammonium ion on argon; CGT 200



Fragment ion spectra of $C_{16}H_{33}N^+(CH_3)_3$ ions (m/z 284) in collision with argon in the high pressure regime of the new $\mathbf{q_2}$ cell. The collision energies noted are the initial values for ions just entering the cell (all ions exiting the cell have axial energies < 1 eV). The annotated fragment ions correspond to formal losses of (C_n,H_{2n+2}), and are products of CSR fragmentations (4) or of the charge-site induced reactions which lead to the same product ion masses (6). Deuterium labelling experiments will be conducted to distinguish between these possibilities.

A NEW DETECTOR FOR MAGNETIC SECTOR INSTRUMENTS BASED ON A SCANNING CCD

Jeffrey W. Finch[1], Brian D. Musselman[1], Gary R. Sims[2], and Fumio Kunihiro[3]

[1]JEOL USA Inc., 11 Dearborn Rd., Peabody, MA 01960, [2]Spectral Instruments, Suite 120 W. Grant Rd., Tucson, AZ 85745, [3]JEOL Ltd., Musashino 3-2-1, Akishima, Tokyo, Japan

Introduction: Static array detectors have been interfaced to magnetic sector instruments for the purpose of improving sensitivity over point detection [1,2,3]. These detectors have typically employed a Chevron MCP phosphor intensifier-photodiode array assembly placed at the focal plane of the mass spectrometer, which is integrated as the magnet is "jumped" in a stepwise fashion over the mass range of interest. While these detector systems have significantly higher sensitivty, there are many disadvantages including the complexity of the system, time required to acquire a single spectrum (due to settling times of the magnet), complex calibration routine, and limited dynamic range In order to overcome these disadvantages, a scanning array detector has been developed for magnetic sector instruments based on a charge-coupled device (CCD) with the goal of providing a simpler, more cost effective detector which can provide a significant improvement over point detection for ESI, LC/MS, and MS/MS 4-sector experiments

Methods: The point detector of an SX102A reverse-geometry (BE) instrument was removed and replaced with a custom CCD array detector [4] as shown in Figure 1. The detector consists of a Chevron intensifier coupled to a 1" CCD array, which is cooled to -40 °C. The detector has an effective center mass coverage of ~4%. As the magnet current is scanned exponentially from high mass to low mass, the ion images are "tracked" across the detector by operating the CCD in *time delayed integration* (TDI) mode In this mode, the speed at which charge is shifted across the CCD is synchronized with the speed of the ion image as it travels across the focal plane Therefore, the ion image is "integrated" as it passes over each detector element in the array, resulting in substantial improvement in signal-to-noise. Ion signals from the CCD detector are input into the APU and are processed in exactly the same fashion as data from the point detector External calibration of the SX102A with the CCD detector was accomplished by collecting a calibration spectrum of ultramark 1621 in FAB mode, and then processing the data using a JEOL Complement Data System running on a Hewlett Packard 32 bit workstation For electrospray measurements, samples were introduced via loop injection into a JEOL Generation 2 ESI source [5] with the ion source operating at 5 kV accelerating potential Gramicidin S and lysozyme (Sigma) were used directly without any further purification, and ESI solutions were made up by diluting stock solutions into a solvent of 1.1 water/methanol with 2% acetic acid

Results and Conclusions: Static images recorded for ultramark 1621 with the CCD array detector on the SX102A instrument indicate that resolution is as high as 6,500 (FWHM, m/z 1422) Scanning resolution of the device is as high as 3,500 at m/z 1422 (FWHM, ultramark 1621) at a scan speed of 60 sec/decade Figure 2 shows a single scan ultramark spectrum recorded at a scan speed of 5 sec/decade, indicating good mass resolution is achievable at scan speeds which are compatible with LC/MS applications, even at higher mass range Mass accuracy for ESI spectra recorded with the new detector at low resolution conditions (R~1,000) is within 0 02 to 0 2 amu. Calibration stability data of the mass spectrometer with the scanning CCD array is shown in Figure 3, where an ESI mass spectrum of gramicidin S was recorded each day over a four day period, using a single external calibration file acquired at the beginning of the first day Day to day calibration stability is excellent and is similar to that observable for point detection over periods of up to a week or longer. ESI spectra for loop injections of lysozyme recorded with the new CCD detector are

shown in Figure 4 Results indicate that sensitivity is a factor of 50 to 100 times greater than point detection, which is similar to ESI data recorded for lysozyme with a static photodiode array detector [2]

SECONDARY ELECTRON MULTIPLIER OPERATING AT FORVACUUM PRESSURE

Alexander A. Makarov, Department of Chemistry and Institute of Mass Spectrometry, University of Warwick, Gibbet Hill Road, Coventry CV4 7AL, UK
Michael Y. Yablokov, Karpov's Institute of Physical Chemistry, Moscow, Russia

INTRODUCTION

Modern secondary electron multipliers (SEM) and microchannel plates (MCP) are acknowledged to operate reliably and effectively at residual gas pressures not exceeding 10^{-4}-10^{-5} torr However, as it is known from the practice of ion trap mass spectrometry, this limit is raised up to few millitorrs when vacuum chamber is filled with an inert gas such as helium. Unfortunately, the transition to similar pressures of air in conventional schemes of SEM or MCP unequivocally leads to breakdown and damage This obstacle results in the necessity of expensive high-vacuum system and seriously limits the perspectives of developing ultra-miniature mass-spectrometers for, e.g., field analysis

The objective of the present work has been the development of an ion-counting detector capable of working at forvacuum pressures of air (i e. up to several millitorrs).

The chosen concept envisaged the conversion of the incident ions into pulses of electrons by a single MCP operating at low gain, acceleration of the electrons to a phosphor and counting of light pulses by a photomultiplier

EXPERIMENTAL

To exclude the dependence of the detected current on residual pressure, the ion flux was simulated by ultraviolet radiation produced by hydrogen-filled UV lamp (Fig 1). Radiation intensity was attenuated by interchangeable diaphragms D of diameters d_1=0.3 mm, d_2=1 mm, d_3=1 5 mm located in atmosphere beyond UV window about 0 3 m away from the detector as well as by a hole of 8 mm diameter in the shielding electrode SE.

Electrons produced by photoelectron emission on MCP are multiplied inside MCP channels. The resulting flux of secondary electrons is accelerated in the gap between MCP and phosphor (both of the diameter 34 mm) and confined using electrode CE. Photon bursts produced on phosphor are detected by photomultiplier PMT (Hamamatsu R1635) and counted by ion counting electronics with adjustable discriminator level

UV lamp LGV-1, MCP 34-10 and phosphor KS-425 were produced by State Optical Institute, St.-Petersburg, Russia

During the optimisation of the detector, electrometer (V7-49, Minsk, Belarus) was also used.

Vacuum chamber is evacuated by turbomolecular pump TMP (TSH 180 H, Balzers) backed by a rotary pump RP. Pressure is measured by preliminary calibrated ionisation gauge IG (PMI-2) The increase of pressure is realised by opening leak connected directly to atmosphere

RESULTS

Firstly, multi-parametric optimisation of detector performance has been carried out at high vacuum (5 10^{-6} torr). The main criteria of optimisation has been minimum dark count rate and maximum counting effectiveness (close to 100%)

To obtain results independent of the nature of incident radiation (so that the results could be applicable not only to photon but to ion fluxes as well), secondary electron current was measured on electrode SE by applying small bias relatively to MCP and switching off bias on MCP. For the largest diaphragm d_3, it has appeared to be 5±1 fA.

The optimised voltages are represented in Fig. 1. Also, dependence of counting rate on MCP voltage is shown in Fig 2. It demonstrates that at MCP voltage of 600-650 V detection efficiency approaches 100% while at higher voltages false counts may occur (i e. signals from electron noise inside the channels may overcome the discriminator level). Analogous dependencies are observed for other voltages. Reproducibility of counting rate after opening to atmosphere and on day-to-day basis was about 10-15%

After optimal voltages has been established, pressure was gradually increased. It has been found that counting rate is independent of pressure within 10%, while dark count rate exhibit dependence shown in Fig. 3, i.e. it stays as low as 1-2 counts/second at air pressures as high as 3 millitorr!

CONCLUSION

On the basis of these experiments, it may be concluded that the main pre-requisites for successful ion counting at high air pressures (up to 1-3 millitorrs) are:

- low electric fields in front of MCP,
- the use of a single MCP in the low-gain regime so that electron currents are as low as possible, however sufficient for the reliable conversion into photons.

The developed multiplier may be used for reducing pumping requirements in miniature mass spectrometers with atmospheric-pressure ion sources as well as in portable mass spectrometers for field applications.

The Direct Imaging of Ions Using a Charge Injection Device (CID) Detector

Steven J. Christopher, Mark A. Parker, and R. Kenneth Marcus

Department of Chemistry
Howard L. Hunter Laboratory
Clemson University
Clemson, SC 29634-1905

Over the last two decades there have been rapid advances in mass spectrometry. In recent years, the majority of research has focused on ion source development, sample introduction schemes, and their coupling to many different mass spectrometer systems, depending on whether a solid, liquid, or gaseous sample is to be analyzed. One particular area of mass spectrometry which has not been emphasized is that of detector technology. Current research in this laboratory is focused on the direct detection and spatial imaging of ions emanating from a radio frequency glow discharge ion source using a charge injection device (CID) detector.

Charge injection devices are two dimensional X-Y addressable silicon detectors that have been successfully employed for the detection of photons and for the imaging of electron beams and soft X-rays.[1] CIDs as ion detectors for MS may offer a number of potentially advantageous characteristics over other detector systems, specifically MCPs coupled to CCDs. This is because direct ion detection eliminates the need for ion beam conversion/transduction into a photon image. Also, the inherent non-destructive readout, antiblooming, and random pixel integration properties of CIDs are well suited to the imaging of ions. Irrelevant data can be ignored or an area of weak ion signal intensity can be enhanced with extended pixel integration. Since the CID is functional to atmospheric pressure, it also holds an advantage over channeltrons and electron multipliers. The push towards portable MS systems may be inhibited by these detectors which have stringent vacuum and high voltage requirements.

A vacuum system devoted to ion imaging has been constructed in-house at Clemson University. This system employs two ion optic configurations and ion images were acquired in the presence and absence of plasma photons. Preliminary MacSIMION trajectory

calculations have shown that ions strike the CID surface with a kinetic energy of approximately 30 eV.

Figure 1 below is a background subtracted ion image acquired after correcting for plasma photon and dark current contributions. The upper line spectrum was acquired with -100 V placed on a wire screen approximately 3 mm from the CID surface. Plasma photons and ion intensity are present in the -100 V image. The background image (middle line spectrum in Figure 1) was obtained while the wire screen potential was held at 0 V. Photon contribution and dark current are present in the image. Subtracting the background image from the -100 V image corrects for photon and dark current contribution simultaneously, revealing the ion intensity component of the signal.

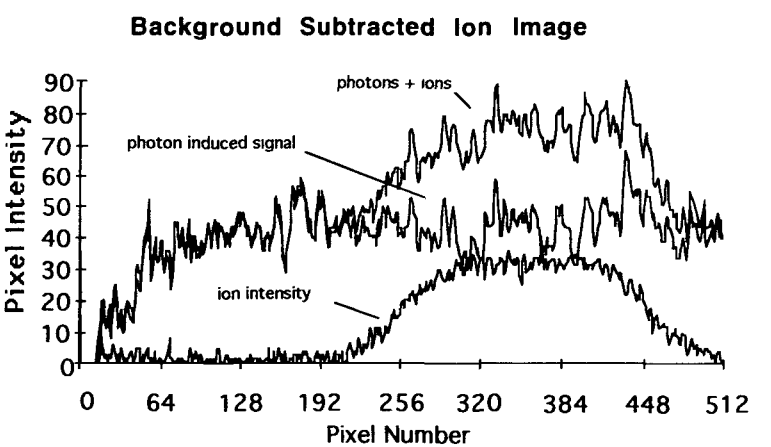

Figure 1. Background corrected ion image.

Development of a Hybrid Mass Spectrometer for Ion Investigations

U. Wilhelm, K. P. Aicher, M. Müller, J. Grotemeyer
Institut f. Phys. Chemie Marcusstr. 9-11, Universität Würzburg
97070 Würzburg, Germany

A hybrid mass spectrometer based on a quadrupole ion trap coupled with a reflectron time-of-flight mass spectrometer have been introduced recently. This hybrid instrument can be used widely for fundamental investigations of ions as well as for analytical purposes.

In this contrubution we demonstrate a new type of coupling of an ion trap with a reflectron- time-of-flight mass spectrometer. The system consists of three main stages: first a desorption chamber utilizing a supersonic jet together with gaseous or laser desorpted of neutrals, a hyperbolic ion trap and a reflectron-time-of-flight mass spectrometer with 1.2 m ion flight path. In our experiment the sample molecules are introduced as neutrals into the ion trap, where the ionization is done by a Nd:YAG pumped dye laser.

The main features of this instrument are long ion storage times, good ion optics in the coupling stage between both mass analysers and relatively high mass resolutions.

The mass resolving power of the hybrid instrument has been measured at Benzene to approximatly 1200. Details of the development and of the ion optics calculations will be shown. Experimental measurements demonstrate the ion storage time of small ions (i.e. Benzene). The storage time of ion masses in the trap can be extended up to 5 s and even longer.

The advantages of the electronic setup of the quadrupol ion trap (variable radio frequency, tunable endcap and ring electrode DC voltages) are presented and therefore the mass selectivity of the instrument is demonstrated (see figure 1). The mass limit of selecting only one ion mass for further storing in the ion trap goes up to about 80 Daltons. Hence the possibility of selecting and storing special ion mass ranges in the quadrupol ion trap will be possible up to a maximum mass of about 1600 Daltons.

Since we are interested in features like different ionization and fragmentation processes of neutrals and ions, a further feature of the instrument is the possibility of secondary activation of ions outside the ion trap. Here secondary activation of ions can easily be performed by induced photodissociation at the space focus of the drift region. The first results of photodissociation on Benzene are presented. The photodissociation was performed with an excimer laser running at 248 nm.

Using the reflectron-time-of-fligth mass spectrometer as an energy analysator there is the possibility to investigate the behaviour of metastable ions. First results on metastable ions are shown at Benzene. The mass resolution we reached in this experiment is about 100 Daltons.

For the desorption of neutral molecules an excimer laser running at 248 nm has been used.

Therefore first results on neutral desorped molecules are shown at Tryptophan.

Applying a jet system with subsequent ionization enables investigations about the trajectories of ions inside the trap (see figure 2). Therefore the reflectron-of-flight mass spectrometer is also handled as an energy analysator. Knowing the exact energy of the ions the starting position inside trap can be fixed.

A Penning Ion Source-Quistor-Quadrupole Mass Spectrometer for Ambient Air Analysis

M. Gaelli and U.P. Schlunegger
University of Berne, Department of Organic Chemistry, Freiestrasse 3,
CH-3012 Berne, Switzerland

Introduction

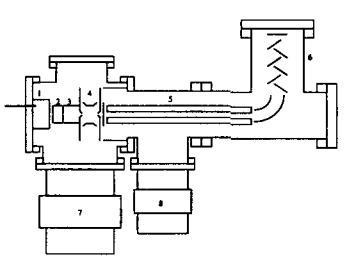
In the 1980's an Environmental Protection Law was passed in Switzerland. Amongst other things, it set maximum limits for organic and inorganic substances in ambient air and emissions. To monitor the observance of these limits an intensive measurement campaign was started. It covered primarily inorganic substances, namely nitrous oxide NO_2, sulfur oxide SO_2 and Ozone O_3.
In the past few years, ozone, the so called summer smog, proved to be the most important problem. As organic substances play an important part in the formation of ozone, a fast and easy method is wanted to monitor these substances.

Commercially available methods usually show drawbacks as

- low time resolution
- low selectivity
- size of the instrument

With this in mind, a new instrument was planned to avoid the problems mentioned above. It is based on an penning ion source [1] and allows accumulation of ions in a quistor.

Instrumentation



The instrument designed is shown in figure 1. The main parts are the inlet, the ion source, a transfer lens system, the quistor, the quadrupole mass filter and the detection system, a secondary electron multiplier (SEM). The system is differentially pumped at three stages.
Typical working pressures are about 5 mbar in the inlet, $4x10^{-4}$ mbar in the ion source /quistor compartment and 10^{-5} mbar in the analyzer compartment.

figure 1: the mass spectrometer. legend: 1 inlet, 2 ion source, 3 transfer lenses, 4 quistor, 5 quadrupole mass filter, 6 SEM, 7 turbo molecular pump, 8 molecular drag pump

The experiment

After ionization, the ions are stored for the desired time and then extracted towards the analyzer. After each extraction pulse, the mass value of the quadrupole mass filter is raised, normally by 0.2 Da. The acquisition is started at the extraction pulse and collecting data for 200 µs. Then a new sequence is started with another ionization pulse.
Pulse lengths are normally a 5 ms delay between extraction and ionization, 1 - 10 ms ionization, 100 - 500 ms storage and 100 µs extraction.

Discussion

Ionization time seems to have a very small influence on the signal intensity in the range investigated (1 - 1000 ms) whereas the signal varies rather strong with storage times. Substances show different "ideal" storage times. Acetone is most intensive after 50 ms, toluene after 500 ms storing.
The very small influence of ionization time displays the high ion yield of the penning ion source.

The spectrum of dichloromethane shows an interesting two-mass downwards shift of the molecular ion peak. As the dichloro-cluster still is visible, this must be due to loss of the two hydrogen atoms.

Applications of Filtered Noise Fields in Ion Trap Mass Spectrometry

Dane Karr, Don Hoekman, and Alice Koski

Teledyne Electronic Technologies, Mt. View, CA

We have described a new method of operation for the Paul ion trap in which a Filtered Noise Field (FNF™) is used to perform Selective Ion Isolation[1]. The FNF is a waveform that is applied to the end electrodes of the trap during, and for a short time after, the creation of ions within the trap (or the introduction of ions into the trap). The waveform ejects undesired ions as they are created so that ions of interest may be accumulated without creating a space-charge condition. Since the trap is filled with only the ions of interest, the original sensitivity of the trap is maintained. The utility of FNF for the ejection of unwanted background ions during a full scan run and for Selected Ion Monitoring (SIM) analyses of low level components in a complex matrix is demonstrated.

We have removed phthalate peaks from the background in the system by employing FNF with "inverse-notches" and we show raw data to display this effect. We have also performed a GC/MS analysis of hexachlorobenzene (HCB) and used "inverse-notch" FNF to selectively remove background ions below 100 m/z, plus 207 m/z from column bleed, plus 281 m/z from column bleed, consecutively. The data show ability of FNF to markedly reduce the baseline in the total ion chromatogram and reduce the number of interfering ions in the mass spectrum.

For SIM analyses, we have isolated characteristic ions of caffeine using a three-notch FNF waveform. We have performed a direct probe analysis of coffee, with and without FNF isolation of caffeine ions. The full scan EI analysis of coffee results in significant space-charging by the end of the run whereas the FNF analysis is able to prevent space-charging throughout the run by retaining only the ions at 194, 109, and 82 m/z.

An additional SIM analysis was carried out isolating major ions from safrole. Safrole was spiked into a base/neutral and organochlorine pesticide mix at 1:10 and 1:100 dilution. The SIM analyses on these mixtures was performed using a four-notch FNF waveform and is compared to the full scan EI run. The figure below is the total ion chromatogram for safrole at a 1 100 dilution (30 pg safrole in 3 ng/component mixture) and detected via FNF by isolation of ions at 162, 131, 104, and 77 m/z. The figure below is the total ion chromatogram for the FNF analysis of safrole at a 1:100 dilution and the corresponding mass spectrum.

DESIGN OF A HIGH FIELD FTICR FOR MALDI AND LD/CI STUDIES

Cynthia Pitsenberger, Paula Lei Qing, Michael Easterling, and I. Jonathan Amster
Department of Chemistry, University of Georgia, Athens, GA 30602

In 1989, an FT-ICR instrument was constructed in this laboratory for laser desorption studies. This instrument was designed primarily to examine the chemical ionization of laser-desorbed neutral peptide molecules, although it has subsequently been used for a number of other types of experiments. This instrument has a number of unique features which have proven useful for ion-molecule studies of laser-desorbed molecules. These features include (1) UHV vacuum with modest pumping. A 330 l/s turbomolecular pump provides a base pressure of 1×10^{-10} torr This low pressure permits reactive ions to be stored for several seconds, and allows ultrahigh resolution mass spectra to be recorded; (2) A two-stage solids sample introduction system to permit laser desorption studies of peptides under ultrahigh vacuum (10^{-10} - 10^{-9} torr); (3) Rapid response to the pulsed introduction of gases. Peak pressures of 10^{-4} torr can be achieved within 120 ms after the pulsed introduction of a gas, and the pressure is found to return to 10^{-9} torr or less within five seconds; (4) Dual laser ports for experiments that require two independent laser beams. This instrument has been used for a variety of experiments, such as chemical ionization of laser desorbed neutral molecules up to 1200 Daltons, MALDI of peptides up to 2000 Daltons, photodissociation and CAD studies of peptides, ion-molecule studies of peptides and amino acids, and measurements of their gas-phase basicities, and quadrupolar axialization and ion remeasurement studies of molecules up to 1200 Daltons. The principle drawback to this instrument has been its 1 tesla electromagnet. This low magnetic field strength leads to several limitations, such as a **low mass range** (the upper mass limit is 2000 Daltons); **rapid radial diffusion** of the ions from the cell at elevated pressures because of the low ratio of B/E (magnetic field to trapping voltage); **poor mass accuracy** at higher m/z values; coupling of the ion motion of closely spaced peaks, resulting in **poor isotope ratios**. Despite these limitations, this instrument has made a significant contribution in demonstrating several new techniques for peptide analysis, albeit with small, model peptides.

We have undertaken the redesign of this instrument to extend the mass range to 50 kDa or more, to apply the techniques that have been developed in this laboratory to biologically significant peptides and proteins. The new design seeks to incorporate many of the desirable features of the original instrument, while adding new high performance capabilities. Figure 1 shows an overhead view of the layout of the redesigned vacuum system. The new instrument has been designed to incorporate a shielded 4.7 tesla superconducting magnet with a 160 mm horizontal warm bore. The 4.7 tesla magnet will extend the mass range of this instrument by approximately a factor of 25, i.e. from m/z 2000 to m/z 50,000. This will permit techniques that we have demonstrated with small, model peptides to be applied to peptides and proteins of biological interest. The shielded magnet allows the turbomolecular pump, pulsed valves, ion gauge, and other integral parts of the vacuum system, to be operated within two feet of the open bore of the magnet. The new cell geometry is a open-ended cylindrical design, with capacitive coupling between the excitation plates and two quadrants of the trapping plates. This design, proposed and implemented by Laude and coworkers, has been shown to reduce the z-axis ejection of ions. The system for introducing solid samples for laser desorption and the design of the laser

optics has been improved. The new design maintains the capability to perform MALDI next to the analyzer cell while preserving ultrahigh vacuum conditions. A sample stub is transferred between the two linear motion sample manipulators outside of the magnetic field of the instrument. A linear motion feedthrough that is attached to the pump down chamber transfers the sample to a linear-rotary manipulator that is part of the ultrahigh vacuum main chamber. The linear-rotary manipulator is used to position the sample near the analyzer cell. Rotation of this manipulator allows different portions of the probe to be brought under the focus of the laser beam. A DC motor controls the rotary position of the manipulator, which can be placed under computer control. A video camera with telescopic optics can be mounted at the end of the main vacuum chamber, to allow the sample to be observed during laser desorption. An internal preamplifier that is mounted next to the analyzer cell, inside the vacuum system has been designed for this instrument by IonSpec. The internal preamplifier has been shown by McIver and Hunter to reduce the effects of distributed capacitance that decrease signal intensity and bandwidth. Quadrupolar excitation capabilities present with the original design have been retained in the new instrument. Two plate quadrupolar excitation, introduced by Laude and coworkers, is implemented in the new design. This allows the detector leads to remain static when switching between quadrupolar and dipolar excitation, and permits implementation of an internal preamplifier. Quadrupolar excitation capabilities present with the original design have been retained in the new instrument Data that illustrates the capabilities of the new instrument will be posted as it becomes available on the Amster home page of the World Wide Web. Come visit our laboratory at **http://amstersgi.chem.uga.edu/**.

We thank our FTICR colleagues for many of the ideas that have been implemented in this design. In particular, we acknowledge Alan Marshall, Robert McIver, David Laude, and Fred McLafferty. The generous support of the National Science Foundation (CHE-9412334) is gratefully acknowledged

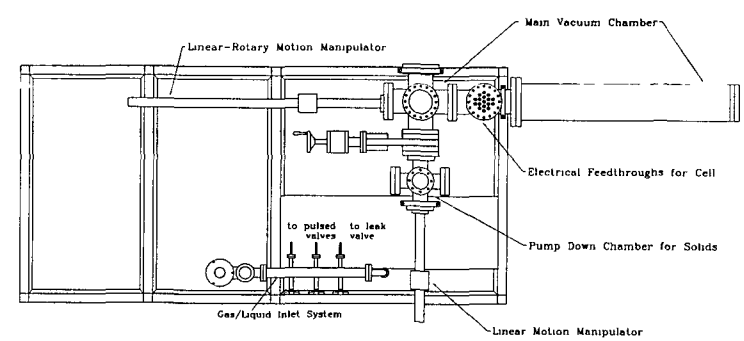

Figure 1. Overhead View of the Redesigned 4.7 Tesla FTICR

Design and Construction of an External Source Fourier Transform Mass Spectrometry Instrument

James A Carroll, Jiangyue Wu, Steven T. Fannin, Sharron Penn, and Carlito B. Lebrilla
University of California, Davis, Department of Chemistry, Davis, California 95616

The design and construction of an external source Fourier trasnform mass spectrometry (FTMS) instrument is described. The cost of the instrument was minimized by using only two stages of pumping and smaller vacuum components than previous designs Differential pumping is provided by a 190 L/s turbomolecular pump, which evacuates the source region, and a 2000 L/s cryogenic pump, which evacuates the analyzer region. Previous designs of FTMS instruments using external ionization sources typically used at least three stages of pumping.

The instrument is designed so that ionization sources can be exchanged quickly and easily. Electron impact (EI), secondary ion mass spectrometry (SIMS), matrix assisted laser desorption/ionization (MALDI), or electrospray ionization (ESI), sources can be coupled to the instrument simply by replacing the front flange of the source cube. The ions are transported from the source to the ion cyclotron resonance (ICR) cell by a single stage RF-only quadrupole ion guide, which focuses the ions through the fringing field of the magnet. The quadrupole rods are 0.78 m in length, which is shorter than previous instrument designs using a single stage quadrupole ion injection system. The ion tranmission efficiency through the rods was estimated to be about 50%, which compares well to the effieciency of similar instruments.

The ICR cell (2x2x4") is located in the homogeneous region of a 3 T superconducting magnet, which is shared with another instrument previously built in our laboratory. Sharing the magnet as well as the external circuitry and data system lead to a significant reduction is cost relative to construction of a separate instrument. Both instruments are secured on carts with wheels. When one instrument is not in use, the other can be rolled into place in the opposite bore of the magnet. This dual chamber design allows the original instrument in our laboratory, which has three stages of pumping, to be dedicated to electrospray ionization. ESI requires the higher pumping capacity of this instrument for adequate performance.

The new vacuum chamber is used mainly for MALDI, although LSIMS can be performed with the same source. Switching between the two ionization techniques requires no hardware modifications, so vacuum does not have to be broken. Simply using the appropriate sample preparation and rotating the sample probe 90° allows access for a laser beam to irradiate the sample for MALDI. The Omega data system (IonSpec. Corp., Irvine, CA) controls the experimental sequence and data processing. A schematic of the instrument is shown in Figure 1.

The performance of the instrument was evaluated using EI, SIMS, and MALDI ionization methods. The mass range is typical of a 3 T instrument. Cluster ions with mass-to-charge ratios up to about 9000 have been detected using SIMS ionization of CsI. Liquid SIMS of orgainc molecules such as oligopeptides and oligosaccharides showed results comparable to those from the original instrument in our laboratory Neither the reduced pumping capacity nor the shorter quadrupole rods have significantly decreased the performance of the instrument for LSIMS ionization.

MALDI performed in the external source provided excellent sensitivity for organic molecules. Figure 2 shows the MALDI Fourier transform mass spectrum of per-O-methyl β-cyclodextrin, which shows a strong signal corresponding to the sodium adduct at m/z 1451 and a signal corresponding to the potassium adduct at m/z 1467. The performance and versatility of the instrument make it a useful tool for the analysis of biological molecules.

In-Cylindrical-Cell MALDI with FT ICR Spectrometer

M.Knobeler, K P.Wanczek, F H Laukien*
Institute of Inorganic and Physical Chemistry, University, D-28334 Bremen, Germany
*Bruker Analytical Systems Inc., Billerica, MA 01821

The interest in the coupling of matrix assisted laser desorption/ionization (MALDI) and a Fourier transform ion cyclotron resonance (FT ICR) mass spectrometer increased in recent years. Several groups introduced different dual cell or near analyzer cell [1,2,3,4] and external [5,6] ionization techniques to take advantage of the features of MALDI and FT ICR. New methods as a gated deceleration potential at the rear trapping plate [1], ion cooling by pulsed gas inlet and axialization by quadrupolar excitation (QE) [2] and remeasurements of the ions [7] were introduced. Our new internal MALDI FT ICR instrument is a very direct method to produce the ions inside the cylindrical analyzer ICR cell.

The experiments were carried out with a modified Bruker CMS-47 spectrometer provided with a 7 T magnet, a pulsed nitrogen laser (337 1nm, 200µJ/pulse) and with one of our six homebuilt moveable vacuum systems This system is equipped with a special push rod system that allows to pump down to a pressure of 1 10^-8mbar in less than 3 min after introducing the sample into the vacuum system.

The target at the probe tip can directly be adjusted to the front trapping grid of the ICR cell. The target is electrically connected to the front grid and becomes a part of it. The center of the target is slight disaligned against the center of the front grid. During experiments the push rod has only to be rotated to hit with the laser different spots at the target.

Different matrices were used The best results were achieved with DHB in isopropanol/water with or without coadded fructose Concentrations of samples were 10^-4M to 10^-7M. 0.1µl to 10µl of the solutions was applied onto the target.

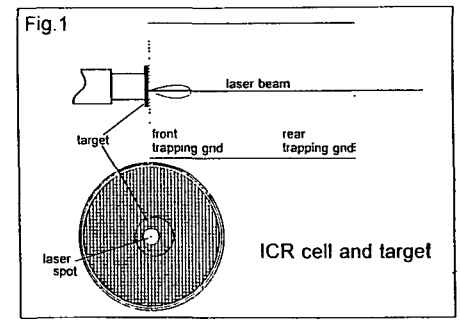
Ions with masses up to 2000 amu could be trapped without gated deceleration potential by asymmetrical trapping potential Spectra with resolved isotopes were achieved. This easier of use technique fulfills most of the requirements to analyze masses up to 2000 amu.

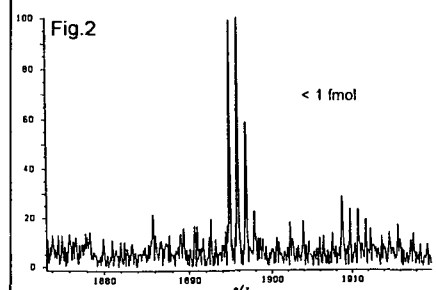
Trapping times up to 30s are achieved for bovine insulin at a background pressure of 1 10^-8mbar without any ion cooling technique.

Bovine insulin was detected at a permanent background pressure of 1 10-^3mbar and 1 10^-5mbar with a resolution of 60 and 450, respectively Spectra of melittin with a resolution of 4,500 at 1 10^-6mbar were achieved

Resolutions better than 50,000 and sensitivities of less than 1fmol were obtained without pulsed inlet of collision gas or quadrupolar excitation. Sensitivities of 10-100fmol and resolutions better than 10,000 were routinely achieved with masses up to 3,000 amu.

The target as a part of the front trapping grid enables a very efficient trapping of the produced ions including long trapping time, high sensitivity and high resolution. Essential are very carefully balanced deceleration voltage and time and trapping voltages at the front and rear grid. Nevertheless, techniques as axialization including remeasurements of one time generated ions should increase the sensitivity and resolution at least by one or two orders of magnitude.





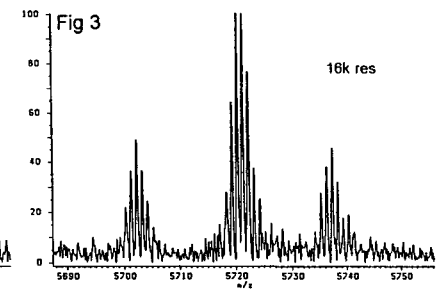


Figure 1: The cylindrical ICR cell. The target becomes a part of the front trapping grid.
Figure 2: Spectrum of gramicidin D after single scan. Less than 1 fmol was consumed. Over 100 comparable spectra were obtained with the 100fmol of sample applied onto the target.
Figure 3: Spectrum with 16,000 resolution of bovine insulin after single scan No ion cooling techniques as pulsed inlet of collision gas or quadrupolar excitation were used.

AN ELECTROSTATIC ION GUIDE INTERFACE FOR ELECTROSPRAY FTMS

Liang Tang, Michelle V. Buchanan, Robert L. Hettich and Gregory B. Hurst
Chemical and Analytical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6365

Introduction

The combination of electrospray (ES) technique with Fourier transform ion cyclotron resonance mass spectrometry (FTICR MS or simply FTMS) has distinct advantages for the analysis of biomolecules, including high analysis speed, high resolution and wide mass range. This report is the first demonstration of combining ES with FTMS using an electrostatic ion guide (EIG). Our approach to the combination of ES and FTMS is designing and constructing a perforated EIG, which is contained in a differentially pumped vacuum housing, to facilitate magnetic fringe field penetration, and establishing conditions for efficient trapping and detecting the ions in a cubic cell.

Experimental

A prototype instrument for coupling an electrospray ion source to FTMS is illustrated in Figure 1. The sample flow rate was typically 5 μL/min and the voltage on the ES tip (2) was 3 kV. A stainless steel capillary tubing (4) wrapped with a heating tape was used for the desolvation of the ES produced ion clusters. A skimmer (5) is opposite to the heated tubing to separate the first pumping stage from the higher vacuum region. The voltage on the skimmer may be varied from 0 to ±120 V, whereas the voltage on the heated tubing is held at ~100 V higher (i.e., more positive or more negative) than the skimmer. A specially designed ion guide was located 33 cm away from the skimmer. The ion guide consists of a stainless steel cylinder (6) and a central wire (7). The cylinder is 5-cm in ID and 75.9 cm in length. The first section of the cylinder (37.5-cm long) was perforated. The central wire (Nichrome) is 0.25 mm in diameter, and is attached to the cylinder. Two stainless steel electrodes were located at both ends of the ion guide. The typical voltages on the ion guide and two electrodes are 5V (cylinder), -15V (wire), 5V (front electrode) and 0V (rear electrode). The FTMS instrument is Nicolet 2000 (Extrel FTMS, Madison) with a 3T magnet. The pressures in the various regions are indicated in Figure 1.

Biochemicals were purchased from Sigma Chemical Co. (St. Louis, MO) and used as received. Protein and peptide solutions were made by dissolving the analyte in HPLC grade methanol. Acetic acid was added to the solutions, as noted in the figure captions. An aqueous solution of 2'-deoxycytidinyl-(3'-5')-2'-deoxyadenosine (dCA) was diluted in methanol [MeOH:H2O=99:1 (v/v)].

Results and Discussion

Marshall and his co-workers [1, 2] demonstrated that the transportation of externally produced ions from a rf glow discharge or thermionic source into an FTICR cell can be achieved by EIG, which can also be used in time-of-flight mass analyzer [3]. The characteristics of EIG include a wide acceptance angle for the externally produced ions, ion focus along the magnetic field lines, low cost in construction and high efficiency in operation. The features prompted us to investigate the use of an EIG for coupling ES with FTMS.

The novel ES-FTMS interface has shown efficacy in the analysis of biomolecules. Using static trapping plate accumulation, ions could be trapped with voltages as low as ±0.5 V (~0.2 seconds). It can be operated in both positive ion mode and negative ion mode, and has been evaluated with a number of peptides, proteins, and nucleic acid materials. The mass spectra of myoglobin and dCA are shown in Figure 2 and Figure 3.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Conclusions

We demonstrated the utility of using a single perforated EIG to introduce ions from an external ES source into FTMS. The interface requires only DC power supplies and can be installed on conventional FTMS instruments with relatively low cost. Ions could be detected without a pulse of buffer gas. The success with this EIG system has encouraged us to modify the interface to optimize ES-FTMS performance.

Interchangeable Electrospray Interface for the Study of Biomolecules using FTMS

M. Kirk Green, Eric Gard, Elvira Camara, Sharron G. Penn and Carlito B. Lebrilla
UC Davis, Davis CA 95616

A versatile, interchangeable electrospray interface has been constructed and installed on an external source quadrupole FTMS. This interface is readily interchangeable with FAB and MALDI sources, with the main requirement being the pump-down time. A heated capillary[1], two skimmers and a set of Einzel lenses are used to deliver ions to the RF-only quadrupole ion guide. Five stages of pumping are employed, using mechanical, turbo and cryopumps. A selenoid-driven shutter on the final lens blocks neutrals after injection of the ion packet.

Kinetic energy distributions of injected biomolecular ions were investigated. For large (10^4-10^5 Da), highly charged species, the kinetic energies were quite favourable to trapping, with sharp peaks at less than 10 eV. Thus lysozyme, for example, gives signals with high S/N using an ion injection tiime of 250 ms. The spectra obtained to date illustrate the ability of the instrument to handle biomolecules ranging from bradykinin (1060 Da) to bovine serum albumin (66,400 Da).

The ability of ESI to produce large gas-phase ions has allowed us to extend our studies of gas-phase H/D exchange of amino acids and peptides[2,3] to larger peptides and proteins, and to multiply-charged species. We have examined the kinetics of exchange for the different charge states of a series of bradykinin analogues and for the proteins lysozyme and cytochrome c reacting with CH_3OD. For the bradykinin analogues, apparent rate constants have been determined. Rates for singly charged species varied from $<10^{-14}$ to 2×10^{-12} cm^3 $molecule^{-1}$ sec^{-1} The rates for the doubly charged ions were always faster than for the corresponding singly-charged species, and fell in the range 6×10^{-14} to 1×10^{-11} cm^3 $molecule^{-1}$ sec^{-1}. The trends in rate constants can be explained in terms of the nature of the specific protonation sites in these peptides. For example, both charge states of bradykinin exchange slowly because the protonation sites are arginines, whose proton affinity is so high that exchange with CH_3OD is unfavourable. In Lys-1-bradykinin, the second protonation site is lysine, which exchanges rapidly[2,3], rendering the doubly-charged species relatively reactive.

Lysozyme undergoes H/D exchange at a much slower rate than cytochrome c. This is probably due to the large number (11) of highly basic arginine residues in lysozyme, which bind the protons so tightly that exchange with the deuterating reagent is strongly inhibited

High-Field Electrospray FT-ICR Mass Spectrometer for Biopolymer Analysis

Ljiljana Paša-Tolić, Jarrod A. Marto, Michael W. Senko, Christopher L. Hendrickson, Forest M. White, Shenheng Guan,* and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State University, 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

* Department of Chemistry, Florida State University

Here we describe the design, construction, and characterization of a new high-field electrospray-ionization FT-ICR mass spectrometer. This instrument, shown schematically in Fig. 1, consists of a modified Vestec ESI source, a homebuilt two-section octupole ion guide, and a high-performance FT-ICR mass analyzer. The dual ion trap is housed within a 6"-diameter horizontal-bore, 6 T magnet (Oxford Instruments, Ltd.). An Odyssey data station Extrel Waters FTMS) is used for collection and analysis of the data. A completely modular differentially pumped vacuum system accomodates the high gas load of the ESI source (1 atm) and ultra-low pressure required for high performance ICR detection ($\leq 1 \times 10^{-9}$ torr).

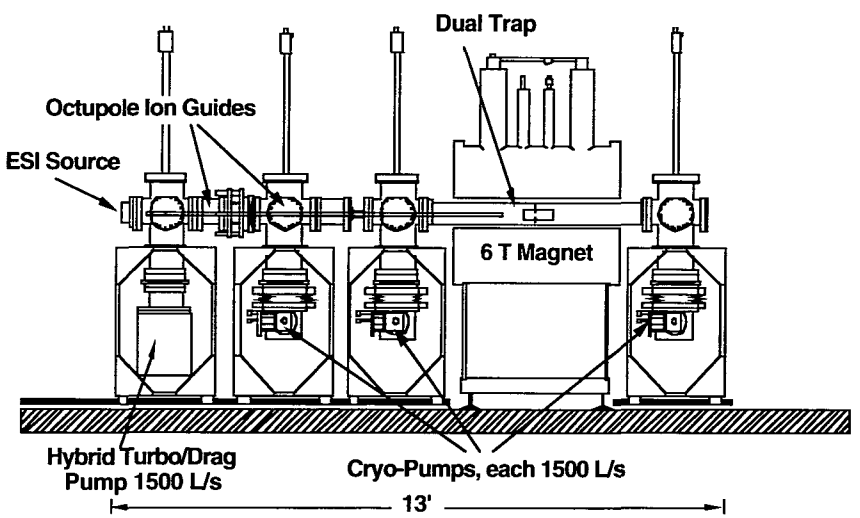

Figure 1. Schematic diagram of NHMFL external source ESI FT-ICR mass spectrometer.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

The system described here is a prototype for a higher performance instrument built around an 8"-diameter horizontal-bore 9.4 T shielded magnet, which will be the highest field FT-ICR magnet in the world, and should demonstarte improved mass resolving power and mass accuracy (which scale as B), upper mass limit (which scales as B^2), maximum ion storage period (which scales as B^2), and other operating advantages. Our design offers two qualitative improvements relative to the currently available instruments: i) novel off-axis ion injection that provides for efficient trapping of a continuously-injected beam of ions having a large m/z and wide distribution in kinetic energy, and ii) simultaneous ion trapping and analysis, exploiting the dual trap for improved duty cycle.

We have characterized the ESI source ion kinetic energy distribution and transmission through the octupole guides. Figure 2 , left, is a mass spectrum collected in the source-side ion trap. After quadrupolar excitation to squeeze the ions to the central axis of the solenoidal magnet, the potential on the conductance limit trap plate was lowered to 0 V, and the ions were transferred to the low-pressure, high-resolution analyzer side of the dual ion trap. Broadband dipolar excitation and detection gave a time domain transient, which, when Fourier transformed and displayed in magnitude mode, demonstrates isotopic resolution of the +4 charge state of the insulin molecular ion (Fig. 2, right). This work was supported by NSF CHE-94-13008, NIH (GM-31683) and the National High Magnetic Field Lab at Florida State U.

The Design and Performance of an In-Field ESI-FTICR Instrument

Qinyuan Wu, Harold R. Udseth, Gordon A. Anderson,, Michael G. Sherman, Steven Van Orden, Ruidan Chen, Steven A. Hofstadler, Dale W. Michell, Alan L. Rockwood and Richard D. Smith*
Pacific Northwest Laboratory, Richland, WA 99352

The coupling of electrospray ionization (ESI) with Fourier Transform Ion Cyclotron Resonance mass spectrometry (FTICR-MS) has been shown to be a promising tool for biological research. Most of the current schemes of combining ESI with FTICR involve forming ions outside the magnet and injecting into the magnetic field through either radio frequency ion guides or electrostatic lenses. Substantial ion losses occur during ion transportation for such external source ESI-FTICR, offsetting the high sensitivity in detection. Alternatively, ESI can be performed inside the magnet bore to significantly increase ion current in the cell [1]. However, such an in-field ESI scheme requires critical differential pumping and ion optics design to maintain ultra-high vacuum in the cell region in order to achieve resolution similar to that obtained from external source scheme.

In our in-field ESI-FTICR instrument (Fig. 1), a home-made ESI probe is inserted into a superconductor magnet (max. 4.7 T, but presently at 1 T) so that electrospray generated ions are confined by the magnetic field and are injected into the ICR cell located 20 cm from the ESI source. The system is equipped with five stages of differential pumping and the base pressure in the ICR cell region is 8×10^{-10} Torr. Injection of ions into the cell is controlled by an in-field shutter which also serves to maintain the ICR cell in ultrahigh vacuum when ESI probe is inserted. The ESI probe can be moved in x-y-z directions, allowing the relative positions of the spray needle to the heated capillary and the capillary to the first skimmer to be independently adjusted. Another feature of this system is that the magnet bore is 11" in diameter (with room-temperature shim) which allows cryo-panels to be inserted and a large 4" cubic ICR cell to be used. This design will also allow us to explore the use of other large and more complex cells to increase the size of the trapped ion population and the dynamic range, particularly in conjunction with the in-field ESI source.

In initial studies, we have obtained 2×10^6 resolving power (>12.5 sec transient) for N_2^+ ions generated by an electron impact source near the cell. Preliminary results show that the measured ESI ion current in the ICR cell increases by at least a factor of 10 when electrosprayed in the 1 T magnetic field. Fig. 2 shows spectra obtained for bovine ubiquitin (M.W.= 8565 Da) under a pressure of about 10^{-7} Torr. As the temperature on the inlet capillary increased (Fig. 2B), higher charge state ions were preferentially dissociated--a process referred to as thermally induced dissociation, or TID. More experiments are underway to optimize the performance of the system.

Performance of an External Cluster Ion Source and Electrostatic Ion Guide

Anthony M. DeSantolo, Mary L. Mandich, and William D. Reents Jr.
AT&T Bell Laboratories, 600 Mountain Ave., Murray Hill, NJ 07974

We have designed and constructed an instrument that produces cluster ions in an external source and transports them via an electrostatic ion guide to the FTICR cell of a 5 3T split-pair magnet A schematic of the cluster source and ion guide is shown in figure 1 Clusters are formed in the source by condensation of the elemental material of interest in a cooling gas The cluster source is a stainless steel block in which a 1/4" diameter target rod is positioned at the side of a channel through which flows 5-25 Torr of helium carrier gas at a rate of 100-500 sccm As the rod rotates and translates in the source, material is ablated off the rod and into the helium flow using the focused output of a XeCl excimer laser (308 nm, 12 nsec pulse width, 160mJ) A 500 mm focal length lens focuses the laser to a ~ 1 x 3 mm oval spot at the elemental target rod At these power densities, the laser creates a plasma above the surface of the rod that contains ionic and neutral species from the target plus electrons and ionized carrier gas species Clusters are formed by bimolecular association of neutral atoms and molecules with both charged and neutral atoms and molecules in the region of the source between the target rod and nozzle exit In the present source configuration, the growing clusters spend ~700μs in the source which allows for tens of thousands of cooling collisions with the helium carrier gas. In addition, the helium gas can be doped with various molecular reagents leading to the formation of multi-component clusters Although the initial plasma created by the laser creates a sufficient number of ionized clusters for detection, further ionization can be accomplished using the output of an electron gun positioned behind the source The clusters and carrier gas exit the source via a conical nozzle (1 mm diameter) into a vacuum of ~10^{-4} Torr Here, the clusters and carrier gas undergo a supersonic expansion and are translationally cooled to ~30K At this point, cluster growth stops and the particle size distribution becomes "frozen"

The high pressure operation of the source requires multiple stages of differential pumping to achieve the high vacuum required for FTMS, while at the same time high cluster ion densities are desired

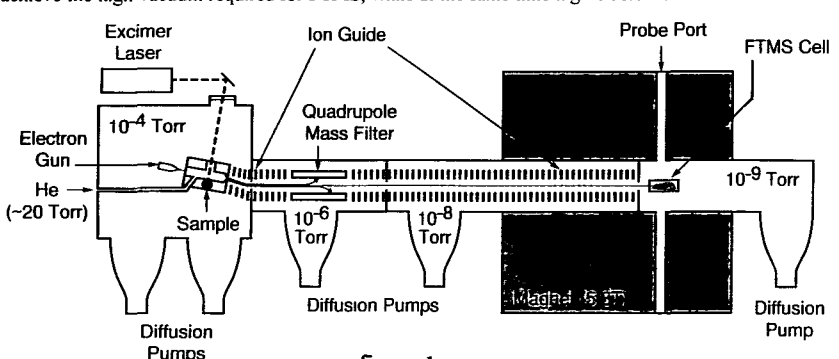

figure 1.

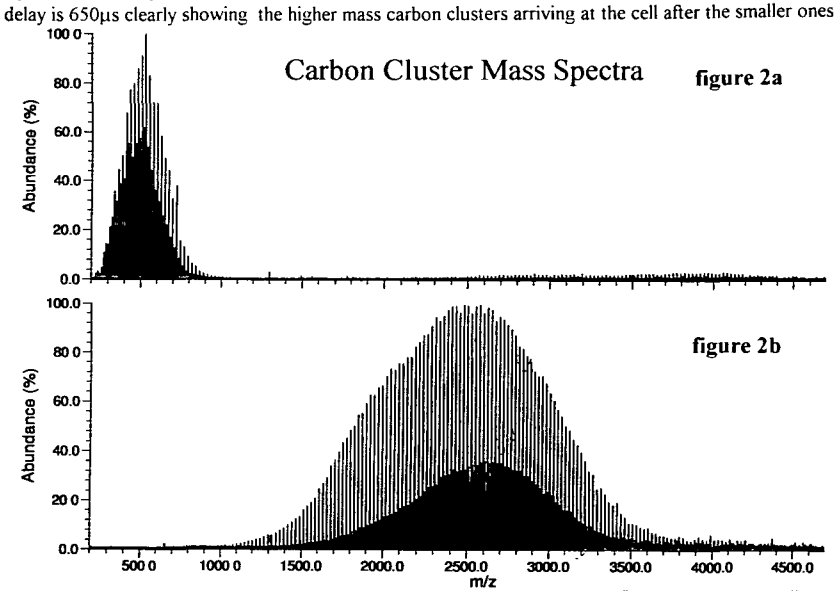
in the trapped ion cell We designed and built our own ion guide based on optimized ion trajectories. The design incorporates ion extraction, focusing, X/Y steering, and an exponential deceleration field to maximize ion throughput from the source, through the three variable(4-8mm) conductance limits separating four stages of differential pumping, to the trapped ion cell After exiting the source, the cluster ions drift for ~1cm at the source potential(+5V to +20V) after which they are accelerated(-100V to -1000V), focused, and steered through the first differential pumping aperture The cluster ions are refocused and steered (if necessary) through each conductance limit. After traversing the length of the ion guide(~2meters), the ions are retarded by an exponential deceleration lens to near thermal velocities and finally focused into the trapped ion cell The ion guide can incorporate a quadrupole mass filter for selecting out a portion of the mass distribution but it has not been used for the results described here Under typical operating conditions, the positive ion current from the source is ~500pA/laser pulse, about 15pA makes it to the trapping cell giving a transmission of ~3% for the entire system Further enhancement of the ion throughput, particularly for the higher mass ions, can be realized by increasing the ion guide voltage. Doubling the field from -500V to -1000V increases the number of C_{200}^+ ions reaching the cell a factor of 2 and the number of C_{288}^+ ions a factor of 4 However, no enhancement is observed for the lower mass clusters

Cluster ions arrive in a 300 - 5000μs wide pulse and are selectively loaded into cell by lowering the potential of the trapping plate nearest the ion guide for ~300μs. This gating sequence is synchronized to the output of the ablation laser Figures 2a and 2b show the positive ion mass spectra obtained from a carbon target rod, with 9 Torr helium in the source, +15V source bias, and a -950V field free voltage In figure 2a the delay between the laser pulse and the gating sequence is 150μs whereas in figure 2b the delay is 650μs clearly showing the higher mass carbon clusters arriving at the cell after the smaller ones



Construction of an ICP/FT-ICR Mass Spectrometer

Eric Milgram,* Cliff Watson, John Eyler
Department of Chemistry, University of Florida, Gainesville, FL 32611-7200

Introduction

Inductively coupled plasma mass spectrometry (ICP/MS) is a powerful technique for elemental analysis. The benefits of this technique include high sensitivity, wide linear dynamic range, relatively simple spectra, and isotopic information The vast majority of ICP/MS instruments are equipped with a quadrupole mass filter which offers a mass resolution no better than about 2,000 This severely limits most analyses due to the isotope of interest having the same nominal mass as a neighboring isotope, or some plasma by product Methods of dealing with this limitation have included chemical separation,[1] principle components analysis,[2] or more commonly, monitoring another isotope, often of much lower abundance. We are proposing construction of an ICP source for use with our Bruker BioApex 70e Fourier transform mass spectrometer If successful, it would be possible to routinely perform analyses that are inconceivable with existing instruments

Source Design

We opted to modify an existing commercial electrospray ionization (ESI) source design instead of designing an entirely new source This was done for several reasons·

1) existing design incorporates differential pumping
2) design and machining time greatly reduced
3) design will be easily adapted by other users with similar ESI sources

A torch support consisting of Delrin and Teflon was constructed to hold and translate the torch in three dimensions A water cooled heat shield/skimmer was designed to cover and protect the atmospheric pressure side of the ESI capillary Figure 1 illustrates a cut away view of the ESI source housing, capillary, and heat shield/skimmer showing insertion of torch support Upon successful completion of our initial studies, we plan to incorporate a quadrupole mass filter into our source to increase sensitivity and improve linear dynamic range if needed

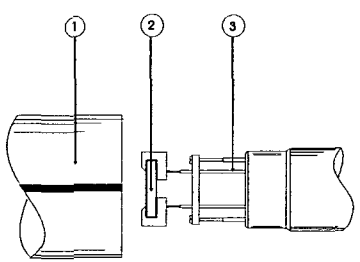
Characterisation of a Novel Ion-Emitter for FT-ICR

Iris Spiess[1], Imke Mass[1], Bernd Görtler[1], Albrecht Glasmachers[2] and Karl Peter Wanczek[1]
1 University of Bremen, Institut of Inorganic and Physical Chemistry, D-28334 Bremen, Germany
2 Ruhr University, D-44780 Bochum, Germany

Introduction :
For generation of ions from samples of low volatility and stability a variety of soft ionization methods are employd. The great advantage of these ionization methods is that samples of low stability like biological molecules and involatile organic and inorganic molecules can be ionized without destruction. A new improved electric pulse induced desorption EPID ionization method is presented. The multi-layer ion emitter of a high net heat capacity of EPID type is characterized by studying fragmentation of anthracene, 18-crown-6, 15-crown-5 with alkali metal and boron nitride.

Experimental:
A push rod of 900 mm length and 22.5 mm diameter is used to place the sample in front of the center of a ***screened ICR cell.*** Alternatively an ICR cell with ***open geomety*** is employed to inject the ions more directly in the center. The emitter is a thin aluminium filament deposited on a plate which also contains the two electrical connections. A short current pulse of 2 ns duration is produced by the discharge of a capacitor. Because of the high heat capacity of the emitter we exclude the possibility of a thermal ionization. In the present study boron nitride, anthracene and crown ethers were used to characterize the fragmentation behavior of the emitter. Anthracene is ionized by EPID and by simultaneous electron impact ionization with an electron energy of 50 eV. The spectra of 15-crown-5 and 18-crown-6 are recorded by emitter ionization and at 70 eV electron energy. The chemistry of the pure crown ethers and the reaction of 15-crown-5 with potassium and cesium ions is studied. Boron nitride is ionized with the new ion emitter. For the study solutions of $1x10^{-4}$ mol/l of anthracene in benzene and of 15-crown-5 and 18-crown-6 in water are prepared and a micro drop is fixed with a microsyringe on the aluminium filament. A dispersion of boron nitride in water is prepared in a ultrasonic bath and also fixed on the aluminium filament. The solvent is vaporized before introduction of the probe in the UHV system.



1 ICR cell

2 emitter

3 electrical feedthrough

Fig.1: *Arrangement of the ICR cell and the probe rod*

The investigation is performed with a Bruker Spectrospin FT-ICR spectrometer equipped with a superconducting magnet of 7.02 T. The control of the experiment and excitation/detection is performed by the Aspect 3000.

Results and discussion:
Anthracene
Figure 2 shows an ICR spectrum of anthracene ionized with the emitter. The only fragmentation that occurs is m/e=152,$C_{12}H_8^+$. The ion m/e=178, the molecular ion, is the most abundant ion. The peaks are compared with an ICR spectrum of anthracene ionized with the emitter and an electron energy of 50 eV. There are more fragment ions because of the high energy of the electrons. By electron impact, additional ions are formed from the neutral molecules also generated from the Epid emitter. Additional electron impact ionization increases the intensity of the molecular ion, m/e=178, by a factor of approximately two.
We used an ICR cell with open geometry to demonstrate the simultaneous trapping of positive and negative ions in combination with the EPID ionization technique. We acquired a spectrum of anthracene introduced by the emitter and methyl iodide.

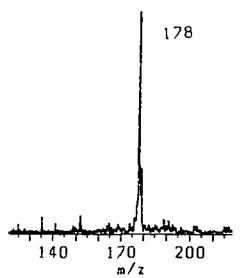


Fig.2: *ICR spectrum ionized with the emitter*

18crown-6 and 15-crown-5
Under our experimental conditions the protonated crown ether is a high abundant ion, due to proton transfer reactions, and not the molecular ion. Further on the experimental conditions do not allow to observe a signal with electron impact ionization only.
We also investigated the ion chemistry of 15-crown-5 with potassium and cesium ions.

Boron nitride
Boron nitride has a melting point of 3270 ^{o} C. With the new ionization method we obtained ICR spectra. The following cluster are detected: $B_{29}N_{29}$, $B_{33}N_{33}$. R.D. Barde et al predicted the bonnynall $B_{24}N_{36}$. We observe $B_{25}N_{37}$ and $B_{24}N_{38}$. In references there exist several theoretical concepts.

Fluorescence and Absorption Spectra of Mass-Selected Trapped Ions

George Jackson,* Yulin Huang, Shenheng Guan,*
Hyun Sik Kim, and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State University, 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

* Department of Chemistry, Florida State University

Ion structure and bonding has conventionally been inferred indirectly from measurements of ion mass and abundance following ion activation by photons or by ion-neutral collisions. Here we present the design and preliminary performance of an instrument designed for direct detection of uv/vis fluorescence and absorption spectra of mass-selected trapped ions. Figure 1 is a schematic representation of the experimental setup. Ions are generated by an off-axis electron beam, followed by azimuthal quadrupolar excitation and collisions with neutral gas to cool the ions and squeeze them toward the central axis of a 7 tesla magnet. Ions of interest are mass-selected and confined in a series of two coaxial open-ended cylindrical ICR ion traps. An excitation laser beam is introduced along the axis of the magnet through Brewster-angle windows located at each end of the vacuum chamber. The arm which contains the Brewster-angle window consists of a Woods horn to deflect scattered excitation laser light from the window and a series of baffles. Laser-induced fluorescence is conducted in a cylindrical mesh-walled trap. A pair of concave mirrors (one spherical and the other ellipsoidal) is mounted outside the mesh to focus fluorescence to the small opening located in the center of one of the mirrors (Figure 2). The fluorescence is then collected perpendicular to the Nd:YAG-pumped dye laser excitation beam by a mirror and prism assembly, and routed through a fiber-optic waveguide feedthrough to a photomultiplier detector located outside the vacuum chamber. The wavelength-dependent signal may be stored in a personal computer for later analysis.

Optical absorption will be detected by a recently developed highly sensitive cavity ringdown method. Highly reflective (99.999%) concave mirrors mounted on each end of the vacuum chamber serve as an optical cavity to trap photons. The ratio of the time constants for exponential decay of the photon leakage from the other end following an initial laser pulse in the absence and presence of absorber is a direct measure of I/I_0 in a Beer-Lambert law. An absorption spectrum is obtained by computer-controlled stepwise scanning of the incident photon wavelength. We shall attempt to measure the direct optical absorption spectrum of ~10^9 mass-selected ions. To date, we have verified experimentally the detection of more than 15 million ions confined in an open-ended cylindrical trap.

FTICR Performance of a 5.3 Tesla Split-Pair Magnet

W. D. Reents, Jr., M. L. Mandich, and A. M. DeSantolo
AT&T Bell Laboratories, Murray Hill, NJ 07974 USA

A unique magnet is used for FTICR detection of particles formed in a pulsed laser vaporization source. This magnet was designed to achieve excellent FTICR performance with large ion populations containing broad ion distributions.

The magnet, built by Oxford Instruments, is a 5.3 Tesla split-pair design. The 2" split allows access to the homogeneous region of the magnet's bore via four perpendicular ports. This access can be used to probe the ion population in the cell, e.g. with photons or chemical reagents. Currently, a pulsed gas valve is attached to one of these ports.

The magnet has an 8" bore tube made of 316SS with metal-sealed flanges on each end. This tube comprises our vacuum chamber, with the homogeneous region located 15" from one end. This large, short bore coupled to our vacuum pumping station (4,000 l/s cryopump and 2,500 l/s LN_2-trapped diffusion pump) results in high conductance (3,000 l/s at cell). A gas pulsed in via the perpendicular access port momentarily raises the pressure in the cell to 0.01 - 1 torr, collisionally stopping all cluster ions injected from the attached laser vaporization source. The pressure returns to the background level (10^{-9} torr) within 3 sec.

The large homogeneous region and wide bore permit use of large cells for trapping large ion populations. This is necessary because of the "bright" pulsed laser vaporization source being used; ion currents of 200 - 600 pA/pulse are generated at the laser source output with 3-5 pA/pulse currently reaching the cell. The high pulsed gas pressure used (0.01- 1 torr) efficiently stops and traps these ions in the cell. A variety of trapped ion cell sizes and geometries have been examined, but the results from only one (4.5" ID x 3.5" long cylindrical cell) is discussed.

The split-pair magnet design conflicts with the high homogeneity magnetic field required for high performance FTICR. The specified homogeneity of 1 in 10^4 over a volume of 1" diameter by 5" in length is exceeded when shimmed (achieved a measured homogeneity of 8 in 10^5). This low homogeneity (actually lower over the full trapped ion cell volume) did not inhibit achieving 640,000 mass resolution at m/z 2786^+ ($^{12}C_{230}{}^{13}C_2{}^+$).

The instrument performs well in terms of detecting broad ion distributions. The performance, however, depends significantly upon rf excitation conditions. Although standard rf chirp produces reasonable mass spectral signals in our instrument with cubic and elongated cells, the short aspect ratio of the cell discussed here results in very irreproducable spectra which represent only a portion of the ion population present (see Figure 1; 331 summed scans). However, when SWIFT® excitation is used, a mass spectrum is attained that represents the broad carbon cluster ion distribution present in the cell (see Figure 2; 260 summed scans). This large ion population is shown in more detail in Figure 3 with additional mass scale expansions. In spite of the large ion population in the trapped ion cell, a mass resolution of 11,000 is easily attained at m/z 4,000.

Performance of a Small Low-field FT/ICR Mass Spectrometer

James Pérez*, Diane T. Leeck, Brandon Beasley and Hilkka Kenttämaa
Department of Chemistry, Purdue University, West Lafayette, Indiana 47906-1393

The development of small Fourier transform mass spectrometers is driven by the potential for their implementation in routine analytical applications. We recently reported on the development of a small Fourier transform mass spectrometer, based on a low field (0.4 T) permanent magnet and an orthorhombic cell (~16 cm^3)[1]. The work presented here provides a systematic study of the base performance of this instrument, equipped with an unscreened cell and a screened cell. The screens used in this work consisted of 0.001 gauge tungsten wire arranged in a crosshatched configuration and with a wire density of 4 wires/cm (11-wire screens). The use of screens has the effect of reducing static electric fields in the cell[2] and this effect was studied by comparing the instrument performance factors with both cell configurations.

A notable difference in the performance between the screened and unscreened cell is the loss in sensitivity associated with the former. This was evident from the results of the ion trapping efficiency and the lower limit of detection experiments. Initial ion intensities originating from the electron ionization (EI) of benzene and carbon tetrabromide were reduced by ≥ 50% in the 11-wire screened cell. Ion trapping efficiency experiments based on the EI of these species suggest that the unscreened cell traps ions more efficiently.

The lower limit of detection was measured by electron ionization and chemical ionization of methyl stearate/methanol solutions of different concentrations. Results from both approaches suggest a sensitivity approximately in the picogram range for the unscreened cell. The sensitivity of the 11-wire screened cell was approximately in the nanogram range by EI of methyl stearate. Sensitivity measurements using the chemical ionization method did not enhance this measurement with the 11-wire screens.

The resolution was evaluated by measuring the heterodyne mode electron ionization mass spectra of the perfluorotributylamine fragment ion with m/z 131. At 16 k datapoints and a heterodyne frequency of about 47 kHz, the resolution was comparable with both cell configurations at about 55 k.

Performance factors which improve with the 11-wire screened cell include the mass range, mass accuracy and the dynamic range. The mass range was based on the EI mass spectra of tri(perfluoroheptyl)-1,3,5-triazine (MW = 1185 Da) and was extended from about m/z 866 to 1185 m/z in the screened cell. The mass accuracy was determined by repeated collection of the EI mass spectra of perfluorotributylamine (PFTBA) over time. The 11-wire screened cell achieves a nearly 50% improvement in the mass accuracy over the unscreened cell. The EI mass spectra of air samples were used to evaluate the dynamic range of the instrument, and was based on the component of air with the lowest detectable abundance. The dynamic range was greater by an order of magnitude in the 11-wire screened cell than in the unscreened cell. Table 1 summarizes the performance factors of this prototype instrument equipped with the screened and the unscreened cell.

Preliminary experiments were also performed using screens with a wire density of 8 wires/cm (20-wire screens). The results obtained to date support earlier SIMION data,

[3] which predicted that the 20-wire screens effect weak trapping potentials in the cell. The instrument performance with the 20-wire screened cell was poor.

Table 1. Comparison of the performance factors of the low-field instrument equipped with the unscreened cell and the 11-wire screened cell.

Performance Factor	Unscreened Cell	11-wire screened cell
Mass Range	4 to < 866 Da	4 to < 1186 Da
Resolution	54 k @ m/z 131 (NDP = 16 k)	58 k @ m/z 131 (NDP = 16 k)
Mass Accuracy	25 - 314 ppm (m/z 69 - 502)	13 - 277 ppm (m/z 69 - 502)
Ion Trapping Efficiency (50% of the initial total ion current)	≥ 1.0 seconds	≥ 0.5 seconds
Dynamic Range	10^2	10^3
Sensitivity (Methyl Stearate)	picogram range	nanogram range

Low Noise ICR Detection Electronics.

G.A. Anderson, J.E. Bruce, S.A Hofstadler, A.L. Rockwood, R.D. Smith Chemical Sciences Department
Pacific Northwest Laboratory Richland, WA 99352

FTICR signal detection offers many challenges; both wide bandwidth and low noise performance are required. Since, the input impedance of the amplifier is a very critical parameter, optimal performance of the preamplifier involves a careful balance of input impedance and noise performance through circuit design and component selection. The FTICR cell and its connections to the preamplifier are another critical parameter in FTICR detection sensitivity.

This work has investigated signal detection electronics for improved FTICR detection sensitivity. Amplifier noise sources are identified and their effect on detection sensitivity are evaluated. A high sensitivity, low noise preamplifier, developed in our laboratory, is presented and its performance is evaluated and contrasted with different preamplifier configurations. The detection circuit is analyzed and the effect of cell and wiring capacitance is discussed. The circuit sensitivity is calculated and compared with measured results. Component selection criteria are discussed and the present state-of-the-art components are evaluated. The effect of pre amplifier cooling is also investigated and the results are presented. Different detection frequency ranges result in different circuit optimization; these effects are analyzed and optimal component values and circuit configurations are shown for different frequency ranges.

Figure 1 shows the equivalent circuit for a FTICR detection circuit. This circuit illustrates the main noise components; amplifier voltage and current noise, and noise current due to input bias resistance Ri. The signal image current has been shown as[1]:

$$Is_{rms} = \frac{Nq^2 rB}{\sqrt{2}md} \qquad \omega = \frac{qB}{m} \qquad Is_{rms} = \frac{Nqr}{\sqrt{2}d}\omega$$

Given the image current and detection circuit capacitance and resistance, the detection system signal components are calculated, as shown in figure 2. This figure illustrates several interesting points; image current increases with frequency, signal voltage is constant with frequency and is inversely proportional to circuit capacitance. For low frequencies current noise dominates, for high frequencies voltage noise dominates. The equivalent input voltage noise is:

$$Vnt = \sqrt{en^2 + \frac{In^2}{\omega^2 Ct^2} + \frac{4kT}{Ri\omega^2 Ct^2}}$$

FETs offer low current noise due to their low input gate leakage currents and are well suited for low frequency operation. At higher frequencies bipolar transistors offer low voltage noise, their voltage noise is due primarily to Johnson noise in the base spreading resistance, which is low. Our work with large biomolecules results in frequencies of 50KHz for m/z 2000 and B equal 7 Tesla. FETs are the best choice for this region.

To support the large biomolecule studies at our laboratory, a FET input amplifier was design and built. The design is based on a cascode configuration proposed by Jefferts[2]. The differential casode amplifier has the following specifications:

Voltage noise	en = 1nv/Hz$^{1/2}$
Current noise	In = 4fA/Hz$^{1/2}$
Input resistance	Ri = 1G
Input capacitance	Cs = 34pF

Cooling the FETs improves the current noise by a factor of 10 and reduces bias current allowing the input resistor value to increase. Increasing Ri reduces the resistor noise current, due to Johnson noise in the resistor. Preamplifier performance shows good agreement with calculated system sensitivity. In conclusion, we have shown the basis for improved studies of large biomolecules through the use of optimal preamp electronics.

We thank the U.S. Department of Energy for support of this research through internal PNL Exploratory Research under contract DE-AC06-76RLO 1830.

Improved Performance of a LabVIEW-Based FTICR Data Station

J.J. Drader, C.L. Hendrickson, J.M. Robinson and D.A. Laude, Jr.; Department of Chemistry and Biochemistry, University of Texas at Austin, Austin, TX 78712

The increasing popularity of FTICR has been paralleled by a demand for a flexible data station which allows users to take advantage of new technological developments and to perform more intricate experiments. The natural approach to the problem is to build a data station which is tailored to the experimental requirements, and can also be easily modified to facilitate new experiments. In this work, we present a PC-based data station that uses LabVIEW software (National Instruments Corp., Austin TX). LabVIEW offers a high level graphical interface which allows operators with minimal programming experience to develop complex programs. Major improvements over previous data stations [1] include increased flexibility in waveform syntheses, sequence editing, and data processing.

The data station was set up as follows: the 486/DX66 PC contains both a National Instruments AT-AO-6 DAC card and a National Instruments GPIB interface card. The LeCroy 9100 arbitrary function generator (AFG) and the LeCroy 9410 digital storage oscilloscope (DSO) communicate with the PC through the GPIB interface. The system control, user interface, and data processing are implemented through virtual instruments (VI's) created LabVIEW 3.1 (graphical programming for instrumentation). VI's are used to create programs that resemble and perform like real instruments even though they are actually software based. The AFG provides two independent channels of arbitrary waveform output. One channel is connected to an amplifier and outputs the dipolar excitation, while the other is available for quadrupolar excitation (QE) or other waveforms. Four of the six DAC channels provide buffered output to control critically timed events. The remaining two DAC's provide the trap voltages. The board also has 8 digital I/O channels, four of which are used for TTL triggers. The signal from the differential amplifier is fed directly in the DSO for digitization before it is transferred over the GPIB interface to the PC where the transient data is processed.

The PC based data station was connected to a 3 Tesla ICR equipped with a concentric tube electrospray ionization source. The basic experimental sequence for ESI/FTICR under LabVIEW control was as follows:

Quench--->Open Shutter--->Pulsed Valve--->Accumulate Ions--->Close Shutter
--->Pump Down-->Excite-->Detect

Examples of the data system operation made use of electrosprayed horse heart myoglobin (MW = 16,951). The Spectrum Viewer was used to determine the frequencies of two charge states (m/z = 864 and m/z = 1234) found in the initial scan (Figure 1). These two frequencies were entered into the Waveform Generator where they were added together to form a double frequency excitation. Applying this excitation produced the spectrum in Figure 2.

SWIFT excitation was used to perform various manipulations of the charge state envelope. The SWIFT waveform is synthesized from a user defined notch spectrum and then stored to the AFG. Figure 3 illustrates the spectrum obtained after applying a notched excitation.

Selective broadband quadrupolar excitation (QE) was employed to cool desired charge states back to the center of the cell. In order to execute this QE remeasurement experiment, the following events were added to the above sequence:

(...Excite--->Detect)--->Pulsed Valve, Trigger QE Box--->QE cooling--->Pump Down
--->Excite---> Detect

As shown in Figure 4, this pulse sequence is an effective method for simultaneously isolating and selectively conditioning multiple ion packets in the ICR cell.

In conclusion, the PC-based data station has proven to be a viable approach for performing FTICR experiments. The LabVIEW software provides a secure foundation for future advances in data station technology. The high level graphical interface makes it simple to modify existing software while retaining the flexibility required to perform difficult programming tasks. National Instruments' continued development of new hardware drivers allows the user to easily upgrade computer peripherals and FTICR hardware.

The data station provides the potential for performing experiments which have not been possible on the commercial systems. For example, performing such experiments as simultaneous QE/SORI-CAD becomes a possibility by taking advantage of LabVIEW's flexible manipulation of FTICR hardware.

A New ICR-Cell for Simultaneous Trapping of positive and negativ Ions

R. Malek, K. P. Wanczek
University of Bremen, Inorganic Chemistry, PO Box 330440, D-28334 Bremen

The conventional setup [1] for **simultaneous trapping of positive and negative Ions** uses two pairs of trapping electrodes, which are at opposite potentials The outer trapping electrodes are solid plates, the inner are grids
A Fourier-Bessel series expansion is used for an **analytical model** of the trapping field. Possible **orbits** for positive and negative ions are identified.
The field is described by the equations:

$$\varphi = \sum_{n=1}^{\infty} B_{0n} \cosh(k_{0n} z)\, J_0(k_{0n}\rho) \qquad (1)$$

$$B_{0n} = \frac{2}{x_{0n}\cosh\left(x_{0n}\frac{L}{a}\right) J_1^2(x_{0n})} \left\{ (V_- - V_+)\frac{d}{a} J_1\left(x_{0n}\frac{d}{a}\right) + V_+ J_1(x_{0n}) \right\} \qquad (2)$$

(J_0: Bessel function; V_-, V_+: Trapping voltages; d: centre hole of the grid; L/a aspect ratio of the ICR cell)
After local linearizations of the electric field, the effective cyclotron frequencies are calculated for SF_5^+ and SF_5^- and compared with high resolution experiments.

Based on the theoretical model a **new ICR cell** is designed that can be described by the **same equations**. The astonishingly **simple** new trapping electrode structure is optimized for **better trapping efficiency and improved signal to noise ratio**. The **new ICR cell** needs a total of four trapping electrodes as well, but has two concentric electrodes in a plane at each side of the trapping cell (see **fig. 1**)
Experiments with a prototype Spectrospin CMS 47, and an additional DOS PC for control of the trapping voltages show the benefits of the new concept.
Broad band spectra show significant improvements in signal to noise ratio with the new cell. In **figure 2** spectra observed with the **old** (2a) and the **new** cell (2b) are **compared**.
Trapping-times, signal intensities and signal to noise ratio for simultaneously trapped positive and negative ions in the new ICR-cell are comparable to the circumstances in a conventional ICR-cell. The improved behavior for simultaneous trapping is mainly due to better charge separation and an advantageous potential distribution.
The mechanisms for simultaneous trapping of positive and negative ions in a cylindrical ICR cell are now completely understood. An analytical model allows predictions on stable ion movements and the detected frequencies. Improved trapping electrodes provide an electric field inside the ICR cell that is ideal for simultaneous trapping of positive and negative ions. Signal to noise ratio

and resolution are significantly improved and in the same range as for conventional ICR spectroscopy with positive **or** negative ions. The improved field and the detailed theory will allow new experiments· Separation of opposite charges can be controlled by changes of the trapping voltages and accelerations of axial movements. Thus total separation and total mixture of particles with opposite charges will be possible This allows ion/ion or electron/ion reactions with defined reaction times and Inverse Charge Collisional Dissociation experiments.

A Scheme for Feedback Excitation in FTICR-MS Based on Multielectrode Trap

Michael V. Gorshkov* **and Richard T. Kouzes**

Environmental Molecular Sciences Laboratory
Pacific Northwest Laboratory, Richland, WA 99352

*Member of the Institute of Energy Problems of Chemical Physics, Russian Academy of Sciences, Moscow, Russia 117829

One of the problems for FT-ICR is the change of the ion cyclotron frequency during the excitation process. There are several reasons for this frequency change: (i) relativistic mass increase, (ii) magnetic field inhomogeneity, (iii) space charge effects, and (iv) trapping electric field inhomogeneity. For example, in a magnetic field B (in Tesla), the cyclotron frequency of an ion of mass μ (in atomic units) will be shifted due to the relativistic effect by 90 $B^3 r_{cm}^2 \mu^{-3}$ Hz, where r_{cm} is the ion cyclotron radius (in cm). It is necessary to make the ion cyclotron radius large enough to generate a spatially coherent ion packet that passes sufficiently close to the detector electrodes to produce a measurable image current. On the other hand, the frequency shift effects increase with radius and present a problem for ion excitation. Excitation of ions of a given m/z by the use of fixed frequency excitation becomes difficult because the ions move out of the resonant condition as soon as their frequency shift becomes larger than the excitation bandwidth [1]. The measurement of the masses of light ions, light ion radial ejection, and the study of ion-molecule processes in the high energy region become difficult as well.

The method for ion cyclotron excitation via frequency capture is based on the use of a feedback loop [2] with a resonant LRC circuit to capture the instantaneous ion cyclotron frequency, plus a multi-electrode ICR trap [3,4]. In order to separate the frequency ranges in which (i) the ions are detected, (ii) cyclotron frequencies are captured, and (iii) the ion cyclotron motions are excited (Fig.1). Frequency multiples are used to avoid undesired feedback loop overload.

We find the following advantages of the proposed method for ion excitation in FT-ICR:(i) excitation of light ions up to extremely high kinetic energy (MeV and higher); (ii) "automatic" phase synchronization of the ions during detection which increases the resolving power; (iii) higher resolving power of the instrument because of the detection of the ion cyclotron signal in the high frequency domain; (iv) higher sensitivity in the case of detection of the ion cyclotron signal from heavy ions because of detection in the high frequency domain.

Universal ICR Ion Trap: Segmented and Optimized for Excitation, Detection and Trapping

George S. Jackson,* Shenheng Guan, and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State University, 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

* Department of Chemistry, Florida State University

Traditionally, ICR ion traps have been constructed from conductive electrodes, each of whose surfaces has the shape of a particular desired isopotential surface: e.g., 3-D axial quadrupolar "Penning" d.c. potential for ion trapping, 1-D linear a.c. potential for dipolar excitation, and 2-D azimuthal a.c. quadrupolar potential for ion axialization. Because no single trap geometry simultaneously optimizes all three such potentials, dozens of different compromised trap shapes are in use. A more general approach is to divide each each electrode into smaller segments and then apply appropriate potentials to each section, as for a recently reported ICR ion trap "linearized" for dipolar excitation and dipolar detection.[1]

Here we extend that idea to its logical extreme: a "universal" trap, consisting of a cubic trap, each of whose sides is divided into a 5 x 5 grid of square electrodes, each with independently controllable a.c. and d.c. voltages. Although there are 5 x 5 x 6 = 150 electrode segments, the high symmetry of the cubic geometry results in relatively few independent voltages: e.g., 7 for dipolar a.c. excitation or detection, 15 for azimuthal quadrupolar a.c. excitation, and 13 for three-dimensional axial quadrupolar d.c. trapping. In fact, only 48 independent voltages are needed to specify all three desired potentials. Thus, many of the electrodes may be wired together, with appropriate switching to change from one experimental event to another. Because the electrostatic trapping field usually remains in place throughout most experimental events, a simple resistive network may be used to switch between dipolar excitation/detection and azimuthal quadrupolar ion axialization.

Numerical simulations (Simion 6.0) confirm significant improvement in each of the three desired potential contour shapes, compared to an unsegmented cubic trap. For example, Fig. 1 demonstrates the much more accurate three-dimensional quadrupolar trapping potential of a segmented cubic trap (left) compared to an unsegmented cubic trap (right). Computer simulations also demonstrate a significant reduction in signal components at harmonic multiples of the fundamental ICR frequency, for a point charge excited to the same radius in cubic (Fig. 2) and "universal" (Fig. 3) traps. The "universal" trap allows for nearly distortion-free excitation and detection at a cyclotron radius extending almost to the radius of the trap itself. We therefore anticipate marked reduction in other non-linear effects (e.g., sidebands and mass-dependent axial ejection) as well as improved efficiency in ion trapping and dipolar or quadrupolar excitation, with corresponding improvement in mass resolving power, mass accuracy, and reproducibility. Work supported by NSF (CHE-93-22824), NIH (GM-31683), and the National High Magnetic Field Laboratory at Florida State University.

Extending the Functionality and Performance of Commercial Ion Traps

McHugh, Sean; Hoekman, Don; Bradshaw, Stephen; Wilson, Ray; Li, Rebecca
Teledyne Electronic Technologies, Scientific Instruments, Mt. View, CA 94043

Due to its software intensive nature, the typical ion trap mass spectrometer may be functionally extended by connecting a smart instrument controller, and a relatively modest amount of additional electronics hardware, to the original instrument configuration.

By adding faster and higher resolution drive circuitry to the RF generator, a Filtered Noise Field (FNF) waveform generator to the end caps, a more sensitive A/D converter to the detector output, and parametric resonance scanning with direct frequency control to the RF drive circuitry, the standard ion trap will operate over a wider mass range, scan much faster, perform true Selective Ion Monitoring (SIM) and tandem mass spectrometry (MS/MS and MS^n), as well as execute multiple scanning modes of acquisition, such as: EI/CI, EI/SIM, EI/MS^n, etc.

The upgrade of the standard ion trap mass spectrometer (*Apogee*) involves the following:

1 - Replacement of the Scan and Acquisition Processor (SAP) with a new interface card, containing instrument control circuitry and programmable endcap drivers.

2 - Replacement of the existing DOS data system with a Windows data system to acquire, process, and display the data.

3 - Adding a smart instrument controller (the electronics tower), containing RF, instrument parameter, FNF waveform, parametric resonance scanning, and acquisition control of the ion trap.

Upgrading a commercial ion trap mass spectrometer has proven to add a tremendous amount of functionality to the basic instrument. In general, this has been achieved by the following:

1 - Direct analog control of the RF drive circuitry.

2 - Direct analog sampling of the multiplier output.

3 - Direct digital control of the instrument's non-scanning functions, such as: heaters, filament, emission current, multiplier, etc.

4 - Adding a smart instrument controller to handle scanning and acquisition.

Performance Enhancement for the HP 5971/5972

*Roy, Laura; Jehnsen, Chris; Hamerly, Thomas; Graves, Peter; Roy, Raymond
Detector Technology, Inc. Sturbridge, MA
Los Gatos Circuits, San Jose, CA

INTRODUCTION

As analytical chemistry advances, mass spectrometers are pushed to their limits in sensitivity and high mass detection. One approach to improving the performance in these areas is to improve the configuration of the continuous dynode electron multiplier(CDEM). Studies have been performed on the Hewlett Packard(HP) 5971/5972 utilizing a high energy dynode(HED) and a newly developed internal power pack. In house and field operations demonstrate the performance enhancement seen when using the HED Power 2000.

METHOD

The current HP configuration does not allow for an easy dynode upgrade. The HED Power 2000 utilizes an internal DC/DC converter which is packaged with the detector. The input to the converter comes from the high voltage applied to the CDEM. The converter output is -4.5KV, and is the voltage applied to the dynode. Because the converter and CDEM share the existing power supply, no additional modifications to the mass spectrometer are required. Upgrading the instrument is as easy as changing the detector.

RESULTS

Tests were performed on the original equipment multiplier and the HED Power 2000. Tests were done by Chris Jehnsen of LGC, San Jose, CA using an HP 5972 instrument. Standard Spectra Autotunes were run on both multiplier, see fig. 1 and fig. 2. After the autotunes were run a 1 microliter injection of .01 ppm Hexachlorobenzene was injected. The signal to noise when using the original equipment multiplier was 22.7:1, see fig. 3. The HED Power 2000 achieved a signal to noise of 62.3, see fig. 4.

APPLICATIONS

When testing at LGC was completed, the HED Power 2000 was ready for field operations. Steve Connor of the New York State Department of Health, Albany, NY used the upgrade to run dioxin tests. Before injecting any samples the HED Power 2000 was tuned using QuickTune. Figures 5 and 6 show the results. Injections of 2 ul were then run. The sample contained 6.92 pg/ul of 2378-TCDF, 7.86 pg/ul of 123478-HxCDF, 8.58 pg/ul of 123678-HxCDF, 8.38 pg/ul of 1234678-HxCDF, 7.36 pg/ul of 123789-HxCDF, and 9.92 pg/ul of 12346789-OCDF. The multiplier was run as 2300 V. Figure 7 shows the before and after results.

CONCLUSIONS

The data collected by Chris Jehnsen and Steve Connor indicated that there was significant improvement in signal to noise and high mass detection when using the HED Power 2000. This CDEM configuration not only enhanced the performance of the instrument but also provided for a quick and easy instrument upgrade. One issue was encountered during this investigation. When using the HP software a parameter must be adjusted. This is the target relative abundance of mass 502. This amount is configured to 3 - 8% and must be changed to 15 - 25% to maximize the performance of the HED Power 2000.

The results shown were selected from a variety of data. This data shows the average improvements seen when using the HED Power 2000 on a clean and uncontaminated instrument. Results may vary depending upon instrumentation and application.

Matrix-Assisted Laser Desorption/ Ionization Ion Trap Tandem Mass Spectrometry of Peptides: A New Excitation Scheme for CID

Jun Qin and Brian T. Chait
The Rockefeller University 1230 York Ave. New York NY 10021

One of the current limitations of MS/MS in the ion trap mass spectrometer is the limited internal energy that can be deposited by conventional resonance excitation. Extensive sequence specific fragmentation of peptide ions in the range of m/z 1000 to 3500 usually requires the deposition of large amounts of internal energy. To make the ion trap a useful analytical tool for protein characterization and identification of post-translational modifications, we need to devise means for inserting sufficient amounts of internal energy in peptide ions to achieve a high degree of fragmentation.

We report a new excitation scheme for collision-induced dissociation (CID) of peptide ions in an ion trap mass spectrometer. This new excitation scheme is capable of supplying large amounts of internal energy as compared with conventional resonance excitation so that peptide ions up to m/z 3,500 can be fragmented to generate extensive sequence specific ions. Fig. 1 shows the RF scan function that we devised to carry out the new excitation procedure. After ions are isolated by reverse- then- forward scan (only forward scan is shown here), the RF amplitude is raised to a higher level in 10 ms ("the slam scan segment") then abruptly dropped to a lower level where ions are excited for a period of between 30ms and 1s. The excitation frequency is ~ 5% red shifted from the resonance frequency and the excitation amplitude (the AC amplitude) is set at the maximum available value (21 V_{p-p}). The resulting product ions are cooled at the same RF level as that used during the excitation segment, and detected by resonance ejection. We term this new excitation scheme as red shifted off resonance large amplitude excitation (RSORLAE). Fig. 2 compares CID spectra of substance P taken with the conventional resonance excitation and the new excitation scheme (RSOLAE). The difference is dramatic. For conventional resonance excitation, only y_n type ions are observed. By contrast, for RSORLAE, both b_n and y_n type ions are observed. since dissociation channels that lead to y_n type ions are lower in energy compared with channels that lead to b_n type ions, the new excitation scheme (RSOLAE) inserts larger amounts of internal energy into peptide ions than the conventional resonance excitation.

Although we do not have a complete understanding of the new excitation scheme, the experiments illustrated in Fig. 3 give insights into the possible underlying principles. Fig. 3 compares the fate of bombesin ions as registered by the detector in the process of ion isolation, excitation and detection when the conventional resonance excitation and RSOLAE were carried out. Most of the isolated bombesin ions are ejected during the excitation process for the conventional resonance excitation at a frequency of 59124 Hz with an AC amplitude of 1.2 V_{p-p}; in contrast, none of the ions are ejected during the excitation process for RSOLAE at 59124 Hz and an AC amplitude of 21 V_{p-p}. The ability of the ions to be retained inside the trap over extended periods of time during the red shifted off resonance excitation process allows the build up of sufficient internal energy so that higher energy dissociation channels can be accessed.

Filtered Noise Fields in a Paul Ion Trap for Multiple MS Analyses

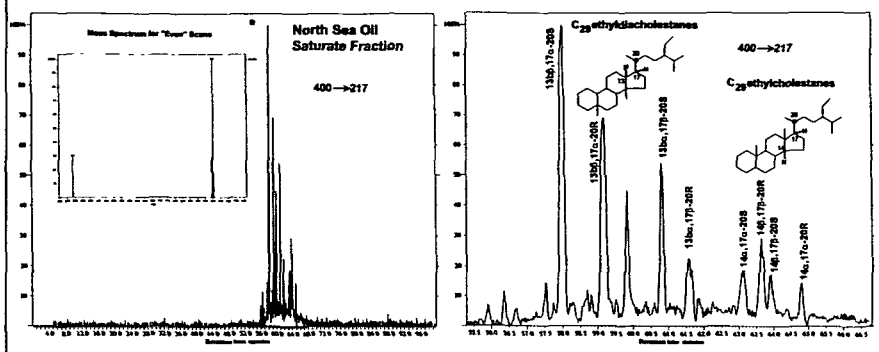
Dane Karr[1] and Clifford C. Walters[2]

[1]Teledyne Electronic Technologies, Mt. View, CA
[2]Mobil Research and Development Corp., Dallas TX

We have described a new method of operation for the Paul ion trap in which a Filtered Noise Field (FNF™) is used to perform Selective Ion Isolation[1]. The FNF is a waveform that is applied to the end electrodes of the trap during, and for a short time after, the creation of ions within the trap (or the introduction of ions into the trap). The waveform ejects undesired ions as they are created so that ions of interest may be accumulated without creating a space-charge condition.

Thus, low levels of components in a complex matrix may be identified by accumulating diagnostic ions for SIM or MS/MS analyses. In addition, since the trap is filled with only the ions of interest, the original sensitivity of the trap is maintained. The combination of high sensitivity (from the ion trap) with high selectivity due to SIM or MS/MS analyses makes it possible to detect minute quantities of material in very complex matrix. The utility of FNF for SIM and GC/MS/MS analyses are demonstrated here.

A GC/MS/MS analysis of sterane biomarkers[2] in the saturate fraction of crude North Sea oil was carried out. We performed Selected Reaction Monitoring (SRM) measurements for the 400 m/z and 414 m/z transition to the 217 m/z product ion. We have used alternating scans so these analyses may be completed in a single GC run. The 217 m/z mass chromatogram for the 400 → 217 m/z transition is shown below. An expansion which includes peak identification is also shown.



In addition, a GC analysis of atrazine spiked into orange juice at a concentration of 20 ppb was performed. We have collected data in full scan EI, an SIM EI analysis, and an SRM EI analysis. The SRM MS/MS analysis is very specific for atrazine in this matrix; the total ion chromatogram is displayed below (the corresponding mass spectrum is inserted).

ADVANCED SWIFT TECHNIQUE FOR MALDI / QUADRUPOLE ION TRAP MASS SPECTROMETER

Vladimir M. Doroshenko and Robert J. Cotter
The Johns Hopkins University School of Medicine, Baltimore, MD 21205

SWIFT (stored waveform inverse Fourier transform) and other related techniques are widely used for broadband excitation of ions in a quadrupole ion trap (QIT) mass spectrometer to perform mass selective accumulation of ions into the trap, ion isolation and fragmentation. With the introduction of nonlinear phase modulation to SWIFT technique, the ejection of ions from the trapping cell compared to that for unmodulated phase case is not *simultaneous* anymore. This fact has not been widely discussed. In this work we have used it to design function for phase modulation which allowed us to achieve unit mass resolution for ion isolation in the range m/z up to 1300. A high performance monoisotopic CID experiments have been demonstrated with the use of these techniques.

Some properties of SWIFT waveforms used can be observed from the data in Figure 1. Small number of points N=2048 was used to design waveformes in Fig. 1 to show the real structure of the SWIFT pulse (the sample interval is equal to 0.8 µs). The frequency band of pulses covers the range from 10 to 560 kHz with the notch of the width of 40 kHz in the waveform in Figure 1a. In many aspects the SWIFT pulse looks like frequency sweep chirp used in FTMS for ion excitation. One can expect from the "sweep" nature of the SWIFT signal that ejection of ions from the trap cell is not simultaneous. The same structure is observed for longer waveforms although it is observable at higher resolution only. Another type of SWIFT pulse used in this work is shown in Fig. 2. This pulse was designed for N=16000 and a 14 kHz frequency interval which is "stretched" in time-domain onto a ~6 ms time interval. On this background a 1 kHz narrow width notch in Figure 2b seems to be very broad. We use such "stretched" SWIFT pulses for increasing the mass resolution during ion isolation.

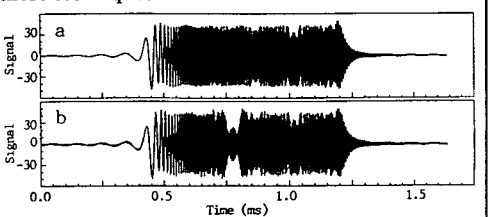

Fig. 1. Broadband SWIFT waveforms (f=10-560 kHz): a- without notches; b- notch at f=250±20 kHz.

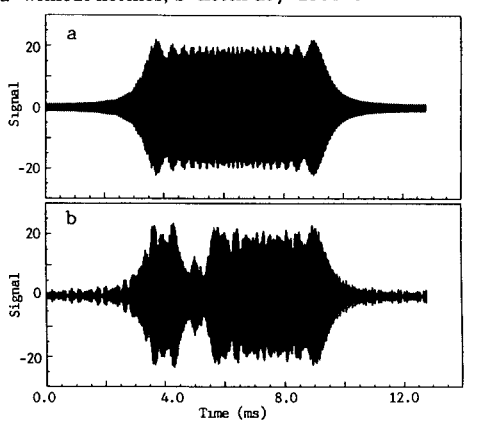

Fig. 2. Narrower band SWIFT pulses (f=208.6-222.3): a- without notches; b- notch at f=212.5±0.5 kHz.

Experiments were carried out on a modified Finnigan MAT ion trap detector. These modifications include additional hardware for interfacing of ITD with laser and external control of the instrument, and developed in-house *TrapWare* software (see *Rapid Commun. Mass Spectrom.* **1994**, *8*, 766). TrapWare designed and loaded waveformes to the memory of a Quatech (Akron, OH) WSB-100/WSB-A12M waveform synthesizer plug-in board connected to an IBM computer, and triggered them when it was necessary during experiment. The instrument scan functions and SWIFT pulses were designed simultaneously using the tables on the computer screen. Thus, the real mass values were used instead of frequencies for SWIFT pulse designing.

A significant increase of resolution for the ion isolation has been observed when after the first coarse isolation step using broadband SWIFT pulses shown in Fig. 1 a narrower band "stretched" pulses shown in Fig. 2 were applied. The example of isolation of monoisotopic species of the protonated ions of Angiotensin I (m/z=1296.7) is presented in Fig.3. A mass selective ion accumulation technique with the use of the SWIFT pulses and multiple laser shots was applied using the *ramped trapping voltage* method for trapping ions which involves ramping of the RF field from small to high trapping values during the ion flight into the center of the ion trap. The increase of resolution for ion isolation obtained for narrower frequency range SWIFT pulses is very similar to the phenomenon observed during the slowered mass scans. The asymmetry phenomenon has been also observed during application of normal and time-reversed SWIFT waveformes which is similar to asymmetry observed for forward and reverse mass scans in the resonance ejection technique. The unit mass resolution isolation technique has been successfully applied for SWIFT-activated CID mass spectrometry of peptides (Fig. 4).

APPLICATION OF TAILORED WAVEFORM GENERATION TO THE QUADRUPOLE ION TRAP

Dennis Taylor, Jae Schwartz, Joe Zhou, Mike James,
Mark Bier, Andy Korsak, George Stafford
Finnigan Corporation, San Jose, CA 95134

INTRODUCTION

A limitation of the ion trap mass spectrometer is the number of ions that can be stored in the quadrupole field at one time and maintain mass resolution Only storing selected ions of interest, or mass ranges of interest, allows the operator to eliminate unwanted background ions while concentrating the analytically useful ions The application of a supplementary AC field, at a predetermined frequency and amplitude, will resonantly excite ions in the axial direction and cause them to be ejected. If a supplementary signal is applied that contains a combination of frequencies (waveform), then mass ranges of ions can be excited and ejected at one time

RESULTS

The SWIFT method was used to produce the waveforms in the Fourier Transform Technique Notice the first half of the waveform contains mostly high frequency components, and the second half of the waveform contains mostly low frequency components Therefore, ion storage using this waveform technique depends on the time the ion is formed or injected in to the trap

Spectral coverage is the relative abundance of the frequency components making up the waveform. The Fourier technique yields a smooth measured abundance across the frequency range of the waveform

The Tailored waveform technique is achieved by summing together a plurality of spaced discrete frequencies covering the range of characteristic motion of the ions of interest This technique yields a much improved time coverage as compared to the Fourier technique This improvement will mean that all ions of interest will be excited and ejected continuously during the waveform application Tailored waveform spectral coverage results are similar to the results obtained using the Fourier technique

CONCLUSIONS

- Tailored waveforms give uniform frequency abundance over the entire time of waveform application
- Both Fourier and Tailored waveform techniques show good spectral coverage characteristics
- Waveforms generated by a Random Noise technique yield poor spectral coverage
- Tailored waveforms, using 500 Hz discrete frequency spacing, provide single mass ion isolation above 1000 m/z

Selective Ion Accumulation in an ICP/ITMS using a Filtered Noise Field

G. C. Eiden, C. J. Barinaga, and D. W. Koppenaal, Materials and Chemical Sciences Center, Pacific Northwest Laboratory, Richland, WA 99352

Selective accumulation of ions in an ion trap mass spectrometer (ITMS) has been characterized using both single frequency and broadband resonant excitation. The goal of this work is to enhance selective accumulation of ions from plasmas and other external ion sources. The charge capacity of the ITMS is 10^6 to 10^7 ions, although the mass spectrum is distorted at much lower space charge. Detection of trace ions necessitates selective detection schemes such as selective trapping or optical detection. We report results of selective trapping studies for Sr, Y, and Zr solutions (100 ppb Y and 1 ppb each Sr, Zr). "Background" ions in mass channels adjacent to the channel of interest is a worst case situation with respect to selective ejection and abundance sensitivity. Real samples will often have matrix ion m/z values much further removed from the m/z of the ions of interest. Thus, we also give results for a multielement solution. Ions from an inductively coupled plasma ion source are endcap injected into the ITMS [1]. Broadband waveforms were generated by an HST-1000 (Teledyne MEC) instrument, using the filtered noise field (FNF) method [2]. The experiment is controlled by the ITMS electronics and ICMS software [3]. The sequence of experimental events is: ion injection at $q_z = 0.4$ (typical), collisionally cool ions, set trapping potential for resonant excitation ($q_z = 0.2$ to 0.6), analysis rf ramp.

The selectivity of the ejection process is determined by the ratio of the ejection efficiency of resonantly excited (target) ions to the ejection efficiency of ions in adjacent mass channels. Using single frequency or broadband excitation of cooled ions, we observe little or no decrease in the number of ions detected in mass channels adjacent to the target ion. A more precise estimate of the decrease is obtained from the slope of the signal versus the duration of the excitation pulse. The selectivity that we report is based on the error in these slopes from a linear regression fit, and thus provides a lower limit for the selectivity. Selectivity relative to ions further removed in m/z is even larger. In Fig. 1, the log of the ion signal is plotted for ^{88}Sr, ^{89}Y, and ^{90}Zr ions for the solution described above. We observe a ~2000-fold reduction in the intensity of the Y intensity and no observable reduction in the ^{88}Sr and ^{90}Zr peaks. Using the slope of the Sr signal versus time, we estimate a single frequency resonant excitation selectivity of ~10^5. Selectivities are much lower for "hot" ions, i.e., those that have not been collisionally cooled.

Figure 2 illustrates the efficacy of broadband excitation in reducing high space charge conditions in the trap. The top trace shows the mass spectrum of a multielement solution under high space charge conditions (~10^4 ions detected). The peaks are severely distorted and the signal at m/z 106 is completely obscured. The bottom trace demonstrates the recovery of mass resolution and sensitivity by selective ion ejection using broadband excitation. The FNF was targeted to remove all ions except for those in a window between 100 and 107 amu. The FNF waveform contained frequency components every 1000 Hz between 10 KHz and 500 KHz, except for a window at 270-295 KHz for which the amplitude of the waveform was zero. Comparison of the bottom

trace with the spectrum at low space charge conditions and no FNF applied (not shown) shows that nearly full sensitivity is retained for peaks between 100 and 106 amu.

We have also characterized single versus multiple frequency excitation with respect to buffer gas pressure and the frequency, amplitude, and duration of the resonant excitation pulse. We have found that the conditions for high selectivity include He buffer gas pressure ~0.2 mTorr (at, or slightly below, where the trapping efficiency versus pressure curve saturates); an excitation amplitude and duration of at least 450 mV (strongly pressure dependent) and 2 msec. Further design criteria for selective ejection and accumulation methods will be developed from these studies and reported in the near future [4].

Automated Resonance Ejection in a Quadrupole Ion Trap Mass Spectrometer

J.Murrell*,P.Watts#, J.F.J.Todd *
*** The Chemical Laboratory, The University, Canterbury, Kent, CT2 7NH, UK**
 # CBDE, Porton Down, Salisbury, Wiltshire, SP4 0JQ, UK

The use of resonance ejection experiments within ion trapping instruments to aid in the deconvolution of complex ion/molecule reaction pathways was first demonstrated by Beauchamp *et al*[1]. They performed double resonance experiments upon an ICR mass spectrometer. A similar approach is taken within this poster whereby a radiofrequency excitation pulse is applied at the same frequency as the secular frequency of a particular *m/z* ratio during the reaction time; hence the ions at that value are ejected and thus prevented from undergoing further reaction. To remove the problem of tuning in the resonance frequency for each individual *m/z* value the performance of a set of resonance ejection experiments has been automated. This is accomplished using *dynamically programmed scans*[2]. The results not only aid in the understanding of the pathways of ion/molecule reactions, they also reveal some information about the physical characteristics of the ion trap. The reaction of the methanol dimer with cyclohexanol will be used to illustrate this technique and show some of the side reactions which may occur. All experiments were performed upon a Finnigan MAT Ion Trap Mass Spectrometer (ITMS) located at the University of Kent. The scan function utilised for each experiment is shown in Figure 1. The vapours of the methanol and the cyclohexanol were introduced into the manifold via leak valves to unadjusted gauge pressures of 2×10^{-6} and 1×10^{-6} Torr respectively. All the experiments were performed by using the same key sequence programme which was input and edited using a FORTH editor available within the ITMS software.

From this a technique a chromatogram-type plot is produced, as shown in Figure 2. Considering the profiles corresponding to the 65^+, 131^+, 133^+, 199^+, and 201^+, it can be seen that the decrease in intensities of the ions relate to the ejection of that particular ion or a precursor of it. When an ejection pulse is applied close to the secular frequency of the ion, normally termed off-resonance excitation, the ion being expelled may fragment which leads to its dissociation products being observed. These dissociation products are formed with a large amount of internal energy and may immediately react with the other neutrals present.

As can be seen in Figure 2, the ions are not ejected at their resonance frequencies but at lower values than expected, i.e. a higher *m/z* ratio or lower q_z value. This probably occurs because commercial ion traps do not possess a pure quadrupole geometry but are of a stretched type.[3] As can also been seen in Figure 2 the width of the resonances increases with the increasing m/z ratio, i.e. lower q_z values. This can be explained by considering both the depth of the potential well and the motion of the ions. At lower q_z values the well depths are shallower than those of higher q_z values and thus less energy is required to eject the ions. In respect to the motion of the ions, by considering the motion of the ion in the terms of a sine wave, for the low frequency, i.e. low q_z situation, the off-resonance excitation is in phase with the motion of the ion for a longer period of time than the higher q_z value case. Therefore at the lower q_z values the ions are excited for a longer periods of time. The combination of these two effects causes ions to be lost from the ion trap over a greater range at the lower q_z values than compared to the higher ones.

The program described within this poster provides another means by which the quadrupole ion trap may be used to understand ion/molecule reactions. There are some interference reactions, e.g. off resonance dissociation, which may occur and have been highlighted. The results also reveal some physical characteristics of the quadrupole ion trap: the ions not appearing at the q_z value at which they would be expected and the greater width of the resonances at lower q_z values as compared to higher ones. Future work will involve the use of this technique to better understand other complex ion/molecule reactions and the nature of ion motion within the ion trap.

Enhancement of Ion Trapping Efficiency in an Ion Trap with a Pulsed Valve

Yang Wang, Michael Schubert and Jochen Franzen
Bruker-Franzen Analytik GmbH, 28359 Bremen, Germany

There is a high probability for ions, which are ionized within a three-dimensional quadrupole field, to be trapped. These ions are damped into the center of the ion trap by collisions with a buffer gas, for example He. The damping results in improvement of trapping efficiency and mass resolution. In practice the buffer gas is introduced into the ion trap with constant pressure. It is much more difficult, however, to trap ions which are produced externally and transferred into an ion trap with some excess energy. A method of enhancing the trapping efficiency for injected ions is the dissipation of the ions kinetic energy by collisional cooling with the buffer gas of increased pressure. However, the application of an increased buffer gas pressure constantly in time results in decreasing mass resolution. A good way to solve the problem is to use a pulsed valve. In addition, an appropriate buffer gas pressure, which may be different from that during the trapping and detecting periods, can improve the fragmentation and trapping efficiency of fragment ions in MS/MS experiments.

As a result of computer simulations, Fig. 1 shows the dependence of ion retention time on the initial phase ωt_0 of the rf voltage, for ions with mass $m = 1060$Dalton and two different He pressures 6.4×10^{-3}mbar (——) and 1.4×10^{-4}mbar (- - -). Although the curves are periodic with phase angle, only one period is shown. The calculation conditions are: trap geometry: $r_0 = 10$ mm, $z_0 = 0.707$ mm; rf frequency: $f = 0.781$ MHz; ion mass: $m = 1060$ Dalton; trapping parameter: $q_z = 0.103$; initial energy: $E_0 = 18$ eV; injection angle: $\theta = 11°$; initial phase of rf voltage: $\omega t_0 = 0.928 \times 2\pi$; initial position: $x_0 = 0$ mm, $z_0 = -0.707$ mm; He pressure: $P = 6.4 \times 10^{-3}$ mbar; time limit of calculation: $0 - 350\,\mu$s. It is clearly visible that ions can be trapped only in a very short time interval during a rf period. A higher pressure increases the ion trapping efficiency.

Experiments are performed in Bruker's ESQUIRE instrument with an electrospray ion source and a pulsed gas inlet system. A few peptide samples are measured, for example, Bradykinin, Cytochrome C and Leucine Enkephalin. The results demonstrate that the trapping efficiency can be enhanced without loss of the mass resolution by using a pulsed valve. Fig. 2 presents the doubly charged MH^{++} ion mass spectrum of Bradykinin ($m = 1060.2$ Dalton) and Fig. 3 the singly charged ion mass spectrum of Leucine Enkephalin (m= 555.6 Dalton). The He pressure is 1.4×10^{-4}mbar (lower peak) and the pulsed He gas pressure is 6.4×10^{-3}mbar (higher peak). With constant He pressure of 6.4×10^{-3}mbar, however, the mass resolution decreases (not shown in

Fig. 2 and Fig. 3).

With a higher He gas pressure in a pulsed mode, MS/MS spectrum of Bradykinin shows increased abundances of fragment ions.

Exciting Waveform Generation for Ion Traps

MICHAEL SCHUBERT · MARCUS NAGEL · YANG WANG · JOCHEN FRANZEN
Bruker-Franzen Analytik GmbH · Fahrenheitstraße 4 D – 28359 Bremen · Germany

For the mass selective collection and storage of ions in rf ion traps during ionization, dipolar excitation with special waveforms can be applied. The accumulation of ions with a selected *m/z*-value requires a narrow notch in the frequency distribution, otherwise ions of more than one *m/z*-value are stored.

It is the objective of this paper to compare the effects of two waveforms calculated by two different phase functions: The quadratic phase function used and preferred by MARSHALL et al., and a random phase function.

CHEN, WANG, RICCA, and MARSHALL proposed a phase-modulated Stored Waveform calculated by Inverse discrete FOURIER Transform (SWIFT) to generate a time-domain pulse for frequencies of preselected magnitude in the frequency-domain.

It is well-known by the work of these authors that the quadratic phase function solves best the problem of the dynamic range of the corresponding time-domain waveform. But this fact should not be overemphasized. Selecting a favorable random phase function and applying this favorable function repeatedly, the dynamic range problem can be solved sufficiently well.

The desired phase-modulated waveform pulse is calculated, by discrete inverse FOURIER transform, on a dedicated transputer board located inside the mass spectrometer. The waveform is stored in a separate memory and clocked out via a digitial-to-analog converter. The transmitted time-domain pulse is applied to the endcap electrode of the quistor.

The ions are generated by an external ion source and accumulated in the trap. Inside the trap, ions can be manipulated, isolated or fragmented and then mass selectively ejected towards an electron multiplier

When the gate is open for ion accumulation and ions enter the ion trap, the stored waveform pulse is clocked out to the endcap electrode. All ions except those of one *m/z*-value are ejected out of the trap by resonant excitation. In this way only desired ions are trapped and damped to the trap's center by the internal damping gas.

If the same favorable waveform pulse is used in subsequent experiments to eject ions of different *m/z* ratios, the RF amplitude of the ion trap has to be adjusted correspondingly. In each experiment the secular frequency of the desired ions must match the notch frequency of the waveform. — A calibration takes care of this adjustment.

A forable frequency spectrum for the stored waveform pulse could be easily imagined: The frequencies have constant amplitudes from 20 kHz to 500 kHz, the narrow notch starts at 151.4 kHz and ends at 154 3 kHz.

Fast FOURIER transform methods operate with discrete frequencies only. The length of the waveform pulse and the frequency differences are interconnected. In the experiences the frequency differences amount to $\Delta\nu$ = 976.6 Hz. The resulting time periode of the time-domain pulse is 1.024 ms. Four neighboring frequencies in the waveform spectrum are set to zero and form the notch.

The time-domain waveform pulses are calculated by discrete inverse Fast FOURIER Transform (FFT) by using the declared favorable frequency spectrum. Both phase functions, quadratic and random, are used. The resulting stored waveform pulse is reflected

43rd ASMS Conference on Mass Spectrometry and Allied Topics

about its time midpoint, equivalent to a time shift. The final time-domain waveform is normalized to the range of the digital-to-analog converter. For use during ionization, the individual waveform pulses are repeated as often as necessary. Apodization is not applied to single pulses, only the whole train of pulses is apodized.

The discrete Fast FOURIER Transform requires endless periodical repetition of the time-domain pulse to exactly reproduce the favorable frequency spectrum. In reality, this cannot be verified. The resulting frequency spectrum of a restricted train of pulses will differ from the original frequency spectrum.

The measured spectra with spectrum analyzer of the phase-modulated stored waveform with quadratic and random phase function differ in their spectral amplitudes by 6 dB. The somewhat lesser spectral amplitude of the random waveform pulse can be easily compensated for by higher amplification

In order to compare the results of quadratic and random phase modulation, a calibration gas is used. All mass-to-charge ratios from 50 u to 400 u are present. In the experiences, for example, the stored waveform pulses are used to isolate the ion with mass-to-charge ratio *m/z*=93 u.

First, the mass spectrum is acquired with a quadratic phased-modulated waveform pulse during the ionization time by exactly the same parameters. The RF-amplitude is set for isolation of ions with mass 93 u. It is interesting to note the raising intensity: The ratio of intensities of the original spectrum to the evaluated spectrum at mass 93 u is 1.8. This effect indicates that the space charge of all the ions in the full mass spectrum hinders the storage of further ions.

Application of the randomly modulated stored waveform, increased in amplitude to compensate for the lower spectral intensity, raises the abundance of the isolated ions of mass 93 u still more, by about 14% whereas all other ions are staying absent. The increase of roughly 14% from quadratic to random phase modulation is reproducible. This raise in intensity between quadratic and random phase modulation can only be explained by the incidental changes of frequencies with time.

In a following experiment, the ionization time is four times longer as usual. The intensity of the isolated ion is raising again with nearly the same factor. This factor is not just four times the intensity, indicating that space charge comes into effect. (If many ions are stored in the trap, the common electrical field cannot be ignored and the quistor is overloaded.) For much shorter ionization times, the proportionality of the ion intensity with ionization time has been verified.

For the selective storage of ions in quistor mass spectrometry with single mass resolution, a random phase-modulated stored waveform can be used with some advantage. The dynamic range and the spectral intensity of the waveform pulses are slightly lower as with quadratic phase modulation, but the storage efficiency is improved. The decrease in spectral intensity has to be compensated for by a slightly higher amplification. With otherwise exactly the same experimental conditions, about 14% more ions can be collected.

With random phase modulation, a single frequency is not just present during a short time period within the frequency sweep, as in the case of quadratic phase modulation. Unwanted ions are excited over longer periods of time, and are excited and ejected more selectively.

Ion Cloud Structure in a Quadrupole Ion Trap

*Gloria A. Bach, Efim A. Dynin, Nicholas J. Kirchner
Massively Parallel Instruments, Inc.

Introduction: We have simulated 1000 ions of three masses confined in a quadrupole ion trap. This work adds the explicit ion-ion repulsion force between each ion to the force on each ion from the Rf field for the three masses. We have quantified the existence of a shell structure consisting of mass separated layers. The spatial density of each layer is dependent upon q_z, damping gas pressure and the trap dimensions. The shell structure appears distinct when both effects of damping and explicit ion-ion repulsion are included in the calculation.

Theory: Calculations were performed on a desktop personal computer with an Intel 486 66 Mhz C.P.U. The analytical potential for the quadrupole ion trap was used, where the end cap electrodes are grounded and ϕ_O is the radio frequency voltage applied to the ring electrode. The potential field inside the trap, $\phi(r,z)$, is

$$\phi(r,z) = \frac{\phi_O}{2r_O^2}(r^2 - 2z^2) + \frac{\phi_O}{2} \qquad (1)$$

r and z in equation (1) are the distances of the ion from the center of the trap in cylindrical coordinate space. The ion / ion interaction force is calculated explicitly for each ion from the sum of all other ions in a given spatial range. The force is calculated from the equation $F = \frac{q_1 q_2}{4\pi\varepsilon_0 r^2}$. q_1 and q_2 are the coulomb charges on the two ions, r is the distance between the two ions, and ε_0 is the permittivity of free space. To speed up the calculation, a sorting algorithm was used to determine the relative closeness of all other ions to the ion of interest. All ions within a distance of 0.5 mm to the ion of interest were included in the ion / ion interaction force sum calculation.

Initial Conditions: 999 total ions were used in each calculation, 333 of mass 200, 300, and 400. Initial kinetic temperature of ions was 298 K, where individual ion temperatures were randomly chosen about a Boltzman distribution. Integration time step = 1×10^{-8} seconds. Collision gas was Helium, at a kinetic temperature of 298 K, with individual values randomly chosen about a Boltzman distribution. Collision probability was calculated using the Lengevin approximation, and collision time was assumed to be instantaneous relative to the integration time step. Starting radius for the ion cloud was 1 mm, where each ion was given a set of random starting coordinates such that the values of r and z for each ion fell between 0 and 1 mm. Initial entry of ions into the Rf field was randomized over the first Rf cycle by starting an equal number of ions into the trajectory loop during each time step of the first Rf cycle. The above initial conditions were stored to a file and re-used in each set of calculations.

Data Collection: Ion trajectories based on initial conditions were run for 1 millisecond before recording final positions. Data collection of final positions consisted of averaging the radial and axial position of each ion over a time period which included at least one cycle of secular motion for all masses. The chosen averaging time was 16 microseconds for the calculations done at 338 Volts, and 4 microseconds for those done at 1692 volts.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

Conclusions: **Damping bath gas** causes the formation of a shell structure separated into mass layers in the quadrupole ion trap. **Ion / Ion interaction**, when combined with bath gas, causes the entire ion cloud to be shifted away from the center of the trap. More specifically, the ion cloud of lowest M/Z retains its shape and is shifted away from the center. The ion cloud of middle M/Z becomes compressed in shape, and its region of maximum density is shifted away from the center. The ion cloud of highest M/Z retains its shape and is shifted away from the center. **Higher effective potentials** cause a decrease in the effects of ion / ion interaction, because the force from the Rf field affects ion motion much more strongly than inter-ion coulomb forces. **In the limit of zero pressure** the shell structure disappears, and the effects of ion / ion interaction are minimized.

A Field-Portable Ion Trap for the Detection of Chemical Weapons Compounds

Palausky, M.A. , Lammert, S.A., Merriweather, R.
Oak Ridge National Laboratory, P.O. Box 2008, Oak Ridge, TN 37831-6120
Sarver, E.W. , Wasserman, M.B.
US Army ERDEC, AGP, MD 21010-5423

The pending ratification of the Chemical Weapons Convention Treaty imposes the almost immediate requirement of on-site inspections of chemical facilities worldwide. In support of this activity, the Defense Nuclear Agency has tasked Edgewood Research Development and Engineering Center (ERDEC) to develop a small, field portable mass spectrometer (the "Generic Detector") which is capable of unambiguous detection of chemical warfare agents and their associated precursors and by-products. Concerns by the chemical industry as to the disclosure of proprietary information necessitates the development of instruments which are specific only to the targeted compounds while remaining blind to proprietary compounds not covered by the treaty. Ion trap MS/MS, with its combination of high sensitivity and selectivity is uniquely suited for this role.

The Generic Detector is based on the Chemical and Biological Mass Spectrometer (CBMS) developed by Bruker-Franzen for the US Army to detect biological and chemical weapons in the battlefield. Analytical sampling inlets for heated direct injection, direct air sampling, thermal desorption and gas chromatography were added in order to accommodate a wider range of sample types. The Generic Detector ion trap mass spectrometer has been specifically designed to be a field portable mass spectrometer. It is small (75 x 43 x 35 cm), light (less than 45 kg) and operates on less than 500 watts of power at 24 V_{DC}. No gas cylinders are needed to operate the instrument because the Generic Detector has a unique electrode geometry and mass analysis scan that allows the instrument to be operated with air and not helium as the buffer gas as well as the gas chromatographic carrier gas. A summary schematic of these features is shown.

Chemical weapons precursors and by-products are typically more polar than the actual agent compounds and therefore analytically more challenging. In general, most of the compounds tested gave detectable responses for injected amounts in the low nanogram range. In addition, the response of the Generic Detector was linear over a range of injected amounts. These results are demonstrated in the calibration curves for 1,4-dithiane.

The GDMS gave a linear response for the compounds tested over ranges from (at the lower end) 0.025-25 ng up to 200 ng. Linearity was good (R > 0.97) for naphthalene, 1,4-dithiane, 2-diethylaminoethanethiol, and two of the phosphonates, DEMP and DEEP. Linearity of DMMP, trichloronitromethane and DIMP was lower, with R values of 0.96, 0.96 and 0.93, respectively. Detection limits for these compounds varied widely, from 0 1 to 35 ng; those for polar compounds were generally at least a factor of 10-100 greater than those for non-polar compounds. Although size considerations for a portable instrument have imposed limitations on the GDMS, in general, good analytical performance is obtained.

Ion Traps as Chemical Sensors

Kevin J. Hart
Chemical & Analytical Sciences Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6120

Direct sampling ion trap mass spectrometers (DSITMS) have been developed or are in the process of being developed for monitoring of chemical components from a large number of sources including ground water wells, incinerator stacks, fugitive process emissions, automobile exhaust, explosives, chemical agents and illicit drugs [1]. With sufficient hardware and software support, automation of all aspects of sampling and ion trap operation is feasible. Thus, there is considerable potential for delivering a ***chemical sensor*** for a large range of organic compounds using ion trap mass spectrometers. Sensors are defined as a transducer with appropriate signal conditioning, computation and data transmission services [2]. Chemical sensors, of course, utilize transducers capable of measuring concentrations of chemical compounds.

The rationale behind using ion traps as the transducer in this scenario is based on the tremendous selectivity obtainable using selected reagent ion chemistry, mass spectrometry / mass spectrometry and/or MS^n and the very low detection limits (eg. sub-part-per billion) obtainable using these instruments. Significantly, many applications require the high selectivity and low detection limits the ion trap affords but can not support the personnel and financial requirements of an analytical laboratory equipped with a conventional mass spectrometer. In some cases, the limiting factor is the time scale in which final results must be logged and acted upon. One of the remaining hurdles for use of ion traps as chemical sensors is the development of a completely automated sampling, ionization, ion manipulation and data interpretation system. Another challenge in making ion traps a more effective detector for sensor applications is to reduce the overall size of the instrumentation which includes the vacuum chamber and all pumps, power supplies, electronics and computers.

The direct sampling interfaces developed at ORNL are an important step in achieving an automated ion trap system. These interfaces have been tested in a number of applications including, for example, incinerator stack monitoring. In one test, a volatile organic sampling train (VOST) was installed on a toxic waste incinerator. A sample stream, consisting of stack gas saturated with water, was pulled through a 100' heated transfer line to one of the field portable ion trap systems designed at ORNL. A heated, continuous air monitor constructed of stainless steel components served as the sampling interface. A T-connector was installed at the VOST / transfer line interface so a Tedlar bag containing VOC gas standards could be connected. The instrument response for 1000, 200 and 50 ppbv chloroform is shown in Figure 1. The exact split ratio between stack gas and standard is unknown. Consequently, the concentrations shown represent upper limits. The data shown do demonstrate the ability of the direct sampling ion traps to monitor VOC's in a real world process stream. Further testing of the ion trap as a VOC continuous emissions monitor is anticipated.

Other advances that will contribute to making an ion trap based chemical sensor a reality include automated gain control [3] and the ability to perform selective ion accumulation and broadband excitation using techniques such as filtered noise field [4]. These techniques will be used to address problems such as space charge and frequency shifts that can reduce the performance of the ion trap. One of the areas of ion trap based

sensor development that is lagging is the development of automated, customizable instrument control and data interpretation software. To alleviate this problem, an instrument control and data analysis system is being developed in LabVIEW, a popular, icon-based data acquisition and data analysis environment [5]. Thus, the ion trap, given a number of sampling, ionization, ion manipulation and interpretation parameters, will be able to output a series of voltages or numbers corresponding to the concentrations of a suite of analytes in a continuous monitoring application. These voltages or numbers can, of course, be used to trip alarms or displayed to the operator. The addition of advanced diagnostics with a number of performance standards to ensure that the ion trap is operating properly will provide a robust chemical sensor.

Electron Capture by Ions in a Quadrupole Ion Trap

Richard W. Vachet, Steven D. Clark, and Gary L. Glish
Department of Chemistry, University of North Carolina, Chapel Hill 27599-3290

Introduction: Electron capture has been implemented effectively as a selective ionization technique for various compounds. It has also been used to study physical apsects of ions. However, since electrons are not trapped under normal conditions in the quadrupole ion trap, reactions involving electron capture have not been investigated thoroughly using this instrument.

Electron capture by ions has been investigated as a function of several operating parameters. These parameters include bath gas pressure, time, type of ion, and number of ions. Electron capture will have implications on various experiments performed in the quadrupole ion trap. In fact the capture of electrons by ions may have analytical applications.

Experimental: Experiments were performed using a modified Finnigan MAT ITMS. Ions were generated by EI. The beam of electrons that served as the neutralization pulse was produced from the same filament used to generate ions. Samples were introduced via a pulsed valve. Since neutrals cannot be directly measured, three experiments were used to determine the extent of neutralization. One experiment served as the main experiment where the ions were generated and then neutralized with a second electron pulse after the unionized sample was pumped away. The second experiment provided the amount of ions generated during the first electron pulse and did not have a neutralization pulse. A third experiment had only the neutralization pulse. The third experiment provided the number of ions generated during the neutralization pulse. The extent of neutralization was determined by adding the intensities of ions from the second and third experiments and subtracting from this the intensity from the first experiment. The percent neutralized could then be calculated by taking this value and comparing it to the intensity from the second experiment.

Results and Discussion: Since electrons cannot be trapped under standard conditions in a quadrupole ion trap, the electrons that are captured are likely secondary electrons produced during the electron beam's interaction with background gases. Low energy primary electrons could also be produced by collisions with background gases or interactions with the RF field upon entering the trap. Figure 1 shows the percent neutralization of the radical molecular cation of dioxane with respect to neutralization pulse length at different pressures of Helium. This graph shows that the pressure of the background has plays a key role in the amount of neutralization. The trend on this graph seems to follow the equation: $I_n = I_o (1-e^{-\sigma N l})$ where I_n is the number of ions neutralized, I_o is the initial number of ions, σ is an electron capture cross section, N is the number of electrons, and l is the path length. If N and l are held constant then ions with different cross sections should be neutralized to different extents. Protonated dioxane which is an even electron species is neutralized to a smaller extent than the odd electron molecular ion of dioxane for a given neutralization period. It should be less likely for an even electron species to capture an electron and become a neutral radical than for a radical cation to capture an electron and become an even electron neutral. To see if smaller differences in electron capture cross sections could be noticed, N- butylbenzene was used. It has a lower neutralization percentage for a given neutralization period. This is attributed to the higher energy of N- butylbenzene's LUMO. Figure 2 shows the comparison of dioxane, protonated dioxane, and N-butylbenzene at a pressure of 1×10^{-3} Torr. It was also seen that varying the number of ions initially present did not change the neutralization percentage. This is expected from the equation above , where changes in I_o should not change the ratio of I_n / I_o.

Conclusions: Positive ions in a quadrupole ion trap capture electrons upon bombardment with an electron beam. The increases in neutralization follow increases in background gas pressure. This suggests that the low energy electrons needed are likely produced during interactions of the primary beam of electrons with background gases. The neutralization follows a typical Beer- Lambert type trend. These results indicate that increases in ionization times should not result in linear increases in ion intensity since some ions formed early in the ionization pulse will subsequently be neutralized. Also different ions show varying extents of neutralization, presumably due to differences in electron capture cross sections. Radical cations are neutralized to a greater extent than are their even electron counterparts. If this technique is sensitive enough to minor changes in electron capture cross sections, it may be useful as a means to differentiate ions, perhaps even isomers.

EXPERIMENTAL STUDIES OF SPACE CHARGE EFFECTS IN A QUADRUPOLE ION TRAP MASS SPECTROMETER

Barrie Ann Shaffer, Joe Karnicky, and S. E. Buttrill, Jr.
Varian Associates - Ginzton Research Center
3075 Hansen Way, Palo Alto, CA 94304-1025

In an rf quadrupole ion trap, ions experience an effective potential which is the sum of their coulombic interaction with other trapped ions and the trapping pseudopotential. We have experimentally probed the potential experienced by trapped ions by precisely measuring their secular frequencies as a function of the trapped ion population.

Isolated ion ejection spectra were observed by using an ion selection waveform to store a single ion mass before a resonant ion ejection process. For examining the effects of clouds of ions of various masses on one another we used ion selection waveforms to store multiple ion masses and observed the ion ejection profiles for each. These experiments were carried out using customized software and a standard Varian Saturn 3 GC/MS equipped with a Wave~Board. All experiments used FC-43 as the sample under conditions where there was no detectable broadening of the peaks in the mass spectrum.

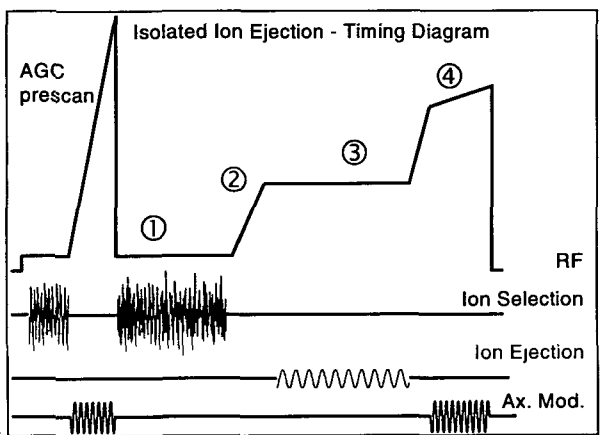

Figure 1.

The scan function for isolated ion ejection spectra is shown in Figure 1. Although an AGC prescan is provided by the software, in all of the experiments described here, the maximum ionization time and sample pressure were adjusted to ensure a constant ionization time. During ionization and for a short time thereafter (1) a tailored waveform is applied to the ion trap endcaps to accomplish selective ion accumulation [1]. The storage level is then raised (2) to establish the desired q_z value for the ejection spectrum. A single frequency waveform is used (3) for the ion ejection, then a narrow mass range scan (4) measures the number of ions remaining. The ejection profile is defined as the percent ion ejection as a function of applied frequency. The amplitude of the single frequency ejection waveform is adjusted to produce 70-90% ejection of the ion mass of interest. Data points are recorded across the ejection profile at 100 Hz intervals. The centroid of the profile is taken as the ejection frequency.

Different behavior is observed for a single mass isolated in the trap compared to a mass stored in the presence of ions of different mass. For a single isolated mass there is little shift in the ejection frequency as the number of stored ions is increased, and the amplitude necessary for ejection changes only slightly. When two different masses are stored, the ejection profile

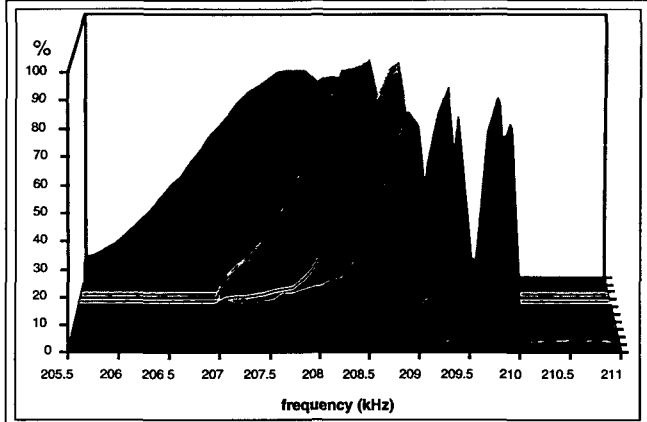

Figure 2. Ejection profile of m/z 364 in the presence of increasing amounts of m/z 264.

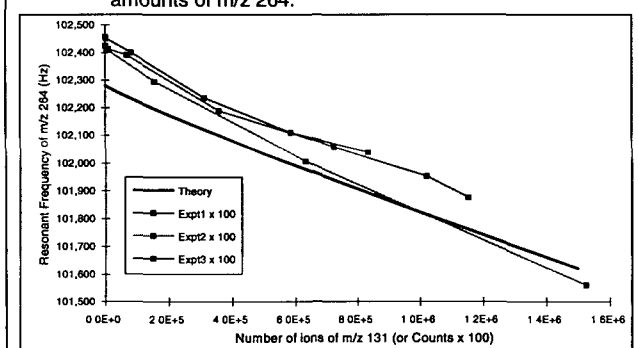

Figure 3. Comparison of predicted and experimental frequencies for m/z 264 in the presence of m/z 131

broadens and shifts to lower frequencies, as illustrated in Figure 2. The amplitude required to produce the ejection profiles of m/z 364 in Figure 2 increased from 0.25 Vpp to 2.40 Vpp as the amount of m/z 264 increased from 7 to 14,000 counts. The amount of m/z 364 was held constant at about 10,000 counts.

The potential due to an ion cloud of a single mass at equilibrium can be calculated using the approach of Guan and Marshall [2]. The potential seen by a high mass ion in the presence of a cloud of low mass ions is the sum of the psuedopotential for the heavy ion and the space charge potential of the light ions. The motion of the heavy ion in this potential may be integrated numerically to obtain the period of its secular motion. The calculated secular frequency for m/z 264 in the presence of increasing numbers of m/z 131 ions is shown as the heavy smooth line in Figure 3. Three sets of experimental data are plotted for comparison. The decrease in ejection frequency for m/z 264 with increasing numbers of m/z 131 and the slight upward curvature of the data are both reproduced by the model.

ELECTROSPRAY / ION TRAP MS^n FOR STRUCTURE ELUCIDATION OF ANIONICS

Robert J. Strife, The Procter & Gamble Co, Miami Valley Laboratories,
P.O. Box 538707, Cincinnati, OH 45253-8707
&
Jae Schwartz, Mark Bier and Joe Zhou, Finnigan-MAT, 355 River Oaks Pkwy.
San Jose CA 95134

Electrospray ionization (ESI) is particularly useful in the analysis of aqueous or mixed organic / aqueous samples. Consumer products (CP's) are often formulated or used in the aqueous phase, and many of their components are amenable to electrospray analysis. Transformation of key components in CP's to other organic structures is a concern in many types of studies like environmental fate, shelf stability and metabolism / toxicology.

The combination of the ion trap with ESI provides several distinct advantages over linear arrays of quadrupoles for structure elucidation of these transformed products including: 1) ion integration capabilities, ideal for a "dim" ion source like ESI; 2) sequential product ion experiments in the time domain (MS^n) so that ions may be refragmented and probed for their organic structure; 3) efficient mass selective storage, via "notched" wave forms, for isolating a component from a mixture and 4) very efficient observed CID efficiencies.

EXPERIMENTAL -- Pure standards were diluted to 1-2 ng/µL for analysis using a prototype of the Finnigan-MAT LCQ. Samples were infused through the electrospray device at 220°C at a flow of 5 µL/min. Ion injection periods from 1 ms to 500 ms were used, with longer times being applied at higher stages of MS^n. Mass selective storage was accomplished by adjusting the q_z value of ions of the desired m/z value to 0.83. A notched wave form of variable amplitude was applied to eject ions of unwanted m/z values. CID was carried out at q_z of the parent ion of 0.2 - 0.3.

RESULTS & DISCUSSION -- C_{10}-linear alkyl sulfonate (C_{10}LAS) is a common component of detergent products eventually discharged into the environment. It is readily obtained as a pure compound, and possesses a "permanently" charged center in view of its high pk_a. We use it routinely to benchmark ESI performance. MS/MS (parent ion 297^-) using an ESI / triple quadrupole instrument (center-of-mass collision energy ~ 5 V), yielded predominantly m/z 183 (charge-remote elimination of octane) and 184 (loss of octyl radical, a "rule violation"). Less intense ions are observed at m/z 80 (sulfite radical anion) and 119.

MS^n analysis (Fig. 1) using the prototype LCQ instrument not only revealed the relationship between these ions but also generated other useful fingerprints for the fragmentation of this compound. Ions of m/z 184 were found to fragment only by loss of H radical to m/z 183. The ion of m/z 119 came from loss of 64 u (SO_2) from m/z 183 (**MS^3**), presumably by rearrangement to the 3-ethenyl phenoxide anion. This anion fragmented by two pathways (**MS^4**): 1) loss of CO with ring contraction to the aromatic ethenyl cylcopentadienyl anion (m/z 91) and 2) loss of acetylene to the phenoxide anion, m/z 93. When isolated and refragmented (**MS^5**), these anions collapsed by loss of acetylene or CO respectively to the aromatic cyclopentadienyl anion (m/z 65). Thus, a characteristic pattern is established for C_{10}LAS, useful for

investigating products of biodegradation (e.g., beta-oxidation of the alkyl chain). We then reapplied this approach to an aromatic polyphenol and generated an **MS^5** fragmentation map. The structure of an isolated impurity was investigated (**MS^6**) and a specific modification of an A-ring hydroxyl to an O-hydroxyethyl moiety was deduced. Furthermore, a second impurity of relatively high molecular weight was isolated ($[M-H]^-$ anion at m/z 579). MS/MS yielded mainly m/z 329 and 273. The ESI / Ion Trap combination allowed refragmentation of these ions (**MS^5**) and a partial structure of the impurity was deduced.

Finally, the LC/MS and LC/MS/MS sensitivity was benchmarked with C_{10}LAS and the prototype LCQ was found to be at least a factor of 20 (conservative estimate) more sensitive in the full-scan MS/MS mode than the ESI / triple quadrupole system (Fig 2). The product ion spectrum showed the principal fragments at m/z 183 and 184 at this low level (20 pg) of C_{10}LAS injected.

Technological Aspects of a New LC/MS^n Quadrupole Ion Trap

Jae C. Schwartz, Mark E. Bier, Dennis M. Taylor, Joe Zhou,
John E.P. Syka, Mike S. James and George C. Stafford
Finnigan MAT, 355 River Oaks Pkwy, San Jose, CA 95134-1991

Inroduction: Most of the developments involving the quadrupole ion trap including ion injection, mass range extension, high resolution, and MS^n capabilities, have been performed on commercially available systems which were designed in 1982 and have pushed the existing hardware and software to their limits. A new ion trap system architecture has been developed which provides the utmost in versatility, programmability, and expandability. This architecture, incorporating a unique electronic and firmware design, has proven to be an ideal system for quadrupole ion trap instrument development. This system architecture provides the foundation for a new generation of commercial quadrupole ion trap products including a new LC/MS^n instrument shown in Figure 1 as well as a GC instrument. Innovations for implementing and putting into practice most of the latest developments into these commercial products were made using this novel system architecture .

Electronics: The digital electronics consists of an embedded 486 (or higher) microprocessor, acquisition and control digital signal processor (DSP) boards, two dual channel digital synthesizers (DDS), an arbitrary waveform generator, serial, IEEE, and ethernet communication boards. The analog circuitry includes a high stability RF amplifier, octopole RF amplifier, DC lens supplies, auxiliary and waveform amplifiers, electrometer, and main power supplies.

Firmware: An embedded Ion Trap instrument Control Language (ITCL) allows real time adjustment of instrument and scan function parameters and allows programming of experiments.

Operating Parameters: In developing the commercial quadrupole ion trap instruments, this powerful combination of hardware and firmware allowed in depth studies and therefore optimization of many fundamental ion trap parameters. In particular, the choice of operating parameters such as RF frequency, scan rate, resonance ejection **q** and amplitude, He pressure, and ring electrode r_0 have been studied both empirically and theoretically, in order to achieve the desired mass range of 2000 amu, maintain unit resolution throughout the mass range, and scan at 5555 amu/sec or faster. The information gained in these studies has also provided insight into how to best implement higher resolution scans. Automated experiments were performed and multidimensional data were acquired covering the data space of resonance ejection amplitude vs. resonance ejection **q** vs. peak width at a variety of fixed combinations of pressure, scan rate, r_0, and RF frequency. By choosing the optimum resonance ejection amplitude for each resonance ejection **q** the data can be simplified to a more informative format as in the example shown in Figures 2. This data shows the effects of scan rate on peak width vs. resonance ejection **q** at the specified values of the other parameters. Theoretical considerations in conjunction with these data suggest that the optimum **q** value for resonance ejection is at a point which maximizes frequency dispersion while keeping scattering effects minimized. The frequency dispersion is given in Equation 1. The theoretical resonance ejection voltage required to eject ions at a constant rate, k, at a constant **q**, neglecting He effects, is given by Equation 2 which indicates a linear relationship with mass and is experimentally demonstrated in Figure 3. A lower RF frequency of 760 Khz and a reduced r_0 of .707 cm can be used with minimum reduction of resolution and space charge limit, but yields a higher mass range.

Scan Functions: The control architecture allows for automated adjustment of the ion trap scan function for performing fully automated Full Scan MS, SIM, SRM, MS^n and higher resolution scans.

Results and Conclusions: A new quadrupole ion trap system architecture has been developed which is ideal for ion trap research and development. This architecture serves as the foundation for new commercial LC and GC MS^n quadrupole ion trap products. The combination of the electronics, firmware (ITCL), choice of operating parameters and scan function design result in many instrument capabilities

including, unit mass resolution throughout the 2000 m/z mass range (Figure 4), higher resolution scans (Figure 5), fully automatic MS^n, SIM, SRM, Zoom Scans, unit resolution isolation up to m/z 1200, single m/z or broad band activation, charge state identification, data dependent scanning and more!

Novel Technologies and Enhanced Features for GC/MS/MS

Eric K. Johnson, Jae C. Schwartz, Dennis M. Taylor,
Mark E. Bier, John D. Ragsdale
Finnigan Corporation, 355 River Oaks Parkway, San Jose, CA 95134

Over the past ten years, much research and development has been devoted to the use of the quadrupole ion trap as a mass analyzer for analytical GC/MS and GC/MS/MS. These devices have principally used internal ionization with a pulsed electron ionization event, followed by ion ejection and detection with a continuous dynode electron multiplier. Although well developed for quantitative target compound analyses where the lowest limit of detection is required, these systems have yet to be fully utilized in some general applications where quadrupole mass filter technology remains dominant.

A novel device has been designed and constructed to test the practical performance of a combination of these two mass spectrometer systems, specific for gas chromatography detection. A conventional high energy electron ion source, a quadrupole ion trap mass analyzer operated in the mass selective instability with resonance ejection mode, and an off-axis post-acceleration dynode detector have been purposefully integrated with a modern instrument control architecture. A schematic of this architecture is represented in Figure 1.

With external ionization, ions are created outside the ion trap and then injected into the mass analyzer, where the analyte neutral population is dramatically reduced With a much lower probability of ion-molecule reactions, the resultant mass spectrum is virtually unaffected by increasing analyte concentration, producing the "classical" spectrum seen on conventional quadrupole filter mass spectrometers. An example of this effect is shown on Figures 2-4 The removal of this "self-protonation" process has been demonstrated for many other susceptible compound classes such as alcohols and esters.

Using this hybrid system, we have determined the operating conditions for the use of external ionization with a quadrupole ion trap that enables high efficiency ion storage and mass analysis over a 10-1000 dalton mass range in both MS and MS/MS modes. A novel technique to optimize the pseudopotential energy well of the quadrupole ion trap during ion injection, has resulted in the ability to quantitatively adjust the ion storage efficiency with increasing mass. The resultant ion ratios have proven to meet, and in many cases exceed the analytical quality of mass spectra derived using a quadrupole mass filter.

An example of this performance is demonstrated by the comparison of the EI spectra of straight chain hydrocarbons (Figure 5) with traditional quadrupole filter spectra (Figure 6). Standard hydrocarbon spectra with molecular ions present cannot be obtained with internal ionization traps It is this type of phenomena, combined with unwanted ion-molecule reactions that have prevented the older technology from routine qualitative unknown analyses. These problems are significantly addressed by the use of ion injection.

The use of resonance isolation and excitation to perform MS/MS and SRM experiments have been successfully demonstrated with this system. All modes, including full-scan and SIM exhibit a surprising increase in dynamic range and ion signal strengths explained in part, by the post-acceleration dynode detector. A further improvement to the limit of detection has been demonstrated by the sequential gating of the electron beam, post-injection, to reduce neutral noise. Combined with high pressure chemical ionization, the electron capture negative ion mode can surpass electron ionization results.

In summary, the data presented here demonstrate how external ionization and post-acceleration dynode detection, used in series with the quadrupole ion trap, have significantly improved the mass spectral performance compared with older methods of ion trap operation.

Triple Stage Quadrupole

Quadrupole Ion Trap Control Language - Power in the Hands of Researchers

Joe Zhou and Jae Schwartz
Finnigan MAT, San Jose, CA 95134

Technical advances of the quadrupole ion trap during the last few years have made it a potentially powerful analytical instrument. Until now, however, software control of the device is still largely based on the old method developed over ten years ago. That is, by constructing scan functions through a series of scan descriptor tables. This method lacks the ability of building scan functions parametrically, *i.e.*, as a function of other parameters and also lacks infrastructures for general programmability, such as real-time decision making and execution flow control. Therefore, newer and more flexible concepts of ion trap control are needed. We developed an innovative technique, called the Ion Trap Control Language (ITCL), to overcome those deficiencies. This language was not only developed for ion trap research but also used as the basis for controlling Finnigan's new commercial ion trap products, *i.e.*, LCQ™ and GCQ™.

At the core of the digital control system are an embedded Intel 486 processor (running the pSOS real-time operating system), two digital signal processors (one dedicated for device control and scanning; the other for data acquisition and processing), and an arbitrary waveform signal generation board. The embedded real-time system communicates with the host computer (a Pentium-based PC with Windows NT operating system) through the Ethernet connection. Several real-time tasks, running on top of the pSOS operating system, are responsible for instrument operations. At the center of the control is the ITCL This language is the window (or interface) through which all ion trap mass spectrometer activities are controlled. It consists of two major tasks: an ITCL compiler task and an ITCL executor task. The compiler takes ITCL programs in ASCII text form as input and compiles them into an executable form. The compiled code is then passed to the executor for instrument control.

The Ion Trap Control Language is a procedural language that is syntactically similar to the popular computer programming language C It has some of the basic programming constructs as any computer language does; it also has system built-in variables and functions that can be used to control ion trap activities. Some of the key features are:

Flow Control Structures. ITCL provides basic constructs for modification of execution flow, such as 'if-else' statement for branching, 'while' loop for repetition, and 'break' statement for jump.

Variable and Function: All ion trap controls are performed through variable access and/or function calls. ITCL provides system built-in variables and functions for basic ion trap operations, such as for scan function creation, for scan execution, for data acquisition, and for data feedback. Users can define and access their own variables and functions as well.

Operators: The language has built-in operators for assignment (*e.g.*, =, +=, -=, *=, /=), arithmetic (*e.g.*, +, -, *, /), relational comparison (*e.g.*, <, >, <=, >=, ==, !=), logical relation (*e.g.*, ||, &&), and logical computation (*e.g.*, |, &).

Virtual Devices: All hardware components (*e.g.*, RF amplitude, DC voltage, *etc.*) that need to be controlled during a scan are treated the same and programmed in a similar fashion. Each device is assigned a unique numeric ID (fully configurable); no knowledge or distinction is made in order to create (through the scan matrix as will be described below) scan functions for a particular device.

Scan Matrix: This is an ITCL construct that is used as the building block to create scan functions for each virtual device. Description of the scan function of each device can be either independent of each other or linked by time events. All ion trap control activities are programmed through this mechanism. One powerful feature of defining scanning functions in this manner is that the scan description created is totally parametric, *i.e.*, can be a function of any ITCL variable

Real-time Data Feedback: Spectral feedbacks, such as the width, mass, or the height of a peak, calculated by the acquisition DSP are readily accessible through system variables or functions. This, in combination with the scan matrix, allows rapid data-dependent modifications of ion trap scan parameters.

Tailored Waveform Calculation: ITCL has the system built-in functions that are used to setup and to calculate arbitrary waveforms with any given number of frequency notches.

Math Calculation: System functions are provided by the language for frequently used math operations (*e.g.*, log, exp, sin, sqrt, *etc.*), and ion trap related calculations (*e.g.*, frequency to q conversion, q to beta conversion, Wronskian *etc.*).

Experiment Data Export: ITCL provides elements to export any experimental data of interest to the host computer numerically or graphically. Any experimental data of interest can be programmed to be plotted, in real-time, through a graph program provided on the host computer.

During the development of Finnigan's latest ion trap systems, the LCQ™ and GCQ™, many of the instrument parameters have been studied for optimum instrument operating conditions ITCL has proven to be a very powerful tool to accomplish this task. Experiments that normally require weeks or months were reduced to hours or days. Advanced scan capabilities of the system, such as data-dependent scans, are also programmed and controlled through ITCL procedures. The concept of achieving ion trap control through a procedural language, such as the Ion Trap Control Language, proves to be very powerful and provides a solid foundation upon which further ion trap research and development can be carried out.

Ion Optics and Design Considerations for a New LC/Quadrupole Ion Trap

Mark E. Bier*, Jae C. Schwartz, Joe Zhou, Dennis Taylor,
John Syka, Mike James, Bill Fies, and George Stafford
Finnigan Corporation, 335 River Oaks Parkway, San Jose, CA 95134-1991

We have coupled an atmospheric pressure ionization source (ESI/APCI) to a high performance quadrupole ion trap mass spectrometer (Figure **1**). The design is compact with the ion beam traveling less than 20 cm from the end of the heated capillary to the detector. The transfer optics, analyzer and electron multiplier are easily accessible by a removable top cover which includes a unique baffle for differential pumping. The rear chamber of the three chamber manifold is maintained at 1.5 X10e-5 Torr(uncorrected) by a unique dual stage turbo molecular pump. The mass range of the instrument was extended to M_{max}=2000Da. by reducing r_o to 7 mm, decreasing the main Rf frequency to 760 kHz, and by resonantly ejecting ions at a q_{eject}=0.83.

Several possibilities exist for gating ions into the ion trap. We have selected to gate ions using the tube lens. Positive ions are stopped by applying ca -140V to the tube lens. Tube lens/CAD is possible in this region. The skimmer lens is also a possible gating element but requires isolation from ground and an additional power supply. Gating with the interoctopole lens causes octopole 1 to trap ions. We transfer ions to the ion trap by using two short octopoles. We use octopoles because they are ion bunchers, especially at high pressures. We use two octopoles because of the need to differentially pump the system. The interoctopole lens serves three functions. One, to transfer ions into octopole 2 from octopole 1; two, to act as a differential pumping barrier; and three, to act as a potential barrier to charged particles that are produced in API sources even with an off-axis heated capillary. These charged particles cause noise spikes at the detector. We discovered that by placing +300 volts on the exit lens of the trap that this noise can be essentially eliminated (Figure **2**). For example, the ESI signal from cocaine $(M+H)^+$ was buried in noise **2a** with the exit lens=0V while **2b** shows a noise free spectrum. Placing several hundred volts on the interoctopole lens sufficiently reduces this noise during the mass analysis portion of the scan function. Once octopole 2 transfers ions directly into the trap, the Rf amplitude of both octopoles is switched off to avoid inducing Rf voltages onto the entrance end cap. Injected ions require helium pressures of ca. 1 mTorr for efficient ion trapping as well as an ion Rf level that is optimum. (Figure **3**). We calculate the optimum injection Rf level for trapping. We have found that if the exit optics are not designed properly the mass spectra may show mass discrimination. We have designed the exit optics with an off axis detector to respond equally to both low and 2000Da ions of high kinetic energy (e.g. 2000Da, 4keV)

Multiple reaction monitoring (MRM) of 10 pg reserpine shows that more than one reaction can be monitored with little loss in the ion trap duty cycle (scan out time is ca. 10 ms). Summing more than one ion current gives improved signal response and thus lowers detection limits. The capillary LC data shows MS/MS of 442.3^{+2} from 7.8 femtomoles of RVYVHPI (Figure **4**) (standard mix provided by Michrom Corp). The 10 fmole level at which this work was conducted is supported by the apparent loss of the two larger peptides of lessor abundance. At this low level, a large portion of these peptides may have adsorbed to a surface.

Particle Resonance's in "Monopole" and Quadrupole Electric Ion Traps

Ralph F. Wuerker

and
Paul Kelly
Teledyne Electronic Technologies
Mountain View, CA 94039-7127

A charged particle in a quadrupole electric trap ("Paul" or ion trap) can be resonated or selectively excited in two completely different ways. The most common method is via an AC signal across the end caps. Resonance occurs when the frequency of the applied signal is equal (tuned to) the natural frequency of the particle in the z direction. For this case, the particle amplitude (in absence of damping) grows linearly in time, until the end caps are reached. Off resonance, the two frequencies (particle and resonating) interact to produce a beat phenomena at one half the difference between the two frequencies, with the maximum excursion being proportional to the resonating voltage.

The second method of resonance has the resonating signal in series with the trapping source of frequency Ω. This is a true parametric resonance which occurs when the resonating frequency is equal to twice the natural frequencies of the particle in either the **z** or **r** directions. At resonance the particle orbit grows exponentially with time, and the particle can experience more oscillations before striking the electrodes. As a result, resolution should be higher. The scheme has the disadvantage that it must started, either by displacing the particle off origin by either end cap resonance or by pulsed excitation.

These resonance techniques are complicated by the mathematics of the ion trap which are Mathieu differential equations, with their own complexities. The resonating sources add additional terms to the equations of motion which further complicate the analysis. The first (end cap) resonating scheme results in a driven Mathieu equation. The second series or parametric resonating scheme results in a Mathieu equation with two different AC drives. Damping, due to background gas, adds further complexity.

The analysis of an ion trap can be greatly simplified by studying the behavior of a charged particle in the stable direction of a DC quadrupole or its equivalent a DC monopole. Such a system is not practical, but is important for the insight that it affords, since, a charged particle in a DC quadrupole obeys the differential equation of harmonic motion. For this case, the particle oscillates harmonically about the origin of the electrode structure at a characteristic frequency of;

$$\omega_{\beta_z} = \sqrt{\frac{2eV_{DC}}{m(Z_o)^2}}$$

where **e/m** is the charge to mass ratio of the particle, and V_{DC} is the trapping voltage between the origin and the end caps, a distance of Z_o away. Application of a resonating voltage across the end caps, results in the well known differential equation of driven harmonic motion, which at resonance ($\omega_d=\omega_{\beta z}$) has the following solution,

$$z = -\left[\frac{eV_d}{2m\omega_{\beta_z} Z_o}\right] t Cos\omega_{\beta_z} t = -\left[\frac{\omega_{\beta_z}}{4}\right]\left[\frac{V_d}{V_{DC}}\right] Z_o t Cos\omega_{\beta_z} t$$

showing that the amplitude grows linearly with time, at a rate proportional to the ratio of the resonating voltage to the trapping voltage. An expression for the resolution **R** of the resonance can be derived. Standard driven harmonic motion theory can be used to derive an expression for the off resonance amplitude. With damping, the amplitude of oscillation grows to a finite value while the frequency for maximum excursion is slightly above and below the $\omega_{\beta z}$ value.

When the resonating voltage is in series with the trapping voltage, one again realizes another Mathieu equation; namely, one which uses the first (**a**=1) unstable solution, the equation of parametric instability, with resonance occurring when the resonating frequency is $2\omega_{\beta z}$. The solution is of the form,

$$z \cong A_o\left[Sin\left(\frac{\omega_p t}{2} + \frac{\pi}{4}\right)\right]\exp\left(\frac{V_p}{4V_{DC}}\right)\left(\frac{\omega_p}{2}\right)t$$

showing that the amplitude in this case grows exponentially with time. If the particle is initially at the origin (A_o=0), the solution is zero for all time and the resonance never occurs, it must be started. Excessive damping will negate the parametric resonance, however the amplitude grows exponentially even in the presence of damping.

A particle in a real AC ion trap oscillates at a subharmonic of the drive frequency ;

$$\left(\omega_{\beta_z}\right)_{AC} = \sqrt{2}\left(\frac{e}{m}\right)\left(\frac{V_{AC}}{Z_o^2}\right)\frac{1}{\Omega}$$

This "resultant frequency" can be substituted into the resonance equations for the DC quadrupole and monopole deriving expressions for the growths of the particle orbit as a function of time for the two resonant situations in an AC ion trap. The effects of damping can be similarly included.

Implications of Ion Population for GC/MS/MS on a Quadrupole Ion Trap

*Scott T. Quarmby and Richard A. Yost
Department of Chemistry, University of Florida, Gainesville, FL 32611

The use of resonant excitation for collision-induced dissociation (CID) on the quadrupole ion trap relies upon accurate knowledge of the parent ion secular frequency. This frequency has been shown to shift as the number of ions stored in the ion trap changes, which causes the CID efficiency to vary significantly [1] GC/MS/MS presents an especially challenging problem because of the wide variation in sample concentration eluting from the GC As an alternative to broadband excitation [1], this work demonstrates the use of mass-selective automatic gain control (MSAGC) [2,3] to regulate the parent ion population for GC/MS/MS. MSAGC, derived from standard AGC [4], calculates an ionization time which will produce the desired parent ion population based upon the parent ion intensity detected during a prescan. By controlling the ion population, only a single resonant excitation frequency and voltage are needed over a wide analyte concentration range.

A Finnigan MAT ITS-40™ with Gatorware software, developed in our laboratory, was used which allowed custom scan functions. A computer controlled frequency synthesizer was coupled to the endcaps through an external balun circuit. Using a constant source of sample, the variations in the optimum resonant excitation frequency and voltage for CID were determined for ion populations from just above the noise to beyond the onset of space charge (loss of unit resolution). For a given ionization time and resonant excitation voltage, data were acquired for different frequencies to determine the most efficient frequency for CID. Plots of the optimum resonant excitation frequency versus the detected ion intensity can be seen in *Figure 1*. The optimum frequency decreased as the ion population increased. In *Figure 2* a plot of the CID efficiency at the optimum frequency versus the detected ion intensity shows that for larger ion populations, higher resonant excitation voltages produced more efficient CID.

The scan function utilized for GC/MS/MS using MSAGC is shown in *Figure 3*. Triplicate injections of the standard solutions were run; the calibration curves obtained are shown in *Figure 4*. For dimethyl disulfide and thiophene, linear dynamic ranges of 5 and 4 orders of magnitude were obtained, respectively. The linear dynamic range for thiophene was smaller because MSAGC was unable to control the ion population for the largest (100 ng) injection. To determine possible matrix effects on this technique, jet fuel spiked with dimethyl disulfide and thiophene was analyzed. The calibration curves obtained are shown in *Figure 5*. The analysis of dimethyl disulfide in jet fuel also had a linear dynamic range of 5 orders of magnitude. For thiophene, however, another compound that produced m/z 84 ions at the same retention time as thiophene was identified. Since the MSAGC prescan only monitored the total number of m/z 84 ions, MSAGC could not distinguish between m/z 84 parent ions from thiophene and from other jet fuel components. For low concentrations of thiophene, most of the fragment ions produced were from other jet fuel components, limiting the sensitivity of the analysis.

The optimum resonant excitation voltage increases as the number of ions stored in the ion trap increases whereas the optimum resonant excitation frequency decreases as the number of ions stored in the ion trap increases. Mass-selective automatic gain control keeps the ion population relatively constant for GC/MS/MS so that a single-frequency and voltage can be used over a wide sample concentration range. GC/MS/MS analysis with high sensitivity and a linear dynamic range of 4-5 orders of magnitude is possible with MSAGC.

The authors would like to thank Timothy Griffin for his work on the Gatorware software and James Stephenson for all of his ideas and helpful discussions. Partial funding for this project was provided by Finnigan MAT and the NASA Space Grant Fellowship supported through the Florida Space Grant Consortium.

INVESTIGATIONS OF MASS SHIFTS IN THE ION TRAP MASS SPECTROMETER

J P DeGnore and R. A. Yost
Department of Chemistry, University of Florida, Gainesville FL 32611

It has been reported that under identical conditions, ions of exactly the same m/z, including positional isomers, will be detected at different m/z values [1] This phenomenon was called a mass shift because the mass, as assigned by the mass spectrometer, is shifted to a value either higher or lower than its nominal mass. Mass shifts would have serious implications for the practical use of ion trap mass spectrometers, particularly for high resolution and accurate mass assignment applications. Previous investigations have shown an apparent mass shift for the positional isomers of trifluoromethyl benzonitrile (TFBN) [1]. These mass shifts have been rationalized as originating from an interaction between the radio frequency (RF) fields of the ion trap and the polarizability of the analyte ion under investigation. Investigations by others have also reported this correlation between mass shift and polarizability of the analyte ion [3]. It has been suggested that ions of different polarizability would have different radial distributions in the ion trap and therefore would be ejected at different apparent masses [4].

Experiments were performed on a Finnigan MAT Ion Trap Mass Spectrometer (ITMS) to examine mass shifts of the M^+ ions of TFBN isomers All experiments used a standard stretched ion trap geometry (z_0 = 0 78311 cm) except for the experiments using the theoretical geometry. The experiments utilizing theoretical trap geometry had a reduced endcap to ring spacing (z_0 = 0.7071 cm) compared to the stretched geometry of a commercially available ion trap such as the ITMS. The results of these experiments are presented in the table below The apparent mass shift between the ortho and para isomers at normal scan rate is +0 8 DAC steps or approximately +0 14 u This mass shift was similar to that previously reported [1] At this scan rate isomeric peaks of m/z 171 are only characterized by only five data points Therefore, the centroid of this profile data may result in errors that would lead to anomalous mass shifts. Shifts of several DAC steps would be more convincing, to better characterize these mass peaks, and to produce shifts of greater than 1 DAC, experiments were performed using a reduced scan rate At a reduced scan rate, more data points can be acquired for improved peak characterization The method of employing an offset DAC summed to an attenuated RF DAC output was implemented for controlling the scan rate [6].

This theoretical trap geometry is expected to produce an increase in the mass shifts[5] The para isomers was shifted to slightly higher mass compared to the ortho isomer. This is in contrast to the results seen for the stretched trap geometry The magnitude of this mass shift at normal scan speed is similar to that in the normal scan rate experiments with a stretched trap geometry However, the reduced scan rate did not correlate well with our normal scan rate results nor with previous results [1]

To further examine if isomeric mass shifts are caused by the interaction of the isomeric polarizability and the RF field, the frequency of the ions were investigated The secular frequency of the ions was determined by varying the axial excitation frequency. This was repeated with various ionization times. The largest frequency difference between ortho and para at the same ion population was less than expected from previous investigations [1]. Also, in contrast to previous investigations, the para isomer is shifted to higher mass than the ortho isomer [1]. To exaggerate mass shifts, the theoretical trap geometry was also used in these experiments In agreement with previous reported results the ortho curve is lower in frequency than the para [1]. However, the largest frequency difference between ortho and para was less then expected from previous investigations [1]

Although the results of the normal scan rate experiment are similar in value to mass shifts previously reported, the results of the reduced scan rate experiments did not produce the same mass shift [1]. The degree of mass shift (in u) seen in previous investigations is much higher than the modest mass shifts seen in reduced scan rate experiments [1] The mass shifts seen in these investigations are small enough that they could be attributed to factors such as quantization noise in the DAC or instrumental calibration drift The axial resonant excitation experiments did not find the expected mass shifts for the same ion population. It is proposed that erroneous mass shifts could be caused by poor peak characterization, inconsistent ion population between isomers, and the error associated with determining a mass shift *based upon only one DAC step*

The Effect of Scan Direction on Mass Resolution in Stretched and Compressed Traps

Mingda Wang

Varian Chromatography System, 2700 Mitchell Dr., Walnut Creek, CA 94598

It is well known that the mass resolution of resonance ejection in a stretched trap depends on rf scan direction [1] because of the introduction of octopole and the higher order electric fields. Frenzen has pointed out that ion secular frequency depends on its oscillation amplitude under such rf electric fields [2]. Bolton has reported that mass resolution gradually improves and reaches a limit when the two end caps are symmetrically stretching out [3].

In a stretched trap, mass resolution in a forward scan is much better than that in a reversed scan. In the presentation, a compressed trap with a positive octopole term, instead of with a negative octopole term in a stretched trap, is introduced. The relationship between the mass resolution and the scan direction is reversed when the sign of the octopole field is changed by replacing the stretched trap with the compressed trap. The reversed scan is created by adding a negative saw function to the sum point of the rf control amplifier during the analytical scan period. This modification enables Saturn data system to record the reverse scanned signal.

Figures 1-2 are the forward and reverse scans in the stretched and compressed traps. The mass unit widths in all scans should be the same though the mass peaks in the scans appear at different positions of mass axis. Comparing Figures 1 and 2, it is apparent that mass resolution depends not only on scan direction but also on the direction of octopole electric field. Figures 3-4 are the SIMION simulation of ion 69 trajectory in the stretched and compressed traps. The maximum step of the SIMION program is extended to 10 million. The trajectory is recorded more than 14 ms at the 0.84 μs/datum sampling rate while the trapping rf level is fixed. Then the time domain signal is subjected to the Fourier transform to obtain the ion secular frequency. The digital resolution of the frequency spectrum is better than 100Hz. Figures 3-4 clearly show **the shift of secular frequency with the amplitude in the stretched and compressed trap are in the opposite direction**. Figures 1-4 reveal that **the unit mass resolution can be easily achieved with normal scan speed (185 μs/amu) when the direction of ion frequency shift is in the same direction of the rf scan**.

It is observed that when the amplitude of the dipole excitation field increases, the absorption peaks become wider and their maxima are shifted. As expected, **the maximum in a stretched trap (top) shifts in the opposite directions to that in a compressed trap (bottom), which agrees with the shift directions of ion secular frequency.**

43rd ASMS Conference on Mass Spectrometry and Allied Topics

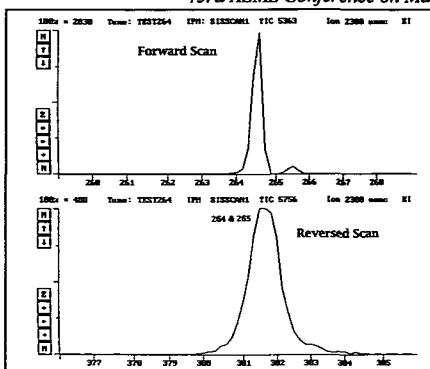

Figure 1: Forward and Reverse Scans in a Stretched Trap. The top and bottom figures are the forward scan and reversed mass spectra of ion 264 & 265 respectively. It is clear that **isotopic peaks of ion 264 and 265 are well resolved by the forward scan and can not be resolved by the reversed scan in the stretched trap.**

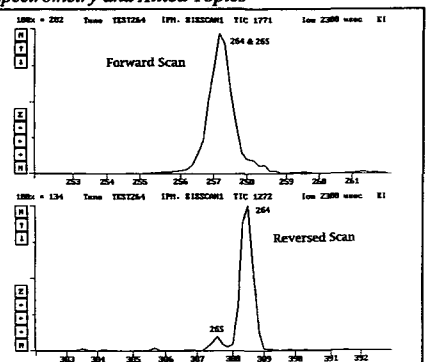

Figure 2: Forward and Reverse Scans in a Compressed Trap. In contrast to the stretched trap, the isotopic peaks of ion 264 & 265 can not be separated by the forward scan (top). But they are well separated by the reversed scan (bottom). It indicates that **mass resolution depends not only on scan direction but also on the direction of octopole electric field.**

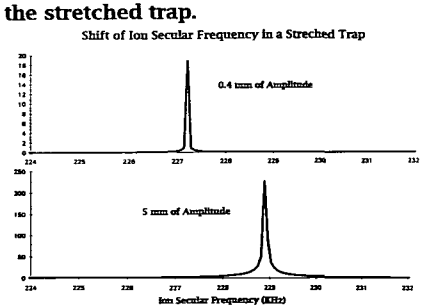

Figure 3: Ion Secular Frequency Shift in a Stretched Trap. Comparing the top and bottom figure, it is clear that in the stretched trap, the secular frequency **gains about 2 KHz** while ion oscillation amplitude increases from 0.4 mm to 5 mm. The secular frequencies are obtained from the Fourier transform spectrum of simulated ion z motion.

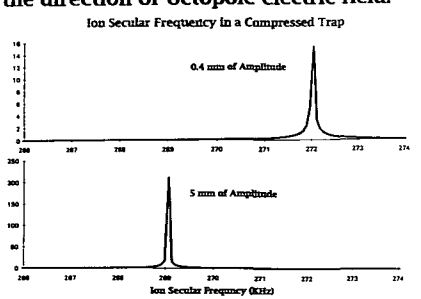

Figure 4: Ion Secular Frequency Shift in a Compressed Trap. The up and bottom figures show the secular frequency in the compressed trap lowers more than 2 KHz when ion oscillation amplitude increases from 0.4 mm to 5 mm. Figures 1-4 reveal that **the mass resolution depends on the direction of ion frequency shift.**

High Resolution Selected Ion Monitoring In An Ion Trap

Greg Wells and Chuck Huston

Varian Chromatography Systems
2700 Mitchell Drive
Walnut Creek, CA 94598

Selective ion monitoring in an ion trap was accomplished by isolating and detecting each target ion successively. The chromatogram could be divided into 200 time segments. In each time segment up to 10 different scan groups could be sequentially acquired. Each scan group could isolate and detect a different ion. In the example (Figure 1) two scan groups were used to alternately isolate selected ions from phencyclidine (PCP) and deuterated phencyclidine (D-5 PCP). The isolation of each mass occured at the same optimum operating point to ensure constant mass dispersion and resolution. The ionization time for each ion could be independently optimized to ensure the maximum sensitivity and dynamic range for each mass.

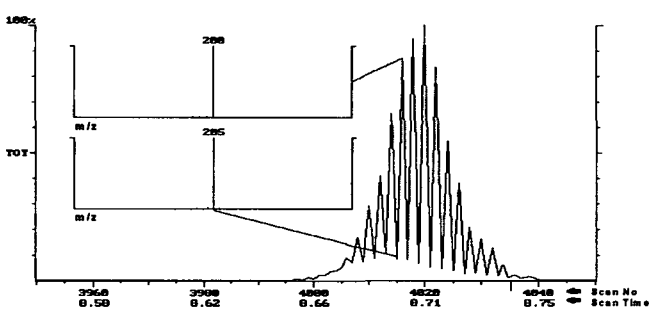

Figure 1

Each set of the 10 successive group spectra could then be merged into a single spectrum for data analysis (Figures 2 and 3).

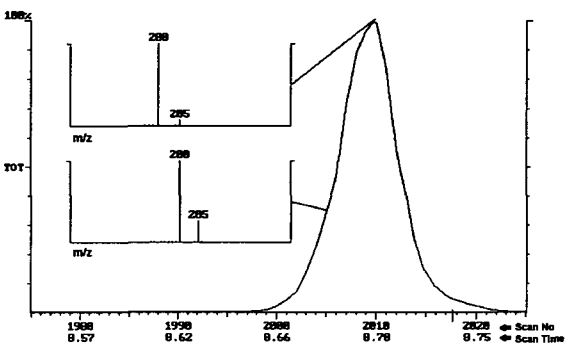

Figure 2

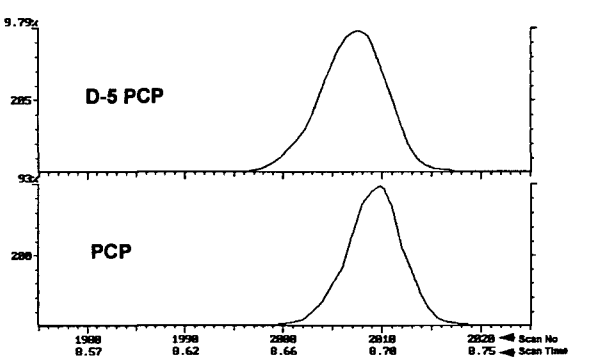

Figure 3

Field Modulated Selective Ion Storage In An Ion Trap

Greg Wells and Chuck Huston

Varian Chromatography Systems
2700 Mitchell Drive
Walnut Creek, CA 94598

Selective ion accumulation in an ion trap during the ionization period was accomplished by the combined application of a multi-frequency waveform to the end caps while the rf trapping field amplitude was modulated (Figure 1). The waveform was constructed from a minimal number of frequency components (<120 frequencies) that spanned the entire mass range and were spaced so that unwanted ions were resonantly ejected while target ions were accumulated during ionization. Modulation of the rf trapping field amplitude causes a frequency modulation of the secular motions of the ions in the trap; this periodically brings the ions into resonance with the frequencies of the supplemental waveform, causing the unwanted ions to be ejected.

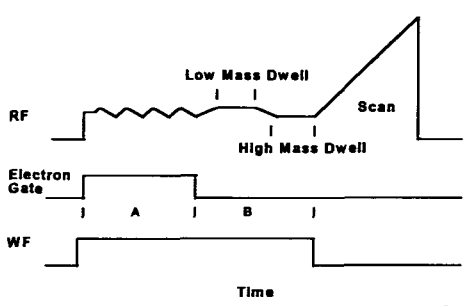

Figure 1

The technique can be extended to the selective accumulation of multiple ions. Figure 2 shows the isolation of m/z=100,131,264 and 414 from FC-43. The technique was used to analyze for Aldrin and Heptachlor Epoxide in an of bell pepper extract (Figure 3). These compounds were undetectable in the normal full scan EI mode.

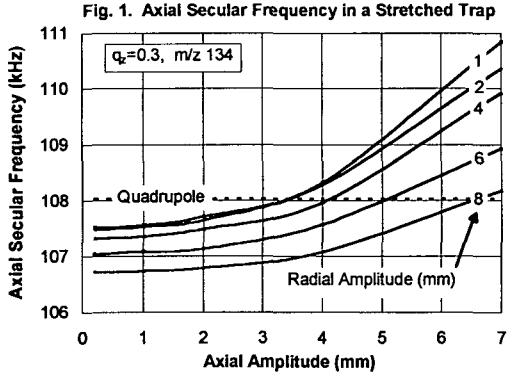
Introduction

The mass intensity signals which are obtained when ions are ejected from an ion trap during a mass-selective instability scan can appear on the mass axis at positions which differ significantly from expected values. Several origins of this *mass displacement* have been proposed. Some, such as space-charge [1], affect all ions to approximately the same degree. Others, such as radial distribution [2], ion-ion interactions [3] and dipole moment [4], appear to be ion-specific and, consequently, are less amenable to correction. It is well known that ion-specific mass displacements observed with *stretched* ion traps are reduced substantially from those observed in traps of pure quadrupole geometry [5]. In both pure quadrupole and stretched traps three potential origins of mass displacement were evaluated: dipole moment, radial amplitude and ion fragmentation.

1) Dipole Moment

- Only the first term in the multipole expansion of a potential is independent of the choice of origin The dipole moment of an ion can vary from zero to infinity as the origin is moved away from the centre of charge.
- Rotational energy levels are populated at room temperature! Consequently, ions are rotating at a frequency greater than that of the RF drive by a factor of at least 10^5.
- *If* an ion had a *permanent* dipole moment comparable to that of the neutral species and *if* the dipole was aligned with the RF field, then the force experienced by an ion located at (0, 0, $0.1z_0$) would be increased by a factor of only 4×10^{-8}.
- Under maximizing conditions, the dipole moment *induced* in DCB by the trapping field would be smaller than the permanent dipole moment of the neutral by a factor of at least 10^4
- Neutral molecules of ortho- and para-dichlorobenzene (DCB) have permanent dipole moments of 2 5 and 0.0 debyes, respectively. To look for correlation between the permanent dipole moment of neutral molecules and mass displacement, the apparent mass difference between ortho- and para-DCB was measured a large number of times, under a broad range of experimental conditions, at intervals which spanned a one-month period Although the uncertainty in individual measurements was large, statistically significant results, were obtained by averaging all the data obtained for each electrode configuration. The mass difference (ortho - para) obtained by averaging the results of ~500 experiments for each trap geometry were 0.003±0.146 u and 0.000±0.066 u for quadrupole and stretched traps, respectively

Fig. 1. Axial Secular Frequency in a Stretched Trap



2) Computer Simulations

Frequency analysis of ion trajectory simulations in a stretched trap at q_z=0 3 demonstrated that an ion's secular frequency is a strong function of its amplitude in both the axial and radial directions Analysis of trajectories in a pure quadrupole trap yielded the theoretically predicted result indicated by the dotted line in Fig 1.

To establish the influence of radial amplitude on apparent mass, simulations were performed on ensembles of ten ions using both pure quadrupole and stretched geometries *M/z* 131 ions were cooled at q_z=0.2, radially excited to specific amplitudes and finally ejected during a mass-selective instability scan by two different methods: resonant excitation at β_z=0 5 and by crossing the stability boundary at β_z=1.0.

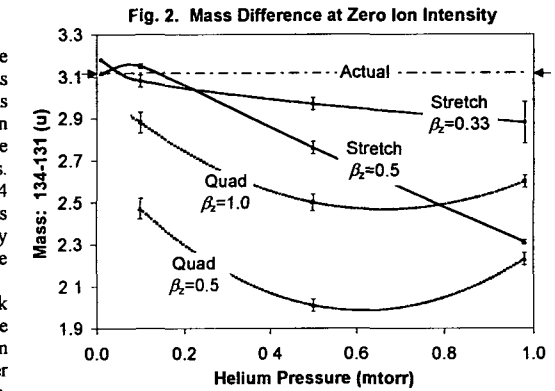
The major findings of these simulation studies were: i) Apparent mass at ejection is unaffected by initial radial position in both trap geometries ii) Ions in a stretched trap are held in a potential well which is significantly deeper than in a pure quadrupole trap. iii) Examination of radial position at ejection shows no significant difference in detection efficiency for either trap type, or ejection method, for initial radial amplitudes less than 3 mm.

3) Ion Fragmentation

The molecular ion of *n*-butylbenzene (NBB) exhibits a significant mass displacement [3,4]. Furthermore, this molecular ion undergoes fragmentation readily when subjected to resonance excitation in the presence of buffer gas. A shift to lower mass of the *m/z* 134 peak occurs when lower-mass fragments fall outside of the region of stability during resonance ejection of the molecular ion

The position of the *m/z* 134 peak of NBB was measured relative to the $C_3F_5^+$ (*m/z* 131) fragment of PFTBA in both quadrupole and stretched traps over a broad range of ionization times, ejection points, and helium pressures. These results have been summarized in Fig. 2 where the 134-131 (NBB - $C_3F_5^+$) mass difference, extrapolated to zero ion intensity, has been plotted as a function of helium pressure

Fig. 2. Mass Difference at Zero Ion Intensity



Conclusions

- The dipolar properties of ions provide an unlikely explanation for the mass displacements demonstrated by some compounds.
- Ion ejection from a stretched trap is delayed with respect to that from a quadrupole trap due to the greater trapping well-depth associated with the former. This ejection delay in the stretched trap is compensated by the tendency to premature ejection brought about by the shift in secular frequency associated with the amplitude of axial motion.
- Fragmentation of ions during resonance-excitation ejection can cause a significant shift to lower apparent mass. This shift can be reduced to zero in a trap of stretched geometry by a combination of one or more of the following conditions: i) reduce the pressure of the buffer gas; ii) eject at the βz=1 stability boundary and/or iii) eject resonantly at a sufficiently low value of qz that lower-mass fragments are trapped

COOLING TIME AND PRESSURE EFFECTS ON COMPETITIVE THERMALIZATION/ACTIVATION PROCESSES BY RESONANCE EXCITATION ON ITMS.

P.Liere[1], T.Blasco[1], R.E. March[2], J.C. Tabet[1]

Mass spectrometers which permit MS/MS experiments involving collision-induced dissociation have been very useful for qualitative analysis as well as for the study of low-energy collision processes and ion/molecule reactions. The ion trap capabilities for MS/MS experiments have been described previously and have demonstrated a high sensitivity and CID efficiency; furthermore, several sequential stages of reaction, mass-selective isolation and excitation, $(MS)^n$, can occur in these instruments Moreover, the time parameter access in the ITMS presents an easy means to study the kinetic and thermodynamic properties of gas-phase ion/molecule reactions.

CID experiments were performed on an ITMS by using the resonance excitation process (or tickle process) whereby an auxiliary voltage was applied on the end-cap electrodes at the fundamental axial secular frequency of the previously isolated precursor ions. Some earlier studies have shown that the internal energy imparted into the parent ions can be changed by introducing a delay between the isolation period and the tickle period.[1] For this purpose, the classical model of n-butylbenzene was used as an "energy thermometer"[2] to estimate the average internal energy deposited into the molecular ion (m/z 134) according to the two product ions' relative abundances, m/z 91 ($C_7H_7^+$) and m/z 92 ($C_7H_8^{+\circ}$), produced from the direct cleavage and rearrangement pathways, respectively. Variation of helium and analyte pressures and of the cooling time before excitation (called t_{cb}) was investigated to have a better understanding of the energetic thermalization and activation processes by resonance excitation.

A Finnigan Ion Trap Mass Spectrometer (ITMS) was used. Helium buffer gas was introduced via a gas chromatograph and transfer line to the ion trap. n-Butylbenzene was introduced via a leak valve into the ion trap. All pressures were measured by a Penning gauge mounted to the vacuum chamber, as described recently [1] In Fig. 1 is shown the scan function used for the MS/MS experiments. The cooling time following isolation and prior to precursor ion (m/z 134) excitation was varied over a time scale 0-100 ms The tickle parameters were q_z (m/z 134) = 0.4, V_{tic} = 0.6 V and t_{ex} = 10 ms (V_{tic} and t_{ex} are defined as the peak-to-peak amplitude and duration of the tickle voltage, respectively).

Some recent studies[3] have shown that insertion of a cooling time in MS/MS experiments can play a great role in the degree of activation of the excited molecular ion. The cooling time causes an ion internal energy decrease in the time scale 0 to 20 ms, as is shown in Fig 2 This effect is due mainly to the thermalization of ion kinetic energy defined as a reduction of both molecular ion kinetic energy and spatial distribution as a result of momentum-exchange collisions with helium buffer gas. The initial internal energy, coming from the electron impact process, is likely thermalized in collisions between the molecular ion and neutral n-butylbenzene. The t_{cb} influence on molecular ion activation, when t_{cb} is prolonged to 100 ms has been discussed already and explained in terms of an accumulation of internal energy during both the cooling time before excitation and the tickle period as a result of collisions of increasing number between the molecular ion and buffer gas atoms.

Buffer gas pressure variation has a more marked effect on the average ion internal energy uptake by the resonance excitation process than does the cooling time variation. The resonance excitation activation process is more and more dominant as the helium pressure is increased. The I_{91}/I_{92} ratio increases from 1.6 to 4 and from 1 to 6 between $1.6.10^{-4}$ torr and $5.2.10^{-4}$ torr at t_{cb} = 0 ms and t_{cb} = 100 ms, respectively. Moreover, only the activation process is observed as P(He) = $5.2.10^{-4}$ torr and only the thermalization process is observed as the helium pressure is low (P(He) = $1.6.10^{-4}$ torr)

There are a number of points which can explain these results: (i) the number of collisions, either between low-kinetic energy molecular ion and helium, or between the excited molecular ions and

helium, is increased during the cooling and tickle periods, respectively, by increasing the helium pressure for a given t_{cb} value, (ii) the dual role of helium, as a target/buffer gas, favors ion dissociation over ion ejection; thus the irradiated ions, having the higher excursion amplitudes from the centre of the ion trap and the higher kinetic energy can be stored and decomposed rather that ejected as the helium pressure is increased (iii) The precursor ion excitation frequency bandwidth (generally measured when 10-20 % of the parent ions are fragmented or ejected) is decreased when the cooling time or helium pressure is increased in our experiments. This "frequency focusing" can play a major role in the tickle process efficiency. Indeed, if the applied tickle frequency and the precursor ion frequency are closer with a larger t_{cb} value or with a higher helium pressure, the average ion excursion amplitudes and ion kinetic energy will be higher for a constant excitation fluence. Thus, the CID process by resonance excitation will be more efficacious for internal energy deposition when the frequency distribution is narrow and overlaps the secular frequency for a given fluence.

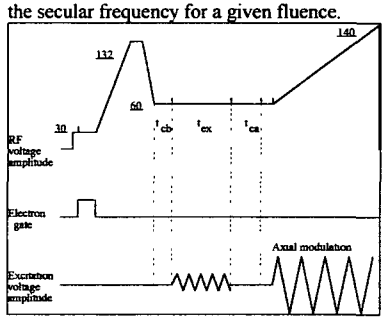

Fig 1- Scan function employed in the tandem mass spectrometry experiments showing cooling times before and after excitation period.

The influence of the analyte pressure and t_{cb} variations on the I_{91}/I_{92} ratio has been investigated, as is shown in Fig. 3. No helium was admitted into the ion trap The I_{91}/I_{92} ratio decreases as t_{cb} is increased to 20 ms and remains constant if tcb > 20 ms The initial internal energy thermalization does not seem to contribute significantly in these experiments despite the neutral pressure increase. This phenomenon is likely due to the space charge effects due to the ion/ion interactions of the molecular ion Thus, these repulsive forces cause ion excursion amplitudes to increase and, therefore, the ion kinetic energy increases thus preventing the thermalization process. On the basis of these experiments, this latter process seems to be optimum for a minimal analyte pressure in the ion trap

QIT/TOF Analysis of Space Charge in a Quadrupole Ion Trap

Ventura,M.C.*, Aldalur,I., Laude,D.A., Department of Chemistry and Biochemistry,
The University of Texas at Austin, Austin,TX 78712-1167

Substantial efforts are made in the interest of avoiding high space charge conditions in performing quadrupole ion trap mass spectrometry. A potential due to space charge perturbs the electric field in the trap and thus the detected ion signal at a certain ion density level in the trap. The effects of peak distortion and mass shifting have been documented[1,2] In order to better characterize ion cloud behavior, a series of experiments was performed with a highly modified Finnigan ITD. A modified endcap electrode and masks are exploited to display information on the effects of space charge in the radial direction under high vacuum and collisional cooling conditions. Finally, the effects of collisional cooling on kinetic energy distributions within the trap may be calculated by employing TOF data from signals collected at various ion flight distances.

The system configuration is presented in Fig.1. The ITD has been oriented to permit horizontal TOF of ejected ions. The ion trap region and TOF region are connected but differentially pumped to maintain high vacuum conditions in the TOF region even during experiments using He buffer gas for collisional cooling. The illustration displays also the variable flight distance detection system. The channeltron detector has been removed from its mount on the ITD manifold wall and installed on the end of a probe translatable through the TOF region.

Fig.2 shows the altered endcap electrode and masks used to analyze ion signals from various radii within the trap. The outer two series of holes drilled into the endcap permit evaluation of the ion cloud at radial extents not available in commercial ion trap spectrometers. A LeCroy 9310 digital oscilloscope was used for high-precision peak shape analysis.

In all experiments, an essentially isolated naphthalene parent ion population (m/z=128) was examined. A q value of 0.23 was used in most experiments whereby background air and water ion trajectories are destabilized during storage, leaving only m/z=128 in the trap before mass-selective instability scanning. Peak shape data obtained from the use of four different masks are analyzed together to examine ion distributions and space charge phenomena in different areas of the trap. Experiments were run under low and high space charge conditions controlled by varying the sample pressure through a variable leak valve.

Kinetic energy distributions are calculated by measuring deviations in the peak width caused by varying ion flight distances necessary for an ejected ion bundle to reach the detector. Using a Gaussian model for the detected signal, a FWHM is measured on a peak, converted to σ, and the time deviation of σ from one flight distance to another yields a velocity relative to the peak centroid. This represents a velocity difference from the mean (a standard deviation) of the ion cloud velocity distribution. The value readily converts into a kinetic energy distribution.

The electrode/mask configurations were used to sample ion populations at various radii within the trap. Peak profiles were obtained for each electrode/mask configuration under low and high space charge conditions. Normal collisional cooling behavior was observed for low space charge conditions in all experiments where ions could be ejected from the center of the trap.

The ion storage time was varied in one experiment under high space charge conditions while monitoring the signal peak height. When no buffer gas was introduced, signal increased to equilibrium in ~10ms for the 7-hole and unmasked electrodes. Collisional cooling with sample neutrals apparently increases signal within these radii until it is counterbalanced by Coulombic effects. For the case where only the center hole radius was sampled, the signal continued to decrease with time. The Coulomb

2 Cleven,C.D.,Cox,K.A. and Cooks,R.G., *Rapid Communications in Mass Spectrometry* vol.8: p.451-454, 1994.

concentration. When He buffer gas was added, however, the cooling effect was observed at this radius as well as the larger radii. The equilibrium signal level was reached at ~8ms in each case.

Resolutions were measured for both high and low space charge conditions for ions sampled from the various radii. Under high space charge, the 12 hole radial section had the best resolution though the signal level was poorer than for center trap samplings. Evidently space charge effects distort the signal in the 7-hole radius at some level, whereas this region exhibits the best resolution under low space charge.

In another experiment the relative mass shift was observed for the 1-, 7- and unmasked electrode configurations, with and without buffer gas. As the number of ions trapped increased from low to high space charge level, the shift of the peak centroid was measured, and relative values were plotted.The largest shift occurred for the center hole electrode where theoretically, the largest space charge exists. Also of note, no mass shift was observable using the unmasked electrode.

Finally, the evolution of the kinetic energy distribution of ions trapped for increasing delay times was determined using variable TOF. The data indicates an exponential focusing of the kinetic energy distributions as a function of the average number of collisions.

Operation of a quadrupole ion-trap mass spectrometer (ITMS) depends on details of ion motion in the trap such as spatial and velocity distributions, effects of gas pressure and ion density, the RF drive frequency, phase and amplitude, and additional (perturbing) fields. In spite of this, relatively few studies have experimentally addressed the motion of ions in ion traps. Trajectories can be calculated and plotted through computer simulations for idealized traps, but the accuracy of modeling real traps has yet to be established. [1,2] We have developed a methodology, based on spatially-resolved photodissociation, for the direct measurement of ion densities in the ITMS. [3-5] Both the ring electrode and/or the end caps can be slotted (>1 mm width) to allow optical access along the trap's axial or radial axes. Measurement of photodissociation products as a function of position and trap operational parameters then allows spatially resolved determination of the number densities of the parent ions.

Recently it has been shown that the mass resolution and mass measurement accuracy of the ITMS depend on both ion density and compound type. [6] Building on these experiments, we have used tomography to determine that ion radial distributions mirror these observations. Briefly, as the ion density increases, the mass peak increases in width, shifts to higher mass, and the radial distribution of the ion cloud increases (Figure 1). We have also found the magnitude of these effects to be dependent not only on ion density and compound but also on ion trap geometry (Figure 2). This data suggests that mass shifts are related to the expansion of the ion cloud in the radial direction. In addition, we have determined that field faults induced by slotting the electrodes for optical access can apparently be compensated for by "super-stretching" (z_0=0.870 cm, r_0=1.0 cm) the trap.

Ion Trap Mass Spectrometry: Variations in Electrode Size and RF Drive Frequency

A.W. Garrett, C.G. Gill, and P.H. Hemberger. Chemical Science and Technology Division, Los Alamos National Laboratory, Los Alamos, NM 87545

The use of smaller electrodes, reduced RF drive frequencies, resonance ion ejection, [1] and nonlinear resonance ion ejection [2] have all been used to increase the 650 amu mass/charge range of the standard Finnigan ion trap mass spectrometer. However, some of these techniques may have detrimental effects on other operational characteristics of the ITMS. Previous work has shown that mass resolution is dependent on ion density and electrode geometry [3]. Two sets of electrodes that are 0.8 (r_0 = 0.8 cm , z_0 = 0.566 cm) and 1.4 (r_0=1.40 cm, z_0=0.990 cm) scale versions of the Finnigan electrodes (r_0=1.0 cm, z_0=0.707 cm) have been machined at LANL in order to investigate the effect of size and RF drive frequency (900kHz-1.25MHz) on mass resolution and relative sensitivity. Comparisons of electrode geometries with endcap spacing for the specific cases of $r_0^2=2z_0^2$ and for a geometry stretched 10.7% in z have also been completed.

A direct drive digital synthesizer, used in place of the standard Finnigan oscillator, provided a means to control the frequency of the RF waveform applied to the ring electrode of each ion trap assembly. The RF circuitry was tuned at each drive frequency for minimum reflected power. The endcap electrodes were maintained at ground and a mass spectrum was generated via mass selective instability; axial modulation was not used. Signal from the preamplifier output (pin JA1) of the Finnigan analog board was directed to a digital oscilloscope where mass peak area and width were measured directly. RF scan rates were determined by the time difference between ejection of the m/z 69 and 131 peaks of FC-43. The RF level was adjusted at each RF drive frequency and electrode geometry to maintain a q_z value of 0.3 at m/z=131.

For each size trap, the width of a mass peak (Δm) increases as the ion abundance increases and as the RF drive frequency decreases (q_z remains constant). In addition, the slope of a Δm vs. ion abundance curve increases as the drive frequency increases (Figure 1). These results are consistent with ion tomography experiments which demonstrate that as ions are confined in a deeper potential well, the ion cloud is reduced in size and ion/ion interactions become more prominent.

As expected, normal sized (r_0=1.0 cm) electrodes stretched along the z axis by 10.7% provide better mass resolution than for the ideal ($r_0^2=2z_0^2$) spacing, but this trend was reversed for the smaller (r_0=0.8cm) electrodes. In addition, the normal sized-stretched electrode assembly provided better mass resolution than either the small-stretched or large-stretched assembly These observations indicate that the optimal separation of the endcap electrodes is electrode size dependent.

It is currently difficult to directly compare results between traps of different size because Δm depends on ion abundance and the correlation between mass peak area and ion abundance is uncertain for a given geometry. However, estimates indicate that the small ion trap is approximately two times less sensitive and the large trap is on the order of 5-10 times less sensitive than the normal sized trap. The sensitivity differences are

likely related to non-optimized spacing of the endcap electrodes for the small and large sized electrode assemblies. Perhaps there is some frequency optimization required also.

The ion trajectory simulation program, ITSIM, has been used to investigate the use of quadrupolar dc pulses to manipulate the ion cloud in an ion trap mass spectrometer. Properly timed dc pulses can be used to optimize the shape and position of the cloud for different experiments. Manipulation of the ion cloud is important in photodissociation and in high-resolution experiments because the performance is dependent on the exact location of the ion cloud. Simulated data for both of these experiments are presented, as are experimental data for the photodissociation experiment.

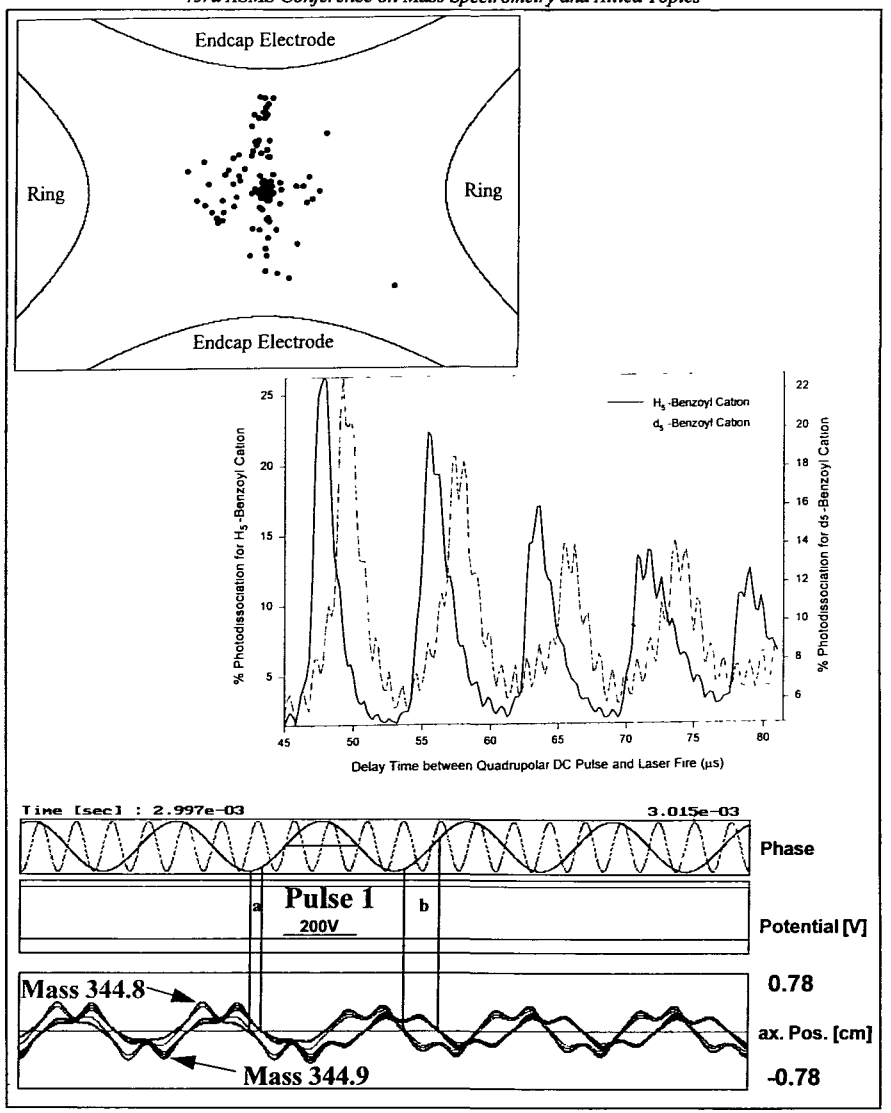
Photodissociation Experiment

When utilizing photodissociation or other laser-based experiments, it is desirable to achieve the highest efficiency possible. In a trapped ion experiment, the photodissociation efficiency may be improved by repeating the irradiation step multiple times as long as the photofragment is not dissociated further. Alternatively, the shape of the target ion distribution can be manipulated so as to irradiate as many of the trapped ions as possible. This is achieved by shaping the ion cloud and in doing this, all ions of the same mass/charge ratio are forced to simultaneously intersect the laser beam. This feature of the quadrupolar pulse means that a mass-selective photodissociation is achieved without prior mass analysis.

Simulations indicate that a quadrupolar dc pulse can be used to force all ions of the same mass-to-charge ratio to be in phase with each other or phase-shifted by exactly 180 degrees. Hence, all the ions cross the z-axis simultaneously every 180 degrees of the radial secular cycle. If a laser beam is focussed collinearly with the z-axis and pulsed at an appropriate time following excitation, it will simultaneously irradiate all ions of a given mass. Besides improving the photodissociation efficiency, the experiment also provides the possibility to photodissociate ions of a particular mass present in a mixture of other ions. Figure 1 shows the spatial positions of ions of two different masses at a specific time following the quadrupolar dc pulse. When ions of a particular m/z ratio are focussed to the center of the trap, ions of different m/z ratios (and different secular frequencies) will still be dispersed in the axial and radial dimension. These experiments were performed using H_5- and D_5 -benzoyl cation at many different delay times (Figure 2), and the expected improvement in performance is achieved.

A New High-Resolution Experiment

Application of quadrupolar dc pulses during dipolar ac activation provides a new method of mass analysis as suggested by simulations of ion motion using ITSIM. The rf/ac signals are phase-locked and a dc pulse is applied at a specific time in the secular motion of a trapped ion population. Application of the pulse at the appropriate time results in increased separation from other ions of different mass-to-charge ratios (Figure 3). After the ions become spatially separated, another dc pulse is applied, again at an appropriate time in the secular period so that only ions of the mass of interest are axially ejected. The simulations show that isobaric ions are completely ejected in one rf cycle, and that complete separation of ions of m/z 344 80 and 344.83 is possible. Alternative experiments in which a series of dipolar dc pulses are used give comparable results, although with somewhat lower mass resolution.



CALCULATION OF PARAMETRIC RESONANCE FOR NONLINEAR ION TRAP

Efim A. Dynin* and Nicholas J. Kirchner
Massively Parallel Instruments, Inc., 2030 Fortune Dr., Suite A, San Jose, CA 95131

The new method of parametric excitation enhances the performance of RF traps by applying pump voltage in series with drive source (1, 2) For linear trapping field the maximum efficiency is obtained when pumping frequency is equal to doubled frequency of secular motion and amplitude of ion oscillations increases without bound. However, nonlinear effects produce a detuning during excitation and modify an ion response. The purpose of present research is to investigate the influence of octupole anharmonicity on the parametrical resonance in the axial direction.

We report results of calculations for a time-dependent spatially inhomogeneous potential

$$\Phi(r,z,t)=\frac{c}{2z_0^2}\left(V_0\cos(\Omega t)-u\cos(\omega t)\right)\left[z^2-\frac{r^2}{2}+\frac{g}{z_o^2}\left(\frac{z^4}{3}-z^2r^2+\frac{r^4}{8}\right)\right].$$

Here r, z - cylindrical coordinates of ion, t - time, $2z_0$ - endcap separation, V_0 and u - trapping and pump voltages, Ω - trapping frequency, ω - pumping frequency Dimensionless parameters c and g depend on trap design

For pure quadrupolar field without pumping ($g = 0$, $u = 0$) the parameter $q = 2ecV_0/(mz_0^2\Omega^2)$ defines the behavior of ion with mass m and charge e. In particular, if $q << 1$ the trajectory is dominated by secular motion with frequency $\omega_0 = \Omega q/(2\sqrt{2})$ and constant amplitude The three additional small field parameters $\alpha = u/V_0$, $\varepsilon = (\omega - 2\omega_0)/\omega_0$, and g are included in numerical integration of the equations of motion for given potential Examples of simulations are presented in figures for the Finnigan MAT ion trap where, according to (3), $z_0 = 7\ 83$mm, $c = 2\ 17$, $g = 0\ 037$ Other parameters used in calculations are $V_0 = 50$ V, $u = 1$ V, $(\Omega/(2\pi)) = 1$ MHz, $(m/e) = 61$, $q = 0.142$ Initially ion has zero velocity and is located at r = 0 with axial coordinate z(t=0) which is shown at the figures.

The general conclusions from calculations are the following.

1- Besides micromotion and secular motion the ion is involved in oscillations with a frequency which may be significantly lower than the secular one (Fig a).

2- The period of these oscillations increases with decrease of $|\alpha|$, $|z(t=0)|$, and $|g|$.

3- The amplitude in resonance has a region of sharp dependence on the pump frequency (Fig b)

4- The maximum of amplitude has weak dependence on initial conditions and is close to $z_0\sqrt{|2\alpha/(gq)|}$

The last estimate was also derived by the analytical approach based on effective potential

$$U_{eff}=\frac{m\omega_0^2z^2}{2}\left(1-\frac{4\alpha}{q}\cos(\omega t)+\frac{8gz^2}{3z_0^2}\right).$$

The ability of such simple model to reproduce the qualitative characteristics may have important applications in the development of new schemes for nonlinear ion trap operation

The Use of Ion Trap Mass Spectrometry with FNF Waveforms for the MS/MS of Cocaine

Mark L. Miller
FBI, FSRTC, FBI Academy, Quantico, VA 22135

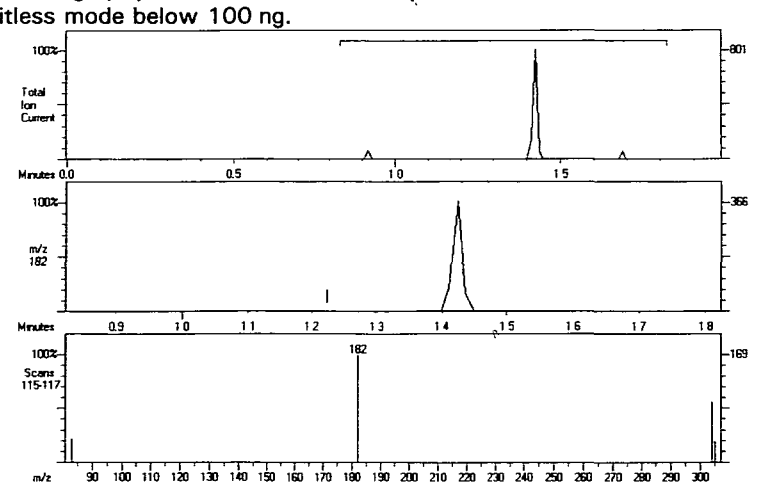
Quadrupole ion trap (IT) mass spectrometry with filtered noise field waveforms (FNF) should permit the trace detection of drugs of abuse in complex samples with high sensitivity and selectivity. The Teledyne 3DQ Discovery is equipped with FNF waveforms and this type of IT has numerous operational parameters. Because of this, extensive optimization is needed to develop mass spectrometry methods on it. An additional set of parameters which has a complex interplay with the performance of the IT is the connection of the gas chromatograph. Electronic pressure control on the GC allows for flexible control of the helium pressure for the carrier gas velocity and the buffer gas pressure in the IT. This was conducted to find the best conditions for the detection of cocaine to enable the trace analysis of drugs in difficult samples.

The difficulty of finding the right IT parameters was initially found when the switch was made from solution standards of cocaine to actual samples of hair extracts containing the drug. EI GC/MS spectra down to 100 pg were obtained on standards using FNF notch filters to block out unwanted ions but the spectrum was still hard to find in the extract analysis data. Similar problems were encountered in the GC/MS/MS mode with CAD FNF waveforms. It was also observed the CAD spectra changed with GC injector head pressure at the time of peak elution.

The FNF software is very flexible but the operational parameters are critical to the success of the experiment. FNF isolation of the cocaine ions after ionization resulted in $(M+H)^+$ at 304 which was much larger (4X to 5X) than the M^+ at 303 that could be isolated during ionization. The $(M+H)^+$ comes from self chemical ionization that occurs at the long ionization times used (50-800 ms). The CAD spectra of cocaine were very sensitive to the tickle voltage over a narrow range of 100-200 millivolts. Below this range few daughters are produced and above it all ions start to disappear. A tickle of 10 milliseconds worked best in that it gave 182 daughter intensities comparable to longer times but still left some 304 intensity. The RF mass for the tickle was less critical than other parameters but at low RF mass levels such as 40, no daughters were generated for cocaine. The FNF notch width was important to both the CAD spectrum and the blocking out of interfering ions. Narrow FNF notches gave the best

balance between parent/daughter intensities and minimum interference. Using the solid probe to optimize the scan function for CAD was helpful but was not sufficient for setting up high sensitivity GC/MS/MS scan functions on its own. Additionally, the scan functions required reoptimization any time the instrument was recalibrated. Attempts were made to overcome this problem by using a CAD "wiggle" where the RF mass is scanned over a narrow range (1-2 amu) during the tickle to compensate for slight changes in the tuning/calibration. However, the wiggle gave lower spectral intensities. Pre- and post-ionization times, and collisional cooling had little effect on the CAD spectral intensity of cocaine under the experimental conditions.

The optimum scan function found thus far is a two step tickle with FNF post-ionization isolation of 304. In the two step process the first CAD tickle uses an RF mass of 60 at 0.2v and the second tickle uses an RF mass of 75 at 2.15v. Another benefit of the two step tickle observed was the reduction in the amount of interfering ions that were not from the CAD process. The cocaine EI base peak of 82 (and other nonrelevant ions) appeared in spectra at much larger intensities than the parents or daughters if proper parameters were not used. With the best scan function found so far, 100 pg (on-column) of cocaine could be detected by MS/MS using a 800 ms ionization time and a split GC injection at 10 psi (0.25mm X 15m column). See figure below. This function was optimized using rapid/high temperature (240°C) split injections. However, the scan function was found to be sensitive to the chromatography because cocaine CAD spectra could not be detected in the splitless mode below 100 ng.



BIOMARKER DETECTION LIMITS UTILIZING A Py-QUADRUPOLE ION TRAP SYSTEM

Franco Basile, Curtis Mowry and Kent Voorhees*
Dept. of Chemistry, Colorado School of Mines, Golden, CO 80401

The Chemical/Biological Mass Spectrometer (CBMS) battlefield detector is composed of an impactor/pyrolyzer, transfer line, membrane interface, and a quadrupole ion trap mass spectrometer (QITMS). The CBMS is designed for real-time, field operation and uses an ion-getter pump and a non-linear quadrupole ion trap which allows operation with air as the buffer gas. Among the biomarker compounds used in the detection and identification of biological threats are isoprenoid quinones and fatty acids. The objective of this work is to characterize detection of these biomarkers with the CBMS system.

FATTY ACID METHYL ESTERS (FAMEs)

Detection Limits: The detection limit of a taxonomically significant methylated fatty acid, palmityl-methyl ester (C16:0 ME, FW: 270) was determined in the CBMS system. The detection limit for C16:0 ME is approximately 50 ng (19 nmol; MS Charge Control; m/z's used= 227, 199, 185, 171, 143; S/N= 10), with the sample injected through the IR pyrolyzer. The amount of "airborne" bacteria that can be detected with the CBMS system based solely on the detection of fatty acid biomarkers can be calculated. The CBMS system is designed to detect 60 CFU/L-air in 2 minutes of sampling (CFU = Colony Forming Units. 1 CFU ≥ 1 bacteria). The impactor has an air intake of 1000 L/s and collects bacteria with an overall efficiency of 50 %. At the 60 CFU/L-air limit, 5×10^6 CFU are collected in 2 min. If one assumes a single-cell mass of about 10^{-12} g, a 90 % water composition, and an average of 4 bacteria/CFU, the CBMS collects about 2 μg of dry cells in 2 min. For a Gram-negative bacteria like *Brucella*, 21% of its dry weight is cell wall, or 0.42 μg. The cell wall contains approx. 18 % lipid by weight or 76 ng of bound and free lipids. With an efficient *in situ* methylation of all bound and free lipids, the detection target of 60 CFU/L-air in 2 min can be accomplished solely based on lipid biomarkers like saturated fatty acids. This result was achieved without an optimization of the membrane interface in the CBMS system.

ISOPRENOID QUINONES

Two general types of isoprenoid quinones are found within eubacteria, benzoquinone-based Ubiquinones (Q-N) and napthoquinone-based Menaquinones (MK-N). Upon electron ionization, each type of quinone produces characteristic fragment ions. These fragments can be used as biomarkers (within the mass range of the CBMS) to aid in the identification of airborne bacteria. For example, Gram-positive bacteria contain only menaquinones, while Gram-negative may contain either type. Detecting the molecular ions of quinones will increase the probability of identification, as the distribution of quinones (with varying length of side chain and saturation) varies among bacteria. The top spectrum contains a full scan of an injection of Vitamin K2 (MK-4). The lower spectra demonstrate the utility of MS/MS in the ion-trap for biomarker detection. By isolating and then fragmenting m/z 225, the structure and therefore identity of this typical Menaquinone fragment can be confirmed.

Both types of biomarkers are sufficiently non-polar to be transmitted through the CBMS transfer line and membrane, and standard electron ionization/CID fragments were observed. Pyrolysis, transfer line, and membrane conditions still need to be optimized to improve detection limits for these important bacterial biomarkers.

ACKNOWLEDGEMENT

ION-MOLECULE REACTIONS OF NO IN THE QUADRUPOLE ION TRAP: IMPLICATIONS FOR BIOLOGICAL METABOLIC STUDIES

Susan F. Silverton, Jodie V. Johnson, Cecilia Basic and Richard A. Yost
University of Pennsylvania, Philadelphia, PA, Villanova University, Villanova, PA and University of Florida, Gainesville, FL

Quadrupole ion trap mass spectrometry (QITMS), with its excellent sensitivity, would seem to be an ideal instrument for real time monitoring of biological reactions in solution. In particular, the ability to monitor volatile products produced by cell populations could provide significant details of cellular metabolism during dynamic changes in cell function.

We have initiated a series of feasibility studies using a membrane interface to deliver gases dissolved in cell culture media to a QITMS. In addition to the compounds of interest, CO_2 and NO, significant amounts of H_2O, N_2, and O_2 are also introduced into the ion trap. Initial experiments showed that the presence of these other components lead to space-charging and ion-molecule reactions which affect the determination of CO_2^+ (m/z 44). However, the differences in ionization potential and proton affinities between CO_2 and NO led us to suspect that ion-molecule reactions of NO in the ion trap might interfere less with the determination of this volatile metabolic product. In these experiments, we have also attempted to reduce space-charging by controlling the ionization time and RF levels, and have investigated ion-molecule reactions of NO^+ (m/z 30) occurring during the chemical ionization of a mixture of water, nitric oxide, nitrogen, oxygen and carbon dioxide.

Methods

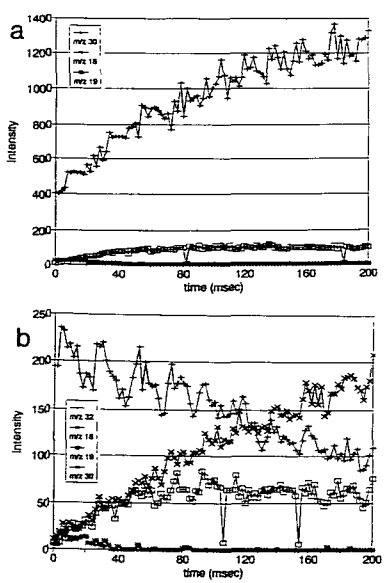

Figure 1 Mass selective CI and ion-molecule reactions of (a) NO (m/z 30) and (b) O_2 (m/z 32)

Ion-molecule reaction studies were performed on a Finnigan ITMS and gases were introduced via metering valves. Upon chemical ionization, N^+, H_2O^+, N_2^+ (or CO^+), NO^+, O_2^+, and CO_2^+ were the major ions produced. In separate experiments, each of these ions was mass-isolated and allowed to react with the gases present for periods up to 200 ms. Several sets of these experiments were performed with different amounts of NO and H_2O present. Note that helium was not present during these experiments.

Results

With only residual water and air present, the pressure in the quadrupole ion trap vacuum chamber was 5.3 $\times 10^{-7}$ torr, indicated. Nitric oxide was added to the vacuum chamber to yield an indicated pressure of 8.3 $\times 10^{-7}$ torr. Then water was added to the vacuum chamber to yield a total indicated pressure of 1.5 $\times 10^{-6}$ torr. Under these conditions, the mass selective reaction of H_3O^+ became the dominate ion following the mass selected CI reactions of H_2O^+, H_3O^+, N_2^+, and CO_2^+ . Based upon their higher ionization potentials, (Figure 2), N_2^+ and CO_2^+ underwent charge exchange with H_2O to form H_2O^+ which subsequently underwent self-CI, i.e. $H_2O^+ + H_2O \rightarrow H_3O^+$. As the proton affinity of NO (113 kcal/mole) is lower than that of water (166 kcal/mole), H_3O^+ did not protonate NO (Figure 1a). Also, as the ionization potential of O_2 is below those of H_2O, CO_2 and N_2, but above that of NO (Figure 2), the reaction of mass selected O_2^+ ions under these conditions yielded predominately NO^+ ions (Figure 1b).

IONIZATION POTENTIAL CHART

ION	M/Z	IE (eV)
N^+ (from N_2)	14	24.3
CO^+ (from CO)	28	19.5
Ar^+	40	15.8
N_2^+	28	15.6
CO^+ (from CO)	28	14.0
CO_2^+	44	13.8
H_2O^+	18	12.6
O_2^+	32	12.1
NO^+(from NO)	30	9.3

Figure 2 Ionization Potential Chart

Discussion

The ability to form and detect NO^+ successfully in the quadrupole ion trap in the presence of significant amounts of H_2O is in direct contrast to our previous attempts to form and detect CO_2^+ under similar conditions. This is due strictly to the relative ionization potentials of the neutral species determining what ion chemistry will occur and thus which ion will predominate in the quadrupole ion trap.

In these metabolism studies, the nitric oxide (NO) produced from the cell cultures will be significantly less abundant than H_2O, O_2, CO_2 and N_2. However, based upon the results above, NO would undergo charge exchange with all of these ionized species to form NO^+ and permit successful detection. Of more concern is the high concentration of water which is present. Although water does not undergo any significant ion-molecule chemistry with NO^+, the formation of abundant H_2O^+ and H_3O^+ ions during ionization leads to severe space charging, while the abundance of neutral water appears to lead to poor overall ion trap performance.

As far as future directions are concerned, the design and construction of a membrane introduction mass spectrometry (MIMS) interface for the on-line measurement of NO levels produced by functional cell cultures using an ITD ion trap mass spectrometer is currently underway. The MIMS is designed to accommodate a 1 ml stirred cell culture beaker and includes an injection port to allow the introduction of reagents to initiate cell events. The design will make use of a jet separator assembly with a coaxial flow of He similar to that reported by Dejarme, et al . [2]. However, in this design, the membrane will be placed directly within the cell culture fluid.

In order to reduce space-charge effects and increase the sensitivity of future NO analyses, stored wave form inverse Fourier Transform SWIFT wave form methods [3, 4] will be implemented to selectively eject all ions except those of the analyte during the ionization period.

Barbiturate Analysis In A Quadrupole Ion Trap: Borinium Adduct Ion Formation

Armando Colorado and Jennifer Brodbelt, Department of Chemistry, University of Texas at Austin, Austin, Texas, 78712.

Introduction. Barbiturates are a powerful class of sedative/hypnotic pharmaceuticals with a diversity of uses, ranging from their utility as anesthetics, to treatment of anxiety, insomnia, and epilepsy. Barbiturate derivatives have a great degree of hydrogen-bonding activity, due to the fortuitous arrangement of hydrogen-bond donor and acceptor groups around the pyrimidine ring. Thus, there has been much use of barbiturates in the modelling and construction of supramolecular assemblies designed with an array of hydrogen bonding interactions. An understanding of the structural features which mediate hydrogen bonding participation in these types of compounds is essential. In the present study, both of these reasons are exploited in order to evaluate a new method for characterizing barbiturate derivatives based on selectivity of hydrogen-bonding interactions. In this report, we exploit the special reactivity of borinium ions to form strong hydrogen bonded adducts with barbiturate derivatives and then undergo characteristic dissociation reactions.

Experimental. Experiments were performed using a Finnigan ITMS operated in the mass selective instability mode. Barbiturates were introduced into the vacuum chamber via a heated solids probe at pressures ranging between 0.9-2.0 X 10^{-6} torr. TMB was introduced through a leak valve at a pressure corresponding to 6 X 10^{-6} torr. One mtorr of helium was added after the CI pressure had stabilized. Ion-molecule reaction periods ranged between 50 and 150 ms. The ion trap temperature was held at 120°C. For mass-selective isolation, a DC voltage was applied with an appropriate rf voltage to the ring electrode. Typical tickle voltages used were between 200 and 400 mV at a q value of 0.4. An activation time of 10 ms was utilized in all experiments.

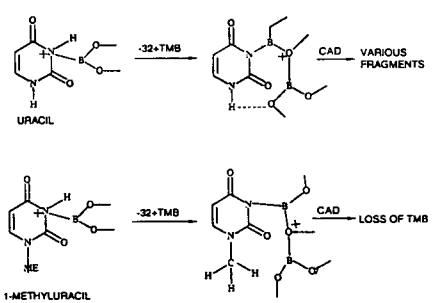
CAD of the Borinium Adducts.. CAD of the borinium ion adduct $[M + 73]^+$ yields an array of fragment ions not observed in the dissociation of the protonated species. As in conventional EI and CI, the borinium adduct ion loses a side chain functional group, however, other numerous dissociation channels are followed and other products resulting from secondary ion-molecule reactions are generated For example, the borinium adduct of amobarbital dissociates by 14 pathways, whereas protonated amobarbital only produced three types of fragments. Likewise, the borinium adduct of hexobarbital dissociates by many more pathways than protonated hexobarbital. There are several possible explanations for the increased variety of fragmentation of the borinium adducts relative to the protonated structures. First, the borinium cation may tend to attack at several competing positions of the barbiturates, whereas protonation may occur only at one site. Second, the borinium adducts likely incorporate multiple hydrogen bonds that enhance specific types of rearrangements and secondary reactions.

One common neutral loss for each of the borinium adducts is the elimination of methanol. As shown later by the use of model compound studies, this pathway is an intramolecular rearrangement involving the elimination of a methoxy group from the borinium portion and an acidic proton from the barbiturate. The difference reflects whether the borinium cation is attached to an oxygen or nitrogen atom. In some cases, the elimination of methanol occurs in conjunction with the loss of the substituent found at the C5 position of the barbiturate.

The most interesting new product observed upon activation of the borinium/barbiturate adduct is the formation of a secondary ion-molecule reaction product, assigned as $[M + 73 - CH_3OH + TMB]^+$. Thus, the $[M + 73]^+$ adduct first undergoes the intramolecular elimination of methanol, then rapidly and spontaneously adds a molecule of trimethylborate. The unusual addition of TMB only occurs in conjunction with the loss of methanol, and attachment of TMB is not observed for the other fragments. This product is seen for barbital and thiamylal directly, and is observed for amobarbital and pentobarbital at long reaction times or higher reagent pressures. With the exception of thiamylal, the attachment of TMB to the $[M + 73 - CH_3OH]^+$ fragment also occurs along with the loss of the side chain functional group at the C5 position for all compounds. In general, the formation and stability of the $[M + 73 - CH_3OH + TMB]^+$ product appears to correlate with the availability of hydrogen bonding sites on the barbiturate ring.

CAD of Borinium Ion Adducts for Model Compounds. The reactions of strategically chosen, simple model compounds give new insight by restricting the number of functional groups in question, and selectively eliminating the interference of other reactive functionalities. Ten model compounds were chosen for this study: urea, uracil, glutaramide, piperidine, pyrimidone, cyclohexanone, barbituric acid, 1-methyluracil, 1,3 dimethylbarbituric acid, and 1,3 cyclohexadione. Upon reaction with the borinium ion, each forms the $[M + 73]^+$ adduct. Results show that six out of ten compounds form the $[M + 73 - 32 + TMB]$ adduct. Thus, the four compounds which fail to form the $[M + 73 - 32 + TMB]^+$ adduct include cyclohexanone, 1,3-cyclohexadione, urea, and 1,3 dimethylbarbituric acid. The functional group responsible for the formation of this interesting adduct apparently is the amine. If the amine is blocked by a methyl group as in the case of 1,3 dimethylbarbituric acid, then no TMB adduct is generated at $[M + 73 - 32 + TMB]^+$. Cyclohexanone is a compound in which methanol loss is not observed for the $[M + 73]^+$ adduct, and thus the secondary ion-molecule reaction product is prohibited. The 1,3 cyclohexadione-borinium ion adduct undergoes the loss of methanol but no TMB adduct is observed, probably due to weak hydrogen-bonding strength of the diketone. As proposed in Scheme 2, certain hydrogen-bonding interactions are critical for promoting the multi-step reaction. The four models that failed lacked one or more features deemed necessary for the reaction.

To characterize the nature of the $[M + 73 - 32 + TMB]^+$ adduct, this adduct was isolated and subjected to CAD. For 1-methyluracil, pyrimidone, and piperidine, the adduct eliminates TMB. This dissociation behavior is characteristic of a weakly bound adduct that simply disassembles when energized. In contrast, the adducts for glutarimide, uracil, and barbituric acid undergo numerous dissociation pathways, including elimination of methanol. This behavior typifies that found for strongly bound species. Therefore, the structures of the $[M + 73 - 32 + TMB]^+$ also seem to differ depending on the nature of the model compound, presumably because of its intrinsic basicity and positions of hydrogen-bonding sites. For example, uracil has two amine sites capable of participating in hydrogen-bonding, whereas in 1-methyluracil, one of the nitrogens is blocked by a methyl group so the acidic hydrogen is gone. This subtle difference may impact the stability of the resulting adducts, as shown in Scheme 1.



Scheme 1

Measurement Of Crtical Energies In A Quadrupole Ion Trap

Armando Colorado and Jennifer Brodbelt, Department of Chemistry, University of Texas at Austin, Austin, Texas, 78712.

Introduction Energy resolved mass spectrometry (ERMS) techniques have been in existence for over a decade. Applications include isomer distinction, evaluation of gas phase acidities , as well as the determination of critical energies (CE) for dissociation (1-4). Collisional activation dissociation (CAD) and photodissociation (PD) are two methods currently employed in obtaining CE's of gas phase ions. Quadrupole ion traps, in general, have never been viewed as optimal instruments for the measurement of critical energies due to the "non-zero" translational energy distributions of trapped ions, the potentially large spread in kinetic energies as ions are accelerated, and the multiple collision conditions in the case of quadrupole ion traps. Hart and McLuckey, however, from the Oak Ridge National Laboratory showed a logrithmic correlation between the threshold resonant excitation amplitudes (TREA) and literature critical energy values in a quadrupole ion trap by studying the kinetics of ion decomposition (5).

This paper introduces a facile and fast technique which allows CE's to be directly evaluated via threshold activation voltage (mV) measurements in a quadrupole ion trap utilizing calibration compounds with well defined dissociation energies. Also, the feasability of utilizing infrared multiphoton photodissciation in the measurement of CE's in a quadrupole ion trap will also be discussed.

Collisional Activation Experiment. All experiments were perfomed in a Finnigan Ion Trap Mass Spectrometer operated in the mass selective instability mode. Samples were introduced into the chamber via a leak valve or solids probe inlet at pressures between 6.0-8.0 X 10^{-6} torr (uncorrected), raised to 1.2 X 10^{-4} torr He (uncorrected) after sample pressures had stabilized. A q-value of 0.4 and an activation time of 10 ms were used for all experiments unless otherwise noted. Ion-molecule reaction times were in the range of 10-150 ms while a cooling time prior to activation was held at 10 ms. The trap temperature was kept at 120 °C. The range of tickle voltages applied across the endcaps were between 10-300 mV. For these sets of experiments, the threshold activation voltage was defined as that voltage where the daughter ion intensity is 10% of the total ion intensity. All samples were purchased from Aldrich Chemical Co. with the exception of anhydrous ammonia (MG Industries).

Collisional Activation of Calibration Compounds. The calibration compounds chosen for this study are tetraethylsilane (0.5 eV), nitromethane (0.7 eV), butylbenzene (1.1 eV), ethylbenzene (1.3 eV), toluene (1.7 eV), and styrene (2.4 eV). A plot of threshold activation voltage vs. literature CE's shows a linear function (Figure 1). A special case is the tetraethylsilane ion which spontaneously dissociates under the current operating conditions and is therefore considered the lower limit for which a threshold voltage can be measured. It is assigned a value of zero.

Effect of Instrument Parameters on Threshold Activation Voltage. The q-value appears to have little effect on the measured threshold voltages, but the activation time has a noticeable effect. Three activation times were utilized to examine the effect on the threshold voltage at three different q-values (0.3, 0.35, and 0.4). At an activation time of 10 ms, a linear relationship is exhibited between threshold activation voltage and critical energies. At 50 ms and 100 ms, however, a non-linear relationship is observed. At these long activation

times, other processes compete effectively with ion dissociation. Most importantly, ion-molecule charge-transfer reactions occur that deplete the fragment ion population.

Correlation of Threshold Activation Voltage and Degrees of Freedom. The energy required to excite a gas-phase ion into the quasi-continuum is highly dependent on the number of vibrational degrees of freedom, because of the ergodic energy distribution. This dependence was studied by measuring the threshold activation voltages of simple protonated aminoalcohols and dehydrated quinolone/aminoalcohol complexes. Results show dehydrated quinolone/aminoalcohol complexes do indeed have higher dehydration thresholds over simple protonated aminoalcohols. For example, protonated aminoethanol had a measured CE value of 1.1 eV versus 1.7 eV for the aminoethanol/nalidixic acid complex. Again, the increased number of degrees of freedom allows energy to be distributed over a larger number of bonds, thus increasing the dissociation threshold.

Collisional Activation of Hydrogen-Bonded Complexes. The determination of hydrogen-bonding interactions is particularly important in molecular recognition, where complexes may be assembled entirely by hydrogen-bonds. Thus, we wished to develop a quantitative analysis of model host-guest complexes. A series of crown ether/ammonium ion complexes were evaluated to correlate the stength of the hydrogen-bonding interactions with structural features. 12-crown-4, 15-crown-5, and 18-crown-6 were allowed to react with the ammonium ion to form the [L + NH_4^+] complexes. Activation experiments showed that the number of available binding sites and the geometry of the interactions affected threshold values. For example, the 12-crown-4/NH_4^+ complex dissociated at a critical energy value of 1.3 eV while the 18-crown-6/NH_4^+ complex dissociated at 2.2 eV. Increasing the basicity and the number of hydrogen-bonding sites of the guest also had an affect on the CE for dissociation. Activation of the 15-crown-5/aminoethanol dimer had a critical energy approximately 0.7 eV higher than the 15-crown-5/NH_4^+ dimer.

Evaluation of Cooperative Interactions of Quinones in an Ion Trap Mass Spectrometer

Brad J. Hall and Jennifer S. Brodbelt
University of Texas at Austin, Department of Chemistry and Biochemistry
Austin, TX 78712

This undertaking examines several aspects of the gas-phase reactivity of a selected group of primarily naphthoquinone and hydroxynaphthoquinones, a series possessing a variable degree of chelation ability. Gas-phase basicities and borinium cation affinities were determined to allow a correlation of the structural factors which mediate the strength of cooperative binding interactions. Selective ion-molecule reactions with dimethyl ether ions were used to evaluate structural aspects of reactivity. Finally, collisionally activated dissociation was used to characterize product structures and probe intramolecular rearrangements.

Selective Reactions of Dimethyl Ether Ions

Upon ionization, dimethyl ether forms a highly selective reactant, $CH_3OCH_2^+$, which promotes methylation or methylene substitution reactions of organic substrates, depending on the occurrence or absence of cooperative interactions. Illustrated in the table, there are clear preferences for formation of $(M + 15)^+$ vs. $(M + 13)^+$, depending on the presence of a hydroxyl group on the adjacent ring (a plus indicates formation). Methylation is a relatively general occurrence, requiring only the presence of a carbonyl oxygen. In contrast, compounds with a hydroxyl group on the ring adjacent to the quinone ring preferentially form $(M + 13)^+$ products. An intramolecular proton transfer is required for the formation of the $(M + 13)^+$ product, thus illustrating the cooperation involved in the process. A couple of interesting exceptions involve lapachol and 1,4 naphthoquinone. Lapachol may exclusively form $(M + 13)^+$ due to the formation of a stable cyclic structure with the reactivity centered around the unsaturated substituent and the hydroxyl group. 1,4 Naphthoquinone shows no reactivity with CH_3OCH_2; however, the molecular ion of this quinone forms an unusual $(M + 16)^+$ adduct upon reaction with neutral dimethyl ether.

Compound	$(M + 13)^+$	$(M + 15)^+$
Lawsone	o	+
Juglone	+	+
Plumbagin	+	+
Menadione	o	+
5,8 DHNQ	+	+
Lapachol	+	o
1,2 NQ	o	+
1,4 NQ	o	o
Chrysazine	+	+
α-tetralone	o	+

Collisionally Activated Dissociation of Protonated Quinones

Loss of one or two CO units is a common feature to many of the quinones, such as 1,2 naphthoquinone, 1,4 naphthoquinone, plumbagin, menadione, and lapachol. However when a hydroxyl substituent is placed on the ring adjacent to the carbonyl groups, loss of water is seen in addition to carbon monoxide loss. Fragmentation of the ring containing the carbonyl groups is activated when substituents are placed ortho to one of the carbonyl groups.

Relative Gas-Phase Basicities and Borinium Ion Affinities

The relative gas-phase basicity spans a wide range of basicities as evident from the anchor positions of some compounds of known basicity. Several definite distinctions can be seen for the two sets of isomers studied. 1,4 NQ is a weaker base than 1,2 NQ which may be due to charge stabilization over the two adjacent carbonyl groups in 1,2 NQ. Lawsone is much stronger in basicity than juglone, chrysazine, and plumbagin, indicating that the hydroxyl group ortho to the carbonyl stabilizes protonation. It is possible that intramolecular hydrogen-bonding occurring in the latter compounds between one carbonyl oxygen and the hydroxyl hydrogen on the adjacent ring is affecting their basicity. α-Tetralone, which has one of the highest basicities, clearly allows substantial delocalization of the positive charge throughout the phenyl ring. By contrast, in lawsone the proton may be stabilized by the interactive hydroxyl and carbonyl group, but the second carbonyl group withdraws electron density through the ring and effectively destabilizes the proton attachment.

1,4Dioxane(186.0kcal/mol)<1,4NQ<Juglone<5,8DHNQ<Menadione<Chrysazine<Plumbagin<Lawsone<1,2NQ<α-tetralone<pyrrole(200.3kcal/mol)<lapachol<2,5Dimethylpyrrole(210.6kcal/mol)

Borinium ion affinities of the quinones were measured because the borinium ion $(CH_3O)_2B^+$, represents a model of a bulky cation with special hydrogen-bonding capabilities. The borinium cations were generated from ionization of trimethylborate, and then ligand exchange experiments were performed in the usual way. The borinium cation affinity parallels the gas-phase basicity scale with two exceptions, lawsone and 1,2NQ For only those two ligands, the order of affinities is reversed This difference is attributed to the ability of the hydroxyl group of lawsone to undergo special secondary hydrogen-bonding with $(CH_3O)_2B^+$.

1,4NQ~Juglone<Menadione<1,2NQ<Lawsone<α-tetralone~Lapachol

Collisionally Activated Dissociation of $(M + 73)^+$ Adducts

In order to better evaluate the nature of the borinium ion adducts, CAD was used to characterize each $(M + 73)^+$ adduct. Loss of methanol is seen for those compounds that possess hydroxyl groups. Clearly the dissociation depends on intramolecular proton transfer, and is indicative of a complex with cooperative functional groups that can facilitate the rearrangement. In contrast the $(M + 73)^+$ adducts for 1,4 naphthoquinone and menadione break apart and regenerate $B(OCH_3)_2^+$. This behavior is indicative of those ligands which have no possibility of competitive intramolecular hydrogen-bonding interactions between one carbonyl oxygen and an adjacent hydroxyl hydrogen. Finally, the $(M + 73)^+$ adduct of 1,2 naphthoquinone shows the interesting elimination of 30 u, assigned as CH_2O. This adduct may be strongly bound due to the cooperative interactions of the adjacent carbonyl groups, yet it does not permit the simple elimination of CH_3OH due to the absence of an acidic hydrogen. Thus, an alternative hydrogen migration occurs with the subsequent loss of CH_2O.

METAL COMPLEXATION REACTIONS OF QUINOLONE ANTIBIOTICS IN A QUADRUPOLE ION TRAP

*Erwin J. Alvarez, Ming Tang, and Jennifer S. Brodbelt; Department of Chemistry and Biochemistry; The University of Texas at Austin; Austin, Texas 78712-1167.

INTRODUCTION

The field of gas-phase organometallic chemistry has generated increased interest and experienced extraordinary development in the last ten to fifteen years [1,2]. Metal complexation can be used as an analytical tool in several ways to enhance the characterization of complex organic molecules, such as drugs or proteins. First, metal ion attachment as an ionization method provides different ways to activate molecules, depending on the identity of the metal ion. Second, metal ionization alters the stabilities of the resulting products, therefore changing the dissociation pathways. In this study, a quadrupole ion trap mass spectrometer has been used to study the reactions between gas-phase monopositive cobalt, copper and nickel metal ions with a group of quinolone antibiotics, synthetic antibiotics that disrupt bacterial-gene replication [3], in order to compare the differences in product formation and trends in dissociation patterns.

EXPERIMENTAL

All experiments were performed in a Finnigan MAT Quadrupole Ion Trap Mass Spectrometer (ITMS). Ion-molecule reaction times ranged between 50 and 100 ms. Collisional activation was performed by the application of an ac voltage of 0.3-0.4 V_{p-p} at the axial frequency of motion of the ion of interest. Typical tickle voltages used were between 900 and 1000 mV. A q value of 0.3 was used; activation times were typically 10 ms. A Quanta Ray GCR-11 Nd:YAG laser (532 nm, 6-7 ns pulse width, 135-155 mJ/pulse) was used for desorbing a pure metal foil.

RESULTS AND DISCUSSION

Ion-molecule Reactions between Quinolone Antibiotics and Monopositive Metal Ions

Quinolone neutrals were allowed to react with Co, Ni and Cu ions formed by means of laser desorption. Metal ionization with copper and nickel ions resulted in adduct ions of the form $(M + Cu)^+$ and $(M + Ni)^+$ respectively while addition-elimination products of the form $(M + Co - 28)^+$ were typically observed when cobalt was employed. The elimination of the CO unit seems to be favored by the formation of a cyclized product which is stabilized by an intramolecular hydrogen bond (Scheme 1). The complexation of the metal ion by the quinolone allows the activation of certain regions of the charged molecule via insertion of the metal ion into particular bonds. This results in access to alternative dissociation channels.

Collision Activated Dissociation of $(M + Co - 28)^+$ Products

Collisional activation of the $(M + Co - 28)^+$ product revealed that dehydrogenation is the predominant fragmentation pathway for all the quinolones except flumequine; for enoxacin and piromidic acid it is the exclusive dissociation channel. The absence of an ethyl group seems to explain why flumequine does not exhibit this loss. Other fragmentation pathways can be rationalized as losses of organic units such as C_2H_2 or CH_4 in which the aromaticity and conjugation factors that provide such great stabilization to the quinolones are not compromised. Alternative fragmentations are viable depending upon the initial insertion point of the metal ion. For example, it is well-known that Co^+ may insert into C-O, C-C, and C-N bonds. For flumequine and oxolinic acid, the CAD patterns of the $(M + Co - 28)^+$ complexes are much more diagnostic than was noted for the CAD patterns of the protonated species. For oxolinic acid, the fragment ions can be used to identify the dioxolane ring, in addition to the ethyl and carboxylic acid substituents.

Collision Activated Dissociation of $(M + Ni)^+$ Products

The predominant fragmentation pathway for the $(M + Ni)^+$ product is the loss of 44 u, which can be rationalized as loss of CO_2 from the metallated quinolone. This process would occur by insertion of the metal ion into the carbon-carbon bond adjacent to the carboxylic acid moiety. In general, the CAD patterns for the $(M + Ni)^+$ ions are most informative (Table 1). For example, the loss of 101 u in the enoxacin spectrum can be assigned as the elimination of CO_2 and part of the piperazine ring. For oxolinic acid, the loss of 104 u represents the elimination of CO_2 and part of the dioxolane ring. For piromidic acid, the loss of 85 u may be assigned as the elimination of CO_2 and part of the pyrrolidine ring. Flumequine shows the loss of 64 u, which likely represents the loss of CO_2 and HF. These CAD patterns offer a highly diagnostic way to identify each quinolone.

Collision Activated Dissociation of $(M + Cu)^+$ Products

Again, loss of CO_2 is common, but there are generally fewer informative fragment ions in these spectra. The copper complexes of enoxacin, oxolinic acid, and piromidic acid all show the significant elimination of 110 u, which must represent the loss of half of the N-ethyl-pyrrolidinone containing the carboxylic acid substituent.

CONCLUSIONS

Metal ionization of quinolone antibiotics with copper and nickel ions resulted in addition products of the form $(M + Cu)^+$ and $(M + Ni)^+$ respectively while addition-elimination products of the form $(M + Co - 28)^+$ were observed when cobalt was used. In most cases, there may be several sites of metal ion insertion, and thus several different structures of cationized quinolones that may undergo diverse fragmentation processes. The CAD patterns of the nickel complexes proved to be the most structurally informative, more so than the fragmentation patterns of the protonated quinolones.

The QUISTOR as a Pulsed-Extraction Source for Time-of-Flight Mass Spectrometry of VOCs in Air

David M. Chambers, Stan W. Thomas, Louis I. Grace and Brian D. Andresen
Lawrence Livermore National Laboratory, Livermore, California 94551

Introduction: Recently, we have been developing the ion trap/time-of-flight mass spectrometer (IT/TOF-MS) as a new instrument for real-time air analysis. The ion trap is an attractive pulsed-extraction source for TOF-MS because of its ion storage capability and its potential for high extraction efficiencies. In the IT/TOF-MS ion trap the entire ion cloud is extracted toward the exit endcap, as compared to 50% in an ion trap mass spectrometer. Moreover, the ion trap pulsed-extraction source can tolerate high background pressures and excessive space charge.

The work presented here focuses on the development of the ion trap to improve the overall performance of the IT/TOF-MS used for air monitoring. A number studies have been performed to determine the best conditions for extraction of the ion cloud with the proper spatial and velocity distributions for focusing in the TOF-MS. Results from these investigations have led to improvements in ion trap operation. Detection limits are generally in the low to sub-ppb (*v/v*) range for analysis between times 10 and 100 ms. Resolution exceeds 2000 m/Δm at FWHM. Mass accuracy is routinely 0.05% and scan-to-scan variations are less than 5%.

Experimental: The IT/TOF-MS instrument hardware was adapted from that available through R.M. Jordan Company (Grass Valley, CA), [1] except that it uses Finnigan-MAT trap electrodes. The ionization source used was an atmospheric sampling glow discharge ionization (ASGDI) source similar to that in reference [2]. Instrument electronics were constructed in house.

Results: The extraction process is the most critical function in the IT/TOF-MS operation because it defines transmission efficiency and resolution for the TOF-MS. Consequently, most of our work has been focused on optimizing ion trap conditions and the extraction procedure. Those changes that have produced the greatest improvement in signal and resolution include *bipolar extraction, rf phase synchronization* and *rf clamping.*

Bipolar Extraction - Ions can be extracted out of the ion trap by applying a positive pulse on the entrance endcap or a negative pulse on the exit endcap [1,3]. The extraction approach that we found to yield the best sensitivity and resolution involves applying an equal, but opposite pulse to both the entrance and exit endcaps. When an extraction voltage is applied to just one electrode, a parabolic field gradient is formed that focuses ions to a point outside the exit endcap. A bipolar field produces a linear accelerating field with little focusing as shown Fig. 1. The use of bipolar instead of unipolar extraction increased resolution from 750 to 2000 m/Δm at FWHM.

Phase Synchronization - Phase synchronization of the extraction pulse with the rf drive potential is performed by triggering the extraction pulse from the same clock used in the rf generator. The effect of rf phase on ion signal is shown in Fig. 2. The most favorable rf phase for ejection occurs between 0 and 90°, when ions are moving toward the center of the trap and are compressed axially. As the phase reaches 180° the ion peak shifts to longer flight times and forms a high-time tail. Longer flight times occur when the ring electrode potential swings low, which decelerates the ion packet. The high-time tail is greatest at 180° because the ion cloud is expanding from the center of the trap along the z-axis.

rf Clamping - Shown in Fig. 3 are spectra for the *m/z* 69 fragment from PFTBA **(a) with and (b) without** clamping of the rf potential on the ring electrode. Extraction was performed at an rf phase of 45°. Clamping the rf lengthens the flight time by 25 µs and narrows the peak width (FWHM) by 4 ns. With no clamping the rf drives to a greater positive potential while the ions are exiting the trap. This broadens the velocity distribution and accelerates ions during the extraction step.

Oxidation of Dye Precursors: Gas Phase Reactions in an Ion Trap MS

Heewon Lee[a], Robert Voyksner[a], and L. Don Betowski[b]
[a] Research Triangle Institute, Research Triangle Park, NC 27709
[b] US EPA, Las Vegas, NV 89193

In the treatment of dye waste, often the most important parameter is the removal of color from the waste stream. Both reduction and oxidation can be performed which eliminate conjugated multiple bonds, removing the majority of the color. Since these approaches could generate a waste stream with higher toxicity than the initial dye waste in some cases, it is an important part of exposure assessment to characterize the reaction products. Previous work in our laboratory explored chemical reduction in solution followed by LC/MS and GC/MS characterization of the reduction products [1, 2]. However, the determination of oxidation pathway of dyes have been limited due to difficulties involved such as side reactions in solvent, sample adsorption, sample complexity, and lack of analytical methods to specifically detect the reaction products To overcome these difficulties the study of oxidation chemistry of dyes within the ion trap mass spectrometer (ITMS) is proposed.

Oxidation studies of nonvolatile compounds such as dyes are possible for ions formed by electrospray that are trapped in the ITMS. Most dyes do not have a significant vapor pressure to permit the study of neutral dye reactions with an oxidant by EI. In this study, the oxidation of dye precursors is performed as the initial stages of oxidation of dyes in the ITMS.

Ozone in oxygen stream is used as a major oxidant in this oxidation study. The compounds investigated include o-toluidine, cis- and trans-stilbene, and isoprene. The experimental parameters evaluated includes the pressure within the trap, reaction time, temperature, and oxidants. Oxidation reaction of o-toluidine, as shown in figure 1 and 2, produces extensive ring opening fragments (e.g. m/z 50 and 65), phenyl (m/z 77), benzyl (m/z 91), and high mass (e.g. m/z 120, 149) ions. The major product of cis- and trans-stilbene oxidation is almost exclusively benzaldehyde and isoprene seems to undergo polymerization followed by successive alkyl loss upon oxidation. It is demonstrated in this study that the MS/MS capability of the ITMS aids in the structure elucidation, and that the storage capability of the ITMS allows for monitoring of oxidation intermediates and products over a wide range of reaction rates. Further study on the oxidation of nonvolatile dyes will be performed using an electrospray ionization method in the ITMS.

Developments in Explosives Vapor Detection by Glow Discharge/Ion Trap MS

Keiji Asano, Gopalakrishnan Vaidyanathan, Douglas Goeringer, and Scott McLuckey
Chemical and Analytical Sciences Division
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6365

The quadrupole ion trap has found great utility in the analytical community due to its high sensitivity and MS^n capabilities. Problems associated with matrix ions filling ion traps have been addressed by mass-selective ion accumulation methods (1-3). The atmospheric sampling glow discharge ionization (ASGDI) source coupled to a quadrupole ion trap used for explosives detection is prone to matrix ion effects because of its large abundance of background ions at low mass. By using a mass selective ion accumulation method such as a filtered-noise field (FNF) (3), matrix ions are ejected allowing for the analyte ions to be concentrated in the trap. This paper will report on the detection limits found for explosives on the ASGDI/Finnigan ITMS using the FNF technology and on initial studies on the performance of the ASGDI/Teledyne 3DQ.

We have previously reported detection limits in terms of concentrations with respect to vapor detection with an estimated "mass" detection limit (4). In this paper, we have determined mass limits by depositing a known amount of explosives onto a capillary tube and placing the tube into a heated inlet leading directly into the ASGDI source. We have determined MS/MS detection limits in the low to sub-picogram range for three explosives, 2,4,6-trinitrotoluene (TNT), cyclo-1,3,5-trimethylene-2,4,6-trinitramine (RDX), and pentaerythritol nitrate (PETN). In all three cases, a FNF waveform (generated by the Teledyne-Hitachi HST-1000 module) was used to selectively accumulate the parent ion of interest which was then subjected to collisional activation. Figure 1 shows the MS/MS spectrum of 0.5 pg of RDX. Most of the parent ion, $(M-NO_2)^{-\cdot}$ has fragmented to the $(CH_2NCH_2NNO_2)^-$ anion. The background peak around m/z 170 could not be ejected without losing analyte ion intensity.

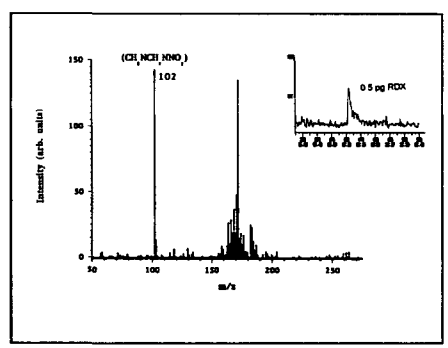

Figure 1

We have coupled an ASGDI source, designed in our laboratories, to the Teledyne 3DQ for continued work in explosives vapor detection. The combination of ion trap technology and FNF in the Teledyne 3DQ provides the capability to perform mass selective accumulation of multiple parent ions and simultaneous collisional activation. With additional FNF waveforms, MS^n experiments (n>2) are also possible. This parallel monitoring has the advantage of speed and improved duty cycle over instruments which perform multiple targeted compound analysis in series. The mass spectra in Figure 2 shows an example of parallel monitoring with three nitroaromatic compounds, DNT, TNT, and tetryl as the targeted compounds in air. Figure 2a shows the mass

spectrum acquired with the FNF set to accumulate the molecular anion of DNT (m/z 182) and TNT (m/z 227) and the $(M-NO_2)^-$ anion from tetryl (m/z 241). Figure 2b is the resulting MS/MS spectrum when a second FNF waveform with three frequencies corresponding to the secular frequencies of m/z 182, 227, and 241 is applied to the end-cap electrodes. Figure 2c shows the mass spectrum obtained when an FNF waveform is applied to isolate ions at m/z 165, 210, and 213 and Figure 2d is the resulting spectrum when an FNF for collisional activation (of m/z 165, 210 , and 213) is applied. The fragments are identified according to their genealogy which was determined by separate MS/MS and MS^3 experiments. The advantage of speed and duty cycle in parallel monitoring comes at the expense of specificity relative to MS^n experiments performed in series.

CAD Spectra of PAHs by Ion Trap and Triple Quadrupole Mass Spectrometry

Witold Winnik,*[φ] Leon Betowski, Robert D. Brittain,[ψ] Alvin Marcus[τ] and Steven Pyle.
United States Environmental Protection Agency, National Exposure Research Laboratory, Characterization Research Division, Las Vegas, Nevada 89193
[φ] National Research Council Associate at the U.S. EPA, Las Vegas, Nevada.
[ψ] Varian Co., Environmental Applications, 2700 Mitchell Drive, Walnut Creek, CA 94598.
[τ] Senior Environmental Employee at the U.S. EPA, Las Vegas, Nevada.

Polycyclic aromatic hydrocarbons (PAHs) are common products of many industrial and natural combustion processes. PAHs are found in grilled meat, tobacco smoke, air-borne particulates, used motor oil and soil. They are produced by practically any process involving combustion of fossil fuels. Because many PAHs are carcinogens, the U. S. Environmental Protection Agency (EPA), through its National Exposure Research Laboratory in Las Vegas, NV must develop analytical methods for determining these ubiquitous pollutants..

The Saturn 3 ion trap mass spectrometer, a recent commercial innovation, can detect analytes at the picogram level in the full-scan mode. This detector has the potential to eliminate or reduce sample preparation steps that would ordinarily be required to concentrate the analytes to levels suitable for detection by less sensitive means. For clean, simple matrices, direct injection of environmental samples would be sensitive, avoid pre-concentration steps or sample clean-up, and generate no waste solvent that would require disposal as hazardous waste.

In addition, ion trap detectors have been configured to perform tandem mass spectrometry (MS/MS). The MS/MS capability enables the ion trap to first isolate or "trap" an ion of interest and subsequently produce characteristic progeny ions. This allows the analyst to unambiguously distinguish the compound of interest from other compounds that yield ions of the same mass-to-charge ratio (m/z). The selective ionization mode of operation allows for the selective trapping of the analyte ions, thus eliminating a great portion of chemical noise. This feature combined with a GC/MS/MS capability of the Saturn 3 ion trap makes it an attractive detector for analysis of compounds in complex matrices.

The nonresonant ion-trap collisionally activated dissociation (CAD) spectra of 16 PAHs are characterized by a high abundance of lower m/z product ions (Fig. 1). Low picogram (or ppb) detection limits were achieved in the full-scan mode. Nonresonant CAD experiments are relatively easy to set up and typically exhibit excellent short-term and good long-term reproducibility. The nonresonant spectrum of pyrene was compared with the sequential, resonant $(MS)^n$ [where n=1-5] experiments performed on the prototype Finnigan ion-trap instrument.[1] The nonresonant pyrene CAD spectrum comprised simultaneously ***all*** the peaks observed in the $(MS)^n$ experiments {(n=2) **202**: 201, 200; (n=3) **200**: 199, 198, 174, 150; (n=4) **174**: 173, 148, 124; (n=5) **148**: 122, 98 m/z [1]}. This high-energy deposition attainable in the nonresonant technique is especially desirable in analyses of very stable molecules.

The nonresonant CAD breakdown curves obtained for the isomeric PAHs indicated a possibility of differentiation of some isomeric PAHs; (this capability was not possible in the experiments performed using the TSQ 700 mass spectrometer). The resonant ion trap CAD spectra of PAHs exhibited a relatively low degree of fragmentation and thus resembled those obtained using the triple quadrupole mass spectrometer (Fig. 1).

Fragmentation Pathways of Triacylglycerols Deduced from Model Compounds

Stroobant V. and de Hoffmann E.

* Mass Spec. Lab., Univ. de Louvain, Pl. Pasteur 1, B-1348 Louvain-la-Neuve, Belgium.

We report a study on the fragmentation under low energy of esters anions from multifunctional alcohols, 1,2 ethanediol (ethyleneglycol), 1,3 propanediol and 1,2,3 propanetriol (glycerol) under DCI ionisation. A Finnigan MAT TSQ 70 was used. The ionisation gas was a mixture of CH4/N2O (75/25) while Xe was used as collision gas.

Fragmentation spectra of the studied multifunctional alcohols.

	Ethanediol diacetate	Ethanediol dipropionate	Propanediol diacetate	Propanediol dipropionate	Name of the fragments
$[M-H]^-$	145	173	159	187	$[M-H]^-$
A	103	117	117	131	$[M-H\text{-ketene}]^-$
B	101	129	101	129	β-ketoacid carboxylate
C	83	111	83	111	acylketene anion
D	61	61	75	75	$[M-H\text{-acylketene}]^-$
E	59	73	59	73	carboxylate
F	57	85	57	85	ketone enolate
G	41	55	41	55	ketene ynolate

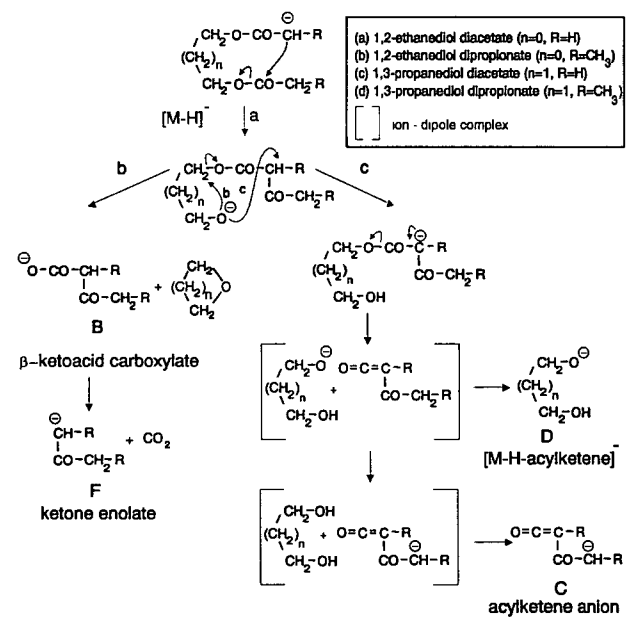
The fragmentation spectra are listed in the Table. The main observed fragments can be explained as resulting from the formation in the first step of an internal β-ketoester by a new gas-phase rearrangement of these enolate anions. This rearrangement logically results from an intramolecular nucleophilic substitution reaction, where the enolic carbanion is the nucleophile (**Scheme, pathway a**). The fate of this rearranged anion depends on the two competitive fragmentation pathways leading to the ketone enolate or the acylketene anion, and is different for these diols esters.

The first pathway corresponds to a second nucleophilic substitution of the ketoester by the alkoxide that yields a neutral cyclic ether and the β-ketoacid carboxylate, an ion often observed in the spectra but at low intensities. The β-ketoacid carboxylate anion

then loses carbon dioxide and produces the enolate anion of the corresponding ketone (**Scheme, patway b**). The fragmentation pathway leading to the ketone enolate is sensitive to the relative positions (1,2 or 1,3) of the esters on the molecular backbone.

The second proposed pathway is stepwise (**Scheme, pathway c**). It starts with a proton transfer from the methylene group between the two carbonyls to the alkoxide anion, followed by the cleavage of the ester bond induced by the negative charge to yield an ion-dipole complex composed of a neutral acylketene and an alkoxide ion. The direct dissociation of this ion-dipole complex competes with a proton exchange inside the complex yielding a new complex constituted by an alcohol molecule and the anion of the acylketene.The fragmentation pathway leading to the acylketene anion is influenced by the presence of an alkyl group on the methylene group between the two carbonyls of the intermediate.

The same rearrangement also occurs in triglycerides. These fragmentations mechanisms allow to explain the structure of fragments observed from triglycerides and known to be useful in position elucidation.



HPLC-MS ANALYSIS OF TRIACYLGLYCERIDES

P.J.W.Schuyl, T. de Joode, G.S.M.J.E. Duchateau and M.A. Vasconcellos
Physical and Analytical Sciences, Unilever Research Laboratory,
PO box 114, 3130 AC Vlaardingen, The Netherlands

Introduction

The Triacylglycerol (TAG) composition is very important for the physical characteristics of edible oils and fats.The degree of unsaturation and the structural configuration of the TAGs are important nutritional aspects.

A method is needed to get both qualitatively and quantitatively of the TAGs in a mixture, if possible in one single analysis:

- the degree and position of unsaturation
- geometry of the unsaturation (cis/trans)
- the Carbon Number (CN)
- length of each fatty acid chain
- sn position of each fatty acid chain

Experimental

HPLC

Separation of TAGs on a Ag silica HPLC-column depends on:

- the total number of double bonds
- the position of the most unsaturated fatty acid chain(s).
- the configuration of the double bonds (cis/trans).

MS

Electrospray is a suitable ionization method to determine the molecular masses of the TAGs.
Due to the apolar HPLC solvents used, methanol and sodium acetate have to be added to the column effluent to create $[M+Na]^+$ ions.

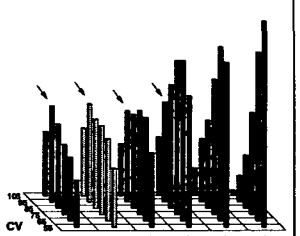
Apparatus

HPLC: Gilson 305/306/306/811B/805S.
column: home made Ag-phase,100x4.6 mm
particle size 3 µm, pore size 100Å.
gradient: ternary gradient of toluene/hexane/ethylacetate in 13 min.
flow: 1.5 mL/min.
post column split: 75:1 to 20 µL/min.
addition: 10 µL/min MeOH/0.1 mM NaOAc

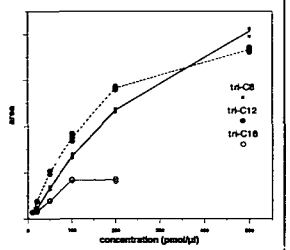
MS: Fisons Trio-2000
ionization mode: positive electrospray
scan range: 500-1000 m/z
scan rate: 2 s/scan
total flow to source: 30 µL/min
source temperature: 100°C
pseudo molecular ions: $[M+Na]^+$

Parameters

Influence of the cone voltage on the response.
The cone voltage (CV) has a major influence on the response of the TAGs. The longer the fatty acid chains, the higher the cone voltage should be to give the highest signal.
At a cone voltage of 95 V the responses of saturated tri-C12 to tri-C18 were about the same, and therefore this value was selected in the further analyses.

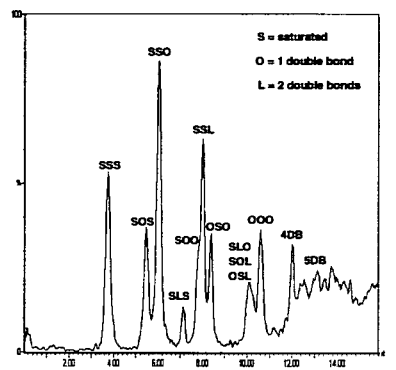


Dynamic range and linearity.
The dynamic range was tested with saturated tri-C8, tri-C12 and tri-C18 TAG at a cone voltage of 95 V. The dynamic range is limited by several factors: The higher the flow to the ESP source, the lower the dynamic range. The longer the fatty acid chain length, the lower the dynamic range. The dynamic range of co-eluting peaks is less than that of a single peak. When the source gets contaminated, the dynamic range and sensitivity will decrease.
By these combined factors the dynamic range is limited to about 10^2.

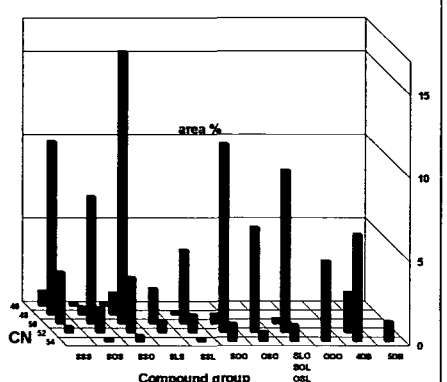


Results

Chromatogram



3D overview



Quantitative results
The results by MS are quite comparable with the results from the by fatty acid methyl ester analysis calculated results and with the results obtained from HPLC-FID analysis, even without using response factors.

Conclusions

Ag-phase HPLC-MS is a suitable method for the analysis of TAGs in complex samples.
Information is obtained on CN and the sn-position of the unsaturated fatty acid
The quantitative results are comparable to the results obtained with the HPLC-FID method.
The detection limit is about 0.2 % for each individual TAG. The cone voltage has to be optimised to get equal responses of the TAGs present in the sample.
MS-MS will give information on the chain length of each individuel fatty acid in the TAG, but on line Ag-phase HPLC-MS-MS is not (yet) possible, because the $[M+Na]^+$ ions do not fragment.

Characterization of a Family of Brain Lipids with Sleep-Inducing Properties

G. Siuzdak, B. Cravatt, O. Prospero-Garica, S. Henrikson, N.B. Gilula, D. Boger, & R.A. Lerner

Departments of Chemistry, Neuropharmacology, and Cell Biology
The Scripps Research Institute
La Jolla, CA 92037

The bioanalytical techniques now available offer increased sensitivity in molecular characterizaton, allowing scientists to study biological fluids and the changes correlated with physical stimuli. Utilizing such techniques, researchers from five different laboratories at The Scripps Research Institute have taken a purely chemical approach to study sleep.

In this study, a compound associated with the sleep-wake cycle was isolated from the cerebral spinal fluid of sleep-deprived cats. In the initial stages of the isolation and characterization of this compound, liquid chromatography and mass spectrometry played an important role. Electrospray ionization, electron ionization, and fast atom bombardment allowed us to discern some of its functional characteristics, including: molecular formula, degrees of unsaturation, a long alkyl chain, and a nitrogen substituent capable of primary fragmentation as ammonia.

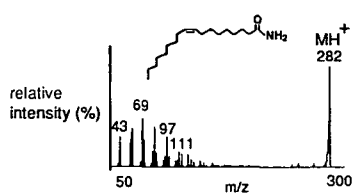


Figure 1. The CSF isolated product, *cis*-9,10-octadecenoamide, shown with ESI MS/MS data.

Initial electrospray mass analysis (PE SCIEX) of the natural compound revealed mass peaks of *m/z* 282 $[M + H]^+$, 304 $[M + Na]^+$, 320 $[M + K]^+$, and 564 $[2M + H]^+$, indicating that the molecular mass of the compound was 281 Da. High-resolution FAB-MS analysis allowed the exact mass measurement of the $[M + Na]^+$ ion, and the observed mass was *m/z* 304.2614 ± 0.0006 Da. This measurement allowed for determination of elemental composition and a best fit for the molecular formula $C_{18}H_{35}NO$, which has a calculated $[M + Na]^+$ *m/z* of 304.2616 Da. Furthermore, tandem mass analysis revealed a distinctive fragmentation pattern in the low molecular mass range consistent with other long chain alkanes, while sequential neutral loss of 17 and 35 from the parent ion indicated loss of ammonia followed by loss of water. Additional MS^3 experiments were performed on the daughter ions of *m/z* 265 and 247. Such MS^2 and MS^3 mass analyses were also performed on various synthetic candidate structures,

and while several products gave spectra quite similar to the spectra of the natural material, only the fragmentation patterns generated from monounsaturated fatty acid amide, *cis*-9,10-octadecenoamide, matched exactly those of the endogenous lipid. Especially useful was the loss of 17 mass units from the parent ion of *cis*-9,10-octadecenoamide, indicating the molecule first fragments at the carbon-nitrogen bond of its terminal amide group to release ammonia.

Table 1. Some evidence that led to the unknown's identity. Ultimately the identity was confirmed by independent synthesis and comparison of the spectral data.

DATA TYPE	SUMMARY OF DATA		
exact mass	$[C_{18}H_{35}NO + Na]^+$	observed actual	304.2614 304.2616
deuterium exchange	*m/z* = 285 $[M\text{-}2H^+\text{+}3D^+]^+$, 2 exchangeable protons		
isotope	Isotope pattern at *m/z* = 282 indicates that *m/z* 282 is not a multiply charged, nor does it have any elements with an unusual isotope pattern (e.g. Cl).		
cationization	Electrospray MS observation of *m/z* 304 $[M + Na]^+$ and *m/z* 320 $[M + K]^+$ confirms that M = 281.		
association	*m/z* 563.6 association product $[2M + H]^+$		
MS^2 data	Fragment ion *m/z* 265 corresponding to $[MH - NH_3]^+$. Fragment ion *m/z* 247 corresponding to $[MH - NH_3 - H_2O]^+$. Lipid fragments		
MS^3 data	Fragmentation of *m/z* 265 » *m/z* 247 (sequential loss) suggests *m/z* 247 fragment is related to *m/z* 265 fragment ion. Lipid fragments		
NMR data	Confirms lipid portion of molecule and configuration of double bond.		
ozonolysis with GC/MS	Identified the location of the double bond.		
IR data	Confirms identity of unknown as *cis* isomer		

We have also detected related compounds in the cerebrospinal fluid of rat and man indicating that *cis*-9,10-octadecenoamide is but one member of a family of fatty acid primary amides differing in the length of the alkyl chain and the position or configuration of the olefin. Mass analysis also identified a compound from the spinal fluid of man and rat with the molecular formula $C_{22}H_{43}NO$ whose MS^2 and MS^3 fragmentation patterns were found to be indistinguishable from those of synthetic *cis*-13,14-docosenoamide. Importantly, we now also show that synthetic *cis*-9,10-octadecenoamide demonstrates sleep-inducing properties in rats.

The Use of Nicotinates and Sulfoquinovosyl Monoacylglycerols in the Analysis of Monounsaturated ω3 Fatty Acids by Mass Spectrometry

Michael Keusgen, Jonathan M. Curtis*, and Stephen W. Ayer
Institute for Marine Biosciences, National Research Council of Canada, 1411 Oxford Street, Halifax, Nova Scotia B3H 3Z1, Canada.

EI mass spectra of picolinyl derivatives of fatty acids and nicotinate esters of long-chain alcohols have been used to locate carbon-carbon double bonds [1-3]. Induced by a hydrogen transfer to the aromatic nitrogen, a regular fragmentation series results due to radical cleavage along the alkyl chain. These derivatives have been tested for a number of standards but have not been fully evaluated for monounsaturated ω3 fatty acids (or the analogous alcohols) since they are not commercially available. We have studied a complex mixture of sulfoquinovosyl diacylglycerols (SQDGs) produced by the microalga *Heterosigma carterae*. One of the fatty acids liberated from these SQDGs was identified as cis 13-hexadecenoic acid (ie 16:1ω3), confirmed by ^{1}H and ^{13}C NMR. The EI mass spectrum of the nicotinate ester derivative suggested an ω4 unsaturation rather than ω3 as deduced from the NMR data. Here we explore this problem further in order to be able to correctly identify C=C double bonds at the ω3 position.

For the nicotinate ester of a saturated fatty alcohol (hexadecanol, figure (a)) a distinct series of charge remote radical cleavages along the alkyl chain is seen, giving ions from *m/z* 318 to *m/z* 178. The ion at *m/z* 332 due to loss of the terminal methyl group ($[M-CH_3]^+$) has a significantly lower intensity than the series from *m/z* 318 to *m/z* 178. Below *m/z* 178, rearrangement processes involving hydrogen transfer onto the ring dominate resulting in ions at *m/z* 137, 151, and 165. The base peak ion at *m/z* 124 is characteristic for nicotinate derivatives[2].

For the nicotinate ester of a fatty alcohol having an isolated double-bond near the centre of the chain (not shown), the mass spectrum shows minimum intensity at the point corresponding to formal cleavage at the double bond plus a mass differece of 26 between adjacent fragment ions. Vinylic cleavage gives low intensity fragment ions whilst allylic cleavage results in enhanced fragment ion intensity. Fragmentation resulting in loss of the alkyl chain terminus results in significant enhancement in intensity.

For the nicotinate ester of an ω3 monounsaturated fatty alcohol (cis 13-hexadecenol 16:1ω3, figure (b)) the minimum ion intensity at *m/z* 288-290 and mass difference of 26 between m/z 276 and 302 wrongly suggest unsaturation at the ω4 position. The fragment ion pattern is a result of two effects:

(i) for saturated alkyl chains $[M-CH_3]^+$ is a relatively weak fragment ion whereas $[M-C_2H_5]^+$ is much stronger. Thus *m/z* 316 has anomalously high intensity for a vinylic cleavage which normally produces low intensity fragments.

(ii) the fragment intensities resulting from cleavages at the isolated double bond as described above. In this case *m/z* 330 ($[M-CH_3]^+$, cleavage at the allylic position) is higher than $[M-CH_3]^+$ for hexadecanol.

The correct assignment is made by considering the regular fragment ion series from *m/z* 276 to *m/z* 178. This suggests that the ambiguous ions at *m/z* 288-290 are vinylic cleavage (expected

to be weak). Thus, the double bond is located in the ω3 position. For an ω4 unsaturation, the peak at *m/z* 276 would have a weaker intensity than the series *m/z* 262 to *m/z* 178 since it would represent cleavage at a vinylic position.

We have also used the sulfoquinovosyl moiety as a "natural derivative" for locating C=C double bonds in fatty acids *via* negative ion LSIMS MS/MS. Sulfoquinovosyl monoacylglycerols (SQMGs) were derived from the SQDG by an enzymatic reaction. Due to the negative charge localized on the sulfonate group, charge-remote fragmentation occurs along the alkyl chain in an analogous way to the charge-remote radical cleavage observed in the positive ion EI mass spectra of the nicotinates. For SQDGs, this type of fragmentation produces very complex MS/MS spectra [4]. For the SQMG which contains hexadecanoic acid, starting from *m/z* 555 (the deprotonated molecular ion) a series of fragment ions is clearly visible. For a saturated fatty acyl chain this series can be explained by the loss of C_nH_{2n+2}. A similar anomaly in the fragment ion intensities for ω3 unsaturation is seen for SQMGs as described above for the EI spectra. As with the latter case, this can be resolved by careful consideration of relative peak intensities [5].

IDENTIFICATION OF FATTY ACIDS AND EICOSANOIDS USING ELECTROSPRAY MASS SPECTROMETRY

James L Kerwin[1] and Lowell H. Ericsson[2], Departments of Botany[1] and Biochemistry[2], University of Washington, Seattle, WA 98195-1330 USA

Introduction Hydroxy fatty acids and other oxygenated fatty acids are found in most major groups of organisms, including prokaryotic bacteria, fungi, molluscs, fish, green plants and mammals. Many of these compounds, especially derivatives of arachidonic acid (20:4ω6), collectively known as eicosanoids, are potent mediators of inflammatory and developmental processes. Since these fatty acid derivatives can be biologically active at nanomolar concentrations or less, there has been much interest in developing specific, sensitive spectrometric and other techniques for their structural identification and quantitation. Electrospray ionization MS and MS/MS is a relatively new technique extensively used in peptide and protein chemistry. Recently we and others have shown that a combination of positive and negative ion electrospray MS and MS/MS can be used with minimal sample preparation to identify intact glycerophospholipid molecular species and relative composition using subnanogram quantities of lipid. This report extends the utility of this mass spectrometric technique by describing spectra of fatty acids, eicosanoids and related oxygenated fatty acids using negative ion electrospray MS and tandem (collisional-induced dissociation) mass spectrometry (MS/MS), emphasizing its utility for rapid and sensitive analyses of biological samples

Results *Fatty acids.* The chain length and degree of unsaturation of fatty acids of complex mixtures of fatty acids can be determined using negative ion ESI MS. Analysis of base-hydrolyzed cod liver oil produced a fatty acid profile and relative composition similar to that found using GC-MS Minimal fragmentation of saturated and monounsaturated fatty acids was found, with progressively greater fragmentation occurring as the degree of unsaturation increased (spectra not shown).

Saturated monohydroxy fatty acids. The MS/MS spectrum of 2-OH stearic acid unexpectedly revealed a prominent peak 46 mass units less than the parent ion (*Figure 1*). This is in contrast to the loss of 44 from the parent ion most fatty acids, presumably from loss of CO_2 from the carboxyl moiety. The most likely explanation of the loss of 46 frrom the parent ion is from loss of CH_2O_2 from the carboxyl end of the compound, perhaps stabilized by resonance as outlined in *Figure 1*.

Unsaturated mono- and di-hydroxy fatty acids. Fragmentation of monohydroxyeicosatetraenoic fatty acids (HETE's) was comparable to that documented by other laboratories using fast atom bombardment MS/MS. Prominent ions found for 6 different HETE's were due to α-hydroxy fragmentation (*Figure 2* and unpublished observations). Fragmentation was confirmed using a d-8 analog of 5-HETE (*Figure 2*). Dihydroxy compounds showed similar fragmentation (*Figure 3*). By increasing the collision gas thickness (cgt) from 160 to 325 (one unit is equivalent to 10^{13} molecules argon/cm^2), additional structural information could be obtained.

Thromboxanes and prostaglandins. Cyclooxygenase products are also amenable to analysis by ESI. Thromboxane B_2 produced two ions using a low CID gas density that were possibly due to partial loss of the oxane ring (*Figure 4*). Six prostaglandins that have been examined produced spectra (not shown) dominated by loss of one or more H_2O molecules and CO_2 using low CID gas density, and fragmentation at carbons adjacent to hydroxyl groups and sites of unsaturation as the cgt was increased. Detection limits for prostaglandins were below 1 picogram.

Leukotrienes. Peptide-containing eicosanoids can be detected at levels near 20 picograms using negative ion ESI MS and less than 1 picogram can yield structurally useful spectra for

MS/MS analysis. Fragmentation of six leukotrienes were similar to those previously documented using FAB MS/MS (spectra not shown).

Soybean lipoxygenase. The well-characterized soybean lipoxygenase (LOX) enzyme was used to show the utility of ESI MS and MS/MS to screen for the presence of oxygenated fatty acids. Products formed by incubating linoleic and arachidonic acids were first identified using negative ion MS. Ions found in this spectrum were subsequently examined using MS/MS. Some peaks in the MS spectrum were shown to be due to decomposition of hydroperoxides formed by LOX metabolism of fatty acids. CID spectra consistent with the presence of both 9- and 13-OH and -OOH 18:2 and at least 3 different 20:4 metabolites were obtained (spectra not shown).

Conclusions Negative ion ESI MS and MS/MS were used to characterize fatty acids, hydro(per)oxy fatty acids, prostaglandins and leukotrienes. The versatility of this technique in examining biological samples using small amounts of material with minimal preliminary chromatographic separation provides an alternative approach to examining these lipid classes.

ESI-MS ANALYSIS OF PAF PRECURSORS IN HUMAN KERATINOCYTES AND CELL LINE

Kathleen A. Harrison, Jeffrey B. Travers, and Robert C. Murphy
National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson Street
Denver, CO 80206

INTRODUCTION

Recent evidence has indicated that platelet activating factor (PAF), a phospholipid lipid mediator of inflammation, is produced by epidermal cells. Gas chromatography/mass spectrometry has been used to detect the stimulated production of PAF from the human keratinocyte-derived cell line called HaCaT cells (1). We have investigated the glycerophosphocholine (GPC) molecular species present in the membranes of HaCaT cells to determine the presence of the biochemical precursors of PAF and to determine their relative abundance in these cells.

RESULTS

Normal phase separation of phospholipid classes was monitored using online electrospray ionization mass spectrometry. The positive ions formed by ESI ionization of a typical glycerophosphocholine molecular species is shown in Figure 1 with the formation of an abundant ion at m/z 782 corresponding to MH^+. The abundance of this ion was found to be related to orifice potential as shown in Figure 2 where the orifice potential was varied between 55 and 150 volts. The MH^+ of this GPC, introduced at 5 μL/min at a concentration of 2 ng/μL, decreased in absolute abundance while GPC, the fragment ion corresponding to the phosphocholine moiety at m/z 184 increased correspondingly (Figure 2).

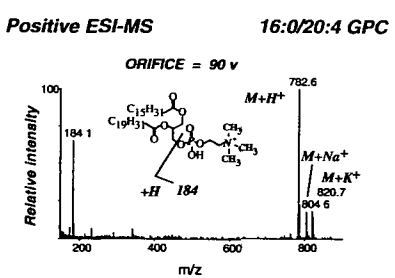

Figure 1 *Positive ions obtained by electrospray ionization mass spectrometry of 1-hexadecanoyl-2-arachidonoyl-GPC.*

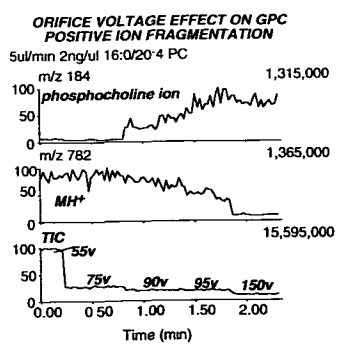

Figure 2 *The effect of orifice voltage potential on the positive ions obtained by electrospray ionization of 1-hexadecanoyl-2-arachidonoyl-GPC. The orifice potential was changed sequentially from 55-150 volts at the times indicated.*

Negative ions formed by electrospray ionization of GPC were also found to be dependent upon orifice potential (Figure 3). An abundant ion corresponding to $[M+acetate]^-$ was observed with the orifice at -55 volts. This ion was converted into the ion corresponding to $[M-CH_3]^-$ at -120 volts (Figure 3). Collision induced decomposition of $[M-CH_3]^-$ was found to be identical to that previously identified for this ion species obtained by fast atom bombardment ionization and tandem mass spectrometry.

The glycerophosphocholines from HaCaT cells were isolated by HPLC and analyzed by electrospray ionization mass spectrometry. From the relative intensities of the $[M+H]^+$, the overall profile of molecular species was determined (Table 1). The fatty acyl substituents were determined from the corresponding collision-induced decomposition of the $[M-CH_3]^-$ ions (data not shown). Based upon the relative abundances of the positive ions, the potential precursors of PAF (alkylacyl-GPC) were found to represent 28.5% of total GPC molecular species.

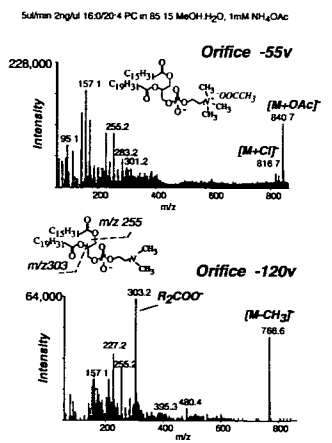

Figure 3 *(A) Negative ions obtained upon ESI/MS of 1-hexadecanoyl-2-arachidonoyl-GPC at an orifice potential of -55 V. (B) Negative ions obtained upon ESI/MS of 1-hexadecanoyl-2-arachidonoyl-GPC at an orifice potential of -120 V.*

Identification of 20-Hydroxyeicosatetraenoic Acid in Rat Kidney Phospholipids

Ying Zhu, John C. McGiff and Michael Balazy
New York Medical College, Department of Pharmacology, Valhalla, NY 10595

Introduction 20-Hydroxyeicosatetraenoic acid (20-HETE) is a product of arachidonic acid and cytochrome P450 ω-hydroxylase and is an abundant microsomal eicosanoid in the rat kidney It is a potent constrictor of the renal vasculature and an inhibitor of renal potassium channels. The vasoactivity of 20-HETE is inhibited with indomethacin indicating that cyclooxygenase is required for its bioactivation. The isolated perfused kidney challenged with angiotensin II released 20-HETE into the perfusion fluid This hormone-mediated release of 20-HETE cannot be inhibited with cytochrome P450 inhibitors Incubations of rat renal slices with calcium ionophore also resulted in formation of 20-HETE, suggesting involvement of phospholipase A_2 in the release of this eicosanoid. We investigated the possibility that 20-HETE may be esterified within kidney phospholipid stores and released following an appropriate stimulus.

Methods Total lipids were extracted by the method of Bligh and Dyer from rat kidneys homogenized in methanol/water (2·3) and were hydrolyzed with and without potassium hydroxide (0 1N)/ethanol solution for 1 hr at 37 °C 20-HETE was quantitated by isotopic dilution electron capture GC/MS Kidney lipids were analyzed on normal-phase (NP) HPLC column (Spherisorb, 150x4 6 mm, 3 μm) eluted with hexane/2-propanol/ethanol/sodium acetate (50 mM)/acetic acid (400 260 100.30 1, pH 6.7). 20-HETE-containing phospholipids were prepared by incubating 20-HETE and *lyso*-phosphatidylethanolamine (*lyso*-PE) or *lyso*-phosphatidylinositol (*lyso*-PI) in the suspension of kidney microsomes for 1 - 4 hr at 37 °C Diacylglycerols (DAGs) were obtained by incubating phospholipids with 10 units of phospholipase C (B. cereus, type XI, Sigma) for 30 min at 37 °C DAGs were extracted with 10% ethyl acetate in hexane and derivatized with pentafluorobenzoyl (PFB) chloride and diisopropylethylamine in benzene The derivative was extracted with hexane and injected into a Hypersil column (20x2 1 mm) and eluted with 0.3% 2-propanol/hexane at 0.5 ml/min. The effluent from the column was mixed with helium (at 50 psi) in the nebulizer of the particle-beam LC/MS interface at the desolvation chamber temperature of 55 °C The interface was connected to the mass spectrometer (Hewlett-Packard 5989A) operating in the electron capture mode with methane flow into the ion source yielding a pressure of 1 3 torr

Results and Discussion Rat kidney total lipids contained endogenous 20-HETE of which 85-90% was in the esterified form The amount of free 20-HETE in the normal rat kidney was 0.26±0.08 ng/μmol phosphorus (P) and increased to 2 42±0 4 ng/μmol P upon alkaline hydrolysis of renal lipids (n=4) Analysis of these lipids by NP-HPLC followed by saponification and GC/MS analyses, revealed that 20-HETE occurred in two fractions· one coeluting with neutral lipids and the other, with fraction containing standard PI However, comparison of chromatographic mobility in NP-HPLC suggested that the endogenous phospholipid containing 20-HETE coeluted with biosynthetically prepared 20-HETE-PE Treatment of 20-HETE-PE with phospholipase C followed by PFB derivatization and analysis by electron capture LC/MS generated the mass spectrum (Fig 2) containing molecular anion at *m/z* 854 (M) and fragment ions at *m/z* 834 (M-HF), 816 (M-HF-H_2O), 814 (M-2HF) The cleavage of the ester bond at C-2 of the glycerol moiety produced anion at *m/z* 513 This spectrum was consistent with the structure of PFB derivative of 1-stearoyl-2-(ω-hydroxyarachidonoyl)-glycerol having the PFB group bound to the ω-hydroxyl of the arachidonate function. The results indicated that the negative ion particle beam LC/MS was a useful technique for characterizing the diglycerol derivative of 20-HETE.

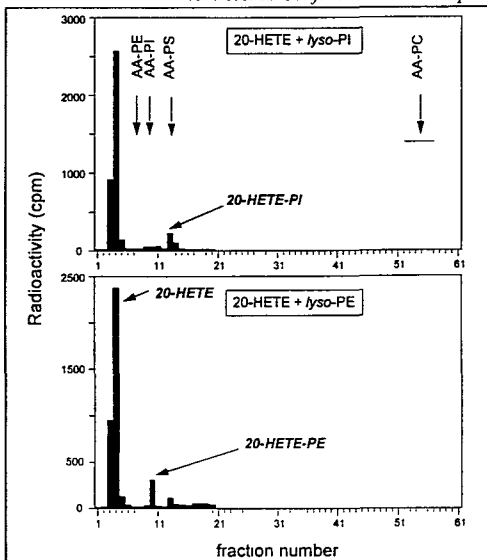

Figure 1. Effect of 1 hr (37 °C) incubations of radiolabeled 20-HETE (25 μM) with *lyso*-PI (top) and *lyso*-PE (bottom) in suspension of kidney microsomes containing CoASH (1 mM), ATP (1 mM) and ATP regenerating system (phosphocreatinine /phosphocreatinine kinase). Microsomes were preincubated with indomethacin (10 μM), baicalein (25 μM) and stilbene oxide (25 μM) for 15 min. After incubation, phospholipids were extracted with chloroform/methanol and analyzed by NP-HPLC. The amount of radioactivity in fractions was determined by scintillation counting In parallel experiments, radiolabeled arachidonic acid (AA) was incubated with microsomes and various *lyso*-phospholipids and analyzed by NP-HPLC Arrows indicate fractions which contained arachidonate-labeled phospholipids

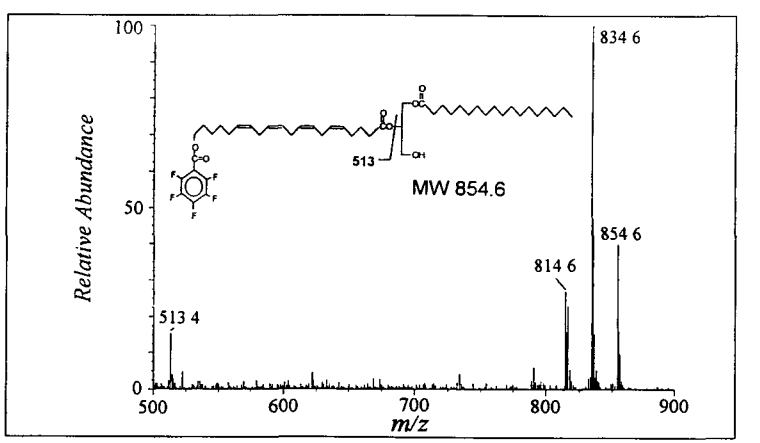

Figure 2 Electron capture spectrum of 1-stearoyl-2-(ω-hydroxyarachidonoyl)-3-pentafluorobenzoyl glycerol obtained by phospholipase C hydrolysis of a product in fraction 10 (Fig 1, bottom) followed by esterification with pentafluorobenzoyl chloride and analysis by particle beam LC/MS

Structural Characterization of Phospholipids by Matrix-assisted Laser Desorption Ionization FT-ICR Mass Spectrometry

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State University, 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

†Department of Chemistry, The Ohio State University
* Department of Chemistry, Florida State University

Here we report successful analysis of each of the four major classes of phospholipids (glycerophosphatidyl-choline, -ethanolamine, -serine, and -inositol) by use of matrix-assisted laser desorption Fourier transform ion cyclotron resonance mass spectrometry. Based on the relative size of the sample probe and laser spot, and assuming even sample distribution on the probe surface, we estimate that ~1.5 picomoles of lipid are desorbed per laser shot (total phospholipid on probe tip ≈ 3.5 nanomoles).

Both positive and negative molecular or quasi-molecular ions may be generated in high abundance. Isolated molecular ions are collisionally activated in the source half of a dual ion trap (~1.0 x 10^{-7} torr argon neutral collision gas), yielding fragments corresponding to polar-head group (positive-ions) or fatty acid side chains (negative-ions). Application of azimuthal quadrupolar excitation following collisionally activated dissociation (CAD) refocuses product ions close to the central z-axis; subsequent transfer of ions to the analyzer ion trap allows for high-resolution mass analysis.

Figure 1 shows representative negative-ion FT-ICR mass spectra for a 1,2-diacyl-glycerophosphoethanolamine (GPE), containing palmitic and oleic acids at the sn-1 and sn-2 positions respectively, generated from TCA matrix at a 5000:1 mole ratio with respect to the analyte. The top spectrum shows GPE molecular anion (m/z = 716) after isolation in the source ion trap, broadband axialization, and transfer to the analyzer trap. The middle and bottom spectra compare collisional activation of the molecular ion in the source side trap followed by either source side dipolar excitation and detection (middle), or broadband quadrupolar axialization and transfer to the analyzer trap (bottom). In each case, collisional activation was performed by sustained off-resonance dipolar irradiation at ~ 1 kHz below the reduced ion cyclotron frequency, ω_+, after optimizing the excitation amplitude and duration to maximize product ion signal magnitude. Collisional activation results in formation of abundant palmitic (m/z = 255) and oleic (m/z = 281) carboxylate anions. Product ion axialization and ion transfer to the low-pressure analyzer trap following CAD clearly results in much greater observed ion abundance and higher mass resolving power compared to CAD and detection in the source trap. For example, signal-to-noise ratio for the oleic carboxylate anion (m/z = 281) is at least 5 times higher and mass resolving power is ~15 times higher ($m/\Delta m_{50\%}$ ≈ 155,095 *vs.* $m/\Delta m_{50\%}$ ≈ 10,236) for analyzer trap detection than for source trap detection). Work supported by NSF (CHE 93-22824), NIH (GM-31683), The Ohio State University, and the National High Magnetic Field Laboratory at Florida State University.

Detection of Phospholipid Molecular Species in U937 Cells using CF-LSIMS

Chun Li* and James A. Yergey
Merck Frosst Center for Therapeutic Research, P.O. Box 1005
Pointe Claire-Dorval, Quebec, H9R 4P8, CANADA

Phospholipids are important constituents of the lipid bilayer of all cell membranes, and are important sources of arachidonic acid for eicosanoid biosynthesis. The analysis of molecular species within a phospholipid class, however, has been a challenging and time consuming task.[1-3] Previously, we developed an LC/MS method using capillary HPLC / continuous-flow liquid secondary ion mass spectrometry (CF-LSIMS).[4] Phospholipid molecular species analysis by CF-LSIMS showed much better sensitivity compared with existing techniques such as static FAB and thermospray LC/MS. A full scan mass spectrum of <1 ng phospholipid injected on column can be easily obtained, in both positive and negative ion modes. Molecular weight, head group and fatty acid chain information can be readily obtained from the primary CF-LSIMS spectra.

Coupling capillary HPLC with CF-LSIMS is particularly useful for the identification of minor species within a complex mixture. Using this technique, molecular species within each phospholipid class isolated from both non-differentiated and DMSO-differentiated U937 cells were readily identified in a realtively short time, and MS/MS analysis was not always necessary. U937 cells and DMSO-differentiated U937 cells are important cell lines which have been used as our primary screening assays for PLA_2 inhibitors. DMSO-differentiated U937 cells released much more arachidonic acid upon Ca^+ ionophore challenge than non-differentiated U937 cells.[5] This dramatic difference in arachdonic acid release may due to the difference in phospholipid composition of the cell membranes or the PLA_2 enzyme activity. The analysis of phospholipid molecular species in the two cell lines using capillary HPLC / CF-LSIMS indicated that no significant difference in phospholipid composition was found between non-differentiated and DMSO-differentiated U937 cell membranes. Each phospholipid class PE, PI, PS and PC isolated from the two cell lines showed identical molecular species profiles. The difference in arachidonic acid release upon Ca^+ ionophore challenge, therefore, must due to the enzyme activity difference between the two cell lines, or the factors affecting the utilization of free fatty acid.

Analysis for Analogs of Phospholipids by FAB Mass Spectrometry

Chungping Yu, Jianxing Huang, and Theodore S. Widlanski
Indiana University, Chemistry Department
Bloomington, IN 47405

INTRODUCTION

Due to the inherent low volatility and thermal lability of naturally occurring diacylglycerylphospholipids, the conventional method for structural analysis of these lipids is to chemically derivatize these analytes to increase volatility, followed by electron impact or chemical ionization mass spectrometric analysis. However this procedure to obtain information of molecular weight, fatty acyl groups, and polar head groups of various lipid classes is sometimes impractical because a complicated chromatographic separation may be required after derivatization. Fortunately, a combination of positive ion and negative ion FAB has been used successfully for structural analysis of underivatized lipids.[1,2] In this paper we report the evaluation under both positive and negative ion FAB conditions of various analogs of phospholipids containing sulfur in the head group. To simplify the structural characterization of these molecules, each lipid is designed to include two identical esterified acyl groups.

EXPERIMENTAL

A Kratos MS80RFAQ was operated at an accelerating potential of 4 KV to collect all the FAB mass spectra. A primary atom beam of Xe was produced using a saddle field ion source operating with an emission current of 2 mA at voltage of 8-9 KV. All the samples were prepared by the following procedure with NBA as matrix. Samples (10-50 mg) were dissolved in either 50 mL of a mixture solvent of methylene and methanol (5:1) or 30 mL of methylene chloride. 2-3 mL of this solution was then mixed with 5 mL of NBA on the copper tip. For lipids **1-9**, an additional 1 mL of 2% sodium acetate solution in methanol was applied to the tip to yield significant sodium adduct ions.

DISCUSSION

Molecular weight information on lipids (**1-6**) can be derived from the abundant $[M+Na]^+$ ions in FABMS spectra. Spectra also show the presence of $[RCO]^+$ ions at m/z 155, 183, 211, and 265, corresponding to $[C_9H_{19}CO]^+$, $[C_{11}H_{23}CO]^+$, $[C_{13}H_{27}CO]^+$, and $[C_{17}H_{33}CO]^+$ ions, respectively. In addition, a few fragments produced either by the loss of one acyl group or by the partial elimination of the head group are observed in the middle mass range of the spectra. Because of the low abundance of these fragments, These ions were not used for the elucidation of any structural information. Under negative ion FABMS condition, these lipids lose the head group moiety, **X** group, to produce abundant sulfonate anions. Other anions recognized in these spectra correspond to the carboxylate anions of the acyl group providing further confirmatory analysis of the acyl group. As expected, the positive ion FAB spectra of **7-9** show the presence of abundant $[M+Na]^+$ ions and $[RCO]^+$ ions. In contrast to the absence or very

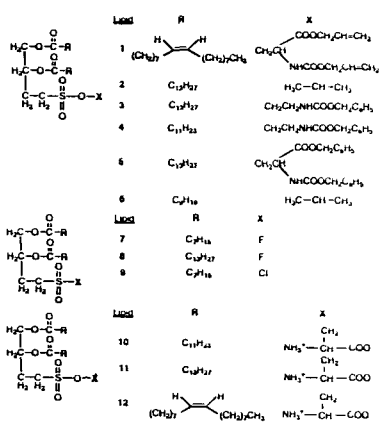
2. Murphy, Robert C. and Harrison Kathleen A. *Mass Spectrometry Reviews* **13**, 57-75 (1994).

low abundance of ions resulting from the cleavage of the carboxylate of the acyl group as seen in the spectra of other lipids, spectra of **7-9** show significant $[M-RCOO]^+$ ions at m/z 281, 365, and 297, respectively. These characteristic fragments can be used to distinguish lipids with sulfonyl head groups from lipids with other type of head groups. In negative ion FAB analysis, the only observed anion corresponds to the carboxylate anion of the acyl group. For lipids (**10-12**) containing serine in the head group, a rather intense $[M+H]^+$ ion is observed in the FABMS spectra without addition of sodium salt in the sample matrix. The basic nature of this zwitterion is probably responsible for the existence of significant $[M+H]^+$ ions. Additional ions are detected at m/z 439, 467, and 521 in the spectra of **10-12,** corresponding to the loss of the RCO fragment from the molecular species. In the negative ion mode, we observed cleavage of the oxygen-carbon bond between the sulfonate and serine to produce abundant sulfonate anions at m/z 533, 589, and 697 for lipids **10-12**, respectively. Once again, these spectra also show the characteristic carboxylate anion of acyl group.

CONCLUSION

In this work, we demonstrate that both positive and negative ion FABMS can be used together to identify the structure of sulfonyl-containing lipids and differentiate the lipids with different head groups. Solubility and concentration of analyte in the matrix and intrinsic properties of head group play an important role in affecting the mass spectrum quality and reproducibility. It is also noteworthy that different acyl groups do not have significant effect on the fragmentation pattern in both positive and negative ion modes. In future work by measuring the relative abundance ratio of the corresponding carboxylate anions, we may extend our study to a determination of the exact position of acyl group at the glycerol backbone of sulfur-containing lipids with two different acyl groups.



Analysis of Polyunsaturated Phospholipid Turnover by Electrospray LC/MS

*Ma, Yee-Chung; Ward Glen; Wang, Tao-Chin; Salem, Jr, Norman; Kim, Hee-Yong; Section of Mass Spectrometry, LMBB, NIAAA, NIH; NIMH, NIH, Bethesda, MD 20892

Phospholipids are not only the major constituents of biological membranes, but also play a role in many important biological functions. The distribution of individual phospholipid molecular species varies in different tissues, suggesting that their synthesis and turnover is differently regulated in various biomembranes. In the central nervous system, a very high abundance of polyunsaturated phospholipids was found. Since maintaining the balance of these polyunsaturated phospholipids is critical in normal brain development, understanding their dynamic changes in early postnatal life is important. In this study, polyunsaturates in the brain of mouse pups were labeled by feeding pregnant mice with deuterium labeled (d_5) linoleic (18:2n6) and linolenic (18:3n3) acid, the precursors of arachidonic (20:4n6) and docosahexaenoic (22:6n3) acid. The turnover of the 20:4n6 and 22:6n3 containing phospholipids in the brain of mouse pups can be assessed by monitoring the d_0/d_5 ratio using the electrospray LC/MS method we developed (1).

The mass spectrometers used in the study include an HP 5989 MS engine and a Finnigan TSQ70 triple quadrupole system, equipped with electrospray interface. The electrospray spectra of phospholipids produced simple MH^+ and $(M+Na)^+$. The response obtained for these phospholipids was similar within the same class but differed between classes. For phospholipids with a given fatty acyl composition, the electrospray technique was most sensitive for PC, followed by PE, PI and PS in descending order. By increasing capillary exit potential, characteristic diacylglyceride fragment ions (DG^+) were induced for all species except PC. Linear response curves were obtained for both MH^+ and DG^+ in the range of 10 pg to 10 ng when deuterium labeled compounds were used as internal standards (Figure 1).

In the animal study, pregnant mice were fed a diet containing deuterium (d_5) labeled 18:2n6 and 18:3n3 starting from 7 days of gestation and continuing throughout the pregnancy and lactation period. After weaning, pups were fed a diet in which most 18:2n6 and 18:3n3 were replaced by non-labeled 20:4n6 and 22:6n3. Ethanol (20 % cal) was introduced in the diet 10 weeks after birth for a duration of 2 weeks. At various time points, animals were sacrificed, the brain lipids were extracted, and both d_0 and d_5 20:4n6 and 22:6n3 containing phospholipids were analyzed by the reversed phase HPLC/electrospray MS method. The d_0/d_5 ratio of individual phospholipids obtained indicated that the turnover rate varied for different molecular species. In general, turnover of 20:4n6 containing phospholipids was faster than 22:6n3 containing phospholipids. Chronic ethanol consumption reduced the turnover of most 20:4n6 containing phospholipids while 22:6n3 containing phospholipids were not affected significantly. An exception was observed for 18:0/22:6-PC in which the turnover rate increased by about 25% (Figure 2).

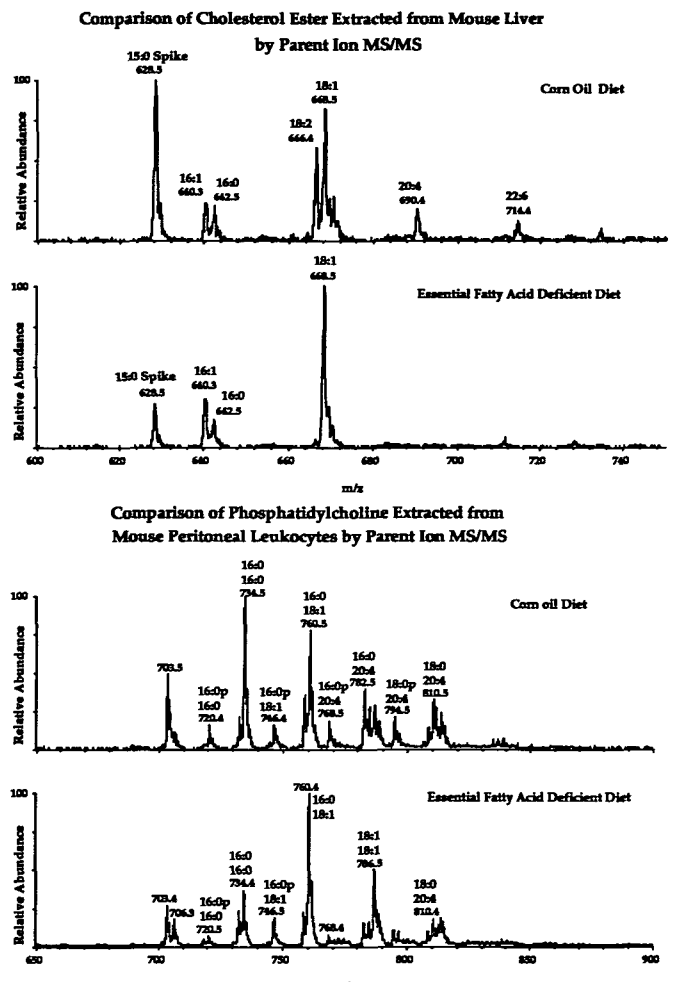
ISOLATION AND IDENTIFICATION OF PHOSPHOLIPIDS IN LIPID EXTRACTS BY ES/MS/MS

Kevin L. Duffin, Mark Obukowicz, and J.J. Shieh, Monsanto Corporate Research, Monsanto Company, St. Louis, MO 63198

Electrospray and tandem mass spectrometry were used to distinguish lipid compound classes and to identify the fatty acids that comprise the particular classes of lipid that were found in various tissue and cell extracts. Tissues and purified cell populations were extracted with chloroform:methanol solvent and the extract was analyzed directly after a simple centrifugation. Ammonium acetate was added to the extract solvent to assist in ionization of the nonpolar lipids that did not already possess a charge. Tandem mass spectrometry was used to fragment intact lipid ions to determine their class and to determine their fatty acid composition. Lipid standards were analyzed initially by these techniques to learn the expected fragmentation patterns of each class of lipid. Many of these results have already been published [1]. Results of these fragmentation studies then were used to identify the lipids found in mouse liver and footpad tissues, and in rat neutrophils. Common fragmentation patterns were observed in each of the different phospholipid classes, which aided in class identification and provided a means to separate phospholipid classes by classical parent ion or neutral loss MS/MS experiments without prior chromatographic separation. Product ion and neutral loss MS/MS experiments were then applied to the characterization of liver tissue, peritoneal leukocytes, and plasma of mice that were fed diets rich in linoleic acid (corn oil diet) or that were essential-fatty-acid-deficient. Lipids were separated and detected by MS/MS using the following fragmentation routes, which were generally applicable to those lipids that are listed:

Lipid	ES-MS/MS Characteristics
Cholesterol Ester	$(M+NH_4)^+$/ m/z 369 fragment ion
Sphingomyelin	M^+/ m/z 184 fragment ion
Phosphatidylcholine	M^+/ m/z 184 fragment ion
Phosphatidylethanolamine	$(M+H)^+$/ loss of 141
Phosphatidylglycerol	$(M+NH_4)^+$/ loss of 172 and 189
Phosphatidylserine	$(M+H)^+$/ loss of 185
Phosphatidylinositol	$(M+NH_4)^+$/ loss of 260 and 277
Phosphatidic Acid	$(M+NH_4)^+$/ loss of 98 and 115
Cardiolipin	$(M+NH_4)^+$/ fragments to form diacylglycerol



MASSIVE CLUSTER IMPACT IONIZATION OF PHOSPHOLIPIDS

Nyla N. Dookeran and Peter J. Todd

Oak Ridge, Tennessee 37831-6365

We used a massive cluster impact (MCI) gun as a source of primary ions to generate positive and negative secondary ions characteristic of phospholipids from three types of samples. These included reference phospholipids dissolved in glycerol and deposited neat on the FAB target of a JEOL SX102A mass spectrometer. We also obtained spectra from animal tissue deposited directly on the probe tip. Except for variations in total secondary ion yield, the mass spectral characteristics of lipids obtained from the three different types of samples are virtually identical. Furthermore, the fragmentation behavior of the ions formed is similar to that reported by others who have used FAB**[1]** and a liquid glycerol matrix. The obvious advantages of the MCI source include minimal sample preparation and secondary ion emission that persists for hours.

The MCI gun is a direct replacement for the JEOL Xe FAB gun. Its operation is based on electrohydrodynamic (EHD) ionization of glycerol, which is supplied from an integral reservoir via a stainless steel capillary. Glycerol cluster ions with a mass distribution extending to 10^7 u, charge distribution in the range of 10^2 and current of about 10-30 μA, are emitted from the gun when a potential of 15-20 keV are applied to the EHD emitter.**[2]** The beam of clusters is focussed and deflected onto the target by a series of lens elements/deflectors. Recent modifications to the original gun design have greatly improved the stability of the emitted beam, and the corresponding secondary ion current.

In the positive secondary ion mode, the presence of phosphatidylcholine is evident by an abundant m/z 184 ion. As with conventional FAB, virtually all the information about the lipids in a sample can be determined in the negative mode,. For example, abundant $[M-15]^-$, $[M-60]^-$ and $[M-86]^-$ are observed from phosphatidylcholine. Abundant $[M-H]^-$ from phosphatidylethanolamines are typically 40% of the base peak intensity, with peaks corresponding to either of the acyl groups as the base peak.

Most importantly, among the most abundant negative secondary ions detected are the acyl groups. Figure 1, for example, shows a region of the negative ion MCI spectrum obtained from a sample of 18:0/18:1 phosphatidylcholine. The two important features of the m/z 281 and the m/z 283 are their intensity in the spectrum and their intensity relative to each other. The former feature permits use of tandem mass spectrometry (MS/MS) to determine their structure, including position of double bonds and the latter permits assignment of the m/z 283 to the sn-1 and m/z 281 to the sn-2 positions of the glycerol backbone of the phospholipid.

Figure 2 shows the partial negative MCI mass spectrum obtained from a sample of 18:1/18:0 phosphatidylcholine deposited directly on the sample probe tip, without any other sample preparation. The abundant m/z 283 and 281 mark the sample as containing 18:0 and 18:1 lipids. Their abundance relative to each other indicate the 18:1 fatty acid is in the sn-1 position and the 18:0 fatty acid is in the sn-2 position. Importantly, the same spectrum was observed after continuous bombardment for more than one hour.

FORMATION OF THE $[M-H]^+$ ION IN THE LSIMS MASS SPECTRUM OF SPHINGOSINE

Eddie A. Chevis & Kenneth L. Busch
Department of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332

Abstract

The mass spectra of sphingosine and its saturated analogs were measured by electron ionization (EI), chemical ionization (CI), and liquid secondary ion mass spectrometry (LSIMS). In EI, the molecular ion can be observed intermittently. Self-chemical ionization predominates at all sample loadings and the protonated molecule $[M+H]^+$ is observed to the exclusion of the molecular ion M^+. The $[M+H]^+$ ion in EI is sometimes accompanied by an ion 2 Daltons lower in mass, $[M-H]^+$. Deuterium exchange experiments suggest that two hydrogens are lost from the hydrocarbon chain to form $[M-H]^+$. In chemical ionization, the choice of the reagent gas strongly influences the extent of fragmentation of $[M+H]^+$. The fragmentation processes observed are similar to those seen in EI, and the $[M-H]^+$ ion is now a constant 10-20% intensity relative to the protonated molecule. The relative intensity of the $[M-H]^+$ ion changes with the proton affinity of the reagent gas chosen for chemical ionization. Finally, in LSIMS, the intensity of the $[M-H]^+$ ion reaches its maximum relative intensity. The similarity of fragment ions in the LSIMS mass spectrum suggests that gas-phase dissociations are predominant.

Introduction

The long chain base sphingosine accounts for about 70% of all sphingolipid molecules isolated from cellular membranes [1]. Initially, the analysis of sphingosine and related compounds by mass spectrometry focussed on the completion of extensive work in the structural elucidation of gangliosides, glycosphingolipids, sphingomyelins, and sulfatides [2]. The development of new ionization methods has greatly aided this task. For example, Rubino *et al.* [2] demonstrated that FAB/MS and high-energy collision-induced dissociation allowed characterization of sphingosine without prior derivatization of the sample molecules. In their work, charge-remote fragmentation of the protonated molecule of sphingosine and its saturated analogs was used to confirm structure and elucidate fragmentation pathways. Sphingosine analysis by thermospray mass spectrometry has been discussed by Thakur and Smith as a potential method of early detection for Fumonisin toxicity. Thakur and Smith [3] demonstrated that native sphingosine and its saturated analogs in serum samples could be detected by thermospray mass spectrometry, with the mass spectra providing both qualitative and quantitative information.

Both FAB and the thermospray studies highlight fragmentation reactions useful for structural characterization of these compounds. The assumption has been that a desorption ionization method is required to produce a molecular ion from these compounds. There are several early reports of the electron ionization (EI) mass spectra of derivatized forms of sphingosine and its analogs [4-7]. However, we found that EI could occasionally be used to generate mass spectra from underivatized sphingosine. Initial results that showed the occurrence of a self-chemical ionization process to form $[M+H]^+$ suggested also that analogies to the mass spectra produced by chemical ionization and LSIMS/FAB could be explored. Such a comparison is one focus of this paper, and we measured chemical ionization (CI) mass spectra, also apparently without precedent in the literature. We completed this study with LSIMS mass spectra recorded in several different solvent matrices to complement and extend the work of Rubino *et al.*

One common feature of positive ion LSIMS/FAB mass spectra is the presence of an ion with mass two Daltons lower than the protonated molecule, viz $[M-H]^+$. A similar ion also often appears in the positive ion LSIMS mass spectra of precharged organic compounds, appearing there as $(C-2)^+$ where C is the mass of the cation. This ion formally corresponds to the product of a dehydrogenation reaction, and usually

appears with 10-20% intensity relative to the intensity of the cation or the protonated molecule. The mass spectra recorded by Rubino et al. contain this ion. The $[M-H]^+$ ion for the saturated compound corresponds in mass to the protonated molecule for unsaturated sphingosine. Another focus of this work is to confirm the origin of this fragment ion as a dehydrogenation reaction, and for the case of sphingosine and its saturated analogs, to explore the mechanism for its formation.

Conclusions

The ability of electron ionization to produce mass spectra for sphingosine was shown in this study. The fact that chemical ionization produces high quality mass spectra supports the assertion that the samples can be evaporated into the source without decomposition from a direct insertion probe. The strong basic nature of the sphingosine was apparent in the self-chemical ionization process observed in EI, and in the relative lack of fragmentation in CI and LSIMS. This study was also focussed on the production of the $[M-H]^+$ ion in each of the ionization methods, and deuterium exchange experiments suggest that the hydrogen that is lost in the dehydrogenation is derived from the alkyl chain of the molecule. There is no evidence for a beam-induced dehydrogenation reaction, and the appearance of the $[M-H]^+$ ion in all ionization methods confirms the origin of this peak in a gas-phase dissociation. Charge-remote fragmentation occurs not only in LSIMS but also in chemical ionization mass spectra.

Characterization of GS-15 and Biomarkers of the Helderberg Formation

Maria P.Ospina*, David H. Powell*, James E. Channel**, Richard A. Yost*
*Department of Chemistry, University of Florida
**Department of Geology, University of Florida

About 280 million years ago the magnetic properties of the sedimentary rocks in about one-half of the North American continent were changed. They were remagnetized over a very large area, and the process that caused this change is poorly understood[1].

In the case of the Helderberg Limestones in New York State, the remagnetization occurred 100 million years after the deposition of the sediment. The direction of the remanant magnetization indicates that the remagnetization occurred 280 million years ago, whereas the limestones were deposited 380 million years ago. The magnetic characteristics of these rocks, indicate that magnetite is the carrier of the magnetization. Estimates of the thermal conditions during burial eliminate the possibility of remagnetization by thermal processes and imply chemical growth of new magnetite. **QUESTION:** Where did the new magnetite come from and how did it get into the rock?

Geochemical models for post-depositional magnetite formation are controversial. It has been suggested that magnetite occurs the limestones as a result of hydrocarbon or associated brine migration[2,3] coeval with the Hercynian deformation of the Appalachian mountains. The grain size of the magnetite particles is in the range of several tens of nanometers with a quite narrow distribution. It is unlikely that the magnetite was formed from an inorganic source. A biological source is more likely.
Three possible biologically based mechanisms have been suggested:

1. Microbial attack of hydrocarbons leading to precipitation of magnetite from bitumen[4];
2. Microbial synthesis of magnetite with subsequent deposition after death as in bacteria that use magnetite particles for orientation
3. Production of magnetite as an end product of microbial metabolism by Fe(III) reducing bacteria.

An anaerobic, rod-shaped bacterium (GS-15) was isolated several years ago from the Potomac river and found to produce ultrafine-grained magnetite with a similar narrow distribution and size to those found in the Helderberg limestones. These magnetite grains are products of GS-15 metabolism. GS-15 can oxidize several aromatic compounds to CO_2 with Fe(III) as the sole electron acceptor[5]. These studies suggest that Fe(III) reducing organisms like GS-15 could be responsible for Fe(III) reduction and formation of post-depositional magnetite.

We have completed a preliminary GC/MS examination of the organic extractables from Helderberg limestone and the magnetite producing bacterium GS-15 in order to test whether a chemical fingerprint is present which may associate the new magnetite in the limestones with a bacterial source.

The dominant organic extractables in the Helderberg limestone are straight-chain aliphatic hydrocarbons ranging from C-15 through C-23 with both even- and odd-carbon numbers exhibited. We have detected the biomarker compounds pristane and phytane in the limestones and also ions that are markers for hopanes and steranes. The pristane:phytane ratio is about 0.5 which can indicate anaerobic environmental conditions. Since the Helderberg limestones have not experienced significant heating after deposition, the organic phase is considered geochemically immature and the pristane:phytane ratio is not conclusive with respect to the oxygenation conditions during deposition. The presence of pristane and phytane can indicate either a

chlorophyll based source or a bacterial origin. The lipids found in the outer membrane of certain bacteria that live only in strong salt solutions has been proposed as an indirect source for the isoprenoid alkanes .[9-13] This biological source is consistent with brine intrusions which have been associated with post-depositional magnetization.[2,3]

The GS-15 bacteria show only C-14 through C-16 fatty acids. The quantity of bacteria available for the extraction was less than half a gram due to the stringent conditions necessary to culture this organism. The analytes detected were therby restricted to the major components.

Future studies will employ larger quantities of GS-15 bacteria to examine the lower concentration fatty acids, terpenes, and precursors of hopanes and steranes. We will also use selected ion monitoring and tandem mass spectrometry to identify further marker compounds in GS-15 and the Helderberg limestone.

Py-MS FAME EXTRACT PROFILING OF PATHOGENIC MICROORGANISMS

Franco Basile, Ted L. Hadfield[1], Dave W. Sickenberger[2], and Kent J. Voorhees
Department of Chemistry, Colorado School of Mines, Golden, CO 80401; [1]Armed Forces Institute of Pathology, Washington, DC; [2]CBDCOM, ERDEC, Aberdeen Proving Ground, MD.

Pyrolysis-mass spectrometry (Py-MS) has been chosen for a new automated, field instrument for the detection of chemical and biological warfare agents (BWAs). Before this technology is implemented in field situations, its ability to identify and detect BWAs must be compared to established bacterial identification system. In this study, Py-MS of fatty acid methyl ester (FAME) extracts is compared to gas chromatography-FAME analysis [1]. The advantage of mass spectrometry over the chromatographic assay is speed of analysis without loss of taxonomic information. Py-MS offers the ability to perform bacterial-FAME analysis under 10 minutes, an order of magnitude decrease in total analysis time over the GC-FAME approach.

Py-MS Analysis of FAMEs from Pathogenic Bacteria

Representative FAME Py-mass spectra from the pathogenic microorganisms studied are shown **Figure 1**. PCA analysis of Py-mass spectra of FAMEs from these microorganisms is shown in **Figure 2**. Four clusters are obtained in this data set, and the large spread of these clusters is a direct result of the wide range of growth conditions used. *Bacillus anthracis* (Gram-positive) was characterized by branched, odd-carbon number fatty acids (br-C15:0 and br-C17:0). On the other hand, *Brucella, Francisella,* and *Yersinia* are all characterized by palmitic acid (C16:0) and mono-unsaturated fatty acids (C18:1 and C16:1). The monounsaturated fatty acid C24:1w15c is a characteristic biomarker present in *F. tularensis*[2]. Samples were analyzed with a mass range of 180-360 amu to include the M-32 fragment ion (m/z 348, loss of MeOH) of the methyl ester of this fatty acid. This important fatty acid is not identified in the MIDI system, which is unable to differentiate *Brucella* from *Francisella* (Only three clusters are obtained in the PCA plot of FAME-chromatograms). No taxonomic information is lost in the Py-MS analysis even though the GC-FAME analysis uses a total of 60 different FAMEs (retention times or ECLs) when compared to only 14 FAMEs (and their fragment ions) used in the Py-MS assay.

ACKNOWLEDGEMENT

The authors (FB, KJV, TLH) are grateful for the generous support from the U.S. Army Research Office/ERDEC (Grant#: DAAL03-92-G-003).

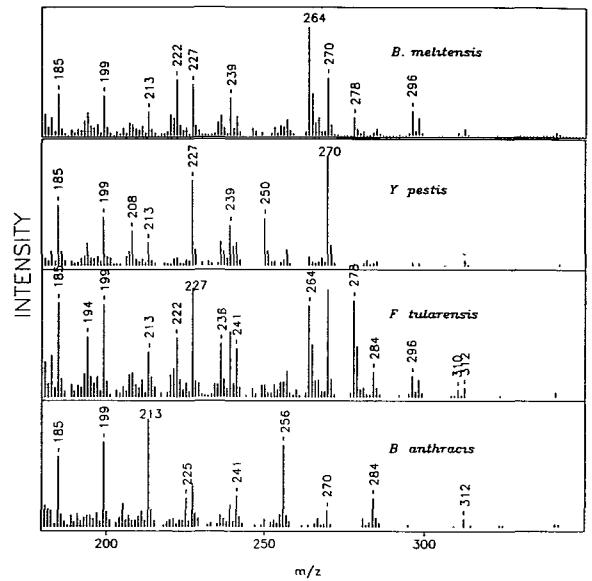
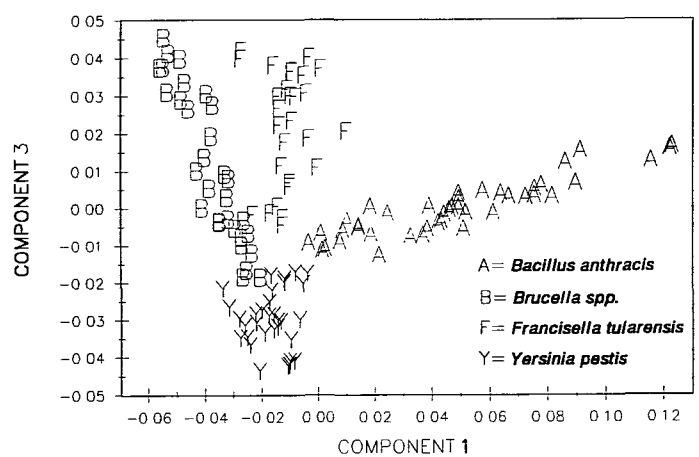
43rd ASMS Conference on Mass Spectrometry and Allied Topics





SPECIES DIFFERENTIATION OF BEESWAXES USING PYROLYSIS MASS SPECTROMETRY

Kent J. Voorhees, Paul T. Kay, and Michael B. Beverly, Dept. of Chemistry, Colorado School of Mines, Golden, CO 80401

The influx of Africanized honey bees, so called "killer bees", from South America has generated an interest and need for a technique to rapidly identify bee species Previous work using gas chromatographic (GC) methods [1,2] have shown chemical differences in beeswax that can be used for taxonomic identification. Curie-Point pyrolysis mass spectrometry (Py-MS) has been conducted on the waxes from several species of bees to determine the feasibility of using this technique as a method for bee identification. Pattern recognition analysis of the wax Py-MS spectra produced clusters that correlated to the bee species

EXPERIMENTAL

An Extrel ELQ-400 triple quadrupole mass spectrometer was used for all analyses All spectra were collected at 70ev ionization energy and over a scan range of 300-700 Da which matched the range of species specific compounds seen in GC analysis. Curie-point pyrolysis was performed at 510° C Wax samples were taken from honeycombs dissolved in chloroform (10 mg/ml) and sonicated for 5 min. An aliquot (3µL) of this suspension was applied to the pyrolysis wires and the solvent evaporated. Pattern recognition of the Py-MS spectra was done with the RESOLVE program developed at the Colorado School of Mines [3]

RESULTS

Principal component analysis of the Py-MS spectra from the waxes of seven species of bees resulted in the clustering of the spectra by their respective species (Figure 1) All of the spectra are clustered by their species except the spectra from the African, *Apis mellifera scutellata* (a), European, *Apis mellifera* (b), and hybrids of the two bees (m), which are enclosed by the inset box The overlapped grouping is expected as the waxes from African and European honey bees is very similar in composition (Figure 2).

A more detailed analysis was conducted on waxes from pure African bees (a), pure European bees (b), African/European hybrids from Texas (t), and African/European hybrids from Mexico (m). Using a pattern recognition technique called supervised rotations, separation of the European spectra from the African and hybrid spectra was achieved (Figure 3). Separation of African and European spectra was brought about by differences in the amounts of similar chemical compounds, an observation reported by other researchers using different analytical techniques[1,2]. That the African (a) wax could not be separated from the hybrid wax from Mexico (m) indicates that the latter wax more closely resembles the African wax (a) than does the hybrid wax from Texas (t). This result supports some theories that bees closer to their tropical origins demonstrate more African than European traits[1]

ACKNOWLEDGEMENTS

We wish to thank Raul Rivera at the USDA Bee laboratory in Weslaco, Texas, for providing African and Africanized wax, and Jerry Webb of Littleton, Colorado for wax samples from the European honey bee

GC-MS TECHNIQUES USED IN EVALUATING ALCOHOL EFFECTS ON LIPID METABOLISM

Robert J. Pawlosky and Norman Salem Jr.
National Institute on Alcohol Abuse and Alcoholism, NIH, Rockville MD.

In the liver, alcohol consumption generally increases lipid peroxidation by generating hydroxyl radicals through the ethanol-induced monooxygenase, P450IIE1. The activation of this enzyme initiates events resulting in the production of aldehydes and F_2-isoprostanes. Both aldehydes and isoprostanes have biological activity which may be associated with some of the known effects of chronic alcoholism. High levels of lipid peroxidation may also lead to losses of polyunsaturated fatty acids, 20:4n-6 (arachidonic acid) or 22:6n-3 (docosahexaenoic acid). These losses may in turn reduce the function of certain cells (e.g. neural cells, platelets, erythrocytes).

Alcohol consumption may also reduce the uptake of essential fatty acids from the diet into the plasma and lower the production of polyunsaturated fatty acids by inhibiting enzymatic activity.

Gas chromatography-mass spectrometric techniques were used to evaluate lipid peroxidation by measuring 4-hydroxy-hexenal, 4-hydroxy-nonenal, and 8-isoprostane-PGF_2-alpha in the plasma of rhesus monkeys. The effects of alcohol on the uptake of deuterium-labeled 18:2n-6 (linoleic acid) and 18:3n-3 (linolenic acid) into the plasma was also evaluated using a stable isotope GC-MS method. The description of these methods is the subject of this presentation.

METHODS

Five rhesus monkeys were maintained on a low essential fat diet. Animals were given free access to a 7% artificially sweetened alcohol solution for 15 months. Four controls were maintained on the same diet and not given alcohol. The effects of alcohol consumption on plasma levels of lipid peroxidation products, 4-hydroxy-nonenal, 4-hydroxy-hexenal, and 8-isoprostane-PGF2-alpha were determined using negative ion GC-MS analysis. To determine whether alcohol had an effect on the uptake of the deuterium-labeled 18-carbon essential fatty acids, d_5-18:2n6 and d_5-18:3n3, into the plasma or the accumulation of deuterium-labeled long chain polyunsaturated fatty acids in the plasma, animals were given a single dose of 100 mg of the deuterium-labeled fatty acids and the blood was analyzed for the labeled fatty acids throughout a two week period.

Extraction-Derivative Formation

I. **Aldehydes.** Tissue samples (3-50 mg) were homogenized in a mixture of 400 ul methanol containing 50 ug/ml BHT, 200 ul of a 2 mM EDTA buffer, pH 7.0, and 200 ul of 0.1M PIPES containing 50 mM PFBHA.HCL, pH 6.5.

Samples were incubated at room temperature for 5 min. to form the O-PFB oxime derivatives. After incubation, 1 ml hexane was added, the mixture was vortexed for 1 min and centrifuged at 1000 g for 1 min. The hexane layer was collected and repeated twice. Hexane was evaporated under nitrogen and samples were dissolved in 50 ul pyridine and 50 ul BSTFA and incubated for 5 min at 80°.

II. **Isoprostanes.** *Solid phase extraction was used to extract the isoprostanes.* 1 ml Bond-Elute C-18 cartridges were conditioned with 2 ml methanol followed by 2 ml distilled water. Aqueous samples were applied and rinsed with 2 ml 80:20 water:methanol. Cartridges were dried under vacuum and rinsed with 2 ml dichloromethane. Isoprostanes were eluted with 1 ml methanol and solvent was evaporated under nitrogen. Samples were converted to PFB esters using 100 ul of PFB-bromide:diisopropylethlamine:acetonitrile 1:100:1000 @ 60°. The reagent was evaporated under nitrogen and 50 ul BSTFA and 50 ul CH_3CN were added to from TMS ether.

III. **Deuterated Fatty Acids:** The deuterated fatty acids were labeled at the ethyl terminal positions. The fatty acids were extracted using the Bligh and Dyer lipid extraction procedure, saponified in a 10% KOH methanolic solution, acidified with HCl, re-extracted into hexane and derivatized to the PFB esters using pentafluorobenzyl bromide.

GC-MS Conditions

I. **Aldehydes & Prostanes:** GC separations were performed on a 30 m X 0.25 mm DB-5 column (J&W) using helium. Samples were injected into a Hewlett-Packard 5989 GC using an on-column injection technique. The oven was at 110° and heated at 20°/min to 315°. Quantification was based on peak area ratios with d_4-PGF_2-alpha, d_3-4-hydroxynonenal, and d_3-4-hydroxyhexenal. Methane was used as the reagent gas (pressure was 4×10^{-4} torr). The source temperature was 200°.

II. **Deuterated Fatty Acids:** Deuterium-labeled fatty acids resolved from the non-labeled materials using a 25 meter polar FFAP capillary column using splitless injection with an oven temperature program of 80°-185°@20°/min, 185°-240°@10°/min and held for 30 min. The fatty acids were quantified using 23:0 as an internal standard.

RESULTS & DISCUSSION

1. The levels of both the 4-hydroxy-hexenal and nonenal were quantified in the plasma using the deuterium-labeled internal standards. The level of 4-hydroxy-nonenal was several orders of magnitude greater in the alcohol consuming animals compared to controls (alcohol mean 2800 pg/ml vs controls mean 150 pg/ml). The level of 4-hydroxy-hexenal was similar in both groups and this may be the result of several factors such as the high reactivity of this compound.

2. The level of 8-isoprostane-PGF_2-alpha was two fold higher in the plasma of monkeys consuming alcohol compared to controls (alcohol mean 170 pg/ml vs controls mean 90 pg/ml).

3. Alcohol did not appear to affect the uptake of either deuterium-labeled 18:2n6 or 18:3n3 into the plasma. This indicates that the loss of polyunsaturated fatty acids from tissues of alcohol exposed animals may not be due to the failure of animals to obtain essential fatty acids from the diet, however, production of long chain polyunsaturated fatty acids from these fatty acids may be affected by alcohol and must be determined.

The authors wish to thank Profs. Eric Van Kuijk for supplying the deuterium-labeled aldehydes and Hermann Esterbaurer for supplying the primary aldehyde standards.

A COMPARISON OF HIGH- AND LOW- ENERGY CID OF DERIVATIZED LIPIDS

W. J. Griffiths, Y. Yang, J. Zhang, J. Å. Lindgren and J. Sjövall
Department of Medical Biochemistry and Biophysics, Karolinska Institute, S-17177 Stockholm, Sweden.

Mass spectrometry has been extensively used in the past in the structure elucidation of lipids. Early work was done by Ryhage and Stenhagen at Karolinska Institutet on the electron impact ionization of fatty acid esters (*Ark. Kemi,* **13,** 523 (1959)), and subsequently GCMS has been extensively used in lipid analysis Since the discovery of FAB in the early 1980:s, this has become the ionization method of choice for the analysis of polar and sensitive lipids, although electrospray ionization is now gaining popularity. Both FAB and ES mass spectra are dominated by strong pseudomolecular ions, and little fragmentation occurs. To increase the amount of structural information, CID spectra are recorded. Gross and co-workers have carried out extensive studies on the CID of lipids (*Int. J. Mass Spectrom. Ion Processes,* **118/119,** 137 (1992)). They found that in keV CID reactions of fatty acids, charge-remote fragmentations (CRF) occur. CRFs also occur in the keV CID of bile acids. In this laboratory we have extensively used FAB and ES with keV CID, in the structural investigation of bile acids and other lipids. Bile acids derivatized with aminosulphonic acids give strong $[M-H]^-$ pseudomolecular anions upon FAB and ES ionization, and CRFs in keV CID reactions (*Rapid Commun. Mass Spectrom.*, **7,** 235 (1993)) Shown in Figs. 1a and 2a are the keV CID spectra of the $[M-H]^-$ pseudomolecular anions of (1a) taurocholic acid and (2a) prostaglandin $PGF_{2\alpha}$ derivatized with aminobenzenesulphonic acid, obtained when using He as the collision gas Charge-remote fragmentations are observed and described in the inset. Very recently we have purchased an OATOF sector, which has been added on to our VG AutoSpec FPD mass spectrometer. This hybrid instruments is described elsewhere at this conference. The collision energy for OATOF operation must be less than 12.5% of the accelerating potential energy When the accelerating potential energy is at 4 keV, as for electrospray operation, the collision energy must be below 500 eV. A point of immediate concern to us was, could CRF spectra be obtained on the OATOF at this collision energy? Shown in Figs 1b and 2b are 400 eV CID spectra of taurocholic acid and derivatized $PGF_{2\alpha}$ obtained using Xe collision gas. Clearly CRF occurs at this collision energy

Fig.1. CID spectra of taurocholic acid $[M-H]^-$ ions (m/z 514). Parent ions generated by electrospray. (1a) Collision energy 4 keV, He collision gas, constant B/E linked scans, ions detected on the focal plane detector. (1b) collision energy 400 eV, Xe collision gas, daughter ions analysed by the OATOF

Fig 2. CID spectra of $PGF_{2\alpha}$ derivatized with aminobenzenesulphonic $[M-H]^-$ (m/z 508). Parent ions generated by (2a) CF-FAB, Collision energy 8 keV, He collision gas, constant B/E linked scans, ions detected on the point detector

Electron Capture Mass Spectrometric Analysis of Lipid Peroxidation Products

Amy J. Grimsrud*, F. J. G. M. van Kuijk#, David W Thomas$, L. Joseph Sears*
Dept. of Chemistry, Montana State Univ , Bozeman, MT
Life Sciences Div., SRI International, Menlo Park, CA
#Dept of Ophthalmology, Univ. of Texas Medical Branch, Galveston, TX

INTRODUCTION. 4-hydroxyalkenals are the major aldehydic products of lipid peroxidation. These alkenals are responsible for many undesirable biological effects, such as inhibition of enzyme activity and inhibition of DNA synthesis. 4-hydroxynonenal can be used as a specific chemical indicator for lipid peroxidation (1). GC/MS electron capture ionization methods can be used for the determination of these compounds, if they are first modified to form PFB-oxime-TMS ether derivatives (1). The purpose of this study was to evaluate conditions that reduce fragmentation of the derivatives in HPEC/MS; and, where fragmentation does occur, to determine the origin of the observed ions

Increased fragmentation is often accompanied by the formation of noninformative ions, such as the O-PFB group at m/z = 196. In the course of the analysis of 4-hydroxynonenal derivatives, significant chromatographic peak tailing in the reconstructed ion chromatogram of m/z = 196 was observed (Fig. 1). EI experiments have shown that this tailing is not due to chromatographic effects The phenomenon of wall related processes has been previously documented by Sears, et.al. (2). Differences in temporal profiles of reconstructed ion chromatograms can be used to elucidate processes which lead to the generation of unexpected ions. Experimental parameters were varied to alter the observed EC spectra. These parameters were buffer gas (N_2, CO_2, CH_4, Ar, and NH_3), source temperature, source pressure, and ion exit slit width. Isotopically enriched $C^{18}O_2$ and $^{15}N_2$ were also used to elucidate the ion source wall related reactions.

DISCUSSION. It is expected that all ions generated from gas phase processes will have the same temporal profile. However, Figure 1 illustrates that the temporal profile of m/z = 196 does not coincide with that of other ions, such as m/z = 283 The extreme tailing chromatographic profile of m/z = 196 is indicative of a wall related process. We have used alternative buffer gases to elucidate the wall related reactions (3). Using NH_3 as a buffer gas gave comparable results to using CH_4 (i.e. tailing temporal profile and a prominent ion at m/z = 196)(Fig. 1).

Figure 2 shows the results from a series of experiments in which N_2 and isotopically enriched gases were used as buffer gases. A prominent ion appears at m/z = 198 when $^{12}C^{18}O_2$ is used in place of $^{12}C^{16}O_2$. Normal N_2 results in the formation of m/z=193, whereas isotopically labeled $^{15}N_2$ results in the emergence of an ion at m/z = 194. .The ^{18}O, ^{14}N, and ^{15}N in the respective spectra must come from the reaction of the analyte at the source wall with products generated from the irradiation of the labeled buffer gas. This provides clear evidence that the temporal distortion of the chromatographic profile of the O-PFB ion is not the result of a simple fragmentation.

Figures 3a and 3b show a comparison of chromatographic profiles and spectra obtained by varying the residence time of the analyte in the source by changing the ion exit slit dimensions. Condition **a** (small slit), results in a spectrum with an intense m/z = 196 peak and a tailing temporal profile. Condition **b** (large slit) yielded little m/z = 196 ion. Its chromatogram shows little tailing. We believe that the small amount of m/z = 196 ion present may be due to the expected gas phase fragment ion formation of O-PFB.

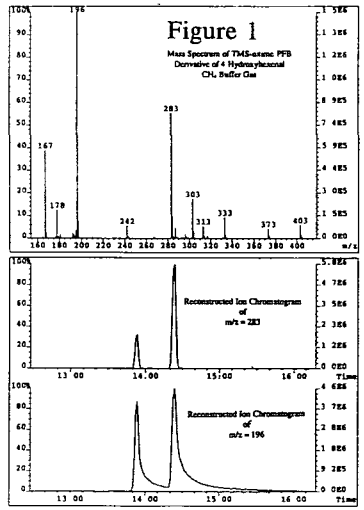
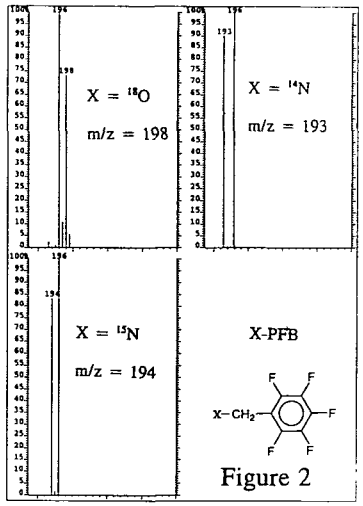
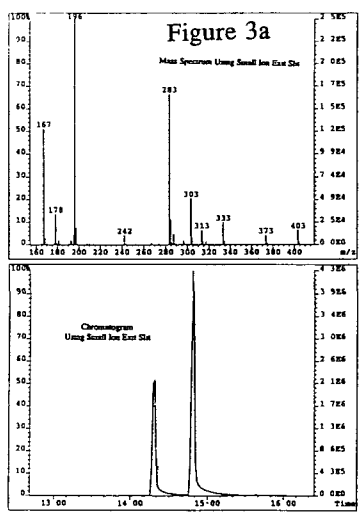
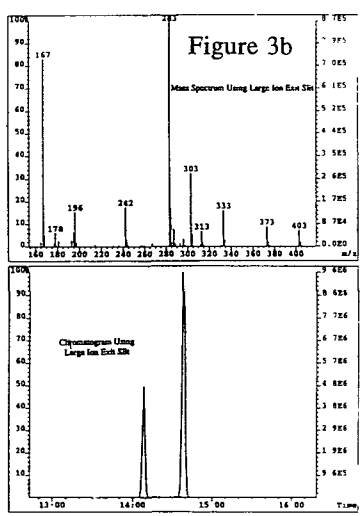
43rd ASMS Conference on Mass Spectrometry and Allied Topics









Analysis of Neurosteroids by Liquid Chromatography/Mass Spectrometry

Hee-Yong Kim*, Elena Romeo and Yee-Chung Ma
Section of Mass Spectrometry, LMBB, NIAAA, NIH
10 Center Dr. MSC 1256, Bethesda, MD 20892-1256

Progesterone and deoxycorticosterone have been shown to be metabolized in brain to 5a-pregnane-3a-ol-20-one (THP or Allopregnanolone) and 5a-pregnane-3a,21-diol-20-one (THDOC), respectively. Electrophysiological studies have indicated that these neurosteroids modulate the GABA/benzodiazepine binding sites. Anxiolytic and hypnotic effects have also been reported for these compounds when they were administered to laboratory animals. Therefore, analysis of these neurosteroids in the central nervous system may provide a biochemical understanding of stress-related situations in humans such as those observed in alcoholics during withdrawal. The best approximation of the brain concentration of these neurosteroids may be made by measuring their level in the cerebrospinal fluid (CSF). In order to develop a sensitive quantitative technique to analyze THP and THDOC along with several other neurosteroids which are normally present at trace levels in CSF, LC/MS techniques using thermospray (TSP), electrospray (ESI) and atmospheric pressure chemical ionization (APCI) were evaluated.

Finnigan TSQ-700 with TSP or ESI/APCI interface was used with following conditions.

TSP	Vaporizer temperature	70°C
	Source aerosol temperature	250°C
	Flow rate	0.5 mL/min
	Mobile phase	0.1M CH_3COONH_4 : methanol gradient
	Column	Waters Novapack-ODS column (2mm x 15cm)
ESI	Capillary temperature	280°C
	Flow rate	0.15 mL/min with approx. 4:1 split
	Mobile phase	H_2O : methanol gradient
	Sheath gas pressure	70 psi
	Auxiliary gas flow	15 flow unit
	Column	Prodigy-ODS column (1mm x 15cm)
APCI	Vaporizer temperature	500°C
	Capillary temperature	150°C
	Mobile phase	1% CH_3COOH : methanol gradient
	Sheath gas pressure	18 psi
	Auxiliary gas flow	5 flow unit
	Column	Waters Novapack-ODS column (2mm x 15cm)

CSF samples were extracted with ethyl acetate and were directly introduced to an LC/MS system.

Various neurosteroids including progesterone, dehydroepiandrosterone (DHEA), dihydroprogesterone (DHP), THDOC, THP, pregnenolone and pregnanolone were detected as $(M+H)^+$ or $(M+H-H_2O)^+$ (Figure 1). Among the three techniques examined, thermospray LC/MS appeared to be most sensitive, yielding a detection limit of 20-50 pg with column separation. Separation and detection of a steroid mixture by TSP at the 250 pg level are shown in Figure 2 as an example. The sensitivity of ESI and APCI was comparable with the detection limit in the range of 50-250 pg. The response curves, generated by selectively monitoring these ions in the presence of deuterated internal standards or 16-dehydropregnanolone (16-DP), were linear over two orders of magnitude with all three techniques. Using TSP LC/MS, pregnanolone, pregnenolone, DHP, THDOC and DHT were identified in human CSF. Their level ranged from 100 to 500 pM in normal CSF.

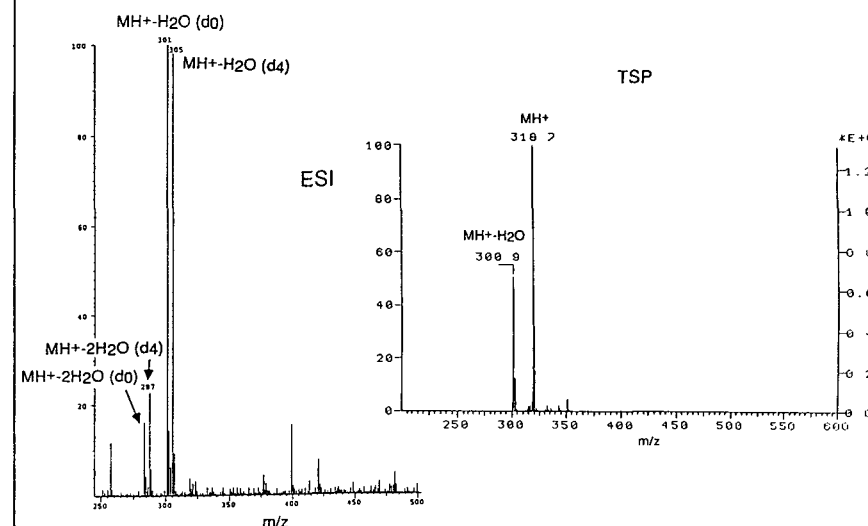


Figure 1. TSP and ESI mass spectra of allopregnanolone (mw=318).

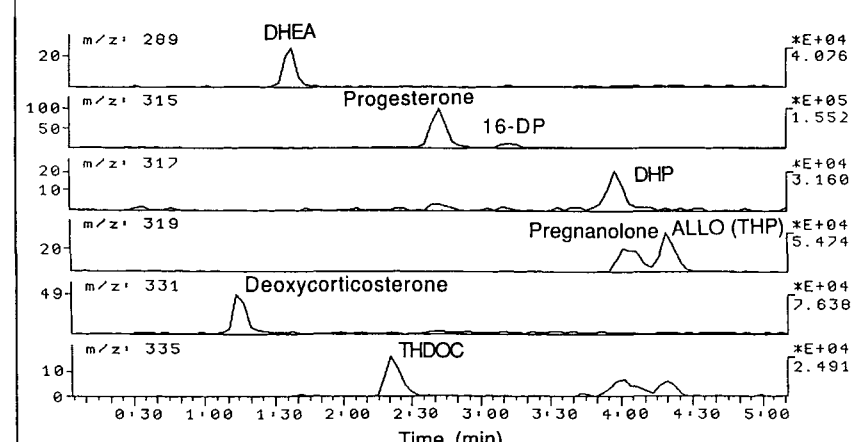

Figure 2. Separation and detection of a neurosteroid mixture by thermospray LC/MS.

MS/MS Study of PBN Spin Adducts from Rat Liver Microsomal Dispersions

Sang, Hong; Janzen, Edward G.; Arimura, Masana;
Kotake, Yashige; DuBose, Coit M.; Poyer, J. Lee
National Biomedical Center for Spin Trapping and Free Radicals,
Free Radical Biology and Aging Research Program,
Oklahoma Medical Research Foundation, 825 N.E. 13th Street, Oklahoma City, OK 73104, USA.

Spin-trapping has proved to be very useful for detecting short-lived radicals in chemical and biological systems. With the spin-trapping electron paramagnetic resonance technique (ST-EPR), determination of the spin adduct structures has been based mainly on the hyperfine splitting (hfs) pattern of the EPR spectra. In many cases, however, the structures of these spin adducts are difficult to determine based on their EPR spectra alone, because the hfs is often insensitive to the molecular structure of the spin-trapped radicals; for example C-phenyl- *N-tert*-butyl nitrone (PBN)-trapped carbon centered radicals all show six-line patterns with only small differences in hfs. Therefore EPR spectroscopy is often not sufficiently definitive to identify the structure of some free radicals, especially when unknown spin adducts are produced.

A combination of the mass spectrometric (MS) technique with ST-EPR is being developed to characterize the structures of free radicals involved in a variety of chemical and biochemical reactions. Analysis by gas chromatography mass spectrometry (GC-MS) of derivatized spin adducts was reported by Abe and coworkers [1]. They demonstrated that unstable spin adducts of PBN and 4-POBN may be derivatized by silylation to produce more thermally stable and volatile compounds for GC-MS. Some radical adducts, however, are stable only in solution. High performance liquid chromatography mass spectrometry (HPLC-MS) offers the advantage of keeping the radicals in solution at least until they enter the ion source. Tomer et al. have developed a technique for the identification of radical adducts in which HPLC/EPR and liquid chromatography thermospray mass spectrometry (LC/TSP-MS) or liquid chromatography electrospray ionization mass spectrometry (LC/ESI-MS) were performed under identical HPLC conditions [2]. In their HPLC/EPR system, in addition to using a UV detector, the EPR spectrometer was used to determine which peaks in the HPLC elution profile were EPR active.

Trichloromethyl free radicals ($\cdot CCl_3$) have been detected by the spin trapping method in rat liver when the animal is subjected to CCl_4 or when rat liver microsomes are treated with NADPH and CCl_4. With the use of HPLC and/or GC-MS, Janzen and coworkers studied the PBN-trichloromethyl adducts from rat liver extracts treated with CCl_4 *in vivo* and *in vitro* [3, 4].

This work has been extended using an MS/MS method to improve the detection of the trichloromethyl-PBN spin adduct from a hexane extract of rat liver microsomal dispersions. Compared to the earlier methods reported, the MS/MS method offers some distinct advantages. MS/MS reduces the need to carry out chromatographic separation. It also is simple, fast and especially useful for the

analysis of radical spin adducts which usually are present at low concentration and not very stable for chromatography.

Since PBN spin adducts usually produce an abundant fragment by EI, namely *m/z* 57 ($C_4H_9^+$), a scan of precursors of *m/z* 57 was recorded during MS/MS analysis to find ions potentially due to PBN spin adducts. Compared to the conventional mass spectra, precursor ion scan spectra can exclude most of the interfering ions derived from the mixture. This approach greatly reduces the number of peaks observed in the spectrum, because only ions which produce *m/z* 57 are detected. However, there are still many other peaks observed in the spectrum because *m/z* 57 is a very common fragment for many organic compounds. For the PBN-CCl_3 spin adduct, the relevant precursor ions are readily recognized because of the chlorine isotope pattern. But for other compounds with no abundant isotope pattern peaks or unknown spin adducts, a scan of precursors of *m/z* 57 may not distinguish which peaks in the spectrum are from PBN spin adducts.

To aid in the MS analysis of spin adducts, deuterated PBN (PBN-d_9) was used. The advantage of using PBN-d_9 is that a major fragment ion present in the mass spectra of any PBN spin adduct is $C_4D_9^+$. The fragment ion of *m/z* 66 (the deuterated *tert*-butyl group) is characteristic and, unlike *m/z* 57, it is not a common fragment for other compounds. The peaks at *m/z* 303, 305 and 307 are assigned to PBN-CCl_3, with a shift of 9 daltons compared to the non-deuterated PBN-CCl_3 (*m/z* 294, 296 and 298). The ions of *m/z* 249 and 251 are also from a PBN-d_9-spin adduct, since these two peaks shift 5 daltons when PBN-d_9 was replaced by PBN-d_{14}. When non-deuterated PBN was used, the peaks corresponding to the same spin adducts were also observed at *m/z* 240 and 242, with a relative intensity about 3: 1. These masses correspond to the PBN-COCl spin adduct, a molecule which was previously postulated as being formed in this incubation system.

The peak at *m/z* 202 corresponds to spin adducts if PBN-d_9 traps a free radical with 16 daltons. A peak at *m/z* 193 was observed in the same experiment when non-deuterated PBN was used. When PBN-d_{14} was used instead of PBN-d_9, this peak shifted only 4 daltons to *m/z* 206. Based on these mass spectra data, the only possible structure which fits these molecular ions (*m/z* 193, *m/z* 202 and *m/z* 206) is hydroxy-PBN, where the hydroxyl group is on the phenyl ring (ortho, meta or para) because the mass spectrum shows that this peak is shifted by 4 not 5 daltons to *m/z* 206 when PBN-d_{14} is used instead of PBN-d_9.

In this study EI with tandem MS, combined with the use of deuterated PBN, has been shown to be a useful technique for the identification of PBN-CCl_3 spin adducts and other PBN spin adducts. In the identification of PBN spin adducts, the scan of precursors of *m/z* 57 was useful as a screening step. The use of deuterated PBN with scanning of precursors of *m/z* 66 can provide more definitive information concerning PBN spin adducts including both known and unknown spin adducts.

Characterization of Glycosylation Sites in Recombinant Proteins by ES-MS/MS

An increasingly large number of recombinantly produced proteins of pharmaceutical interest are found to be glycoproteins. The biological activities of these glycoproteins are often significantly related to the carbohydrate structures on their surfaces. It is therefore important to develop facile and rapid procedures that will provide, beyond the site and type of linkage, sufficient structural information so that these glycans may be initially characterized and subsequently monitored for stability.

We have utilized a combination of procedures performed on a triple quadrupole electrospray instrument towards the detailed characterization of glycosylation sites. Low sample consumption is achieved by using capillary columns for LC / MS. Glycosylated peptides often do not elute as sharp or distinguishable peaks due to heterogeneity. These are readily located by application of stepped orifice and parent ion scan techniques which generate carbohydrate specific fragment ions. O-linked sites are recognized by comparison with a PNGase F deglycosylated sample (1).

We show that both the structure of an O-linked glycan and the peptide it is linked to can be identified from high orifice voltage LC / MS spectra. Several O-linked glycans were shown to be GNac-Hex-NANA and -(NANA)$_2$ (Fig.1). The identification of a peptide with N-linked carbohydrates of the complex type was achieved by matching the spectra of its glycoforms with a table of possible structures and the resulting masses. High mannose N-linked peptides are recognizable by the sequential loss of only hexoses. We show that with N-linked glycopeptides, a single stage fragmentation by CAD in MS2 typically results in a resistant fragment that is the peptide itself plus the GNac attached to an Asn. The sequence of the peptide and the Asn to which the GNac is attached can be obtained by first dissociating the carbohydrate moiety at the source with high orifice voltage. The remnant peptide plus GNac is than sequenced by fragmentation in MS2 (Fig.2).

43rd ASMS Conference on Mass Spectrometry and Allied Topics

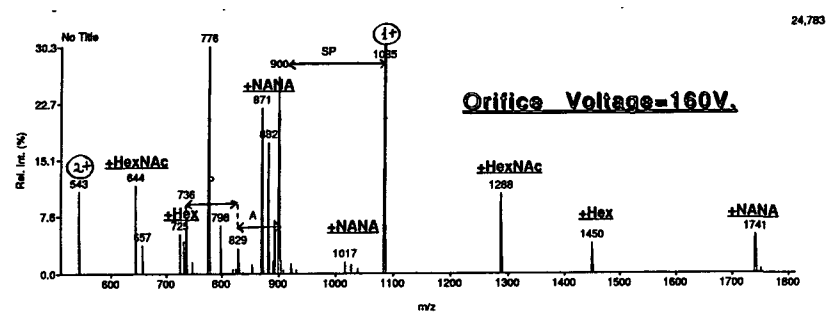

FIG. 1 High orifice voltage LC / MS. Fragmentation spectra of peptide A shows glcosyl moiety to consist of NANA-Hex-GNac. A second structure with an additional NANA was also identified. A partial amino acid sequence was observed.

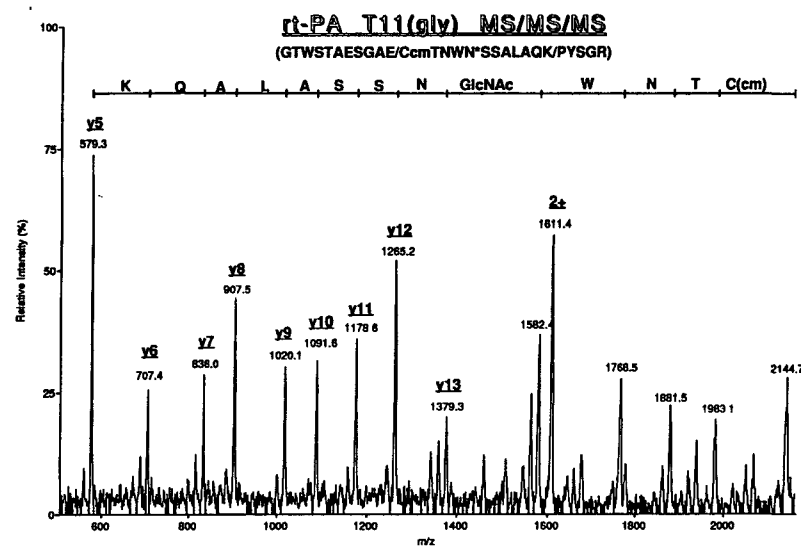

FIG. 2 Peptide sequence of N-glycosylated tPA T11 obtained by 2-step fragmentation process. Carbohydrate moiety was first removed by fragmentation at source using high orifice voltage. The resistant peptide plus GNac at 1612 Da wasthen fragmented by CAD in MS2. The GNac was shown to be attached to the Asn proximal to the C-terminus.

DETERMINATION OF *N*-LINKED GLYCOSYLATION IN EXTERNAL INVERTASE BY MALDI-TOF MS

Chenhui Zeng and Klaus Biemann
Dept. of Chemistry, Mass. Institute of Technology, Cambridge, MA 02139

Invertase (E.C.3 2.1.26, β-D-fructofuranoside fructohydrolase) from *Saccharomyces cerevisiae* is an enzyme that catalyzes the hydrolysis of sucrose into fructose and glucose The glycosylated form of invertase (external invertase) contains as much as 50% of its mass as polymannan (1) in 14 potential *N*-linked glycosylation sites (sequons) (2) Therefore, it has long been used as an ideal model for the study of the function of oligosaccharides in glycoproteins. The external invertase that we studied was purified from a commercial product presumably derived from the SUC2 gene (1) The amino acid sequence of invertase had been derived from the corresponding DNA sequence (1). It has also been reported that 13 of 14 potential sequons are either fully or partially glycosylated (3), and the glycosylation at four sequons had been found to contain long oligosaccharide chains ($GlcNAc_2Man_{>50}$), while other sequons contain short glycan chains ($GlcNAc_2Man_{8-14}$) except sequon 5 which is not glycosylated (4) The conformational structure of the short chain oligosaccharides (Man_{8-14}) isolated from invertase has been assigned by high-field one-dimensional ^1H NMR spectroscopy combined with α-1,2-linkage-specific mannosidase digestion (5).

In this report, we determined the degree of glycosylation by MALDI-TOF MS and, for the first time, present MALDI-TOF mass spectra to show the whole glyco-profile of the intact external invertase As shown in Figure 1, the signal of this glycoprotein covers mass range from 78 kDa to 115 kDa, and its average molecular weight was then determined to be 96 kDa. By combining enzymatic digestion and MALDI-TOF MS, we determined the distribution of glycosylation at each sequon. Our results generally agree with the published data (4), but some differences were noted and more detailed information has been obtained. For instance, sequons 1, 7, 9, and 11 were reported to be glycosylated with more than 50 mannoses (4). However, in this study, sequons 1, 7, and 11 were in fact determined to contain Man_{4-43}, Man_{8-80}, and Man_{6-64}, respectively, while sequon 9 was observed to contain only Man_{9-11}. Figure 2 shows an example of how MALDI-TOF MS reveals the distribution of high mannose oligosaccharides (Man_{8-80}) attached to a single glycosylation site.

During this study, Post-Source Decay (PSD) using a MALDI-TOF MS in the reflectron mode was also applied to sequence some enzymatic peptides to confirm and correct the amino acid sequence originally derived from the DNA sequence (1). To date, three amino acids have been found to be fully or partially modified; asparagine in position 65 is completely replaced by histidine, while the alanine and valine in positions 58 and 412 were observed to be partially replaced by threonine (~50%) and alanine (~40%), respectively The PSD spectra of the peptide (G^{56}-W^{66}) that contains two of the three modified amino acids are shown in Figure 3 Thus there must be two amino acid sequences In one, only one amino acid is modified (N^{65}-H^{65}) while the other one has threonine and alanine at 58 and 412, respectively. The amino acid sequence isotherwise almost identical with the one deduced from the SUC2 gene and that DNA sequence hasrecently been verified by Dr. F Maley. Therefore, these two invertase sequences must be derived from two modified DNA strains which may be called genes SUC2a and SUC2b

Characterizing the N-Glycosylation of Corticotropin Releasing Factor-Binding Protein *A. G. Craig, S. W. Sutton, J. Vaughan, S. C. Koerber and W. H. Fischer. The Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, P.O. Box 85800, San Diego, CA 92186-5800.

Corticotropin Releasing Factor-Binding Protein (CRF-BP) is a 35 kDa protein originally purified from human plasma which has been proposed to protect the maternal endocrine system from high levels of CRF produced by the placenta during pregnancy. CRF-BP inhibits CRF-induced ACTH release from pituitary cells in vitro (1). Based on the protein sequence, Asn180 was proposed as a site of N-linked glycosylation.

We have investigated the use of anti CRF-BP serum and matrix assisted laser desorption (MALD) to measure CRF-BP recombinantly expressed in Chinese Hamster Ovary Cells. We observed inhibition of ion formation in MALD spectra measured from rCRF-BP in a variety of forms (affinity and reverse phase purified) In contrast, immunoprecipitation of rCRF-BP (incubation overnight at 4°C in a 50 mM Hepes buffer with antisera raised against either an N-terminal CRF-BP peptide or the intact rCRF-BP) and rinsing of the pellet formed (20 min. centrifuge @ 15000 rpm) with 50 mM Hepes buffer (x2) and subsequent addition of 5 µl of 0.1 % aqTFA and application of an aliquot (0.5 µl) of this solution to a thin film of α-cyano-4-hydroxy cinnamic acid resulted in intact CRF-BP ion formation as shown in Figure 1(a), measured with a Bruker Reflex operated in the linear mode. It is possible that the elimination of MALD inhibition is due to the specificity of the immunoprecipitation resulting in a rinsing from the sample of contaminants or salts which are not removed by other purification procedures. Alternatively, the antibody precipitation may be altering a more intrinsic property of the protein relating to its amenability for ionization. Clearly, the presence of the antibody does not inhibit ion formation. Using this sample preparation technique we have measured the intact mass of recombinant CRF-BP after enzymatic treatment with peptide N-glycosidase-F (PNGase-F) as shown in Figure 1(b), indicating that the glycan molecule mass is approximately 1.5-2 kDa.

Figure 1(a) **N-Glycosidase-F treatment of CRF-BP**

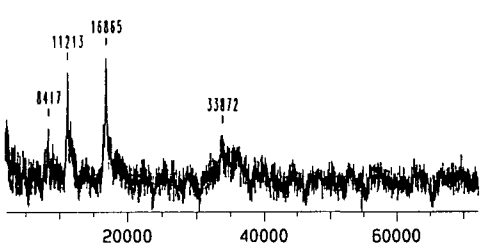

Figure 1(b) **CRF-BP (Untreated)**

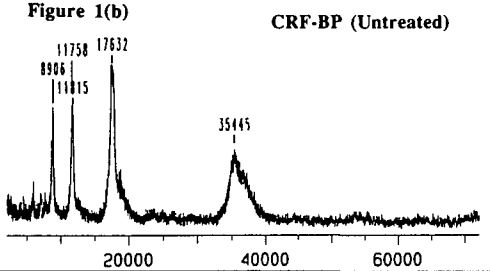

In addition, the CRF-BP glycopeptide has been identified from a tryptic map of CRF-BP in order to obtain more detailed information on the nature of the glycan structure and to verify that Asn180 is the only site of glycosylation. Figure 2(a) shows the MALD mass spectrum of the 180-192 fragment which was obtained after tryptic digestion followed by TCEP reduction (2), while Figure 2(b) shows the spectrum of the same fraction isolated after PNGase-F treatment. The mass shift observed indicates a more accurate mass of 2207 Da for the major glycan species, while the intense fragment ion is characteristic for the presence of sialic acid (3),. Using the previously proposed strategy of Huberty et al. (3), we searched for N-linked glycan structures containing sialic acid in The Complex Carbohydrate Structure Database (4, 5) and found that only two previously reported structures are consistent with the observed glycan mass. These two structures, $(Gal)_2(Man)_3(GlcNAc)_4(Neu)_2$ (2206 Da) and $(Fuc)_2(Gal)_2(Man)_3(GlcNAc)_4(Neu)$ (2207 Da), differ in the degree of sialic acid present (one or two sialic acid molecules). After treatment of the 180-192 glycopeptide with neuraminidase the MALD mass spectrum contained a species consistent with loss of two sialic molecules from the glycan (data not shown). On the basis of these measurements we propose that the glycosylation present on CRF-BP is consistent with the previously reported glycan structure $(Gal)_2(Man)_3(GlcNAc)_4(Neu)_2$.

CHARACTERIZATION OF A PLASMINOGEN ACTIVATOR WITH LC, CE, ESI-MS AND MALDI-TOF MS

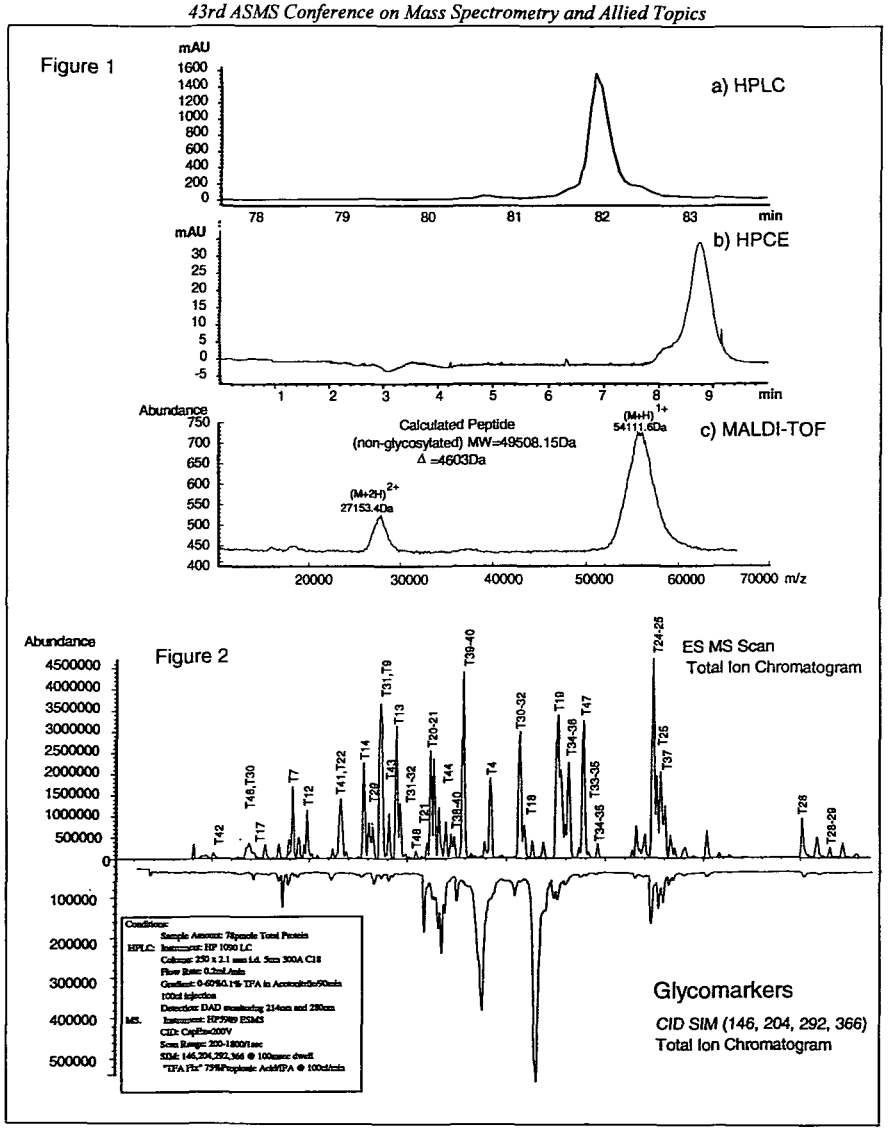
The development of a glycoprotein as a new pharmaceutical is a challenging exercise as the heterogeneity of the carbohydrate can hinder analytical methods targeted at monitoring product consistency for regulatory agencies, such as the FDA. Desmodus Salivary Plasminogen Activator (DSPAα1) is a single chain plasminogen activator derived from Desmodus rotundus (vampire bat) salivary glands. DSPAα1 is a serine protease that plays a role in clot lysis. DSPA is known to be heterogeneous when expressed in CHO cells. It is a large (441 amino acids) complex molecule of calculated (non-glycosylated) average molecular weight 49,508 Da with six sites for potential glycosylation, four O-linked and two N-linked. It has been proposed, based on homology with other serine proteases that there are 28 cysteines forming 14 disulfide bridges.

In order to effectively characterize such a complex molecule, a variety of analytical techniques must be employed. The analytical approach used was to start at the gross level of intact protein and use analytical techniques applicable to such a complex, high MW sample. Following this characterization, the greater detail of the peptide map from an endoprotease Arg C digest was examined, followed by individual fractions from the digest. Thus the focus moved from more global properties of the sample to increasing degrees of detail. At each level, HPLC, LC/MS, HPCE and MALDI-TOF were applied. At the more global level, it is not possible to discern the detailed information of the specialized techniques. On the other hand, it is difficult to synthesize data from the more specific into a more global picture. This problem of context of scale of macromolecular analysis is at the heart of the need for multidimensional analysis. With samples of this complexity, no one technique yields the required depth of structure information combined with ready linkage to the overall structure of the macromolecule.

Initial examination of the intact glycoprotein (Figure 1) by HPLC shows that the sample is quite pure, and at least in terms of hydrophobicity, relatively homogeneous, although product variants may not be separated under the applied conditions. The HPCE separation (based on charge rather than hydrophobicity) is useful to further characterize the purity and homogeneity. The MALDI spectrum reveals that the protein has ~4600 Da due to glycosylation. The peak width of ~5 kDa relates to the degree of microheterogeneity of glycosylation. At higher levels of detail, LC/MS plays a crucial role in characterizing the peptide map generated by proteolytic digestion (Figure 2). Fractionation of the complex regions (areas containing glycosylated peptides) of the peptide map followed by HPCE and MALDI-TOF provide additional degrees of information. All of the techniques used have proven to be highly complimentary in the analysis of DSPAα1. More effective techniques are required for the integration of information from higher dimensional data generated by the combination of these techniques.



Analysis of parotid gland oligosaccharides by MALDI mass spectrometry

David R. Wing, Niall O'Donnell, Thomas J. P. Naven, David J. Harvey,

Oxford Glycobiology Institute, Department of Biochemistry, University of Oxford, South Parks Road, Oxford, OX1 3QU, UK.

Introduction

MALDI Mass spectra of complex oligosaccharides give abundant $[M + Na]^+$ ions which provide compositional information on the constituent monosaccharides, but no information on the sequence, branching or linkage patterns of these residues. Such information has previously been obtained by exoglycosidase digestion with the products being monitored by radioactivity following gel filtration chromatography. MALDI provides a more satisfactory solution to oligosaccharide detection by giving much higher resolution and by not requiring radioactive detection. In this report, MALDI and exoglycosidase digestion are used to examine the detailed structures of neutral *N*-linked oligosaccharides from human parotid gland glycoproteins.

Experimental

Oligosaccharides were released from the glycoproteins by hydrazinolysis and the neutral sugars were obtained by enzymatic removal of the sialic acids. These oligosaccharides were separated into 3 fractions by Bio-Gel P4 gel filtration chromatography and examined by MALDI (2,5-DHB matrix) using a Fisons VG AutoSpec-QFPD magnetic sector mass spectrometer fitted with an array detector. Fractions were then incubated successively with exoglycosidases (see Figure legend) with each product being examined by MALDI. Oligosaccharides were also converted into their 2-aminobenzamide derivatives and separated by normal-phase HPLC using a polyhydroxyethyl aspartamide column (200 x 4.6 mm). Fractions were examined by MALDI and FAB (as methylated derivatives) mass spectrometry and by MS/MS (linked scan).

Results and Discussion

Three crude fractions were obtained by Bio-Gel P4 chromatography, the fraction centred around 16 glucose units (GU) contained mainly biantennary oligosaccharides with from 1 to 5 fucose residues. Successive exoglycosidase digestion (Figure), FAB and MALDI mass spectra were consistent with these compounds having fucose substitution at position 6 of the reducing terminal GlcNAc residue and at positions α1-2 and α1-3 to the outer arm galactose and GlcNAc residues respectively. The 20 GU P4 fraction contained corresponding triantennary oligosaccharides with up to 7 fucose residues, and traces of the corresponding tetraantennary compounds. Fragment ions in the MALDI and FAB spectra of individual compounds separated by HPLC showed a preference for an asymmetrical distribution of fucose residues between the antenna in oligosaccharides where not all possible substitution positions were filled.

Analysis of the N-linked oligosaccharides of human C1s using electrospray ionisation mass-spectrometry

Y. Petillot[1], P. Thibault[2], N. Thielens[1], V. Rossi[1], M. Lacroix[1], B. Coddeville[3], G. Spik[3], V. Schumaker[4], J. Gagnon[1] and G. Arlaud[1].
[1]Institut de Biologie Structurale (CEA/CNRS), Grenoble, France. [2]Institute for Marine Biosciences, Halifax, Canada. [3]Université des Sciences et Technologies, Lille, France. [4]University of California, Los Angeles, U.S.A.

C1s, the serine proteinase responsible for the enzymic activity of human C1, the first component of the classical pathway of complement, bears two oligosaccharide chains linked to asparagine residues 159 and 391. With a view to gain information on the structures of these oligosaccharides, human C1s (**Fig.1**) and various of its fragments and peptides were subjected to electrospray ionisation mass spectrometry and monosaccharide analyses [1].

These analyses indicate that three major C1s species are observed (**Fig.2**), varying according to their oligosaccharides structure :

(i) species **A** (M=79,318 ± 8Da) contains a biantennary, bisialylated oligosaccharide at both positions 159 and 391 (calculated M=79,300);

(ii) species **B** (M=79,971 ± 8Da) contains a biantennary oligosaccharide at position 159, and a non-fucosylated triantennary oligosaccharide at position 391 (calculated M=79,957);

(iii) species **C** (M=80,131 ± 8Da) contains a biantennary oligosaccharide at position 159, and a fucosylated triantennary species at position 391 (calculated M= 80,103).

If one only takes into account these three major species **A**, **B**, and **C**, which are present in equimolar amounts and, altogether, represent approximately 75-80% of the C1s population, the average mass of C1s, determined experimentally, is 79,807 ± 8Da (calculated value=79,787).

The MS analyses performed on fragment C1sα (**Fig.3**) corroborate our previous data indicating that C1s undergoes only partial (about 50%) hydroxylation of Asn134. Together with the analysis performed on peptide C1sA 154-195 (**Fig.1**), they also provide indirect evidence for the occurrence of a third, minor post-translational modification (M=132± 2Da) taking place within the N-terminal region of C1s (positions 1-153), and which is therefore independent of the oligosaccharide linked to Asn 159.

Beta 2-Microglobulin (β_2M) is the protein precursor of amyloid deposits associated with dialysis-related amyloidosis (DRA), a major complication of chronic hemodialysis.[1] DRA patients suffer from degenerative bone and joint disease, including carpal tunnel syndrome. Recently, advanced glycosylated end-products (AGE) of β_2M have been potentially linked to DRA.[2]

Although there is a clear association between chronic hemodialysis and the development of amyloidosis, there is no clear correlation between β_2M serum levels and the occurrence of DRA. It is important then to address how β_2M may be present in the sera of DRA patients. Clinical measurements of β_2M species in serum, including AGEs, might identify patients at risk for developing DRA.

In this work, we demonstrate that matrix-assisted laser desorption/ ionization (MALDI)[3,4] mass spectrometry is an extremely useful and rapid means to investigate the nature of glycosylation of β_2M and can detect β_2M and β_2M-AGE in sera at low picomole levels. Previously, MALDI was used to determine the number of glucose molecules which can react with bovine serum albumin *in-vitro*.[5]

MALDI data were obtained on a linear time-of-flight mass spectrometer equipped with a 337 nm nitrogen laser. Serum samples were filtered through 30,000 MW cutoff microfilters. 1 µl samples were mixed with 10 µl of saturated matrix in 7:3 acetonitrile:water. Matrices included α-cyano-4-hydroxycinnamic acid and sinapinic acid. To prepare the β_2M-AGE, 2 mg/mL of β_2M was incubated at 37 °C for 1 month with 0.1M glucose in 100 mM phosphate buffer (pH 7.4) containing 200 units/mL penicillin.

The MALDI mass spectrum of the distribution of β_2M-AGE products from incubation of β_2M with glucose is shown in figure 1. The inset shows an expansion of the molecule ion region. The high mass end of the distribution can be seen to extend to the neighborhood of 12,868 D, expected for the condensation with 7 glucose molecules, consistent with the results of a detailed study by Miyata.[6] The MALDI mass spectra of an equimolar sample of β_2M and β_2M-AGE added to bovine serum and of an unspiked serum sample from a dialysis patient are shown in figures 2 and 3, respectively.

Characterization of Human Chorionic Gonadotropin by HPLC/MS

Chaunliang Liu and Larry D. Bowers
Department of Patholoigy and Laboratory Medicine
Indiana University
Indianapolis, IN 46202-5120

Human Chorionic Gonadotropin (hCG) is a two subunit glycoprotein hormone of importance in some carcinomas and in athletic drug doping. The β-subunit (145 amino acids) is unique to hCG whereas there is identity of the alpha subunit with leutinizing hormone, thyroid stimulating hormone, and follicle stimulating hormone. Recent evidence suggests that the "nicking" of the β-subunit and the carbohydrate composition of the chain may help to identify the source of hCG. We are interested in the potential of HPLC/MS analysis of the β-subunit as a legally defensible identification of hCG in cases of athletic doping.

We have studied hCG using microbore HPLC/MS (Sciex, API III tandem mass spectrometer). The detection of the N-terminal portion of the β-chain was easily accomplished, and microheterogeneity of the carbohydrate could be localized more to the ^{13}Asn site. Observation of the C-terminal end of the molecule proved difficult, due to the presence of four closely associated O-linked carbohydrates. Using neuraminindase and O-glyconase, we were able to observe partially digested peptides from the C-terminal end.

We have characterized a number of different "nicked" and proteolytic species arising from β-hCG using HPLC/MS. The β-hCG was isolated using SPE, reductively alkylated with vinyl pyridine, digested with either trypsin or glu-C protease. Using the Glu-C protease, we studied the action of elastase on the β-hCG, which should "nick" the protein chain. HPLC/MS results suggest that elastase "nicks" hCG at 44,45 and 42,43; this does not agree with earlier work published on this hydrolysis using classical methodology.

Glycosylation Site Mapping of glycoproteins by MALDI-TOF MS

Yi Yang, Ron Orlando
Complex Carbohydrate Research Center, University of Georgia, Athens, GA 30602

A strategy based on MALDI-TOF MS was developed here as a sensitive, direct and fast way for the glycosylation site mapping of glycoproteins. Initially, the glycoprotein backbone was cleaved enzymatically, and a portion of the resulting peptide/glycopeptide mixture was analyzed directly by MALDI-TOF MS. A second aliquot of the trypsin-digested glycoprotein was further treated with N-glycanase to selectively release the N-linked carbohydrate chain, followed by MALDI-TOF analysis. The N-linked glycopeptides in this mixture can be easily identified by comparing these two MALDI-TOF spectra, since the molecular weights (MWs) of these glycopeptides decreased by the mass of their carbohydrate chains, while the MWs of both peptides and O-linked glycoepeptides were unaffected by this enzymatic digestion procedure. A third aliquot of the trypsin-digested glycoprotein was further treated by a combination of N-glycanase and O-glycanase, as well as neuraminidase if sialic acid was present, to remove both the N- and O-linked carbohydrate. The O-linked glycopeptides can then be identified by the comparison of the MALDI-TOF spectrum from this step to that from the N-glycanase treatment. These comparisons provided the mass of each carbohydrate chain and the peptide to which it was attached. Combined with standing Carbohydrate Structure Database (CarbBank), these comparisons can also be used to determine the possible structures and the heterogeneity of carbohydrate side chain. For example, Fig. 1 shown that peptides T7 (Asn-81), T11 (Asn-138) and T12 (Asn-158) in asialofetuin were identified as N-glycosylation sites and T19 as the O-glycosylation sites.

On the other hand, the total molecular weight of carbohydrate was approximated by anhydrous HF treatment of the intact glycoprotein, which cleaved both the N- and the O-linked oligosaccharides. This was shown by the shift in the molecular weight of avidin, which clearly demonstrated that avidin has only one N-glycosylation site (Fig. 2). This can be used to confirm that all of the oligosacchaide chains were found in the glycosylation site mapping procedure described in the preceding process.

The primary advantages of our MALDI-TOF approach towards glycosylation site mapping were its simplicity (no separation required) and sensitivity (1-10 picomoles).

Phytopathogenic fungi produce cell wall degrading enzymes (CWDEs) which they utilize during their colonization of host plants. Endopolygalacturonases (EPGs), considered to be among the first CWDEs released by an attacking fungus, hydrolyze homogalacturonan of the plant cell wall in to oligogalacturonide fragments. Polygalacturonase inhibiting protein (PGIP) is a plant cell wall associated protein that inhibits the activity of fungal EPGs and facilitates the formation of mid-sized oligomers of homogalacturonan that have been shown to elicit plant defense responses. Thus, the interactions of fungal EPGs and plant PGIPs are prime candidates for involvement in resistance to fungal attack. It is known that both EPGs and PGIPs exist in a variety of non-glycosylated and/or glycosylated states, depending upon the origin of these glycoproteins. It has been of interest to determine the possible role of the glycosylation in EPG -PGIP interactions. It is generally believed that knowledge of the carbohydrate structure(s) and their site-specificity from both EPGs and PGIPs will lead to a better understanding of the role of these glycoproteins in the resistance of plants to fungal attack. In this study, we used matrix assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry to characterize the glycoproteins and site specific glycoforms present in both EPGs and PGIPs which are isolated from *Fusarium moniliforme* and *Phaseolus vulgaris* respectively.

Mass spectra were run on Hewlett Packard LDI 1700XP time-of-flight mass spectrometer operated at an accelerating voltage of 30 kV, an extractor voltage of 9 kV, and a pressure of approximately 3.1 x 10^{-6} torr. A 1:1:1 mixture of equine heart cytochrome C (MW=12,360), equine heart myoglobin (MW=16,950), and bovine serum albumin (MW=66,465) was used to calibrate the MS to give a mass accuracy of approximately $\pm$ 0.1%. Samples were desorbed/ionized from the probe tip with a nitrogen laser (l=337nm) having a pulse width of 3 ns and delivering approximately 5.6 mj energy/laser pulse. The mass spectra of proteins were recorded over a mass to charge (m/z) range of 1-150,000, using a deflector to attenuate the detected abundance of ions below 2,000 m/z and α-cyano-4-hydroxycinnamic acid was used as a matrix.

The molecular weights obtained for HPLC (Fig.1) purified EPGs from SDS-PAGE were 48.5, 45, 41.5, 38 kDa respectively for four different glycoforms. Treatment of the intact glycoproteins with enzymatic and chemical deglycosylation methods followed by SDS-PAGE revealed that the EPGs are N-glycosylated, but provided no information about the size and number of glycosylation sites. In order to characterize and locate the carbohydrate moieties, different glycoforms of EPG separated by HPLC were analysed by MALDI-TOF. It is apparent from the spectra (Fig. 2) and the molecular weight (36,197Da) calculated from the nucleotide sequence that the mass differences between these different forms may each be accounted for by one N-glycosylated carbohydrate moiety. The mapping of the tryptic peptides (derived from trypsin digestion of EPGs) before and after N-glycanase treatment by MALDI-TOF is being used to locate the N-glycosylation sites in these EPGS.

Characterization of the Nodulation Factors Produced by *Bradyrhizobium elkani*

V.S.K. Kolli[!], R.W. Carlson[!], N.K. Peters[+] and R. Orlando[!].
[!]Complex carbohydrate Research Center and Department of Biochemistry and Molecular Biology, The University of Georgia, 220 Riverbend, Athens, GA 30602-4712.

Gram-negative soil bacteria of the genera *Azorhizobium*, *Bradyrhizobium* and *Rhizobium* establish symbiotic relationships with leguminous plants through the formation of root nodules[1]. The nodulation process is controlled by both bacterial and plant genes. The expression of the bacterial nodulation genes is activated by flavanoids secreted by the plant roots. This activation leads to the synthesis of extracellular signals called the nod factors. The nod factors are chito-oligosaccharides of three to five 1,4-β-linked N-acetyl glucosaminosyl residues, which are N-acylated on the terminal non-reducing glucosaminosyl residue and may be further modified by the addition of another glycosyl residue or other modigying group such as sulfate, carbamyl, acetyl, and /or glycerol substituents (fig1). In the present study, we used FAB mass spectrometry and tandem mass spectrometry to characterize the low abundance lipo-oligosaccharides fractionated from the cell cultures of *Bradyrhizobium elkani.*

Mass spectra were run on a JEOL (Tokyo, Japan) SX/SX 102A tandem mass spectrometer operated at 10 kV accelerating potential. Ions were produced by JEOL FAB gun operated at 6 kV in a conventional FAB ion source. The samples were dissoved in dimethyl sulfoxide and 1μL aliquots were mixed with an equal volume of the FAB matrix, thioglycerol on the probe tip. Collisional activation was performed in the third field free region using helium as the collision gas. The helium pressure was sufficient to attenuate the primary ion by beam by 75%. The collision cell was floated at 3 kV providing a collision energy of 7 kV. All the mass spectra are averaged profiles of 3 scans as recorded by the JEOL complemnt data system.

The HPLC eluted various fractions of *Bradyrhizobium elkani* are subjected to FAB mass spectrometry for characterization of lipo-oligosaccharides. The MS results showed that some of the compouds have similar structrures previously reported for *Bradyrhizobium japonicum* and *Bradyrhizobium elkani*[2]. Four new lipo-oligosaccharides were identified from the FAB MS and MS/MS data (one of them is shown in fig2); they have the structures, NodBe-V(Cb,C16:0,MeFuc), NodBe-V(Cb,C16:0,Nme,MeFuc), NodBe-V(2Cb,C16:0,MeFuc) and NodBe-V(C18:1,Fuc,Gro).

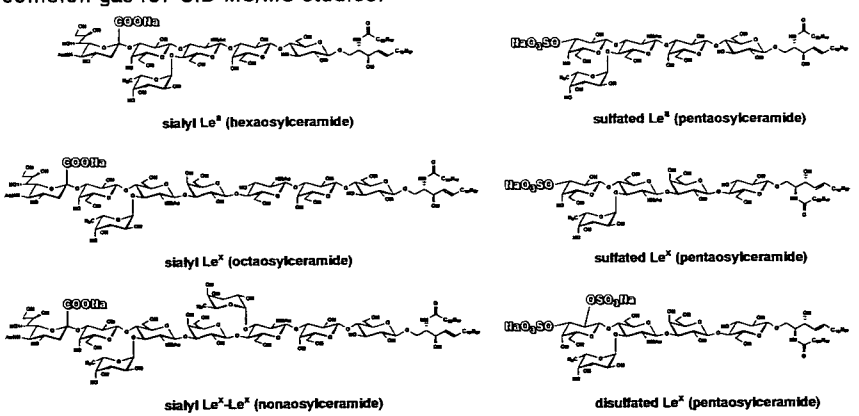
FAB and ESIMS of Acidic Glycosphingolipids
---Le^x- and Le^a-derivatives

Y.Ohashi, T.Ii, S.Kurono, T.Ogawa and Y.Nagai
The Institute of Physical and Chemical Research (RIKEN)

Objective and Methods

Fucose-containing branched trisaccharide units, called Lewis-type sugar chains, are possible ligands to selectins if the position 3 of the non-reducing end galactose is substituted with an acidic group such as a sulfate or sialic acid. Fast atom bombardment (FAB) and electrospray ionization (ESI) were applied to synthetic glycosphingolipids to obtain basic fragmentation patterns. Once the methodology has been established, it will be applicable to determine the structure of trace amounts of biologically important real samples. ESI analyses were performed on the samples shown in scheme 1 using a Finnigan TSQ 700 mass spectrometer. These samples had typical concentrations of 100 pmol/μL in a 1:1 solution of CH_3OH and $CHCl_3$. FAB measurements were also carried out and in this case thioglycerol, for (+) FAB, and triethanolamine, for (-) ion modes, were used as the matrix. Argon gas of 40eV at 0.2 Pa was introduced as the collision gas for CID-MS/MS studies.



scheme 1
Le-type acidic glycosphingolipids

Results

a): Sulfated Le^x- and Le^a- glycosphingolipids; Positions of sulfate groups can be determined in the (+) as well as in the (-) mode according to the fragmentation patterns of Le-type oligosaccharides (to be published). Distinction of Le^x- from Le^a - type glycosphingolipids was successfully implemented by (-)FAB CID-MS/MS only by having the $[C_2\text{-Na+H}]^-$ ion, not by having the $[M\text{-Na}]^-$, as the precursor; the C3-linked fucose of Le^x is more readily eliminated as a neutral molecule in the negative ion mode generating the(Z1β-H-Na)$^-$ fragment ion in addition to the (Y1β +H-Na)$^-$. On the other hand, Le^a, which has a fucose group linked to C4 of GlcNAc, eliminates the fucose giving rise to the (Y1β +H-Na)$^-$ only (Fig. 1).

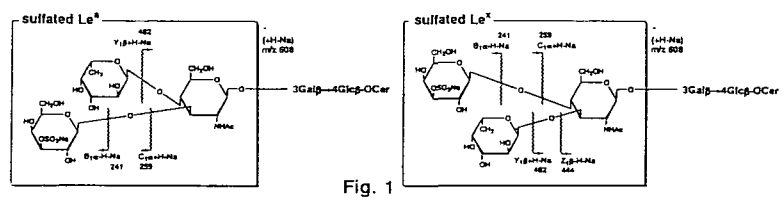


Fig. 1

b): Sialyl Le^x-glycosphingolipids; The above-stated fragmentation rule does not apply, however, to sialylated Le- sugar chains, because the less acidic carboxylate group fails to retain the negative charge at the reducing end, giving abundant ceramide-side ions (Y-ions) even in the negative ion mode. Thus the key ion corresponding to $(C_2\text{-Na+H})^-$ does not appear in the normal spectrum.

c): Positive Ion mode; Contrary to the general belief that acidic glycoconjugates give higher ion intensities in the negative ion mode, positive ion mode is also as informative and sensitive method as the negative ion mode.

d): Conclusions: Acidic glycoconjugates of high molecular weight can be analyzed by ESI and/or FAB mass spectrometry yielding information which sometimes exceeds NMR spectrometry. An interesting phenomenon in the (-)ESI spectra of these acidic glycolipids is that the second (-) charge to produce a double-charged ion is gained by an extra deprotonation or an attachment of an abnormal negative ion such as Cl^- or $(C_4H_9O_2)^-$, as reported previously for neutral glycolipids(1).

MALDI-MS ANALYSIS OF GANGLIOSIDES FROM HUMAN GRANULOCYTES

Jasna Peter-Katalinic[1], Bernd Stahl[2], Michael Karas[2], Franz Hillenkamp[2], Franz-Georg Hanisch[3], Heinz Egge[1], Johannes Müthing[4]

INTRODUCTION:

Granulocytes are the second most abundant cells in peripheral blood. Their primary function is phagocytosis and the engulfing of pathogenic microorganisms. Peripheral blood lymphocytes, momocytes and granulocytes have distinct glycosphingolipid fingerprints [1]. The predominant ganglioside species of granulocytes belong to the neo-lactoseries (Galß1-4GlcNAcß1-3)nGalß1-4Glcß1-1Cer (where n=0-2) [2]. Terminally sialylated gangliosides were shown to be able to serve as receptors for influenza viruses A and Sendai virus via carbohydrate chains on their cell surfaces [3]. The carbohydrate structures of lower homologues were identified to belong to the unbranched neolacto-series by sequencing using (-)FAB-MS of the native gangliosides and the methylation analysis [4].

RESULTS:

In this contribution a structural study of ganglioside homologues of higher molecular weight by MALDI-MS after permethylation is presented. This approach was shown to be of excellent applicability for neutral glycosphingolipids [5] and for gangliosides [6] in subpicomole quantities of biological material.

2,5-Dihydroxybenzoic acid (DHB) was used as a solid matrix for analysis of up to tetradecasaccharide ceramide molecular ions in the mass region of 2000-4000 Da by (+)MALDI-MS. From the m/z values of molecular [M+Na]+ ions in pure fractions and in mixtures, the composition of the carbohydrate and ceramide portions were deduced and compared to the diagnostically significant fragment ion data, obtained by FAB-MS [7]. Due to the high sensitivity of MALDI-MS even minor components of ganglioside polar fractions - representing complex mixtures - were detected. The fucosylation and sialylation status was analysed.

Epitope analysis was performed using monoclonal antibodies CSLEX1 and CDw65 (VIM2), which allow the distinction of isomeric hexasaccharide structures sLe^x and VIM2:

STRUCTURAL STUDIES ON SIALYLATION OF GANGLIOSIDES FROM DEVELOPING CHICKEN BRAIN BY ELECTROSPRAY MASS SPECTROMETRY

Jasna Peter-Katalinic[1], Alison E. Ashcroft [2], Brian N. Green [2], Franz-Georg Hanisch [3], Johannes Müthing [4]

[1] Institute for Physiological Chemistry, University of Bonn, Germany
[2] FISONS Instruments, VG BIOTECH, Altrincham, UK

[4] Institute for Cell Culture, University of Bielefeld, Germany

INTRODUCTION:

Gangliosides constitute a heterogeneous group of sialylated glycosphingolipids differing in both the oligosaccharide and ceramide composition. The majority of brain ganliosides belong to the ganglioseries of glycolipids and contain invariable tetrasaccharide backbones with variable numbers of sialic acid residues [1]. The diversity of sialic acids has been well established. Despite the clear developmental changes noted in various organs, their biological role remains unclear [2]. The studies regarding the developmental regulation of Neu5Gc in isolated organs of various animals showed changes in the glycoconjugates, located mainly in the ganglioside fraction [3]. Gangliosides of embryonic chicken brain have been found to be expressed transiently during prehatching brain development [4]. The predominant "c"-type substitution pattern of sialic acids was revealed by sequencing using (-) FAB mass spectrometry of native [5] and (+)FAB-MS of permethylated [6] samples. The FAB-MS analysis of the permethylated G_{T1b}, G_{Q1b}, G_{Q1c}, G_{P1c} and G_{H1c} gave clear-cut fragmentation patterns concerning the carbohydrate sequence and the ceramide composition (C18:0 fatty acid and 4-sphingenine), but molecular ions were only of low abundance [6]. A carefull analysis of the sialic acids derived fragments at m/z=376 ($NeuAc^+$), 737 ($NeuAc_2^+$) and 1098 ($NeuAc_3^+$) gave rise to the assumption, that in 0-30% of the terminal sialic acid moieties NeuGc instead of NeuAc were present, as documented by specific shifts of 30 Da each [7]. In order to prove this very unusual assumption two control analyses of total sialic acids after release from parent gangliosides by hydrolysis using GC/MS and HPLC were performed [8,9] and the NeuGc level found to be lower than 1%. Direct sialylation analysis of the molecular ions in native material was necessary to clear this point and to explain the previously not reported expression of NeuGc sialic acid in perinatal chicken brain.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

RESULTS:

In this contribution a sialylation analysis of native tri- to hexasialogangliosides using negative ionization electrospray mass spectrometry using picomol quantities of biological material will be presented. (-)ES-MS in MS1 of G_{T1b}, G_{Q1b}, G_{Q1c}, G_{P1c} and G_{H1c} were dominated by molecular ions of gangliosides or their sodium salts, singly charged at higher skimmer voltage and doubly and triply charged at decreased voltage. The lipid portion derived fragment ions were represented mainly by anions arising after loss of one-to-three sialic [Neu5Ac] acid moieties from the molecular ion(s), whereas the carbohydrate derived fragment ions were the monocharged mono-to-three sialic [Neu5Ac] acid residues after loss of one water molecule. The presence of functional modifications in sialic acid moieties like lactones, O-acetylation, O-methylation, N-glycolylation and others [2] would result in relative shifts of m/z values by -18, +42, +14, and +16 a.m.u. respectively. None of such shifts were observed in respective molecular and/or fragment ions in (-)ES-MS. The fragmentation tendancy as observed in MS1 was followed after low energy CID in MS2. Sugar ring cleavages were not observed. Quantitative differences in the daughter ion abundances were diagnostically used for assignment of positional isomers G_{Q1b} and G_{Q1c}.

ESI-MS AND ESI-CID-MS/MS OF COMPLEX NEOLACTO-SERIES GLYCOSPHINGOLIPIDS

Steven B. Levery, PE-Applied Biosystems Division, 850 Lincoln Centre Drive, Foster City, CA 94404; **Mary Ellen K. Salyan, Mark R. Stroud**, The Biomembrane Institute, 201 Elliott Avenue West, Seattle, WA 98119

Studies on the structures of glycosphingolipids (GSLs) from both normal and pathological tissues have produced important findings on various aspects of cell surface biochemistry, including previously unsuspected details of ABO blood group immunochemistry and the aberrant glycosylation of tumor cells. The increasing complexity of compounds of interest has fostered a continuing need to examine the potential of state-of-the-art instrumentation for their analysis. Based on the promising results of other groups showing the efficacy of ESI-MS for solving glycan structural problems, we have explored its use for the analysis of more complex GSLs of interest.

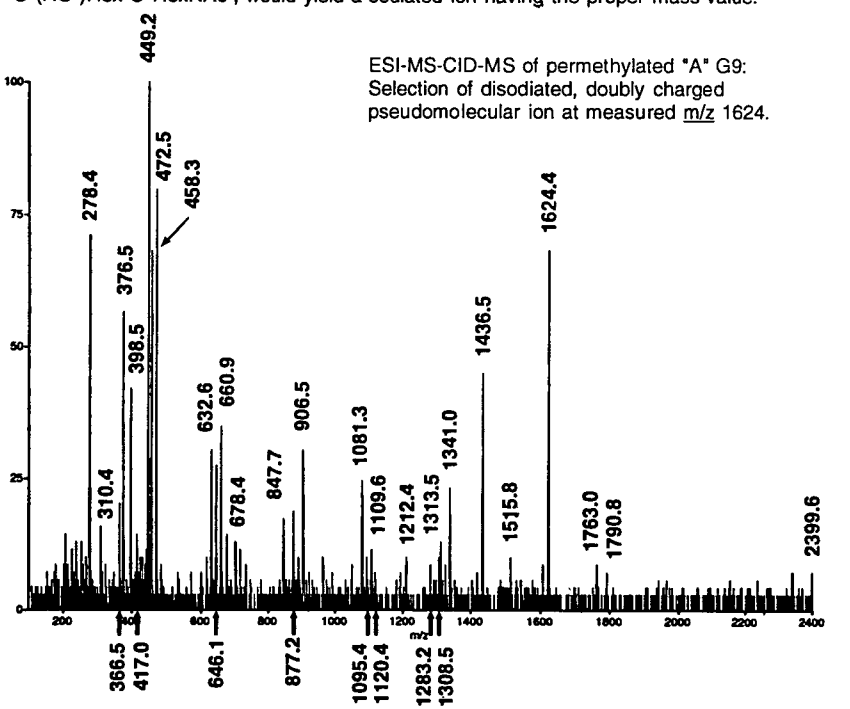
Permethylated GSLs were analyzed on a PE-SCIEX API-III triple quadrupole mass spectrometer with an IonSpray source, operating in the positive ion mode. Samples dissolved in MeOH containing 1 mM of either ammonium acetate or formic acid were introduced by direct infusion. Single quadrupole MS produced abundant sodiated molecular ions as well as fragments originating from the non-reducing end of the glycan, similar to those observed previously in EI- and FAB-MS. In some cases, accompanying fragments also retained a sodium atom. Observed in CID tandem mass spectrometry of mono- and disodiated molecular species were numerous glycan sequence-related ions originating from both the reducing and non-reducing ends, as well as ions from internal sequences. These data were sufficient to deduce the complete "skeletal" sequence of complex GSLs, including a branched undecaglycosylceramide having an A blood group hapten on one arm and sialic acid on the other:

```
GalNAcα1→3
          Galβ1→4GlcNAcβ1→6
  Fucα1→2                    Galβ1→4GlcNAcβ1→3Galβ1→4Glcβ1→1Cer
NeuAcα2→3Galβ1→4GlcNAcβ1→3
```

In ESI-MS of the permethylated compound, a set of abundant disodiated, doubly charged pseudomolecular ions, at nominal monoisotopic m/z 1608, 1622, and 1636, represented deoxyHex•NeuAc•Hex_5•$HexNAc_4$ attached to ceramides predominantly consisting of d18:1 sphingenine combined with 20:0, 22:0, and 24:0 fatty acids, respectively. Also observed were less abundant trisodiated, triply charged pseudomolecular ions at nominal monoisotopic m/z 1079.67, 1089.00, and 1098.33, respectively. Non-reducing end sequence-related fragments were observed for the sialylated arm at nominal m/z 376, 344, and 312 (NeuAc, successive losses of MeOH); 580 (NeuAc•Hex); 825 and 793 (NeuAc•Hex•HexNAc); and for the A blood group hapten arm at nominal m/z 260 and 228 (HexNAc); 883 (deoxyHex•Hex•$HexNAc_2$). Fragments containing both arms and the branching Hex were observed weakly at m/z 1897 (deoxyHex•NeuAc•Hex_3•$HexNAc_3$) and abundantly at m/z 2142 (deoxyHex•NeuAc•Hex_3•$HexNAc_4$).

A typical MS-CID-MS pattern, in this case selecting via Q_1 for the disodiated pseudomolecular ion at nominal m/z 1622 (1624 measured), is reproduced below. Under these conditions, sodiated ions were predominant, with some persistence of disodiation in the

larger fragments. Unsodiated ions appeared only at measured m/z 376.5 (NeuAc); and 449.2 and 417.0 (internal -O-Hex-O-HexNAc-). Disodiated fragments include those at m/z 1436.5 (loss of NeuAc from the pseudomolecular ion); 1308.5 (loss of Cer); 1212.4 (loss of NeuAc•Hex•HexNAc); 1120.4 (loss of both NeuAc and Cer); 1095.4 (loss of -O-Hex-O-Hex-O-Cer). Monosodiated "A-type" fragments yielding the glycan sequence of two types of non-reducing terminals included those at m/z 660.9 (deoxyHex•Hex•HexNAc); 906.5 (deoxyHex•Hex•$HexNAc_2$); 398.5 and 366.5 (NeuAc); and 847.7 (NeuAc•Hex•HexNAc). Monosodiated internal fragments included those at m/z 472.5 (-O-Hex-O-HexNAc-); 1790.8 (loss of NeuAc and -O-Hex-O-Hex-O-Cer). Of particular interest is the fragment at m/z 458.3, which was observed abundantly in all spectra of branched neolacto-series gangliosides (three analogs, including the non-blood group core structure VI^3NeuAc-iso-nLc_8Cer), but not in any unbranched analogs (VI^3NeuAc-nLc_6Cer and IV^3NeuAc-nLc_4Cer). This ion is believed to arise from the sodiated fragment (m/z 1341.0) representing the blood group terminal tetrasaccharide attached (by its β1→6 linkage) to the internal -O-Hex-O-HexNAc-. Neutral loss of the tetrasaccharide branch, leaving the N-acetyllactosamine unit as -O-(HO-)Hex-O-HexNAc-, would yield a sodiated ion having the proper mass value.



GLYCOSPHINGOLIPIDS FROM BOVINE RED BLOOD CELLS AND FOETAL CALF BRAIN

Hélène Perreault[1,3], Omanand Koul[2], Jacqueline Street[2], Robert H. McCluer[2] and Catherine E. Costello[1,4]

[1]Dept. of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139; [2]Eunice Kennedy-Shriver Center for Mental Retardation, Waltham, MA 02154; Present addresses [3]Dept. of Chemistry, University of Manitoba Winnipeg, Manitoba, Canada R3T 2N2; [4]Dept. of Biophysics, Boston Univ. School of Medicine, Boston, MA 02118.

Introduction. Stage-specific embryonic antigen (SSEA) glycosphingolipids (GSLs) found in the central nervous system are involved in regulating cell-cell recognition, targeting and migration of cells during development. SSEA-1 (Lewis x) GSLs are biosynthesized in the brain by fucosylation of lipid substrates with the core structure [Gal-GlcNAc-Gal-Glc-Cer] and higher analogs through the action of fucosyltransferase enzymes. In order to optimize methodology to allow for the structural determinations of SSEA-type GSLs from foetal calf brain, potential substrates for the fucosyltransferases of this class were first isolated from bovine red blood cells and mouse kidney cells, purified using chromatographic techniques, derivatized and characterized by LSIMS, MS/MS and linear and PSD MALDI-TOFMS. The methods were then applied to fractions from foetal calf brain.

Experimental. Neutral glycolipid fractions were isolated from beef red blood cells[1] and mouse kidney cells[2] according to Li *et al*[1] and McCluer *et al*[2]. Complex neutral GSLs were isolated from foetal (1st trimester) calf brain according to Hakomori *et al*[3]. LSIMS and MS/MS experiments were performed with a JEOL HX110/HX110 (E1B1-E2B2) instrument, at +10kV accelerating voltage. High energy collisions with helium were induced at 7keV in a cell (helium) located between MS-1 and MS-2. For linear MALDI-TOFMS, modified VT2000 (Perseptive Biosystems Inc.) instrument was used. PSD MALDI-TOFMS experiments were conducted at Merck Co. (Rahway, NJ) by Dr. P. Griffin on a Vision-2000 instrument (Finnigan Corp.) For both types of MALDI-TOF experiments, a nitrogen laser source (337 nm) generated the radiation and the matrix was 2,5-DHB. Permethylation of the GSLs was effected as described by Ciucanu and Kerek[4]. The gas-to-solid method[5] was used for peracetylation.

Results. GSLs from bovine red blood cells (Fractions **7** and **PG**, ca. 10 nmol available) and mouse kidney cells (Fraction **6**, ca. 15 nmol) were examined prior to the feotal calf brain fractions. Microscale analysis was conducted to allow for determination of sugar content. Gas phase peracetylation of the fractions allowed for acquisition of structurally significant LSIMS and MS/MS spectra, and permethylated derivatives produced abundant Z_0-type ceramide ions which could be analyzed by MS/MS. Linear mode MALDI-TOFMS experiments on the native and derivatized compounds also played a major role in structure elucidation. The number of methyl and acetyl substitutions were helpful in distinguishing Hex, Fuc and HexNAc residues. Structures containing up to eight sugar residues were identified, and heterogenous ceramides were encountered, with modifications that include hydroxylation, additional sites of unsaturation and variation in alkyl chain lengths. The fractions from foetal calf brain (**r6, r8 and r10**) were available in much smaller quantities (ca. 1 nmol); MALDI-PSD (<1 pmol) experiments instead of MS/MS were acquired for fragmentation data. Gas phase peracetylation performed on 500 pmol of **r10** allowed for acquisition of structurally significant LSIMS data (250 pmol). LSIMS and MALDI-PSD data were complementary in some aspects. The fractions were found to be GSL mixtures with heterogeneity in the ceramide chains. Table 2 summarizes the results obtained from all mass spectrometric investigations. Details of structures of **r6** and **r8** are still uncertain; MALDI-PSD-TOFMS experiments are underway to clarify remaining features.

Detailed Characterization of Glycosphingolipids by ES-MS-CID-MS

Bruce B. Reinhold, Song Ye, Vernon N. Reinhold, John V. Brigande, and Thomas Seyfreid, Boston University School of Medicine and Boston College

Gangliosides are a family of sialic acid-containing glycosphingolipids which are amphiphillic compounds of the outer leaflet of plasma membranes. Although they are found in nearly all vertebrate tissues, gangliosides are most heavily concentrated in neurons of the central nervous system. They are thought to function in a variety of membrane mediated phenomena including cell-cell and cell-matrix interactions (Ledeen, 1989; Varki, 1993). Additionally, many studies indicate that ganglioside biosynthesis and expression are developmentally regulated, suggesting an important role in neuronal proliferation, migration, and differentiation.

Comparative studies on the occurrence and distribution of vertebrate brain gangliosides have revealed considerable variability in composition and concentration across phylogeny (Avrova, 1971; Rahmann and Hilbig, 1983). However, studies on vertebrate embryos have suggested similarities in ganglioside composition. Gangliosides GD3 and GM3, for example, dominate the early embryonic patterns of some vertebrates (Bouvier and Seyfried, 1989). Von Baer recognized in the early 19th century that highly diverse vertebrate morphologies develop from common vertebrate forms and Darwin proposed that the similarity in embryonic structure across different species is a reflection of a common descent. In this century, these observations are being translated into molecular terms. Due to their widespread distribution and complex molecular architecture, comparative studies of ganglioside structures should provide insights into fundamental biochemical homologies that exist in evolutionary and fetal development.

The gangliosides extracted from adult skate (*Raja erinacea*) brains provide a good example of the analytical challenge such studies represent. HPTLC analysis of these gangliosides (resorcinol staining) revealed many multiply-sialyted bands that did not migrate with known standards. Methylation and ES-MS of the total acidic glycolipid extract provided a complicated picture of ceramide and carbohydrate heterogeneity including structures containing up to seven sialic acid residues. ES-MS-CID-MS of doubly and triply charged ions using a TSQ 700 triple quadrupole provided extensive characterization of branching isomerism in the carbohydrate and allowed mass assignments for both the sphingosine and amide linked alkane chain (Reinhold, 1994). Collision spectra of skate brain gangliosides containing one, four and five sialic acid residues are illustrated.

DETERMINATION OF THE GLYCOSYLATION POSITION IN MONO-*O*-GLYCOSYL FLAVONOIDS

Q. M. Li, H. Van den Heuvel and M. Claeys
University of Antwerp (UIA), Department of Pharmaceutical Sciences, Antwerp, Belgium

In a previous study we have shown how flavonoid O-diglycosides can be differentiated from flavonoid *O,C*- and *C*-diglycosides and how unambiguous information on the carbohydrate sequence can be obtained for *O*-diglycosides by performing low-energy CID on $(M + H)^+$ ions and tandem mass spectrometry [1]. In a continuation of this study we now demonstrate how these methods can be applied to characterize the aglycone part and obtain information on the glycosylation position in flavonoid *O*-glycosides.

The glycosylation site in *O*-glycosyl flavonoids is generally established rather indirectly by applying UV-spectroscopy and resorting to various specific shift reagents. A suitable analytical method has been reported previously by Sakushima and Nishibe [2], which involves methylation, chemical hydrolysis, isolation of the methylated aglycone, preparation of the trimethylsilyl derivative in order to derivatize the free hydroxyl group, and, finally, EI/MS analysis. Our more direct mass spectral approach is partly inspired by this method and also involves derivatization to the methyl phenolether derivative. Following methylation with diazomethane, the methylated mono-*O*-glycosyl flavonoid is ionized by fast atom bombardment, which results in the formation of protonated molecules, as well as protonated aglycone ions. In a subsequent step, a product ion spectrum of the protonated aglycone ions is obtained using low-energy collisional activation. The detailed analysis of the product ion spectrum allows to infer the position of the free hydroxyl group, which corresponds to the glycosylation position in the intact mono-*O*-glycosyl flavonoid.

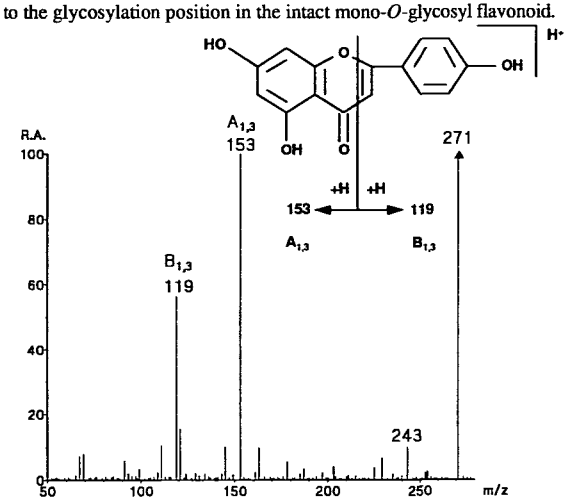

Fig.1. Low energy CID spectrum obtained for the protonated aglycone ions (Y_0^+) of apigenin 7-*O*-neohesperidoside.

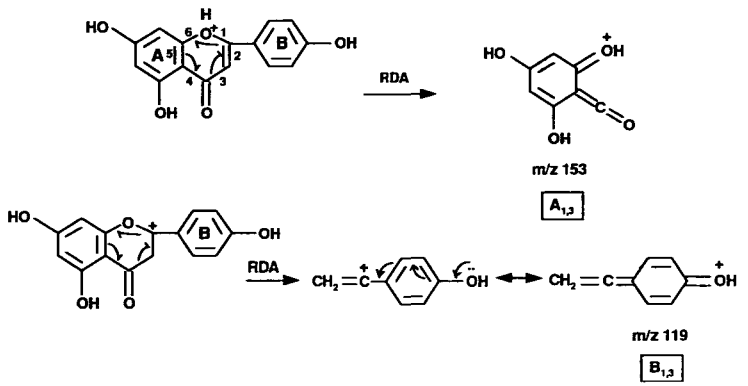
Figure 1 illustrates the low-energy CID spectrum obtained on the FAB-generated Y_0^+ ions (*m/z* 271) of apigenin 7-*O*-neohesperidoside. The abundant product ions at *m/z* 119 ($B_{1,3}$) and *m/z* 153 ($A_{1,3}$) are rationalised by Retro Diels-Alder fragmentations in the C ring and are typical of the apigenin aglycone part (Scheme 1). With respect to the ion nomenclature used to denote fragment ions typical of the aglycone part, a systematic ion nomenclature is proposed in which the bonds broken in the C ring are indicated with subscripts.



Scheme 1

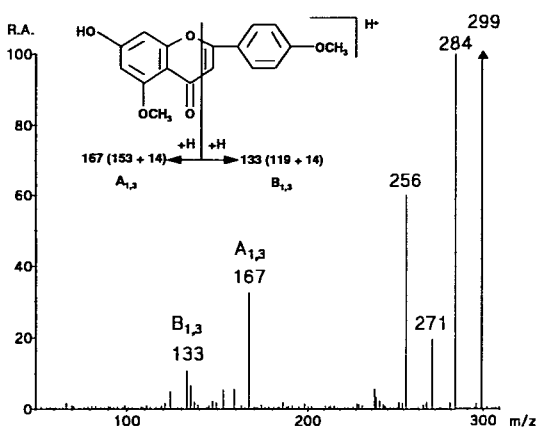


Fig.2. Low-energy CID spectrum obtained for the protonated aglycone ions (Y_0^+) of methylated apigenin 7-*O*-neohesperidoside.

Figure 2 shows the low-energy CID spectrum obtained on the Y_0^+ ions (*m/z* 299) of the sample of apigenin 7-*O*-neohesperidoside following methylation with diazomethane. The $B_{1,3}$ ions (*m/z* 133) have shifted by 14 u, indicating that the 4'-hydroxyl group of the B ring was free. The $A_{1,3}$ ions (*m/z* 167) also show a mass increase of 14 u which is consistent with glycosylation in the A ring. Taking into account the lower reactivity of the 5-hydroxyl group towards glycosylation, it is logical to propose glycosylation at the 7-*O* position. It is also pointed out that the Y_0^+ ions fragment by loss of a methyl radical; this rather uncommon transition from even-electron to odd-electron ions was found to be characteristic of phenolic methyl ether groups.

Plant polypehnols, syn vegetable tannis, constitute one of the most distinctive groups of higher plant secondary metabolites.[1] Hydrolyzable tannins consist of polyesters based on gallic acid and/or hexahydrocyddiphenic acid and their derivatives (Figure 1). The propensity of polyphenols to bind with protein, nucleic acids, and carbohydrates protects the plant from both microbial and animal predators[2] Protein binding is thought to contribute to the astringent flavor notes found in beverages such as teas, cocoa, wines and beer[1] The extent of this interaction is governed by the number of phenolic moieties and how they are linked together Techniques to characterize both types of structural differences are necessary to elucidate these interactions This study reports the first application of direct introduction electrospray mass spectrometry, and reverse phase LC/MS to study the constituents of hydrolyzable tannins

Two Finnigan (San Jose, CA) TSQ-700s were used in this study The first was fitted with Finnigan electrospray ionization source which was held at 4 5 kV above ground potential to produce positively charged ions A sheath liquid of 2-methoxyethanol was flowed at 5 µL/ min Nitrogen sheath and auxiliary gas also were present. The temperature of the heated capillary was set at 190°C The resolution of the mass analyzers were opened to 2 Da wide to improve delectability The other TSQ was equipped with an EI/CI source Sample was introduced using a direct insertion probe or particle beam Negative chemical ionization with ammonia (1 3 Torr) generated sample ions The mobile phase for LC/MS experiments consisted of A (100% water + 0.1% NH_4OAc + 0.1% HOAc) and B (100% acetonitrile) and was delivered as a gradient The mobile phase was delivered to a 1 mm Hypersil C8 (Keystone, Bellefonte, Pa) at a rate of 50 µL/min Hydrolyzable tannins samples, derived from Aleppo (*Quercus infectoria*) and Chinese (*Rhus semialata*) galls and Tara (*Caesalpinia spinosa*) fruit, were obtained from Omichem (Belgium). Approximately 0 8 mg of sample were added to 1 mL of a solution containing 94% A 6%B

The number of gallic acid residues attached to each molecule was determined by 1) normal phase chromatography, 2) direct loop introduction of sample into mobile phase flowed into the electrospray ion source, and 3) negative chemical ionization with sample introduced on the DIP probe or by particle beam Similar results were obtained for electrospray and normal phase experiments while only fragment ions were seen in the chemical ionization experiments. Figures 2, 3 and 4 show the electrospray mass spectra obtained on each of the samples However, information on structural isomers were not obtained in these experiments. Some separation of isomers was observed when reverse phase HPLC and LC/MS was performed (Figure 5) Mass spectrometry made it easy to deduce the extent to which peaks with differing numbers of gallic acid residues overlap

LOW-ENERGY COLLISION INDUCED DISSOCIATION OF PROTONATED GLYCOALKALOIDS AND RELATED AGLYCONES

M. Claeys[1*], H. Van den Heuvel[1], S. Chen[2], P. J. Derrick[2], F. A. Mellon[3] and K. R. Price[3]

[1]Department of Pharmaceutical Sciences, University of Antwerp (UIA), B-2610 Wilrijk, Belgium
[2]Warwick Institute of Mass Spectrometry, University of Warwick, Coventry, CV4 7AL, U.K.
[3]Institute of Food Research, Norwich Laboratory, Colney, Norwich NR4 7UA, U.K.

The glycoalkaloids are a group of nitrogenous, steroidal glycosides found in common food plants of the solanum species, including potatoes, tomatoes and aubergines, which are of biological interest and concern because of their toxicity. The high-energy collision-induced dissociation (CID) behaviour of protonated glycoalkaloids has recently been examined and has been shown to yield information on the linkages and the positions of the sugars in the carbohydrate part[1]. In a continuation of this study we have compared low- and high-energy CID of the $[M + H]^+$ ions of the nitrogenous steroids, tomatidine, solasidine, demissidine and solanidine, and of the glycoalkaloids, α-tomatine, α-chaconine and α-solanine, in order to determine to what extent these collisional activation methods can provide structural information on the aglycone and carbohydrate parts. The low-energy CID spectra were examined in an effort to define which particular fragmentations, among the many typically observed during high-energy CID, can also be induced by low-energy collisions. The low-energy CID spectra were recorded on a Fisons VG70SEQ mass spectrometer, equipped with a caesium ion source.

The mass spectral data obtained on the protonated aglycones show that low-energy CID gives rise to the formation of diagnostic product ions, which can be interpreted as the products of charge-driven reactions. In the case of demissidine and solanidine, abundant ions are present at m/z 150/151 and 204/205, which can be rationalised by rearrangement reactions and are most pronounced at very low collisional activation energies. Scheme 1 and Figure 1 give low-energy CID data obtained for the $(M + H)^+$ ions of α-tomatine and tomatidine respectively. A rationalisation for the formation of the ions at *m/z* 273 and 161 is given in Scheme 2. Low-energy CID of the protonated glycoalkaloids yields product ions which are characteristic both of the aglycone part and of the carbohydrate sequence. With respect to the carbohydrate sequence, Y_n^+ ions and low intensity Z_n^+ ions (ion nomenclature according to Domon and Costello[2]) are formed.

3 Inst. f. Biochem. and Molec. Physiol., University of Potsdam, Germany
* present address: MILUPA AG, Research Department, D-61381 Friedrichsdorf, Germany

Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry (MALDI-MS) has been been established as a valuable tool in the analysis of glycans and glycoconjugates (1-3). Recently quantitative analysis of cyclic bacterial β1-2 glucans has been performed by MALDI-MS and HPLC (4). In this contribution a systematic analysis of periplasmic glucans is reported, including reference analysis using High Performance Anion Exchange Chromatography (HPAEC-PAD) and Fast atom Bombardement (FAB-MS). In *Escherichia coli* the synthesis of periplasmic glucans known as Membrane Derived Oligosaccharides (MDO) appears to be controlled by various enviromental factors (5). New analytical methods are needed for investigation of the products of this highly regulated process. UV-MALDI-MS was performed using 3-aminoquinoline and 2,5-dihydroxybenzoic acid as matrices MDO derivatives with acidic side groups were analyzed in both, positive and negative ion mode. The number and type of substituents of the oligosaccharides was determined by comparing the mass spectra before and after hydrogen fluoride / alkaline treatment. The pattern of neutral glucans of *Erwinia chrysanthemi* obtained by HPAE-chromatography was analyzed by MALDI-MS after fractionation of distinct peaks (Fig. 1). Each fraction was further analyzed by methylation analysis showing that differences in retention times are resulting from different numbers of β1-6 branches of the isomeric molecules (Tab. 1).

EXAMINATION OF CHITIN-METAL INTERACTIONS BY ES AND MALD IONIZATION MASS SPECTROMETRY

Mona Shahgholi, Mark M. Ross and John H. Callahan, Code 6113, Chemistry Division
Naval Research Laboratory, Washington, DC 20375.

Marine algal exudates are rich in exopolysaccharides that can bind a variety of trace metal ions in their environment. The metal scavenging properties of these polysaccharides are important to study because they affect the bioavailability, toxicity, and biogeochemical fate of trace metal ions in the ecosystem (1). In this study, chitin is used as a model for the study of metal-organic interactions using electrospray (ES) and matrix-assisted laser desorption (MALD) ionization techniques. The objectives of this study were twofold. One is to develop proper sample preparation protocols for the analysis of this large heterogeneous biopolymer by ES and MALD. The second is to assess the utility of ES and MALD in addressing the metal binding processes.

Chitin is a (1-4)-2-acetamido-2-deoxy-beta-D-glucan commonly found in the exoskeletons and cuticles of many invertebrates and in the cell walls of most fungi and algae (2). Purified chitin must be first hydrolyzed into segments of reasonable mass range. Chitin oligosaccharides were prepared from chitin (Sigma) by hydrolysis in 11M HCl at 10 C for eight hours, conditions under which the chitin oligosaccharides remain N-acetylated (3). After the acid was neutralized by NaOH, the oligomers were purified on Bio-Gel P-2 (Bio-Rad). Under these conditions oligomers containing up to 8 N-acetyl glucosamine residues could be isolated. These hydrolysate mixtures were characterized directly by both MALDI and ESI. The hydrolysate thus prepared was mixed with dihydroxybenzoic acid (10 mg/mL in 90:10 v/v ethanol:water) for the MALDI experiments. For the ES experiments, the hydrolysate was diluted with methanol. After confirmation of the presence of chitin oligomers, the hydrolysate was subjected to on-line, microbore LC/ESIMS (4) using a capillary packed with 7 micron porous graphitic carbon. A variation of the on-line technique was used in off-line LC (with a graphitic carbon column from Shandon Scientific) to generate fractions containing each oligomer, which were then used for further study. These studies also focussed on the behavior of chitosan, which is the deacetylated form of chitin. Chitosan should bind metals with greater affinity than chitin.

Both oligosaccharides were evaluated by ES and MALD before and after addition of metal ions. Several metals from the transition group, alkali, and alkali earths were selected for these studies. Both doubly-charged and singly charged metal bound oligosaccharides are apparent in the ES spectra; however, the MALD spectra only show singly charged adducts. For example, ESI spectra showed the presence of both $[M+Cu]^{2+}$ and $[M-H+Cu]^{+}$ ions, but MALDI spectra only gave $[M+Cu]^{+}$ species (although it was not clear from the low resolution spectra obtained that proton loss had not occurred). CAD experiments were performed on various chitin adducts (H^+, Na^+, Mg^{2+}, Cu^{2+}, and Ni^{2+} were studied) using a triple quadrupole instrument, and the fragments generated were compared for the various metals. In general, collisional activation of the singly-charged species resulted in glycosidic bond cleavages. Fragments from protonated ions suggested that protonation occurred on the glycosidic oxygen. Sodium and magnesium adducts also gave primarily glycosidic bond cleavages, although the role of the ion is unclear. However, with the addition of Cu and Ni (to form $[M-H+Me]^{+}$ ions), the most abundant fragment ions observed involved cross ring cleavages. Moreover, a different cross ring cleavage was observed with each ion. The results suggest that specific chelation of each ion by the chitin may induce the cross ring cleavage. Fragmentation of doubly charged ions was also studied. Many of the same pathways were observed in the fragmentation of doubly charged ions as with singly charged species. However, doubly charged species also underwent charge separation upon activation. Future studies will focus on determining

whether specific chitin-metal interactions induce the observed cross ring cleavages and whether multiple metal addition can be observed by ESIMS. CAD studies of chitosan may help elucidate the role of metal interactions in fragmentation, as chitosan binds metals much more strongly than chitin.

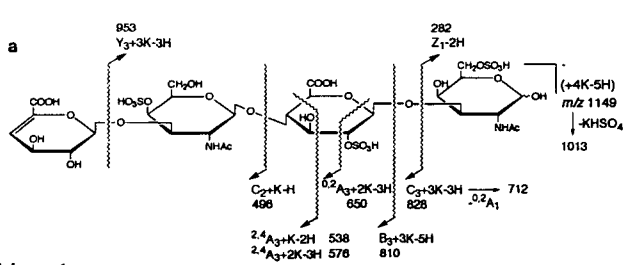
FAB-MS/MS of Immunoreactive Tetrasaccharides from Chondroitin Sulfate

Mamoru Ohashi[a], Tadashi Ii[a], Masayuki Kubota[a], Takashi Hirano[a], Keiichi Yoshida[b] and Sakaru Suzuki[c]
[a] Department of Applied Physics and Chemistry, The University of Electro-Communications, Chofu, Tokyo 182, Japan
[b] Tokyo Research Institute, Seikagaku Corporation, Higashiyamato-shi, Tokyo 189, Japan
[c] Institute for Molecular Science of Medicine, Aichi Medical University, Nagakute, Aichi 480-11, Japan

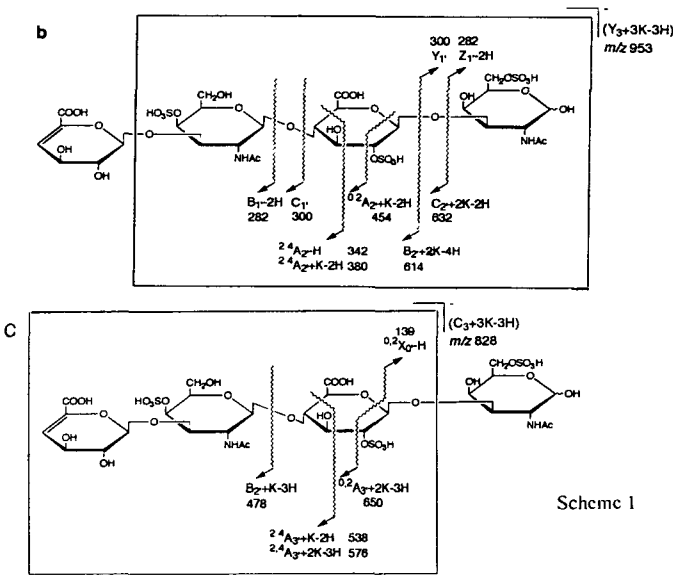
In 1987 Yamagata et al. demonstrated that tetrasaccharide trisulfate and tetrasaccharide tetrasulfate fragments isolated from shark fin by chondroitinase AC digestion are the smallest chondroitin sulfate fragments that can inhibit the binding of the anti-chondroitin sulfate monochronal antibody MO-225 to various types of chondroitin sulfate proteoglycan derived from avian and mammalian tissues[1]. The structures of these compounds were deduced on the basis of the unsaturated disaccharide structures obtained by condroitinase ABC digestion. However, direct evidence to support the tetrasaccharide structures is still required Herein, we report that FAB CID-MS/MS of the molecule related ions and fragment ions has been successful in the confirmation of the proposed structures.

Materials and methods: Tetrasaccharide trisulfate(**1**) and tetrasulfate(**2**) were prepared according to the literature[1]. The mass spectra were measured with a Finnigan MAT TSQ 700 triple stage quadrupole mass spectrometer equipped with an Ion Tech FAB gun. A Xe beam with an energy of 8 keV was used. Thioglycerol and triethanolamine were used as the matrices in the positive- and negative-ion modes, respectively. The CID-MS/MS were recorded using argon as the collision gas typically at 1.0 mTorr to reduce the parent ion beam by approximately 30%. The collision energy was 5 eV or 30 eV.

Results and discussion:
Tetrasaccharide trisulfate(**1**): The structure of (**1**) and the fragmentation of the negative ion CID-MS/MS of (**1**) are shown in Scheme 1; (a) the $[M + 4K - 5H]^-$ ion (m/z 1149) as the parent ion; (b) the fragment ion that corresponds to $[Y_3 + 3K - 3H]^-$ (m/z 953) as the parent ion, (c) the fragment ion that corresponds to $[C_3 + 3K - 3H]^-$ (m/z 828) as the parent ion. These CID-MS/MS clearly indicate that a sulfate group is present at the C-2 position of the glucuronic acid moiety on the reducing end site of (**1**). The CID-MS/MS of the disaccharide ion at m/z 496 which corresponds to $[C_2 + K - H]^-$ is almost superimposable on the FAB CID-MS/MS of the molecular related ion $[M + K - 2H]^-$ of the potassium salt of 2-acetamido-2-deoxy-3-0-(β-D-gluco-4-enepyranosyluronic acid)-4-O-sulfo-D-galactose(ΔUA-GalNAc4S)[2]. This confirms the location of the sulfate group at C-4 in the galactosamine moiety on the non-reducing end site of (**1**). On the basis of these results the complete structure of the tetrasaccharide trisulfate(**1**) is now confirmed.



Scheme 1



Scheme 1

Tetrasaccharide tetrasulfate(**2**), the fragmentation of the negative ion CID-MS/MS of the molecule related ion$[M + 5K - 6H]^-$ (m/z 1187) as the parent ion clearly confirms the structure of (**2**) as shown in Scheme 2. The CID-MS/MS investigation of the FAB fragment ions of (**2**) in a way similar to that of (**1**) also confirmed the location of the sulfate groups. These results confirm the structures of tetrasaccharide trisulfate and tetrasulfate as previously reported by Yamagata et al.

Mass Spectrometric Determination of an Octasulfated Disaccharide.

E. Watson, A. Termin, B. Shah., A. Bhide, T. Zamborelli and A.Venot.

Amgen Inc., Amgen Center, Thousand Oaks, CA 91320

Highly acidic compounds are difficult to analyse by matrix-assisted laser desorption ionization mass spectrometry. Very recently Juhasz and Biemann reported the use of arginine containing peptides to produce non-covalent complexes that survived as intact species when subjected to MALDI-MS (1). In this report we have used fully sulfated trehalose, (8 sulfate residues), as a model compound to evaluate the use of these arginine/lysine containing peptides as a means of forming stable noncovalent complexes for the characterization of these highly charged species by MALDI-MS. The extent and stability of complex formation is shown to correlate with the number of arginine groups present. No stable complexes were detected when lysine was substituted for arginine.
ESI mass spectrum of trehalose sulfate in 1% formic acid is shown in Figure 1. The mass spectrum was dominated by multiple sodium adduct containing species. The molecular weights of these various species were determined and are listed in Table 1. The relative intensity of these ions suggested that 3 species, containing 6, 7 and 8 sulfates were present in essentially equal amounts. From these results it was not possible to determine whether this represented the species distribution in solution or whether sulfite was being eliminated during ESI mass spectrometry.
The structures of the synthesized peptides used in this study are:

IRRERNKMAAAKSANAAAELTDTL	3 Arg
IRRERNKMAAAKSANARRELTDTL	5 Arg
IRRERNKMAAAKSRNRRRELTDTL	7 Arg
IRRERNKRRARKSRNRRRELTDTL	10 Arg
IRRERNRRRARRSRNRRRELTDTL	12 Arg
RIRRERNRRRARRSRNRRRELTRTLR	15 Arg

The mass spectra were all obtained using 2,5-DHB as the matrix. When the number of arginines was 10-15, the most abundant complex ion arose from a 1:1 complex with little or no elimination of sulfite, Figure 2.
There were no additional peaks due to sodium cationization. Ionic complexes were apparent using all of the peptides, with the exception of those containing only lysine, indicating the importance of arginines in forming these noncovalent complexes. These results demonstrate that the fragmentation decreases with increase in the number of arginines present.

Electrospray Mass Spectrometry of Heparin-Derived Glycosaminoglycan Disaccharides

Eric Watson and Flora Yao

Amgen Inc., Amgen Center, Thousand Oaks, CA 91320

Heparin is a glycosaminoglycan that inhibits blood coagulation through the activation of antithrombin III (ATIII). It consists of sequences of uronic acid and glucosamine disaccharides in which the uronic acids could be O-sulfated at C2 and the glucosamines O-sulfated at C6 and/or C3. In addition glucosamine residues could also be N-acetylated or N-sulfated. As a result there are at least eight different dissacharide units, each characterized by a unique uronic acid and glucosamine residues.
We have evaluated the use of negative ion ESI mass spectrometry with CID in the free-jet-expansion region of the API interface as an alternate fragmentation technique to collision- induced ESI-MS/MS for obtaining structural information on heparin-derived GAGS.
The effect of orifice potential on the mass spectra was evaluated by increasing orifice potentials in steps of 20V from -50V to -220V. From -50V to -120V, a significant increase in the extent of fragmentation was observed. At orifice potentials from -120V to -250V, there was no further changes in the fragmentation pattern but there was a gradual decrease in sensitivity at the higher orifice potentials. Common fragmentations are seen to arise by simple cleavage on either side of the glycosidic oxygen accompanied by hydrogen attachment to the fragment bearing the charge. Other structurally significant ions arise from cross ring cleavages. The mass spectra of all of these species are sufficiently different such that they can be readily distinguished from one another. Figure 1 shows the negative-ion ESI spectrum of the disaccharide 11A at (A) -50V, (B) -120V and (C) CID-MS/MS.

The utility of the method has been evaluated using a series of authentic GAGS derived from heparin that differ solely in their degree of sulfation. All of the fragmentation patterns were sufficiently different such that they could be used for the identification of these disaccharides. These results show that positional isomers for the series 1A-1VA and 1S-1VS can be readily distinguished using the technique described here. The advantage of the described method is that a single set of instrumental conditions are used to fragment all of these species. Furthermore, the simplicity of this approach has the potential in characterizing GAGS introduced from an on-line separation technique such as capillary electrophoresis.

CE/MALDI - MS of Mixtures of Heparin Derived Oligosaccharides

A.Rhomberg, P.Juhasz[1)] and K.Biemann
Department of Chemistry, MIT, Cambridge 02139

Heparin and the closely related heparan sulfate are linear and highly acidic polysaccharides that are involved in a wide variety of biological phenomena. They interact with the components of the blood coagulation cascade, induce the formation of new blood vessels in wound healing and tumor metastasis, control the bioavailibility of many proteins and, as membrane bound coreceptors, control the specificity and binding of growth factors and other molecules involved in cell signalling [1]. Our interest focuses on biologically active oligosaccharides, 5-20 saccharide units in length. Heparin/heparan sulfate has a characteristic disaccharide repeat unit consisting of an uronic acid (iduronic or glucuronic acid) and glucosamine. Both can have different degrees of sulfation/acetylation. Sulfation and acetylation are carried out by a number of different enzymes This process leads to a high variability in sequence and complex mixtures of oligomers if the chain is degraded. We therefore employ capillary electrophoresis as a final purification step before performing enzymatic digestion and mass spectrometry. Capillary electrophoresis was carried out using a Beckman PAC/E 2050 and a Hewlett Packard ^{3D}CE. Fused silica (Polymicro) and LPA capillaries (Bio-Rad) of I.D /O.D.: 75/363 µm were used. The lengths were l/L 50.3/57.0 and 70/78.5 respectevly. Analytes were detected @200 nm (indirect detection), or @ 230/214 nm (direct detection). A voltage of 30 kV (reversed polarity) was employed. For fraction collection migration times (t_{det})were predetermined and elution times (t_{el})calculated based on the relationship $t_{el}=t_{det}*L/l$ Prior to the elution of an analyte the voltage was interrupted and each compound eluted at 30 kV into a modified microcentrifuge vial containing 5 µL of phosphate buffer (5 mM, pH=7,0). All steps were carried out fully automatic using the autosampler features of the CE instrumentation. For enzymatic digestions 1 µL of native heparinase I (Sigma) containing 1 unit activity was added to 3-5 µL CE-fraction and digested @30°C for 10 min-24 h. Mass spectrometry was performed on a Vestec VT2000, linear Time-of-Flight instrument. Samples were prepared by mixing 9 µL matrix solution (15 mg/mL caffeic acid or 25 mg/ml 3-hydroxypicolinic acid/D-fucose 90:10) with 1 µL of 0,1 mg/ml $(RG)_{15}$ solution (RG = arginylglycyl). 1 µL of CE-fraction or enzyme digest were added. 1 µL of the resulting mixture was deposited on the target.

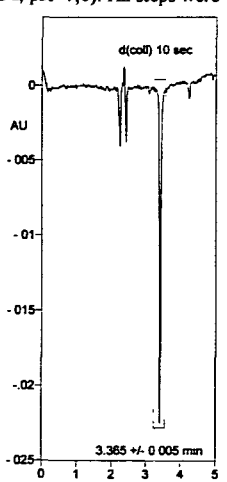

Figure 1

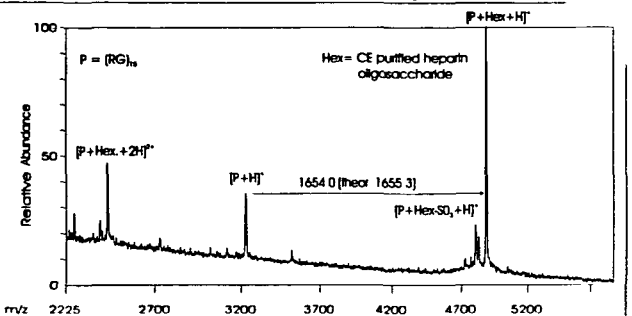
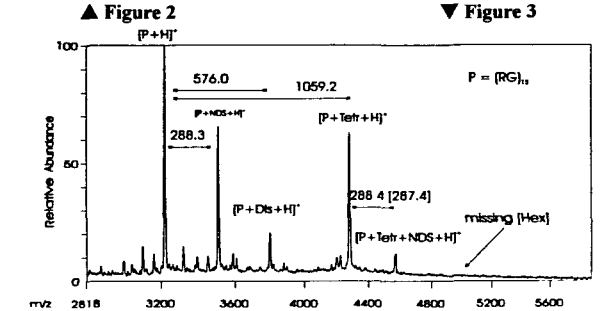
Results: Heparin/heparan sulfate oligosaccharides obtained by different procedures were purified by CE and collected fractions analyzed by MS. Oligosaccharides generated by enzymatic digestion contain α,β unsaturated acids (UV maximum: 232 nm). For a mixture of unsaturated hexasaccharides up to 20 components were resolved. Heparin oligosaccharides, prepared by nitrous acid degradation followed by borohydride reduction, have an anhydromannitol at the reducing end and do not adsorb in the UV. It is nevertheless possible to analyze such compounds by CE trough the use of indirect detection, for example with 1,5 naphtalenedisulfonic acid as background adsorber. A negative peak, generated by ionic displacement, results from the analyte ion. Figure 1 shows this for oligosaccharides prepared by nitrous acid treatment, and prepurified by ion exchange chromatography. The compound migrating at 3.37 min was isolated by pooling fractions from 10 runs into 5 µL of buffer. A 1 µL aliquot complexed with the sythetic peptide $(RG)_{15}$ was used to obtain the spectrum shown in Figure 2. From the molecular weight we calculated the molecule to contain 8 sulfate and no acetyl groups. Information on the stereochemistry of the uronic acids was obtained by digesting the remaining 3 µL of the CE-fraction with heparinase I After 10 min the hexasaccharide had been completely converted to a tetra- and a disaccharide [Figure 3] After prolonged digestion the tetrasaccharide was further cleaved into two disaccharides. Due to the specificity of the enzyme for iduronic acid, it can be deduced that no glucuronic acids were present in the molecule, because the hexasaccharide had been completely digested. Furthermore it was possible to assign the location of most sulfate groups.



▲ Figure 2



▼ Figure 3

Conclusions: The examples demonstrate that though CE is a microanalytical technique, it is possible to purify heparin oligosaccharides in quantities of 100 fmol -10 pmol and obtain mass spectra on the purified compounds and their enzymatic digestion products. Off-line coupling of CE and MS in this case is essential for obtaining both molecular weights for intact oligosaccharide and its enzymatic fragments Independent optimization of CE and MS conditions allows simultaneous achievement of optimum separational and spectral quality. The methodology should ultimately lead to the sequencing of defined heparin molecules to aid understanding of the biological action of this molecule.

INTRODUCTION

In a previous comparison of FAB, ^{252}Cf-PDMS and Ionspray ms for the direct analyses of synthetic sulphated pentasaccharides, FAB was favoured for the unambiguous assignment of molecular masses of unknowns although FAB was also the least sensitive of these techniques [1]. At that time the direct analyses of these pentasaccharides, all variants of the minimal pentasaccharide sequence exerting AT-III mediated anti-Xa activity, with Ionspray ms was complicated both by strong cationisation caused by the presence of up to 11 sodium counter-ions and the large influence on these spectra caused by small changes in instrumental parameters. In a novel Ionspray approach, a variety of oligosaccharides from an enzymatic digestion of glycosaminoglycans was analysed as ion-pairs with both TetraPropyAmmonium (TPA) and d_{28}-labelled TPA [2]. We now report an extension of the latter method applied for Ionspray ms analyses of various sulphated oligosaccharides obtained from a research program for the preparation of synthetic antithrombotics [3].

RESULTS AND DISCUSSIONS

The octa-sulphated pentasaccharide Org 31540 was desalted with Dowex.H$^+$ and flow injection Ionspray spectra were obtained both with d_{28}-labelled TPA and non-labelled TPA (Fig. 1). The ions shown are doubly charged (ΔM=93; TPA=186) and e.g. m/z 1031 contains 3 TPA groups as it shifts towards m/z 1073 with d_{28}TPA (((1073-1031)*2)/28). From these ions the molecular mass can be calculated and averaged (1507 Da). Similar Ionspray spectra were obtained by desalting during on-line reversed phase lc-ms using both TPA and d_{28}TPA as ion-pairs and an acetonitrile gradient on a 300Å C_4-column (not shown). On-line lc-ms desalting was not always effective for higher sulphated oligosaccharides with e.g. molecular masses > 2500 Da; the resulting Ionspray spectra could therefore not be used anymore to assign molecular masses unambiguously.

This problem was solved by post-column membrane ion suppression. With this method cations present (TPA$^+$ and Na$^+$) are replaced for H$^+$ from the regenerant and subsequently the (TPA) pairing reagent is added again. As an example of this technique the lc-ms spectra of an octadeca-sulphated decasaccharide are shown (fig. 2). With this approach TBA could be used instead of d_{28}-labelled TPA (fig. 2 top) as post-suppressor addition of TBA does not affect chromatography. With the combined spectra both the charge-state of the ions (-6), the number of counterions and, as a result, the molecular mass (4143 Da) could be calculated unambiguously. This example illustrates the successful application of this extended Ionspray approach for synthetic oligosaccharides with a larger molecular mass and sulphated at a higher degree than compounds obtained from digests of glycosaminoglycans before [2].

MASSIVE CLUSTER IMPACT IONIZATION OF SACCHARIDES

Nyla N. Dookeran and Peter J. Todd
Chemical & Analytical Sciences Division
Oak Ridge National Laboratory
PO Box 2008, Bldg. 5510A
Oak Ridge, Tennessee 37831-6365

We studied the utility of ionizing saccharides by massive cluster impact (MCI), a form of secondary ionization wherein the primary ions are high molecular weight clusters. For a number of compounds and classes, MCI yields copious secondary ions without prior derivitization or the need to find a suitable matrix. In fact, MCI can be used for *in situ* ionization of some analytes directly from biologic tissue. For the simple sugars and disaccharides we studied, we found that *persistent* (e.g. > 2 h) positive and negative secondary ion emission could almost always be detected from pure samples. We characterized the secondary anions from a variety of saccharides by tandem mass spectrometry (MS/MS), and found the behavior of the MS/MS spectra to be consistent, sensible, diagnostic and invariant with the dose suffered by the sample.

The MCI gun is a direct replacement for the JEOL Xe FAB gun. Its operation is based on electrohydrodynamic ionization of glycerol, which is supplied from an integral reservoir via a stainless steel capillary. Glycerol cluster ions with a mass distribution extending to 10^7 u, charge distribution in the range of 10^2 and current of about 10-30 μA, are emitted from the gun when a potential of 15-20 keV are applied to the EHD emitter.[1] The beam of clusters is focussed and deflected onto the target by a series of lens elements/deflectors. The negative mass spectra produced by using the MCI gun show the anion series 151, 243, 335, ... etc, characteristic of glycerol clusters plus acetate.

Sample preparation for ionization of saccharides was minimal. Samples were mixed with conc. NH_4OH, and allowed to rest for about 0.5h. Generally secondary emission of anions characteristic of various saccharides was less intense than those of the cluster series. However, such emission typically persists for hours after continuous impact by massive clusters. The advantage of this persistence is that it permits MS/MS spectra to be obtained continuously and summed. For example, Figure 1 shows the MS/MS spectrum of sucrose m/z 341, $[M-H]^-$. Cleavage of glucose from fructose is clearly evident by the predominant peak at m/z 179. The MS/MS capability is essential for analysis of saccharides directly from plant tissue. Figure 2 shows the MS/MS spectrum of the m/z 341 obtained directly from a piece of banana placed on the probe tip and subjected to MCI.

LC-ESIMS and In-source CID of Derivatized Oligosaccharides

Subhodaya Aduru and Kym F. Faull
Dept of Chemistry & Biochemistry and Psychiatry & Behavioral Sciences.
University of California Los Angeles, Los Angeles, CA 90024

Separation of oligosaccharides by conventional HPLC methods is complicated because of their high polarities and their detection is difficult because of the lack of UV absorbing groups To provide an easy and simple way to perform on-line LC-ESIMS of oligosaccharides trimethylaminophenyl ammonium (TMAPA) labeling (1) is used to enable the separation on a polyhydroxyethyl aspartamide column under hydrophilic interaction (HILIC) conditions and their detection by electrospray ionization mass spectrometry (ESIMS). TMAPA treatment provides a stable cation in ESI-MS even at high orifice potentials because of the permanent positive charge on them This in turn leads to good sensitivities during on-line LC-ESIMS.

Trimethylaminophenylammonium chloride (0.5 mg) and sodium cyanoborohydride (1.25 mg) were dissolved in 354 ul of water containing 41 ul of glacial acetic acid. 40 ul of this reductive aminating solution was added to the dry oligosaccharide (0.1-10 ug) and heated at 363 K for one hour and then dried in vacuum centrifuge. The dried residue was redissolved in 0.1% TFA /90% Acetonitrile, pH adjusted to 3 0 by ammonia (solvent A) and analyzed by mass spectrometry or injected onto polyhydroxyethyl aspartamide column (2.00 mm i.d , 25 cm length) equilibrated in solvent A The column was eluted with an increasing gradient of water (1%/min). The effluent from the column was connected directly to the electrospray ionization source of a Sciex API III mass spectrometer.

Figure 1 shows the total ion chromatogram for the resulting separation of a mixture of TMAPA tagged malto-oligosaccharides. The peaks A, B, C and D correspond to glucose, maltotriose, maltopentaose and maltoheptaose, respectively The corresponding ESI mass spectra for maltopentaose and heptaose show the singly charged TMAPA cations at m/z 963 and 1288 respectively. The intensity of the signals for the oligosaccharide TMAPA cations was found to be uninfluenced by orifice voltage above 35V indicating their high stabilities.

The TMAPA tagged oligosaccharides did not fragment under in-source CID conditions to give any structurally significant fragment ions. Therefore, peracetylation of the malto oligosaccharide TMAPA was carried out in an attempt to produce a derivative which might yield structurally significant fragment ions. Peracetylation of TMAPA labeled oligosaccharides was carried out by adding 50 ul of a 2:1 mixture of trifluoroacetic anhydride and glacial acetic acid. After sonicating for 10-15 minutes the reaction mixture was dried in a vacuum centrifuge, redissolved in 0.1% TFA/ 90% acetonitrile and analyzed on the Sciex instrument. ESI mass spectra of peracetylated oligosaccharide TMAPA at low orifice potentials show doubly charged, protonated molecular cations and no significant fragment ions. At high orifice potentials only doubly charged, sodiated molecular cations and sequence specific fragment ions are observed. Figure 2 shows the fragmentation of peracetylated maltoheptaose TMAPA at the glycosidic linkages at an orifice potential of 120V. The fragment ions observed are from the reducing end containing the glycosidic oxygen and one positive charge. Hence a mixture of oligosaccharides is tagged with TMAPA which facilitates their separation and detection and subsequently peracetylated to obtain structurally meaningful fragment ions.

Improved MS Analysis of Oligosaccharides Derivatized as Fluorinated Glycosylamines

Huang, Z.H., Xu, Naxing, and Gage, D.A.

MSU-NIH Mass Spectrometry Facility, Department of Biochemistry, Michigan State University, East Lansing, MI 48824

Major methods currently used for the direct sequence determination of oligosaccharides involves the introduction of a chromophoric, lipophilic, or charged tag to the molecule prior to analysis by mass spectrometry. The derivatizing function is chemically bonded to the analyte at the reducing end either by direct condensation with an amine, e.g., 2-aminopyridine (glycosylamine-type) or by reductive amination using an amine, e.g., p-aminobenzoic ester and borohydride (amino-deoxyalditol)

Though successful in analytical practice, these methods are tedious and time-consuming, requiring subsequent purification and desalting by HPLC or other means. Sequence data can usually be provided by using PI-(glycosylamine) or NI-mode (amino-deoxyalditol) of ionization, however, only limited information was available regarding the connection pattern of parent sugars.

To overcome these difficulties, we describe here a simple protocol for oligosaccharide analysis based on the used of glycosylamines containing a fluorinated aniline residue.

Methods

Derivatization: The oligosaccharide, 10 µg was allowed to heat with an excess of m-tetrafluoroethoxyaniline (TFEA) in a mixture of HOAc in 8:2 MeOH-water at 80°C for 1-2 h. The resulting mixture was evaporated under reduced pressure at < 50°C to provide product for direct MS analysis.

Mass Spectrometry:

FAB-MS - JEOL JMS-HX110 double focusing mass spectrometer for FAB-MS. Matrix: glycerol-thioglycerol-dimercaptosuccinic acid (G+TG+DMSA) for PI-, thioglycerol-hydroxyethyl disulfide (TG+HEDS) for NI-FAB.

MALDI-MS - PerSeptive Biosystems Voyager Elite mass spectrometer equipped with a nitrogen laser (337 nm, 3 ns pulse). Matrix: alpha-cyano-4-hydroxycinnamic acid

Results

* The "one-vial derivatization" shows complete conversion, requiring no transfer and additional purification, and possible for handling low µg of analytes
* Strong and sustained ion signals (30-50 x increase in intensity) can be obtained, greatly facilitating MS/MS measurements.

* Unambiguous information regarding the sugar sequence (Y-ions) can be obtained under PI-FAB CID conditions. Using this method the sequence of xyloglucans obtained from cyclamen seed was determined and the results were in full agreement with that by NMR.
* Characteristic fragmentation patterns were obtained for disaccharides with different linkage position under NI-FAB CAD-MS, suggesting potential use for isomer discrimination purpose.
* Low picomole detection can easily be achieved under PI-MALDI, further studv on post-source degradation is in progress.

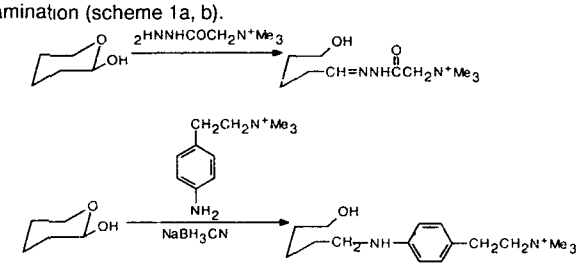
MALD/I and electrospray mass spectrometery of cationic oligosaccharide derivatives.

T. J. P. Naven and David J. Harvey
Dept. Biochemistry, University of Oxford, Oxford, OX1 3QU, UK.

Oligosaccharides exhibit poor ionisation efficiencies in both MALD/I and electrospray (ESI) compared with peptides. We have investigated this poor ionisation efficiency by derivatising oligosaccharides with cationic compounds: Girard's T reagent and *p*-aminophenethyltrimethylammonium acetate (APTMA). The former proceeded by way of hydrazone formation whilst the latter via reductive amination (scheme 1a, b).



Scheme 1a, b (remaining hydrogens, hydroxyl groups and monosaccharides have been omitted for clarity)

The Girard's T derivatisation required no clean-up step prior to MALD/I and ESI, whereas the APTMA derivatisation employed separation on a normal phase amide column. Both compounds possessed a constitutive cationic site and this component enhanced the ionisation efficiency of the oligosaccharide derivative in both MALD/I and ESI. In MALD/I both derivatives formed the M^+ ion (as opposed to the sodium and potassium adduction observed for underivatised oligosaccharides), in ESI the Girard's T derivative formed only the singly charged ion M^+, whereas the APTMA derivative multiply charged, with the $[M^++H]^{2+}$ the most intense ion. The detection limits determined are shown in table 1.

Table 1 Comparison of detection limits obtained by MALD/I and ESI for derivatised and underivatised maltoheptaose. (- detection limit not determined any further because of the presence of the unreduced species).**

Derivative	MALD/I		ESI	
	Ion formed	(fmol)	Ion formed	(fmol)
Underivatised maltoheptaose	$[M+Na]^+$	400	no signal	
Girard's T	M^+	50	M^+	12
APTMA	M^+	800 **	$[M^++H]^{2+}$	3

Matrix Assisted Laser Desorption Ionization with an External Source Quadrupole FTMS for the Analysis of Oligosaccharides

Carlito B. Lebrilla, Steven T, Fannin, James A. Carroll, Jiangyue Wu
Department of Chemistry, University of California, Davis, CA 95616

Oligosaccharides have many diverse and important roles in biological systems It has been determined, for example, that saccharides (in the form of glycoconjugates) play important roles on the surfaces of cells such as recognition processes and binding of cells to antigens, hormones, enzymes, proteins and to other cells.[1] As a result, the interest for the development of analytical methods for their characterization has increased.

With the advent of new soft ionization techniques, e.g , Matrix Assisted Laser Desorption Ionization (MALDI), mass spectrometry has become an attractive method for the structural analysis of compounds with biological origin. The MALDI technique favors the production of pseudomolecular ions for large thermally labile compounds and therefore MALDI has proven to be particularly useful for biological applications

It has been shown that MALDI can be successfully coupled to an external source Quadrupole Fourier Transform Mass Spectrometer (FTMS) for the analysis of peptides and proteins.[2] Experiments in our laboratory have been performed to determine the utility of MALDI coupled with an external source Quadrupole Fourier Transform Mass Spectrometer (FTMS) for the analysis of various oligosaccharides

Figures 1 -4 show examples of MALDI/FTMS spectra of various oligosaccharides analyzed. The MALDI source was produced by simply removing a stainless steel mesh which functioned as part of a side electrode of a LSIMS source With this modification, either ionization method (LSIMS or MALDI) could be used without any other modifications to the hardware A nitrogen laser (337 nm) was mounted on the FTMS system frame, aimed and focused directly at the sample 2,4-Dihydroxybenzoic acid was used in ethanol. Oligosaccharide concentrations ranged from 0.5 to 2.5 mg/ml in methanol. Typical matrix/analyte molar ratios ranged from 300 1 To 1000:1. The analyte and matrix were applied (1μlit each) to a stainless steel probe tip and dried with a stream of air. The probe tip was inspected for proper crystal formation before each experiment

The spectra demonstrate that the combination of MALDI and external source FTMS is a promising technique for the analysis of oligosaccharides. Little fragmentation is observed, providing intense pseudomolecular ion signals. Most recently, we have begun an investigation for the analysis of branched oligosaccharides. Figure 5 shows a MALDI/FTMS spectrum for Trifucosyllacto-N-Hexaose extracted from human milk The spectrum indicates strong pseudomolecular ion signal, loss of fucose monomers and the presence of the characteristic $^{0,2}A$ fragments due to a reducing sugar

MALDI-MS Applications: Carbohydrates

K. O. Börnsen, M.D. Mohr, H. M. Widmer; Ciba-Geigy Ltd., Basle, Switzerland

During the last years matrix assisted laser desorption and ionization mass spectrometry (MALDI-MS) has become a well established analytical method in biochemistry, especially in the field of peptides. High sensitivity, broad mass range, absence of any fragmentation (in linear time of flights instruments) and fast sample preparation are the main reasons for this success. However MALDI measurements of carbohydrates reached not the quality of peptides measurements. Therefore new methods and strategies have been developed in our laboratory to produce better spectra with a high reproducibility. Improvements, limitations and the behavior of carbohydrates with MALDI will be presented.

After a matrix evaluation it was found that a 3:1 mixture of dihydroxy benzoic acid (DHB) and hydroxy isoquinoline (HIC) /1/ as matrix yielded in best results for carbohydrates. This additive to the classic DHB matrix effects a much better crystallization behavior, but the original matrix properties of the DHB, however, are conserved. With this new matrix mixture it was possible to reach sample detection limits of 5 fmol/µl (equivalent to an amount of 0.5 fmol on the probe tip). By doing fast vacuum drying /2/ of the matrix/sample solution, a high reproducibility and quantitative data could be reached as well.

For further improvements, a desalting method of a few microliter on membrane, was applied to carbohydrate samples /3/. A membrane (Millipore, MF, pore size 0.0025 µm, diameter 25 mm) has been allowed to swim freely on a pure water surface. Five microliter were applicated by a micro pipette onto the membrane. After 30 to 120 minutes of dialysis the sample was sucked off again by the pipette. Especially dextran sulfates samples as examples for sulfated carbohydrates could been measured after desalting on a membrane swimming on water with 0.5% TFA easily. Figure 1 shows the spectra before and after a dialysis of this sample. The new matrix mixture together with this sample pretreatment was applied to dextran oligomers which could be determined up to n=90.

Nafion membranes demonstrate very interesting properties when used for ion exchange and purification of oligosaccharides from peptides. As an application for this, oligosaccharide libraries are measured. These samples derived from glycoproteins are often contaminated by huge levels of proteins as it is shown in Figure 2a. After a five minutes purification of 10 µl sample solution on a Nafion membrane all peptides are adsorbed onto the membrane surface. The resulting oligosaccharide solution is shown in Figure 2b.

These examples show how an optimal sample pretreatment and a good matrix can lead to strong improvements in MALDI experiments.

ANOMERIC CONFIGURATION OF SUGAR NUCLEOTIDES BY FAB MS/MS

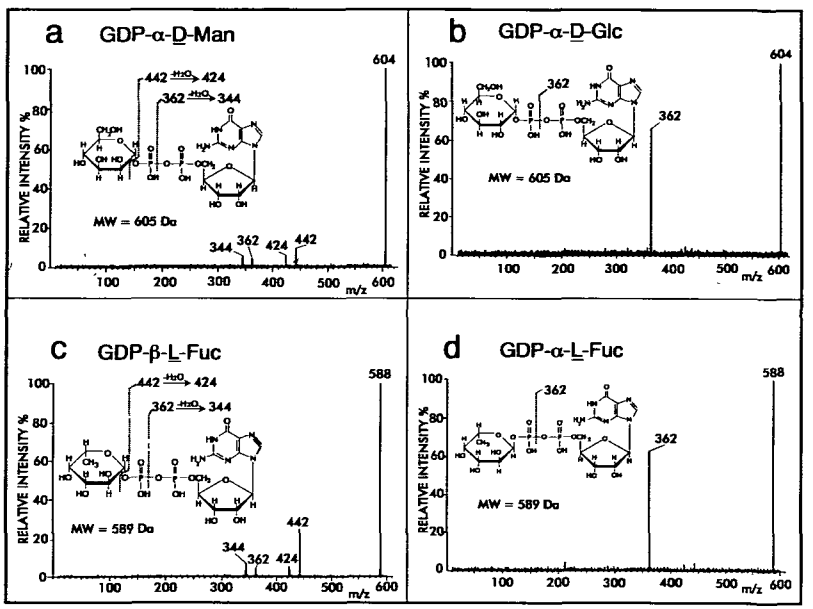
WOLUCKA, B. A., de HOFFMANN, E.

MASS SPECTROMETRY LABORATORY, UNIVERSITY OF LOUVAIN,
DEPARTMENT OF CHEMISTRY, PL. PASTEUR 1,
1348 LOUVAIN-LA-NEUVE, BELGIUM

Until now, the anomeric configuration of sugar nucleotides was usually determined either by non-destructive physicochemical methods, such as NMR and optical rotation measurements, or by different hydrolytic treatments, including alkaline hydrolysis or enzymatic cleavage with specific exoglycosidases and pyrophosphatases, followed by a comparison of the obtained degradation products with authentic sugar and glycosyl phosphates standards. We report here a method using FAB/MS/MS with a Finnigan TSQ70 mass spectrometer.

Very low energy collision induced dissociation, at 0.5 collision offset voltage, of the deprotonated molecules of glycosyl esters of nucleoside pyrophosphates results in distinct fragmentation patterns depending on cis/trans configuration of the phosphodiester and 2"-hydroxyl groups of the glycosyl residue. Sugar nucleotides with cis confguration produce, in MS/MS, only one, very intense fragment corresponding to nucleoside monophosphate, whereas those with trans configuration give weak signals of nucleoside di- and mono- phosphates and their dehydration products.

As shown by a study of twelve different sugar nucleotides, this empirical rule holds for sugar nucleotides having a free 2"-hydroxyl group and no alternative charge location. Owing to its simplicity, sensitivity and tolerance of impurities, the fast atom bombardment tandem mass spectrometry represents a suitable method for determining the anomeric linkage of glycosyl esters of nucleoside pyrophosphates if the absolute configuration of glycosyl residue is known and the compound fulfills the above mentioned requirements.



The figure displays negative ion FAB MS/MS product ion spectra from the $[M-H]^-$ deprotonated molecule of:
(a) guanosine 5'(α-D-mannopyranosyl pyro-phosphate) (GDP-α-D-Man);
(b) guanosine 5'(α-D-glucopyranosyl pyro-phosphate) (GDP-α-D-Glc);
(c) guanosine 5'(-L-fucopyranosyl pyro-phosphate) (GDP-β-L-Fuc);
(d) guanosine 5'(α-L-fucopyranosyl pyro-phosphate) (GDP-α-L-Fuc).
The collision-offset voltage in MS/MS experiments was 0.5 V.
In a and c, the 2" OH and phosphoester of the sugar moiety are in trans, while they are cis in c and d.

LC-MS/MS of Carbohydrates with Post Column Addition of Metal Chlorides using a Triaxial Electrospray Probe

Martin Kohler and Julie A. Leary, College of Chemistry*
University of California, Berkeley, CA 94720-1460

Introduction

The growing interest in the biological role and pharmaceutical application of carbohydrates has led to an increasing demand for faster and better analytical methodology [1]. Based on recent work in our laboratory on differentiating calcium and magnesium coordinated trisaccharides using ESI-MS/MS [2], a method for on-line formation of carbohydrate-metal complexes was developed. After purification by liquid chromatography, the sample is mixed with a metal chloride solution directly within the electrospray ion source, where a carbohydrate-metal complex is immediately formed. Depending on the metal chosen one observes either increased sensitivity in detecting the carbohydrate or informative MS/MS data for structural analysis. The work presented herein focusses on three issues using electrospray ionization: 1) sensitivity enhancement of the oligosaccharide-alkali metal complexes versus the protonated species, 2) the application of post column addition (PCA) of LiCl to enhance the detection limits in LC-MS, and 3) the use of post column addition of $CoCl_2$ and on-line LC-MS/MS in obtaining specific structural information.

Experimental

A commercially available triaxial electrospray probe (Fisons Instruments) was used for the experiments described. This probe consists of three coaxial stainless steel tubes. The sample is delivered to the innermost tube, the metal chloride solution flows through the tube in the middle and the nebulizer gas is delivered by the outermost tube. Conventional (MS) and tandem electrospray mass spectra (MS/MS) were collected on a VG-BioQ (Fisons Instruments) triple quadrupole electrospray mass spectrometer, equipped with an octapole collision cell. Argon was used as a collision gas at a pressure of 1.0–1.2 x 10^{-3} mbar. The collision energy (E_{lab}) was set between 20 and 80 eV.

Results and Discussion

Using a mixture of cellobiose, di-N-acetylchitobiose, Lewis X, and LNFP-V, the formation of oligosaccharide-alkali metal complexes by PCA of metal chlorides of lithium, sodium, potassium, rubidium, and cesium was investigated and their abundances were compared to the protonated species. As expected, a very high coordination affinity of these four oligosaccharides was found for lithium and sodium. For cellobiose, the signal of the $[M+Li]^+$ ion was found to be approximately 70 times more abundant than the corresponding $[M+H]^+$ signal. In an LC-MS experiment with 10 pmol of the carbohydrate mixture, the $[M+Li]^+$ ion was detected at a total sample consumption of 1.7 pmol. However, a sharp drop in affinity is found when alkali metals of larger ionic radii, such as potassium, rubidium, and cesium are used as the PCA reagent. All four oligosaccharides investigated show a gradual decline in affinity in going down the group I metals. The thresholds for the concentration of the PCA reagent and detection sensitivities of the oligosaccharide are in the same range, and in some cases better, than that obtained when an individual carbohydrate is premixed with LiCl without use of the triaxial probe.

In order to obtain linkage specific fragmentation for branched oligosaccharides and structures containing N-acetyl functionalities, experiments with post column addition of $CoCl_2$ were carried out. Since the affinity of cobalt to carbohydrates is considerably lower than that observed with alkali metals, the experimental conditions to form carbohydrate-cobalt complexes like $[M+Co-H]^+$ and $[M+CoCl]^+$ were investigated carefully. LC-MS/MS data were obtained for sample amounts ranging from 1 nmol (Lewis X, LNFP-V) down to 200 pmol (cellobiose and di-N-acetylchitobiose), corresponding to sample consumptions of 83 pmol and 17–33 pmol, respectively (see Figure). Post column addition of metal salts using a triaxial electrospray probe is a versatile technique to form metal complexes of carbohydrates for subsequent on-line MS and MS/MS analysis. The application of this technique for analysis of other compounds like peptides is considered to be straightforward.

Kinetic Energy Release Measurements of Oligosaccharide-Metal-Ligand Isomers Using FAB and ES Ionization

Glenn Smith, Geoffrey Bott†, and Julie A. Leary
Chemistry Dept., University of California, Berkeley, CA 94720
†G.B. Scientific, 701 DeLong Ave. Navato, CA 94945

Previous research in our laboratory has involved complexing $Co(acac)_3$ with various dialkyl tartrates and measuring the KER of ions generated from the unimolecular dissociation of the precursor complex (1) In so doing, we have shown that MIKES can be used to differentiate D- and L- enantiomers of these tartrates. By extending this methodology to mono- and di-saccharides we are capable of distinguishing α and β glycosidic linkages. Additionally, by measuring the KER following the unimolecular dissociation of various nickel complexes possessing monosaccharide-aminal ligands, differentiation of the stereochemistry of hydroxyl groups in isomeric hexose units is possible. The effects of different ionization methods (FAB and ESI) on the unimolecular KER values was also determined.

Two isomeric disaccharides, laminaribiose (β 1,3 glc-glc), and nigerose (α 1,3 glc-glc) were complexed with either racemic $Co(acac)_3$ in the presence of R,R or S,S threohydrobenzoin (THB), or with resolved Δ $Co(acac)_3$. In both cases the disaccharide displaces one of the acetylacetonate ligands to generate a positively charged complex consisting of Co^{3+}, two acetylacetonate ligands, (-1 charge each) and one neutral disaccharide. This precursor ion at m/z 599 is transmitted into the MIKES cell and allowed to undergo unimolecular dissociation. The KER of one of the product ions, m/z 500, is subsequently measured.

In the presence of the chiral resolving agent, R,R- or S,S-THB, a difference in KER accompanying the dissociation is observed for the two isomeric $Co(acac)_2$/disaccharide complexes. Table 1 lists all the KER values obtained for the $Co(acac)_2$/disaccharide complexes both with and without THB as well as for the complexes made with the resolved Δ $Co(acac)_3$. The difference in the KER values indicates a variance in the structure of the two disaccharides. Specifically the differentiation results from the presence of an α or β glycosidic bond between the otherwise identical monomers.

The THB appears to selectively complex one enantiomer of the $Co(acac)_3$, leaving the other free to complex with the disaccharide. The values obtained using the resolved Δ $Co(acac)_3$ suggest that the R,R-THB selectively complexes with the Λ form of $Co(acac)_3$ in the racemic mixture, thus leaving the delta form available for complexation to nigerose of laminaribiose. The use of optically resolved Δ $Co(acac)_3$ supports this hypothesis as observed in Table 1. This is evidenced by the fact that the KER for nigerose/Co(acac) in the presence of R,R-THB is the same as that of the nigerose/Δ Co(acac) complex. The same holds true for the value obtained for the laminaribiose complex in the presence of R,R-THB.

The identification of the stereochemistry of the C-2 hydroxyl group on a monosaccharide, and therefore the distinction between mannose and glucose, was also achieved by observing the unimolceular dissociation of an octahedral complex in which the monosaccharide was complexed to a transition metal ion. In this case, either mannose or glucose was reacted with the octahedral nickel tris-diamino propane complex, yielding the octahedral bis-monosaccharide aminal nickel complex (2). The precursor for this complex, m/z 529, and m/z 293 representing a $Ni(NH_2(CH_2)_3NH_2)$•monosaccharide complex were each analyzed by MIKES, and KER measurements determined for various product ions as shown in Table 2.

Both ESI and FAB ionization produce these precursors, which upon unimolecular dissociation give rise to two, three and four carbon neutral losses, some of which demonstrate different KER values when compared to its isomer. Since the stereochemical difference between mannose and glucose is in the axial vs equatorial positioning of the hydroxyl group at C-2, it seems likely that the monosaccharide coordinates differently to the nickel and this difference in structure is reflected in the different KER values obtained.

ESI-MS/MS Study of Co, Zn, Mn, Cu, and Ca Complexes of Oligosaccharides

Emily M. Sible, Steven P. Brimmer, and Julie A. Leary*
University of California, Department of Chemistry
Berkeley, CA 94720

Previous research in our laboratory has focused on the determination of linkage positions from the MS/MS spectra of linear and branched Ca^{2+} and Mg^{2+}-coordinated oligosaccharides(1). Our current study seeks to extend this methodology by investigating the difference in structural information obtained when various metals are coordinated to two structurally-related carbohydrates, a hexose trimer and a di-N-acetyl pentamer.

Complexes of the trimer, α1,3-α1,6 Mannotriose and the pentamer, Conserved Trimannosyl Core, with the chloride salts of Ca, Mn, Co, Cu, and Zn were made using electrospray ionization in a VG Bio-Q triple quadrupole mass spectrometer. The most abundant precursor ions and the most informative MS/MS spectra were obtained by optimizing variables such as the skimmer voltage, the metal to carbohydrate concentration ratios, the collision energy and the collision gas pressure.

The use of different metals had a significant effect on the optimum carbohydrate to metal ratio, the detection limit of the carbohydrate and the relative abundances of the [M + Metal Chloride]$^+$, [M + Metal - H]$^+$, and the [M + Metal]$^{2+}$, as can be seen in Table 1. For example, changing the concentration of mannotriose from 100 pmol/μl to 10 pmol/μl for either Co or Zn coordination causes the optimum ratio of metal to carbohydrate to change from 1:5 to 1:10 for Co and from 1:10 to 1:100 for Zn. The ionic radii of the metals appear to play an important role in the efficiency of coordination to the oligosaccharides. Ionic radii of 100-110 ppm form the best complexes to carbohydrates(2). The weakness of the Zn^{2+} and the Cu^{2+} complexes may be explained by the fact that their ionic radii are significantly smaller than these values. Table 2 demonstrates the amount of metal needed to produce the most abundant precursor ions and the effect the ionic radii of the metal may play on this ratio.

Examination of the data indicates that the metal used significantly changes the amount of structural and linkage information available from the MS/MS spectra. The Ca^{2+}-coordinated trimer at a concentration of 50 pmol/μl gave the most definitive linkage information for the mannotriose, thus supporting our previous work(1). This was in contrast to the pentamer which gave the most structural and cross-linkage information when coordinated to Mn^{2+}. However, this MS/MS of the pentamer did not permit the unambiguous assignment of the specific linkages in the carbohydrate. Because the dissociation pathways of these complexes were sufficiently different, further investigations of various pentamers, both with and without N-acetyl functionalities, are

currently underway to ascertain specific linkages as well as information regarding the effect the N-acetyl functionality has on metal coordination.

MS/MS of both the pentamer and the trimer when coordinated to Cu and Zn provided no significant structural or linkage information regardless of the collision energy, carbohydrate concentration, or gas pressure used. However, in all cases (even those with Cu or Zn coordination), the first loss observed is that of the hexose ring substituted at the C-3 position, as previously indicated in our studies(1).

In-source and post-source decay fragmentation of oligosaccharides ionized by MALDI

David J. Harvey[1], Glen Critchley[2] and E. Anne Maisey[2]

(1) Oxford Glycobiology Institute, Department of Biochemistry, University of Oxford, South Parks Road, Oxford, OX1 3QU
(2) Fisons Instruments, VG Analytical, Floats Road, Wythenshawe, Manchester, M23 9LE, UK

Introduction

Ionization of complex oligosaccharides by MALDI on linear time-of-flight (TOF) instruments produces strong $[M + Na]^+$ ions with little or no apparent fragmentation. Although mass measurement of these ions can lead directly to a composition in terms of the isobaric monosaccharide content, there is no information relating to sequence, branching or linkage of the constituent sugar residues. When recorded on a magnetic sector instrument, on the other hand, weak fragments are observed which reveal much of this structural information. We have now examined these fragment ions and compared them with fragments observed by post-source decay (PSD) on a TOF instrument fitted with a reflectron.

Experimental

Oligosaccharides were of the type found in glycoproteins (*N*- and *O*-linked) and containing from 3 to 13 monosaccharide residues. In-source decay (ISD) was examined with a Fisons VG AutoSpec QFPD mass spectrometer fitted with an LSI nitrogen laser (20 Hz) and an array detector. TOF PSD spectra were examined with Fisons VG TofSpec E and SE instruments by stepping the ratio of acceleration voltage and reflectron voltage over the required mass range (7 segments were used) with the nitrogen laser (337 nM) firing at 50 shots/segment. 2,5-DHB was used as the MALDI matrix in both cases.

Results and Discussion

In-source fragmentation consisted mainly of glycosidic cleavages of the type common to FAB spectra, together with the production of a few ions that were formed by cleavages of the C_1-C_0 and C_2-C_3 bonds (loss of 101 Da) and cleavage of the C_2-C_3 and C_4-C_5 bonds (loss of 161 Da) of the reducing-terminal GlcNAc residue (Fig. 1). Glycosidic cleavage from the reducing terminus resulted in loss of intact monosaccharides [B-type cleavage, Domon and Costello nomenclature (1)], whereas loss from the non-reducing termini involved elimination of sugar moieties lacking one oxygen atom (Y-type cleavage). There was some evidence to suggest that loss of the sugar residues attached to the 3-position of the branching mannose occurred in preference to loss from the 6-position (Fig. 2) although the number of samples was limited.

The PSD spectra (Fig. 3) were similar in that glycosidic cleavages predominated but the ions produced by ring-cleavage of the reducing-terminal sugar residue were weaker than by ISD. Matrix ions were absent, thus allowing more low-mass fragments to be seen than with ISD.

Oligossacharide Structure Determination on an Ion Trap

Michael R. Asam & Gary L. Glish
Department of Chemistry
University of North Carolina
Chapel Hill, NC 27599

Introduction: Oligosaccharides are important elements in intra- and inter-cellular/molecular recognition mechanisms. Linkage types are part of the information that determine the tertiary structure of oligosaccharides and the tertiary structure is what determines specific recognition, so easily obtained linkage sequences will provide valuable information for computer and other modeling of cellular signalling interactions. Hofmeister et. al.[1] have shown that lithium cationized oligosaccharides have specific MS/MS dissociation patterns indicative of the carbohydrate linkage under low energy CID conditions in a hybrid mass spectrometer. We have used electrospray ionization on a quadrupole ion trap mass spectrometer to examine MS/MS disaccharide dissociation patterns under ion trap conditions. Our studies have concentrated on disaccharides complexed with lithium and sodium.

Experimental: The two sugars gentiobiose and sophorose were provided by Julie Leary of the University of California at Berkeley. The other disaccharides, trehalose, nigerose, lactose, and sucrose were obtained from the Sigma Chemical Company. All electrospray sample solutions were made by dissolving 0.85 mg of a disaccharide into 5 mL of a 75% methanol, 20% water, 5% acetic acid solution to make the concentration 500 μM. Lithium chloride and sodium chloride were dissolved in the 75% methanol, 20% water, 5% acetic acid solution to obtain 500 μM solutions as well. Prior to electrospraying, equal volume amounts of a disaccharide solution and an alkali cationic solution would be mixed on a vortex mixer and then taken into the electrospray syringe. A Harvard Apparatus syringe pump was used at a flow rate of 1μL per minute The electrospray source system is described elsewhere[2] with A1at 60 0 V, AL1 at 28 0 V, AL2 at 27.5 V, and A2 at ground. The instrument used was a Finnigan ITMS and the data collection software was from Finnigan (Revision B).

Results: The same dissociation patterns as those found by Hofmeister et. al. were observed for MS/MS experiments of the lithium cationized disaccharides (see Table 1) The same dissociations for MS/MS experiments of the sodium cationized disaccharides were observed with the exception that collision-induced dissociation (CID) was more difficult to effect, i.e., dissociation of the parent peak required more energy than in the lithium cationized case for all the disaccharides except gentiobiose and sucrose (see Table 2). MS^3 experiments on the $-C_2H_4O_2$ ion show dissociation to the $-C_4H_{10}O_5$ and $-C_6H_{12}O_6$ ions. MS^3 experiments on the $-C_3H_6O_4$ and $-C_4H_6O_4$ ions show dissociation to the $-C_6H_{12}O_6$ ion exclusively. MS^3 experiments on sodium cationized ions were far more sensitive than MS^3 on lithium cationized ions.

Discussion: It is interesting that the lithium cationized species behave differently than the sodium cationized species. If one imagines that the coordinating forces the alkali metals experience are similar it seems logical that the sodium cationized species should behave the same as the lithium cationized species and even loose their cations more readily, thus making CID fragmentation less efficient (due to sodium loss). The experimental data demonstrating that sodium cationized species are harder to dissociate suggests

[1]Hofmeister, G.E., Zhou, Z. & Leary, J.A. (1991) *J Am. Chem Soc. 113*, 5964-5970.
[2]Van Berkel,G.J , Glish, G.L., McLuckey, S.A (1990) *Anal. Chem. 62*, 1284-1294

that the coordinating forces experienced are different. The source of this difference has not been determined, but one possible suggestion is that the second ring of the disaccharide is coordinating to the sodium due to its larger size relative to lithium contributing additional stabilizing energy. Computer modeling experiments are underway to help determine if this suggestion is plausible. The mechanisms postulated by Hofmeister et. al. appear to be valid since MS^3 analyses show that $-C_2H_4O_2$ ions can dissociate to $-C_4H_{10}O_5$ ions.

Table 1: Lithium Cationized MS/MS Product Ions (*m/z*)

Compound	Linkage	289, $-C_2H_4O_2$	259, $-C_3H_6O_4$	229, $-C_4H_6O_4$	187, $-C_6H_{10}O_5$	169, $-C_6H_{12}O_6$
gentiobiose	β-1,6	X*	X	X	X	X
lactose	β-1,4	X		X	X	X
nigerose	α-1,3		X		X	X
sophorose	α-1,2			X	X	X
trehalose	α-1,1				X	X
sucrose**	α-1,2				X	X

*An X indicates the presence of an ion at that m/z resulting from the indicated neutral loss
**Sucrose is glucose-α(1,2)-fructose and the other sugars are glucose-x(x,x)-glucose (or galactose).

Table 2: Sodium Cationized MS/MS Product Ions (*m/z*).

Compound	Linkage	305, $-C_2H_4O_2$	275, $-C_3H_6O_4$	245, $-C_4H_6O_4$	203, $-C_6H_{10}O_5$	185, $-C_6H_{12}O_6$
gentiobiose	β-1,6	X*	X	X	x	x
lactose	β-1,4	x		x	x	x
nigerose	α-1,3		x		x	x
sophorose	α-1,2			x	x	x
trehalose	α-1,1				x	x
sucrose	α-1,2				X	x

*An X indicates the presence of an ion in comparable abundance to the lithium cationized product ion resulting from the indicated neutral loss. Smaller x's indicate the presence of the product ion, but at an abundance much lower than that for the lithium cationized product ion for that neutral loss.

Conclusions: Our results for lithium cationization corroborate Hofmeister et. al.'s findings and our results for sodium cationization show the same fragmentation patterns, but the conditions needed to obtain fragmentation of the sodium cationized disaccharides are somewhat different. In addition, we have been able to show through MS^3 experiments that the dissociation mechanisms postulated by Hofmeister et. al. are correct. The ion trap seems well suited for these types of analyses since MS^n is routine, i.e., as would be needed for tri-, tetra-, etc. saccharides. Such experiments will be undertaken in the near future.

High energy CID spectra of complex oligosaccharides ionized by MALDI.

Robert H. Bateman[1], Martin R. Green[1] and David J. Harvey[2]

Introduction

Complex oligosaccharides ionized by MALDI give spectra containing dominant $[M + Na]^+$ ions which are excellent for profiling oligosaccharide mixtures obtained from biological sources. Although such ions give some compositional information on the oligosaccharides, no information is present relating to the sequence, branching or linkage of the constituent monosaccharides. Fragments produced by post-source decay, examined on a time-of-flight instrument, provide only partial information. More information should be present in high energy collision spectra but such spectra are not obtainable on a scanned magnetic sector instrument because of the pulsed nature of the ion source. We have, thus, examined the high-energy collision spectra of $[M + Na]^+$ ions produced by MALDI (2,5-DHB matrix) from complex oligosaccharides using a magnetic sector instrument fitted with an orthogonal TOF analyser.

Experimental

Spectra of typical *N*-linked oligosaccharides (high mannose and complex) were examined with a VG AutoSpec-TOF mass spectrometer. This instrument has a double focusing magnetic sector and an orthogonal acceleration time-of-flight mass analyser in a tandem configuration. The MALDI source uses a pulsed 337 nm nitrogen laser and is held at 8 kV. The magnetic sector was used to select the precursor ion at a resolution of approximately 1500 (10% valley) and these ions were collisionally activated at 800 eV energy using xenon. The complete packet of precursor and product ions resulting from each laser pulse was orthogonally accelerated into the time-of-flight mass analyser and the product ion spectrum was recorded using a 1 GHz time-to digital converter. This process was repeated for each laser pulse at a repetition rate of 10 Hz until most of the sample loaded onto the target had been consumed.

Results and Discussion

The fragment ions in the high energy collision spectra were considerably different from those produced by either post-source decay (PSD) on a time-of-flight instrument or by in-source decay on a magnetic sector mass spectrometer. Ions in the high energy spectra were produced both by glycosidic cleavage and, more significantly, by ring cleavage. Major differences between the PSD and high energy spectra included a series of ions produced by cleavage of the C_1-C_2 and C_0-C_1 bonds of most constituent monosaccharides and which provided considerable structural information. These ions enabled branching patterns to be obtained from most oligosaccharides examined, particularly the high-mannose compounds (Fig. 2). Many more fragment ions, containing mainly the non-reducing terminal residues, appeared at low mass (Figs. 1-3) than in the PSD spectra. Ring cleavage also resulted in loss of carbon atoms 1 and 2 from the reducing-terminal GlcNAc. Complex oligosaccharides (see Fig. 3) produced major ions by cleavage adjacent to the GlcNAc residues of the antennae.

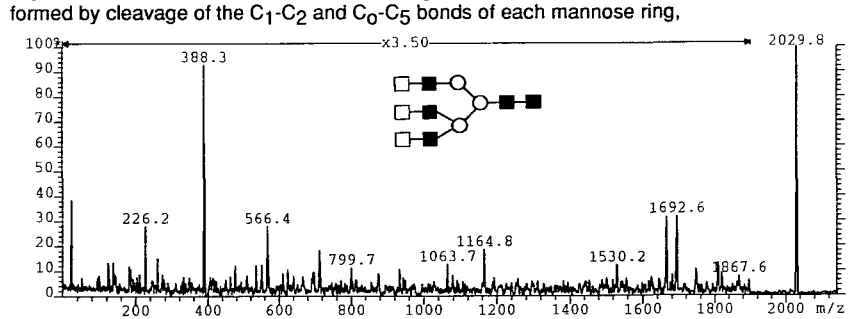

Fig. 3. MALDI OA-TOF spectrum of $(Gal)_3(GlcNAc)_5(Man)_3$ (symbols as Fig. 1 plus □= Gal). Ions at *m/z* 1664 and 1692 are formed by loss of Gal-GlcNAc by glycosidic and ring-cleavage (C_1-C_2 and C_0-C_5 bonds of GlcNAc) respectively. *m/z* 1164 is loss of $(Gal)_2(GlcNAc)_2Man$.

USING AEROSOLS FOR MALDI LIQUID INTRODUCTION

Gang Wei, Xun Fei, Lin He, and Kermit K. Murray
Department of Chemistry, Emory University, Atlanta, GA 30032

Aerosol matrix-assisted laser desorption/ionization was developed two years ago as a method for coupling direct liquid introduction with MALDI mass analysis.[1] The approach is simple: rather than depositing the solution of matrix and analyte on a solids probe, the matrix and analyte solution is sprayed directly into the mass spectrometer. A high speed pumping system and a heated drying tube are used to remove solvent and carrier gas, producing dried aerosol particles containing matrix and analyte. The collimated aerosol beam is irradiated with a 355 nm frequency tripled Nd:YAG laser and the resulting ions are mass analyzed in a linear time-of-flight mass spectrometer. The aerosol MALDI apparatus has been successfully coupled with liquid chromatography for on-line LC/MALDI-MS.[2]

A second aerosol MALDI apparatus, based on the original apparatus design,[3] has been constructed at Emory University. Two initial modifications have been made: one is the replacement of the metal nebulizer with a glass concentric nebulizer, and the second is delayed ion extraction. The glass nebulizer provides a reproducible spray as well as improved nebulization efficiency. A plot of pressure in the ionization chamber and the flight tube as a function of liquid flow rate is shown in Figure 1. The carrier gas flow rate was 0.25 L/min. Chamber pressures are acceptable up to a liquid flow rate of at least 1.5 mL/min. At a typical liquid flow rate of 0.5 mL/min., the chamber pressures are three to ten times lower with the glass concentric nebulizer than with the metal nebulizer.[3] Further improvements are currently being sought that will allow aerosol MALDI operation with a smaller and less expensive pumping system.

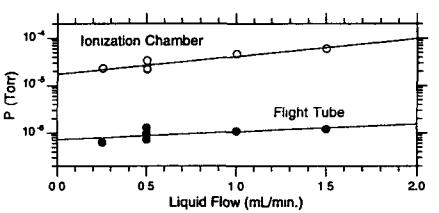

Figure 1. Operating pressures in the aerosol MALDI apparatus using a glass concentric nebulizer.

Aerosol MALDI delayed ion extraction provides information that is of fundamental interest as well as useful in designing instrument improvements. Figure 2 shows aerosol MALDI mass spectra of vitamin B-12 at successively larger delay times between the laser pulse and the 3 kV, 40 ns rise time pulsed extraction. The vitamin B-12 $[M\text{-}CN+H]^+$ and $[M\text{-}CN+Na]^+$ peaks occur at 70 µs flight time. Peak broadening results from ion velocities toward and away from the detector. A longer delay or a larger ion velocity will result in a greater ion spatial spread when the acceleration field is activated. The rate of peak broadening thus gives an indication of the velocities of the photoejected species.[4]

Peak widths for 21 vitamin B-12 data files (five of which are shown in Figure 2) are shown in Figure 3. The peak width was obtained from a fit to a gaussian functional form. Calculations show that the peak width at zero delay time is due almost entirely to the approximately 0.2 mm width of the ionizing laser beam. Additional broadening is due to the component of the ion velocity along the flight tube axis. A fit to these data was performed using an average ion velocity component to generate a gaussian peak width and convoluting this peak with the zero delay time peak. The average ion velocity was optimized in a least squares fit to the data and this fit is shown as a line in Figure 3. The resulting velocity for vitamin B-12 is 740 ± 100 m/s and is consistent with other determinations of the velocity of

MALDI formed ions.[5] Experiments are currently underway to limit the detector solid angle in order to resolve peaks corresponding to the forward and backward ejection velocity components.

Design parameters of a gridless ion mirror for post source decay analysis

Jianru Zeng, Michael Karas, Franz Hillenkamp

Institute for Medical Physics and Biophysics
Robert-Koch-Straße 31, 48149 Münster, Germany

Although either linear or reflectron time-of flight instruments can be used with their respective advantages and disadvantages for the measurement of intact MALDI-ions, structure elucidation of analyte ions based on metastable-ion analysis (PSD-analysis) requires a reflectron instrument. All reflectron configurations, single-, double-stage and gridless ones, can be used, in principle, but, with differences in their practical performance, e.g. in the range of the usable "mass window" and thus, the number of steps required to register a complete PSD mass spectrum.
In this poster, the performance of a gridless ion mirror for PSD analysis is reported. For the configuration used (VISION 2000, Finnigan MAT) a potential distribution within the ion mirror can be chosen , which optimizes time- and space focusing relatively independently of each other. The ion optical calculations (SIMION) were verified experimenally, followed by an empirical optimization of the potential settings Under optimized conditions, a large usable mass window and good mass resolution can be achieved even with a standard small detector (20 mm diameter) (Fig. 1).

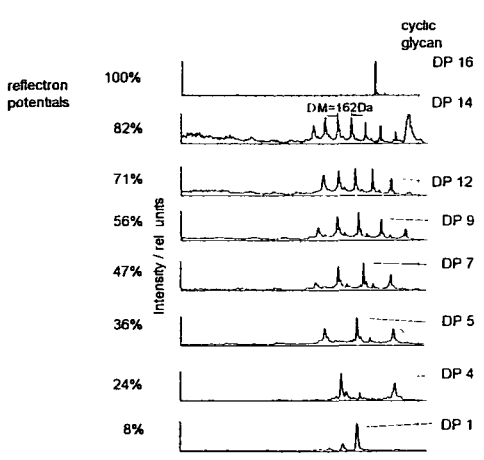

Figure 1: Post source decay spectra with different reflectron potentials for Vision 2000. "Mass window" is more than 40%. Analyte: cyclic glucan DP 16; Matrix: 2,5-DHB; Laser: 337 nm

In a single-stage RE-TOF-MS, a linear relationship exists between the flight time and metastable-fragment ion mass. In a two-stage reflectron TOF-MS, theoretical calibration based on instrument geometry and measurement of ion source and reflectron potentials is possible. In a gridless reflectron analyzer, however, this method of calibration is no longer applicable because of the penetration of the reflectron electric field into the "field-free" drift region. It appears straightforward to test an empirical calibration procedure. One concern is whether a calibration function indepent of the individual mass windows can be obtained. Figure 2 shows a window-independant calibration function: (M-Mc)/M= f[(t-to)/t]. In this figure, relative flight time differences are plotted vs. the relative mass difference. Using this calibration function combined with a correction factor for the postacceleration SEM detector, all fragment masses have been determined to better than 0.5 Da, resulting in average accuracy of better than 0.1%.

Precursor ion selection is also very important for post source decay analysis. The resolution of precursor ion selection is influenced not only by the geometry of blanker but also the TOF resolution at the location of beam blanker (which represented by linear TOF spectra). Delayed ion extraction can improve the resolution of linear TOF and thus the resolution of precursor ion selection, as shown in Figure 3. In this case the resolution is about 90 (Figure 3).

A Method for Acquiring Daughter-Ion Spectra in a Reflecting TOF Instrument

G. Westmacott, W. Ens and K.G. Standing
Dept. of Physics, University of Manitoba, Winnipeg, Canada, R3T 2N2

Reflecting time-of-flight mass spectrometers provide an elegant method of obtaining daughter-ion spectra from metastable decay of selected parents [1]; the method is widely used in matrix assisted laser desorption/ionization (MALDI). For one- or two-stage mirrors, daughter ion peaks with molecular mass (m_d) near the parent mass (m_p) have comparable resolution to the parent and appear in the spectrum close to their correct mass according to the usual calibration preformed with known parent ion species. This is because the daughter ion energy is close to optimum for the mirror so it provides a compensation for the fraction of energy lost $(m_p-m_d)/m_p$ in the decay, as well as focusing for the energy spread. However, the energy of smaller daughters is further from the optimum, resulting in broader peaks and greater displacement from the usual mass position. For this reason, daughter ion spectra are normally acquired in segments with different mirror voltages. As the mirror voltage is reduced to optimize for a given daughter ion, the daughter ion flight time increases to that of the parent ion. This procedure requires a different calibration for each voltage which must be measured accurately, and a rather complicated algorithm to reassemble a single mass spectrum

We have developed an alternative method which is the same in principle but has practical advantages. Instead of leaving the target voltage constant and reducing the mirror voltage, the mirror voltage is left constant and the target voltage is increased. This has advantages because the flight time and the calibration depend strongly on the mirror voltage but only weakly on the target voltage; accurate measurement of the voltages is not necessary. As the target voltage is increased from the optimum for the parent ions, V_o, to V_a, to bring the average energy of a selected daughter ion mass to the optimum, its flight time is decreased to its correct m/z value predicted by the original parent ion calibration. That is, when V_a/V_o is close to m_p/m_d, the daughter ion energy is close to the optimum energy for the original mirror setting and so its mass can simply be determined from the original calibration. Of course, for ions within a segment that deviate from the optimum ratio, a small correction is still necessary, which for a single-stage mirror has a simple linear dependence on the flight time. Finally, since a single calibration applies at least approximately to all the segments, they may be simply joined together end-to-end to reassemble a single mass spectrum. Fig. 1 illustrates this for substance P.

For a single stage mirror the difference between the fragment ion apparent mass (the mass of the fragment as determined from the parent calibration) and the calculated fragment ion mass m_d is given by

$$\Delta m_d = (V_a/V_o)\, m_d{}^2/(4m_p) - m_d/2 + (V_o/V_a)(1/4)$$

where V_o is the acceleration voltage that optimizes the mirror for the parent ions Fig. 2 shows the results for substance P showing Δm_d versus m_d for four different V_a/V_o ratios. Fitting the above equation to the data gives effective ratios of the accelerating voltages. Applying the same correction Δm_d to the fragment ions of bradykinin, using the effective accelerating voltages as determined from the substance P data, gives corrected masses usually within ± 0 5 u of the calculated masses for similar steps in V_a as shown in Fig. 1.

[1] X. Tang et al, Rapid Comun Mass Spectrom. 3 (1989) 443.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

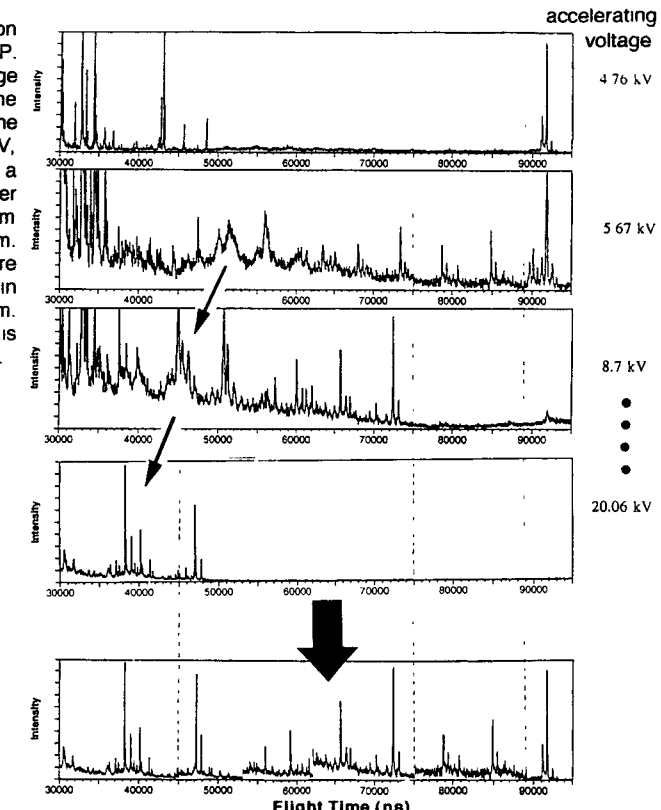

Fig 1. Fragment ion spectra for substance P. The accelerating voltage is increased from the optimum value for the parent ion V_o = 4 76 kV, bringing the energy for a segment of daughter ions in each spectrum close to the optimum. These segments are simply joined together in the bottom spectrum. The mirror voltage is constant at V_m = 5.6 kV.

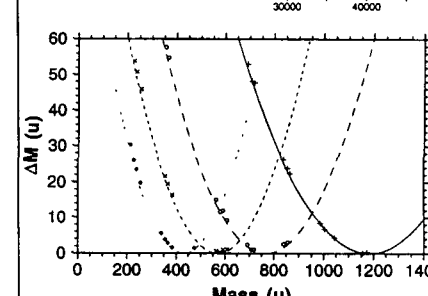

Fig 2. The difference between apparent and calculated fragment ion masses for substance P is plotted for four different accelerating voltages, V_a, correspond to ratios V_a/V_o = 1.19 (+), 1.83 (o), 2.46 (x) and 3.23 (♦), where V_o = 4.76 kV. Fitting the theoretical function for Δm_d gives effective ratios of the accelerating voltages V_a/V_o = 1 14, 1.76, 2.36 and 3 13 respectively. The mirror voltage is constant at V_m = 5.6 kV.

Time of Flight PSD Measurements with Precursor Ion Selection

Introduction

MALDI TOF MS has been used successfully to obtain structural information from a variety of biological molecules, including peptides (1). To obtain useful post source decay information from a multi-component sample, such as an enzymatic digest of a protein, it is essential to devise a method that detects fragment ions which result from only a single parent ion in the mixture. To this end, an ion preselection devise has been designed with a transmission window resolution of at least 150 m/Δm. Presented here is an example of ion preselection, and peptide sequencing directly from a tryptic digest of myoglobin at the 100-500 fmol level with average mass errors of better than 0.05% for FAST™ PSD fragment ions.

Methods

All measurements were performed on a Bruker REFLEX TOF MS (Bruker Analytical Systems, Inc., Billerica, MA) configured with a Nitrogen 337nm laser. Reflectron mode spectra were acquired using a V-trajectory two stage gridless reflector

Horse heart myoglobin (Sigma) was denatured in a 30% methanol solution adjusted to pH approx 7.5 with ammonium bicarbonate. This solution was diluted with distilled water to 5% methanol, and the myoglobin was digested with sequencing grade modified trypsin (Boehringer Mannheim) overnight at room temperature. Aliquots of this digest were acetylated with acetic anhydride / methanol. Acetylation was performed on the sample stage. Aliquots of 100 and 500 femtomole were spotted on the sample stage with alpha-cyano-4-hydroxycinnamic acid (Sigma) matrix by the conventional dried drop method.

FAST spectra were acquired after the ion preselector was set to permit transmission of the parent ion of interest only. Preselection in the first field region is done with a pulsed deflection unit (FastFilter™) which has a set of deflection plates connected to a +/- 1 kV power supply and controlled with a fast pulse generator (Model DG 535, Stanford Research Sys., Stanford, CA)

Results

PreSelection of Ions using FastFilter A useful ion preselector provides a narrow transmission window to isolate a unique peptide ion, and its associated metastable species, only. It is also important to ensure that mass assignments are not altered by the preselection process. (Figure 1) shows a molecular weight spectrum of three synthetic peptides with nominal masses of 1425, 1434 and 1443 Da measured with and without the preselector. Note the baseline resolution of 160, without a mass shift, for preselection of the 1434 Da species.

FAST Analysis of Myoglobin Tryptic Peptides Despite the significant difference in precursor ion intensity resulting from a tryptic digest, FAST spectra obtained still contain many well resolved fragment ions even for low intensity tryptic peptides. Since only a very small portion of the

sample spot is consumed per FAST measurement, many tryptic peptides can be measured from the same 1 ul sample deposition to produce a quality FAST spectrum.

Assignment of post source decay ions is greatly facilitated through comparison with FAST spectra of the corresponding acetylated peptides. For example, comparison of the FAST spectra of the native 1854.8 Da peptide (Figure 2) and its acetylated version (Figure 3) unambiguously identifies the b3 to b8 ions. Clear assignment of b type ions also helps to identify the y type ions, such as y9 to y15 here, as well as "internal" fragment products.

Conclusions

The utility of FAST analysis for peptide sequencing from a unfractionated protein digest at the low femtomole has been shown. A precursor ion selector (FastFilter) capable of a transmission window resolution of at least 160 is now available for the Bruker REFLEX TOF MS. The FastFilter, combined with the low sample consumption of MALDI, permits the acquisition of multiple high quality peptide post source decay spectra from a single protein digest spot. Comparison of FAST spectra of native peptides with those of a simple derivative, such as amine terminal acetylation, affords true peptide sequencing from digests.

High Resolution Precursor Ion Selection for Post Source Decay Experiments

Armin Holle, Melvin A. Park, Detlev Suckau; Bruker-Franzen Analytik GMBH, Fahrenheitstr. 4, 28359 Bremen, Germany

In the past few years, matrix assisted laser desorption/ionization - time-of-flight mass spectrometry (MALDI-TOF) has grown rapidly in its importance in the analysis of biological molecules. As an extension of MALDI-TOF, post source decay (PSD) has become an accepted and frequently used method for obtaining sequence information for picomole amounts of low molecular weight (< ~2000 amu) peptides [1]. We have developed a precursor ion selector (preselector) which allows one to select ions on the basis of their time-of-flight (TOF), that is their mass. PSD analysis can then be performed on these ions free from the interference of other mixture components [2]. Such an experiment is in fact a tandem MS analysis.

Samples of 10000 Da MW poly(ethylene glycol)(PEG) were dissolved in sinapinic acid in a ratio of about 1:1000. Angiotensin II samples were prepared by dissolving the peptide in sinapinic acid in a ratio of 1:5000. Mass spectrometric analyses were performed in a Bruker Reflex™ TOFMS. The preselector we have developed is of the Bradbury-Nielson type. It consists of a set of electrodes which lay across the ion beam. Ions are gated by applying equal potentials of opposite polarities to adjacent electrodes.

As in any tandem mass spectrometer one of the key specifications is the mass resolution with which precursor ions can be selected. We measured the mass resolution of our preselector using samples of 10 kDa MW PEG. The PEG was measured in linear mode and produced ions at every flight time in the range of interest. As seen in the figure, the ion intensity can be used as a measure of transmission efficiency under various preselector conditions. Measured in this way, the resolution of our preselector was found to be about 120.

However, unlike other spectrometers, the useful mass resolution of the first stage of a tandem TOF mass spectrometer cannot be based simply on the parent ion signal. Although in general the useful resolution of the preselector decreases with decreasing daughter ion mass, we found that our preselector provides high resolution preselection (~100) over a wide mass range.

In practical terms, if one has a peptide mixture with, for example, peptides of mass 990 amu, 1000 amu, and 1010 amu, one can obtain a daughter ion spectrum of each peptide with nearly no interference from the other peptides in the mixture.

Probing the Outer Limits of Performance for MALDI-TOF MS and MS-MS

Marvin Vestal, Peter Juhasz, Calvin Blakely, and Stephen Martin
PerSeptive Biosystems, Inc., 500 Old Connecticut Path, Framingham, MA 01701

I. Background. In a very early work Wiley and McLaren [1] described a "time-lag energy focusing" technique for correcting initial velocity distributions in a two-field, pulsed ion source. In this instrument the ions are produced in a field free region, and the accelerating field is turned on by application of a fast pulse at a predetermined delay time after initial ion formation. More recently, Brown *et al.* [2] and Reilly *et al.* [3] have applied similar mass analyzers to MALDI, and have shown significantly improved resolution for selected masses as a function of the delay time and the pulsed field in the ion source. Following the approach of Wiley and McLaren theoretical expressions for the optimum time delay and maximum mass resolution have been derived. Most important prediction of the theory is that the maximum mass resolution scales linearly with the effective length of the TOF analyzer.

II. Experimental. Three geometries were compared in the present study: TOF analyzers of 1.3m (*RP*), 2.1m (*EL*), and 4.2m (*XL*) drift lengths. All of these analyzers were equipped with a single-stage coaxial ion mirror. The delayed extraction ion source had two-stage acceleration. Three high voltage power supplies, a delay generator, and a fast high voltage switch used for delayed ion extraction. This arrangement provided three independently variable parameters: the extraction delay, the field prior to ion extraction, and the extraction field. The high voltage supplies were independently variable up to 30kV *via* 16-bit DACs. The time delay is set by a computer controlled delay generator. The high voltage switch had a transition time of 20 nsec.

III Results. Significantly improved mass resolution was found in delayed extraction MALDI over static MALDI amounting to a factor of four in the linear mode and a factor of two in the reflector mode. Figure 1 compares mass resolution obtained on the 1.3m and the 4.2m analyzers in the linear mode. Although the resolution is clearly proportional with the drift length the proportionality is weaker than linear. In the reflector mode a closely linear relationship was observed as demonstrated in Figure 2. The maximum resolution observed on bovine insulin was in excess of 12000.

Mass accuracy also increased in proportion with the mass resolution. The increase over static MALDI is around 5-10fold.

Chemical noise due to ion fragmentation in the accelerating field is reduced in the delayed extraction experiments. An overall increase in ion stability was verified by the decreased level of metastable ions in the PSD spectra in delayed extraction mode. Signal-to-noise, however, remained the same as in static MALDI due to a less noisy background.

High resolution mass spectra can be obtained for peptide mixtures with delayed extraction in both linear an reflecting analyzers without the severe discrimination often encountered in static MALDI.

Applying a slightly retarding field in the ion source prior to ion extraction has the beneficial effect of substantially reducing the matrix background without compromising the resolution or sensitivity.

ENHANCING RESOLUTION IN LINEAR MALDI-TOF MS

Scot Weinberger, James Kenny and Rich Kornfeld
Hewlett-Packard Company, Bay Analytical Operation, Palo Alto, CA. 94304

Introduction

Much of the popularity of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) is due to its ability to determine molecular weights of polymers, especially biopolymers, present at femtomole levels in complex samples rapidly without significant operator expertise. In most cases linear MALDI-TOF MS produces spectra with resolution that may compromise the ability to assign molecular weight accurately or to differentiate between species of similar mass present in a mixture. One alternative is to use non-linear (reflectron) time-of-flight instruments to correct for peak broadening due to initial kinetic energy distributions. However, such approaches suffer from decreased sensitivity, increased system complexity and cost, and limited resolution improvements above 5 KDa.

This presentation discusses how optimizing sample preparation, laser spot profile , imparted kinetic energy, flight tube pressure, signal processing and data selection improves resolution in linear MALDI-TOF MS. The importance of these factors is tested across a broad molecular weight range(572-66430 Dalton) using the HP G2030A MALDI-TOF MS system and LeCroy 1 GHz oscilloscope

Results Summary

The Table below summarizes the importance of factors affecting resolution at low and high mass and provides a very brief description of the reason for the factor's importance.

Factor	Importance at Low MW (< 2000 Da.)	Importance at High MW (> 10000 Da.)
Sample Preparation	Prepare uniform, flat co-crystals	Minimize unresolvable adducts
Laser Spot Profile	Minimize multi-path trajectories, initial kinetic energy distribution	#
Kinetic Energy (see Fig 1 and 2)	Adjust for best peak profile definition	Maximize kinetic energy for improved sensitivity
Pressure(<10-6 torr)	#	Minimize free flight collisions
Signal Processing (see Fig 3 and 4)	Choose high bandwidth and high data acquisition rate	#
Data selection	Reject poor single shot data	#

- This factor is not of major significance in this mass range.

Resolution improvements range from a factor of five for VPDPR to virtually none for BSA.

Introduction:

Laser Desorption Ionization (LDI) and Matrix Assisted Laser Desorption Ionization (MALDI) have both been demonstrated as very useful and sometimes essential ionization methods for studying cluster ions as well as in biological research. To combine the attributes of these ionization methods with those of a sector instrument would lead to several advantages, but is not a trivial matter. It has, however, been realized previously[1,2] through an iterative process by operating the magnet (B) in static mode with an array detector compiling small mass ranges until the complete spectrum is achieved. The work presented here demonstrates another strategy, which will allow for shorter analysis times and less sample consumption. It involves the incorporation of an inductive detector[3] between the electric (E) and magnetic sectors of an EB double focusing sector instrument. In this manner the electric sector can function as a crude time-of-flight (TOF). With the inductive detector triggered by the laser pulse, a complete TOF mass spectrum of the major components of the sample can be obtained with as little as one laser pulse. This quick assessment allows higher resolution spectra to be obtained by either of two methods. One is by operating the magnet in static mode with the Position and Time Resolved Ion Counter (PATRIC) collecting ions within the +/- 4% mass window passed by the magnet. This window is centered around the ion of interest determined from the inductive detector. The other method is by scanning the magnet over a small mass range around the ion of interest using the secondary electron multiplier (SEM).

Experimental:

A Finnigan MAT 900 double-focusing EB sector instrument was modified to include the inductive detector. A 3M fiber optic with a 600μm core diameter is introduced through the GC inlet of the ion volume. The FAB probe was used with a 30° stainless steel tip. A Tektronix TDS 420 oscilloscope was used to collect and display the signal from the inductive detector. A Continuum Surelite II Nd:YAG laser using the third harmonic (355nm) was used for all experiments. The power density was measured to be ~10^7W/cm^2. For the LDI studies, CsI and RbBr were analyzed (data not shown). For the MALDI studies, several small peptides were analyzed. The matrices used include saturated sinapinic acid (SA), 2.5M 2,5-dihydroxybenzoic acid (DHB) and 0.1M α–cyano-4-hydroxy(trans)cinnamic acid (4-HCCA). Trifluoroacetic acid was added to all matrices (0.1%).

Results:

Several known samples were run to obtain a calibration curve, shown in Figure 1, and also to demonstrate the use of the inductive detector to obtain LDI/MALDI spectra. Examples of an inductive detector trace and the corresponding higher resolution spectra (from the PATRIC) are shown in Figures 2a-2c for Substance P. Figure 2c shows the PATRIC spectra of an unknown which was observed in the inductive detector trace. This demonstrates the effectiveness of the strategy.

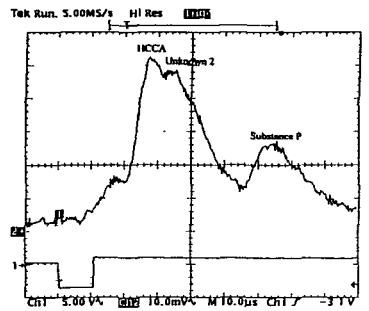

Figure 2a. Inductive detector trace of MALDI of Sub. P/4-HCCA (one laser pulse)

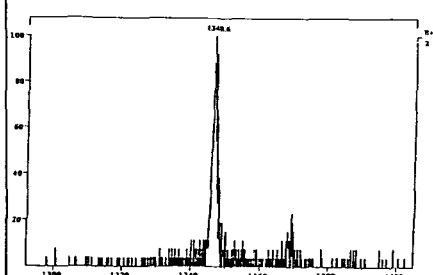

Figure 2b. PATRIC spectrum of Sub. P

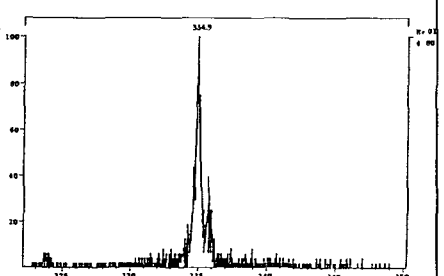

Figure 2c. PATRIC spectrum of an unknown seen in Figure 2a

Conclusion:

A new strategy for obtaining LDI/MALDI spectra on a sector instrument has been demonstrated. With the incorporation of an inductive detector, a quick assessment of the ions present in the sample can be obtained. This knowledge then allows high resolution spectra to be obtained with less analysis time and sample consumption. Although currently the time-of-flight resolution is notably poor, it is sufficient to elucidate the correct mass of the ions of interest with little or no need for adjusting the suspected mass range.

High Resolution Array Detection of the Ions Formed by MALDI

Y.Itagaki, T.Fujita, H,Naoki and T.Nakajima
Suntory Institute for Bioorganic Research
Mishima-gun Osaka, Japan 618

Introduction

Recently, Matrix Assisted Laser Desorption Ionization Time-of-Flight mass spectrometry (MALDI) has become important method for desorbing intact molecular ions of large molecules with high sensitivity and much less competition between hydrophilic and hydrophobic compounds in mixture However, the resolution obtained by TOF is low and can cause problem to differentiate mixtures which have small mass difference even at low mass range It has been discussed that the feasibility, the advantages and the disadvantages of the MALDI-array detector equipped double focusing mass spectrometer capability (1,2) to overcome the resolution problem of TOF. They have confirmed the usefulness of MALDI-sector MS observing the high resolution (R=4500 FWHM with substance P) and wide mass range (to 25,000) capabilities. We have also placed MALDI system at the position of ion source of the MS-2 of 4-sector tandem mass spectrometer combined with a focal plane array detector. This system was applied for the analysis of crude natural products such as neurotoxins extracted from spider venom which have mass range 500 to 3000 where monoisotopic separation are required Those data were evaluated together with FAB-sector MS and MALDI-TOF spectra.

Experimental

MALDI-sector MS experiments were performed on the MS-2 of JEOL HX110A/110A tandem mass spectrometer equipped with a focal plane array detector. Nitrogen laser 337nm with 3nsec pulse duration was used for the ionization One spider venom gland was homogenized in 2ml of 0.1% TFA/60% CH_3CN /H_2O solution. After the elimination of M.W. over 3000 using a microcon 3 (Amicon,Inc. Beverly,MA), Samples (1μl or 1/10th conc.1μl solution) were dissolved in a 5μl of saturated DHB in 50/50 (vol.%) EtOH/H_2O solution and potassium(K), oxalic acid or sucrose co-matrix DHB solutions. μ-Column HPLC/Continuous flow FAB/MS experiments were also performed on the same mass spectrometer with the 5μl/min. flow rate. MALDI-TOF spectra were measured on a PerSeptive Biosystems Voyager RP with linear and reflector mode

Results

A resolution of 6300(FWHM) has been achieved for acylpolyamine, $(M+H)^+$= m/z658 and the number of pixels between m/z 658 and 659 was 165 which allows to perform high resolution measurements As a screening method of acylpolyamines from single spider venom, we have established the μ-column HPLC-continuous flow (FRIT)-FAB/MS method (3) and confirmed 39 acylpolyamines were stored in the spider *Nehila clavata* venom gland (Fig.-1) MALDI spectra of the same crude extracts were obtained with the use of K containing DHB and sucrose co-matrix DHB. Both potassium(K) adduct and protonated acylpolyamines peaks were observed but minor substances and the compounds next to major acylpolysmine peaks were not easily identified from a K containing DHB matrix used MALDI spectrum Sucrose-comatrix used MALDI spectrum, on the other hand, the intensities of K attached molecular ions were reduced significantly and increased the intensities of protonated molecular ions. These signal intensity change allows to confirm the existence of minor acylpolyamines (Fig.-2).

Conclusions

MALDI-double focusing mass spectrometer equipped with an array detector was successfully used for the identifications of glutaminergic blocker neurotoxins (acylpolyamines) from crude extracts of a spider venom gland. The addition of K and (K+ sucrose or oxalic acid) to the matrix were effective to confirm the existence of minor toxic compounds because of the competitive formations of cluster ions between samples and sucrose or acid. In this case, clear monoisotopic resolution was necessary to differentiate minor toxic compounds from 1 to 2 Da different major toxins. MALDI-sector MS spectra were compared with the μ-column LC-FAB/MS, Static FAB/MS and MALDI-TOF spectra and showed its advantages and capabilities of a mixture analysis.

Accurate Mass Determination with MALDI/FTMS using Internal Standards

Carlito B Lebrilla, Steven T, Fannin, Jiangyue Wu, Melanie A. Franklin, Tadeusz F. Molinski
Department of Chemistry, University of California, Davis, CA 95616

An important feature of mass spectrometry is the capability for providing the exact mass of an ion and therefore allowing absolute identification of its elemental composition High resolution mass spectrometry is necessary for this type of analysis. Accurate mass determination is typically performed with multiple focusing instruments or Fourier Transform Mass Spectrometry (FTMS).

Experiments have been performed for the accurate mass determination on a group of biologically active cyclic bromotyrosine derivatives known as Bastadins. These compounds were extracted from *Ianthella Basta*, a marine sponge collected on the Great Barrier Reef.[1] Accurate mass measurements were performed on known and two unknown Bastadins using an internal standard, two calibrant technique with an external source Quadrupole FTMS system.[2,3] Matrix Assisted Laser Desorption Ionization (MALDI) was chosen as the ionization technique due to its inherent ability for producing very little fragmentation and instead favoring pseudomolecular ion formation of thermally labile compounds. In this regard MALDI has proven to be particularly useful for biological applications.

Accurate mass determinations in FTMS require that the frequencies of the ions be stable. If external calibrants are to be used, then the frequencies must remain constant for a long period of time. With internal calibrants, the frequencies must be stable only during the detection period (typically less than a few seconds). Such factors as the homogeneity of the magnetic field and the static electric field used for the trapping potential, can affect the stability of the ion's cyclotron frequency Although the 3 Tesla superconducting magnet used in our laboratory provides less than 20 ppm mass accuracy using external calibrants, it does not fulfill the rigorous requirement for publications of new compounds (5 ppm or less). In these cases, an internal calibration technique is necessary to obtain accurate masses

Figures 1 and 2 show examples of spectra using an internal standard, two calibrant technique for two unknowns, a newly isolated Bastadin (unknown # 1) and its permethylated derivative (unknown # 2), respectively. The internal standards used for these experiments were α-Cyclodextrin (maltopentaose for unknown # 1) and Gramicidin S These calibrants were chosen primarily for the mass range of interest and to bracket the mass of the sample as closely as possible. Rigorous experiments have not yet been performed to determine the largest possible mass range between the two calibrants that would still provide acceptable results.

Multiple mass measurements of the unknown permethylated Bastadin were performed (Table1) and an average value of the exact mass was obtained corresponding to 1014 9143. The closest molecular formula for the unknown is $C_{38}H_{36}Br_4N_4O_8Na$, which has a theoretical mass of 1014.9164 producing a deviation of only 2 1 +/- 1.5 ppm. Based on these results and NMR data this compound was determined to be the tetramethyl derivative of a new Bastadin, referred to as Bastadin 20.

Quasimolecular peptide $(M+H)^+$ and oligonucleotide $(M-H)^-$ ions, generated by matrix-assisted (DBA/fructose and HPA) laser desorption/ionization (frequency-tripled Nd:YAG or pulsed N_2 laser), are cooled and axialized[1] by azimuthal quadrupolar irradiation in the presence of argon collision gas in the source compartment of a dual cubic Penning trap. Following ion transfer to the low-pressure "analyzer" trap, and optimization of various experimental parameters (source trap gating; source trap pressure; source trap azimuthal quadrupolar excitation duration and amplitude; trapping potential) high FT-ICR mass resolving power and mass accuracy in the low ppm range are obtained for ions generated *inside* a 3.0 tesla selenoidal magnet (Fig. 1).

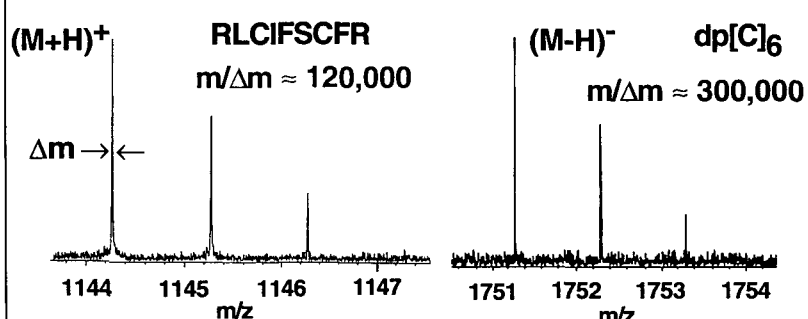

Figure 1. Representative high resolution MALDI FT-ICR magnitude-mode mass spectra of a nonapeptide, Arg-Leu-Cys-Ile-Phe-Ser-Cys-Phe-Arg (left), provided by S. Gaskel, and an oligonucleotide, pd[C_6], (right). The experimental event sequence and parameters work equally well for other samples in the same m/z range.

High mass resolution is important for resolving adducts and chemical modifications of a peptide/protein or oligonucleotide/DNA, and for facile determination of the degree of deuteration from an H/D-exchange experiment. Time-domain signal damping may arise from unimolecular decomposition, collisions of ions with background neutrals, and spatial inhomogeneity of the electric and magnetic fields inside the ICR trap. Here, ions are generated with laser power just above the threshold for ion formation; ions are then decelerated by gated trapping, and further cooled and axialized. After ion transfer to the analyzer half of the dual trap, collisional relaxation at ~1-2 x 10^{-9} torr is slow, and the time-domain ICR signal persists for approximately one minute. However, distortion of the overall electric potential in the trap from a three-dimensional axial quadrupolar potential, generated by the presence of many ions in a Penning trap, produces two undesirable effects. First, the FT-ICR mass spectral peaks are inhomogeneously broadened; for heavy ions, the instantaneous ICR frequency drifts during detection because the electric potential shape changes with ion radius. Frequency drift may be compensated and virtually eliminated[2] to yield ultrahigh mass resolving power. Second, ions of nearly equal cyclotron frequency couple by their Coulomb interaction to become synchronized to a single ICR frequency. Coalescence of closely-spaced resonances to form a single FT-ICR mass spectral peak whose width is less than the separation between its constituent ion resonances is illustrated (Fig. 2) by the high resolution spectrum of deuterated leucine enkephalin and a simulated spectrum for a Lorentzian peak with the same line width and degree of deuteration (deconvoluted from experimental data). Preliminary ion trajectory calculations (Simion 6.0) confirm that Coulomb-mediated interactions result in coupling of closely spaced resonances for high-mass ions under typical FT/ICR MS operating conditions. Coalescence may be counteracted by reducing the number of ions, and by increasing the magnetic field strength and/or ICR orbital radius.[3] Work supported by NSF (CHE-93-22824), NIH (GM-31683), and the National High Magnetic Field Laboratory at Florida State University.

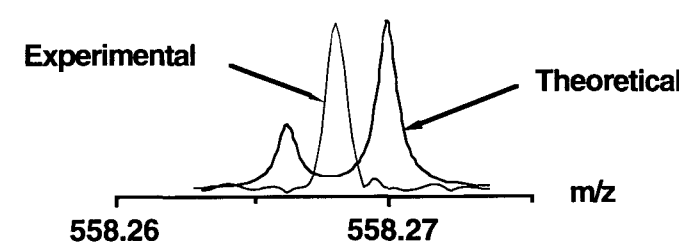

Figure 2. Coulomb-mediated coalescence in a MALDI FT-ICR high-resolution magnitude-mode mass spectrum of partially deuterated leucine enkephalin. Although experimental mass resolving power is high (m/Δm ~ 500,000), the $^{12}C^2H/^{13}C^1H$ doublet is not resolved (compare to the theoretical doublet computed from two magnitude-mode Lorentzians whose widths are the same as the experimental peak width), due to Coulomb interactions between ions of nearly identical mass-to-charge ratio.

Peptide Mapping and Sequence Analysis by MALDI FT-ICR Mass Spectrometry

Touradj Solouki, Ljiljana Paša-Tolić, George S. Jackson,* Shenheng Guan* and Alan G. Marshall*

Center for Interdisciplinary Magnetic Resonance, National High Magnetic Field Laboratory, Florida State University, 1800 E. Paul Dirac Dr., Tallahassee, FL 32310

* Department of Chemistry, Florida State University

One of the advantages of matrix-assisted laser desorption ionization (MALDI) is the ability to generate peptide and protein ions for the direct analysis of relatively impure samples such as enzymatic digest solutions. To date, most MALDI-based peptide mapping and sequence analyses of proteins have employed time-of-flight instruments. However, the low mass resolution of the TOF technique severely limits mass measurement accuracy. Here, we present MALDI FT-ICR mass analysis of enzymatic digest mixtures. In a simple extraction scheme, the tryptic digest solutions are crudely purified by using sep-pack C18 mini-extraction columns. The resulting mixtures are mass-analyzed with a 3 tesla Waters Extrel FTMS-2000 dual-trap FT-ICR mass spectrometer.

Apart from the direct information obtained from the high-resolution mass spectrum, the collision-induced dissociation (CID) and MS^n capabilities of FT-ICR help to determine the amino acid sequence of the fragment ions beyond what is obtained from enzymatic digestion. Moreover, by combined use of ion axialization excitation and remeasurement techniques,[1,2] mass spectra may be obtained from sub-femtomole quantities of peptide samples. Figure 1 shows MALDI FT-ICR mass spectra obtained from femtomole amounts of cytochrome c (horse) tryptic digest solution ionized by a single N_2 laser shot (Model VSL-33ND, Laser Science, Inc., Newton, MA) in the source-side trap (~2 x 10^{-7} torr argon collision gas). The top spectrum shows a representative positive-ion mass spectrum of tryptic digest products. The second spectrum from top shows a selected ion (at m/z 1616) after isolation by SWIFT excitation, axialization, and detection. The third remeasured mass spectrum contains a CID product (MS/MS) after SWIFT isolation (at m/z 1487, loss of lysine excluding NH_3) followed by axialization. Ion dissociation was induced by sustained off-resonance irradiation (SORI) at ~800 Hz below the reduced ion cyclotron frequency of the parent ion; excitation duration and amplitude were optimized for each experiment to maximize the product ion signal magnitude. Finally, a second SORI yielded CID products of the same batch of ions (at m/z 1487); after a series of axialization/remeasurement cycles the MS/MS/MS from the same initial batch of ions was obtained. *These are the first MS^n results that show real-time display of gas-phase fragmentation of the biomolecular ions for several stages of CID from a single batch of ions by use of repeated remeasurements.* Work supported by NSF (CHE-93-22824), NIH (GM-31683), and the National High Magnetic Field Laboratory at Florida State University.

#Department of Chemistry, The Ohio State University

We present a combination of two methods that significantly improve sensitivity for analysis of biomolecules by MALDI FT-ICR mass spectrometry: (a) sample deposition onto small indentation on the probe tip, and (b) multiple remeasurement of axialized ions. Laser desorption/ionization was performed with a Laser Science, Inc. cartridge-type pulsed N_2 laser (Model VSL-33ND, Newton, MA) operating at a wavelength of 337.1 nm with a pulse width of 3 ns. FT-ICR mass spectra were acquired at 3.0 tesla with a dual-trap Waters Extrel FTMS-2000 (Extrel-Waters, Madison, WI) instrument.

To reduce the amount of sample deposited on the probe tip, we constructed a probe tip with series of small indentations, such that attomoles of sample could be placed on these small spots. A Vickers microhardness tester (series 200 Wilson-Tukon) was used to confirm that the indentations were aligned with the laser beam. To mark the sample probe tip at the laser focal point, we applied a thin film of 4-nitroaniline on the probe tip and several laser shots were fired to remove the organic layer at different probe rotational positions; these laser spots were identified and marked under the diamond-tipped microhardness tester with 1000 kg load. The probe tip and indentation marks (~100 micron deep and ~5 x 10^{-4} mm^2 area) are shown schematically in Fig. 1. Two pins were used to lock the position of the probe tip onto Extrel's standard autoprobe. Results were highly reproducible from one marked spot to another, confirming the laser alignment accuracy and spot placement.

The FT-ICR detection limit was further reduced by combining azimuthal quadrupolar excitation in the presence of collisional cooling to axialize the ions,[1] with repeated ion remeasurement.[2,3] Ion multiple remeasurement enhances the signal-to-noise ratio and thus lowers the detection limit achievable with FT-ICR. Representative mass spectra for ~8 attomoles of substance P, applied to the sample probe, from a single data acquisition (top) and accumulation of time-domain signals from 40 repeated measurements (bottom) are shown in Figure 2. To date, eight attomoles is the lowest reported detection limit for MALDI FT-ICR/MS. Work supported by NIH (GM-31683) and the National High Magnetic Field Lab at Florida State University.

High Mass Analysis in Fourier Transform Mass Spectrometry

Jie Yao, Salvador J. Pastor, Charles L. Wilkins,
Department of Chemistry, University of California-Riverside, Riverside, CA 92521, USA

Matrix assisted laser desorption/ionization (MALDI) is a widely utilized technique allowing the detection of ions with masses as large as several hundred thousand daltons. In the past, time of flight mass spectrometers have been the instruments of choice for such applications. Recently, MALDI has been combined with Fourier transform mass spectrometry (FTMS), which is capable of high resolving power, precise mass measurement, ion remeasurement, and simultaneous detection of all ions. However, a current limitation of MALDI-FTMS mass spectral measurements is the inherent difficulty in trapping high mass species. Due to the MALDI desorption process, molecules and ions are ejected from the matrix surface with kinetic energies that scale directly with their mass.[1] As a consequence, ions of higher m/z and thus higher kinetic energies are inefficiently trapped by the low voltage trapping potentials that are standard to the FTMS experiment. The trapping problem was partially solved by introduction of a gated trapping protocol in which a 9-volt deceleration potential was applied to the rear trap plate of a cubic cell to slow ions that were entering the cell. Using this method, Castoro and co-workers[2,3] were able to show the successful analysis of singly charged biomolecules with molecular masses as great as that of carbonic anhydrase (MW = 29,000). For higher mass ions it was necessary to increase the trapping voltage and to average multiple spectra in order to improve the signal-to-noise ratio since very few ions were being trapped.

In an attempt to further extend the detectable mass range of singly charged ions using MALDI-FTMS, we have designed an electrostatic field deceleration method where decelerating voltages up to 75 volts are applied not only to the rear trap plate of the source side of a dual cubic cell, but also to the excitation and receiver plates of the cubic cell. This "five-plate" trapping method shows improved trapping efficiency during the ionization event. Simulations (MacSimion, Version 2.03, Montech Pty Ltd., Monash University, Victoria, Australia) show that application of voltages to five plates of the FTMS cell forms a "cuplike" electrostatic field in which ions can be more efficiently trapped. Simulated ion calculations show a much improved potential surface that is conducive to better trapping because off-axis ions are less likely to be ejected (neutralized on cell plates). Figure 1 is a simulation of the field map which results if 50 volts are applied to the rear trap plate and 20 volts to both the excitation and receive plates. The 5-plate trapping approach does not require cell modification. Instead, DC pulses and excitation pulses are separated in time and controlled by existing FTMS software. This setup allows maximum flexibility and control for an FTMS experiment without impairing the ability to do lower mass high resolution work.

When this 5-plate trapping method is applied, high mass ions with large translational kinetic energies can be trapped efficiently and detected. Using this approach, low resolution spectra of carbonic anhydrase (MW=29,000), egg albumin (MW=45,000), and bovine albumin (MW=66,000) have been obtained. Because the new decelerating method requires no modification to the existing cell, it is also possible to obtain high resolution spectra for compounds with masses of ca. 14,000 daltons and lower. Utilizing the 5-plate trapping method, a bovine insulin spectrum with a resolving power of 20,000 was obtained. It is not yet possible to obtain higher resolution for the higher mass proteins. Some of the probable causes of the poor mass resolution include the large collisions with neutrals, possible enhancement of metastable decay of the molecular ions as a consequence of internal excitation during the MALDI process, and difficulties in exciting high mass ions into coherence.

The axialization technique has provided particularly useful for enhancement in mass resolving power.[4,5] In a typical axialization experiment, a quadrupolar r. f. field at the unperturbed cyclotron frequency of ions is applied to the excitation and receive plates, thereby converting ion magnetron motion into

cyclotron motion. The present buffer gas cools the ions through ion-neutral collisions, thus driving ions to the center of the cell. In this paper, we combine the axialization technique and 5-plate trapping method to improve mass resolving power. High mass ions are formed by laser desorption/ionization and trapped by 5-plate trapping field. Then ions are axialized in the source cell in the presence of buffer gas and transfered to the analyzer cell for high resolution detection.

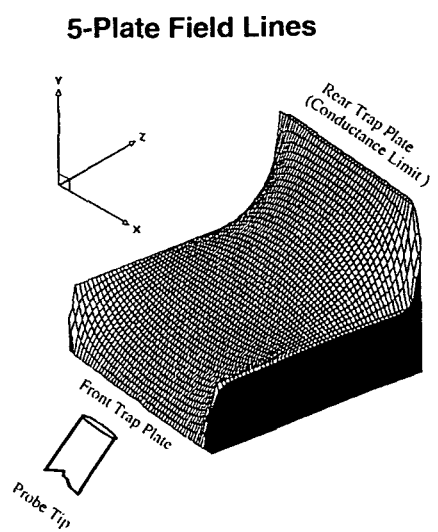

Figure 1: Five-plate trapping field lines calculated by MacSimion (Version 2.03, Montech Pty Ltd., Monash University, Victoria, Australia) for 50 V on the rear trap plate and 20 V on both the excitation (yz-plane) and receive (xz-plane) plates. The magnetic field lies along the z-axis.

Further improvement of Mass Accuracy in MALDI reTOF MS of Peptides

O. Vorm, P. Mortensen, and M. Mann
European Molecular Biology Laboratory (EMBL)

Introduction

We show how spectrum calibration can be carried out routinely and computer automated using only matrix peaks and giving no apparent error. Thus odd peak shapes becomes the main source of error. However, when "fast evaporation" sample preparation is used along with a reflecting TOF instrument, peptides in the mass range up to 2500 Da are usually analyzed with isotope resolution and well defined peak shapes.
In combination, a mass accuracy around 50 ppm is routinely obtained without the use of internal standards, even for demanding samples such as peptide maps obtained from subpicomole amounts of proteins isolated by SDS-PAGE.

Methods

Sample Preparation: Micro-crystalline matrix surfaces were prepared by the fast evaporation procedure (1, 2) we presented at ASMS '94.
Mass Spectrometry: All mass spectra were obtained on a modified Bruker REFLEX TOF Mass Spectrometer (Bruker-Franzen Analytik, Bremen, Germany). The original data acquisition system was replaced by a LeCroy 9350AM 1 gigasamples/sec digital storage oscilloscope (LeCroy Corporation, Chestnut Ridge, NY, USA) from where single shot spectra were transferred to a Macintosh PowerMac 7100/80 computer (Apple Computer Inc., Cupertino, CA, USA) via a National Instruments NI DAQ GPIB controller board (National Instruments, Austin, TX, USA). Control of all data acquisition parameters, the transfer and subsequent averaging of spectra as well as all further data processing was carried out using the computer program "LaserOne" developed in-house. LaserOne takes advantage of the features in AppleScript™ All automation of data recording, calibration and exchange of data with other computer applications was accomplished via scripts.
Detector Gating and Spectrum Calibration: Detector bias gating (3) has been developed in-house to avoid charge depletion in the detector. A further advantage is, that the lower value of the gated bias potential can be set to enable the clear and noise-free detection of the most prominent matrix ion signals while keeping these signals within the dynamic range of the device used for recording the TOF trace. This feature, when combined with the surface sample preparation procedure, yields well defined matrix ion signals with high resolution and symmetrical peaks. Consequently, a multi-point least-mean-squares fit to the measured flight times and calculated masses of several matrix peaks can be used for an accurate time to mass calibration of the spectrum. Since the low mass signals also appear highly reproducibly from sample to sample the fitting parameters were easily and reliably obtained by a computer algorithm without human control.

Conclusions

- The time to mass conversion of MALDI TOF spectra can be based on multiple matrix peaks. The procedure is easily automated and virtually always yields reliable calibration.
- The calibration contributes very little to the experimental error, and the remaining cause of error is poorly defined peak shape of the measured signal.
- Easy MALDI samples are usually measured with an accuracy better than 0.05 Da.
- Even for rather challenging samples, an accuracy better than 0.1 Da is typically achieved for the full range of isotope resolved peaks in MALDI reflector TOF spectra.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

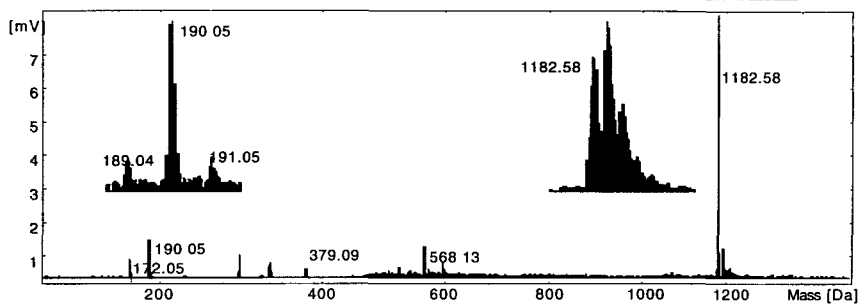

Fig. 1 MALDI reflector TOF spectrum of the peptide LHRH (calc. monoisotopic MH^+ 1182.581) recorded with detector gating, where the detector turned fully active after m/z 450. The left insert in the spectrum is a zoom of the matrix monomer peaks and the right insert is the isotope cluster of LHRH.

Fig. 2 Mass error (in Da) in peptide maps of proteins isolated by SDS-PAGE.

As a statistical example for calculating our mass accuracy for "real-life" samples, we examined all the peptide maps obtained from digests of proteins that were isolated by SDS-PAGE and subsequently identified by MALDI-MS and database search at EMBL from January to May of '95. This corresponds to roughly 500 identified peptides from around 50 identified proteins. In most cases subpicomole amounts of protein were present in the gel (as judged by the stain) and low femtomole amounts were applied to MALDI-MS. Several of the used peptide maps were recorded, calibrated and stored automatically as batch runs without operator interaction.

Orthogonal Injection MALDI

R. G. Dworschak, W. Ens, V. Spicer, K. G. Standing, A. V. Verentchikov
Dept. of Physics, University of Manitoba, Winnipeg, Manitoba, Canada, R3T 2N2

As described in an accompanying abstract [1] there is considerable advantage to decoupling the desorption process from the extraction process in matrix-assisted laser desorption/ionization by time-of-flight. This reduces the metastable decay caused by collisions in the plume, and allows time-lag focusing as described by Wiley and McLaren [2]. Improved resolution in the linear mode has already been demonstrated using delayed extraction in the axial geometry [1]. However, based on the success of orthogonal injection in our electrospray-TOF instrument [3], we believe even greater improvement is possible using orthogonal-injection in combination with an ion mirror. Since the plume in MALDI is forward-directed, the velocity and spatial spreads orthogonal to the plume should be considerably smaller than in the parallel direction. We have exploited the fact that a time-of-flight instrument is relatively insensitive to spreads orthogonal to its axis.

We have constructed a source geometry almost identical to the one used in our ES/TOF instrument [3], but with the final aperture of the ES apparatus replaced by a target probe integrated with the acceleration rings so as not to perturb the field. Ions are desorbed from the probe in zero field by a laser pulse and are allowed to drift to the axis of the spectrometer where they are injected into the DC extraction region by a pulse applied to the back electrode. The back electrode and the pulsing electronics may be floated up to 30 kV, and the final grid is grounded. Figure 1 shows a schematic of the source, acceleration and drift region of our instrument. The computer triggers the digital delay generator which simultaneously starts the transient recorder, fires the laser and triggers the extraction pulse. Note that the drift region is only 37 cm in this prototype instrument.

The source has recently been completed and spectra of molecular ions of matrix, benzoperylene, melittin, insulin and myoglobin have been extracted in a short linear TOF spectrometer. Figure 2 shows the minimum peak widths of 10, 20, 40 nS for the molecular ion peaks of matrix, insulin, and myoglobin respectively. These spectra were obtained by optimizing the extraction pulse voltage with a fixed acceleration voltage of 15 kV and a laser spot size of approximately 1 mm. In addition to the improved resolution, prompt fragmentation is observed with melittin.

A Charge Detector for High Mass MALDI Ions

Carsten Lautz, Ute Bahr, Ulrich Röhling and Franz Hillenkamp

Institute for Medical Physics and Biophysics
University of Münster
48149 Münster, FR Germany

For several years the new ionisation method MALDI has been used for the analysis of large bioorganic molecules. In the case of MALDI the molecular ions - up to 300,000 Da - are for the most part singly charged and analyzed by time-of-flight (TOF) mass spectrometers. For detection of the ions, discontinuous secondary electron multipliers (SEM), microchannelplates (MCP) or combinations of both are used.

The major problem in the detection of high mass ions is the low efficiency of ion/electron conversion due to the low impact momentum of the ions on the detector surface. P W Geno et al [1] measured a "threshold" velocity of 10^4 m/s for an efficient ion/electron conversion for smaller ions, to achieve this velocity molecules of 10 kDa mass require an acceleration potential of 5 kV, molecules of 55 kDa mass (Albumin) already one of 30 kV. Using high acceleration voltages causes insulation problems and short flight times of the ions requiring fast and expensive A/D-converters. Postacceleration by conversion dynodes in front of the detector often decreases the mass resolution, because signals from ion/ion-conversion often overlap ion/electron-conversion and broaden the ion peaks

A detector is described here which, similar to a Faraday cup, measures all incoming charge and is fast enough for the analysis in a TOF mass spectrometer.

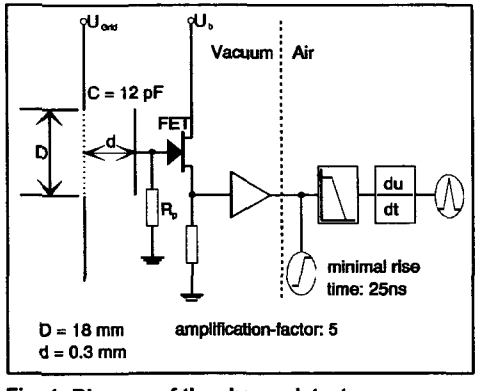

Fig. 1: Diagram of the charge detector

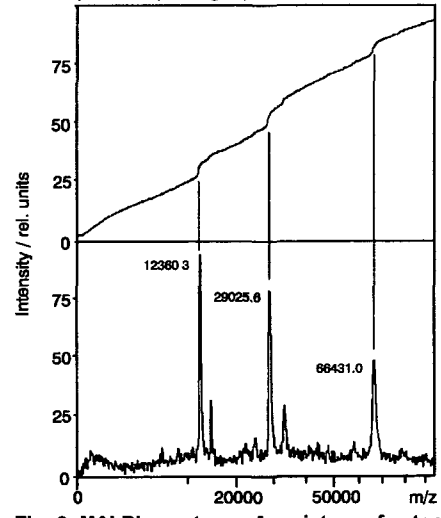
The 12 pF combined capacitance of the charge collector electrode and the FET imput paralleled by the FET imput resistance of 1 GΩ form the charge integrator. The FET functions as an impedance converter to the 1 KΩ imput of the amplifier The overall upper cutoff frequency of 6 MHz of the system, corresponding to a minimum risetime of 25 ns, is determined essentially by the amplifier. 18,000 ions are needed to obtain a step with signal-to-noise-ratio of 2.

The resulting staircase function must be differentiated electronically to obtain a normal mass spectrum (see fig. 2).



Built into the differentiator is another low-pass frequency filter to limit the high-frequency noise. For optimal performance this frequency should be variable: With increasing mass, the intrinsic mass resolution and thereby the intrinsic signal risetime decreases as does the signal intensity. For optimal performance (S/N and m/Δm) different differentiators were therefore used to receive spectra with signals in the range of 137 - 150,000 Da. A Finnigan MAT VISION 2000 intrument in the reflector configuration with a 5 kV acceleration energy was used.

For small ions (up to 2,000 Da) the mass resolution is limited by the rise time of the charge detector, up to 10,000 Da the mass resolution in the differentiated spectrum is limited by the

Fig. 2: MALDI-spectrum of a mixture of cytochrome C, carbonic anhydrase and bovine serum albumin with DHBs as matrix obtained with the charge detector
top: step function
bottom: electronically differentiated spectrum

cutoff frequency of the differentiator In the mass range between 10,000 Da and 30,000 Da the mass resolution obtained from the step function as well as the differentiated signal of the charge detector is superior to a SEM, for which the secondary ion signal of the post-acceleration SEM broadens the peaks. For higher mass ions the mass resolution is only negligibly affected by the secondary ion signal and mass resolutions are equal for both detectors.

At a mass of 1,000 Da the sensitivity of the SEM exceeds that of the charge detector by a factor of 1.6. At a mass of 70,000 Da this difference has shrunk to a factor of 1.1. These observation makes the charge detector particulary suited for the detection of high mass ions.

The absolute measurement of the ion charge by the detector allows the investigation of secondary surface effects in dependence on impact energy and ion mass by variation of the grid voltage

Application of MaxEnt to MALDI Mass Spectrometry

Xiaokui K. Zhang*, Anthony G. Ferrige** & Henry M. Fales*

MALDI coupled to time of flight mass spectrometry is recognised as one of the most powerful techniques for the study of large biologically important molecules. In comparison with other commonly used techniques, it is generally highly sensitive, is tolerant to solvents and buffers and is relatively easy to use. However, it does suffer the serious disadvantage that it is a low resolution technique, particularly for masses above 12000 Da where reflectron refocussing is not useful. This poor resolution performance arises from many factors including the initial energy of the ions, the location of ion formation and the strength and stability of the laser power. As a consequence, peaks may be very broad and, typically, in the range 20000-100000 Da peaks may have a full width at half-height of anything between 100 & 1000 Da, depending on their mass and the instrument operating parameters. Therefore, the spectra of mixtures of similar compounds may easily overlap to produce a poorly resolved peak envelope. Since peak maxima are dependent on the extent of peak overlap, it follows that some means of revealing the underlying structure is required. When internal standards are used as a means of improving the calibration accuracy, it is considered that calibration peaks must be cleanly separated from the peaks of interest for reliable mass measurement of either. This is unfortunate because it is obvious that the calibration peak should be as close as possible to the analyte peak for calibration extrapolation to be reliable.

Quantified MaxEnt is a well-known probabilistic method which is used to reconstruct the underlying sharp information contained in many types of spectra data and images. More recently, the mathematics have been developed further and the technique has been successfully applied to electrospray data for generating highly resolved zero-charge spectra and to ICP-MS data for automatically providing fully quantitative elemental analyses. Whatever the application, it is important to realise that the data are not processed in any way. They are only used for comparison with reconstructions of the data so that result quality may be assessed. Therefore, in the case of electrospray data, the reconstruction of the data is generated from trials which guide the computation to the best reconstruction of the zero-charge spectrum which, when convolved with the optimised peak profile model and an integer charge distribution, gives the best fit with the data. We present below a further practical development in applying the MaxEnt technique to MALDI-TOF data.

In this application, the sample is a mixture of four oligonucleotides. Peak overlap is severe and accurate mass assignment is impossible. Two experiments were performed - one using an external standard which was then combined with the sample acquisition and another which included an internal standard which overlapped with the analyte peaks. The data, reconstructed data and MaxEnt results for the two experiments are shown in Figures 1 & 2 respectively, along with the fully quantified masses.

In conclusion, it is clear that MaxEnt is capable of revealing the underlying sharp information contained in data and providing quantified results of high accuracy, even when (and preferably!) calibration peaks overlap the analyte. Of course, the information must be in the data to begin with and a potential future development could be a "quality meter" output from MaxEnt to guide the spectrometrist among compromises in spectral conditions to optimise the information from a given sample.

Scanning Electron Microscopy as a Tool to Investigate Sample Morphology Effects in Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry

A. Westman and E. Barofsky
Department of Agricultural Chemistry, Oregon State University, ALS 1007, OR 97331-7301, USA

One of the most important factors effecting matrix-assisted laser desorption/ionization (MALDI) is the method of sample preparation. Sample preparation involves co-crystallization of the analyte molecule with an excess of low mass, photoabsorbing, organic molecules – the matrix. Although it has been demonstrated that a number of compounds from different chemical classes are suitable as matrices in MALDI, there is still considerable uncertainty about the possible roles of the matrix. Factors such as morphology of the matrix-analyte film and molecular co-crystallization have been stressed as important for obtaining useful MALDI spectra [1, 2].

In this study samples for matrix-assisted laser desorption/ionization (MALDI) mass spectrometry have been prepared with several different techniques. The samples have been studied in a scanning electron microscope (SEM). The size, shape and surface density of the micro crystals formed was found to depend strongly both on the matrix material and on how the matrix/protein solution was applied to and dried on the metal backing. When a droplet of the matrix/protein solution is deposited on the metal backing and left to dry completely in ambient air, the result is a carpet of micro crystals of different size and orientation. Local crystal morphology varies considerably across the sample (fig. 1). When fast crystallization is induced immediately after the matrix/protein solution have been deposited on the metal backing a more homogeneous layer of smaller micro crystals is formed (fig. 2). All the samples investigated in this work (except the fast evaporation [3] samples) look the same in a light microscope However, the SEM micrographs reveal strikingly different sample morphologies. We suggest therefore that SEM micrographs of samples should more often be published together with the mass spectra This would make it easier to separate the effects of sample morphology from those of instrumentation and thereby make comparisons of performance between different experimental set-ups possible. Attempts are under way in our laboratory to further investigate the role of sample morphology in MALDI by directly comparing spectra from samples with different morphologies.

Nanoscale Sample Manipulation and Preparation Method for MALDI MS

Rafael E. Golding, Randy M. Whittal and Liang Li*
Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2

In a typical matrix-assisted laser desorption ionization (MALDI) experiment, 0.5 to 1.0 μL of a 1 μM solution is loaded to a sample probe for mass analysis. Sample is usually distributed over a 3 to 10 mm^2 area. However, only a small amount of sample is consumed. In order to preserve valuable samples available only in very small quantities (e.g. intracellular fluid), a reliable, reproducible and accurate sample delivery system is necessary to place the sample solution on the tip of the mass probe.

The system developed in this work is able to deliver volumes from 0.02 nL to 130 nL accurately depending on the length of the liquid column inside a capillary tube, and the I.D. of the tube. The delivery system is composed of a screw capped 2 mL glass vial connected to two fused silica capillary tubes and one PTFE tube (Figure 1). The connections are sealed using a silicone chromatographic septum. One of the capillaries has a tapered end and it is calibrated for the desired volume. The second capillary tube (50 μm I.D.) acts as a pressure attenuator. With the use of 10 μm to 200 μm I.D. capillaries, delivery of accurate volumes can be made over a large range. A disposable syringe is connected to the PTFE tube (300 μm I.D.) and provides the vacuum/pressure driving force necessary to move the sample inside the tube.

The matrix preparation technique of Vorm *et al.* [1] was used to prepare the matrix layer. α-cyano-4-hydroxycinnamic acid was dissolved in 99% acetone / 1% water at a concentration of 24 mg mL^{-1}. 0.7 μL of matrix solution was delivered to the stainless steel probe tip. An even solid matrix layer of very small crystals (0.5 - 2 μm in diameter) is formed.

All the operations of filling the capillary with the sample solution, and delivering the selected volume on the mass probe were performed under a microscope. A standard microscope slide holder was used for aligning the capillary tube and locating the sample on the center of the 4 mm diameter probe tip. The analyte solution spreads on the matrix layer instantly and dries in 1-5 seconds depending on the volume delivered. The evaporation of the liquid solution inside the capillary tube is very low. It ranges from 0.0017 nL/min for a 10 μm I.D. capillary to 0.60 nL/min for a 200 μm tube.

Figure 2 shows that a rapid decrease in the analyte spot area can be seen when the sample volume is reduced, especially under 0.4 nL. This behavior means that the sample will be confined in a smaller area producing higher analyte concentration per area unit.

The MALDI spectra were collected on a linear time-lag focusing time-of-flight mass spectrometer [2]. Two different samples were analyzed. A rhodamine labeled trisaccharide (B-MCO-TRSE) and the peptide bradykinin. A MALDI spectrum of B-MCO-TRSE is shown in Figure 3. The average spectrum was obtained from 0.1 nL of a 1 μM solution of the analyte delivered on the probe. This corresponds to 100 amol of the trisaccharide. In Figure 4, the average spectrum for 0.15 nL of a 1 μM solution of bradykinin is presented. The total amount in this case is 150 amol.

In conclusion, we have developed a method where exact and very small sample volumes can be accurately located on the mass probe tip. A smaller sample spot area produces higher analyte concentration per area unit on the solid matrix layer. Mass spectra for a total loading of 100 to 150 amol of material give spectra with signal to background ratios well above the detection limit. We plan to extend the use of this system to the analysis of single cell intracellular fluid.

Methods for Modifying the MALDI Process by Jian Bai, Xiaoli Liang, Yan-Hui Liu, and David M. Lubman, Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109

Introduction MALDI is characterized by a sharp threshold behavior, which implies that minimum laser energy needs to be absorbed by the microvolume of the matrix/analyte to result in the desorption/ionization process, and this is directly related to the density of matrix molecules probed by the laser beam. The MALDI sample preparation requires the mixing of analyte molecules with an excessive amount of matrix so that the density of the matrix molecules of a typical sample preparation is almost saturated. Additives to matrices/co-matrices have been used for improving the MALDI MS performance (1-3). This work reports the preliminary results of using additives to the commonly used matrices for the mediation of the MALDI process. The effect of additives of different physical and chemical properties and photoactivities on MALDI MS sample preparation and performance is evaluated, such as resolution, sensitivity. Initial results indicate that additives of various properties can serve as a general means of improving the MALDI MS performance for certain matrices

Experimental A linear TOF mass spectrometer with a microsphere plate detector was used for detection, and 355 nm laser radiation for LD/I. All the materials were used as purchased, and were dissolved in acetonitrile/water (1:1) at appropriate concentrations DHB and α-CHCA were used as two model matrices, and additives of different photoactivity, acidity, and volatility, including glutathione (GTTh), 4-nitroaniline (4-NA), and vanillin (VN), among others, were tested as additives. The analytes used were a peptide mixture and lysozyme.

Results and Discussions Obvious improvements were generally observed for additives to DHB, but not for α-CHCA. These results are dependent on the additives and the type of analyte. GTTh as an additive to DHB with a molar ratio of 1/4 provided the best results for all of the analytes, where enhanced resolution and reproducibility were achieved. 4-NA as an additive to DHB also improved the reproducibility of the MALDI MS signal, and tended to generate more multiply charged species for lysozyme. VN as the additive to DHB showed improvement in the analysis of lysozyme, but showed suppression effect on the larger peptides in the CNBr digest. The Figure shows the MALDI MS spectra obtained with GTTh and 4-NA as additives to DHB for the analysis of lysozyme (left) and the peptide mixture (right).

The improvements can be atributed to the homogeneous nature of the sample/matrix deposit from visual inspection when additives were used, where addition of the correct amount of GTTh or VN to DHB can result in very thin and homogenous film like sample/matrix deposit. Addition of 4-NA to DHB showed moderate improvement in the sample/matrix deposit homogeneity. Optimization of the molar ratio of additives to DHB was required in the case of GTTh or VN; an excessive amount of GTTh can result in total loss of the effectiveness of the DHB matrix. 4-NA, on the other hand, allows a much wider range of variation.

The MALDI MS spectra with DHB alone as the matrix showed dramatic variations in terms of resolution, intensity, and signal profiles as the laser spot was scanned over the probe tip by moving the focus lens laterally. This may be associated with the inhomogeneity of the sample deposit, but most importantly, may reflect the sensitive response of such a sample deposit to the laser intensity variations brought about by moving the focus lens. In fact, slight adjustment of the laser intensity can result in very different mass spectra when using DHB as the matrix (results not shown). These variations were almost totally eliminated when GTTh was added to DHB with a molar ratio of 1/4. We atribute this partly to the

dilution effect of GTTh on DHB, which makes the sample deposit less responsive to slight laser intensity variations.

Conclusion The initial results indicate that the use of additives to matrices may provide a general and simpler means of improving the current matrix systems Continuing efforts are needed to evaluate the effects of additives on the MALDI process, and to further characterize additives for such purposes.

Novel Sample Preparation for MALDI

H. J. Köchling and K. Biemann
Department of Chemistry, MIT, Cambridge, MA, 02139 USA

The widespread use of Matrix-Assisted Laser Desorption/Ionization (MALDI) within the mass spectrometry community has identified sample preparation as being critical for attaining optimal results. With the goal of achieving better control of sample preparation in MALDI, we have conducted experiments where the deposition of matrix has been separated from that of the analyte. Extremely homogeneous thin films were formed on Time-Of-Flight (TOF) mass spectrometer targets by pneumatic spraying of solutions containing only matrix. Both alpha cyano-4-hydroxycinnamic acid (αCCA) and 2,5-dihydroxybenzoic acid (DHB) were used to produce matrix films by this method. Aqueous solutions of analyte alone (without matrix) were then applied in the conventional manner onto the dry matrix films. As a demonstration of the versatility of the matrix films, a pre-prepared film of αCCA was sprayed with High Pressure Liquid Chromatography (HPLC) eluent and the resulting deposits were analysed by MALDI.

EXPERIMENTAL

Matrix films were produced by using a LC-TRANSFORM model 101 (Laboratory Connections, Marlborough, MA), introducing matrix solution with a syringe pump. Matrix solution was propelled by a nebulizing gas stream and the resulting spray dryed and focused by a heated sheath gas onto a rotating TOF target. Matrix films of αCCA were produced from a 5g/L solution in 1:1 (v/v) acetonitrile/water. For DHB films, a solution at one-half saturation (~10g/L) in water was used. HPLC experiments were performed by using the LC-TRANSFORM to spray the HPLC eluent onto a rotating TOF target previously coated with a matrix film of αCCA. All mass spectrometry experiments were conducted on a modified VT2000 linear TOF mass spectrometer (Vestec Corp., Houston, TX).

RESULTS AND DISCUSSION

The matrix films were deposited in the shape of an annulus. Both films had a center radius of 11 mm but were of different widths. The αCCA matrix film was 6 mm wide and was composed of two distinct layers, a light green bottom layer, which was very well adhered to the surface of the target, and a loose, powdery top layer, darker green in appearance although equally homogeneous. This top layer was removed by gentle wiping with a cotton swab to expose the lower layer, onto which samples were spotted for MALDI analysis. The DHB matrix film was composed of a single homogeneous layer, 4 mm in width and matte grey in color. It was also extremely well bonded to the target surface.

The principle benefits that the matrix films provided over the standard MALDI sample preparations derived from their much greater homogeneity. This resulted in superior MALDI spectra, as shown in Figures 1A and 1B for DHB by using bovine ubiquitin and in Figures 2A and 2B for αCCA by using ribonuclease A. Figure 3 shows the MALDI analysis of an αCCA matrix film sprayed with HPLC eluent from the separation of a three-component mixture. Mass spectra were acquired from regions of the matrix film corresponding to the HPLC peaks containing Substance P (Fig.3A), insulin (Fig.3B) and ubiquitin (Fig.3C).

CONCLUSIONS

Separating the deposition of matrix from that of analyte has been shown to allow better control of the sample preparation step in MALDI. A process based on pneumatic spraying was developed to produce stable, long-lived matrix films of αCCA and DHB. This process was shown to be capable of producing homogeneous matrix films regardless of the solubility characteristics of the matrix materials tested. The excellent homogeneity of the resulting matrix films facilitated the acquisition of MALDI spectra that exhibited increased sensitivity, larger signal/noise ratio and greater resolution than spectra acquired from corresponding conventionally prepared samples. The remarkable adhesion of the matrix films to the surface of the TOF targets and their ability to be pre-prepared allowed their use in an off-line HPLC detection experiment using MALDI. These same qualities permit their use in time studies and where extensive washing of MALDI samples is desired.

Investigation of Sample/Matrix Preparation in MALDI by Confocal Microscopy

Yuqin Dai, Randy M. Whittal, and Liang Li*
Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2

Matrix-assisted laser desorption ionization (MALDI) mass spectrometry has become widely used for biomolecule analysis. In MALDI, the method of sample/matrix preparation plays a central role for achieving optimal performance. Detection sensitivity, selectivity, mass resolution, and other performance indicators are strongly dependent on the sample/matrix preparation. Thus, the understanding of chemical and physical phenomenon underlying the sample preparation process is very important. It is hoped that these studies would ultimately lead to rational design of improved methods for sample preparation in a wide range of applications.

We report herein a non-intrusive method to examine the sample/matrix preparation process. In this method, the analyte is tagged with a fluorescent group. The matrix and analyte samples are prepared under the same conditions as those used in conventional MALDI experiments. Laser confocal microscopy is then used to examine the matrix/analyte crystals The fluorescence and reflectance (or transmittance) images generated from the confocal microscope can provide information on the analyte and matrix crystal distribution, respectively.

In confocal microscopy, a laser beam is focused onto a small spot in an object. The illuminated spot is viewed with a specially designed optical system consisting of several lenses and apertures so that only signals emanating from this spot are detected By rastering the light beam, an image of the complete specimen can be obtained. Unlike conventional light microscopy, the confocal microscopy technique provides high contrast with the elimination of out-of-focus light interference. One can also slice very thin optical sections out of a thick sample specimen to obtain a 3-dimensional view at extremely high resolution (e.g , 200 nm lateral resolution and 400 nm axial resolution). The Molecular Dynamics Multiprobe 2001 confocal laser scanning microscope is used for the generation of all images reported herein.

In this presentation, we show that this method can be used to map the analyte distributions within the solid matrix crystals. For the samples prepared by using the dried-droplet method, we observe the analyte incorporation into small matrix crystals. More significantly, we find that the analyte is not uniformly distributed among many crystals formed on the sample surface This is shown in Figure 1 where the fluorescence image (analyte) and transmittance image (matrix) are reconstructed from multilayer scans and superimposed, representing a 3-dimensional image. In this case, the analyte is fluorescein isothiocyanate (FITC) labeled bovine insulin and the matrix is 2,5-dihydroxybenzoic acid (DHB). The MALDI spectrum of this chemical reveals that it is a mixture of insulin with one and two labeling groups attached. The bright area in the crystals shown in Figure 1 represents the fluorescence image of the analyte. As Figure 1 shows, several analyte domains are observed. By examining the entire sample/matrix regions on the substrate, it is also found that there is no direct correlation between the

43rd ASMS Conference on Mass Spectrometry and Allied Topics

location of the analyte domains and the physical appearance of the crystals. In contrast, large crystals grown by a slow process display much more uniform analyte distribution (figures not shown). This indicates that the speed of crystal formation plays an important role in entraining analyte. The same observations are found for other commonly used matrices such as sinapinic acid (SA) and several other fluorescent labeled oligosaccharides, peptides, and proteins. In addition, we have used the confocal microscopic method to examine sample/matrix containing two analytes with different labeling groups. By exciting and detecting fluorescence signals at different wavelengths, we can map the individual analyte distribution in the matrix crystals. We find that the analytes are not coherently distributed in the matrix. One type of analyte may reside in one region of a crystal and another region of the crystal may contain the other analyte only. There are regions where both analytes are present. This double-labeling imaging work is very useful for designing better internal standards for quantitative analysis by MALDI.

There is a report [1] indicating the possible correlation between the analyte distribution in the matrix crystals and MALDI analyte signals. Our confocal imaging results provide further evidence of this observation. Strong and much more reproducible analyte signals can be obtained from the crystals containing the analyte whereas the regions containing little or no analyte give only matrix peaks Thus, sample/matrix preparation methods that provide uniform analyte distribution would improve the signal reproducibility in MALDI. The sample preparation method reported by Vorm et al [2] is very effective in obtaining more reproducible signals. In this method, sinapinic acid matrix solutions are prepared in acetone. A drop of matrix solution is applied to the MALDI sample probe. The droplet spreads and dries very quickly, leaving a thin layer of matrix crystals. Analyte samples are then placed on top of the matrix layer and allowed to dry The color coded fluorescence and reflectance images (not shown) obtained by using confocal microscopy clearly show that the analyte is much more uniformly distributed on the sample surface. The use of confocal microscopy for developing more effective means of sample preparation for highly sensitive MALDI quantitation is currently underway.

Influence of Sample Preparation on Time-Dependent MALDI MS of Proteins

Gary Lavine and John Allison
MSU/NIH Mass Spectrometry Facility
Michigan State University
East Lansing, MICHIGAN

We have been developing a number of approaches for acquiring MALDI spectra, that may be more representative of the experiment than a single transient (from a single laser shot) or the sum/average of 20-200 transients. Using a larger laser spot size, "Big Spot MALDI", we have found that the experimental results are more reproducible. Also, many useful spectra can be obtained without having to move the laser. In addition, we realized that each MALDI mass spectrum, from each transient, is unique. With subsequent laser shots, resolution and composition of the spectra can vary. Thus, we generate and collect a number of "component spectra" from a MALDI experiment, where each is the sum of 10 successive transients. With this set of spectra, time-dependent variations can be more clearly realized. We use these tools here to investigate some approaches to MALDI target preparation.

In the past few years, a number of techniques have been described to yield improved MALDI performance, by changing the approach to sample and matrix deposition on a target. We compare three methods in this study. The first approach was our standard approach of codepositing a solution of α-cyano-4-hydroxycinnamic acid and 2 pmol each of bradykinin and insulin, and allowing the solvent to evaporate. The second was an approach to yield a layered target. The matrix is applied first in this technique, and a solvent system such as acetone selected to allow for very rapid evaporation, yielding smaller crystals. The analyte solution is then applied *on top* of these matrix crystals, and the solvent allowed to evaporate. It has been suggested that this leads to improved performance. A third approach we refer to as the crushed crystal method. Here, solid matrix is crushed into the target surface before solutions are applied. It is believed that this will place on the surface microcrystalline deposits which result in a more uniform surface, by seeding crystal growth evenly across the target.

We have analyzed the targets made in these ways at a number of laser power settings, collecting component spectra over a period of time. A more sensitive characterization method to allow for differences to be realized is what we call "power titrations". In this experiment, a series of component spectra are again collected from a single location on the target, although each component spectrum

is taken at a different laser power. Thus, a range of powers are sampled (constantly increasing, beginning at the power threshold for desorption/ionization of the matrix). The spectra are generated by beginning well-below the MALDI laser power threshold, and incrementing power after each set of 10 transients. The first spectrum shown was obtained with that power setting where matrix ions were first observed.

When these sets of spectra are compared, using targets prepared by the three methods selected for this study, it is clear that each yields different results. The mass spectra can be segmented into three regions. In the low mass region, there are peaks representing alkali ions and low mass ions derived from the matrix. All of these are clearly most intense when the standard method is used. In the "middle mass region", the three again yield different results. The standard method is best here, generating the smallest number of (and least intense) matrix-related peaks that lie above the peak representing the protonated matrix molecule. (This is particularly important when relatively low MW analytes are being analyzed.) At the high mass end of the spectra, where the two analyte peaks appear, the most surprising result is from the layered target. This case yields the largest difference in relative responses for bradykinin and insulin, with the signal representing protonated insulin being very weak, even at high powers.

Finally, we evaluated matrix additives and their influence on response. We were particularly interested in fucose as a nonabsorbing matrix additive. It had previously been reported that sugars can extend the signal duration for peptides. Our time-dependent data clearly support and show this observation.

While each approach yields unique spectra, and there are clear *differences* between them, we were unable to document major improvements over the results obtained for our standard preparation procedures. Surely, this is at least in part laboratory and instrument-dependent. When this comparison is reproduced on a reflectron-TOF instrument, more differences may be realized.

Dependence of Resolution on Laser Power in MALDI-TOF MS

Pao-Chi Liao and John Allison
Department of Chemistry, Michigan State University, East Lansing, MI 48824

Time-of-flight (TOF) mass spectrometry is most commonly used with matrix-assisted laser desorption ionization (MALDI). A dominant factor that influences the mass spectral resolution in a MALDI-TOF experiment is the laser irradiance [1]. It has been reported that the mass resolution dramatically decreases when laser powers much higher than threshold are used. For simplicity, we will discuss "power" instead of "irradiance" in this report. Most MALDI spectra reported in the literature represent the summation or average of 20-200 mass spectral transients, which may be obtained from multiple locations on the MALDI target or obtained using a variety of power settings (or, single shot spectrum may be presented). Conclusions such as the high power-low resolution relationship seem to evolve from the analysis of such summed spectra, or from the spectrum resulting from a single laser shot. We recently showed that the mass spectral transients of MALDI-TOF MS rapidly change with time, and an evaluation of the component spectra may yield different conclusions than evaluation of a single summed spectrum [2]. We use this tool of time-dependent MALDI data analysis to investigate details of the power-resolution relationship here.

All MALDI results were obtained on a ResearchTec TOF mass spectrometer (Vestec Corp., Houston, TX), used in linear mode, equipped with a nitrogen laser (model VSL-337ND, Laser Science, Newton, MA, 337 nm, 3-ns pulse, 250 μJ/pulse). Laser power is attenuated using a variable attenuator (model 935-5-OPT, Newport, Fountain Valley, CA) with a computer-controlled stepper motor, corresponding to an on-screen number ranging from 0 to 2,400. A larger number results in a higher laser power. Laser powers in this report are not expressed on an absolute scale, but relative to the value at the D/I threshold. The threshold laser power will be designated here as P_t (m, A), where P_t is the threshold power at which the analyte, A, generates observable signals (S/N > 5), using the matrix, m. The threshold laser power P_t (αCN, I), where αCN represents α-cyano-4-hydroxycinnamic acid and I represents insulin, corresponds in our instrument to a counter reading of 1200. When the stepper motor position was set at a point corresponding to a counter reading of 1800, the corresponding laser power is expressed in the text as 1.50 P_t.

If the typical approach of evaluating summed data is used, the resolution decreases considerably with increasing laser power. However, we have found that the resolution of all of the mass spectral transients accumulated, when a typical summed MALDI spectrum is obtained, is not constant. By collecting successive MALDI mass spectra, it is seen that the laser power/resolution relationship is more complex than is realized from a single spectrum representing many laser shots. When a sample is irradiated by a fixed laser power at the same spot, signal intensities decrease, and resolution increase with successive laser shots. As shown in Figure 1, the intensity of the insulin

signal decreases with component spectrum number (increasing number of laser shots), regardless of which laser power is used. The signal lasts longer when higher laser powers are used. The data in Figure 1a correlate with experience - signals "last longer" and are more intense at higher powers. The resolution in all of the component spectra is not constant. The data show that the resolution increases with component spectrum number. When the laser power is 1.80 P_t (αCN, I), the measured resolution starts at ~ 100 and increases to ~ 300, while the intensity falls, with increasing component spectrum number. That is, the "low power resolution" (300 ~ 400) can be realized when "high power" is used. The data also suggest that there may be a correlation between resolution and peak intensity.

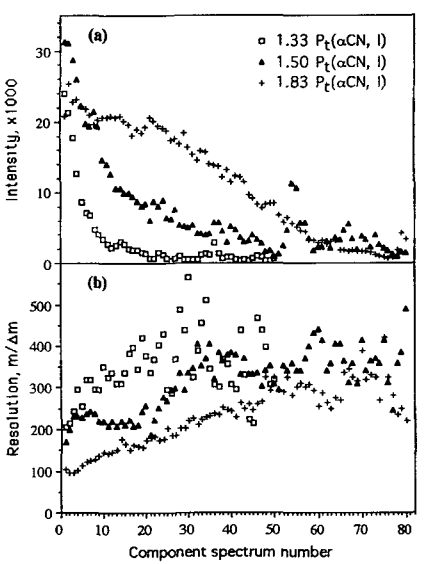

Figure 1 The (a) peak height and (b) resolution of the insulin signal obtained at different laser powers are plotted against component spectrum number. The experiment was configured so the laser fires 10 times in 2.5 seconds. Every 10 mass spectral trasients are summed as a component spectrum.

Big Spot MALDI- Advantages of Irradiating Large Portions of the Target

Joseph Hiller, Gabriella Szekely and John Allison
MSU/NIH Mass Spectrometry Facility
Michigan State University
East Lansing, Michigan 48824

MALDI evolved through a history of Laser Desorption and ablation techniques. It has continued to re-define itself into a separate, physically different method of encouraging molecules to acquire a charge and leave the solid state. Its present utility lies primarily in the ability to produce simple spectra which can be easily interpreted. In general, as the laser process becomes ablative with increasing pulse power, the complications of interpreting the spectra with increasing laser power grow rapidly.

To study a physical process, the physical situation should be such that the region studied ought to be as large and uniform as possible in order to exclude edge and other non-uniformity effects. Ignoring the issue of variable sample preparation, there are two classical options to accomplish this in MALDI: Locate the individual features that formed at the same time (approximately similar size and appearance crystals) and study many of those sites; or, Expand the spot size to cover a significant portion of the inhomogeneous surface. The observation that "sweet spots" exist that allow desorption at lower thresholds than others, suggests that better signal-to-noise may be obtainable with increased spot size to sample more "sweet spots" simultaneously. Increasing the spot size also helps ensure that if new features are encountered in samples, they will also be sampled.

The instrument is a VESTEC 2000 MALDI/TOF. The lens which is used to focus the light from a nitrogen laser, has been removed and placed on an XYZ translational stage. The translational stage is positioned such that the plane of the lens is perpendicular to the direction of the laser beam. In practice, this amounts to assuring that the laser continues to illuminate the same location of the sample as the lens is moved to new positions. Bradykinin has been purchased from Sigma. A concentration of 1,000 picomole/µl is prepared and 5,000 pM is deposited in a series of microcentrifuge vials. The vials are dried in a vacuum centrifuge and stored a -60°C until needed. MALDI surfaces are prepared from solutions of 10pM/µl of bradykinin in 0.1% trifluoroacetic acid. A solution of 1:1 0.1% trifluoroacetic acid to acetonitrile is saturated in the matrix, alpha-cyano-4-hydroxycinnamic acid is prepared and allowed to warm to room temperature. Each sample pin is prepared by placing 1µl of bradykinin on the probe tip, quickly followed by 1µl of matrix solution. Pins are then air dried and examined under a microscope. Those pins which have irregular coatings due to loss of solution over the edge, or other reasons, are discarded.

All spectra are taken from a fresh location so as to minimize damage to the sample surface. Spectra are the result of 10 individual TOF spectra which have been averaged on a Tektronix 520 digital oscilloscope prior to downloading to a computer. Each spectrum is saved and the next one taken as rapidly as possible using a digital device constructed to close the circuit for the joystick control provided with the VESTEC 2000. While the laser is pulsed at 4 Hz, the downloading of the spectra to the computer causes the time between spectrum acquisitions to be approximately 20 seconds. During this period, the laser beam is not moved from the initial spot. This produces a series of Time Dependent spectra which can be viewed in two or three dimensions using the GRAMS 386 software provided with the instrument.

Examining the spot area as a function of the lens position, the relationship of spot size to a fixed power/unit area required to produce ions (threshold power), can be deduced to be of the form:

$$P_{(thrsh)}^{1/2} = C_1 + C_2 * L$$

where L is the distance the lens is moved from the focal point, and C_1 and C_2 are constants for a particular lens' focal point (15 cm. for this instrument) and wavelength of light (337 nm). Determining the relationship between the lens position and the threshold power for a particular sample will determine the behavior of the instrument. For this system, the relationship between the lens position agrees with the above form.

Several spot sizes were examined for their Time Dependent MALDI spectra with intensity of the $(M+H)^+$ generated from the sample at the beginning of the analysis between 40 and 80% of the saturation level. All spot sizes examined produced acceptable MALDI spectra. As the spot size was increased, it became easier to predict the laser power at which the $(M+H)^+$ would be at near 75% of saturation for a new spot. This method of choosing the laser power for comparison was chosen to ensure the signal remained on scale during the measurement.

Increasing the spot size generally increases the length for which the Time Dependent experiment continues. Signal from the $(M+H)^+$ ion continues for a longer period, and appears more reproducible for the larger spot sizes. At very large spot sizes, however, where more than approximately 50% of the tip is illuminated, the signal again lasts less time. This observation may be due to heating of the pin surface by the laser.

At these larger spot sizes, the laser power used to illuminate the target is as much as ten times higher than that used for the focused spot. Upon removal of the sample holder from the vacuum, the temperature can be as much as 10°C higher. The longest lasting spot size corresponded to approximately 17 mm. along the translational stage, which places the sample at a position of 1.7 mm. from the focal point.

Using the Big Spot (L=1.7 cm) we have been able to acquire approximately 6-8 times as many spectra from the same point as can be acquired for the focused point. The Time Dependent spectra are also more uniform in profile along the time axis. For the first time we have found that we can readily reproduce the results of signal intensity, etc. for identically prepared sample. Threshold measurements have also become more reliable. The use of the Big Spot has provided the pathway for the development of other methods of sample diagnosis, such as Time Dependent MALDI and Power Titration MALDI, in which the laser power is increased linearly as spectra are acquired.

The Behavior of Peptide Mixtures in MALDI-MS

Joseph Hiller, Gary Lavine, Gabriella Szekely and John Allison
MSU/NIH Mass Spectrometry Facility
Michigan State University
East Lansing, Michigan 48824

We have been developing some new tools to characterize in greater detail the MALDI-TOF experiment. One goal is to understand in more detail the use of MALDI for mixture analysis, and to develop approaches that yield improved results. First, we increase the size of the laser spot used. This results in the irradiation of a more representative subset of the crystals on the surface, improving reproducibility, and allowing many spectra to be obtained without moving the laser during acquisition. This is important in experiments where multiple transients are accumulated. The second difference in our work, is that we can generate and collect a number of component spectra, for a given laser power. In our work, each successive set of 10 transients is summed into a single component spectrum. In subsequent component spectra, there are changes in resolution and relative intensities of the various peaks, clearly showing that all MALDI spectra are not the same - they change with time. A third approach that we use is called a power titration. In this technique, component spectra (again sums of 10 transients) are acquired at a number of increasingly higher laser powers. Thus, once one realizes that MALDI spectra are not all the same, and change in time (subsequent laser shots), we can work on a complex power/time/spectra surface. One can obtain time-dependent spectra at a fixed power, or change power and time simultaneously while acquiring spectra.
We have performed power titrations, acquiring a series of spectra with increasing power from a single large irradiated spot, for a synthetic mixture of peptides which include bradykinin (M_r = 1060), angiotensin (1297), melittin (2847), insulin b chain (3498), insulin (5734), cytochrome C (12446) and myoglobin (16891) - using alpha-cyano-4-hydroxycinnamic acid as the matrix, and a linear TOF instrument. The results are typical of MALDI analyses of mixtures of peptides. When equimolar amounts of each mixture component are used, signals representing bradykinin and insulin dominate. As power is increased, matrix peaks appear first. At higher powers there is a fairly regular trend indicating that desorption/ionization thresholds for each component vary with peptide molecular weight.

We have found several instances of suppression effects, where one component seems to suppress the signal of another, and frequently find melittin to be involved in such observations. In simple binary mixtures of melittin and bradykinin, clear

43rd ASMS Conference on Mass Spectrometry and Allied Topics

changes in relative response and desorption/ionization power thresholds are apparent as the amount of mellitin present is varied. When melittin is not present in the larger synthetic mixture, it is easier to detect the higher MW components of the mixture. In particular, melittin appears to dramatically suppress the signal for insulin in the synthetic mixture. We note that melittin is considered as a strongly basic polypeptide.

Using time-dependent spectral acquisition, and power titrations, we also note substantial differences in the responses of components of our synthetic mixture as a function of target preparation technique. In these experiments, we frequently start with separate solutions of matrix and analyte. Both use volatile solvent systems that can quickly be removed. Rather than mix them both prior to deposition on the probe, we can deposit some amount of each solution. If order is important, there are two possibilities. If one microliter of the peptide mixture is applied to the solid support first, followed by one microliter of the saturated matrix solution, this yields relatively poor performance. Application of the matrix solution first gives higher sensitivity for detecting the components of the synthetic mixture used here. In comparing these two approaches to solution deposition, we do note that, although application of the sample solution *first* resulted in a poorer representation of the mixture, it yielded the strongest signal for one particular component, angeotensin.

The power titration method for MALDI TOF MS is a very sensitive probe of the influence of various mixture components as well as the methods of preparation. It appears that, if the relative responses of components of a peptide mixture are to be used to determine relative amounts in the sample, spectra obtained at high power are preferable to use in such analyses. High powers increase the likelihood that minor components and larger analytes will yield signals, and represents conditions under which relative response factors are relatively constant.

MALDI Calibration and the Effect of Separate Layers of Sample and Standard

J. Zhou and T. D. Lee
Beckman Research Institute of the City of Hope
Duarte, CA 91010

The method most commonly used in MALDI to prepare samples is to evaporate a solution containing matrix and sample. When using this "dried droplet" method of preparing the sample, suppression of one protein signal often occurs in the presence of another. The degree of suppression depends on the molar ratio of proteins and matrices, the nature of the proteins, and the method of handling the sample. This suppression problem complicates the use of a internal protein standard to calibrate the mass scale. Often, samples must be prepared with different sample, standard ratios in order to obtain good ion intensities for each protein. When sample amounts are severely limited, it is not possible to prepare a number of samples with different concentrations of internal standard.

Recently, Xiang and Beavis developed a new sample preparation method to quickly grow a protein-doped polycrystalline matrix film [1]. Using our own variation of this technique, it is possible to deposit sample and standard in separate CHCA matrix layers. Samples were prepared by first depositing 0.5μl of a saturated solution of a-cyano-4-hydroxy-cinnamic acid (CHCA) in 1:1 water: acetonitrile onto the stainless steel sample stage of a Shimadzu Compact MALDI III TOF-MS. After 15s, the stage is washed leaving only a thin layer of matrix on the surface of the sample well. Additional matrix (~3 μl) is added to form a thick matrix pad. The first protein solution (0.5-5 pmole/μl in 1:1 0.1% aqu. TFA: acetonitrile) is added to the matrix pad and evaporated to dryness. The second protein is added in the same solution only containing 20% glycerol. After 3 min, the remaining solvent is removed from the sample pad by dipping the slide in water then air dried. Collected spectra are the average of a 100 laser shot scan across the sample.

Samples prepared using the layered method avoid the suppresion effects associated with the dried droplet method (Figure 1). With each successive scan, the signal of the protein in the top layer decreases. Thus, it is always possible to obtain a spectrum with good intensities for sample and internal standard ions. Thicknesses of the top protein layer were found to be inversely proportional to the molecular weight of the protein sample (~3μm for trypsin inhibitor, 20 kDa and ~0.4μm for BSA, 67 kDa). The observed mass value of the sample protein does not vary systematically with increasing scans over the sample. The mass measurement error for large proteins (> 15 kDa) was found to depend strongly on which order the proteins were layered in the sample (Figure 2). Proteins deposited in the bottom layer had a larger energy deficit as the result of increased numbers of collisions with neutral matrix ions during the MALDI process [2]. This complicates the use of the layered sample preparation method for internal calibrations, but does not entirely preclude its use. If the standard protein is always deposited in the top layer, using exactly the same proceedure, the calibration error increases with increasing molecular weight. A correction factor empirically determined for each standard protein can be used to adjust the value of the observed mass.

Charge State Distribution Shifting of Protein Ions Observed in Matrix-Assisted Laser Desorption Ionization Mass Spectrometry

J. Zhou and T. D. Lee
Beckman Research Institute of the City of Hope
Duarte, CA 91010

Recently, Xiang and Beavis reported that a thin polycrystalline film, consisting of microcrystals of protein-doped matrix, could quickly form on a previously deposited layer of the same matrix (1). The film strongly adheres to the substrate so that it can be more easily washed and samples can be prepared in the presence of high concentrations of glycerol and even 6 M urea. While experimenting with our own version of Beavis method using the CHCA matrix, we observe significant increases in the intensities of higher charge state species for large proteins when the polycrystalline film was formed in the presence of glycerol or urea.

Experiments were conducted in a Kratos Compact MALDI III time-of -flight mass spectrometer (Shimadzu, Columbia, MD). All spectra were collected in the linear mode without using the reflectron. Spectra are an average of 100 laser shots over 2 mm long sample well. The CHCA matrix was prepared as a saturated solution in 0.1% TFA and acetonitrile (1:1 v/v). Proteins were dissolved in 0.1% TFA. Like the Beavis method, the initial layer of matrix was formed by drying about 4 ml of matrix solution on the sample well (2 mm x 1 mm). The matrix pad is then smeared with a microscope slide. Loose matrix powders were removed by tapping the sample slide. Protein solutions (a few pmole total amount) were mixed with matrix solution and applied to the matrix pad and allowed to dry completely. When glycerol was added to the sample-matrix solution (20% by volume), there was no obvious change in drop volume after a few minutes and the remaining liquid was removed from the pad by dipping the slide in room temperature water for two minutes.

The effect of effect of depositing the sample in the presence of glycerol is illustrated with the analysis of phosphorylase a (Fig. 1). When the sample is deposited on a preformed matrix pad (Fig. 1b), there is a noticable shift to higher charge states compared to the spectrum obtained by drying the sample, matrix solution directly on the bare stainless steel stage (Fig. 1a). In the presence of glycerol (Fig. 1c), a bimodal distribution is observed. With an increase in laser power, the higher charge state distribution decreases (Fig. 1d.). The bimodal distribution is generally not observed for most proteins, but the shift to higher charge states is a general phenomenon for many proteins larger than 30,000 Da. Other matrixes were studied (sinipinic acid, HABA) but no difference was observed when samples were prepared with glycerol. Depositing a thin layer of glycerol on samples already on the sample stage had no significant effect. These results indicate that glycerol is incorporated into the crystal structure along with the protein and either alters the structure of the protein or changes the chemistry responsible for charging the protein ions during the desorption process.

We were unable to obtain any evidence that differences in the spectrum reflected differences in the conformation of the protein in solution. Indeed, the fact that both glycerol and urea show the same effect would argue against that conclusion. As evidenced from CD data obtained on BSA, glycerol stabilizes the alpha helical structure while urea denatures the protein into a random coil. Using this sample preparation method, it may be possible to obtain MALDI spectra on magnetic sector or FTMS instruments that have limited mass ranges compared to time-of-flight analyzers.

OPTICAL CHARACTERIZATION OF THE MALDI PLUME*

Gregory B. Hurst, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37831-6365

The development of matrix-assisted laser desorption/ionization (MALDI) by Karas, Hillenkamp *et al.* has brought an entire new class of large-molecule applications within the reach of mass spectrometry [1]. However, the ionization efficiency and therefore the sensitivity of the technique could be improved if details of the ionization mechanism were understood more thoroughly. The environment in the MALDI plume may influence the ionization of the analyte, in analogy to the effect of pH on biomolecules in solution. Optical probing techniques, such as laser-induced fluorescence, allow some characteristics of the plume environment to be studied directly [2]. This paper describes measurement of wavelength-dispersed fluorescence produced in MALDI experiments in a time of flight mass spectrometer (TOF-MS).

An in-house-constructed linear TOF-MS for MALDI using a Laser Photonics LN203C pulsed nitrogen laser (337 nm) was modified to allow collection of the fluorescence related to the laser desorption event. A 5 cm quartz lens inside the vacuum chamber collimates the light emitted from the sample, and directs it through a quartz viewport. A second lens outside the chamber focuses the light into a UV-transmitting fiber optic (3M, FT-1.0-UMT) leading to a 0.5 meter focal length monochromator. Fluorescence spectra were obtained by scanning the monochromator while recording the output of an attached photomultiplier tube.

Samples investigated included 2,5-dihydroxybenzoic acid (DHB) and chrysene added to the probe tip as a solution or as a methanol slurry. Typical operating pressure in the mass spectrometer was in the 10^{-7} torr range. For obtaining desorption-laser-induced fluorescence spectra, the laser power density was approximately 10^{6} to 10^{8} W cm^{-2}. Solution-phase excitation and emission spectra of DHB in 1:1 (v:v) acetonitrile/water were obtained using a scanning fluorescence spectrophotometer (Perkin-Elmer model LS-5B) with slits set for 3 nm.

Figure 1 compares fluorescence spectra of DHB obtained by monitoring the emission resulting from laser desorption in the TOF-MS (Figure 1, A-C) and in acidic solution (Figure 1D) Spectra A-C were obtained consecutively by repeating a monochromator scan while illuminating the same sample spot with the desorption laser. Relatively narrow features are observed at 423 nm and 533 nm in A, which are less intense in B and nearly absent in C. This could be due to a laser-induced change in the sample, such as photochemical decomposition of the solid material on the probe, gradual removal of material from the sample by ablation, or changes in the crystal structure. The overall broad envelope of the emission observed in Figure 1 A-C matches the broad conventional fluorescence emission spectrum shown in Figure 1D for DHB in acidic solution. Because of potential complications due to the acid-base chemistry of DHB, desorption-laser-induced emission from chrysene, a polycyclic aromatic hydrocarbon with well known spectroscopic properties was examined (Figure 2.) Compared to the literature solution-phase fluorescence spectrum [3], the overall maximum is somewhat red-shifted, and the vibronic structure is obscured. In contrast to the DHB spectra, no narrow features are seen.

One possible explanation for narrow features in the DHB spectra in Figure 1 A-C is fragmentation of the organic molecule into smaller, highly-fluorescent species such as H, C_2, OH, etc. which have relatively narrow emission spectra. However, literature spectra of several such small molecules [4] do not match the observed narrow features in Figure 1 Another possibility is gas-phase fluorescence from DHB molecules or ions that have been cooled by expansion of the laser-produced plume into the vacuum subsequent to the desorption event. While the data presented here are preliminary, the presence of narrow features in the DHB spectra and their

43rd ASMS Conference on Mass Spectrometry and Allied Topics

absence in the chrysene spectrum suggests that the chemistry of the desorbed compound may determine whether such features are observed. An obvious difference between DHB and chrysene is the presence and absence, respectively, of -OH and -COOH functional groups. Further experiments to determine whether there is a correlation between presence of narrow emission features and the ability of a compound to perform as a MALDI matrix are planned.

Recently matrix assisted laser desorption ionization (MALDI) mass spectrometry has been successfully applied for detection of DNA fragments with mass up to 500 mer[1,2]. This success was possible after finding a few matrices that play a key role in transporting analyte molecules and molecular ions into gas phase. Unfortunately, the search for new matrices is still an empirical procedure in view of the lack of detailed understanding of the complicated MALDI process However, it is generally accepted that the laser evaporation of the matrix with dissolved guest molecules is the starting point of MALDI The absorption of laser energy should be quickly and efficiently converted to heat to produce evaporation of the matrix substance Here we present a new technique involving broad band acoustical monitoring of solid state matrix samples as a method of investigation of the light-heat conversion process[3]. Generally, laser acoustic pulse generation can be treated as a result of thermal expansion of a thin layer of a substance heated by laser radiation. Therefore an acoustic signal can be used for calorimetric characterization of the thin layer of irradiated substance

In our experiments we investigated the amplitudes of an acoustic signals generated in 3-hydroxypicolinic acid (3-HPA), picolinic acid (PA), composite matrix (PA+3-HPA), and 3-aminopicolinic acid (3-APA) versus the laser pulse energy. A nonlinear dependence of the acoustical signal on laser fluence was found for PA, PA+3-HPA, and 3-APA matrices under irradiation by 7 nsec laser pulses at 266 nm Near linear dependence was found for 3-HPA at 266 nm There was no strong deviation from linear power dependence for any of these matrices at 355 nm. We found some correlation of the nonlinear acoustic pulse generation and the capability of the given compound to produce DNA ions in the MALDI experiment.

A comparative study of laser acoustic generation of solid matrices and their aqueous solutions showed that the observed acoustical nonlinearity is related to multiphoton (multistep) absorption rather than an ablation (desorption) process. We believe a multiphoton absorption involves high excited energy levels of matrix molecules leading to the process of light-heat conversion. Energy relaxation from high excited electronic states can occur through fast nonradiative transitions This can provide, probably, more efficient channels of laser heating of the matrix substance than one photon excitation through relatively long lived first singlet (or triplet) energy states.

Finally, one can expect the compounds that exhibit the characteristic of multiphoton absorption should be more promising for use as matrices in MALDI.

Matrix-Assisted Laser Desorption/Ionization of Cytochrome c
λ = 337 - 450 nm

Xiangjun Chen and Ronald C. Beavis
Department of Chemistry
New York University Medical Center
550 1st Avenue
New York, NY 10016

The protein ion emission properties of MALDI matrices have been investigated quite carefully in the wavelength range of 250-350 nm, by a number of groups using a wide variety of lasers. These experiments have been unable to determine whether single or two photon absorption is responsible for protein ion emission. They have also shown that protein ion emission is not very sensitive to wavelength in this range.

This study presents the protein ion emission properties of MALDI matrices in the near ultraviolet, in the wavelength range of 337-450 nm. At these wavelengths, almost all biologically derived polymers are transparent, so all laser energy will be transferred to the matrix, without the possibility of simple resonance transfer of energy to the biopolymer. Most of the common matrices also become transparent in this wavelength range The behavior of protein ion threshold fluence has been studied as a function of wavelength and matrix.

The matrix-assisted laser desorption time-of-flight mass spectrometers commonly used in analytical laboratories currently use low power nitrogen lasers. The experimental setup allowed the easy comparison of longer wavelengths with a standard nitrogen laser. A linear time-of-flight mass spectrometer (custom built at New York University Medical Center) was used to detect protein ions. The laser illumination system was configured in two parts: a transmitter, which focused the light from the laser into a fiber optic; and a receiver, which focused the light emerging from the fiber optic into the ion source. Two transmitter assemblies were constructed and mounted at the output of the two lasers used in this study: a nitrogen laser (λ = 377 nm) and a tunable titanium:saphire laser with second harmonic generation (λ = 350 -450 nm). The receiver was mounted on the time-of-flight mass spectrometer, with the fiber optic mounted in chuck so that it could be easily removed. To change between the nitrogen and titanium:saphire laser, the only alteration was removing one fiber optic from the receiver chuck and replacing it with the fiber optic from the other laser.

Part of the results are shown below Three matrices were used in the study: α-cyano-4-hydroxycinnamic acid, indole acrylic acid, and 3,5-dimethoxy-4-hydroxycinnamic acid (sinapic acid). The wavelength maxima (λ_{max}) for protein ion production are shown in Table 1.

matrix	λ_{max} (nm)
α-cyano-4-hydroxycinnamic acid	434
indole acrylic acid	428
sinapic acid	398

Table 1. The maximum wavelength for producing cytochrome c ions in three common MALDI matrices.

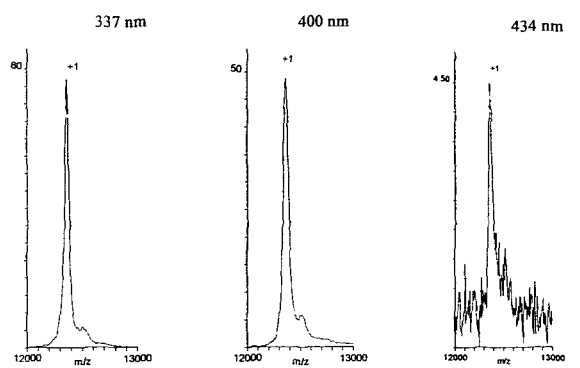

Figure 1 The molecular ion region of MALDI at three different wavelengths, using α-cyano-4-hydroxycinnamic acid as the matrix. Protein-doped matrix crystals were prepared using the dried droplet method, with using 0.5 µl droplets of 1 µM horse muscle cytochrome c in matrix-saturated 2.1 water:acetonitrile. Spectra were obtained near the ion production threshold laser fluence.

Influence of both esterification and target preparation on matrix-assisted laser desorption ionization time of flight mass spectrometry of an aromatic polyester.

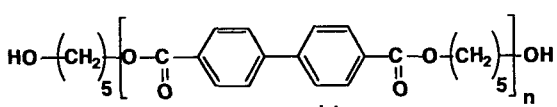
MALDI-TOF has been recognized as a powerful technique for the mass determination of large molecules [1] and for direct mixture analysis [2]. Polyesters are a challenge to the mass spectroscopist since they exhibit very broad asymmetrical molecular weight distributions and often a low solubility. We present results concerning the influence of both esterification with TFA and target preparation on the MALDI mass spectrum characteristics and on the molecular weight distributions of an aromatic polyester. MALDI mass spectra were performed on a home-built linear TOF (1,35m flight path -20KeV ion energy) using a pulsed N_2 laser.

Firstly, a « conventional » sample preparation method was used: matrix and analyte solutions were mixed and 1 µl was deposited onto the metal tip (« 1 step » method). Solubilization of the aromatic polyester requires the presence of TFA. The mass spectrum of compound 1 using 2,5-dihydroxybenzoic acid (2,5-DHB) as matrix and THF:TFA (0,1%) as solvent, exhibited the Na^+ and K^+ cationized oligomer peaks (fig.1).



compound 1

The $\overline{M}_n$, $\overline{M}_w$ and I_p values determined from this spectrum, were respectively 2164, 2582 and 1,19. SEC values have not been obtained for this compound, due to its insolubility in THF, and NMR measurements gave $\overline{M}_n$=3200. A discrimination against the higher mass oligomers could originate from a poor incorporation of the polymer in matrix crystals. The mass spectrum of compound 1, using pure TFA as polymer solvent and 2,5-DHB in THF as matrix, shows peaks corresponding only to the Na^+ and K^+ cationized diesterified oligomers. The $\overline{M}_n$ and $\overline{M}_w$ values were lower than those obtained with THF:TFA (0,1%) despite the better solubility of the polyester in pure TFA.

So, we tried a « 2 steps » method [3] in which matrix and analyte handling are completely decoupled: 1µl of the matrix solution (0,1 M 2,5-DHB in THF or 0,1 M α-cyano-4-hydroxy-cinnamic acid (HCCA) in acetone) was deposited onto the probe tip ; then 1µl of compound 1 solution (10^{-4} M in TFA) was applied. For both matrices, the « 2 steps » method induced an increasing of the $\overline{M}_n$ and $\overline{M}_w$ values. Typically with HCCA (fig. 2), $\overline{M}_n$, $\overline{M}_w$ and I_p were respectively 4002, 5122 and 1,28.

In conclusion, the « 2 steps » method offers several advantages:
(i) sample surface becomes more homogeneous, leading to easier and faster data acquisition.
(ii) less discrimination against the higher mass oligomers.
(iii) the diesterification induces a shift toward higher masses (+192 uma), so matrix cluster peaks do not interfere with the lower mass oligomers peaks.

Mechanistic Studies of the Cationization of Synthetic Polymers by Alkali Metals in the Matrix-Assisted Laser Desorption/Ionization Experiment

Richard C. King, Robert Goldschmidt, Yansan Xiong, and Kevin G. Owens*, Department of Chemistry, Drexel University, Philadelphia, PA 19104

Alkali metal cationization of several classes of synthetic polymers (notably the polyglycols and polymethacrylates) occurs via a gas-phase ion-molecule or excited state molecule-molecule reaction[1]. Laser post-ionization (and laser photodissociation) experiments of the neutrals desorbed during the MALDI process suggest that the alkali metal salt of the matrix (in this case 2,5-dihydroxybenzoic acid, DHB) is the preferred form of the ionizing reagent. Furthermore, the supersonic expansion conditions that occur as a result of disintegration of the matrix crystal provides the necessary collision frequency and relative energy distributions to virtually ensure the reaction of the neutral species in the plume and the cationization reagent.

Addition of the alkali metal salt of the matrix at the level of 10% was shown to effectively ionize materials without significantly affecting the desorption behavior of the protonated DHB material[2]. The matrix salt is not incorporated into the crystals with the analyte; proximity of the ionization reagent to the matrix dispersed analyte is sufficient for efficient ionization. When attempting to analyze a polymer sample by MALD/I, it would be advantageous to know whether matrix salt addition would be beneficial and if so, which salt would be best to use. In this work we examine the effect of added matrix salt for selected polymer samples to determine whether trends may be seen in the effectiveness of matrix salt addition and cation preference.

Results and Discussion

Cation Affinities: When a PEG 1000 sample is mixed with a single DHB salt (in all cases mixed at the level of 10% with the protonated form of the matrix), all of the observed PEG oligomer peaks are cationized by the expected alkali metal ions. In comparing the different alkali DHB ionization reagents, it appears that the largest peak intensity is found with potassium salt addition and the lowest from the lithium salt addition. Similarly, when a polytermethylene glycol (PTMEG) 1000 sample is mixed with a single DHB salt, all of the observed PTMEG oligomer peaks are cationized by the expected alkali metal ions. However, the largest peak intensity is observed with lithium salt addition and the lowest from potassium salt addition.

When an equimolar mixture of PEG 1000 and PTMEG 1000 is added to the potassium salt of the matrix, only PEG oligomers are observed. When this same equimolar mixture of PEG and PTMEG is added to the lithium salt of the matrix, however, strong lithium cationized PTMEG oligomers are observed while only weak lithium cationized PEG oligomers are apparent. From these data it appears that PEG has a higher affinity for or forms a more stable cationized species with potassium, whereas PTMEG has a higher affinity for lithium.

When the PTMEG sample is added to an equimolar mixture of the three alkali metal salts of DHB together, it is found that with increasing of laser intensity, the relative ratio of the various cationized species change. It appears that the potassium cationized oligomer peaks decrease in intensity, while the lithium cationized peaks remain constant or slightly increase. This change may be due to the laser intensity directly (changing the numbers of ions formed or destroyed during the laser pulse), or could a function of the spatial distribution of the salts in the solid crystal (as higher laser power may create ions from a larger or deeper sample spot). When the PEG 1000 sample is similarly added to an equimolar mixture of the three alkali metal salts of

DHB, the sodium and potassium cationized oligomers are easily observed, while the lithium cationized peaks are very weak.

Mechanism of ionization: There are at least two explanations for the results obtained when studying the method of cationization by the alkali metal salt of the matrix[1]:

- The bare cation is released from the gas phase matrix salt by a photodissociation reaction. In the expanding plume above the surface, there is a large amount of matrix neutral, matrix salt neutral and some polymer neutral which can collide with the reactive bare cation to produce the characteristic ion signals. The energetics provided by the high pressure gas expansion into the surrounding vacuum and kinetics of the two processes provide the necessary collision frequency and relative energy distributions to virtually ensure the reaction of the neutral species in the plume and the bare cation.

- Collisions between the excited state matrix salt and the neutrals in the expanding matrix plume may result in the formation of the cationized species seen in the spectra. Such collisions may also provide the energy needed to fragment the excited state matrix salt into the bare cation and the remaining $(M-H)^-$ ion observed in the negative ion spectra.

Conclusions

The addition of a small quantity of the alkali metal salt of the matrix (~10% of the level of the chosen matrix) is effective for producing abundant cationized samples of most oxygen containing polymers. The results shown here provide information concerning the mechanism of ionization and the relative affinity of different polymers for different cation species.

Cation Affinities: Experiments with mixed samples or mixed ionization reagents indicates that the two polymers studied show different affinity towards the different cations. PEG is preferentially cationized with potassium ions, while PTMEG is preferentially cationized with lithium. The affinity of the various polymers for different size cations is likely due to their differing chemical and gas-phase structures. These cation affinities will have a significant impact on the analysis of polymer blends if a limited number of sample preparation conditions are employed. Work is continuing to understand these affinity differences, and to uncover whether different sample preparation strategies may decrease this sampling discrimination.

Mechanism of ionization: Results obtained when studying the method of cationization by the alkali metal salt of the matrix[1] suggest that the bare cation may be released from the gas phase matrix salt through a photodissociation reaction. The expansion conditions then provide the necessary collision frequency and relative energy distributions of the analyte and cation to virtually ensure the reaction of the neutral species within the expanding plume. A second possibility is that the cation is transferred between the excited state matrix salt and the neutrals through collisions in the expanding matrix plume. Such collisions may also provide the energy needed to fragment the excited state matrix salt into the bare cation and the remaining $(M-H)^-$ ion observed in the negative ion spectra.

Separation of the Desorption and Ionization Events in the Matrix-Assisted Laser Desorption/Ionization Experiment

Richard C. King and Kevin G. Owens*, Department of Chemistry, Drexel University, Philadelphia, PA 19104
Scott D. Hanton, Air Products & Chemicals, Inc., Allentown, PA 18195

An understanding of the cationization mechanism operating in the matrix-assisted laser desorption/ionization (MALD/I) technique has allowed us to experimentally separate the desorption and ionization events. Several new matrix materials are demonstrated that effectively isolate and desorb several types of synthetic polymers, but do not ionize these materials. Separation of the desorption and ionization events allows the experimenter greater latitude to optimize each event independently and to either simplify or improve the information of the final MALD/I spectrum.

The likely functions that a successful MALD/I matrix must possess has been discussed by a number of authors[1-3]. Generally, a MALD/I matrix is something that disperses and isolates the analyte, absorbs the energy from the laser field, vaporizes to form gas phase materials, and provides an ionization route suitable to the chemistry of the polymer sample. Clearly the matrix needs to fulfill a number of different functions. We can demonstrate that the desorption and ionization functions can be separated, and that these functions can be accomplished by different chemical species in the functional matrix. Desorption reagents tend to absorb the laser energy efficiently and fragment producing a supersonic expansion of gas phase species from the sample surface. Good desorption reagents include: sinapinic acid, 2,5-dihydroxybenzoic acid, and thiourea. The ionization process is believed to be a gas-phase chemical ionization reaction that occurs just above the surface of the sample after the desorbing laser pulse. Different chemical functionalities are optimized with different ionization reactions. Unsaturated hydrocarbon polymers will readily silver cationize, oxygen-containing polymers (e.g., polyglycols, polyesters and polyacrylates) will cationize with the alkali metals, and amine functional polymers tend to protonate. For unsaturated hydrocarbon polymers silver acetylacetonate (AgAcAc) is used, while the alkali metal salts of 2,5-dihydroxybenzoic acid are utilized for oxygen-containing polymers. We have found that the ionization reagent needs only to be in close proximity to, not incorporated into the matrix crystals.

We can demonstrate that the desorption and ionization functions of the MALD/I matrix can be separated, and that these functions can be accomplished by different chemical species in a combination matrix. The combination matrix must contain functionality to perform all of its different roles. If any of the roles are not fulfilled, the MALD/I experiment will yield incomplete or no ion signal. We will show examples of the consequences of not fulfilling either the desorption or ionization role, and then show how to design single, double and triple reagent matrices to ensure desorption and ionization for these polymers.

The data on this poster demonstrate that desorption and ionization are separate events in the MALD/I experiment. Most importantly, it is not necessary for a single molecule to carry out all the functions of a MALD/I matrix. These functions can be carried out by separate components of a mixture of molecules, with each optimized for best MALD/I results.

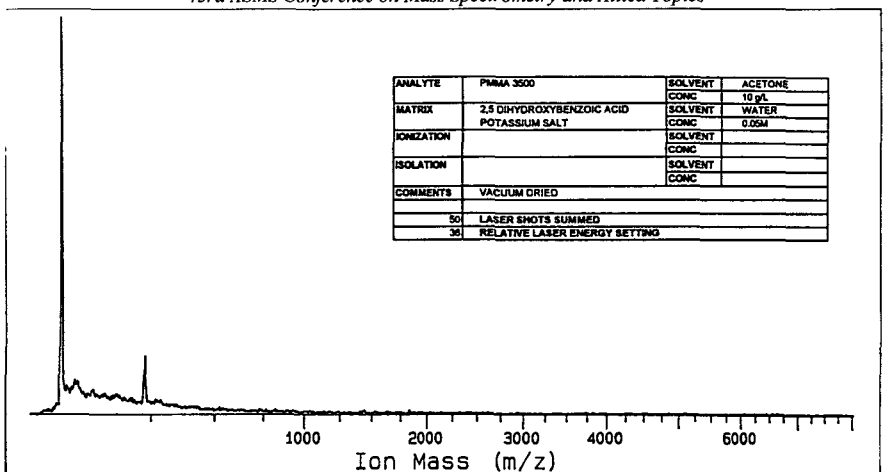
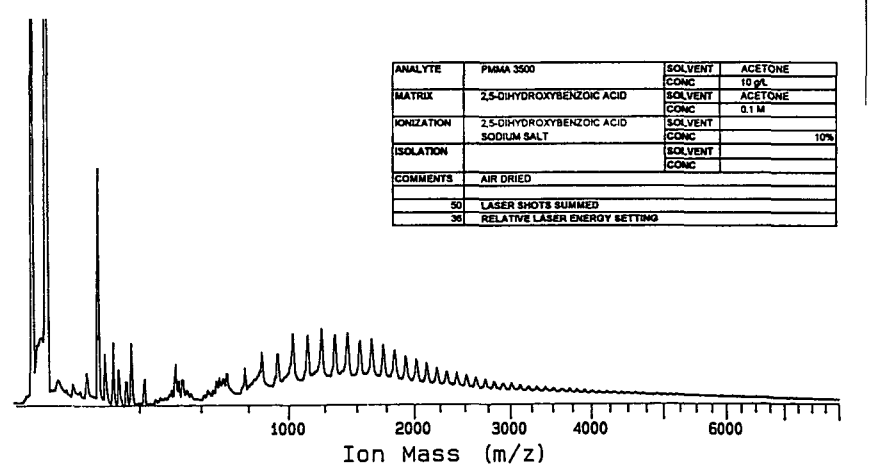
43rd ASMS Conference on Mass Spectrometry and Allied Topics





The alkali metal salts of the carboxylic acid matrix compounds acts as an efficient source for alkali metal reagent ions in the MALD/I experiment. The spectrum on top was obtained using the potassium salt of 2,5-dihydroxybenzoic acid (KDHB) as the matrix for a polymethylmethacrylate 3500 polymer sample. Although this absorbs 337nm light quite effectively, no oligomer ions are observed. When the system is modified by reducing the matrix salt concentration to 10% with the balance being the hydrogen form of the matrix, polymer ions are readily observed. In the former case the pure KDHB was unalbe to effectively desorb the analyte from the surface.

Evalution the Matrices used in MALDI by Their FAB Mass Spectra

Hsing-Long Chei and Jentaie Shiea*
Dept. of Chemistry, Natl Sun Yat-sen Univ.,Kaohsiung, Taiwan 804

The organic matrix used in matrix assisted laser desorption ionization (MALDI) play essential role both in ionization and desorption However, the choice of and search for the suitable matrix for protein analysis by MALDI is still a trial-and-error procedure. Since both FAB and MALDI are type of desorption ionization, the processes of phase transition and ion formation occurred in MALDI may be similar to those in FAB Therefore, the role of the matrix used in MALDI may be better understood by interpreting their FAB mass spectra. In this study, 25 organic compounds which are recognized as potential MALDI matrix were chosen as the analyte The FAB mass spectra of each analyte dissolved in glycerol was obtained. Since the laser desorption ionization (LDI) mass spectra of these compounds have been reported previously by Hillenkamp et al.[1], we then compared the mass spectra of the compounds obtained by FAB and LDI. It was found that except for four compounds, the major analyte ions found in FAB and LDI spectra are nearly identical. According to the type of the ions in FAB mass spectra, the investigated compounds can be divided into four classes. The classification of the first three classes is based on the value of $M^{\ddagger}/MH^{+}$ and the compounds in the last class produced both MH^{+} and MH_2^{+} ions

		As good MALDI matrix
Class 1	$M^{\ddagger}/MH^{+} > 1$	No
Class 2	$M^{\ddagger}/MH^{+} = 0$	No/Yes
Class 3	$M^{\ddagger}/MH^{+} < 1$	Yes
Class 4	$MH^{+}/MH_2^{+} > 1$	Yes

Except for few compounds, very similar classification of the organic matrixes has been suggested by Hillenkamp et al [1] by their LDI mass spectra. Table 1 indicates the usability of each compound as the matrix in MALDI for protein analysis. The data was quoted from the paper published by Hillenkamp et al. in 1992[1]. It can be seen that the compounds in class 3 and 4 are all good MALDI matrixes but all the compounds in class 1 and partial compounds in class 2 are not good MALDI matrixes. Since its very hard for the radical ion (class #1) and the ion with high gas phase basicity (some in class#2) to donate protone to the analyte, good MALDI spectra are imposible to obtain. It was also reported by Hillenkamp et al.[1] that for the compound such as indole-2-carboxylic acid the ratio of $M^{\ddagger}/MH^{+}$ on LDI mass spectra varied with the energy of the laser beam. Figure 1 show LDI mass spectra of indole-2-carboxylic acid at (a) 266 nm and (b) 337 nm. It can be seem that $M^{\ddagger}$ instead of MH^{+} was generated in the condition of higher energy deposition (i e. 266 nm, Figure 1a) To simulate the variation of energy deposition in FAB, the viscosity of the matrix was changed by 1) using more viscous FAB matrix such as diglycerol instead of glycerol (Figure 2) or by 2) lowering the glycerol matrix temperature by immersing the FAB probe into liquid nitrogen after sample application (Figure 3).

It can be seen when the viscosity of the matrix was increased the type of the indol-2-carboxylic acid ions on mass spectra was also changed from $M^{\ddagger}$ to $M^{\ddagger}/MH^{+}$ We have previously reported that as the viscosity of the FAB matrix increasing, the energy deposited on the molecule also increasing[2]. This will shorten the time of ion-molecule reaction which is responsible for the formation of MH^{+} ions. This is the reason why higher MH+ signal for the sample with lower viscosity is observed for there is enough time for ion-molecule reaction to be occurred. Owing to less ion-molecule reaction time is available for the sample with higher viscosity, more of the radical ions ($M^{\ddagger}$) shall be generated.

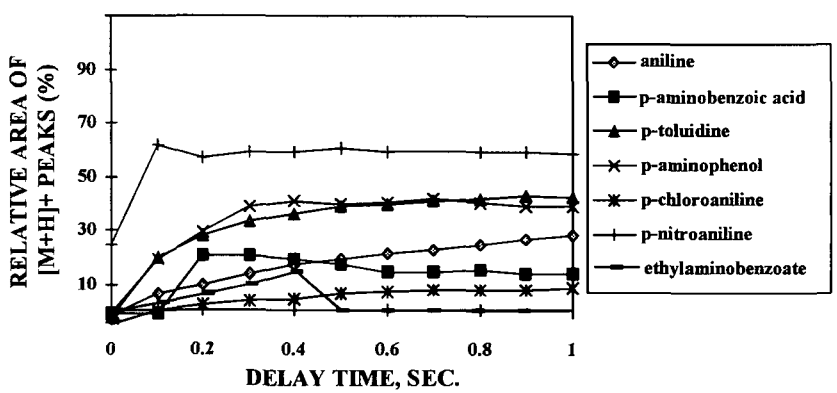
COMPARISONS OF PROTON TRANSFER REACTIONS OF MALDI MATRICES

Gary R. Kinsel, C. Mark Land, Angela Walker and Nan Li
The University of Texas at Arlington, Department of Chemistry, Arlington, TX 76019

The mechanism of matrix to analyte proton transfer during matrix assisted laser desorption ionization (MALDI) remains poorly understood. A variety of mechanisms have been suggested including excited state proton transfer, matrix ionization followed by proton transfer from the radical cation and matrix self-protonation followed by proton transfer to the analyte molecule. We have begun an investigation of the proton transfer reactions of a series of para substituted aniline molecules which serve as model MALDI matrices in a 3 T FT-ICR MS. This series of model matrices was chosen because the variations in the electron withdrawing and releasing ability of the para substituent should induce systematic and predictable changes in the proton affinities of the neutral and/or ionized matrices. Previously performed semiempirical calculations (PM3 type) of the heats of formation of the matrix neutrals and ions and proton affinities of the radical cations support the qualitative predictions.[1] Furthermore, the efficiencies of this same series of para substituted anilines as MALDI matrices has already been investigated experimentally.

Para substituent	Calculated M Proton Affinity (kcal/mol)
$-NO_2$	197.3
-CN	204.2
-COOH	205.7
-COOEt	207.4
-Cl	210.3
$-CH_3$	213.6
-OH	214.5

Initial studies focused on the self-protonation reactions of the substituted aniline compounds. These studies were performed by ionizing the matrix by electron impact in the ICR and then varying the delay between the end of the ionizing event and the excite and detect event During this time the radical



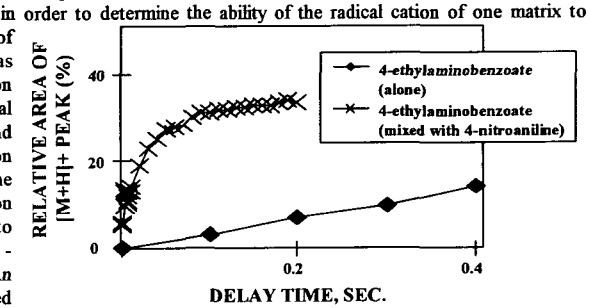
cations of the matrix could interact with residual neutral matrix molecules in the ICR and undergo proton

[1] Gimon-Kinsel, M., Preston-Schaffter, L.M , Kinsel, G.R., Russell, D.H. *J Am. Chem Soc* (manuscript in preparation)

43rd ASMS Conference on Mass Spectrometry and Allied Topics

transfer from the radical cation to the neutral molecule. For all matrices listed self-protonation is observed suggesting that in all cases the proton affinities of the neutral molecules are higher than the proton affinities of the radical cations. The highest degree of self-protonation is observed for 4-nitroaniline with the self protonation reaction occurring at the fastest rate. 4-nitroaniline also yields a very stable protonated molecule while the protonated 4-aminobenzoic acid, 4-aminophenol, 4-methylaniline and 4-chloroaniline undergo fragmentation following the self-protonation reaction. The trend in degree of self-protonation does not reflect the trend in calculated neutral molecule proton affinities. This result indicates that the trend in the differences in the proton affinities of the radical cation and neutral molecules do not reflect simply the proton affinities of the neutral molecules.

In order to assess the absolute proton affinities of the model substituted aniline matrices, mixed matrix studies were performed in order to determine the ability of the radical cation of one matrix to protonate the neutral molecule of another matrix. Thus far, it has been found that the proton donating abilities of the radical cations reflect the expected trend based on the relative electron withdrawing ability of the substituent in the para position *i.e* lowest proton affinity to highest: $-NO_2$, -CN, COOH, -COOEt, -Cl, CH_3, -OH. An example of this type of mixed matrix study is shown for a mixture of 4-nitroaniline and 4-aminoethylbenzoate. Note that the rate of protonation of the 4-aminoethylbenzoate increases to the rate of self-protonation of 4-nitroaniline when the two matrices are mixed.



A significant question which has arisen in the course of this investigation relates to the ability of the 4-nitroaniline radical cation to protonate a peptide or protein. Our studies indicate that the 4-nitroaniline M^+ is a stable species with a proton affinity that must be less the neutral molecule value of 197 3 kcal/mol. If this numerical assignment is correct, the 4-nitroaniline $^{M+}$ should be readily able to protonate a peptide with an approximate average amino acid proton affinity of 212 kcal/mol.[2] However, studies of the wavelength dependence of MALDI suggest that at wavelengths where abundant radical cations are formed, less efficient proton transfer to the analyte occurs. Future studies of reactions of electron impact ionized matrices with laser desorbed neutral peptides will attempt to determine whether the M^+ of MALDI matrices do or do not have the ability to transfer a proton to an analyte protein in order to assess the involvement of this ion formation mechanism in the MALDI.

Semi-Empirical Study of Proton Transfer in MALDI-MS of Small Peptides

Mehrnoosh Sadeghi and Akos Vertes
Department of Chemistry, The George Washington University, Washington D.C. 20052

The mechanism of ionization in matrix-assisted laser desorption/ionization (MALDI) is still not clearly understood. A theoretical study of hydrogen bond formation and proton transfer between the matrix and selected analytes in MALDI is presented. Different types of hydrogen bonds: a) bifurcated, b) intra, and c) intermolecular were investigated within the structure of the analytes alone and in complexes with the matrix. Proton affinities of the amino end group, the peptide bond, and the side chain of the peptides were investigated and compared.

In the large systems of our interest, ab initio calculations were not feasible. Among semi-empirical methods, AM1 developed by Dewar and coworkers, was chosen as an appropriate method for the study of hydrogen bonds in analyte-matrix systems [1]. Since hydrogen bonded structures and energies have been included in the parameterization of AM1, this method is successfully applied for the study of chemical reactions and mechanisms including hydrogen bonded systems. Geometry optimizations were carried out using the AM1 method as implemented in the MOPAC 6.0 package. The code was running on a 100 MHZ, R4000 workstation (IRIS Indigo XZ4000, Silicon Graphics, Mountain View, CA) Equilibrium geometries and dynamic reaction paths were visualized by the XMOL package (Version 1.3.1, Research Equipment Inc.).

The initial geometries of selected analytes (Gly-Gly, Gly-Ser, Gly-Gly-Gly, and His-His) and the matrix (3,5-dimethoxy-4-hydroxycinnamic acid or sinapinic acid, SA) were optimized separately. Geometries were defined in terms of internal coordinates and optimized for every relative configuration. For the optimization of the matrix-analyte complexes, the hydroxyl of the carboxylic group on the matrix was directed toward the site of interest on the analyte.

Investigation of the optimized geometries allowed us to locate intramolecular hydrogen bonds in the analytes. Bifurcated and intermolecular hydrogen bonds were observed between the analyte and matrix molecules. The intermolecular and bifurcated hydrogen bonds between Gly-Gly and SA are shown in Figure 1. In the case of His-His, in addition to these hydrogen bonds between matrix and analyte, an intramolecular hydrogen bond is also formed within the His-His molecule.

In order to study the energetics of hydrogen bond formation in the complexes, the sum of the heat of formations obtained separately for the analyte and matrix molecules was compared to the value obtained for the complex (Table 1) The difference is due to the intermolecular hydrogen bond formation in the complex. In every configuration the entire analyte was moved toward the matrix to obtain heat of formation diagrams. The presence and position of a minimum in the diagram revealed the formation of hydrogen bond between the two species (Figure 2). The calculated length and heat of formation of the hydrogen bonds are within the known range of 272 to 307 pm and -6 86 to -31.4 kJ/mol, respectively [2]

Proton affinity values were calculated for every dipeptide while the site of protonation was varied. These values were different depending on the site of protonation (see Table 2) The results seem to indicate that for every dipeptide the amino terminus is more susceptible to protonation than the peptide bond. As it has been shown, increasing the number of glycine residues leads to an increase in proton affinity [3]. For a basic dipeptide like His-His, the side chain has the highest proton affinity. The increased proton affinity of basic side chains points to their role in MALDI of proteins.

INTERNAL ENERGIES OF IONS FORMED BY MATRIX-ASSISTED LASER DESORPTION IONIZATION

Mary Gimon Kinsel, Kent J. Gillig, Lloyd W. Sumner, Ricky D. Edmondson, and David H Russell, Laboratory for Biological Mass Spectrometry, Department of Chemistry, Texas A&M University, College Station, Texas 77843

It is becoming increasingly clear that the internal energies of the analyte ions generated in MALDI vary significantly depending on the experimental parameters such as (1) matrix compound, (2) matrix additive (co-matrix), (3) laser irradiance and (4) sample preparation. The effect of these parameters is particularly evident in the amount of dissociation undergone by the analyte ions. Analyte metastable decay leads to poor resolution in linear TOF studies and analyte sequence information if the metastable decay product ions are separated and mass analyzed using an ion mirror. In an FT-ICR analyte dissociation limits the time that the analyte ion signal may be detected. We have used both TOF and FT-ICR experimental methods to characterize the internal energies of the analyte ions formed using several MALDI matrices.

TOF Experiment and Results

Retarding field experiments using a modified TOF mass spectrometer were performed to measure the contribution of metastable decay neutral products to the observed analyte signal. The corresponding metastable decay product ions were then separated and mass analyzed by scanning the voltage applied to the two-stage reflectron ion mirror. Figure 1 compares the metastable decay of the peptide RPPGFS (M_r = 659.3 Da) as a function of MALDI matrix. The common MALDI matrix α-cyano-4-hydroxycinnamic acid yields the mass spectrum shown in Figure 1a The product ions are referred to using the nomenclature suggested by Roepstorff and Fohlman.[1] The dominant ions correspond to sequence ions containing the C-terminus, y_4 and y_5. An almost complete series of b_n-ions is observed (b_1, b_2, b_3, b_5, and b_6) as well as a_n-17 ions. Several product ions containing neither the N- nor the C-terminus are observed in low abundance. Overall, 92% of the analyte $[M+H]^+$ ions decayed. In contrast, the metastable decay of RPPGFS is much reduced when 4-hydroxy-3-iodo-5-nitrobenzoic acid is used as matrix (Figure 1b). The dominant ion is the intact $[M+H]^+$ ion. The y_4 and y_5 remain the preferentially formed product ions. However, only 75% of the analyte $[M+H]^+$ ions have undergone metastable decay.

FT-ICR Experiment and Results

To further probe the internal energies of MALDI formed ions we implemented a series of FTICR experiments to obtain information regarding the chemical reactivities of laser desorbed species ($[M + H]^+$, M^+, or fragment ions). Ions fragment considerably on the millisecond time scale but the mechanism of positive analyte fragment formation is suppressed by specific collisional gases. The collisional gases most efficient at reducing fragmentation are Nitric Oxide and Oxygen.

FACTORS INFLUENCING METASTABLE FRAGMENTATION IN MALDI TOF/MS

Steven Colby, Chris Houston, Noah Christian, Randy Arnold and James P. Reilly
Department of Chemistry, Indiana University, Bloomington, IN 47405

Time-of-flight mass spectra of proteins recorded using matrix-assisted laser desorption/ionization (MALDI) often appear remarkably simple. Parent ion peaks are dominant features, while signals corresponding to multiply charged or cluster ions are normally quite small. In early MALDI studies, it was believed that ion fragmentation is virtually non-existent. However, primarily through the work of Spengler and his collaborators, it has become evident that metastable fragmentation is a rather ubiquitous phenomenon [1,2]. The impact that metastable fragments have on TOF mass spectra obviously depends on whether or not they are separated from parent ions by electric fields outside of the source region of the instrument. Ion reflectrons are often employed to accomplish this separation. However, a simple postacceleration field at the end of the drift region of a linear TOF instrument can be similarly effective.

Figure 1 displays a diagram of our TOF mass spectrometer. Grid spacings are on the order of 1 cm and the drift tube is about 21 cm in length. MALDI generated ions are extracted from the source region of the instrument using a pulsed drawout field that is applied at an optimal time delay. Space-velocity correlation focussing [3,4] is used to establish the characteristics of this pulsed drawout field.

Figure 2 displays a positive ion MALDI TOF spectrum of lysozyme (m/z 14306). DC voltages applied to grids G0, G1, G2 and G4 were 15.0, 15.0, 12.06 and 0 kV, respectively. A 2 kV drawout pulse was applied to grid G0 3.6 microseconds after the desorption light pulse. The very sharp peak at 37.3 microseconds TOF corresponds to parent ions while the hump in front of this results from small fragment ions that move ahead of the parent ions in the postacceleration region of the instrument. In contrast, Figure 3 displays a negative ion MALDI TOF spectrum of lysozyme. A number of different voltage conditions were investigated, but in no case were we able to produce a spectrum quite like the positive ion version of Figure 2. Negative MALDI ions do not appear to break down into fragments that are as small as their positive ion counterparts. In addition, the parent to fragment abundance ratio is smaller in the negative ion case.

To demonstrate how much simpler the mass spectrum can appear when ions are not accelerated at the end of the drift region, we recorded data with a very different set of grid voltages. With G0, G1, G2 and G4 at -20 kV, -20 kV, -1.9 kV and -1.9 kV, respectively, and an optimized ion drawout pulse, we

observed the negative ion lysozyme spectrum of Figure 4. In this case, fragments formed in the drift tube are not sufficiently energetic to be detectable by our microchannel plates, so the broad underlying fragment ion pedestal that dominates the spectra in Figures 2 and 3 is not present.

Photodissociationexperiments and Investigations on the MALDI Process

Matthias Amft, Johann M. Grundwürmer, Roland Finsterer, Hou-Jun Yang and Jürgen Grotemeyer

Institut für Physikalische Chemie Universität Würzburg, Marcusstr. 9/11
D-97070 Würzburg, Germany

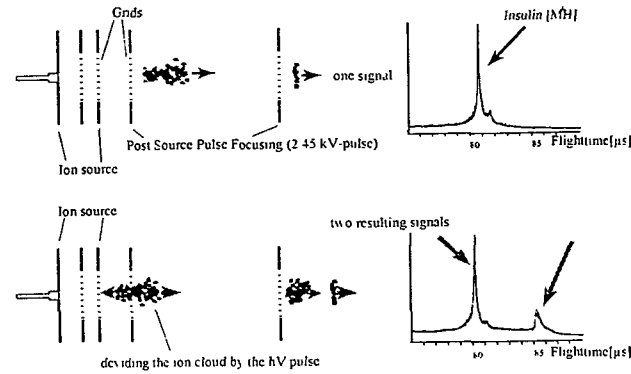
Subsequent fragmentation of molecular ions formed in the matrix assisted laser desorption and ionisation (MALDI) process can be induced by the absorption of photons. The experiments were performed in a home made linear-time-of flight-mass spectrometer that has been equipped with a postsource pulse focusing (PSPF) device[1]. Ion desorption was achieved by a frequency tripled (λ=355 nm) Quanta-Ray DCR11 Nd:YAG-laser. For fragmentation a "Laser Mark 960" CO_2-laser from Lumonics was used, that emitted light at 10.6 µm.

The molecular ions were fragmented in an additional field free drift region, which was placed in between the acceleration fields. This is advantageous, as an undefined fragmentation place, caused by a large laser focus, does not lead to different energies of the fragment ions.

Peptides like mellitine, gramicidine and insuline could be fragmented by CO_2-laser irradiation. Peaks can be made visible in the high mass region of mellitin spectra when PSPF is applied, however it is not clear at the moment, if these peaks are caused by CO_2-laser irradiation. Sometimes fragment ions are detected even when the fragmentation laser is switched off. Both, metastable decay in the field free region or ion formation at the desorption place could account for this observation. Calculations of the expected mass resolution for both processes seem to exclude metastable decay.

Additionally, the PSPF device opens up the possibility to split up the ion cloud in two parts at a given point of time. This is illustrated in figure 1. By varying the delay of the PSPF pulse, information about the ion distribution can be gained. Different matrix substances lead to different flighttimes and ion distributions.

Fig.1) Ion cloud separation using the PSPF-method



Furthermore effects on the focusing behaviour of ions caused by changing the ion source geometry and voltages were investigated by SIMION calculations[2]. The quality of the spectra could be improved either by increasing the field strength or by changing the desorption place. The experimental results can be explained by ion optic effects.

Photochemical versus Thermal Mechanism for MALDI Probed by Backside Desorption

Hanno Ehring, Cesar Costa , Plamen A. Demirev, Bo U.R. Sundqvist
Division of Ion Physics, Department of Radiation Sciences, box 535,
Uppsala University, Uppsala, S-75121, SWEDEN

The exact nature of the MALDI of large biomolecules still remains under discussion. One of the important issues to resolve is the contribution of photochemical and photothermal effects in the formation and ejection of large biomolecular ions in the gas-phase as a result of UV or IR laser pulse irradiation. We have performed laser desorption in two laser beam incident geometries with respect to the sample surface - frontside and backside. To that end we use specially fabricated holders, onto which the samples are deposited. The sample holders consist of quartz glass onto which an Au layer with a thickness of 2000Å was evaporated. Different samples - small peptides (gramicidin S, and valinomycin) with and without a matrix (DHB), C_{60} fullerenes, or alkali halides - have been deposited on the Au layer. The home-built MALDI-TOF system with optical ports that allow irradiation of one-and-the-same sample both from the front and the backside, has been already described in detail [1]. A Nd - YAG laser (355 nm, 6 ns pulse width, 300 μm spot size), or a N_2 laser (337 nm, 4 ns, 200 μm) are used to irradiate the samples from the front or the back, respectively. The typical fluences are between 20 to 50 mJ/cm^2 for frontside, and 20 to 100 mJ/cm^2 for backside desorption. Since the absorption of the UV light at that fluence by 2000Å Au layer is complete, only thermal effects can contribute to the backside desorption.

Mass spectra of CsI obtained from the front and backsides are essentially indistinguishable, with a minor difference in the applied laser fluence (15 and 21 mJ/cm^2, respectively). Typical mass spectra for gramicidin S are shown on Fig. 1. While with a matrix the protonated molecular ion peak **[M+H]$^+$** is observed, without a matrix only the corresponding alkali cation adducts with the neutral molecule, **[M+Na]$^+$** and **[M+K]$^+$**, are detected in frontside desorption. Backside desorption of gramicidin S + DHB gives only the cationized species, which is indicative of a thermal desorprion process. Thermal effect is also observed in the backside spectrum of C_{60}, in which a broad shoulder, extending several μs after the main peak, is observed, due to the well-known phenomenon of delayed ionization of thermally-excited fullerenes. In contrast, the C_{60} molecular ion peak in frontside desorption is much sharper, indicative of prompt (multiphoton) ionization process.

While good quality spectra of peptides, like insulin and cytochrome C, with intense molecular ion peaks have been obtained in MALDI from the frontside, no such peaks corresponding to the molecular ions have been observed upon backside desorption of the same samples. All discussed results point to the conclusion that laser-induced photochemistry, e.g. protonation-deprotonation reactions between excited matrix molecules and the analyte [2], plays a major role in MALDI of peptides.

Probing the Dynamics of MALDI Ion Formation

Ricky D. Edmondson, Karen K. Campo, and David H. Russell
Laboratory for Biological Mass Spectrometry
Department of Chemistry, Texas A&M University
College Station, TX 77843

We have observed that when thin films of matrix/analyte are prepared two thresholds exist for ion formation in MALDI. At low laser fluences(2mJ/cm^2) ions are produced from the first laser shot on each spot, but are then quickly depleted. In order to generate more ions from the same spot, fluences must be increased three to four times. Ions are then produced for many consecutive shots from that sample spot. This paper will discuss sample preparation techniques, along with the results of studies that compare the ions formed at the two thresholds.

The samples are prepared by depositing 1 µl of the matrix solution on a highly polished stainless steel surface and allowing it to dry. Twenty to 100 nl of analyte are then applied to the dried matrix. The analyte solution partially redissolves the matrix, but the undissolved matrix serves as nucleation sites for the matrix/analyte to crystallize. The outer circle seen in figure 1 shows where this recrystallization occurs. This sample preparation enhances the ion production at low laser fluences. Linear TOF spectra were taken of Vitamin B_{12} and mellitin with alpha-cyano-4-hydroxycinnamic acid at both ionization thresholds. When compared to the high fluence spectra , the low fluence spectrum of mellitin showed an abundance of analyte ions over matrix ions, in addition to higher resolution of the molecular ion region (5500 m/Δm).

The high fluence spectra of Vitamin B12 is consistent with previous studies as the most abundant ion is the loss of the cyano ligand, and no intact molecular ion is observed. However, in the low fluence spectrum

the intact molecular ion is a prominent peak. The results from these studies suggest that the ions formed at low laser fluences have more narrow energy distributions than ions formed at the higher fluences as well as lower internal energies. We have developed a model to explain the differences between the high and low threshold spectra. We would argue that the ions formed at the low laser fluence are related to a surface component. Whereas the high fluence threshold ion production is more related to the bulk sample. After the loosely held material from the surface is desorbed more energy is required to desorb material that is tightly bound to the bulk sample.

Water as a Matrix in Infrared MALDI-MS

Stefan Berkenkamp, Michael Karas, Franz Hillenkamp
Institut für Medizinische Physik und Biophysik der
Westfälischen Willhelm Universitat Munster, FRG

Matrix-assisted Laser Desorption/Ionization mass spectrometry (MALDI-MS) has become a widely used technique for the analysis of large biological molecules Whereas UV-MALDI is now widely applied, Infrared MALDI-MS is still in a rather experimental stage with only a few laboratories working on its development Some advantages, such as better preformance in the mass range above 100kDa, have been reported Using Er-YAG-Lasers emitting at a wavelength of 2 94 µm a host of potential matrices are available with a strong absorption at this wavelength, primarily resulting from O-H and N-H stretching modes at ca. 3µm Among the potential advantages of IR-MALDI are the availibility of more or less physiological, non denaturating matrices with approximately neutral pH such as glycerol and Tris

Water, in the frozen state to provide compatibility with the vacuum requirements of the spectrometer, appears particulary attractive in this respect and was recognized early as a potential matrix because of its strong O-H stretching mode near 3 µm Interest in water as matrix derives primarely from the fact that it is the major constituent of most biological samples

A reflectron TOF instrument of 3 5 m equivalent flight length and a 12 kV acceleration potential was used for all experiments Working pressure in the sample chamber is 3×10^{-4} Pa Ions are detected by a conversion dynode (ion impact energy 20 - 27 kV, depending on ion mass) mounted 1 cm in front of a venetian blind secondary electron multiplier (EMI R2362) Single pulses of an ER-YAG laser (SEO 1-2-3, Schwartz Electro Optics, USA) of ca 150 ns duration at a wavelength of 2 94 µm are focused to a spot diameter of ca 180 µm with a 45° angle The instrument is equipped with a liquid nitrogen (LN) cooling stage. The temperature of the stainless steel substrate is monitored with a thermocouple with an absolute accuracy of ± 5 K

All attempts to obtain protein spectra from samples of bulk, frozen aqueous solutions by variation of all accessible parameters gave very poor results under almost all conditions predominantly water cluster signals up to a mass of ca 5000 Da were obtained Protein signals with poor signal-to-noise-ratios could only be obtained from the outermost rim of the sample and only in ca 5 - 20% of the exposures The situation changes dramatically if the samples (typically 3 µl of a 10^{-3} M solution) are first „dried" under ambient conditions (remaining the water of hydration at the protein) before being frozen to LN-temperature. Similarly, a few flakes of lyophilized protein can be frozen directly. The frozen samples are then introduced into the instrument and kept at low temperature The dried frozen samples form a thin, optically homogeneous and transparent layer, the rim of which is barely visible under microscopic observation. Spectra of superior quality and very good reproducibility can be obtained from all locations within the 3 mm diameter sample area Some temperature dependence is observed. Best results are obtained in the range of 170 - 200 K, but spectra can be obtained up to temperatures of 240 - 270 K, depending somewhat on the specific analyte under investigation Mass resolution (FWHM) of 300 - 350 is routinely obtained for proteins up to a mass of 20 kDa, selected spectra exhibit a mass resolution of up to 700 (Figure 1). This contrasts to a resolution of 150 - 200, obtainable with this instrument for standard preparations of the same proteins under optimal conditions in UV- and IR-MALDI Salt additions lead to a degradation of signal quality, as is also known for standard preparations, but even a physiological NaCl-concentration does not totally suppress the protein signals The threshold irradiance for protein detection is ca. 3×10^{6} W/cm^2, quite comparable to values needed for standard preparations in the UV as well as IR. Near threshold irradiance very little to sometimes no matrix signals are recorded in the low mass range These signals increase appreciably with increasing irradiance, as is commonly observed in MALDI-MS

The mass resolution of the protein signal, however, remains essentially unaffected with an up to eightfold increase in irradiance.

The practical application of MALDI with an ice matrix currently is still somewhat limited by accessable mass range (for pure air dried aqueous solutions, the upper mass limit so far is ca 30 kDa) and by sensitivity. Spectra have been obtained from air dried 10^{-5} M solutions, but with a substantially decreased signal-to-noise ratio and a strong low mass signal background compared with 10^{-3} M solutions. At the present state a minimum amount of ca. 1 pmol is needed for a successful protein analysis.

Since the exact amount of protein-hydration can not be predicted under experimental conditions, protein single crystals of Lysozyme were grown, frozen, and analysed by IR-MALDI-MS without matrix addition (Fig 2; since crystals are grown with $NaNO_3$ as precipitant, mass spectra obtained are of somewhat inferior quality due to salt content) The water content of protein crystals of Lysozyme is reported to be about 30% in vol The molar matrix/analyte-ratio therefore can be estimated to be ca 250, about three orders of magnitude lower than in a common MALDI preparation (10^5). Futhermore the „Matrix" is contributed by the analyte itself which again distinguishes the sample preperation with water as matrix from common matrix preparations

Very important information on the desorption/ionisation process can be gained from these experiments Theories and experimenatal evidences concerning mechanisms for desorption/ionisation and the concept of matrix-assistance in UV-MALDI can certainly not be adapted for IR-MALDI without reconsideration

Paul Humphrey[3] & David Dingley[3]
1 - Shimadzu Corporation, Kyoto, Japan, 2 - Shimadzu Europa GmbH, Duisberg, Germany,
3 - Kratos Analytical, Manchester, UK.

Initial experiments in the development of Matrix Assisted Laser Desorption/Ionisation[1,2] involved the use of an ultra fine metal powder (UFMP) to promote energy transfer. This was later largely superseded by the use of aromatic acids such as(sinapinic acid, 2,5-dihydroxybenzoic acid and a-cyano-4-hydroxycinnamic acid. These matrices all result in the generation of large numbers of ions particularly in the mass range 100-500 Da. For the analysis of small samples (m/z <500 Da) there can be considerable confusion and overlap of peaks making interpretation difficult.

As the laser is fired at an involatile, thermally labile sample competing reactions of vaporisation as opposed to decomposition occur. As is shown in figure 1, at low temperature decomposition will dominate whereas at higher temperatures vaporisation will be favoured.

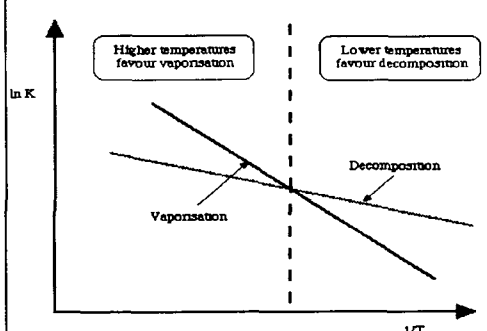

Figure 1 - Temperature dependance of rate constant

It therefore follows that raising the temperature as rapidly as possible to as high a value as possible will generate more and more gas-phase molecules and minimise decomposition. This is the first requirement for MALDI of thermally labile materials, to generate intact molecular ions.

The diameters of the UFMP particles are very small (100-1000 Å) which result in the absorbance being very efficient across a wide wavelength range. The material has a low heat capacity which combines with the absorbance to promote rapid heating. If the powder is mixed uniformly with a sample this will result in easy and immediate transfer of the laser energy.

The experiments were carried out on a KOMPACT MALDI III produced by Kratos Analytical. This is a

combined linear & reflectron bench-top system featuring a sealed unit nitrogen laser (λ = 337 nm) and optional extraction voltages of 6 or 20 kV Sample solutions were prepared having concentrations in the range 1 mg/ml to 1 µg/ml in a suitable solvent system (distilled water and/or methanol). A 1 µl droplet of this solution was placed on the multi-sample slide together with 1 µl of a matrix suspension. This latter was produced from a suspension of 10 mg/ml of 200 Å cobalt powder in ethanol or acetone. The mixture was allowed to dry for a few minutes in air to remove volatile solvents before the slide was introduced into the instrument.

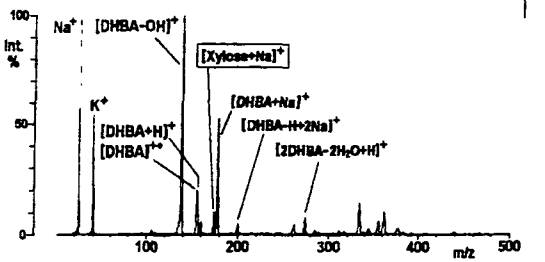

Figure 2 - MALDI spectrum of xylose using DHB as a matrix

The spectra in figure 2 show a comparison of spectra from xylose ($CHO(CHOH)_3CH_2OH$ - MW = 150.13 Da) acquired a) conventionally using a matrix of 10 mg/ml of 2,5-dihydroxybenzoic acid (DHBA) and b) using UFMP as a matrix. In each case the $[M+Na]^+$ ion dominates the xylose spectrum but in the spectrum with DHBA it is very difficult to identify this in the plethora of peaks due to matrix ions and attendant fragments, adducts and multimers. In the spectrum with UFMP greatly simplified and subsequently much easier to interpret.

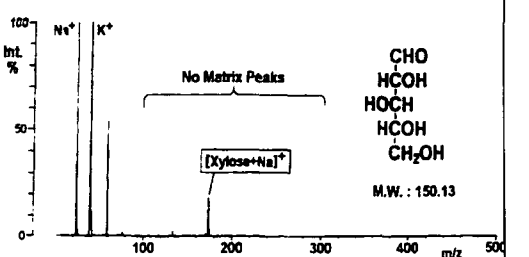

Figure 3 - MALDI spectrum of xylose using UFP as a matrix

Ultra-fine metal powder has the following advantages over conventional organic matrices -

(i) No background ions in the mass range 100 - 500 Da
(ii) Efficient energy absorption across a wide range of wavelengths (UV, Vis, IR)
(iii) Low chemical activity
(iv) Stable at room temperature and in ambient light

These factors make it an attractive alternative to more common matrices in the analysis of low mass (< 500 Da) materials.

Hydroxy Benzophenones: A New Class Of MALDI Matrices For Proteins/Peptides

*Duane Reiber and Robert S. Brown, Department of Chemistry and Biochemistry, Utah State University, Logan, UT 84322-0300

Matrix-assisted laser desorption/ionization (MALDI) has become a widely accepted technique for the mass spectrometric analysis of many classes of biomolecules. The identification of new matrices for MALDI is important both from a practical and mechanistic standpoint. While many of the most successful UV-MALDI matrices are aromatic carboxylic acids, a smaller number of matrices (such as 7-hydroxy coumarin) have been reported that may involve excited state enhanced proton transfer reactions. Benzophenones are known in the literature to exhibit long lived triplet states when excited in the UV. A series of multiply hydroxy substituted benzophenones (no carboxylic acid groups) have been utilized for UV-MALDI (337 nm) with various peptides and small proteins in a linear time-of-flight mass spectrometer (TOF-MS) equipped with delayed pulsed ion extraction. The more useful compounds as MALDI matrices included the following: 2,4-dihydroxy benzophenone; 4,4'-dihydroxy benzophenone; 2,4,4'-trihydroxy benzophenone; 4-hydroxy benzophenone and 2,2',4,4'-tetrahydroxy benzophenone.

Many of these compounds are equally as effective at protonating larger proteins such as cytochrome C as the more conventional aromatic carboxylic acid MALDI matrices (such as ferulic acid). The successful protonation by these hydroxy substituted benzophenones, given their lack of any acidic group to serve as a proton donator, suggest that for at least for this class of MALDI matrices, excited state processes must play an important role. In the excited state, the hydroxy substituents would be expected to become acidic enough to account for the proton transfer processes that are observed. Mass resolution obtainable with these hydroxy substituted benzophenones is also comparable to conventional MALDI matrices. This would suggest that the ionization time frame is not affected by any long lived triplet state. Given the collision rates expected from the dense plume model for MALDI, it is probably not surprising that excited state species would rapidly return to their ground state, thus rapidly quenching the ionization process. These hydroxy substituted benzophenones are also different from conventional MALDI matrices in that essentially no radical cations of the matrix are observed in the low mass region of the MALDI spectra. This region is dominated almost exclusively by protonated ions of the matrix. Almost no matrix degradation ions due to loss of water are observed for these hydroxy substituted benzophenones. This is in sharp contrast to what is observed for MALDI matrices such as sinapinic and ferulic acid. Dehydration is only significant in the 2,2' substituted benzophenones which can undergo intramolecular loss of water which is stabilized by formation of a six member ring. Significantly less (organic) matrix adducting to analytes is observed with the hydroxy substituted benzophenones when compared to may common MALDI matrices (i.e., ferulic acid or 2,5 dihydroxy benzoic acid). Cationization is, however, much more prevalent with the hydroxy substituted benzophenone matrices. Particularly troublesome have been iron (II) cation attachment species (i.e., $[M-H+Fe]^+$). These adduct ion species can be suppressed by the addition of a weak acid salt such as ammonium oxalate. These species are probably normally suppressed in acid MALDI matrices due to the large H^+ concentration favorably shifting the solution equilibrium.

The extent of rapid metastable ion decay is also significantly reduced with the hydroxy substituted benzophenones that have been studied. While the type of fast metastable ion decay is similar to conventional MALDI matrices (Table I), the extent and intensity is reduced. This trend is reversed in the negative metastable ion decay spectra obtained for the hydroxy substituted benzophenones (see figure 1). In addition, a series fragment ions are observed which are not typically produced in positive ion spectra.

Synthesis of MALDI Matrices and Correlation with Ion/Neutral Populations

*Lloyd W. Sumner, Ricky D. Edmondson, Mary Gimon Kinsel, Rick Hammon, Gary Sulikowski, and David H. Russell
Laboratory for Biological Mass Spectrometry, Department of Chemistry, Texas A&M University, College Station, TX 77843

The ability to selectively utilize MALDI matrices to control the extent of internal energy transferred to the analyte during the ionization process would be highly useful. Ideally this parameter would be based on matrix structure and could enable the mass spectrometrist to select a matrix to meet his specific application Low energy transfer matrices could be used to obtain maximized quasi-molecular ion intensities while high energy transfer matrices could be used to promote prompt fragmentation or metastable decay in MS/MS experiments for structural elucidation. At present, our ability to predict energy transfer between the matrix and analyte is very limited. To probe this phenomenon in a systematic fashion we have attempted to synthesize a series of substituted cinnamic acid analogs to correlate matrix structure with the internal energy exchange occurring during the protonation reaction. The synthetic compounds compliment the limited quantity of compounds commercially available and both are listed in TABLE 1. Simultaneous positive-ion and neutral MALDI-TOF mass spectra of substance P and renin substrate were obtained on a Vestec Voyager Elite MALDI-TOF mass spectrometer operating at an acceleration voltage of 25kV. The instrument was equipped with an electrostatic particle guide and an ion mirror. Averaged MALDI mass spectra of 50 laser shots, obtained with a LSI nitrogen laser, were recorded on two separate oscilloscopes.

TABLE 1. MALDI Matrices

1.) 4-hydroxy cinnamic acid
2.) 4-hydroxy-methyl cinnamate
3.) alpha-aceto-4-hydroxy-ethyl cinnamate
4.) alpha-carboxy-4-hydroxy cinnamic acid
5.) 4-hydroxy-3,5-dimethoxy cinnamic acid
6.) alpha-cyano-4-hydroxy cinnamic acid
7.) alpha-cyano-3-hydroxy cinnamic acid
6.) alpha-cyano-4-hydroxy-3-methoxy cinnamic acid
9.) alpha-thio-4-hydroxy-3-methoxy cinnamic acid
10) alpha-phenyl-4-hydroxy cinnamic acid

The spectra were correlated to the internal energy transfer (i.e. fragmentation) to the analyte by measuring the ratio of the absolute intensities of the protonated to the neutral molecular species. A plot of these ratios is presented in Figure 1. Post source decay mass spectra were also obtained. Illustrative mass spectra of a low and high energy transfer matrix are presented in Figure 2a & 2b The lowest energy matrix observed was 4-hydroxy cinnamic acid. This compound had an ion/neutral ratio of about 32 which is three times higher than the commonly accepted low energy transfer matrix, 4-nitro aniline (ion/neutral ratio = 10) Several high energy transfer matrices were observed. These included the established hydroxy-alpha-cyano cinnamic acids, 4-hydroxy-3,5-dimethoxy cinnamic acid, and more interesting, the methyl synthetic esters Simple esterification of 4-hydroxy cinnamic acid to 4-hydroxy methyl cinnamate dropped it's ion/neutral ratio from 32 to 1.5. A similar observance was made for alpha-aceto-4-hydroxy ethyl cinnamate which also had a low ion/neutral ratio of about 0.5 Finally, the alpha-phenyl cinnamic acid also performed well as a high energy transfer matrix as suggested by Brown (Proceedings 42nd Annual ASMS conference).

New Matrices for Matrix Assisted Laser Desorption/Ionization (MALDI) MS

Joern L. Krause and Urs P. Schlunegger

Institute of Organic Chemistry, University of Berne, Freiestr. 3, CH-3012 Berne / Switzerland

Introduction:

A large number of very different compounds have been tested with success as matrices for Matrix-Assisted Laser Desorption/Ionization (MALDI) MS since the introduction of this new technique into the MS field in 1988.

The UV-absorption is of special importance for the selection of new potential matrices. Compounds like salicylic acid, which contain a phenolic hydroxy group in ortho position to a carbonyl function often show a special behaviour under UV-irradiation [1,2]. UV-irradiation induces an intramolecular proton shift along the H-bond in these molecules, yielding a metastable excited state [3]. The excitation wavelength of those transitions is in general located in the ultraviolet region. With respect to this it is sensible to test compounds showing the described transition as new potential matrices.

Methods:

All presented MALDI-MS measurements have been carried out on a home built linear Time-of-Flight instrument. A pulsed nitrogen laser was used for desorption/ionization of the samples.

For the determination of the UV-absorption, UV-Vis spectra of all tested compounds have been measured in ethanolic solution (1 E-4 mole/l) on a Perkin-Elmer UV-Vis spectrophotometer).

Conclusions:

The results show that compounds which perform a proton transfer under UV-irradiation are actually usable as matrices for UV-MALDI MS. The resolution that can be achieved differs significantly from compound to compound. For substances like 5-methoxy-salicylic acid, salicylic amide, 5-chloro-salicylic amide or 5-chloro salicylic acid we obtained resolutions in the spectra of bovine insulin which are comparable to the resolution which can be achieved using sinapic acid as a matrix. In single shot spectra, salicylic amide allows a resolution of up to 1100 (m/Δm) for bovine insulin. We did not succeed to collect a spectrum with a similar or even better resolution with any other matrix. Regarding the measured absorption coefficients of matrices, showing the described transition under UV irradiation, it becomes obvious that the absorption of those compounds is significantly weaker as it is for compounds like sinapic acid or α-cyano-4-hydroxy-cinnamic acid. This could be the reason for the high ion intensity which may be achieved using a-cyano-4-hydroxy-cinnamic acid as a matrix. Such a high UV-absorption (200 times better as salicylic amide) leads to the high sensitivity of this matrix. The sensitivity of salicylic amide should be much better using radiation of about 300 nm wavelength. This was checked by using chlorinated salicylic amide (5-chloro-salicylic amide) as a matrix. 5-chloro-salicylic amide is absorbing the laser radiation about 8 times better as salicylic amide. This leads to a 3 times better sensitivity.

Whether the described proton transfer and the resulting metastable excited state is involved in the ionization process or if it just offers an absorption band in the used wavelength area is so far not clear. Further work is going on.

Amino Acid Composition and Wavelength Effects in Matrix-Assisted Laser Desorption Ionization

Zohra Olumee and Akos Vertes
Department of Chemistry, The George Washington University, Washington D.C. 20052

Despite the success of MALDI for molecular mass determination of large synthetic and bio-polymers, the mechanism of ion formation in the laser desorption process is not well understood. In extending the applications of MALDI-MS, low ion yield and variable ionization efficiency are two important limiting factors [1]. In order to examine the origin of these differences, we eliminated some of the complexities involved in the desorption of proteins. Short peptides of varied composition were used to explore the role of individual amino acid residues in the MALDI process. Our objective was to explore the efficiency of proton transfer, shot-to-shot variations of signal intensity, and the effect of excitation wavelength in ion formation. A linear time-of-flight mass spectrometer was used with two laser sources. Shot-to-shot variations of the laser pulse energy were measured by a pyroelectric joule meter. Fluctuations in the laser intensity were <5%. The ten different di- and tripeptides (listed in Table 1) and four peptides containing aromatic residues (Trp-Gly, Gly-Phe, Ala-Phe, and Tyr-Gly-Gly) were dissolved in 0.1% trifluoroacetic acid (TFAA). About 2μL aliquot of the analyte was mixed with 10 μL of saturated solution of the matrix (sinapinic acid, SA). To eliminate the effects of inhomogeneities, spectra were collected from randomly selected spots on the probetip.

Although several matrices and a large variety of irradiation conditions were used, attempts to obtain MALDI spectrum for N-methylacetamide (N-MAA) was unsuccessful. These negative results indicated that in short peptides the C=O of an isolated peptide bond was not the likely site of protonation. In the presence of end groups and in the case of longer peptides, however, one can not exclude the participation of the peptide bond in accommodating the proton. Table 1 summarizes the relative and absolute intensities and their standard deviations for the $[M+H]^+$ ions. Peptides containing non-polar amino acid residues (Gly-Gly and Ala-Ala) produced weak signal both in absolute and in relative intensities. As a general trend an enhancement of ion yields with increasing chain length was noticeable even for peptides with non-polar side chains. These observations were consistent with earlier FAB studies on gas phase proton affinities of short peptides [2]. Protonated molecular ions were abundant for short peptides containing basic and/or polar residues. The effect of basic residues (Arg and His) was very pronounced in absolute as well as in relative ion intensities. Lys-Lys however, showed very similar behavior to Gly-Gly indicating a profound departure from being the second most basic residue in liquid phase (pK=10.0).

Multiple shot MALDI flight time spectra of dipeptides Gly-Gly and His-His are presented in Fig. 1. Despite the large fluctuations in signal intensity, the response from His-His was consistently stronger and showed smaller relative error (see Table 1). In order to probe shot-to-shot variations in the signal, 50 consecutive spectra were analyzed in terms of analyte to matrix intensity ratios. The histogram of peak intensity ratios is shown in Fig. 2. The relative standard deviation of the ratios shows a dramatic drop from 50% for Gly-Gly to 18% in the case of His-His. This improvement in signal quality correlates with differences in proton affinity between the two dipeptides.

Shorter wavelength dye laser excitation (280 nm) resulted in substantial enhancement of ion formation from peptides containing aromatic side chains. Furthermore, stronger signal was observed for peptides containing non-polar amino acid residues. The sharp increase in the ion yield for peptides with aromatic residues points to the possible role of analyte excited states in ion formation. These observations are of importance in exploring the rules of selective ionization for different components in a protein mixture. The findings are especially relevant in sequencing studies, where digestion of proteins leads to relatively short peptide chains with an increased chance of lacking the residues promoting ionization.

Investigation of Selective Peptide Ionization with Various MALDI Matrices.

James A.Blackledge*, Anthony J. Alexander, and David W. Dodsworth
Bristol-Myers Squibb, PRI
P.O. Box 4755
Syracuse, NY 13221-4755

The excellent sensitivity, high sample throughput, and capacity for mixture analysis that is inherent in the technique of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) has made it a popular method for the mapping of protein digests. In the course of such work, we have recently observed that certain MALDI matrices display a high degree of selectivity for individual peptides in a peptide mixture, which could potentially lead to erroneous conclusions about sample purity or result in certain mixture components being unobserved altogether. Previous reports have demonstrated that different matrices have varying degrees of sensitivity over different mass ranges (1), and that comatrix mixtures containing carbohydrate are effective in promoting simultaneous desorption and ionization of all components in a multicomponent mixture (2). Surprizingly, we observed that sinapinic acid (3,5-dimethoxy-4-hdroxy-cinnamic acid), which is not commonly used for peptide mapping, displayed the least amount of selective ionization in our peptide map, and therefore provided the best representation of the true sample mixture. In order to further investigate this phenomenon across different MALDI matrices, a series of three synthetic peptides were analyzed by MALDI-MS, both individually and as a mixture, using sinapinic acid (SA), α-CN sinapinic acid (α-CN SA), and a dihydroxybenzoic acid/fucose comatrix (DHB/Fuc).

Figure 1 displays the spectra of a representative RP-HPLC fraction from the protein digest, acquired in the three different MALDI matrices. Note that all of the ions above m/z ~ 3,000 Da., which are present at good intensity in SA, are severly reduced in both the DHB/Fuc. and α-CN SA matrices. The cluster of ions between m/z 2,000-3,000 in this fraction gives good signal intensity across all three matrices. However, comparison of the baseline noise reveals that the absolute signal for this cluster of ions, most especially the ion at m/z 2,380, is greatly enhanced in the DHB/Fuc. and α-CN SA matrices.

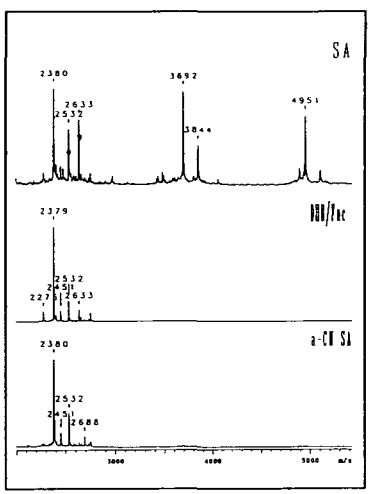

Figure 1. Representative digest fraction, analyzed in three different MALDI matrices.

Figure 2 contains the spectra acquired from a mixture of three synthetic peptides (see table), in the three different MALDI matrices. The same amount of material was loaded onto the sample stage for all three spectra. When analyzed individually, all three peptides gave good signals in all three matrices. However, when analyzed as a mixture, peptides B and C had reduced ion intensity. Peptide A also had a reduction in ion intensity as part of a mixture in α-CN SA, but was actually increased in SA and DHB/Fuc. All three components yielded discernable signals as part of a mixture, in all three matrices. Note the contaminant at m/z 1,819 Da., which is seen only in SA.

Out of some 50 different ions detected in the peptide map, only one species was not readily detected in SA. This fact, coupled with the observation that the relative intensity of the ions in the SA spectra correlated well with the relative concentrations of the peptides in the mixture, led us to conclude that SA was the matrix of choice for peptide mapping. However, the situation is somewhat different with the test peptide mixture. All of the test peptides gave good signals in all three matrices, when prepared as individual components. Unlike the trend seen in the digest fractions, where the enhancement/suppression of mixture components was consistent across both DHB/Fuc. and α-CN SA, with the test peptide mixture all three matrices gave different results. Our results show that, on the basis of "recovery" of signal intensity for the individual components in a mixture, SA is more effective than either DHB/Fuc. or α-CN SA as a matrix. Although none of the three peptides were completely suppressed in the test mixture, in any of the three matrices investigated, peptide C gave a very weak signal in both SA and DHB/Fuc., which is surprising considering that its composition is 50% arginine, the most basic amino acid residue. However, both SA and DHB/Fuc. resulted in strong suppression of at least one mixture component, clearly an undesirable situation. On this basis, the moderate suppression of all mixture components seen in α-CN SA may not be a severe limitation, as it reduces the possibility of a component being suppressed altogether.
Clearly, the choice of best matrix for the analysis of a peptide mixture must be determined experimentally.

Conclusions

- More than one matrix is often necessary to fully characterize a peptide digest fraction.
- Different matrices enhance/suppress different mixture components. This effect cannot be easily correlated with simple changes in basicity or hydrophobicity of individual peptides.
- For a given matrix the spectrum of a simple peptide mixture is not the sum of the spectra of the individual components. The underlying reasons for this are unclear.

Peptide	Sequence*	Molec. Wt.

Effects of Substrates on the Ion Yields for Mixture Analysis by MALDI MS

Xiaoli Liang, Jian Bai, Yan-Hui Liu and David M. Lubman
Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109-1055

Introduction

The suppression effect in which signals of certain components in a mixture are absent or indiscernible tends to be ubiquitous among desorption ionization techniques, such as FAB MS and PD MS. In MALDI MS, despite its tolerance to contaminants, the suppression effect caused by buffer or surfactants has been observed and the sample preparation has been addressed to increase the tolerance of MALDI toward contaminants through the use of a variety of schemes, such as simple washing, fabrication of matrix crystals and films, and the use of active substrates.

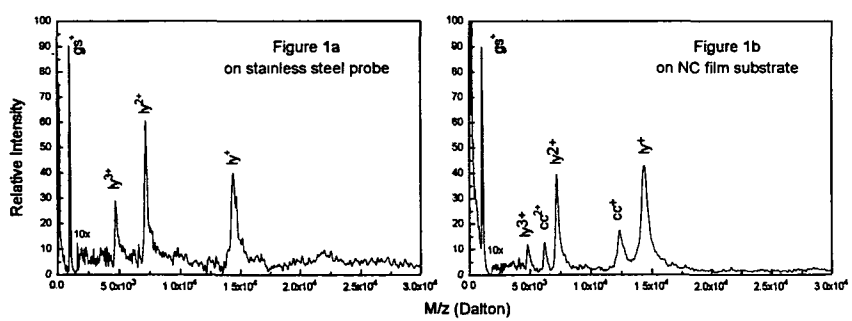
Several classes of compounds, such as gramicidin S and insulin, have also been found to suppress the ion signals of other components in a mixture. In this work, different substrates prepared from nitrocellulose (NC), Nafion, polystyrene (PS), polymethylmethacrylate (PMMA), and poly(styrene-co-2-acrylamide)sulfonic acid, have been used to alter the interactions among analytes, matrix and substrates, as well as the crystallization, thus to alleviate the suppression effect among analytes of interest in mixture analysis.

Method

Mixture of gramicidin S (gs), cytochrome *c* (cc), and lysozyme (ly) was used as a model system in this work. Polymer substrates were prepared by dissolving polymers in THF (NC in acetone). Both heating treated and untreated polymer substrates were tested and compared with the stainless steel probe. In the case of heating treatment, the polymer film was melted on a hot plate, and then cooled down to room temperature. The analyte mixture was added onto the stainless steel probe or the film, and allowed to incipient dryness before the application of matrix.

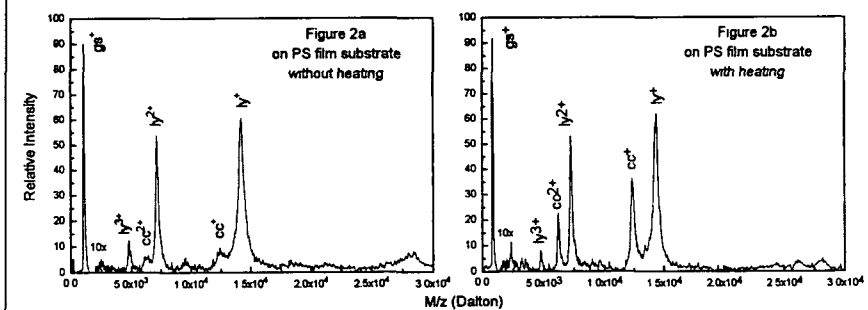
Results and Discussion

Signal of cytochrome *c* was indiscernible using CHCA as the matrix on a stainless steel probe tip with the traditional premixing method. When a thin NC film was used, the suppressed signal can be clearly observed. (Figure 1). The other substrates mentioned above generated similar results with CHCA as the matrix. Other matrix materials, were also tested on the polymer substrates. However, multiply charged ions were observed with caffeic acid matrix on these substrates; relatively poor



resolution was obtained with DHB matrix, while SPA provided different signal profile on different sample spots.

In the case of polymer substrates, heating of the films before application of the sample was found to improve the ion yields considerably (Figure 2), where the intensities of both singly- and doubly-charged ions of cytochrome *c* increased dramatically. It was found that without heating, PS can not form a homogeneous film , and the analyte mixture tended to scatter over the substrate upon application. After heating, a more uniform hydrophobic film was formed. Similar improvements were also experienced for the other two polymeric films. This phenomena may be due to the fact that more homogeneous hydrophobic film was formed during the heating treatment.



The mechanism of the suppression effect is not well understood yet. The fact that this effect can be alleviated by the use of hydrophobic film, indicates that the suppression effect may be related to the hydrophobicity properties of the analytes and the sample surface. It has been proposed that hydrophilic peptides were suppressed in the presence of hydrophobic peptides in FAB MS (1,2) and PD MS(3). If this is true in MALDI MS, it is easily understood that hydrophobic film can reduce the suppression effect, since the hydrophobic film will repulse the hydrophilic analyte to the sample surface and make it accessible for the MALDI MS analysis. Another possible explanation is that the films provide uniform sites for nucleation compared with the stainless steel probe (4). Therefore, the proteins with different properties can be incorporated into the matrix equally. However, more experimental evidence is needed to confirm this hypothesis.

Conclusion

The use of polymeric film as substrates improved the ion yields dramatically despite that the mechanism is not clear yet. Future work will focus on the mechanism studies and the application of polymeric substrates for the MALDI MS analysis of complex mixtures.

Surface Modification of Active Substrate Applied in MALDI MS

Yan-Hui Liu, Jian Bai, Xiaoli Liang, and David M. Lubman, Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109-1055

Introduction. On-probe purification scheme of using active substrate such as Nafion has been employed in MALDI MS process to eliminate the deleterious effect of impurities and produce homogeneous desorption of all components in protein/peptide mixtures One particular concern is the possible adsorption of analytes of interest by the active substrate, which may lead to unrecoverable loss through various interactions, such as hydrophobic and ionic interactions associated with most polymeric surfaces. This is particularly true when analyzing relatively pure samples, where less impurities are competing for the possible adsorption sites. This work shows the effect of modification of the Nafion substrate on detection of protein/peptide mixtures.

Experimental. Nafion or modified Nafion substrate was obtained by applying 2 µl of the solution onto a stainless steel probe tip and air-dried. Modification of the Nafion substrate involved mixing of the Nafion solution with cetylpyridinium chloride (CPC), fucose, or tributyl phosphate (TBP). CNBr digest of cytochrome C (CC) was used as a model system in this work. Caffeic acid (CA) in 50% acetonitrile acquous solution was used as matrix. MALDI MS was performed on a linear TOF with postacceleration and a 355 nm laser was used for desorption/ionization.

Results and Discussion. Desorption of all fragments in a protein mixture from a Nafion substrate is more uniform than that from a stainless steel surface (1). However hydrophobic/ionic interactions between proteins and Nafion can prevent the sensitive detection of all fragments in a protein mixture. Figure 1 shows MALDI MS spectrum of ~ 1 pmol of cytochrome C digest on the Nafion substrate. No digest signal was obtained. By adding certain kinds of modification substances the adsorption effect can be alleviated.

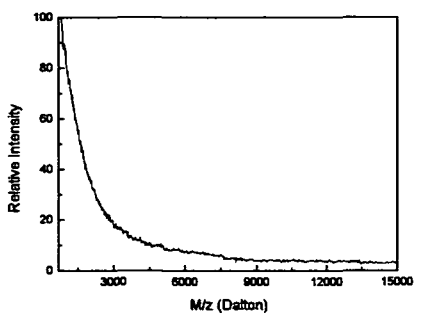

Figure 1. MALDI MS of CC digest on Nafion.

Figure 2 shows the effect of modification of Nafion with TBP by adding 1 µL of TBP to 10 µl of Nafion. Figure 2a is the spectrum obtained by adding CA before the sample was dried while 2b is by adding CA after sample was dried on the substrate. Similar results were obtained by modification of Nafion with fucose.

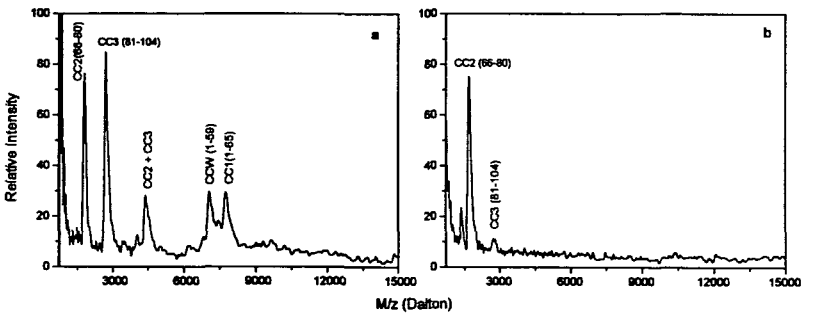

Figure 2. MALDI MS of CC digest on TBP modified Nafion.

Figure 3 is MALDI MS spectrum by modification of Nafion with CPC (20 mg/mL). No difference was observed by adding CA before or after the sample was dried These results show that CPC modified Nafion substrate can effectively eliminate the adsorption of proteins by Nafion

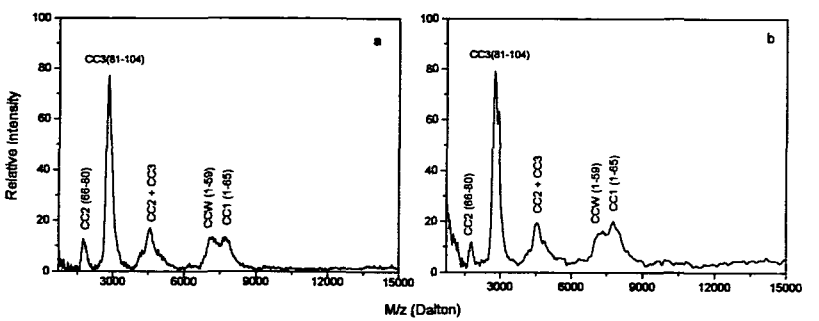

Figure 3. MALDI MS of CC digest on CPC modified Nafion.

Conclusion. This study shows that adsorption of proteins/peptides by active substrate can limit the sensitivity of MALDI MS detection. Modification of the sample loading surface in MALDI MS has the potential to alleviate the adsorption of proteins by the polymeric surfaces and hence enhance the sensitive and uniform desorption of all components in protein/peptide mixtures. Future work will focus on fabricating of composite substrates that retain the purification capability, but do not have adverse effect on MALDI MS detection.

Polymers as a Probe Element for Surface Enhanced Neat Desorption (SEND);

*Patrick Bardel and T. William Hutchens, Food Science and Technology Department, University of California at Davis, Davis, CA 95616.

BACKGROUND AND SIGNIFICANCE

Matrix-Assisted Laser Desorption/Ionization (MALDI) mass spectrometry has become a powerful tool for characterization of biological samples [1] In 1993, our laboratory has introduced new methods for the desorption of biopolymers into the gas phase using probe ***surfaces chemically defined***. This new strategy, involving probe elements with **Surfaces Enhanced for Neat Desorption (SEND)**, makes use of several different modes of EAM immobilization.[2] We have now investigated the relative importance of the phenolic ***OH*** and carboxylic ***COOH*** groups present in the 3 most used matrices (i.e., α-cyano-4-hydroxycinnamic acid (CHCA), sinapinic acid (SA) and 2,5-dihydroxybenzoic acid (DHBA)). Chemical information gathered in these experiments were subsequently used in the design and construction of laser desorption probe elements (i.e., polymers or solid phase) to be used in the SEND mode. Preliminary results based upon the ***covalent*** attachment of EAM to polymeric supports are presented here.

METHODS

α-cyano-4-acetylcinnamic acid, 3,5dimethoxy-4-acetylcinnamic acid, 2-acetyl-4-hydroxybenzoic acid, and α-cyano-4-methoxycinnamic acid and derivatized polymers were synthesized according to reported procedures.[3] Chemical composition of these products was verified by ^{1}H and ^{13}C Nuclear Magnetic Resonance Chemical modification of the solid phase compounds was ascertained by ^{13}C Cross Polarization Magic Angle Spinning (CPMAS) NMR analysis

The samples were analyzed with modified Hewlett Packard LDI 1700XP laser desorption/ionization time-of-flight mass spectrometers. Spectra shown have been accumulated from typically 50 laser shots.

RESULTS AND DISCUSSION

The OH and COOH groups present in most MALDI matrices were chemically altered and tested as potential MALDI matrices. Ether, oxirane, amide and ester bonds were formed. Of these four groups only the acetate derivatives of α-CHCA, SA and DHBA could be used as matrices. In particular, the acetylated α-CHCA (Figure1, 2) proved to be an efficient matrix due to the photochemical lability of this linkage Subsequent chemistry was attempted with solid phase compounds (Figure3, 4) and polymeric materials. Preliminary results confirmed previous trends and indicated that covalent attachment of α-CHCA to polymeric surface through its phenolic group can be exploited to design efficient SEND probe elements.

CONCLUSIONS

Chemical evaluations of the importance of OH and COOH groups present in most MALDI matrices led to several observations:

- the photochemical lability of some chemical bonds can be exploited to attach matrices to surfaces.
- appropriate design and construction of defined probe surface to enable desorption of intact macromolecules can be achieved through covalent linkage of usual MALDI matrices to a large variety of material (solid phase compounds, synthetic polymers).
- the use of different synthetic polymers should enable the development of a new variety of specifically designed probe elements containing the required number of EAM for desorption of large proteins.

Intoduction

In order to understand the functioning mechanisms of proteins, it is necessary to precisely characterize their structure. Nuclear magnetic resonance, circular dichroism as well as X-ray crystallography have been the most common techniques used to probe the three-dimensional conformation of these macromolecules. Mass spectrometry (MS), which has proved to be a powerful technique to study the primary structure of proteins, has been used only recently to probe conformational properties. Studying the charge state distributions by electrospray ionization (ESI) MS, several authors monitored conformational changes induced by organic solvents, pH, temperature or site-directed mutagenesis. Furthermore, the rate of hydrogen/deuterium (H/D) exchange, which depends on the solvent accessibility was recently probed by MS to get information on protein conformation or protein-ligand interaction.

To further investigate conformational changes induced by site-directed mutagenesis, we have adapted the H/D exchange procedure proposed by Zhang & Smith (1), using on-line HPLC/ESI-MS to carry out our experiments.

We compared *Rhodobacter capsulatus* cytochrome c_2 wild type with the P35A and G34S mutants, proteins expressed in a *Rb. capsulatus* strain that lacks a chromosomal copy of the cytochrome c_2 gene. The conformational properties of *Rb. capsulatus* cytochrome c_2 were characterized by the combined data obtained from hydrogen / deuterium exchange, protein chemistry and electrospray ionisation mass spectrometry.

1- Zhang Z. and Smith D.L. (1993), Protein Science, 2, 522-531.

Methods

After incubation in a deuterated solvant, proteins were digested with immobilized pepsin iunder conditions of low back-exchange and the resulting peptides where analysed using LC/ESI-MS.

Results and discussion

In an initial step we probed mutant stability by studying the charge state distribution in H_2O. We obtained approximately the same results for the WT and the mutants P35A and G34S with a maximum at +8.

To further investigate the influence of mutations we used H/D exchange. After one hour of incubation in D_2O, the H/D exchange equilibrium was reached. Mass increases showed that the conformational stability is influenced by the mutations, the G34S mutation having a stronger effect than the P35A one.

In order to characterize segments of the cytochrome c_2 influenced by the mutations, we have undertaken the H/D exchange studies of proteolytic peptides

using the previously described procedure. This procedure was developed and optimized on *Rb. capsulatus* cytochrome c_2 WT. The reproducibility of peptic cleavage and chromatographic profiles was useful to identify the peptides. Molecular mass analyses of deuterated peptides allowed the calculation of a mass increase, directly linked to the number of incorporated deuterium. Assignements of the sequences were realised using the MacBiospec software and Edman degradation. Three peptides were found with slow H/D exchange rates, five with medium H/D exchange rates and three with high H/D exchange rates. Our results were in good agreement with previous H/D exchange studies in NMR except for the N-terminal region. The N-terminal helix located within peptide [1-26] was found to be stable in the NMR studies. The medium exchange rate observed for this fragment could be explained by the length of the peptide which corresponds to the N-terminal helix ([3-13]) and the heme binding region ([14-26]).To better study the peptide [1-26] we performed a chymotryptic digestion and measured the H/D exchange rate after deuteration by LC/ESI-MS. Peptides [1-10] and [11-26] had slow and medium exchange rates, respectively, which is in good agreement with previous H/D NMR studies. Furthermore, overlapping peptides with different exchange rates provided detailed information about local H/D exchange rates. An example is presented by fragments [66-71] and [66-74]. Comparison of those two fragments allowed us to localize the additional deuterium on the three C-terminal residues. Therefore peptide [66-71] exhibits a slow H/D exchange rate whereas peptide [72-74] exhibits a high H/D exchange rate, results confirmed by H/D NMR studies.

Mutated amino-acids in cytochrome c_2 were chosen because they were highly conserved among the class-I cytochromes c and for their roles in the stability of the three-dimensional structure.

First, no significant modification of exchange rate was found for peptide [27-37] where the mutations are localized. The mass increase of 1 Da for P35A mutant is only due to one additional exchangable amide hydrogen, resulting from the mutation.

For both mutants, 3 peptides had an increase in their H/D exchange rate: [1-26], [38-51] and [52-59]. Both mutants seemed to induce the same conformational changes on these last two peptides, but in different ways. The decrease of stability in P35A mutant could be explained by the loss of the ß-turn which would probably induce a local modification of the backbone stability. G34S mutation induced the same modifications but it would be linked to the breaking of hydrogen bonds. Furthermore, both mutants showed an increase in H/D exchange rate of the peptide [1-26] indicating an influence on the N-terminal helix stability. This result is explained by the putative role of the N-terminal helix in the heme binding and in the conformational stability.

The methodology we developped on *Rhodobacter capsulatus* cytochrome c_2 is highly reproducible and sensitive. The use of this procedure has allowed the characterization of cytochrome c_2 regions influenced by mutations, in good agreement with previous NMR studies.

Association of H/D exchange and ESI-MS appears to be a very powerful way for screening the conformational changes induced in proteins by site-directed mutagenesis. It could also be applied to the characterization of regions implicated in protein-protein or protein-DNA interactions.

Probing Conformation and Dimerization in Yeast Hexokinase with ESIMS

Klaus Eckart and Joachim Spiess; Department of Molecular Neuroendocrinology, Max Planck Institute for Experimental Medicine, Hermann-Rein- Str. 3, D-37075 Goettingen

INTRODUCTION

Hexokinase is an important glycolytic enzyme catalyzing the ATP-dependent phosphorylation of glucose to glucose-6-phosphate. The enzyme has a molecular mass of 54,000 and may be present under non-denaturing conditions as monomer or dimer depending on the pH (1). Analysis of the hexokinase conformation with X-ray diffraction in solution revealed a reduction of the radius of gyration from 24.73 Å to 23.78 Å. This reduction was induced by glucose binding (2). Since it was demonstrated that the conformational streptavidin change induced by biotin binding could be analyzed with electrospray ionization mass spectrometry (ESIMS) (3), it was anticipated to establish such analysis for protein ligand systems exhibiting relatively low affinity. This would render this method applicable to many biologically interesting ligand protein systems such as neurotransmitter and neuropeptide receptors.

The possibilities and pitfalls for the detection of specific noncovalent complexes with ESIMS were reviewed recently (4). It was stated that the specificity has to be demonstrated by i. e. the formation of complexes with a certain stoichiometry, independence of the complex formation of concentration changes, and control experiments with altered complex components.

Detection of the hexokinase glucose noncovalent complex ($k_D=10^{-4}$ M) appeared to be difficult, because even the extremely stable biotin streptavidin noncovalent complex ($k_D=10^{-15}$ M) could be dissociated easily by skimmer CAD in the electrospray interface. The pH dependent dimer dissociation was therefore used to establish almost suitable conditions for the analysis of native hexokinase. With in those conditions the effect of specific ligand binding was than investigated.

METHODS

Mass spectral investigations were carried out on a VG Analytical AutoSpec-T tandem mass spectrometer. The instrument was fitted with the Fisons electrospray interface incorporating a hexapole lens for higher ion transmission and the stainless steel spray needle in combination with the pepperpot counter electrode for better stability when spraying buffered water solutions. The liquid was delivered with an infusion syringe pump. The hexokinase concentration was 10 µM. Samples were injected into a 20 µl loop of a Rheodyne 8125 injector. The spray chamber was not heated. The spray was stabilized with a 14 l/h oxygen stream and desolvated with a 300 l/h nitrogen stream. The sampling cone voltage offset was set to 300 V. The instrument was operated with a fully opened collector slit. The magnet was scanned over an appropriate mass range with a scan rate of 5 seconds/decade. Calibrations were performed with CsI. More conditions are given in the figure.

RESULTS AND DISCUSSION

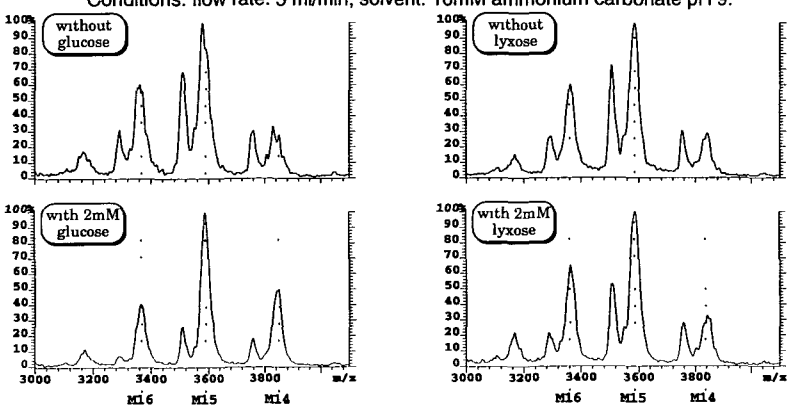
The known pH dependent dissociation of the hexokinase dimer in solution (1) could also be detected with ESIMS. At pH 5 no significant dimer dissociation was observed, whereas at pH 10 the majority of the enzyme was dissociated into the monomer. It should be mentioned that the dimer is partially dissociated when the spray chamber was heated to 80°C. The lower sampling cone voltage offset needed in the case of a heated spray chamber did not compensate for the heat-induced dissociation.

These results provided strong evidence for the native conformation of the hexokinase investigated. In addition, the activity of the enzyme was assessed by glucose phosphorylation.

This test became important, because the commercially available hexokinase preparations had to be desalted with microcon 30 ultrafiltration devices for use in ESIMS. The activity assay revealed conservation of the enzymatic activity after desalting.

Addition of 2mM glucose to hexokinase in ammonium carbonate buffer, pH 9, enhanced M14 compared to M16 (Fig. 1). This effect was not detected with the same amount of lyxose, which is known not to be phosphorylated by hexokinase. The effect is more pronounced when mannose is added in comparison with glucose in the ammonium acetate buffering system. These differences may reflect the two times greater affinity of mannose to hexokinase compared with glucose.

Figure 1: The effect of 2mM glucose and 2mM lyxose to yeast hexokinase.
Conditions: flow rate: 5 ml/min; solvent: 10mM ammonium carbonate pH 9.



Beside the observed change in the charged state pattern of hexokinase, a small mass shift of the hexokinase signals to higher m/z values was observed (Fig. 1). Different k_D values for the dimer dissociation of the different isoenzymes may also serve as an explanation. It should be mentioned that four isoenzymes could be detected by comparison of different hexokinase preparations with ESIMS.

With the observation of the specific glucose effect on yeast hexokinase we demonstrated for the first time the use of ESIMS for the detection of a specific low affinity noncovalent interaction. The exclusive detection of the dimer at low pH in addition suggested that yeast hexokinase was not significantly denatured during the electrospray spray process.

The shift of the hexokinase multiply charge state pattern induced by glucose and mannose binding is compatible with the known decrease of the protein radius. Calculation of the differences in the molecular surface on the basis of the estimation of a ball type shape resulted in a reduction of 7% equivalent to reduction of the average charge from +15 to +14. The observed shift is much less, but it has to be considered that the model used for this estimation represents only an approximation to the real situation.

ESI-TOF-MS Studies of the Refolding and Assembly of Soybean Agglutinin

Xue-jun Tang*[1], Igor Chernushevich[2], Sanat Saha[1], C. Fred Brewer[1] and Kenneth G. Standing[2]
[1]Department of Biochemistry, Albert Einstein College of Medicine, Bronx, New York 10461, USA
[2]Department of Physics, University of Manitoba, Winnipeg, manitoba, Canada R3T 2N2

Soybean agglutinin (SBA) is a noncovalently bound tetrameric glycoprotein. Recent studies of SBA using ESI-MS [1]have revealed that native SBA consists of five major different subunits with four of them truncated at the C-terminus. The subunit composition of six isolectins, designated as SBA-I to VI, has been determined by ESI-MS and found to consist of two intact and two C-terminal truncated subunits composing the tetramers. More recently, we have demonstrated that the noncovalently bound SBA tetramers (~116,000 Da) can be detected using an ESI-TOF mass spectrometer [2]. Moreover, the ESI-TOF-MS technique allowed us to obtain information on the quaternary structure. In our present investigations, the refolding of a pure isolectin, SBA-I, which consists of two intact (α, MW 29438 Da) and two identical C-terminal truncated (β, MW 28001 Da) subunits in equal abundance, has been performed, and the refolding products were subject to analysis using ESI-TOF-MS.

On chromatofocusing using a PBE column at pH range of 7.4-6.5, native SBA-I gave a single peak at pH 6.95 (figure 1a). When the refolded SBA-I was subjected to chromatofocusing, at least four distinct peaks were eluted at pH values of 7.0, 6.4, 5.9 and 5.5 (figure 1b), indicating probable formation of new species. The first peak in the chromatofocusing profile of the refolded SBA-I, eluted at the pH value corresponding to native SBA-I, contains only about 25% of the total proteins eluted. The materials in the rest of three major peaks were pooled together and were designated as combined peak.

Figure 2 shows the ESI-TOF mass spectra of the native and the refolded SBA-I tetramers. The native SBA-I sample (figure 2a) gave only one series of multiply charged ions corresponding to the intact SBA-I tetramer. However, the 1st peak (figure 2b) yielded two sets of multiply charged ions, with one set corresponding to the native SBA-I and the other set representing a new tetramer. The new tetramer, is found mainly in the 1st peak and makes up about 25% of the tetramers eluted in the 1st peak. The measured mass of the new tetramer (113,812 Da) is about 1349 Da lower than that measured from the Native SBA-I (115,161 Da), a value close to the mass difference between the α and β subunit, suggesting the subunit composition of the new tetramer is $\alpha\beta_3$ The spectrum of the combined peak gave only one relatively broad peak with a mass (115,314 Da) corresponding to $\alpha_2\beta_2$ tetramer.

The pH shifts for the tetramers in the combined peak may, perhaps, be due to the tetramers in the combined peak incorporating extra amounts of buffers and salts during the refolding process, since the mass peak of the tetramers (figure 2c) is broad and shifted to higher mass compared with that of the native tetramer (figure 2a). The pH shifts may also be due to the different quaternary structures of the tetramers acquired in the refolding process. In order to address this question, we performed fragment ion analysis of these multiply charged tetramers. Figure 3 shows a segment (m/z 3600-4900) of each fragment ion spectrum obtained from the native SBA-I, the 1st peak and the combined peak. As can be seen, the $\alpha\beta$ heterodimers are dominant species in all the fragment ion spectra, suggesting that the α-β interactions are much stronger than α-α or β-β interactions, and that the spatial arrangement of the subunits α and β are similar in all the tetramers consisting of $\alpha_2\beta_2$. The $\alpha\alpha$ and $\beta\beta$ homodimers are present in low relative abundance except for the 1st peak. For native SBA-I (figure 3a), $\alpha\alpha$ and $\beta\beta$ homodimers are ~8-10% of the $\alpha\beta$ heterodimer, respectively, calculated using +13 and +15 charge states. $\alpha\alpha$ increases to 25% and $\beta\beta$ to 35% of the $\alpha\beta$ heterodimer for the 1st peak, consistent with the spectrum of the 1st peak (figure 2b), which suggests that the 1st peak contains ~25% of the $\alpha\beta\beta\beta$ tetramers.

The results obtained from ESI-TOF-MS analysis of the SBA-I refolding products shows that during refolding small amount of new isolectings were produced, most of which consists of three c-terminal truncated and one intact subunits, and they are also less stable than the native isolectins. However, the majority of the refolded isolectins have a quaternary structure similar to the native isolectins. The new peaks observed in chromatofocusing are probably due to isolectins with a different extent of incorporation of buffer and/or salt molecules during the refolding process.

Rapid Deuterium Exchange-in Time for Probing Conformational Change

Kuruppu Dharmasiri and David L. Smith, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588

Isotopic exchange of protein backbone amide hydrogens has been used extensively as a sensitive probe of protein structure. One of the salient features of hydrogen exchange is the vast range of exchange rates in one protein. Isotopic exchange methods have been used to study the structural features including protein folding and unfolding (1), functionally different forms of proteins (2), protein-protein complexation (3), and protein stability parameters (4). Many backbone amide protons that are surface accessible and are not involved in hydrogen bonding undergo rapid deuterium exchange. In order to study, fast exchanging amide protons, fast exchange-in times are necessary.

A rapid mixing apparatus has been developed which facilitates deuterium exchange experiment as rapid as 200 msec. The apparatus consists of an exchange chamber and digest region on-line. A flow of D_2O buffer solution (pD = 7.2) and protein enters the first mixing chamber in order to start the exchange reaction. Sample flow from the first mixing chamber flows through the length of tubing (length and diameter as well as flow rate determine the incubation time) At the end of the incubation time, the deutarated sample flows into a second mixing tee, where deutarated protein is mixed with a buffer solution (pH=2.2) to quench the exchange reaction and pepsin to digest the deuterated protein. The combined solution flows through another tubing section for 5 minutes while being digested. The resulting peptic digest is then separated by HPLC and analyzed by mass spectrometry for the deuterium content. The digest region and the HPLC column were cooled to 0°C to minimize the back-exchange. The total flow (50μL/min) from the microbore HPLC was introduced into the ESI source. The mass spectrometric analysis was accomplished with a VG Autospec high resolution mass spectrometer equipped with a focal plane array detector. The peptide fragments were identified by tandem mass spectrometry.

The cytochromes C are small globular proteins that involved in electron transfer reaction of the eukaryotic respiratory chain. Electrons in the heme group of the cytochromes C shuttled between the reduced (Fe (II)) and the oxidized (Fe (III)) states. It is believed that the reduced and oxidized cytochromes C have similar protein structures but different heme oxidation states. Another cytochrome C of interest is the apocytochrome C which is lacking heme group and tertiary structure In this study, reduced, oxidized, and apo cytochromes C have been studied by the rapid deuterium exchange methodology combined with mass spectrometry.

Various segments of the protein can be analyzed for deuterium incorporation with time. The exchange data provide the information about solvent accessibility of localized segments along the backbone of the protein. Figures 1a and b show the change in deuterium incorporation for two segments of the protein 95-104 and 83-94 respectively. Apocytochrome C shows the largest deuterium incorporation and reduced form shows the least for these two segments. Some segments show very little change in deuterium incorporation between reduced and oxidized forms (e.g.. segment 1-10).

In addition to the peptide fragments, undigested cytochrome C was observed during mass spectral analysis. As shown in Figure 2, the deuterium exchange curves for reduced and oxidized cytochromes C show that deuterium uptake is less in the reduced form. Difference in deuterium uptake shows the stability of reduced form over the oxidized form at pD = 7.2. Our results show that the on-line hydrogen exchange mass spectrometry coupled with proteolytic fragmentation can be used to rapidly (< 30 min.) identify localized conformational changes in proteins.

ESI-MS OF PROTEIN NONCOVALENT TETRAMERIC ASSOCIATIONS AT HIGH *m/z*

Brenda L. Schwartz, David C. Gale, Ashutosh Chilkoti[1], Virginia F. Smith[2], Linda L. Randall[2], Patrick S. Stayton[1], and Richard D. Smith, Chemical Sciences Department, Pacific Northwest Laboratory, Richland, WA 99352
[1]Center for Bioengineering, University of Washington, Seattle, WA 98195
[2]Department of Biochemistry and Biophysics, Washington State University, Pullman, WA 99164

Electrospray ionization mass spectrometry (ESI-MS) has demonstrated broad applicability in the analysis of liquid-phase noncovalent complexes. Successful detection of these complexes by ESI-MS relies on the use of proper solution conditions and careful control of instrumental variables in the atmosphere-vacuum interface region. For large multisubunit proteins, electrospraying from near-neutral pH aqueous solutions, rather than from conventional acidic solutions, is often essential *in detecting the biologically active form of the protein. However, the limited gas-phase charging* typically observed for these proteins, presumably due to their compact quaternary structures, necessitates the use of mass spectrometers capable of extended *m/z* range detection (>3,000).[1]

The protein streptavidin (M_r ~ 53.1 kDa) exists in its active form as a noncovalent tetramer, which is comprised of four identical polypeptide-chain subunits, each containing a ligand binding site. Streptavidin, similar to avidin, exhibits an extremely specific and strong affinity ($K_D \sim 10^{-15}$M) for biotin (M_r = 244 Da). The intact tetrameric form of the avidin-biotin noncovalent complex has previously been observed utilizing a low rf frequency extended *m/z* range (~45,000) quadrupole mass spectrometer.[2] The ability to probe by ESI-MS relative noncovalent binding of two structurally similar ligands, biotin and 2'-iminobiotin (M_r = 243 Da, $K_D \sim 10^{-7}$M), to streptavidin was investigated.[3] The inherent variations in structural properties between these ligands give rise to their vast differences in binding affinities. Several protein:ligand molar ratios and incubation times were selected, in addition to altering conditions in the interface region (i.e., capillary temperature) to monitor the appearance of the specific complexes, and to subsequently induce their dissociation.

Solutions containing 1:10 streptavidin:ligand molar ratios in 10 mM NH_4OAc (pH 8.6) were analyzed by positive-ion ESI-MS following an incubation period of several minutes. The spectrum of the 1:10 streptavidin-iminobiotin sample (Fig. 1a) indicates that the intact noncovalent complex is not observed even under gentle ESI interface conditions. The experimental M_r of 53,128 ± 55 Da calculated from the tetramer charge states (Q^{16+} to Q^{13+}) corresponds in mass to the unbound streptavidin tetramer. Under identical conditions, a short incubation time for the 1:10 streptavidin-biotin sample (Fig. 1b) was sufficient to produce ions corresponding to the stoichiometrically specific association of four biotins binding to the protein, as indicated by the M_r of 54,081 ± 55 Da. Only under extremely mild interface conditions, combined with a larger iminobiotin concentration and longer incubation period, was significant binding for this complex detected. In addition, an intact noncovalent complex formed between streptavidin and a synthetic 5'-biotinylated 12-base pair oligonucleotide (5'-Biotin-dACTTATCTTTCT-3', M_r = 3956 Da) was observed. Negative-ion ESI-MS of a 1:5 protein:ligand solution in 20 mM NH_4OAc (pH 8.6) produces intense ions (Q^{17-} to Q^{14-}) for the complex (Fig. 2). The experimental M_r of 68,873 ± 70 Da is consistent with the predicted solution behavior for the binding of four biotin-oligonucleotides to the streptavidin *tetramer. These results demonstrate the ability of ESI-MS for probing relative stabilities of* noncovalent complexes, and prove that these complexes detected are structurally specific, and are not due to nonspecific interactions.

Introduction.

Alzheimers disease is a major social and health problem facing the developed countries because of the increasing longevity of their populations and hence is the subject of much current research. Amyloid β peptide (1-40) together with some smaller related peptides, are normal proteolytic products of a large transmembrane glycoprotein and are major components of the characteristic, practically insoluble, amyloid depositions found in the brains of Alzheimers patients *In vitro*, these peptides have been shown to readily aggregate and form insoluble amyloid fibrils similar to the brain depositions, but are also found in a soluble form in the cerebrospinal fluid and serum of subjects both with and without the disease

Recently, it was shown[1] that amyloid β peptides in these extracellular fluids do not normally aggregate because they are sequestered by one or more of the proteins, particularly transthyretin (TTR), present in these fluids Here, we summarise unsuccessful attempts to show similar sequestering of amyloid β peptides by TTR using electrospray mass spectrometry (ESI-MS)

Results and Discussion.

TTR samples from three sources were analysed by ESI-MS in the denatured state, i e. as the monomer, to check their authenticity and purity These analyses were carried out in 50% aqueous acetonitrile containing 0.2% formic acid All 3 samples showed substantial and different heterogeneity Furthermore, the peaks corresponding to the sequence mass of TTR (13761 4) indicated the unmodified TTR to be present only as a minor component in all 3 cases (Figure 1). Nevertheless, when the TTRs were analysed in water containing 5-10mM ammonium acetate at physiological pH, they produced 3 peaks corresponding approximately in mass-to-charge ratio to the expected non-covalent tetramer complex (55046) with 15-17 charges. It was only possible to approximately determine the mass-to-charge ratios of the tetramer due to the broad nature of the peaks. This latter was attributable, at least in part, to the heterogeneity of the monomer.

Amyloid β peptides (1-40), (1-28) and (12-28) were analysed by ESI-MS and found to be pure and to have molecular weights which agreed with those calculated from their sequences. However, when the amyloid peptides were incubated with TTR at 37°C and physiological pH, there was no evidence that the TTR sequestered the peptides (Figure 2), even though the peptides were added at levels up to 10 times molar excess over the TTR. The occurrence of complexes between the TTR and the amyloid peptides would have resulted in a substantial increase in mass-to-charge ratio However, in some cases, because of the broad nature of the tetramer peaks and the occurrence of 3 peaks with 15-17 charges, overlap of the complex ion, for example with 17 charges, could be expected to occur to some extent with the un-complexed TTR ion with 16 charges The use of more homogeneous TTR would be beneficial in obviating this difficulty

Conformational Changes and Molten Globule States of Proteins Detected by Matrix-Assisted Laser Desorption Mass Spectrometry

Houjun Yang, Xiaoling Li and Jürgen Grotemeyer*
Institut für Physikalische Chemie, Universität Würzburg, Marcusstr. 9/11, D-97070 Würzburg, Germany.

It is shown that simultaneous to the unfolding of hen-egg white lysozyme and horse heart cytochrome C the sequential conformational changes and molten globule states can be detected by the combination of proteolysis and matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS). This is demonstrated by the differences among the products and the time courses of native lysozyme as well as those unfolded in 1M and 3M guanidine hydrochloride (GuHCl) when they were proteolyzed by proteinase K and followed by MALDI-MS. Due to the absence of disulfide bonds in the cytochrome C molecule, it is more sensitive to the disturbance of the denaturant. The partially unfolded state as detected at low concentrations of guanidine hydrochloride in our experiment resembles in a way a molten globule state. One of the unique properties of the method described herein is to measure directly the peptide fragment liberated from proteolysis of the protein. It allows the identification of the sensitive sites susceptible to denaturation, which are subsequently cleaved by proteinase K proteolysis.

1. Conformation changes during unfolding.

Our results suggest strongly that the conformational changes happen in the lysozyme molecule while it is incubated with GuHCl at a concentration lower than 3 M. This is demonstrated by the differences among the time courses of native lysozyme, which unfolded in 1 M GuHCl and which in 3 M GuHCl while they were proteolyzed by proteinase K. Due to the abscence of disulfide bonds in cytochrome C molecule, it is more sensitive to the disturbance of the denaturant than lysozyme, the method can even to be employed to tell the differences between those unfolded in 0.5 M and 1 M GuHCl. The increase in rates and products of proteinase K digestion with the increase of GuHCl concentration suggests the gradual opening up of the molecule.

2. Relation of the partially unfolded to the molten globule state.

The partially unfolded state as detected in our experiment at low concentration of GuHCl before gross conformational changes occure resembles in a way the molten globule state[1,2,3]. If the unfolding of lysozyme in GuHCl occures by a simple two-state mechanism, all the time courses of proteinase K digestion of lysozyme in 0M, 1M, and 3M GuHCl would be coincident. The fact that this is not the case demonstrates unequivocally that partially structured intermediates are populated during unfolding at low concentrations of GuHCl. The molecule of lysozyme unfolded in dilute GuHCl is partially loosened up especially in the active site as indicated by the peptide fragments, Thr_{89}-Gly_{102} and/or Ser_{91}-Gly_{104} (in 1M GuHCl) as well as Ala_9-Phe_{34}, and thus open to attack by proteolytic hydrolysis without noticeable changes in its secondary structure. All the above is consistent with the concept of the molten globule state.
Cytochrome C takes stable conformation in the buffer without GuHCl, and denatured conformation at high concentrations of GuHCl (1 M and 3 M). The stable conformation induced by 0.5 M GuHCl represents such one as to have secondary structure and compactness similar to native protein but lack tertiary structure indicated by the more exposured conformation to be hydrolyzed, the concept of molten globule state holds also for cytochrome C.

3. Location of the area sensitive to denaturation

One of the unique properties of the method described herein is to measure directly the peptide fragment resulted from proteolysis of the protein. It allows to identify the sensitive sites susceptible to denaturant and subsequently to cleavage by proteinase K proteolysis. The results from proteinase K digestions of lysozyme at different concentrations of GuHCl indicate the active site to be easily disturbed by the denaturant at low concentrations of GuHCl. Both the fragments, Thr_{89}-Gly_{102} and/or Ser_{91}-Gly_{104} are related much to the binding sites of Asp_{101} and Asp_{103} in the active site, and the fragment Ala_9-Phe_{34} is released exactly by cleavage of the peptide bond of Phe_{34}-Glu_{35}, where the Glu_{35} is a residue in the active site. The results could be explained reasonably by conformational changes happening at the active site, and provide support to the suggestion that enzyme active sites are situated in a limited and flexible regions and are therefore more easily perturbed than the rest of the molecule [4]. The inhibition of lysozyme activity by GuHCl seems unreasonable because this would prevent the active site cleft to proteolysis.
A close examination of the peptide fragments generated from cytochrome C at various concentrations of GuHCl shows the β-turns and coiled area are susceptible to proteolysis. The peptide fragments produced from the unfolded states involve the heme group and the heme ligand His_{18} as indicated by Val_{11}-Val_{20}, $AcetylGly_1$-Gly_{34} and Phe_{10}-Gly_{41} in the case of proteinase K digestion of cytochrome C in 0.5 M GuHCl. This site-directed determination of the unfolding of the molecule induced by denaturant provides a sensitive way for detections of conformational changes.

Acknoledgement

Unusually Strong Binding of A Noncovalent Gas-Phase Spermine-Peptide Complex and Its Dramatic Temperature Dependence

Rong Feng, American Cyanamid Co., P.O. Box 400, Princeton, NJ 08543

Naturally present polyamines, which play essential roles in various cell events, are known to cause conformational changes in nucleic acids. Spermine, in particular, has also been found to induce α-helix formation in an acidic peptide by forming a specific noncovalent complex with the peptide. In this study, electrospray ionization mass spectrometry (ESI-MS) and MS/MS techniques were utilized to characterize the complex formation between spermine and a spermine-binding peptide (SBP) having an amino acid sequence of AcYEQAAEQQEAAQEACONH$_2$ (MW$_{av}$ 1606.6 Da). The experimental data revealed an unusually strong binding complex between spermine and the peptide, and showed that the gas-phase stability of the complex was heavily influenced by the ESI interface temperature.

A Finnigan TSQ 700 triple quadrupole mass spectrometer was used for the ESI-MS and MS/MS studies. The peptide and spermine were dissolved in pure H_2O to form the complex and the samples were sprayed at a flow rate of 1 - 2 μl/min without organic modifier, unless otherwise noted. The ESI needle was held at ±4.0 kV and ambient temperature for positive and negative ion production. The electrosprayer was assisted by a coaxial pneumatic nebulizer to pulverize the aqueous sample solution; the coaxial liquid sheath makeup flow was not used. The temperature on the ion inlet capillary at the atmosphere/vacuum interface region was varied from 100 to 300 °C to probe the effects of thermal heating on the complex stability. The gas-phase dissociation patterns of the low- and high-temperature complexes were studied using MS/MS technique with the argon collision gas at 1.5 mTorr; the collision energy was varied from 10 to 60 eV.

SBP, an acidic peptide containing 4 glutamic acids, could be detected as either deprotonated negative ions or various cation adducts. Despite the weak binding constant (~10^4 M^{-1}) of the spermine-peptide complex in solution, its noncovalent gas-phase complex was readily detected using ESI-MS. The complex could be observed as positive ions but not as negative ions, indicating that the acidic residues in the peptide could no longer present themselves as free anions due to their active participation in complexing spermine.

In contrast to the weak binding in solution, the complex exhibited an unusually strong binding in the gas phase, as shown by collisionally-activated dissociation (CAD) studies of the complex ions in the Q2 collision chamber. In fact, the noncovalent complex would not dissociate until the cleavage of a covalent bond had occurred at high collision energy (Fig. 1). The gas-phase dissociation of the singly charged complex ion (*m/z* 1810) yielded a major product ion at *m/z* 1709, whose mass was 101 Da higher than the free peptide ion (*m/z* 1608). This indicated that the total binding energy of the complex in the gas phase exceeded that of a covalent bond (50 - 120 kcal/mol). This dramatically enhanced complex stability in the gas phase may be due to increased Coulombic stabilization energy of the opposite charges in the solvent-free environment. Although the effect of the dielectric constant of water (κ = 80) on the Coulombic interactions of closely placed charges (several Å in distance) is still not fully understood, it is expected that ion solvation stabilizes charges and reduces the attraction (or repulsion) between them. Therefore, the stability of a charge-coupled complex should increase upon transition from solution to the gas phase.

Interestingly, the gas-phase binding strength of the spermine-peptide complex could be greatly weakened by heating the ion flux in the capillary interface. At high interface temperature (>200 °C), the

43rd ASMS Conference on Mass Spectrometry and Allied Topics

collisional dissociation of the complex in the Q2 collision chamber occurred predominantly via breaking the noncovalent interactions, *i.e.*, shedding an intact spermine ion. The large difference in binding energies at different temperatures could be due to drastically different gas-phase conformations of the spermine-peptide complexes. The weak complex produced at high temperature might have significantly less α-helical structure than the strong complex produced at low temperature. Since the peptide α-helical structure plays the critical role in spacing the negatively charged acidic residues at appropriate intervals for coupling with the positive charges on spermine, heat-induced structural distortion in the peptide could cause significant charge decoupling in the complex, thus losing much of the strong binding interactions that hold the complex tightly together.

When the spermine-peptide complex was prepared in 1:1 CH_3OH/H_2O solution, the interface temperature required to weaken the complex to yield *noncovalent* collisional dissociation increased to 250 °C (*vs.* 200 °C in H_2O), reflecting a substantially enhanced complex stability in the presence of CH_3OH (Fig. 2). This is consistent with the known fact that organic modifiers such as CF_3CH_2OH or CH_3OH typically increase peptide α-helicity in solution. Circular dichroism and hydrogen/deuterium exchange experiments should shed more light on the complex conformations at low and high temperatures.

These ESI-MS data show that at least two conformations of the SBP-spermine complex exist in the gas phase, despite the absence of the stabilizing solvent molecules. The drastically different collisional dissociation patterns indicate that the low- and high-temperature complexes have very different gas-phase structures. The extremely strong binding of the low-temperature complex also demonstrates the greatly increased significance of the electrostatic stabilization in the gas phase *vs.* in solution.

Acknowledgment: The author thanks Jean Lefebvre for kindly providing the spermine-binding peptide for the ESI-MS studies and Pat Mowery for helpful discussions.

Conformation of Chaperone Bound Ligands Probed by ESI MS

Carol V. Robinson, Michael Groβ,
Christopher M. Dobson and Sheena E. Radford
Oxford Centre for Molecular Sciences,
South Parks Road, Oxford, OX1 3QT, UK.

Introduction

Protein folding in the cell is assisted by a host of helper proteins including the molecular chaperones which are thought to safeguard newly synthesised proteins from aggregation and other misfolding events. To unravel the molecular details defining the mechanism of action requires a novel approach to the problem of how to determine the conformational properties of a relatively small protein in the presence of the large 800KDa chaperone oligomer. Here we describe the development of one such approach, shown schematically in figure 1, and its extension to include other protein ligands and cofactors

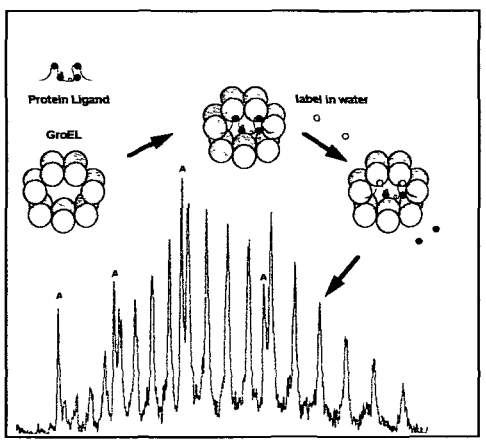

Figure 1:Schematic representation of the experiment designed to monitor hydrogen exchange in a chaperone-protein substrate complex. The black and open circles represent D and H respectively. The charge states labelled A represent the series of multiply charged ions arising from the substrate; the remaining peaks are from the GroEL monomer.

Results and Discussion

A number of control experiments were carried out to assess the feasibility of monitoring different conformational states by ESI MS. Measurement of hydrogen exchange from random coils, partially structured molten globules and native states were found to be in complete agreement with similar measurements by NMR. Such measurements are possible since conditions have been developed in order to preserve deuterium labelling even in extremely labile states such as molten globules (1).

Analysis of the hydrogen exchange kinetics and peak width data for an α-lactalbumin-GroEL complex have shown that the chaperone bound protein ligand is intermediate between the native and random coil states and most closely resembles the molten globule state.

More recently other chaperone - protein complexes have been examined. The stable complexes of dihydrofolate reductase (DHFR) and human α-lactalbumin with GroEL have been analysed using this technique. Furthermore, the non-covalent complex formed between GroEL with the co-factors GroES and ATP/ADP, has been examined and demonstrates that ATP/ADP is associated with the GroEL oligomer since the increase in mass associated with the attachment of ADP (+424) is seen only on the GroEL ion series.

Conclusion

Our recent results have demonstrate the feasabilty of detecting hydrogen exchange protection by ESI MS in the central cavity of GroEL. Further work will assess the hydrogen exchange protection of other ligands and the chaperone GroEL and examine conformational changes upon ligand and cofactor binding.

Studies of H/D exchange of Peptides by using aerosol MALDI

Xiaona Wei, Michelle D. Beeson, David H. Russell
Texas A & M University
Laboratory for Biological Mass Spectrometry
Department of Chemistry
College Station, Texas 77843

Hydrogen-deuterium (H/D) exchange measurements are becoming increasingly important in studies of the conformation and folding dynamics of proteins. The amide hydrogens of a peptide are labile to exchange with deuterium in solution but the exchange rates are related to the stability of secondary and tertiary structures. Mass spectrometry can be used to probe the conformation of the peptides/proteins by detecting the extent and/or rate of hydrogen-deuterium exchange[1].

One of the collaborative research project of the Laboratory for Biological Mass Spectrometry is to develop methods of investigation H/D exchange of model peptide (mw 1000-3000daltons)[2,3]. One of the methods we are evaluating for this project is aerosol-MALDI-TOF. The potential advantage of the method is the ability to sample directly the solution phase system, the aerosol MALDI mass spectra are less complex than the ESI spectra, typically only containing the $[M+H]^+$ ion, ion yield are insensitive to the presence of salts and buffers[4], and the experiment can be performed using a range of solution and solvent conditions[5].

Figure 1 are the spectra of Bradykinin H/D exchange. Bradykinin (mw=1060.2) contains a total of 17 labile hydrogens accessible. Three of the hydrogen atoms are involved in hydrogen-bonding that induce a β–turn and a partial helix. Fourteen hydrogen exchange was observed. Bradykinin spectra obtained in CH_3OH and CH_3OD indicate that the H/D exchange measurements are reproducible. Figure 2 are the H/D exchange spectra of Angiotensin II. An m/z shift of 22 was observed from 20 exchangeable protons. The H/D exchange efficiency was 110%. Spectra showed reproducibility in exchanges.

One major limitation of the current aerosol MALDI apparatus is the mass resolution. The mass resolution currently attainable on the aerosol MALD apparatus is not sufficient to distinguish between the exchange of ±1 hydrogen atom above m/z 1000. The $[M+H]^+$ ion signal corresponds to a distribution of deuterated species and the ^{13}C isotopic pattern. The incompletely resolved $[M+H]^+$ ion and the adduct ion signals may also contribute to the broadening. The number of exchanged hydrogens is determined by the mass increase of the peak centroid between the spectra before and after deuteration. The m/z resolution limit impedes accurate m/z assignment.

We are presently at the design stage of a second generation apparatus. The second generation instrument will consist of a microspray nebulizer, a wire ion guide system and a reflectron. Proof of concept experiments have been performed on our new PerSeptive Biosystems, Inc. Voyager Elite, and the Voyager Elite extended geometry instruments. Figure 3 and Figure 4 are MALDI-TOF mass spectra of Bradykinin and Melittin obtained using the Voyager Elite and the Voyager Elite Extended Geometry Instrument. The results for the experiment suggest that we can obtain unit mass resolution for peptides up to mass 5,000.

PROBING HIGH ORDER STRUCTURE OF PROTEINS BY H/D EXCHANGE/ESI-MS

Claudia S. Maier, Ok-Hee Kim and Max L. Deinzer
Department of Agricultural Chemistry, Oregon State University, Corvallis, OR 97331-7301

Very promising H/D exchange protocols in combination with mass spectrometric methods (especially ESI-MS) have been reported for probing global protein solution-conformations [1, 2], gas-phase conformations [3] and transient folding intermediates [4]. In these experiments all H/D exchange events were monitored by measuring the resulting mass increases during exchange-in reactions and the mass decreases during exchange-out experiments with deuterium labeled proteins. The resulting global structural information allowed distinguishing different conformations, but the methods possess limited ability to assign exchange rates to specific regions of the polypeptide chain. The mapping of exchange rates to specific regions of the polypeptide chain is a major assumption in correlating information obtained from H/D exchange experiments to structural features.

We evaluated two appoaches to increase the structural resolution of H/D using directly coupled microbore LC-ESI-MS and MSMS. The combination of chromatography and mass spectrometry provides flexibility in the choice of solvent systems during the labeling procedure. In the first approach, melittin was used as a model peptide because of its modest size and exclusive α-helical secondary structural elements (under conditions used). Fully deuterated melittin was injected onto a C8-column after prescribed incubation periods in methanol/water/acetic acid (pH 3 2) and the exchange-out events were directly monitored by on-line coupled ESI-MS. As evident from the obtained kinetic profile (figure 1), the exchange-out behavior is slowed down and this is the expected behavior of amide deuterons involved in hydrogen bonds [5]. The method presented here demonstates only the exchange-out behavior of the backbone amide deuterons. Microbore LC-ESI-MSMS experiments on fully-deuterated melittin enabled the direct localization of the two α-helical domains because the exchange-out of deuterons takes place relatively slowly during the chromatographic passage. Therefore, the observed fragment ions allowed the computation of the amide deuterons remaining at each residue By using the present method the number of deuterons remaining correlated directly with the degree of secondary structural stabilization at each backbone amide (figure 2). In previous work the number of exchangeable hydrogens are not specifically related to the amide hydrogens but includes the side chain hydrogens as well [6].

Secondly, the compatibility of the protein fragmentation method with directly coupled microbore LC-ESI-MS and MSMS was demonstrated using cytochrome c as a model system. This technique was first established by Rosa and Richards [7] and extended by Zhang and Smith by using FAB-MS for determination of deuterium content of the resulting peptides [8]. In the present procedure native cytochrome c was incubated in D_2O (pH 6) over different periods and immediately digested with pepsin at pH 2.5 at 0°C for 10 min. The digestion was terminated by freezing in liquid nitrogen, left frozen until it was injected onto the microbore C18-colum and eluted with aqueous acetonitrile/0.1 % trifluoroacetic acid gradient at 0°C over a period of 30 min. Because the incubation periods were varied, the complete analysis time (30 to 45 minutes depending on the retention time of the peptide) was fixed and the analysis condition were optimized to minimize back-exchange The molecular weight increase of the peptic peptides was determined after different incubation periods and the number of NH remaining was computed (figure 3). However, kinetic profiles [8] provide no information about regions in which amide hydrogen exchange takes place. Therefore, online microbore LC-ESI-MSMS was performed. This enabled us to locate domains with the highest content of amide hydrogens remaining within the polypeptide chain, e.g. in peptide 83 to 96 the region of residue 90 to 96 which represents the N-terminal part of the C-helix of cytochrome c (figure 4). A comparable labeling procedure was used to obtain compatible H/D exchange

maps for fully deuterated cytochrome c. The present H/D labeling experiments in combination with fragmentation method supplemented by MSMS provides detailed H/D exchange maps for the peptides which reflect the secondary structural construction of the protein.

Studies of Partially Folded Proteins at Acidic pHs by H/D Exchange and ESI-MS

Xue-jun Tang* and Fang Wang
Department of Biochemistry, Albert Einstein College of Medicine, Bronx, New York 10461

A major experimental approach to understanding the protein folding process has been the structural characterization of partially folded equilibrium states using various experimental techniques including circular dichroism (CD) and NMR [1-3]. ESI-MS permits the accurate measurement of protein molecular mass (≤0.01%) at picomolar quantities, making H/D exchange in combination with ESI-MS an attractive choice for protein conformational studies [4,5]. In the present investigation, partially folded apomyoglobin (apo-Mb) and cytochrome c, induced by salts [3], detergents or hydrophobic solvent 2-propanol at pH 2, were characterized using CD and H/D exchange monitored by ESI-MS.

CD and H/D Exchange Rate Measurements of Acidic Compact States. Figure 1 shows the CD spectra of myglobin in H_2O at pH 6, in 10 mM HCl at pH 2 and in 10 mM HCl with the addition of CCl_3COONH_4 salt, and the H/D exchange rates of myoglobin in the corresponding deuterated solvents. The CD spectrum of myoglobin (holo-Mb) in 10 mM HCl at pH 2 (figure 1a), indicates a complete loss of α-helicity, suggesting that the protein was in a maximally unfolded state [3]. The addition of CCl_3COONH_4 salt to the acid unfolded protein solution induced a refolding transition with an increasing in the α-helical content as the concentration of the CCl_3COONH_4 increases. This transition reached a plateau at about 15.3 mM CCl_3COONH_4, having an ellipticity at 222 nm of -13,553 indicating a helical content of ~61% of Mb in H_2O, which is consistent with the findings of Goto et al [3]. Apo-Mb contains 153 amino acid residues with 121 residues in α helical conformation according to the X-ray crystallographic data, and a total of 262 exchangeable hydrogens. H/D exchange rates obtained for apo-Mb and holo-Mb are consistent with the CD measurements. Holo-Mb underwent the least exchange, and even after 30 min, 80 labile hydrogens remained unexchanged. Since the exchange of the labile hydrogens exposed to solvents are fast, the remaining hydrogens are expected to be those involved in hydrogen binding in α-helices or those located on side chains buried inside the hydrophobic core of the protein [2]. As the protein was denatured in 10 mM DCl (holo-Mb became apo-Mb), the number of hydrogens being exchanged increased considerably and only 13 backbone hydrogens remained after 35 min. The solutions containing CCl_3COOND_4 have exchange rates that decreases with an increase of CCl_3COOND_4 concentrations. For the solution containing 12.2 mM CCl_3COOND_4, the 61 unexchanged hydrogens at 34 minutes are ~50% of backbone hydrogens that are in the helical conformations of native myoglobin, which is in agreement with the CD data.

Effects of Different Salts and Detergents on Acid-Unfolded Proteins. Figure 2 shows the refolding transitions of apo-Mb and cytochrome c at pH 2 induced by salts or detergents. For the three salts selected, our CD results are consistent with those of Goto et al. who reported that the order of effectiveness for inducing the refolding transition was: ferricyanide > sulfate > trichloroacetate > thiocyanate > perchlorate > iodide > nitrate > trifluoroacetate > bromide > chloride. Our H/D exchange data, however, indicate that trichloroacetate (TCA) is more effective than sulfate in inducing folding. The discrepancy between the relative amount of the secondary structures derived from CD data and from H/D exchange data, is due to different principles of the two techniques. CD measures average amount of secondary structures at a given time. By contrast, H/D exchange monitored by ESI-MS reflects the amount of stable folded structure lasted through the time of exchange. Thus, the conformational information obtained from the H/D exchange is complementary to that from CD. For the three chosen detergents, the H/D exchange data agree with the CD data for both proteins and the order of effectiveness for induce folding is SDS > CTAB > CHAPS. It is noteworthy that the three detergents are of different classes, SDS being anionic, CTAB being cationic and CHAPS being zwitterionic, along with the hydrophobic solvent 2-propanol, are all effective in inducing the refolding transitions. Although both SDS and TCA are monovalent anions, the fact that SDS is about 100 times more effective than TCA, and that the monovalent cation CTAB is as effective as TCA or the divalent anion sulfate, in inducing protein refolding, suggests strongly that hydrophobic interactions may play an important role for bringing about the conformational transitions.

Disulfide bridges assignments of homologous vegetable proteins

Guy P.[1], Saint-Pierre C.[1], Gagnon J.[1], Marion D.[2] and Forest E.[1]

1 Institut de Biologie Structurale, 38027 Grenoble, France.
2 INRA, 44072 Nantes, France.

We have studied a new family of cysteine-rich proteins of vegetable origin. These are single chain polypeptides of about a hundred amino-acid containing eight or ten cysteine residues involved in four or five disulfide bridges. The assignment of these disulfide bridges required the use of a rather complex strategy, in order to study cysteine residues in close proximity.

Puroindoline, the first protein studied, was extracted from wheat endosperm. The puroindoline sequence has been previously described as a 115 polypeptide chain containing ten cysteines all involved in disulfide bridges. Using electrospray ionization mass spectrometry (ESI-MS) we have shown that the protein is heterogeneous, composed of several forms with N- and C-terminal extensions and / or deletions [1]. To better characterize the structure of this protein, the topology of disulfide bridges has been assigned.

Puroindoline was digested with thermolysin and trypsin, then analyzed by µHPLC / ESI-MS. The resulting digest fragments were purified by reverse-phase high performance liquid chromatography (rp-HPLC).

The 2543 Da tryptic and 3854 Da thermolytic fragments were reduced with tris-(2-carboxyethyl)-phosphine (TCEP). Two disulfide bridges were assigned after ESI-MS-MS and Edman degradation analysis.

The 5830 Da and 6000 Da tryptic fragments were sequenced by Edman degradation. These fragments were composed of 5 peptides linked by 4 disulfide bridges. We submitted the 5830 Da tryptic fragment to endoprotease Glu-C sub-digestion. After rp-HPLC purification and ESI-MS analysis of the resulting sub-digested fragments before and after reduction, we have assigned a third disulfide bridge. The 6000 Da tryptic fragment was partially reduced with TCEP for 8 min at pH = 3.0. The 1944 Da partially reduced compound was purified by rp-HPLC and analyzed by both ESI-MS and MALDI-MS. Alkylation by iodoacetamide of free thiols, followed by Edman degradation analysis, provided explicit assignment of a fourth disulfide bond. Based on these results we have deduced the last disulfide bridge **(Fig. 1)**. We have observed that fragmentation of disulfide linked peptides occur under the MALDI process **(Fig. 2)** [2].

We are currently applying this strategy to a lipid transfer protein (LTP), another basic and cystine-rich protein of wheat endosperm, of known three-dimensional structure. A comparison of the disulfide bridge patterns between both proteins will give some elements of the three-dimensional structure of puroindoline.

DETERMINATION OF DISULFIDE BONDS IN PROTEINS WITH ABD-F

Umamaheswari Rajamani, Lewis Pannell, Danny Sackett, Han Le and Paolo Lecchi
Laboratories of Analytical Chemistry and Biochemical Pharmacology
NIDDK, NIH, Bethesda, MD 20892-0805

Objective

To develop a simple colorimetric method for the assay of free cysteines versus those involved in disulfide bonds The method should involve minimum manipulation of the protein, with all reactions ideally performed in the UV cell.

Method

4-(Aminosulfonyl)-7-fluoro-2,1,3-benzoxadiazole (ABD-F) reacts very readily with thiols It gives a colorimetric species, ABD-SR, which has a maximum absorbance at 385nm and fluoresces at 514nm. The reagent reacts with the free S-H and forms a new covalent bond with the elimination of H-F at slightly basic pH Traditional reducing agents are thiols themselves (dithiothreitol or mercaptoethanol) and will also react with ABD-F in the same way free cysteines do Therefore these must be removed after the reduction and before reaction with the ABD-F Tributylphosphine (TBP), while a little more difficult to work with, will readily reduce proteins and not react with ABD-F Therefore it is an ideal reagent for this work TBP may be added even after the ABD-F without problems

Reagents and Equipment

Denaturing buffer: Na_2HPO_4 (0 08M), EDTA (1 7mM), guanidine HCl (4M)

Proteins used Ribonuclease A, Superoxide dismutase, β-Lactoglobulin, Tubulin, Enolase

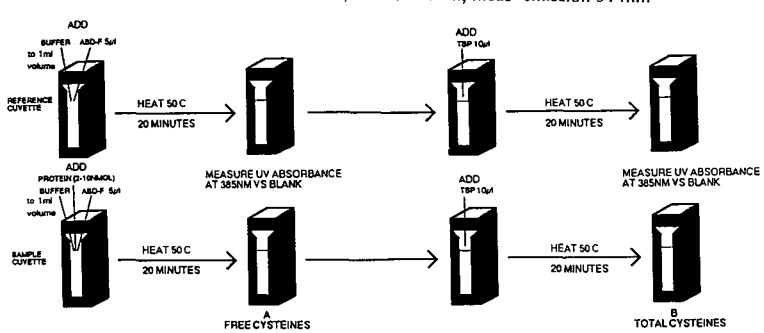
ABD-F 40mM in DMSO

TBP 12μl of TBP dissolved in 1ml methanol and stored under nitrogen

UV Cells Both 1ml and 50μl cells used were purchased from Hellma (Forest Hill, NY)

UV Measurements Beckman DV-65 UV/VIS at 385nm

Fluorescence Meas Perkin-Elmer MPF-66, excite 385nm; meas emission 514nm



The ratio of the free cysteines is calculated from the ratio of absorbance A / absorbance B Increased sensitivity is possible with the use of smaller UV cells (50μl) with only 0 2-1 nmol of protein required Better still, using the fluorescence of the ABD-Cysteine adduct, only 100pmol of protein gives very consistent results When the sample is reduced to 10pmol, more variability occurred However the answer is still unambiguous at these low levels

Table I · Measurement of Protein Disulfide Bonds in 1ml UV Cells using ABD-F and TBP

Protein	Ribonuclease A	Superoxide-dismutase	β-Lactoglobulin	Tubulin	Enolase
Free / total Cysteines	0/8[1]	1/3[1]	1/5[1]	8/10[2]	1/1[3]
Free cysteine absorbance	-0 007	0 043	0 073	0 523	0 032
Total cysteine absorbance	0 337	0 148	0 395	0 649	0 032
Free / total measured	-0 02	0 29	0 18	0 81	1 0
Free cysteines calculated	-0 08[4]	0 87	0 92	8 1	1 0

[1]Reported in the Swiss Protein database
[2]Tubulin was reported to contain one disulfide and 8 free cysteines per monomer unit of 50kD Others have reported fewer disulfides
[3]Only single cysteine is present (Swiss protein database)
[4]The measured negative value is within experimental error of the correct value of "0"

Although this method determines the ratio of free cysteines to those in disulfide bonds, the free measurement along with a precise knowledge of the protein concentration will surfice as the ABD-cysteine absorbance at 385nm is ϵ_{385}7800 However, as the second step consumes no more protein, this is not a worthwhile savings Conversely, the concentration of the protein can be easily calculated from the absorbance of the reduced protein and a knowledge of the number of cysteines present

Conclusion

A method has been developed for the simple and rapid determination of the number of free versus disulfide bonded cysteines in a protein All reactions may be carried out in the UV cells and the same solution of protein is used for obtaining the number of free and total cysteines Using 1ml UV cells, the measurement is possible on 2-10nmol of protein By adapting the method to fluorescence assays, the amount of protein was reduced to 10-100pmol.

LOCATING DISULFIDE BONDS IN PROTEINS FROM AIDS RELATED RESEARCH

Lewis Pannell, Umamaheswari Rajamani, Han Le and Paolo Lecchi
Laboratory of Analytical Chemistry, NIDDK, NIH, Bethesda MD 20892-0805

Introduction Much of work has gone into the three dimensional structure of compounds targeted for their anti-HIV properties. This has been mainly performed by NMR and X-ray crystallography A good understanding of the "shapes" of compounds that are effective against AIDS allows for the development of designer drugs As a result, a number of requests have been made for identifying the disulfide bonds in proteins to help clarify the ambiguities that have been observed by other structural techniques

Method The method discussed in poster ThPG261, ABD-F/TBP is used to identify the number of cysteines involved in disulfide bonds If free cysteines are present, then the protein is capped with iodoacetic acid. Digestion of the protein (3-6nmol) with TPCK treated trypsin in ammonium bicarbonate or ammonium acetate buffer was performed overnight at 37°C The digest could be followed directly with CZE and was separated into 20+ fractions by HPLC MALDI (Kratos MALDI III) spectra were obtained on each fraction using 4-hydroxy-α-cyanocinnamic acid as matrix and the mass assignments were confirmed by FAB (JEOL SX102)

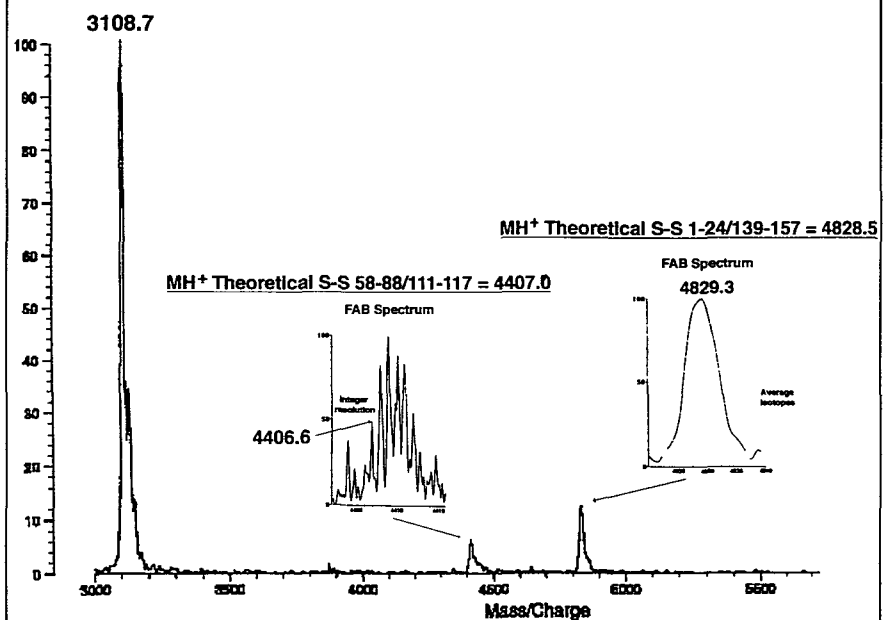
Human IL10 Mutant. A mutant 160 amino acid IL10 protein was studied as its mass was approximately 300 amu too high when examined by electrospray It was only modified from IL10 by the replacement of Tyr-153 by a cysteine An examination was made of the Wild-type protein first and all the non-cysteine containing pieces were identified From this fraction 11 was found to contain a peak at 2984.3 (MALDI and FAB) corresponding to a disulfide bond between Cys-12 and Cys-108, and the second disulfide peptide was located in fraction 20, corresponding to Cys-62 linked to Cys-114 This matched the previously reported disulfide bond locations The mutant protein was then examined Cysteine containing pieces are marked in bold

Ser Pro Gly Gln Gly Thr Gln Ser Glu Asn Ser Cys Thr His Phe Pro Gly
Asn Leu Pro Asn Met Leu Arg|Asp Leu Arg|Asp Ala Phe Ser Arg|Val Lys|
Thr Phe Phe Gln Met Lys|Asp Gln Leu Asp Asn Leu Leu Leu Lys|Glu Ser
Leu Leu Glu Asp Phe Lys|**Gly Tyr Leu Gly Cys Gln Ala Leu Ser Glu Met**
Ile Gln Phe Tyr Leu Glu Glu Val Met Pro Gln Ala Glu Asn Gln Asp Pro
Asp Ile Lys|Ala His Val Asn Ser Leu Gly Glu Asn Leu Lys|Thr Leu Arg|
Leu Arg|Leu Arg|Arg|**Cys His Arg**|**Phe Leu Pro Cys Glu Asn Lys**|Ser Lys|
Ala Val Glu Gln Val Lys|Asn Ala Phe Asn Lys|Leu Gln Glu Lys|Gly Ile
Tyr Lys|**Ala Met Ser Glu Phe Asp Ile Phe Ile Asn Cys Ile Glu Ala Tyr**
Met Thr Met Lys|Ile Arg|Asn

An examination of the wild-type IL10 by electrospray gave the correct mass of 18646 8 Da (theoretical 18647 6 Da) However the mutant gave 18894 4 Da (theoretical 18587 5) and from previous experience the extra mass (approx 305 amu) was predicted to come from a glutathione adduction The theoretical mass for the glutathione-mutant adduct is 18892.5 Da which agrees well with the measurement After digestion with trypsin, the fractions were analyzed as before and all the non-cysteine containing pieces appeared in the same

fractions No equivalent disulfide peptide was found in fraction 11 as with the wild-type protein suggesting that this connection did not exist Two disulfide pairings were identified in fraction 20, one matching the wild-type for Cys-62 to Cys-114 and the other corresponding to a disulfide bond between Cys-12 and Cys-153 (meas 4829.3, calc 4828.5) The remaining tryptic peptide, 108-110, was found in another fraction with glutathione attached The NMR determined structure had to be modified to accommodate the disulfide connections.

MALDI SPECTRUM OF FRACTION 20 FROM TRYPTIC DIGEST OF MUTANT



HGF N-Domain

As part of an examination of some mutant hepatocyte growth factor proteins, an initial examination of the disulfides in the N-domain of the protein was undertaken The spectra of the digest fractions revealed an ion at m/z1141 5 which could be assigned to the disulfide between Cys-44 and Cys-54 (calc MH⁺1141 6) and another fraction contained the other disulfide piece between Cys-40 and Cys-66 (meas 2820.6, calc MH⁺2820 8) A number of other intense peaks in the MALDI and FAB spectra could not be assigned and are still a mystery

A number of other proteins related to the AIDS research at NIH have been successfully studied

Identification of Cross-Linking Peptides Using ESI and MALDI-TOF MS

John C. Le [1], Mitsuru Haniu [1], Thomas Horan [2], Viswanatham Katta [1], Tsutomu Arakawa [2] and Michael F. Rohde [1]

[1] Protein Structure and [2] Protein Chemistry, Amgen, Inc., Thousand Oaks, California 91320

Information regarding the conformation of many recombinant proteins is important for understanding their structure-function relationships. This information often extends beyond the primary structure and thus relies on crystallization or NMR data. However, it is difficult to obtain conformational differences due to tertiary structure and carbohydrate complexities. Therefore, other analytical schemes to elucidate this essential information are of great interest.

In conjunction with peptide mapping and N-terminal sequence analysis to monitor possible conformation of proteins, the focus of this presentation was to implement both linear and reflectron modes of MALDI-TOF and ESI mass spectrometry for the identification of inter- or intramolecular cross-linking peptides by cross linkers such as disuccinimidyl suberate (DSS) and disuccinimidyl tartarate (DST) of recombinant human proteins.

To prepare and identify cross-linked peptides, several cross-linkers including DST were reacted with E.coli expressed protein. The cross linked proteins were subsequently digested by trypsin and fractionated by RP-HPLC according to the literature (1). Figure 1 shows the peptide map of the cross-linked protein. The peak at 29.6 min. was identified as DST- linked peptide (Mr= 1564) by electrospray ionization (ESI) mass spectrometry as shown in Figure 2a. We suspect that the DST-linker peptide has undergone nucleophilic attack by water, re-arrangement and dehydration. The fragmentation pattern of this cross-linked peptide obtained by collision induced dissociation (CID) of m/z 782.7, a doubly charged ion, verified that the DST linker was attached to the N-terminus (Figure 2b).

Recently a novel approach was developed to use cross-linkers to probe possible conformation and surface interaction of recombinant human proteins. This strategy was verified by the involvement of disuccinimidyl suberate (DSS), a 12 angstrom cross-linker, that reacts primarily with the ε-amine of lysine (K) side chains and links to the primary amine of methionine (M) **of synthetic peptides** (2). Figure 3 shows an ESI mass spectrum of a RP/HPLC fraction of this cross-linked peptide at Mr= 1245.38 and its proposed covalent structure (insertion).

Approximately 5 pmols of the above synthetic cross-linked peptide was subjected to mass and sequence determinations by MALDI-TOF-MS analysis. It is noteworthy that in sinapinic acid (SA) matrix only the molecular ion (m/z 1246.5) was observed (Figure 4a). Under similar instrument conditions and with significantly less laser power, alfa cyano-4-hydroxy cinnaminic (4HCCA) matrix generated both the molecular ion and apparent prompt fragmentation of the N-terminal amino acid residues [M+H] -X ions; The observed m/z 900.10 corresponds to the loss of tripeptide M-T-P (Figure 4b). This phenomenon is currently under investigation. Table 1 summarizes the calculated and the observed fragment ions. The MSMS spectrum of m/z 1246.5 by MALDI post- source decay (PSD) (Figures 5) showed a similar fragmentation pattern that supports the assignment sequence of this peptide.

The electrospray ionization spectra were obtained on a API Sciex III. The MALDI spectra were obtained on a PerSeptive Biosystems Voyager RP mass spectrometer.

Synthesis of Disulfide Linked ß-Actin Peptides.

F. Aladar Bencsath[1,4], Archil Shartava[2], Carlos A. Monteiro[2], and Steven R. Goodman[2,3]

[1]Department of Biochemistry and Molecular Biology, [2]Department of Structural and Cellular Biology, [3]USA Comprehensive Sickle Cell Center, University of South Alabama, Mobile, AL 36688; [4]Gulf Coast Seafood Laboratory, FDA, Dauphin Island, AL 36528

Identification of a specific disulfide linked peptide in the tryptic digest of irreversibly sickled cell (ISC) ß-actin has been facilitated by the availability of a reference peptide, which was characterized by liquid chromatography (LC) and mass spectrometry (MS). LC provided the peptide's retention time. MS (with fast atom bombardment ionization; FAB MS) provided the peptide's molecular ion mass and the masses of other diagnostic ions in the mass spectrum, and tandem MS provided a product ion pattern in the MSMS spectrum. The retention time and the masses of the diagnostic ions helped to locate the peptide among the LC fractions, and the product ion spectrum of the molecular ion proved identity.

While it is relatively easy to obtain linear peptides from advanced commercial biotechnology laboratories, modified (e.g., acetylated, glycosylated, phosphorylated, disulfide linked) peptides are harder to acquire. Such peptides may have to be specially prepared by the investigators themselves.

In earlier labeling and HPLC & MS studies, we found evidences (Shartava et al, J. Cell Biology, 1955; ASMS 1994, Proceedings p.1161) that the ^{284}Cys and the ^{373}Cys (and with them the tryptic peptides CDVDIR and KCF) are linked by a S-S bridge in the membrane protein ISC ß-actin, while they exhibit free sulfhydryl groups in the ß-actin from the normal red blood cell.

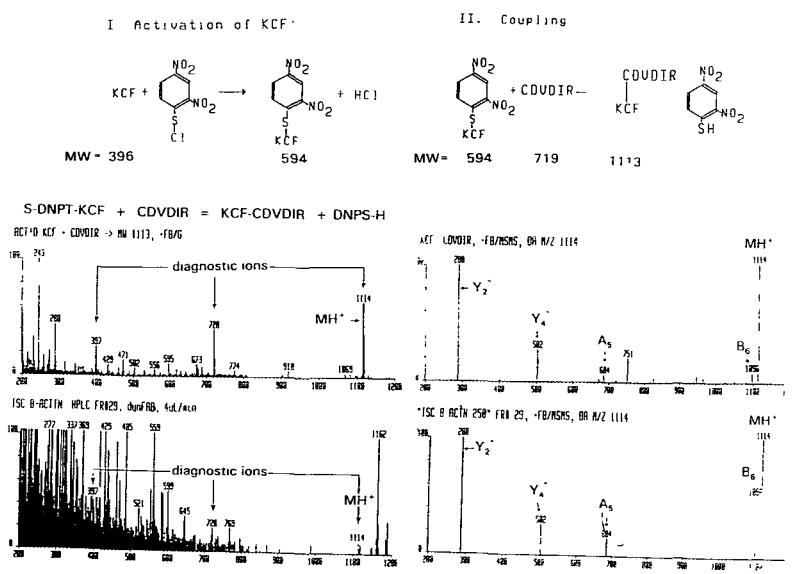
To isolate and identify this important disulfide linked peptide, we synthesized the corresponding model compound using, with some modification, a sulfhydryl labeling process for proteins which was introduced by Drewes and Faulstich (Anal. Biochem. 188:109, 1990). The first step of the synthesis was the activation: the thiol group in one of the two peptides (KCF) was transformed into the S-dinitrophenylthio derivative (S-DNPT-KCF) using the 2,4-dinitrophenyl sulfenylchloride reagent. The activated peptide was isolated from the excess reagent and the formic acid solvent by the help of the solvent mixture tetrahydrofuran/toluene, and centrifugation. The second step was the coupling: the dried activated peptide was dissolved in aqueous methanol and was allowed to react with the second cysteine-containing peptide (CDVDIR) in an aqueous ammonium hydrocarbonate buffer, to form the desired disulfide linked peptide KCF-CDVDIR. The bright yellow color of the liberated 2,4-dinitrothiophenol signaled the successful coupling, which was complete in minutes.

The first step of the synthesis was carried out in a conical centrifuge tube, the second step in an injection vial, and also on the MS/FAB probe tip. We optimized the

synthesis in preliminary experiments while preparing the cysteine-glutathione disulfide linked peptide. It seems that the method is generally applicable for the generation of asymmetric cystine peptides containing only one single S-S bridge.

The FAB mass spectrum of the disulfide linked peptide KCF-CDVDIR exhibits, beside an intense molecular ion m/z 1114, the molecular ions of the component peptides (m/z 397 and 720). Their presence in the spectrum must be the result of the often observed reductive process in the FAB-matrix glycerol.

HPLC separation of the raw product presented three components: the major product KCF-CDVDIR (fraction #29), the minor side-product S-DNPT-CDVDIR (fr#37), and the excess reactive intermediate S-DNPT-KCF (fr#38). We found in fr#29 of the tryptic hydrolyzate obtained from ISC-actin all three diagnostic ions. The MSMS product ion spectrum furnished from the molecular ion m/z 1114 contained identical fragment ion masses as the corresponding spectrum from the synthetic model compound, which proved identity. This is the first direct proof of the presence and location of an S-S bond in the ISC ß-actin, which seems to be the dominant factor causing the irreversible locking of the membrane skeleton into the sickled shape.



DETERMINATION OF THE LOCATION OF THE CYS IN PEPTIDES BY TANDEM MS/MS STUDIES.

* O. V. Nemirovskiy; M. L. Gross
Department of Chemistry, Washington University, One Brookings Dr., St. Louis, MO 63130

The interaction of transition-metal ions (especially Fe) and sulfides are common in all forms of life and are found at the active centers of a wide variety of redox and catalytic proteins, such as ferrodoxins, rubredoxins, and metalloenzymes. In most ferrodoxins, and in all rubredoxins, the protein ligands are cysteins, which provide thiolate donors to the Fe center.

On the basis of evidence that iron atoms are held in proteins by cystein ligands, we are using iron as an "indicator" of the location of Cys residues in peptides. This strategy was applied to series of cystein-containing pentapeptides with different position of the Cys residue along the peptide backbone. Upon FAB ionization metal-ion/peptides were readily desorbed into gas phase as (peptide - H + Fe)$^+$ complexes. Formation of iron-bis(pentapeptide) complexes was also observed under the same conditions.

Mass spectrometric experiments were performed with a VG ZAB-T, four-sector instrument of BEBE (reverse Mattauch-Herzog) design equipped with a Cs$^+$ gun operated at 30 kV. Data acquisition was carried out with OPUS V 3.1X data system and interfaced to mass spectrometer by a VG SIOS I unit. CAD spectra were collected with MS2 at 50% main beam suppression with helium as the collision gas and array detection. The collision cell was floated at 4kV. The matrix used for desorption of metal-peptide complexes was a 1·1 mixture of glycerol and thioglycerol containing 0.5 F solution of metal nitrate.

The position of the Cys residue in analyzed pentapeptides is a major influence on the fragmentations of the iron-bound peptide complexes [(M - H + Fe)$^+$]. Specific interaction of the iron atoms with the thiol group of the Cys side chain leads to the formation of the unique fragmentation patterns with abundant **(a_n - H + Fe)$^+$** ions, where *n* is the position of the Cys residue with respect to the N-terminus of the peptide backbone (Fig. 1). The formation of these ions may proceed by two different mechanisms which involve hydrogen transfer either from an amide group or from the side chain. Isotope labeling experiments show that only an amide hydrogen is involved in the formation of (a_n - H + Fe)$^+$ ions (Scheme I) When peptide contained two Cys residues an interesting internal ion was observed in CAD spectrum, and the expected, however less abundant, (a_n -H + Fe)$^+$ ions. The mechanism for the formation of an internal ion (*m/z* = 305) is suggested to require the interactions of the iron atom with both thiol groups of the Cys side chains. This strong interaction principally directs the fragmentation upon CA at the periphery of both cysteins.

Iron-bis(pentapeptide) complexes decompose upon CA overwhelmingly by losing a pentapeptide to form an iron-bound pentapeptide (*m/z* = 516). In addition, an abundant ion at *m/z* = 548 is observed, and corresponds to the formation of (peptide - H + Fe + S)$^+$ ions. The mechanism for the formation of these ions requires oxidation of the thiol groups to -S -$^{\cdot}$S- bond.

These preliminary results provide encouragement for the development of a method for the determination of the location of the disulfide bonds and total content of cystein residues in small proteins and peptide fragments in digests.

Identification of a Cysteine Substitution in Recombinant Human Granulocyte Colony Stimulating Factor by Peptide Mapping-Electrospray Mass Spectrometry

Che-Hung Yeh, Nicole Tedeschi, and Alan C Herman
Amgen, Inc., Amgen Center, Thousand Oaks, CA 91320

Introduction

Several amino acid misincorporations have previously been identified in recombinant human proteins produced in *Escherichia coli* These have included norleucine substituted for methionine (Lu, *et. al*, 1988, Tsai, *et. al*, 1988) and glutamine substituted for histidine (Lu, *et.al*, 1993). In order to characterize trace amounts of heterogeneous forms of granulocyte colony stimulating factor (G-CSF) the unwanted chromatographic fractions from a routine purification were examined by reverse phase high pressure liquid chromatography (RPC). One of these column fractions contained a previously unobserved G-CSF form (Form X). RPC of this material followed by post-column derivitization with Ellman's reagent suggested that this form had only one disulfide bond instead of the two normally found in G-CSF This new G-CSF form was purified and further analyzed by a combination of LC-MS, peptide mapping, amino acid analysis and amino terminal sequencing. These analyses suggested that $cysteine_{64}$ had been replaced with an as yet unidentified amino acid.

Results and Conclusions

The data presented here suggest that in a small amount of G-CSF the $cysteine_{64}$ residue is substituted with another amino acid. This substituted form is subsequently removed from the product during the routine purification procedure. By collecting chromatographic fractions normally discarded, this form was obtained in suitable amounts for characterization. Although the data presented here clearly show a substitution of this cysteine, the nature of that substitution has not yet been confirmed. The amino acid composition data suggest no obvious amino acid substitution. The SV8 peptide is sufficiently large that it is difficult to achieve further analysis. Additionally, the sequence of the peptide is such that it does not lend itself to further digestion. One possible substitution is aminobutyric acid (Abu). It is feasible that the cysteinyl transfer RNA could charge with Abu in place of Cys. This would not, however, explain why the substitution only appears at the Cys_{64} position and not the other Cys positions. The replacement of a single cysteine would result in two free sufhydryl groups on the molecule. The elution of Peak X on RPC coincides with the elution of misfolded G-CSF containing only one disulfide (partially reduced). If the peak detected with Ellman's reagent were a mixture of Peak X and partially reduced G-CSF a free sufhydryl value of 2.5 would be obtained.

In data not presented, a secondary form of Peak X was identified in which the substitution of Cys_{64} was a glycine. This was determined by Edman sequencing

43rd ASMS Conference on Mass Spectrometry and Allied Topics

of the peptide and confirmed by mass spectrometry. Glycine represents a single base pair change from cysteine and is a wobble base.

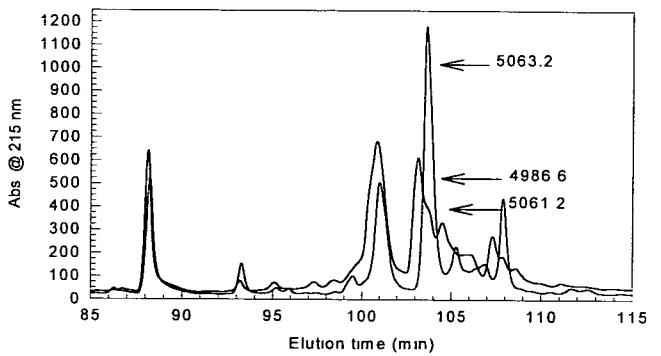

Figure LC-MS of carboxymethylated SV8 peptides. The region of the peptide map from 85 to 115 minutes is presented here in greater detail. The red trace is G-CSF standard protein, the blue trace is Form X. This area of the map was further analyzed by LC-MS to determine the mass of the individual peptides. Peptide A from the G-CSF standard has a mass of 5063.2 which is consistent with that predicted from its sequence. A corresponding peptide is present in Form X which is probably due to contamination with normal G-CSF A second peptide (Peptide B) elutes slightly earlier with a mass of 4986.6. Since this mass difference is greater than that found for the intact protein by 60 mass units, it suggests that the modification has occurred on one of the cysteine residues, preventing carboxymethylation

followed by loss of residues from outside the S-S link and finally cleavage within the S-S link at the Asp- residue formed on deamidation Table 1. The structures of the peptides produced by cleavage within the S-S link were determined by MS-MS analysis (VG Biotech Quattro II). The peptides formed from tocinoic acid (2) and [lys8]-vasopressin (3) were analogeous to those obtained fron oxytocin (1, Table1) Somatostatin (3) gave a much more complex series of peptides due to both cleavage and varying degress of dehydration of its Ser- and Thr- residues. Cleavage within the S-S link again occuring at the Asp- residue formed on deamidation. In marked contrast to the results reported by Bauer *et al.*,(*J.Protein Chem.*1993,*12*,759-764.) where the majority of the small S-S linked peptides obtained from the oxalic acid hydrolysis of echistatin lacked the N-H and C-OH terminii from one chain, only one peptide of this type (MH^+, m/z 725) was observed in this study from both oxytocin (1) and tocinoic acid (2).

Disulfide Structure Study of EGF domain of Neu Differentiation Factor (NDF)

Viswanatham Katta, Naili Liu, Shi-Yuan Meng, Tom Zamborelli, John Mayer, Hsieng Lu and Shinichi Hara
Amgen Inc., Thousand Oaks, California 91320-1789.

Neu Differentiation Factor (NDF) was discovered as a ligand to stimulate autophosphorylation of Her-2 receptor expressed in mammary tumor cells. Form the cDNA sequence, precursor form of NDF (pro-NDF) was predicted to contain an immunoglobulin-like domain, epidermal growth factor (EGF) like domain, a single transmembrane domain, and a variable length cytoplasmic domain. It has been shown that NDF isoforms are generated by alternative splicing of the gene. α and β isoforms of EGF-domain peptides were expressed in E.coli and their structure studied. We discuss here the results for α-2 isoform.

The α-2 isoform is a 65-residue peptide with a calculated average mass of 7369.5 Da. It has six cystines forming three disulfide bonds. Both electorspray (Finnigan TSQ 7000) and MALDI (Perseptive Biosystems, Voyager RP) spectra exhibited the expected major species at 7369 Da and in addition a minor form at 16 Da higher (methionine oxidation), and two minor forms at -28 Da and -255 Da (C-terminal processing).

In order to study the disulfides, the protein was digested with endoproteinase Lys-C. The analysis of the digest mixture by linear MALDI-TOF showed the major disulfide containing peptides, but the map was not complete. The individual peptides were HPLC fractionated, Edman sequenced as well as analyzed by mass spectrometry.

The Post Source Decay (PSD) spectrum of a peptide at m/z 1838 (a predicted Lys-C peptide CQPGFTGARCTENVPMK with an internal disulfide bond) is shown in Figure 1. The fragmentation observed is typical to that observed in low energy CAD, i.e. sequential fragment ions were observed only upto the core disulfide, and no fragments of the peptide portion inside the loop are observed. This is in contrast to the prompt fragmentation at the S-S bond observed for intermolecularly disulfide bonded peptides (1). When the disulfide is internal, even at very high laser fluences, such fragmentation is not observed.

Figure 2a shows the linear MALDI spectrum of a peptide with two disulfide bonds obtained from 4HCCA matrix. Facile prompt fragmentation clearly identify that Lys-C peptides K2, K4, and K5 are disulfide bonded, but doesn't give a clue about the correct linkage. The PSD spectrum of the molecular ion (Fig 2b) showed, two groups of intense peaks with 32 Da spacing, similar to earlier observations (2). However, the center peak is weaker. Few fragment ions were observed, but assignments could not be made. To identify the actual linkages, on probe digestion of the peptide with endoproteinase Glu-C was carried out. The MALDI spectrum showed a new peak at m/z 2121, that indicated cys-14 is linked to cys-34 (Figure 2c). The PSD spectrum of m/z 2121 (not shown) verified that indeed these cystines are linked.

A minor form containing a mispaired disulfide also was identified and verified by PSD analysis.

Introduction

All snake venoms contain multiple toxic principles which act in combination to produce the lethal action. The proportion and distribution of the active components varies from species to species and together with anatomical and morphological criteria, the activity profile of the venom can provide a means of species identification. As a generalization, the venoms from members of the *Elapidae* family of snakes (cobras and mambas) contain mainly neurotoxin activity while the venoms of rattlesnakes and vipers (*Crotalidae*) primarily affect cardiovascular and hemostatic mechanisms. Exceptions exist such as *Crotalus durissus terrificus* (tropical rattlesnake) which is a true rattlesnake applying biological criteria, but shows a similar venom activity profile to that of the cobras and mambas.

Molecular weight profiles of snake venoms can be of value to the biochemist to indicate the binding of enzymes in assays or to provide a confirmation for sequences of extracted peptides. Additionally, we were interested to see whether it was possible to provide a means of species identification for venomous snakes, based on the electrospray spectrum and resultant mass profile obtained for each venom.

MALDI-TOF-MS and electrospray-MS can provide complementary data for the determination of snake venoms MALDI-TOF-MS reveals inherent differences in the compositions of venoms from unrelated snakes but clusters of proteins with molecular masses greater than 10000 daltons could not be resolved. Flow injection electrospray-MS cannot provide a complete picture of the venom composition. However, electropsray profiles are markedly different between species so that the detail of this incomplete picture is sufficient to discriminate between species.

Results and Discussion

Flow injection (10 µL/min) spectra of 32 snake venom solutions (1mg/mL) were acquired using a VG Quattro II triple quadrupole mass spectrometer. MS analyses were performed over a mass range of 500 to 3500 at 10 sec/scan for 10 scans and MS/MS analyses were performed over a mass range of 50 to 2500 at 10 sec/scan.

Spectra from the venoms of the elapids were simple and typically dominated by peptides of molecular masses ca. 6000-9000 daltons (cobras and mambas) or ca. 13000 daltons (kraits, coral snakes, tiger snakes and brown snakes). A typical spectrum from the venom of *Bungarus fasciatus* (banded krait) is shown in Figure 1.

Spectra from the venoms of the crotalids were complex and were typically dominated by proteins of molecular masses ca. 14000 or 23000 daltons. Altering the cone voltage had a significant effect on the spectra obtained where low cone voltages (ca. 30 V) improved the response of proteins of molecular masses ca. 23000 daltons. For some venoms, high cone voltages (ca. 90 V) could improve the relative response for proteins of molecular masses ca. 14000 and 29000 daltons. A typical spectrum from the venom of *Bitis arietans* (puff adder) is shown in Figure 2.

Several venoms were chosen from closely related snakes. The spectra of three spitting cobras seemed to be virtually identical. Closer study revealed minor differences resulting from the presence of a few unique peptides or major differences in the relative ion abundances of toxins which were common to all three venoms.

A further tool for the investigation of common toxins is tandem mass spectrometry of the multiply charged ions within the flow injection electrospray spectrum. The identical product ion MS/MS spectra from the $(M+6H)^{6+}$ ions of higher abundance peptides in the venoms of *Naja naja* and *Naja naja atra* suggest the presence of common toxins and therefore some evolutionary relationship.

From these experiments we conclude that the electrospray spectra and resultant molecular mass profiles obtained for each venom can provide a basis for species identification of venomous snakes.

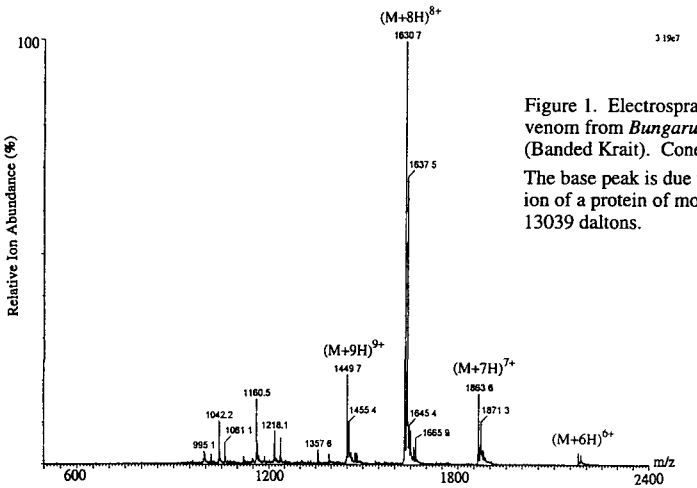

Figure 1. Electrospray Spectrum of the venom from *Bungarus fasciatus* (Banded Krait). Cone Voltage = 65 V. The base peak is due to the $(M+8H)^{8+}$ ion of a protein of molecular weight 13039 daltons.

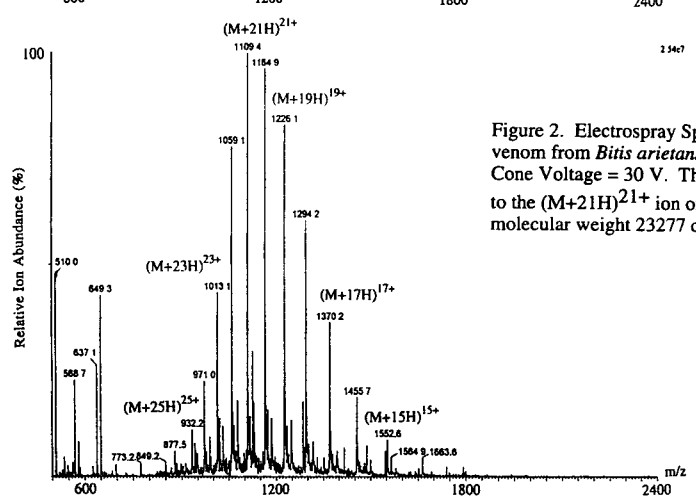

Figure 2. Electrospray Spectrum of the venom from *Bitis arietans* (Puff Adder). Cone Voltage = 30 V. The base peak is due to the $(M+21H)^{21+}$ ion of a protein of molecular weight 23277 daltons.

MS Investigation of the Molecular Mechanism of Action of Cytotoxin B

Matthias Wilm, Ingo Just*, Jörg Selzer*, Klaus Aktories* and Matthias Mann
European Molecular Biology Laboratory, Meyerhofstr. 1, 69 012 Heidelberg, Germany
**Institute for Pharmacology and Toxicology of the University of Saarland, 66 421 Homburg, Germany*

The toxins A and B from clostridium difficile cause antibiotic - associated pseudo membranous colitis. They act in cultured cell lines by inducing the disaggregation of the microfilament cytoskeleton. The GTPase RhoA plays an important role in the formation and regulation of the cytoskeleton. Toxin B treated RhoA loses its property to be a substrate for the ADP-ribosyltransferase C3 from Clostridium botulinum suggesting the possibility that RhoA is modified by toxin B. Recombinantly expressed RhoA was treated with toxin B and investigated mass spectrometrically[1].

The HPLC purified protein was measured on a tandem mass spectrometer (API III, Sciex, Ontario, Canada) equipped with a very stable, low flow NanoElectrospray source[2]. The protein was detected in its native and in a modified form. The mass difference of 162 Da suggested that a hexose was covalently bound to the protein. To localize the modification in the protein RhoA and ToxB treated RhoA were digested by Lys-C. The peptides were separated on a Sephasil RP-C18 column. The peptide (Asp28 - Lys51) had an altered retention time in the modified RhoA digest by the hexose modification as shown by electrospray mass spectrometry (fig.1). Tandem mass spectrometric sequencing localized the hexose to its N-terminal 16 amino acid (fig. 2). For a final localization the modified peptide was subdigested with pepsin. The unseparated peptide mixture was analyzed by NanoES and the modified peptide [(Asp28 - Glu40) + 162 Da] was found. MS/MS sequencing of this smaller peptide allowed the determination of threonine 37 as the modified amino acid (fig.3). Using radioactively labeled UDP-hexoses it could be shown that only UDP-glucose serves as co-factor for ToxB. Site directed mutagenesis confirmed the localization of the modification. A parallel investigation on toxin A exposed RhoA showed that the molecular mechanism of toxin A and toxin B from Clostridium difficile is the same[3].

THE ANALYSIS OF CYANOBACTERIAL TOXINS BY TANDEM MASS SPECTROMETRY

Vanessa C.M. Dale and Keith R. Jennings,
Institute of Mass Spectrometry and Department of Chemistry,
University of Warwick, Coventry, CV4 7AL, U.K.

Several cyanobacteria genera, including *Microcystis, Anabaena* and *Nodularia*, produce cyclic hepatotoxins. *Microcystis Aeruginosa* is known to be responsible for livestock death and human illness. The general structure of microcystins is cyclo (-D-Ala-L-X-erythro-D-methyl-aspartate-L-Z-Adda-D-isoglutamic acid-N-methyl-dehydro alanine). Five amino acids, including Adda, are invariable microcystin constituents, while the others, X and Z, are variable. X may be leucine (L), arginine (R) or tyrosine (Y); Z may be arginine (R), alanine (A) or methionine (M). The three microcystins -LR, -RR and -YR and Nodularin were studied of which only the microcystins are discussed here.

The CID spectra of the protonated precursors of the toxins yield only limited structural information because the proton binds at several sites on the peptide. Since a metal cation is larger than a proton, it normally co-ordinates with the heteroatoms of the amino acids, requiring the peptide to adopt a particular configuration thereby promoting more specific types of fragmentation that result in a CID spectrum that is both structurally more informative and is simpler than that given by the protonated molecule. A detailed study has been carried out of the CID spectra of ions produced by both the protonation and the cationisation of the cyanobacterial toxins some of which are presented and discussed.

High energy collision induced dissociation (CID) spectra were obtained using a Kratos 'Concept' II HH four sector instrument with an LSIMS source and floated collision cell Low energy CID spectra were obtained using a Fisons 'Quattro' II triple quadrupole mass spectrometer fitted with an ESI source. The high energy CID spectrum of the $[M+H]^+$ ion of mcyst-LR gives low mass ions at m/z 59, 70, 87, 100 and 112 that all arise from the Arg residue. The abundant ion at m/z 135 arising from cleavage of the Adda side-chain, has been assigned as $[PhCH_2CH(OCH_3)]^+$, indicating that the toxin contains this unusual amino acid residue A radical species of the same mass, 135 Da, can be lost to yield an ion of m/z 860 of lower abundance, resulting from homolytic cleavage of a C-C bond of the Adda side-chain. Cleavages through the peptide ring produce ions of m/z 155, 213 and 239. Mechanisms have been proposed which support the assignments Mdha+Ala+H^+, Glu+Mdha+H^+ and CO+Glu+Mdha+H^+ for these ions respectively. These amino acids, Glu, Mdha and Ala are all invariable in the microcystins. Although Mdha+Ala+H^+ has been postulated as the elemental composition of the m/z 155 ion, based on accurate mass measurement, we suggest $CH_3CH_2CH_2CO$+Mdha+H^+ as an alternative plausible assignment since a resolution in excess of 12,000 is required to distinguish between these possibilities.

For mcyst-RR and mcyst-LR, the most abundant adduct ions formed were $[M+Li]^+$ and $[M+2Li-H]^+$ respectively. The high energy CID spectra contain peaks due to ions formed by the loss of neutral species from the Adda and Arg side-chains. Losses from the latter give ions of m/z 985, 971 and 957 for mcyst-RR which result from heterolytic cleavages involving a 1,4-H-rearrangement, suggesting that Li^+ attachment occurs at a site removed from the Arg side-chain. Losses from the Adda side-chain produce ions of m/z 938, 922 and 909. Loss of 135 Da, described above, occurs by homolytic cleavage whereas losses of 106 and 122 Da are the result of rearrangements. The loss of 106 Da is thought to occur by a 1,2-elimination involving the movement of a methyl group to give $PhCH_2CH_3$; the loss of 122 Da occurs

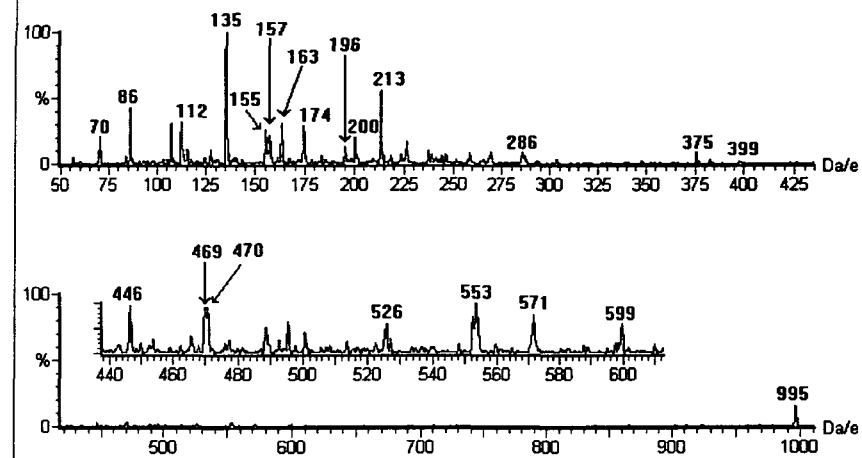

Fig. 1. Low energy CID spectrum of the $[M+H]^+$ ion of mcyst-LR obtained using ESI.

as a result of a further loss of CH_4 These losses are observed for all four toxins, indicating the presence of the Adda side-chain. Other high mass ions, resulting from partial losses of both the Adda and Arg side-chains result from homolytic cleavages that involve electron migration to form a closed-shell ionic species. All $[M+Li]^+$ ions, unlike $[M+H]^+$ ions, yield ions of m/z 189, and the $[M+2Li-H]^+$ species of mcyst-LR gives this ion and one of m/z 196, supporting the view that they contain the metal cation. Many other low mass ions originate from the ring of the cyclic peptide and contain the metal cation associated with the amino acid residues Glu, Mdha and Ala for which mechanisms have been proposed. In the CID spectrum of the $[M+2Li-H]^+$ ion of mcyst-LR, several low mass ions appear in which co-ordination of two lithium ions is postulated and the ions at m/z 31 and 56 correspond to $[LiOH]^+$ and $[LiCNO]^+$ respectively. These ions indicate that the basic side-chain of the Arg residue is a favourable site for Li^+ ion association.

The ESI-MS of cyanobacterial toxins has been reported previously. The low energy CID spectra given by the toxins contain peaks due to many fragment ions for which assignment is often difficult. Many ions formed under high energy CID conditions are not observed but fragmentations that arise from cleavages that occur around the Arg residue are very common. The ion of m/z 157 comprises the entire Arg side-chain together with the bound proton Other fragmentations in this region lead to the formation of the ions H_2N+Arg+H+H^+ and H_2N+Arg+CO-H+H^+, m/z 174 and 200 respectively, the mechanisms involving two sequential hydrogen transfers Those ions labelled in the above spectrum have been assigned structures and, in many cases, mechanisms to explain their formation have been proposed.

We thank the University of Warwick for financial support during this work.

STRUCTURAL ANALYSIS OF CONOTOXINS BY MASS SPECTROMETRY

Takemichi Nakamura[1], Michael Fainzilber[2], Eliahu Zlotkin[3], and A. L. Burlingame[1], 1. Dept. Pharmaceutical Chem., Univ. California, San Francisco, CA94143-0446; 2. Molecular Neurobiology, Free University of Amsterdam, The Netherlands; 3. Dept. Cell Animal Biology, Hebrew Univ. Jerusalem, 91904 Jerusalem, Israel

Conotoxins, a variety of peptide neurotoxins found in venom of *Conus* sea snails, are indispensable tools for neurophysiology and potential leads for structure based drug design [1]. Precise structural analysis of diverse conotoxins is an important task since the unique and specific biological activity of each toxin is directly related to unique structure of each molecule. Mass spectrometry is becoming an essential tool for structural study of these relatively small cysteine-rich peptides [2,3], typically consisting of 10 to 30 amino acid residues, partly because there are a number of possibilities for posttranslational modifications.

Many conotoxins have amidated C-termini as many other classes of bioactive peptides do. Finding and/or establishing the structures of those amidated peptides is usually a task for mass spectrometry. One practical way to do the job is to measure the molecular weight of the peptide of interest with an accuracy of better than a half unit mass and then compare the value with the calculated mass based on the peptide sequence. Although it is very simple, the requirement of knowing complete sequence is an obvious drawback of this method. Recently, we found that a combination of the CPase-Y ladder sequencing method and MALDI reflectron TOF mass spectrometry is another practical approach for establishing C-terminal amidation. Figure 1 shows a MALDI reflectron TOF spectrum of a CPase-Y treated Asp-N fragment from a conotoxin, TxVIIA. Thanks to the resolution and mass accuracy provided by an reflectron analyzer, one can confidently establish the C-terminal sequence of ---L(or I)F-NH_2 but not ---L(or I)F-OH by observing the mass differences of 146 and 113 from the "undigested peptide" at *m/z* 1529.9. Furthermore, a partial one unit mass upward-shift in the isotopic ion distribution of "undigested peptide" was observed (Fig. 1, inset), i.e., the relative intensity of "^{13}C-isotope peak" was visibly higher than that observed in the sample before CPase-Y treatment or in a theoretical pattern (data not shown). The partial one unit shift is attributable to a partial deamidation from the C-terminal residue by CPase-Y, which has amidase activity as well. This provided further support for the C-terminal amidated structure. It should be noted that this partial unit mass shift may be used to establish C-terminal amidated structures like -Glu-NH_2, -Asp-NH_2, or -Asn-NH_2, for which the mass of the amidated residue fits the mass of other residue.

γ-Carboxylation of Glu residue is another posttranslational modification frequently found in *Conus* peptides. Several strategies based on mass spectrometry have been used for identification and sequencing of γ-carboxyglutamic acid (Gla) residue in peptides and proteins [4,5]. However, those methods involve rather complex chemistries and are relatively time consuming. Recently, we found that it is possible to obtain structural information of a Gla containing peptide more directly by using a simple methylation procedure and high-energy CID tandem mass spectrometry. This allowed us to identify and sequence Gla residues rather easily with confidence. Figure 2 shows an example of the high-energy CID mass spectrum of a Gla containing conotoxin fragment after methylation. The intense immonium ion at *m/z* 174 (marked as γ) and the b-series ions clearly show presence and position of the Gla residue.

This work was supported by grants from NIH (RR01614) and NSF (DIR8700766).

STRUCTURE-FRAGMENTATION CORRELATIONS OF PROTONATED ACTINOMYCINS#

D. Thomas, M. Morris, J.M. Curtis and R.K. Boyd, Institute for Marine Biosciences,
National Research Council, 1411 Oxford Street, Halifax, Nova Scotia B3H 3Z1, Canada.

The actinomycins are amongst the most effective anti-tumour agents known, but are highly toxic. Synthetic variants, which combine the therapeutic activity with lower toxicity, are highly desirable. The present work is devoted to understanding the MS/MS fragment spectra of actinomycins, to assist with structure determinations of new variants. Structurally, the actinomycins comprise two cyclodepsipeptide rings (5 residues per ring), each of which is attached to an aromatic chromophore by amide linkages. The chromophore structure appears to be invariant in nature, but synthetic variants with aromatic substitutions are known. Natural variants correspond to amino acid substitutions in the depsipeptide rings. Actinomycin D is shown as its protonated form (presumed ground state) in **I**.

Cyclic peptides present a challenge for MS/MS analysis due to difficulties in distinguishing a sequence from its *retro*-sequence (1). The present work adopted the strategy of Barber *et al.* (2), which assumes that the unknown structure is related to a known structure (*e.g.* actinomycin D) *via* one or more amino acid substitutions. In order to use this strategy effectively it is necessary to understand the fragmentation mechanisms, and to this end six actinomycin standards of established structures were studied by low-energy CID using a triple-quadrupole instrument (PE/SCIEX API III+). Some of these standards involved substitutions on the aromatic ring of the chromophore, while the others involved amino acid substitutions. From the resulting mass shifts, it was possible to propose chemically reasonable fragmentation mechanisms for protonated actinomycins, as extensions of previous work (2,3). Fragmentation of a cyclic peptide requires that at least two bonds be broken, and in the case of the depsipeptide rings in actinomycins we agree with earlier workers (2,3) that the lactone linkage appears to be the first cleaved. It is supposed that collisional activation mobilizes the ionizing proton from the most basic site (see **I**) to the one of the lactone linkages as in **II**, and that the primary product of ring opening is **III** where dhThr is the dehydro-threonine residue. In **III** the ionizing proton can readily move to more basic amide sites in the ring-opened peptide, and can thus initiate formation of the familiar **b** and **y** fragment ions. Some fragment ions were also observed which correspond to losses from both of the peptide moieties, and structures **IV** and **V** are postulated structures which rationalize the observed behaviour.

In addition to the mass shift information, the proposed mechanisms were supported by accurate mass measurements of fragment ions formed in the skimmer region of an electrospray source using a Fisons Instruments ZAB-EQ double focussing instrument operated at a resolving power (10% valley definition) of 7000. Sodiated polyethylene glycol ions were more suitable reference ions than their protonated counterparts, since they better survived the CID conditions in the skimmer region of the API source.

Fragment ion spectra of MH^+ ions of impurities in the standard actinomycin samples were then interpreted in terms of structure using the strategy of Barber *et al.* (2) and the present proposed mechanism. Some degree of success was achieved (4), but it seems appropriate to mention here the major limitations. The low-energy MS/MS approach can not distinguish between structural isomers (and gives no information on optical isomers). Since the chromophore ring is much more stable than the peptide moieties it is not possible to observe fragments in which the chromophore rings are separated and the peptides essentially intact. Therefore it is not possible to distinguish between the α and β rings (see **I**).

AC toxin (CyaA), a virulence factor from *Bordetella pertussis*, the bacteria which causes "whooping cough", is now known to be palmitoylated at residue Lys 983 (Hackett et al.,1994,*Science* 266, 433-435). This posttranslational modification is necessary for the biological activity of the177.5 kD protein, in order for it to catalyze the conversion of ATP to cAMP in eukaryotic target cells. AC toxin is also known to be hemolytic for sheep red blood cells. This activity is also dependent on the presence of the palmitoyl group. The acylation is believed to be catalyzed by an accessory protein, CyaC. To facilitate the production of large quantities of AC toxin for various structural and functional studies, the genes for CyaA and CyaC were expressed in a recombinant *E. coli* system. The recombinant AC toxin, in both its CyaC activated and its CyaC deficient form, was characterized by MALDI-TOF and triple quadrupole ESI mass spectrometry. The recombinant protein was found to differ slightly from the protein expressed naturally in *B. pertussis*. The CyaC active form was acylated at Lys 984 with myristate as well as palmitate, with about 13% of the active form myristoylated. About one third of K861 was palmitoylated, unlike the native toxin. The recombinant toxins possesed an extra Thr residue at the N-terminus, thus the slight difference in residue numbering between native and recombinant forms. *E. coli* expressed CyaC activated AC toxin has similar toxin activity, but reduced hemolytic activity, in comparison with AC toxin from *B. pertussis*.

Identification of Post-translational Modifications for Cytochrome $P450_{lin}$

Rong Huang, Dipak Ghosh, Irwin C. Gunsalus, and Kenneth L. Rinehart
School of Chemical Sciences, University of Illinois at Urbana-Champaign, Urbana, IL 61801

Cytochrome P450 enzymes are a class of proteins involved in the oxidative synthesis and degradation of a variety of compounds. It has been reported that a number of hepatic P450s can be phosphorylated by purified protein kinases. Phosphorylation can also be stimulated *in vivo*. This modification may have potential importance for the control of enzyme activity, and perhaps also the regulation of P450 degradation. We first reported evidence of possible sulfation or phosphorylation for bacterial P450 enzymes, i.e., $P450_{lin}$ and $P450_{cam}$, at the 1993 ASMS conference [1]. For $P450_{lin}$, the ESIMS spectrum showed two components at 82 Da and 157 Da higher masses than the calculated molecular weight based on the amino acid sequence (i.e., 45,638 Da). Thus the number of phosphate or sulfate groups on the protein was initially suggested as two. In our continuing effort to characterize $P450_{lin}$, we have determined one modification site using mass spectrometric methods.

When native $P450_{lin}$ was digested with trypsin and separated by HPLC, two fractions both showed peaks at *m/z* 2338 in FABMS spectra (Fig. 1). The fraction eluting 2 min earlier also showed a peak at *m/z* 2418. It is well documented that phosphorylated or sulfated peptides tend to lose a phosphate or sulfate during the FAB ionization process. The typical pattern in Figure 1 indicates that the *m/z* 2418 peak corresponds to the phosphorylated or sulfated *m/z* 2338 peptide, which is at amino acid positions 27-46. It is supported by the fact that the modified peptide is eluted earlier than the normal peptide in reversed phase HPLC. Also, when both fractions are subjected to a secondary protease V8 digest, a common peptide at *m/z* 1194 (positions 35-46) is found in both fractions. This further supports the conclusion. Three residues Tyr^{31}, Ser^{36}, and Ser^{39} are therefore potential modification sites. The exact identity of the modification, i.e., phosphate or sulfate, has not been determined due to limited mass resolution.

The second assumed phosphate or sulfate, however, has never been found. The evidence obtained so far argues in favor of other explanations for the additional 157 Da in the ESIMS spectrum. It was noticed that the protein tends to lose ca. 160 Da from the molecular weight in urea solution. No intermediate mass loss (i.e., 80 Da) is observed. Phosphates and sulfates in general are stable under similar conditions. Also judged by their UV absorption, the modified peptide (*m/z* 2418) discussed above was in much smaller amount than the normal peptide. This indicated the majority of the protein components were not phosphorylated or sulfated. It was in line with the ESIMS spectrum of the intact protein, which indicated the minor component at 82 Da higher mass. One of the possibilities for the additional 157 Da was substrate binding. The substrate, linalool, has a molecular weight of 154 Da. It was ruled out based on spectral properties of P450 proteins. Substrate-bound P450 proteins have UV absorption at 390 nm compared to 419 nm for substrate-free proteins. The protein sample used to obtain the ESIMS spectrum was found to be substrate free. So far the instability of this modification (ca. 157 Da) has hindered its identification.

When native $P450_{lin}$ protein was digested with trypsin without denaturation, a peptide with molecular weight of 3801 Da was observed (Fig. 2). It did not correspond to any expected tryptic peptide based on the protein sequence. After the digest mixture was treated with dithiothreitol (DTT), this peptide disappeared while two new peptides with molecular weights of 1891 Da and 1912 Da were observed. They corresponded to amino acid positions 193-208 and 341-359, respectively, with Cys^{201} and Cys^{355} in the respective peptide. Apparently the two cysteines were linked by a disulfide bond (3801 + 2H = 1891 + 1912). However, an amino acid sequence homology analysis indicated that Cys^{355} was conserved in all P450 enzymes with known sequences and should be the heme binding residue [2]. The observed disulfide bond was likely due to partial denaturation.

In conclusion, one modification site for $P450_{lin}$ has been located within three possible residues. The other modification group is suggested as different from phosphate and sulfate. One disulfide bond is also observed.

An ESI MS Study of the Soluble Methane Monooxygenase Enzyme System

Armelle Buzy, Amarbalita Bhambra, Patricia C. Wilkins, Howard Dalton and Keith R. Jennings
Departments of Chemistry and Biological Sciences, University of Warwick, Coventry CV4 7AL, UK.

Soluble methane monooxygenase (**sMMO**) is a multicomponent non heme iron-containing enzyme system present in methanotrophic bacteria. It catalyses the NAD(P)H- and O_2-dependent oxidation of methane to methanol [1]. Current interest in the enzyme resides in its broad substrate specificity such that it may be used *inter alia* for the biotreatment of halogenated hydrocarbon pollutants [2]. Detailed structural investigations of sMMO have therefore been undertaken in order to understand its enzymatic mechanism. In this work we report the application of electrospray ionization mass spectrometry (ESI MS) used in combination with data obtained from Edman degradation and molecular biology for the characterisation of soluble MMO from the methanotrophic bacterium, *Methylococcus capsulatus* (Bath), the first system to be purified [3].

The enzyme system consists of three proteins, **A**: the hydroxylase, (RMM 251 kDa), **B**: the regulatory protein (RMM 15.5 kDa), **C**: the reductase (RMM 38.6 kDa). All three proteins are necessary for enzyme activity. The hydroxylase is a non-heme diiron protein consisting of 3 non-covalently bound protein chains (α, 60 kDa; ß, 45 kDa and γ, 20 kDa) of $\alpha_2\beta_2\gamma_2$ stoichiometry. LC/MS analysis of **protein A** gave the profile shown in Fig. 1. The 3 subunits were identified in the 3 main peaks observed (Fig. 2). However, the spectrum extracted from the peak eluted at 37.5 min was shown to correspond to at least 3 proteins of measured RMM 60520 3, 59774.9 and 59972.9 Da. The first one was attributed to the α-subunit, as its RMM calculated from the DNA sequence is 60501.3 Da. The 2 other proteins were found to correspond in mass with proteins truncated after the 8th and the 6th residue (expected RMM 59757.5 and 59956.7 Da), respectively. The difference of about 18 Da observed for the 3 species remains to be explained (post-traductional modification, amino acid substitution, chemical modification, etc...). The ß- and γ-subunits give also RMM that disagree with the gene sequence data (measured RMM of 45000.2 and 19716.0 Da for expected RMM of 44875.6 and 19710.5 Da). The sequence deduced from molecular biology experiments suggested a RMM of 15886.8 Da for **protein B**, but SDS analysis of the purified protein showed the presence of two proteins of RMM ca. 16000, one being the expected protein and the other that obtained by truncating this protein after the 12th amino acid residue, inactive in native MMO assays. The ESI spectrum confirmed the presence of the truncated form but revealed an error in the expected protein sequence and demonstrated the presence of several minor species resulting from the loss of N- and C-terminal amino acid residues. Studies are currently being undertaken to investigate the role of the truncated form and to determine whether or not it exists in other methanotrophic bacteria. The measured RMM obtained for **protein C** was in good agreement with the mass of the protein containing 2 iron atoms linked to 4 cysteine residues and with at least 4 other cysteine residues linked by disulfide bridges. The fact that the metal centre is not removed during the mass analysis suggests that the iron atoms are very tightly bound in the native protein. This tight binding may account for the lack of inhibition of sMMO activity observed with most chelating agents.

ES-MS ANALYSIS OF RESORCINOL SUICIDE SUBSTRATE BINDING TO CYTOCHROME C PEROXIDASE

Daniel R. Doerge[1], Rao L. Divi[1] and Therese Hutton[2]
[1]National Center for Toxicological Research, Jefferson, AR 72079, U.S.A.
[2]VG Organic, Altrincham, Cheshire WA14 5RZ, U.K.

INTRODUCTION

Resorcinol and derivatives, consumed by humans through foodstuffs, food preservatives, drugs, hair dyes and groundwater, are toxic to the thyroid in humans and experimental animals causing goiter (enlargement of the thyroid) and, possibly, thyroid cancer. Yeast cytochrome c peroxidase (CcP) is a well studied enzyme (mw 34 kDa) known to differ from the classical peroxidase, horseradish peroxidase, by virtue of the formation of a catalytic amino acid radical upon reaction with H_2O_2. The present studies were undertaken to determine if the presence of a protein radical site(s) in oxidized CcP would confer susceptibility to inactivation by resorcinol, as observed previously for thyroid peroxidase, and provide support for the proposed mechanism of amino acid modification. In addition, we sought to use electrospray MS to provide evidence for the site and stoichiometry of covalent binding.

EXPERIMENTAL

Homogeneous yeast CcP was generously provided by Dr. James Erman (Northern Illinois University). MS measurements were performed using a VG Platform single quadrupole mass spectrometer (VG Organic, Altrincham, U.K.) or a Quattro II triple quadrupole mass spectrometer (VG Organic, Altrincham, U.K.). Protein samples (ca. 1 mg/ml in 10 mM ammonium acetate, pH 7.0) were diluted 2-fold into 50% aqueous acetonitrile containing 0.05% formic acid immediately before ES/MS analysis. Positive ion data were acquired over the range of *m/z* 500-2000 in MCA mode. The instrument was calibrated using the multiply charged ion peaks from a separate introduction of horse heart myoglobin (Sigma M-1882, M_r = 16,951.5 Da) at a concentration of 10 pmol/μl in 50% aqueous acetonitrile containing 0.2% formic acid and data were acquired under the same conditions as the CcP samples. Subtracted data were processed by MaxEnt to convergence using 1 Da/channel resolution.

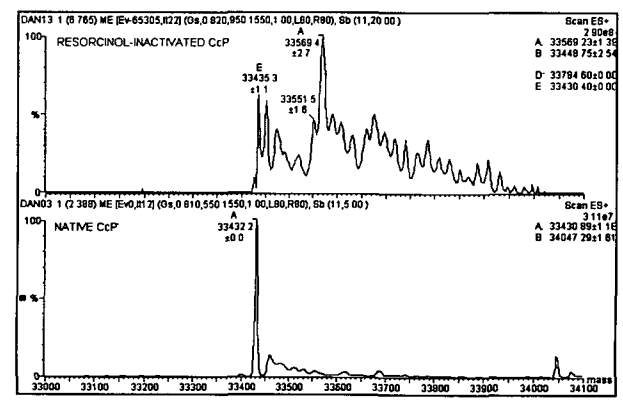
RESULTS AND DISCUSSION

Incubation of CcP with resorcinol in the presence of H_2O_2 produced time-dependent loss of enzymatic activity (ca. 70%) that was not restored by dialysis or chromato-centrifugation as a treatment to remove all small molecules. Changes in the visible spectrum of the enzyme were also observed concomitant with resorcinol-mediated CcP inactivation. When CcP was similarly inactivated in the presence of ^{14}C-resorcinol, radiolabel became incorporated into the protein (7 mol/mol CcP). This suggested that amino acid residues of the apoprotein were modified concomitant to enzyme inactivation. This hypothesis was investigated using ES/MS analysis of native and inactivated CcP. Figure 1 (bottom panel) shows the results from MaxEnt processing of the ES mass spectrum for native CcP in acidic aqueous acetonitrile. The presence of two overlapping series with molecular weights of 33,432 Da and 34,048 Da was observed. These components were assigned to the apoprotein and the native heme-containing protein, respectively, corresponding to Δm = 616 Da for ferric protoporphyrin IX (mw = 615 Da). ES/MS analysis of resorcinol-inactivated CcP gave rise to a complex mixture of overlapping

components (see Figure 1) that upon MaxEnt processing gave a major component with molecular weight of 33,569 Da (Δm = 137, see Figure 1 top panel). This corresponds within experimental error to addition of one resorcinol unit ($\Delta m \approx 108$) and addition of two oxygens (Δm = 32). Smaller peaks that could correspond to native CcP (33,435 Da), oxidized CcP (33,451 Da, Δm = 16), addition of a second resorcinol unit to the major component (33,676 Da, Δm = 107) and addition of a third resorcinol unit to the major component (33,785 Da, Δm = 109) were also observed. The putative oxidations observed could be due to oxidation of methionine or tyrosine residues as previously observed following treatment of CcP with high concentrations of H_2O_2. However, no change in ES mass spectrum was observed upon addition of H_2O_2 at the levels used in this study (data not shown).

The visible spectral changes observed could be the result of perturbations in the protein ligands to the heme iron or direct binding to the porphyrin ring. The ES mass spectra of native CcP contains a peak consistent with ferric protoporphyrin IX ($M + H^+$ = 616 Da); however, the ES mass spectrum of resorcinol-inactivated CcP contains a small peak with a mass corresponding to addition of one resorcinol moiety (Δm = 108) in addition to a larger peak corresponding to the unmodified heme. These results suggest that binding to the apoprotein is primarily associated with CcP inactivation and that heme modification may be a secondary event.

In the proposed mechanism for suicide inactivation, the reaction of CcP compound ES with resorcinol would generate CcP compound II (1-electron oxidized above the native state) and a reactive resorcinol radical at the active site. Radical coupling would lead to a protein adduct. The observation of a major component in the ES mass spectrum of resorcinol-inactivated CcP corresponding to addition of one resorcinol moiety provides further support for the proposed mechanism. The present data do not permit identification of the residue(s) modified in the presence of resorcinol but future studies of peptides derived from modified CcP should be valuable in identifying amino acid radical intermediates.



INTRODUCTION

Conidae are a group of venomous marine gastropods (~500 species) that are common in tropical and sub-tropical waters. Venom contained in the venom ducts of *Conus* species are used in conjunction with harpoon-like radular teeth to rapidly immobilize prey. These venoms have yielded a wide variety of *novel* bioactive peptides that act selectively on mammalian targets, including the sodium and calcium channels and nicotinic acetylcholine receptors [1-2]. For our studies venom is taken from individually dissected venom ducts and from the milking of certain species(Fig.1). The venom is typically subjected to reverse phase HPLC and the eluting conopeptides simultaneously monitored by UV and MS as depicted in Fig.2

EXPERIMENTAL

Mass spectra were acquired on a PE SCIEX API111 triple quadrupole mass spectrometer, equipped with an atmospheric pressure ionization source. When fractionation was not required TurboIonspray was used to allow the introduction of the complete eluant from the HPLC.

Reverse phase HPLC of the crude venom extracts and UV monitoring were affected on a Perkin Elmer Series 200 HPLC pump and a 785 UV detector respectively. Crude venom (1-2mg) was fractionated on a 250x4.6mm Vydac C_{18}, 300Å, 5µm column at 1mL/min using a gradient of 0-20%B over 5 min, 20-40%B over 45 min, 40-80%B over 5 min and finally 80%B for 10min, where A is 0.1%TFA and B is 90% acetonitrile/10% 0.09%TFA (aq).

Isolated conopeptides were characterized by a combination of Edman chemistry, MS, MS, MS/MS, chemical and enzymatic modification.

CONCLUSIONS

- LC/MS utilizing the Ionspray interface has proved a powerful tool to unravel the complexity of cone shell venoms.
- The sensitivity of the method allows for the first time the detailed analysis of crude venom from individual cone shells.
- Extensive venom composition variability observed within several species. This variability is seen between individuals on (i) the same reef (ii) distant reefs within the GBR complex and (iii) reefs from different hemispheres.
- Milked venom and duct venom exhibit great differences in complexity and composition.
- Milked venom composition changes with time in captivity.

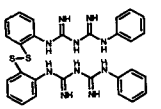
ANALYSIS of HUMAN CYTOMEGALOVIRUS (HCMV) PROTEASE INHIBITION REACTIONS by ELECTROSPRAY IONIZATION MASS SPECTROMETRY (ESI/MS)

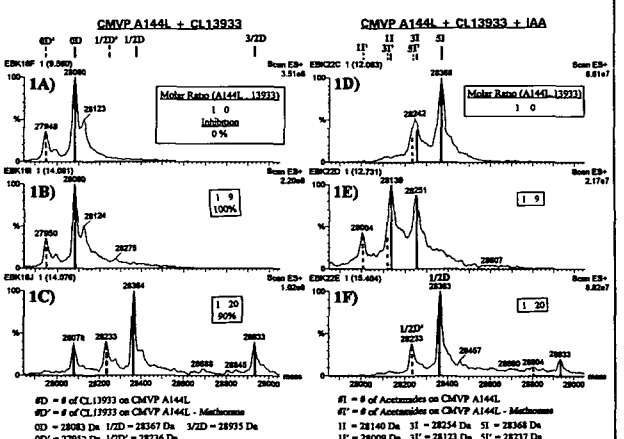
Marshall M. Siegel, Keiko Tabei, Geraldine A. Bebernitz, Jeffrey D. Hulmes, Ellen Z. Baum
American Cyanamid Company, Medical Research Division, Lederle Laboratories, Pearl River, NY 10965

INTRODUCTION HCMV is an opportunistic pathogen which can cause disease or death in immunocompromised patients. The 28 kDa protease encoded by the HCMV UL80 gene is essential for viral replication and is an appropriate target for an antiviral drug. Using random screening methods, compound CL13933 (a symmetrically-substituted disulfide with MW 568), was found to inhibit recombinant HCMV protease. To better understand the nature of the chemical reaction between the protease and inhibitor, ESI/MS was used as the detector for the reactions.



RESULTS & DISCUSSION The inhibition of HCMV protease A144L (MW 28,083) by CL13933 was found to be irreversible, as defined by the failure to recover enzymatic activity upon removal of the free compound either by gel filtration or by dialysis. Since CL13933 contains a disulfide bond, the mechanism of action for the compound suggested reaction(s) with the cysteine residue(s) of HCMV protease. Figs. 1A, B and C illustrate the transformed ESI mass spectra of A144L HCMV protease incubated with 0, 9, and 20-fold molar excess, respectively, of CL13933 (2h, 25°C). The masses of zero, one half, and three halves CL13933 adducts are indicated by 0D, 1/2D, and 3/2D, respectively. Peaks labeled ' are lacking the amino terminal methionine residue and behave exactly as their counterparts containing methionine. (The weak shoulders ~41 Da higher than the main peaks correspond to carbamylation of protease during purification from urea). At a molar ratio 9:1 of CL13933:protease, no changes in the spectra are observed (cf. Fig. 1A with B). At 20:1 of CL13933:protease, covalent adducts between CL13933 are observed (Fig. 1C). The protease contains 5 cysteine residues. To determine whether (and how many) cysteines reacted with CL13933, the free cysteines in these samples were quantitated by alkylation with iodoacetamide (IAM, Δ = 57). The resulting transformed ESI mass spectra are shown in Figs. 1D, E and F. The masses of one, three, and five alkyl groups are indicated by 1I, 3I, and 5I, respectively. Alkylation experiments demonstrate that less IAM-protease adducts are generated with increasing the molar ratio of CL13933 to protease (cf. Fig 1D with E) until only minor changes are observed (Fig 1F) relative to the unalkylated reaction (Fig. 1C). These results, and reduction experiments with β-mercaptoethanol, demonstrated that at 9:1 CL13933:protease, two intramolecular disulfide bonds were formed within the protease, and that at 20:1 CL13933:protease, a disulfide bond was formed between the protease and half a molecule of CL13933.

To identify the disulfide pairs which form in HCMV protease, tryptic digests of CL13933-treated A144L protease were prepared. The isolated fragments were analyzed by Edman sequencing and ESI/MS. The identified disulfide pairs were Cys138-Cys161 and Cys84-Cys87. These data suggest that specific pairing of cysteines occurred, as opposed to scrambling of the inter-

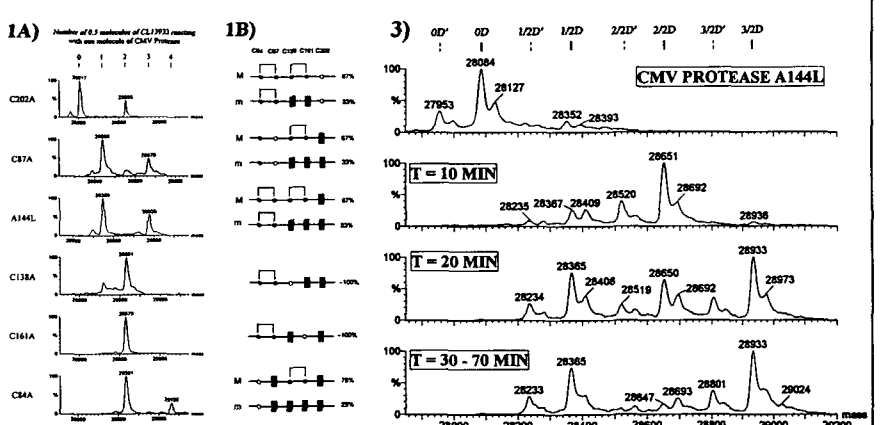


molecular disulfides. An adduct between Cys202 and a half molecule of CL13933 was also detected.

To elucidate the role played by each of the cysteines in HCMV protease in the inhibition of protease activity, each of the five individual cysteine residues was mutated to alanine (C84A, C87A, C138A, C161A, C202A). Each of the mutant proteases were found to be enzymatically active, but only mutants C138A and C161A were not inhibited by CL13933, suggesting that the disulfide between Cys138-Cys161 is responsible for the inhibition of the protease. The reactivity of the five different cysteine residues of HCMV protease was determined by incubating the mutant proteases with excess CL13933 (CL13933:protease, 6:1, 4h) and examining the products by ESI/MS (Fig. 2A). The proposed identity of the major (M) and minor (m) mass spectral peaks are illustrated in Fig. 2B. The HCMV protease is depicted as a line. Filled circles represent cysteines present in each protease; open circles are alanines substituted for cysteines. Filled rectangles are half molecules of CL13933. Disulfide bonds are indicated by bars (⌐¬) connecting two cysteines.

The proposed mechanism for the inhibition of HCMV protease by CL13933 uncovered a previously unreported feature of the enzyme: the presence of multiple reactive cysteines which are capable of thiol-disulfide exchange. The disulfide pairs are Cys84-Cys87 and Cys138-Cys161; Cys202 is unpaired. At low concentrations of CL13933, the thiols of Cys87, Cys138, and Cys161 react with CL13933, forming a transient covalent adduct. The other member of the pair (Cys84, Cys161, and Cys138, respectively) then displaces CL13933 by thiol-disulfide exchange, forming intramolecular disulfide(s). Cys84 is presumed to be non-reactive; it may be protonated or inaccessible to the compound in the native protease. At high concentrations of CL13933, covalent adducts between CL13933 and HCMV protease are observed, resulting from simultaneous reaction of Cys138 and Cys161 with CL13933, preventing thiol-disulfide exchange; also, Cys202 forms an adduct with CL13933 and does not participate in intramolecular disulfide bonding. Since Cys84 cannot react with CL13933 directly, but only acts to exchange adduct from Cys87, an adduct of five halves CL13933 is not observed.

Kinetics studies of A144L protease with CL13933 (1:20) by ESI/MS (Fig. 3) can be explained in terms of this model. At 10 minutes, the addition of 2/2 CL13933 adducts is observed but at later times it disappears, and 1/2 and 3/2 CL13933 adduct appear. This can be explained by the rapid simultaneous addition of 1/2 CL13933 at both Cys138 and Cys202 (2/2) and later addition of 1/2 CL13933 at Cys161 to the adducted protease (3/2) or the release of 1/2 CL13933 from Cys138 by producing a disulfide bond with Cys161 (1/2). This kinetics model is consistent with similar kinetics studies of C202A with CL13933.



Evaluation of the Role of Hydrophobicity and the Role of Suppression in the Mass Spectrometry of MHC Peptides.

Amina S. Woods, Alex Huang, Robert Cotter, Drew Pardoll and Elizabeth M. Jaffee, Departments of Oncology and Pharmacology, Johns Hopkins School of Medicine, Baltimore, MD 21205

Recent advances have been made in the identification of specific gene products that represent tumor antigens. These antigens are peptide fragments of cytoplasmic proteins that are expressed bound to Class I MHC. In the case of human melanoma, the peptides were identified and sequenced by mass spectrometry. Our group has been utilizing MALDI in combination with exopeptidase digests as a method for sequencing MHC Class I antigens. Some modification of this approach have resulted in important visualization thereby allowing sequencing of the isolated peptides. In particular, we took advantage of the hydrophobicity of peptides to improve their detection.

To assess the role of hydrophobicity, equimolar solutions of synthetic MHC peptides of various hydrophobicity (as calculated by the Bull and Breese index [BBI]) were used.

peptide #1 FERFEIFPKE BBI= -3500, MW = 1341.7 Da
peptide #2 TYQTRALV BBI= -290, MW = 1107.3 Da
peptide #3 SIINFEKL BBI= -3790, MW = 963.3 Da
peptide #4 IYSTVASSL BBI= -3120, MW = 939.5 Da

Peptide Solutions: Peptides were diluted in 20% acetonitrile: 80% water: 0.1% TFA pH = 2.0. All solutions contained an equimolar amount of each of the 4 peptides. The following concentrations were prepared 10 pmoles/ul, 1 pmole/ul, 100 fmole/ul and 10 fmole/ul. Saturated solutions of Ammonium citrate dibasic (AC) and ammonium bicarbonate (AB), pH = 5.0 and 8.5 respectively, were used. Matrix: Saturated solution of α-cyano-4-hydroxy-cinnamic acid in 50% ethanol-water pH = 1.25. Each peptides solution was spotted 3 times on a sample slide, followed by the addition of matrix, or buffer and matrix, and left to dry at room temperature.

1: 0.3 ul peptides + 0.3 ul/matrix pH = 1.5
2: 0.3 ul peptides + 0.3 ul AC + 0.3 ul/matrix pH = 4.0
3: 0.3 ul peptides + 0.3 ul AB+ 0.3 ul/matrix pH = 7.2

Washes were done with 1ul of cold deionized water. The spectra were acquired before and after washing with water on a Kratos Kompact MALDI III (Manchester, England).

The analysis of the peptide mixture shows that hydrophobicity is not the only factor that plays a role in the desorption of the various peptides present in our mixture. The salt content, the pH of the solution as well as the concentration of the solutions played a role. The data from the 0.01 pmole/ul

solution was reported but should be considered unreliable because the spectra have an uneven base lines, and some molecular ions (MH^+) are barely above the noise level.

Salt contents: The washed samples showed an improvement in sensitivity and resolution and less suppression for the 10, 1 and 0.1 pmole/ul solutions.

Solution pH: The samples to which ammonium citrate was added (pH = 4.0), showed the most improvement in sensitivity, resolution and the least suppression. The samples to which ammonium bicarbonate was added showed some improvement in sensitivity and resolution and almost as much suppression as the non buffered samples, except for the washed samples, which showed less suppression than the ones that were only buffered.

Solution Concentration: The suppression increased as the sample concentration decreased. As a whole suppression was less marked in washed samples, regardless of their concentration.

The above results suggest that peptide suppression is not related to hydrophobicity.

- Salt content seems to aggravate suppression, and the washing of the sample matrix mixture after it is dried improves sensitivity and resolution as well as decrease suppression in spite of the possibility of sample loss.
- Solution pH seems to be the parameter that has the most significant effect on improving sensitivity and resolution as well as decreasing suppression. The most favorable results were obtained at pH 4.0 by addition of ammonium citrate buffer (pH = 5.0). The results generated at pH 7.2 by addition of ammonium bicarbonate showed some improvement. The non-buffered samples (pH 1.5), showed the most suppression. All samples regardless of pH were improved by salt removal.

In conclusion our data shows that pH and possibly the number of basic residues (arg, lys), do play a role in the desorption of peptides by MALDI. Peptide #2 contains 2 arg, peptide #1 contains an arg and a lys, peptide #3 contains one lys and peptide #4 contains none. We used both dibasic (pH 5.0) and tribasic (pH 7.5) ammonium citrate buffers. The effect of the tribasic buffer were similar to those obtained with ammonium bicarbonate, thus pointing that the improvements are probably due to the pH of the solution rather than the ammonium citrate *per se*.

Identification of Peptides Associated with Class II MHC Molecules

Theresa A Addona[1], Jeffrey Shabanowitz[1], and Donald F Hunt[2]
[1]Department of Chemistry, University of Virginia, Charlottesville, VA 22901
[2]Departments of Chemistry and Pathology, University of Virginia, Charlottesville, VA 22901

In the last few years, a number of different techniques have been applied to the sequencing of processed peptides in association with both class I and class II MHC molecules(1-5) These results include allele-specific motifs for various class I MHC molecules, and the general features of peptides bound to class II MHC molecules. Identifying these characteristics has led to considerable progress in understanding the pathways through which the peptides are produced and presented Given a known protein, sequence motifs for class I associated peptides have been used to predict optimal peptides for binding From these predictions, peptides responsible for eliciting an immune response have been identified (6).

The determination of sequence motifs for class II peptides is not as definitive Most of the class II associated peptides sequenced to date are nested sets derived from the same source protein, and share a common core sequence, but differ at both the amino and carboxyl terminal ends. Despite the lack of a length restriction, predictions for optimal peptide binding to class II molecules can be made, but presentation of these peptides on the cell surface is not known

The application of precursor ion scans on internal fragments in the core sequence of class II associated peptides was investigated as a general method for the identification of related, processed peptides in a complex mixture The complete sequences of twenty peptides extracted from class II molecules DR(w4,w14) were determined by microcapillary HPLC/electrospray ionization/tandem mass spectrometry The principal ion series in the product ion spectra recorded on triply and quadruply charged ions, consisted of multiply charged, high mass y ions and their internal cleavage fragments Precursor ion scans recorded on the internal cleavage fragment at *m/z* 1327 (DDTQFVRFDSD) of the synthetic peptide VDDTQFVRFDSDAASPRTEPR, showed that this fragment is derived predominately from the intact peptide and y_{20}^{+3}, and to a lesser extent, from the doubly charged internal fragment at *m/z* 1021. To test the application of this approach, precursor ion scans were recorded on a complex mixture from which DR(w4,w14) associated peptides had been sequenced. Figure 1 shows the ESI mass spectrum with the characterized peptides indicated by *. The complete sequences of these peptides are shown in Table 1. Those peptides that have already been identified to yield *m/z* 1327 by product ion scan are observed in the precursor ion scan and are also indicated by * (Figure 2) Most notably, peptide number 10 is not observed since this peptide cannot fragment to the selected product Other precursors that have not been identified, but contain a *m/z* 1327 in their product ion spectrum include *m/z* 733, 914, and 930

MHC CLASS II-ANTIGEN PROCESSING: CHARACTERIZATION OF THE MAJOR COMPONENTS IN SUBCELLULAR FRACTIONS

Ashley L. McCormack, Jimmy K. Eng, Paul DeRoos [1], Alexander Y. Rudensky [1], and John R. Yates, III
Department of Molecular Biotechnology and
[1]Department of Immunology, University of Washington, Seattle, WA 98195

In the past several years electrospray ionization tandem quadrupole mass spectrometry has made an impact in many areas of biology, especially immunology and the study of antigen presentation by major histocompatibility complex (MHC) class I and class II molecules (1). We are developing methodology to study the generation of MHC class II-peptide complexes. The cellular processing of MHC-peptide complexes has been studied extensively; however the exact mechanisms are unknown Previous research has suggested that MHC class II molecules move from the golgi complex to late endosomes (2) Then class II molecules accumulate in dense MIIC compartments where endogenous peptides bind to class II molecules. Finally the complex moves through the endosomal pathway to the cell surface. Exogenous peptides have also been found to accumulate in MIIC vesicles, where binding to class II molecules may occur. Here we present data from the analysis of peptide mixtures derived from subcellular fractions enriched with components of the endocytic pathway.

Our preliminary study focuses on utilizing µ-LC-MS/MS and database searching methodology to characterize the peptide components in subcellular fractions, including identifying protein origins and identifying the cleavage sites in the protein Lysed cellular material, including intact vesicles, was fractionated by density using a sucrose gradient (2). Fractions were assayed using known marker proteins and pooled accordingly Vesicles were lysed using acid conditions and components were fractionated using a 3,000 Da and/or 10,000 Da cut-off membrane filter. Peptide mixtures were analyzed directly with µLC-MS, automated µLC-MS/MS, and database searching.

Complex mixtures of peptides were found in all fractions, except those enriched in plasma membrane In the other fractions, large peptides, with molecular weight distributions of approximately 3.5 to 11.7 kDa were observed, as well as a complicated mixture of many smaller peptides. To facilitate sequencing, large molecular weight peptides were separated from smaller peptides using a 3000 Da cut-off membrane filter. The low molecular weight mixtures were analyzed using automated µLC-MS/MS, Figure 1. Uninterpreted spectra were used to search the *Mus musculus* subset of the OWL database, using the program SEQUEST as described by Eng and coworkers (3). Sequence data was obtained on peptides in fractions containing late endosomes and ER, Table1a, and in fractions containing MIIC, late endosomes and ER, Table 1b.

Each of these fractions contained over one hundred peptides. An average of 35 peptides per pooled fraction were analyzed by a single MS/MS experiment Currently we are adapting the automated MS/MS program, as well as the chromatography conditions to maximize the number of peptides analyzed. However, many of the peptides in these two fractions are present in higher charge states (greater than +3) and were not sequenced.

In most of the peptide sequences, the cleavage sites are consistent with an acid protease, such as cathepsin D or E. It has been suggested that acid proteases, such as cathepsin D and E, are important in the processing of MHC class II-peptide complexes (4). Peptides from human keratin and calreticulin were also identified; these proteins are common contaminants in protein samples handled by humans. It is interesting to note that these peptides also contain the correct cleavage sites, suggesting that these peptides were processed in the cells

µLC-ESI/MS/MS has proven to be a powerful technique for study of antigens presented by MHC molecules. Extending this approach to study antigen processing pathways provides insight into the mechanisms of antigen processing, selection, and presentation. Future studies will include pulsing the cells with hen egg lysozyme, followed by subcellular fractionation, and identification of lysozyme peptides in each pooled fraction by µLC-MS/MS.

A Study of Analyzing Femtomole Amounts of Peptides with Continuous-Flow FAB

A. B. Whitehill,* I. Vidavsky, and M. L. Gross
Department of Chemistry, Washington University, One Brookings Drive, St. Louis, MO 63130

We have undertaken a study to investigate peptides isolated from major histocompatibility complex (MHC) molecules of the class II type, resulting in the need to be able to determine low picomole to femtomole amounts of peptides with 10 to 20 residues and corresponding molecular masses of approximately 1000 to 2000. To complement the biological experiments, mass spectrometric analysis needs to yield accurate molecular weight and structural information. Although the biological factors warranting such an endeavor are significant in their own right, this study will concentrate on our efforts to develop a mass spectrometric method for these peptides.

When dealing with small amounts of material, sample handling and detection must be scrutinized. In this study, samples were introduced with continuous flow-FAB via a commercially available VG probe. To optimize detection limits, a series of synthetic peptides were used to evaluate the following:

Sample analysis was performed with a VG ZAB-T four-sector mass spectrometer of BEBE design. Ions were created with a cesium ion gun and accelerated by an 8 kV potential. Molecular weight determination was accomplished by scanning MS1 (E_1B_1) with a mass resolving power of 2000 and at a rate of 15 seconds per decade over the appropriate mass range resulting in a scan time of approximately 11 seconds (two second delay between scans). Selected ion monitoring experiments were done by calibrating with a pair of known masses and stepping the voltage for the desired mass.

Samples were introduced with a continuous flow-FAB probe of screen and wick design. Peptides were dissolved in a 68% water/27% acetonitrile/3% glycerol/2% TFA matrix and introduced through a 350 μm O.D. x 50 μm I.D. fused-silica column. Solution flow was accomplished by inserting the capillary in a sample holder (bomb) pressurized to 23 p.s.i. with helium gas. Ionization and desorption occurred as the capillary delivered the solution to the screen where FAB occurred.

The first step in our analysis was to assure steady sample delivery at a flow rate of approximately 1.7 μL/min. This rate was chosen because the minimum sample volume that can be reproducibly handled with this technique is approximately 10 μL, resulting in a sample analysis time of six minutes. The water/glycerol/acetonitrile mixture is sufficient for steady matrix flow, but a protonating agent such as trifluoroacetic acid (TFA) must be added at an optimum level. This was evaluated by monitoring the molecular ion abundance for desorption from a series of 70% water/27% acetonitrile/3% glycerol matrices varying in TFA content from 0 to 3%. Two commercially available peptides (substance P and bradykinin) were monitored and both showed maximum signal to noise for matrices containing 2% TFA. For further experiments, a matrix of 67% water/27% acetonitrile/3% glycerol/2% TFA was used because the resulting ion current was steady and the extent of protonation was maximum.

After establishing the most effective matrix, selected ion monitoring (SIM) experiments were carried out to determine if samples were being spread while in the silica column, resulting in dilution and a higher limit of detection. A series of 20-s injections of hen egg white lysozyme peptide (HEL 52-61) at concentrations of 550 and 110 fmol/μL were analyzed and showed small amounts of peak tailing and spreading occur. In the 110 fmol/μl injections the sample consumption is 55 fmol, shorter injections and lower concentrations should yield detection limits of <10 fmol.

The detection limits for scanning experiments need to be evaluated for the analysis of fractions of unknown peptides. Different concentrations of various peptides were flowed for a fixed amount of time (approximately 1.8 minutes) and volume (3 μL) and spectra recorded. Table 1 is a summary of scanning

data for a series of peptides, and shows that a fairly wide range of detection limits (S/N = 3) are observed. One explanation for the range of detection limits is that hydrophobic peptides assemble on the surface of the matrix and are desorbed more effectively whereas hydrophilic peptides remain in the water-based matrix. Peptide hydrophobicity has been measured by a variety of experimental methods. Bull and Breese[1] measured surface tension of single amino acids whereas Hearns[2] et al. measured RP-HPLC retentions of peptides with a series of stationary and mobile phases. In both cases, a hydrophobicity index is established for single amino acids, and the peptide values are the sum for the sequence. Table 1 shows that detection limit decreases with increasing hydrophobicity, inferring that hydrophilic discrimination is occurring.

After determining that hydrophobicity affects detection limits of solutions containing single peptides, the effect of peptide mixtures on LOD was investigated. Full scan spectra were recorded for a series of peptide mixtures at known concentrations and summarized in Table 2.

Every peptide shows an increase in detection limit. This is probably due to a decrease in surface concentration of the peptide at the FAB probe tip, particularly for peptides of similar hydrophobicity. If true, the detection limit for a hydrophobic peptide in mixture with a hydrophobic peptide will not be affected. Table 2 shows that this is not the case as the detection limits of hydrophobic peptides, substance P and HEL 52-61, are made worse when the peptide is mixed with a more hydrophilic peptide. Although we have only limited sets of data, this suggests that hydrophobic/philic properties do not account for the behavior of mixtures of peptides in flow FAB.

Table 1. Scanning detection limits of various peptides.

Peptide	*m/z* $[M + H]^+$	Det. Limit (fmol/μL)	Amount (fmol)	B&B value[1]	Hearn value[2]
Bradykinin	1060.6	320	945	-940	5.3

Identification of Influenza Epitopes Presented by Hemagglutinin Transfected Cells

Pamela H. Gulden*, Scott Tykodi#, Jeffrey Shabanowitz*, Thomas Braciale# & Donald F. Hunt*

*Department of Chemistry,and #Beirne Carter Center for Immunology Research and Department of Microbiology, University of Virginia, Charlottesville, VA 22901.

Major Histocompatibility Complex (MHC) membrane proteins present peptides to T cells of the immune system. Endogenously derived proteins, i.e., those produced inside the cell, are presented to $CD8^+$ T cells by Class I MHC. When an endogenously derived protein is either mutated by cancer or the result of a virus, peptides are produced that are foreign to the immune system. The recognition of a foreign peptide associated with Class I MHC by $CD8^+$ T cells initiates a Cytotoxic T Lymphocyte (CTL) response, resulting in death of the diseased cell.

The peptide sequence that elicits a CTL response when in complex with MHC is referred to as an epitope. Peptide epitopes are of use in the development of vaccines and therapies for viruses and cancer. Hemagglutinin, the major membrane-associated glycoprotein produced in cells as a result of influenza infection is known to contain epitopes recognized by CTL of individuals infected with the influenza virus.[1] Using cells transfected with hemagglutinin DNA, the goals of these studies were to 1) sequence influenza peptide epitopes derived from hemagglutinin, and 2) determine whether peptide affinity for MHC determines which foreign peptides are displayed on the cell surface.

Since Class I MHC proteins preferentially bind peptides with particular amino acids at certain positions (motifs)[2], it should be possible to predict which peptides of a foreign protein would bind to a particular Class I MHC allele. Peptides presented by Class I MHC molecules on the surfaces of hemagglutinin transfected cells were extracted and subsequently sequenced using a Finnigan-Mat TSQ 7000 instrument, following reverse-phase HPLC fractionation.

Of the eighteen synthetic K^d motif containing hemagglutinin peptides tested for K^d binding capacity, only the two that exhibited the greatest affinity, TYVSVGTSTL and LYQNVGTYV, were both present on the cell surface and able to stimulate a CTL response *in vitro*. These results indicate that peptide affinity for Class I MHC plays a crucial role in determining which peptides of a foreign protein will be presented to the immune system. Importantly, these data also show that the predicted influenza CTL epitopes are generated *in vivo*, lending support to the rational design of vaccines and therapies for intracellular pathogens employing synthetic peptides.

Table 1: Peptide sequences were chosen that fit the K^d binding motif Predominantly Y and sometimes F at position 2, L, I, or V at C-terminus. In the sequences listed, K^d anchor positions are underlined. Peptides were synthesized using standard FMOC chemistry with a Gilson AMS 422 peptide synthesizer Binding capacity was determined by binding inhibition of a known K^d influenza peptide epitope from nucleoprotein. The assay readout was Cr[51] release from lysed target cells

Proteolytic Processing of Ovalbumin by the Murine Proteasome

Gina M. King, Jeffrey Shabanowitz, and Donald F. Hunt
University of Virginia, Charlottesville, VA 22901

Gabi Niedermann and Klaus Eichmann
Max-Planck-Institute for Immunology, Freiburg, Germany

A complex mixture of more than 10,000 peptide fragments derived from cellular proteins is displayed on the surface of nucleated mammalian cells by class I molecules of the major histocompatibility complex (MHC). Cytotoxic T lymphocytes (CTL), killer cells, bind to class I molecules, sample the peptides presented, and lyse those cells that display peptides derived from viral infection or other disease states. One mechanism for peptide presentation involves proteolysis of cellular proteins in the cytoplasm, followed by transport of peptides into the endoplasmic reticulum, a compartment where peptide-MHC I complexes are assembled. Once peptides become associated with class I molecules, the resulting complex moves to the cell surface. The initial degradation of proteins to peptides in the cytoplasm is thought to occur by a 700 kDa multi-component enzyme complex called a proteasome. The specificity of the enzymes in this complex determine, in part, which peptide fragments are generated from a particular protein and presented to the immune system. Cytokines such as interferon gamma and other cellular factors have been found to affect the cleavage specificity of the proteasome (1). Here we describe the use of mass spectrometry to follow the production of peptides from a portion of a 44 kDa glycoprotein, ovalbumin, by a murine proteasome.

Two different synthetic 22-mers, found in the ovalbumin amino acid sequence, were subjected to proteolytic degradation by the proteasome and sampled at various time points (only 36 hr. data shown). Digests were carried out in vitro with 20mM HEPES buffer, 5mM magnesium chloride, 1mM EGTA, 300 fmol of purified murine proteasome, and 5 nmol of peptide at pH=7 8 All degradation products were analyzed directly with a Finnigan TSQ700 mass spectrometer equipped with on-line microcapillary HPLC and electrospray ionization source. Peptide products were collisionally dissociated and sequenced. Relative abundances of peptides produced by the proteasome were determined by spiking known amounts of several peptide standards into the product mixture and performing co-elution experiments. The immunodominant peptide, SIINFEKL, generated from YVSGLEQLESIINFEKLTEWTS, was identified as the most abundant digestion product at all time points. This finding is consistent with other studies performed with ovalbumin derived peptides and proteasomes (2)(3). The SIINFEKL peptide binds with high affinity to the class I molecule and elicits a strong CTL response in vivo(2). The sub-immunodominant peptide, KVVRFDKL, generated from YTQINKVVRFDKLPGFGDSIEA, was identified as one of the least abundant digestion products at all time points. The KVVRFDKL peptide similarly binds with high affinity to the class I molecule but had not been detected on the cell surface as a processed antigen by CTL assays. Analysis of the products generated from the second 22-mer showed that the expected epitope was mostly cleaved in half by the proteasome, and only a very small amount of the KVVRFDKL peptide remained after the 36 hour digestion. KVVRFDKL was not present at detectable levels in the 72 hour digest (data not shown).

Since both peptides discussed bind with similar affinities to MHC-I molecules but only the SIINFEKL peptide is produced in large quantities after digestion with the proteasome, we conclude that peptides must be generated in sufficient quantities by the proteasome to be detected by the immune system. Our study demonstrates that the enzyme specificity of the proteasome complex contributes to the selection of protein fragments presented to the immune system. Studies on processing two synthetic 44-mers and the native protein are in progress.

The immuno response of T cells requires an antigen to be recognized. We have demonstrated before[1] with the model protein antigen Hen Egg Lysozyme (HEL), that this response to proteins involves unfolding and degradation to peptides that are recognized on the surface of antigen-presenting cells (APC) in association with the major histocompatibility complex (MHC) molecules. Previous results[2,3] showed that T-cells, after activation by I-A^k type APC, respond to a synthetic 10-mer residue, HEL 51-62. Similarly, T cells after activation by I-E^k type APC, respond to a 13-mer, HEL 84-96. HPLC chromatography of the mixture extracted from MHC class II complexes of APC after treatment with HEL gave the immuno active fractions that were analyzed by MALDI-TOF and cf-FAB MS. The major components were HEL 48-63, 48-62, 48-61 for I-A^k type APC and HEL 84-97, 84-98, 84-102 for I-E^k type APC.

To extend the understanding of the protein antigen processing mechanism producing the peptides that are presented to the T cells, we started working on characterizing peptides produced from a series of mutated HEL proteins. These m-HELs are engineered by oligonucleotide-directed mutagenesis of the cDNA that encodes the HEL, and produced by expression of HEL (or mutated HEL) genes in the APC. The mutation of HEL molecules was directed at altering the presentation of the 48-62 region, but preserving the structure and folding of wild HEL. The mutated HELs are modified also by adding a linker and a transmembrane segment. This strategy utilizes much lower amounts of protein(by several orders of magnitude) than used in external infusion, to allow study of mutated HELs.

To test the feasibility of this strategy, initial studies were done on peptides extracted from the MHC of I-A^k type APC expressing a gene encoded for wild type HEL, a 14 amino-acid linker and a 30 amino acid transmembrane segment. Two main peptide fractions were found to be immuno active. These fractions were studied by MALDI-TOF. Initial study by linear MALDI-TOF found the immuno active fractions to be cleaner than those from the experiment where HEL was infused externally, and the fractions contain one main peptide. The higher amount of immuno active peptide allowed reflectron-TOF measurements at unit resolution to confirm the molecular weight to within 100 ppm or better accuracy (when external calibration was used). Comparison of the measured M.W. to those of all the possible peptides containing the critical epitop gave us two candidates peptides, HEL 48-62 and HEL 48-63. PSD spectra of the two peptides and comparison to a synthetic analog allowed complete sequencing. The structure of these peptides was determined to be DGSTDYGILQINSRW and DGSTDYGILQINSRWW, which is HEL 48-62 and 48-63 (see figure 1). This result is nearly the same as that obtained previously[1].

Thus, sufficient amounts of HEL are generated and processed within the cell to allow characterization of the recovered fragments by this stategy. APC cells expressing mutated HELs proteins are currently being grown, and characterization of the peptides presented would allow detailed investigation of antigen processing and fragment binding to class II MHC molecules.

Annelid hemoglobins (Hbs) have a high mass (~3 5MDa) and consist of ~144 functional globin chains (16-18kDa) and ~36-40 linker chains (24-32kDa) necessary for the formation of the native structure Some of the different chains are monomeric but others form disulphide-bonded multimers e.g dimers (leech), trimers (earthworm) or tetramers Also, depending on the species, some chains are glycosylated. Thus the mixture of proteins produced from denatured annelid Hbs is generally complex e g denatured earthworm Hb contains ~15 major proteins and glycoproteins with molecular weights between 16 and 53kDa

A basic step in investigating the tertiary structure of these Hbs is to determine the precise masses of the non-covalently bound proteins present in the native molecule and also, by reducing and reducing/derivatising the native Hb, determine the masses of the chains which make up the multimers From such data, particular chains can be unambiguously associated with particular multimers and chain sequences (if known) validated. We have used electrospray ionisation mass spectrometry (ESI-MS) with maximum entropy (MaxEnt) processing of the m/z data to analyse several native annelid Hbs and their reduced/derivatised/ deglycosylated products without prior chromatographic separation MaxEnt automatically disentangles the complex multiply-charged data as it is originally produced by the mass spectrometer and presents each protein as a single peak on a true molecular weight scale The precision of mass measurement from ESI-MS-MaxEnt data is generally better than 0 01% MaxEnt also enhances the resolution

Samples (0 2-0 5μg/μl of 50% aqueous CH_3CN plus 0.2% HCOOH) were analysed on a VG Quattro II Scanning was from m/z 550-2500 (10sec/scan) and data collected over 5-10min Data were processed using the MaxEnt software supplied with the instrument.

Spectra from a marine worm (*Tylorrhynchus*) Hb are shown as typical examples in the Figure Panel (A) shows the m/z data from the native Hb and (B) after processing by MaxEnt Present are a monomer (M), linker degradation products (L3-L5), a trimer (T) and a dimer (D). Panel (C) is the result from mildly reduced Hb showing the appearance of 3 trimer chains (IIA, IIB & IIC) and 2 linkers (L1 & L2) which are dimeric in the native Hb. The reduced Hb (5μg/μl Hb in H_2O +2mM DTT) was analysed after simple dilution (x1/10) i.e without purification Panel (D) is the result from fully reduced/carbamidomethylated (Cam) Hb, showing all the chains, except the monomer, plus an appropriate number of Cam groups

Below are summarised the masses for *Tylorrhynchus* (3 determinations) derived from the reduced/Cam data (Reduced Mass) and are within 0.01% of the masses calculated from the sequences with Cys reduced (Sequence Mass) Measurements from the native Hb (Native Mass) agree well with the masses Calculated from Reduced Masses when allowance is made for the number of disulphide bonds present The measured mass of the monomer is outside experimental error of the sequence mass, inferring the sequence is incorrect

CHARACTERIZATION OF THE HEMOGLOBIN OF *CEBUS APELLA* BY MALDI-MS

Tun-Li Shen[1], Robert B. Johnson[2], Steven Buck[2], Morris Goodman[2], and Douglas A. Gage[1]
[1]Department of Biochemistry, Michigan State University, East Lansing, MI 48824
[2]School of Medicine, Wayne State University, Detroit, MI 48202

The primary function of hemoglobin, a tetrameric molecule that consists of four globin chains, is to transport oxygen in vertebrates. Hemoglobin in adult vertebrates has the structure $\alpha_2\beta_2$, and fetal hemoglobin has the structure $\alpha_2\gamma_2$. The timing and control of the expression of globin genes during development varies among different species[1]. Like humans, the primate *Cebus apella* has two γ-globin genes. Genetic analysis indicates both genes have potential to encode a complete γ-globin chain. The main objective of this work is to establish the identity of the γ-globin chain(s) expressed in the fetus of *C. apella*.

The primary structure of the *C. apella* γ-globin chains deduced from the cDNA sequence are shown below. The two γ-globin chains have the same structure except the amino acid residue 117 of the Cebus apella γ1-globin chains is Val rather than Ile; γ1: MW 15923, γ2: MW 15937.

1 MSNFTAEDKAAITSLWAKVNVEDAGGETLGRLLVVYPWTQRFFDSFGSLS
51 SPSAIMGNPKVKAHGAKVLTSLGEAIKNLDDLKGTFGQLSELHCDKLHVD
101 PENFRLLGNVLVTVLA*I*HHGKEFTPEVQASWQKMVAGVASALGSRYH

The γ-globin chains of *C. apella* were characterized by the following MALDI-MS experiments: molecular weight measurements, tryptic digestion and peptide mass mapping, and TCEP reduction of intact globins and tryptic peptides. All the MALDI spectra were obtained on PerSeptive Biosystems Voyager Elite mass spectrometer. Experiments were performed using α-cyano-4-hydroxycinnamic acid as the matrix. Tryptic digestion were carried out in 400 mM TrisHCl (PH 8.0), 6 M guanidine, 40 mM $CaCl_2$, sequencing grade modified trypsin was then added with a protein/enzyme ratio ~ 20 (W/W). Digestion mixtures were analyzed by MALDI-MS without further fractionation or purification. Tris(2-carboxyethyl)phosphine hydrochloride (TCEP) is an effective reagent for complete reduction of disulfide bonds[2]. Reduction of the globin chains were carried out with a fifty-fold molar excess of TCEP solution in a water bath at 37° C for half an hour.

The molecular weight of three rpHPLC-purified globin chains suggested that γ2-globin chains are the predominant polypeptide chain expressed in fetal *C. apella*. One peak CaE displayed MH^+ ion at 15137 close to the predicted mass of γ2 containing the initiator methionine. The MALDI spectrum of a second globin peak contained a MH^+ ion at m/z 15852, which is consistant with γ2 globin that is N-acetylated at ser-2 after loss of the initiator methionine. The MH^+ ion of a minor HPLC peak, CaD, did not correspond to the predicted mass of any globin chain. The observed MH^+ ion at m/z 16162 (see Figure 1) was approximately 300 Da higher than that expected for the γ2 chain (with ser-2 N-acetylated). Since this mass increment is close to that produced by a glutathione adduct (+305Da, γ-glu-cys-gly), we speculated that this modification could have produced the mass discrepancy. Therefore, a reduction experiment to remove the putative glutathione adduct which supported this hypothesis was carried out (see Figure 1 inset).

The key tryptic peptide that distinguishes the globin γ1- from γ2- globin is the fragment that encompasses the amino acid residue 117 (Val vs. Ile, Δ 14 Da). The sequences for the key peptide fragments of γ1-, and γ2- globin chain are: [106-121]

43rd ASMS Conference on Mass Spectrometry and Allied Topics

γ2: LLGNVLVTVLA*I*HHGK (MH^+ at m/z = 1684); γ1: LLGNVLVTVLA*V*HHGK(MH^+ at m/z = 1670)

The results from the tryptic digests show that all globins contain the MH^+ ion at ~ m/z 1684 and are thus γ2. Treatment of HPLC fraction CaD with TCEP, followed by MALDI-MS analysis supported. The TCEP reduction of the CaD tryptic digest produced a mass shift of ~ 300 Da for the m/z 2850.6 peak to m/z 2540.6 which corresponds to peptide [84-105] (calculated m/z 2542), which containing cysteine-94.

2. E. J . Zaluzec, D. A. Gage, and J. T. Watson, *J Am. Soc. Mass Spectrom.* 5, 359(1994).

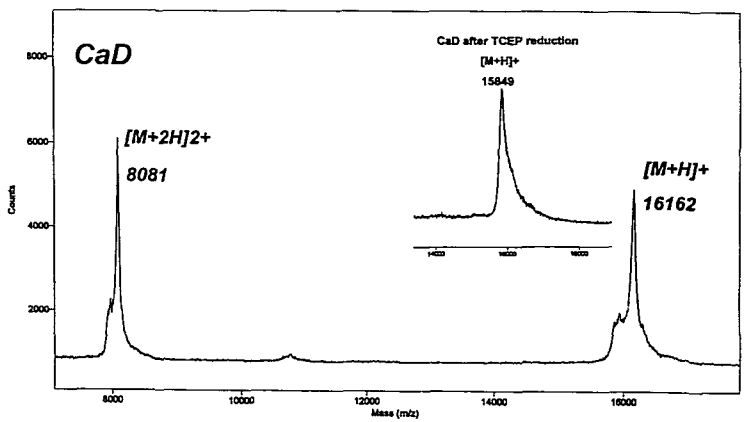

Figure 1. MALDI spectrum of CaD showing a prominent peak at m/z 16,162 for the protonated molecule, with a corresponding doubly-charged peak at m/z 8081. A shoulder is present on the low mass side of the $[M+H]^+$ peak which is close to m/z 15842. Reduction of the sample with TCEP produced a shift in the mass of the product from m/z 16,162 to 15189 (see inset). This shift in mass is close to that expected for the reductive cleavage of a glutathione adduct. Thus the peak at m/z 16,162 is interpreted to represent γ2 modified by glutathione addition.

CHARACTERIZATION OF THE HEMOGLOBIN FROM *BUENOA SCIMITRA*

Z. R. Kong,[§] K. L. Rinehart,[§] C. R. Vossbrinck,[†] R. Huang,[§] R. M. Milberg,[§] F. R. Sun [§]

Introduction

Hemoglobins have been found in the tissues of only four groups of insects: chironomids, gasterophilids, notonectids, and corixids. Because of their unusual functions, the hemoglobins from the Notonectidae, including *Buenoa* and *Anisops*, are particularly interesting,[1,2] but the structures, properties and functions of the hemoglobins in *Buenoa* remain unexplored. In order to understand the structure and function relationship of *Buenoa* hemoglobin, it is essential to know the protein sequence. The amino acid sequence of the hemoglobin's major component (Hb) from *B. margaritacea* was assigned previously.[3] Due to their similar functions in the insects' lives, it was assumed that the sequence of *Buenoa scimitra* Hb was similar to that of *B. margaritacea* Hb. In this work, we present mass spectrometric strategies and results in the characterization of the primary structure of *B. scimitra* Hb.

Experimental

Hemoglobin was collected from the insects' abdomens as described previously.[4] Purification of Hb was performed using reversed phase HPLC with CH_3CN (0.045% TFA and 10% H_2O) and H_2O (0.05% TFA) being used as delivery solvents.

Tryptic digestion of Hb was accomplished using trypsin in NH_4HCO_3 and urea solution (pH 8.4). *S. aureus* V8 digestion of Hb was accomplished using endoproteinase Glu-C in Na_2HPO_4 buffer (pH 7.7). The enzyme to substrate ratio was 1:50 (wt/wt).

ESIMS spectra were acquired on a VG Quattro mass spectrometer. LR/FAB spectra were obtained on a VG ZAB-SE mass spectrometer. MALDI spectra were acquired on a VG Tof-Spec time-of-flight mass spectrometer with a UV (337 nm) nitrogen laser. HR/FABMS data and FABMS/MS spectra were obtained on a VG 70-SE 4F mass spectrometer.

Results and discussion

Tryptic digestion of purified Hb yielded more than 20 peptides. Comparison of these results with those of *B margaritacea* revealed that most of peptides were expected, but some were unexpected $(M+H)^+$ ions. It was assumed that the expected peptides had the same amino acid sequences as those of *B. margaritacea*. These expected peptides were further characterized by MS/CID/MS and HR/FABMS.

For the unexpected $(M+H)^+$ ions, including *m/z* 2310, 1368, 933, 904, amino acid sequencing was only achieved on an ion at *m/z* 467.4, which was a doubly charged ion corresponding to the peptide at *m/z* 933. The amino acid sequence, H-TLQEMGVR-OH, was deduced from the CID spectrum (Figure 1). This sequence corresponded to amino acid positions 91-98, with Lys replaced by Arg at position 98 in the primary structure of *B. margaritacea* Hb.

S. aureus V-8 digestion was performed on Hb under specific conditions so that the protein was specifically cleaved at C-terminal aspartic acid and glutamic acid residues. The digest was analyzed by LC/ESIMS, ESIMS and MALDIMS. Comparison of these results with those from computer-assisted *S. aureus* V-8 digestion of *B margaritacea* Hb revealed that a peptide containing the amino acid homolog, Arg-98, showed up in the digest.

The enzymatic digestions provided two sets of Hb peptides. Proper alignment of these peptides was accomplished, which led to the Hb sequence. When Lys-98 in *B. margaritacea* Hb is replaced by Arg-98 in *B. scimitra* Hb , the molecular weight shifts to 17,707 Da by an increase of 28 mass unit. This molecular weight matches the experimental molecular weight determined by ESIMS, suggesting that there was only one amino acid difference between the two hemoglobin's major components.

Because the specificity of enzymes cannot be relied upon all the time, unexpected cleavages are frequently encountered. A computer-assisted search for the possible amino acid sequences of unexpected peptides was performed.

Conclusion.

The primary structure of *B. scimitra* Hb has been assigned by mass spectrometric methods. Comparison of this sequence with that of *B. margaritacea* Hb leads to the conclusion that there is only one amino acid difference. Their sequential similarity suggests that the Hb tertiary structures in the *Buenoa* genus are similar, which lead to similar functions and properties of the hemoglobins in the insects' lives. It has been reported that the functions of the hemoglobins are cooperative, that is, the binding of oxygen at one heme facilitates the binding of oxygen to the other hemes. Therefore, it is necessary to explore the hemoglobin's minor components. Protein sequencing of the hemoglobin's minor components is in progress.

HEMOGLOBIN ANALYSIS BY ELECTROSPRAY IONIZATION MASS SPECTROMETRY: QUADRUPOLE vs. MAGNETIC SECTOR.

Earl L. White, Mary S. Uhrig, Betsy A. Reed-Bombick and Inhou Chu, Product Evaluation Group, Research and Development Department, R.J. Reynolds Tobacco Co., Winston-Salem, NC 27102

INTRODUCTION

A method to detect relatively small changes in molecular weight of macromolecules was necessary to investigate intact hemoglobin molecules for possible adduct formation. Electrospray ionization mass spectrometry (ESI-MS) is a soft ionization technique whose utility is best suited for molecular weight determination of large molecules. Hemoglobin is a large tetrapeptide containing a pair of α- and non-α chains with 141 and 146 amino acid residues each, respectively. Hemoglobin is believed to form covalent adducts with several compounds commonly found in the environment. ESI mass spectrometry utilizing both quadrupole and electric/magnetic sectors for analysis can be used for studying macromolecules. Human hemoglobin samples were analyzed with both of these techniques and compared. The objective of this study was twofold. 1). To compare ESI-MS hemoglobin data from quadrupole and magnetic sector mass spectrometers. 2). To determine if relatively small molecular weight differences (~100 daltons) could be detected in intact hemoglobin from human lysate samples.

EXPERIMENTAL

Sample Collection and Preparation. Ten mL of blood sample were centrifuged to generate packed red blood cells, wash three times with 0.9% saline and lyse w/deionized water. The lysate was then washed with toluene to remove small organic compounds, centrifuged and dialyzed at 4 °C for 2 days. The hemoglobin lysate samples were diluted 1000 fold with a 0.1% formic acid-MeOH or $CH_3CN:H_2O$ (50:50) solution, filtered with a Amicon 10kDa cut-off filter and desalted with 200 μL of 0.1% formic acid.

Electrospray Ionization Mass Spectrometry. A Fisons Quattro II and AutoSpec EQFPD mass spectrometers were used for analyses. Ionization mode was positive ion electrospray. The scan range was 980-1300 amu and a scan time of 5 seconds/decade for the sector instrument. The sample was introduced by loop injection and the mobile phase was 50:50 $MeOH:H_2O$ + 1% acetic acid. The flow rate was 10 μL/min.

DISCUSSION

Quadrupole Data:

AFS Control (adult, fetal and sickle cell) was used for calibration of the instrument. Maximum entropy calculations (MaxEnt®) were performed to further enhance the resolution. The results of desalting was clearly demonstrated.

Magnetic Sector:

The expanded region of an ESI spectrum acquired at a resolving power of 15,000 (m/z = 1007-1012 amu, z≈15 for α-chain) depicted well resolved ^{13}C contributions. However, spectra acquired at nominal mass resolution closely resembled that of the quadrupole.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

RESULTS

Molecular weights for adult human α- and β-hemoglobin chains were found to be 15,126.36±0.02 and 15,867.49±0.51 Da (quadrupole) and 15,126.01±0.48 and 15,867.48±0.92 Da (magnetic sector), respectively. Molecular weights for the heme plus α-chain (15,741 Da) and heme plus β-chain molecular weight (16,482 Da) were easily determined by both techniques. Glycated α- and β-chains (m/z = 15,288 and 16,029 Da, respectively) were detected with both systems, but with more interference in the quadrupole analysis. These results show that relatively small differences in the molecular weight of hemoglobin can be detected with this technique allowing exploration of adduct formation. Data from the magnetic sector instrument were superior, even at nominal-mass resolution. Maximum entropy calculations appeared to enhance resolution such that quadrupole analyses might be sufficient for exploring adduct formation.

SUMMARY

Electrospray ionization mass spectrometry was used to show that relatively small differences could be easily detected with this technique. The accuracy of the technique was found to be 0.003% (daltons), on the average. Molecular weight increments/decrements greater than 14 daltons could be easily detected. Deconvoluted/transformed spectrum for AFS sample indicates that a higher resolving power would significantly enhance the capabilities for detecting small molecular weight differences and would be required for detecting molecular weight changes less than ± 14 daltons. Desalting samples reduced Na^+ and K^+ adduct formation, therefore enhanced resolution for minor component detection.

Table 1. Expected vs. Observed Molecular Weights for Various Globulin Chains of Hemoglobin.

	Molecular Weight (Da)		
Hemoglobin Chain	Expected	Observed*	%RSD
α-Chain	15,126.4	15,126.9	0.003
β-Chain	15,867.2	15,868.1	0.006

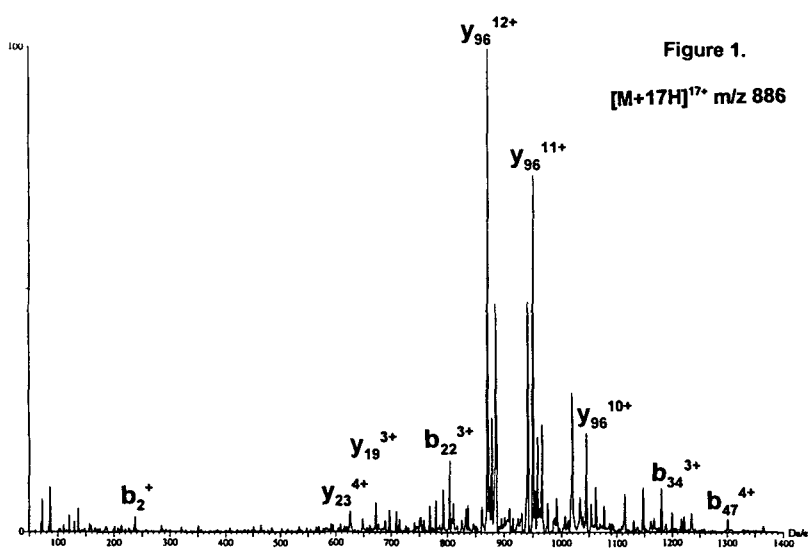
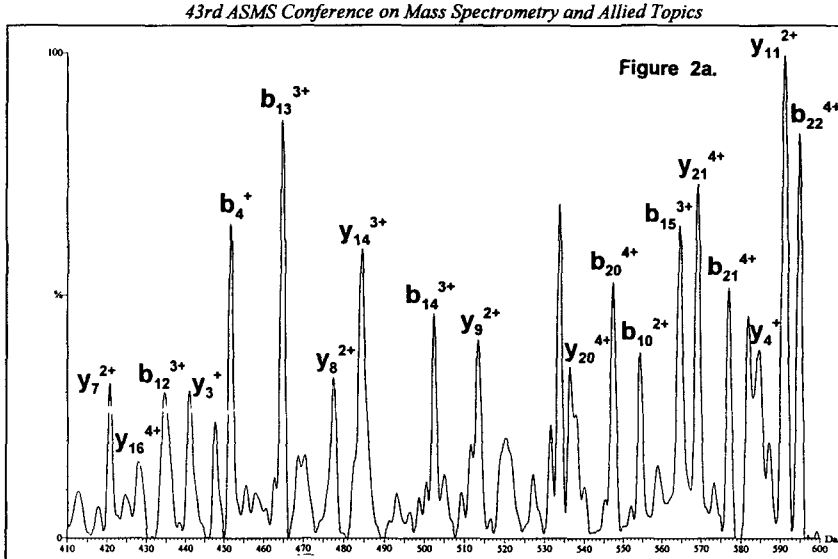
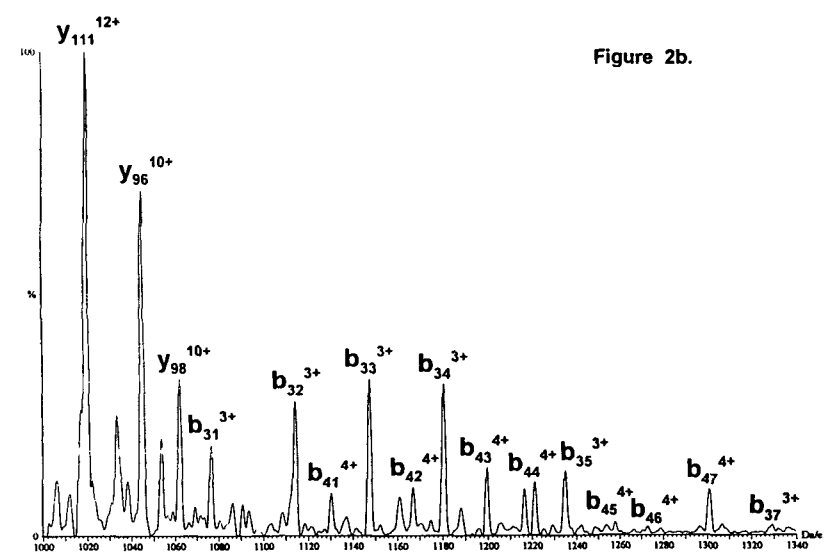
Aberrant haemoglobins in the blood of humans may have a range of effects on the carrier from no abnormal activity to severe conditions such as sickle cell anaemia. Most clinical conditions are due to the variation of one or two amino acids along the alpha chain (141 residues, 15126.4 Da), the beta chain (146 residues, 15867.2 Da) or the delta chain (146 residues, 15924.3 Da) of the haemoglobin unit, altering both the primary structure of the protein, and in many cases, its mass. Multiply-charged ions of the intact chains may be observed by means of electrospray ionisation (ESI) and a quadrupole mass analyser

The masses of the alpha and beta chains can be measured to within 0.01% so that a shift in mass as low as 1 Da can be detected. Where variant and normal chains coexist, a difference of 6 Da can be detected. This study has led to the development of optimised conditions for the electrospray ionisation of a range of haemoglobins for both ESI/MS and ESI/MS/MS. Results are illustrated by CID of the human δ chain.

Low energy CID of the δ chain (15924.3 Da) of Hb A_2 is shown in Figures 1 and 2 for the $[M+17H]^{17+}$ ion where approximately 40% of the amino acid sequence may be identified from the C- and N-terminal ions. The sequence ion series b_2 to b_{47} and y_1 to y_{111} cover the entire δ chain so that the position of an amino acid substitution may be located along the molecule.







ISOLATION AND IDENTIFICATION OF GLOBULIN CHAINS OF HUMAN HEMOGLOBIN BY ELECTROSPRAY IONIZATION MASS SPECTROMETRY.

Inhou Chu* and Earl L. White, Product Evaluation Group, R.J. Reynolds Tobacco Company, Bowman Gray Technical Center, Winston-Salem, NC 27102

Introduction

Separation and quantification of hemoglobin adducts present a great challenge to many scientists [1]. GC/MS continues to be the method of choice for the analysis of hemoglobin adducts, even though laser-induced fluorescence spectrometry has shown some promising results [1]. In order to determine hemoglobin adducts by GC/MS, the adduct molecule has to be released from the hemoglobin and converted to a volatile form amenable to gas chromatography. This requires hydrolysis and derivatization of the samples which might be very destructive and sometimes, produces artificial results [1]. Aromatic amine adducts, for example, might generate free aromatic amines after the conversion which are indistinguishable from free amines that might arise from other sources.

We have initiated a systematic research program to study the interactions between hemoglobins and aromatic amines directly. Here, we present some of our initial results which include both isolation and identification of the globulin chains by HPLC/MS. Other approaches include enzymatic digestion of adduct molecules and synthesis of samples with higher hemoglobin/adduct ratios which are still under investigation.

Experimental

Sample Preparation Blood samples in this study were collected from both smoker and non-smoker volunteers. The samples were centrifuged to give packed red blood cells. The red blood cells were washed three times with 0.9% saline, lysed by the addition of deionized water and extracted with toluene to remove small organic molecules. The globulin chains were prepared by adding hemoglobin lysate samples to cold acidified acetone solution. The resulting white precipitates (globulin chains) were separated with a type-40 filter paper and washed several times with HPLC grade acetone.

Instrumentation The instrument used in this work is a high flow rate (up to 1 ml/min.) HPLC-electrospray mass spectrometry system. The column effluent was split approx. 1:1 to both a UV detector and the mass spectrometer for simultaneous detection. The multiply charged electrospray ionization/mass spectrometry (ESI/MS) spectra of separated hemoglobin or globulin chains were deconvoluted to molecular ions and the masses between smoker and non-smokers globulin chains were compared.

The LC/MS interface was a dual stage electrospray ion source purchased from Analytica of Branford, Inc., (Branford, CT) and recently upgraded to accommodate high flow rates. A HP5988A quadruple mass spectrometer (Palo Alto, CA) operating in the full scan mode with a scan range of 600-1500 amu at 0.1 s/scan was used in all experiments. Applied voltages for the electrical elements were optimized while constantly infusing sample solution into the electrospray source. The most sensitive capillary exit potential (EL) was determined by monitoring the ion signal of loop injections of human hemoglobin sample (1/100 dilution). The observed peak area was plotted against EL to determine the optimum capillary exit potential for this investigation.

Result and Discussion

The two major peaks observed in the LC/MS chromatograms of human hemoglobin samples (Figure 1) were identified by ESI-MS as the β- and α-chains, (molecular ions of 15,865

Da and 15,126 Da, Figure 2), respectively. Total ion chromatograms from lysate samples and those precipitated with the cold acidified acetone solution were essentially identical, which suggests that hemoglobins were denatured prior to detection, possibly in the HPLC column. The next step of our researches will be focused on the analyses of synthetic hemoglobin-aromatic amine adduct molecules. The positive identification of the active binding site(s) of the human globulin chains can be accomplished by analyzing the enzymatic digested hemoglobin adduct molecules utilizing the same techniques employed here.

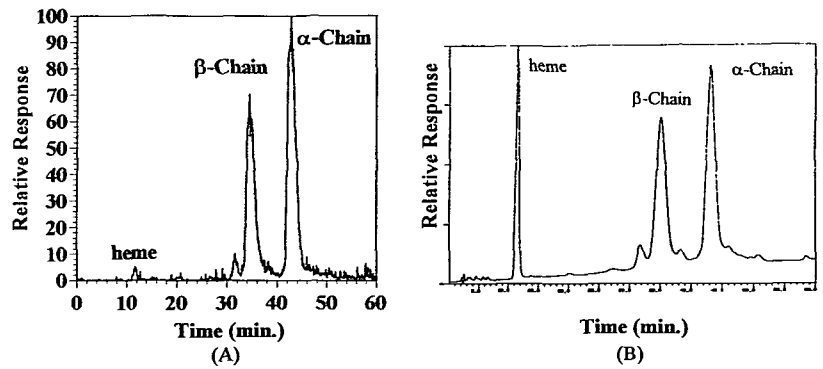


Figure 1. Chromatograms of (A) HPLC/MS and (B) HPLC/UV. Mobile phases: A: 60% CH3CN (0.1% TFAA) and B: 20% CH3CN (0.1% TFAA). Gradient: 50% A to 70% A in 15 min., followed by 70% A to 80% A in 30 min. HPLC column: Vydac C4 column.

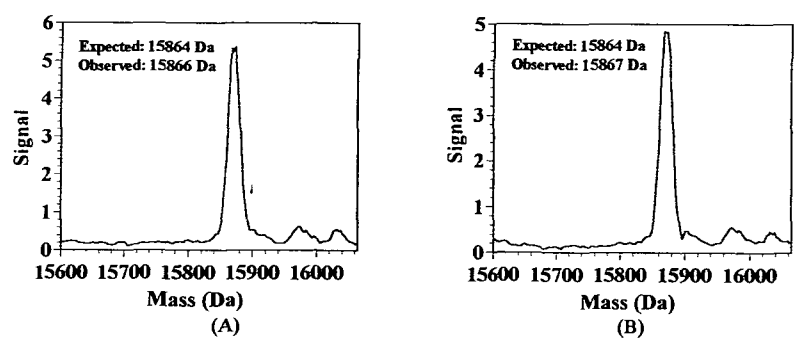

Figure 2. Deconvoluted spectra of (A) human α-chains (expected 15126 Da, observed 15126 Da) and (B) human β-chain (expected 15864 Da, observed 15867 Da).

A Structural Assignment for a Stable Acetaldehyde-Lysine Adduct

[1]Karen P. Braun, [2]Robert B. Cody, [3]Dane R. Jones, and [1]Charles M. Peterson
[1]Sansum Medical Research Foundation, Santa Barbara, CA 93105
[2]JEOL USA, Inc., 11 Dearborn Rd., Peabody, MA 01960
[3]California Polytechnic State University, San Luis Obispo, CA

Introduction. Acetaldehyde is the first oxidation product of ethanol *in vivo*. Lysine residues in proteins such as hemoglobin have bee implicated as target structures for acetaldehyde adducts resulting from ethanol consumption. Although the presence of both stable and unstable acetaldehyde-hemoglobin adducts has been established, the structural characterization of the adducts has received relatively little attention. As a model for such adduct formation, we studied the peptide pentalysine *in vitro*. Pentalysine has several sites for adduct formation. The amino terminal amine group as well as the epsilon-amine groups of each lysine sidechain can serve as potential sites for modification by acetaldehyde. Mass spectrometry, nuclear magnetic resonance, and Raman spectroscopy were employed to demonstrate that acetaldehyde forms a stable linkage to lysine amine groups via a Schiff base.

Methods. *Sample preparation.* Pentalysine (1mM) was purified by reversed-phase HPLC prior to reaction with 1.5, 5, or 8 mM acetaldehyde and incubation at 37°C for 1 hour. Excess unreacted acetaldehyde was removed by ultrafiltration.

Mass spectrometry. Electrospray ionization (ESI) spectra were obtained by using a reverse-geometry double-focusing magnetic sector mass spectrometer (SX102, JEOL, Peabody, MA), equipped with an electrospray ionization source (Analytica, Branford, CT). Samples were diluted 1/10 with a 1:1 mixture of methanol/water containing 0.5% acetic acid and introduced into the ESI source by flow injection at 2µl/min. An unreacted sample of pentalysine was also analyzed as a blank. The ESI mass spectra were dominated by doubly charged species and a trace of singly charged species. Linked scan MS/MS spectra (He collision gas) were also obtained for the doubly charged species from the adduct ions by decreasing the accelerating voltage by 0.5.

Fast atom bombardment (6 keV Xe fast atom beam) mass spectra were also obtained for the samples by using another magnetic sector mass spectrometer (HX110, JEOL, Peabody, MA) and a glycerol matrix.

Results: When a 1.5:1 mole ratio of acetaldehyde to peptide was used, a monadduct was observed (data not shown). Likewise the deconvolved ESI mass spectrum of the model peptide (lys)5-OH following incubation with 20 µM acetaldehyde showed a single acetaldehyde adduct at mass 684 Da. However, when an excess of acetaldehyde was used, the number of

adducts observed increased. For the 8:1 mole ratio acetaldehyde:peptide mixture, five different adducts are observed with masses 684, 710, 736, 762, and 788 Da, respectively. The difference in mass in each case indicates a structure consistent with a Schiff base (a difference of 26 Da as shown in Figure 1, peaks labeled A,B,C,D, and E). Of particular interest is the decreasing relative abundance of adduct with increasing number of Schiff base adducts per molecule. In the sample shown, 40% of the peptide sample had at least 2 adducts, 20% of the molecules have at least 3 adducts, and less than 10% of the sample molecules have 4 or 5 adducts.

Linked scan MS/MS spectra were obtained to ascertain the points of acetaldehyde adduct formation (Table I). For these experiments, pentalysine-acetaldehyde adducts were generated by the addition of acetaldehyde in an 8:1 mole ratio (acetaldehyde to peptide). The pattern of y- and b-type fragment ions (y4+26 and b1+26 Da) is strongly suggestive of modification at the first and second positions of the N-terminus of the peptide. Weak b and y fragments for residues 3,4, and 5 suggest but do not confirm the presence of modifications on those sidechains.

Table 1. Observed product ions from linked scan for precursor m/z 684

N-terminal fragments	Observed b-ion mass	Observed b+adduct mass	C-terminal fragments	Observed y-ion mass	Observed y+adduct mass

Introduction

Mutations in the alpha and beta chains of human hemoglobins ('variant hemoglobins') may lead to serious physiological disorders in the host Mass spectrometry, in conjunction with separation techniques and/or enzyme digestion, has been in use for a number of years in the identification of hemoglobin variants [1,2] In using such methodologies, the structures of many known variants have been confirmed, and new variants have been characterised The advent of electrospray ionization, and its use in quadrupole-based instruments, now allows for the analysis of intact hemoglobin chains by analysing whole blood that has been diluted by a factor of 500 without other preparation

Methodology

Whole blood was diluted 500-fold in 1 1 acetonitrile water, containing 0 2% formic acid 10uL injections of the resultant solution were made into a solvent stream flowing at 5uL/min and passed to the ionization source of a VG Quattro II instrument Normal mass spectra were acquired by scanning from m/z980-m/z1400 in 8 seconds Product ion spectra were acquired after passing the mass-selected precursor ions of interest at appropriate resolution into a hexapole collision cell containing $2x10^{-2}$mbar of methane, and scanning the final quadrupole The collision voltage was typically ramped from 70V @ m/z50 to 45V @ m/z1500 during each 10 second scan in order to generate as much structurally-significant information as possible. Data were acquired for periods of up to 10 minutes

Results and Discussion

A sample was received from a patient believed to be the carrier of a variant hemoglobin beta chain Isoelectric focusing suggested that the variant was either Hb-Camden(Δm=+1) or Hb-Hope (Δm=+58), both of which were shown to be incorrect by mass spectrometry, which demonstrated a mass difference of +14Da, leading to 49 possible sites for single amino acid substitution Product ion spectra from the 16-protonated species from both the normal and the variants globins were compared and the mutation was determined to be in the first or second residue from the N-terminus from the comparison of the $\mathbf{b_2}$ ions in the partial spectrum shown in Figure 1 As the β_2 residue (His) cannot be replaced by single amino acid to give the necessary change in mass, the site of substitution was determined to the β_1 (Val→Leu/Ile) This is a previously unreported mutation, but is isobaric with Hb-Raleigh which shows a substitution at β_1 (Val→acAla). Further chemical analysis would be necessary to unequivocally determine the variant, although the number of possibilities is significantly reduced

An unknown hemoglobin variant was shown to contain a heterozygous alpha chain with a mass difference of 18Da, giving rise to 18 possible sites for single amino acid substitution of Met for Leu (human alpha globin contains no Ile) Product ion spectra from the 18-protonated normal and variant α-globins were compared and a difference was noted in the m/z values for the ion ascribed as $\mathbf{y_{12}}^{2+}$ (8 9Th) (Figure 2), locating the mutation in the final 11 residues of the molecule, at α_{136} Further evidence for the α_{136} mutation is derived from the presence of ions ascribed as $\mathbf{y_4}^+$ and $\mathbf{y_5}^+$ which are not shifted in the product ion mass spectrum of the variant Hemoglobin exhibiting the mutation α_{136} (Leu→Met) has previously been reported as Hb-Chicago

Introduction

For the analysis of complex physiological and biological samples that contain a large variety of different components, a highly resolved separation of the mixture is essential for the subsequent characterization of every single component. Common separation techniques for this purpose are SDS-PAGE, HPLC and CE Recently, Matrix-assisted Laser Desorption/ Ionization Time-of-Flight Mass Spectrometry (MALDI/TOF-MS) has been applied for mass determination of mixture components previously separated by the above methods Here, MALDI was used as a detector for the HPLC fractionation of human blood plasma The different fractions have been collected and mixed with matrix in the usual preparation, i.e. HPLC was coupled off-line to MALDI

Objective Human blood plasma contains a large variety of peptides and proteins in very different concentrations Is the combination of HPLC and MALDI capable to establish a protein map of such a complex mixture? Besides the number of detected proteins also the accuracy of their mass determination is a main criterion

Methods

Sample Preparation Human Blood Plasma was fractionated by two different modes

1. Reversed-Phase HPLC was used only, 29 fractions were collected.
2. The combination of Anion Exchange HPLC and Reversed-Phase HPLC was used, resulting in a more detailed separation into about 120 fractions

In both cases, 1µl of each fraction was mixed with 1µl matrix solution on the MALDI target Matrix was a 9:1 mixture of salicylic acid and 5-methoxysalicylic acid, dissolved at 10 g/l in 9 1 0 1% aeqeous TFA / acetonitrile The MALDI mass spectra were calibrated using Bovine Insulin, Cytochrome C or BSA regarding to the measured MW of the samples.

Exp Setup MALDI instrument was a VISION 2000 reflector-type TOFMS (Finnigan MAT)

Results

When human blood plasma is analyzed by MALDI directly, only a few proteins can be detected with a low signal intensity besides the main component, HSA (fig.1) This demonstrates that for a more detailed investigation a previous separation is essential. After reversed-phase HPLC (fig.3) each fraction still contained up to 10 different components (fig 2) to accelerate the MS analysis of the complete plasma and to avoid a too excessive dilution, that might lead to the loss of components with low concentrations Summarizing all fractions, about 80 diffferent peptides/proteins have been detected, among which ca 50 could be identified by comparison with databases (fig.4) The results of the more detailed fractionation by subsequent anion exchange and reversed-phase HPLC resembled those obtained by reversed-phase HPLC only. However, the latter, easier separation may even be more suited for off-line HPLC/MALDI, as more proteins could be detected MALDI provides for a high sensitivity for the detection of each species, as can be seen in the spectra of fractions that contain several proteins with quite different concentrations The biomolecules have been detected with an overall mass accuracy in the range of 0 033%

The Metal Ion Affinities of Biomolecules Determined by the Kinetic Method

Blas A. Cerda and Chrys Wesdemiotis
Department of Chemistry, The University of Akron,
Akron, Ohio, 44325-3601, U.S.A.

Since a great number of biomolecules require the presence of metal ions for their activity and/or their structural integrity, the role of metal ions in biological processes is varied and essential. One important factor that influences metal ion-biomolecule interactions is the relative intrinsic bond strength between the ionized metal and the various possible binding sites within the hydrophobic interior of the biomolecule. This important thermochemical property can be obtained based on the gas phase unimolecular dissociation of metal ion-bound heterodimers containing the biomolecules of interest (kinetic method).[1] Here we used this method to determine the relative copper (I) affinities (Cu^+A) of amino acids (a.a.) and the alkali metal ion affinities (M^+A) of DNA nucleobases.

Copper(I) affinities of amino acids. For the 20 common alpha-amino acids, we find the Cu^+ affinities to increase in the order Gly < Ala < Ser < Val < Leu < Ile < Thr < Pro < Asp < Asn < Glu < Phe < Tyr < Cys < Gln < Met < Trp < His < Lys < Arg and their values fall within <20 kcal/mol. For comparison, the proton affinities of amino acids cover a range of >33 kcal/mol. Correlation of the experimentally derived Cu^+A order to the reported proton[2] and sodium ion[3] affinity orders of amino acids points out that the Cu^+-A.A. bond is longer and less covalent in nature than the H^+-A.A. bond. Increasing the alkyl side chain of the amino acid, and hence inductive effects, augments the proton affinity substantially more than the Cu^+A. Further, soft donor groups, such as SH of cysteine, SCH_3 of methionine or the aromatic π-electrons of phenylalanine, stabilize Cu^+-A.A. bonds more than H^+-A.A. or Na^+-A.A. bonds

Alkali metal ion affinities of nucleobases. The kinetic method can provide absolute metal ion affinities, if reference bases of known M^+A are available. In such a case, heterodimers of the biomolecule of unkown M^+A (B) and the reference bases (B_i) are investigated (eqs 1 and 2):

$$B\text{-}M^+\text{-}B_i \xrightarrow{k} B\text{-}M^+ + B_i \quad (1a)$$

$$B\text{-}M^+\text{-}B_i \xrightarrow{k_i} B + M^+\text{-}B_i \quad (1b)$$

$$\ln (k_i/k) = [M^+A(B_i) - M^+A(B)] / RT \quad (2)$$

We used this relationship to appraise the Li^+ and K^+ affinities of the nucleobases, thymine, adenine, cytosine, and guanine, using aniline, pyridine, and n-propylamine as reference bases for the K^+A,[4] and pyridazine,[5] pyridine, dimethylformamide,[6] glycine, alanine, and valine,[3] for the Li^+A of the nucleobases.

Based on eq 2, plotting ln (k_i/k) vs. $M^+A(B_i)$ gives both RT and $M^+A(B)$. Such a plot for which B = cytosine is shown in Figure 1. From the slope and intercept of this graph, the effective temperature (T) and the K^+A of cytosine are found to be 442 K and 24.4 ± 0.3 kcal/mol, respectively. Similar plots for the other nucleobases and for heterodimers of Li^+

lead to the affinities summarized in Table 1. The proton affinities of these nucleobases[7] are also included for comparison. From the data in this table it can be seen that the proton and alkali metal ion affinities decrease in the order Gua > Cyt > Ade > Thy. This common behaviour is consistent with all three cations being hard Lewis acids. Finally, for a given nucleobase the affinities decrease in the order: PA > Li^+ > K^+A. Evidently, the bond strength decreases as the ionic radius of the Lewis acid increases, presumably because of lowered covalent bond character.

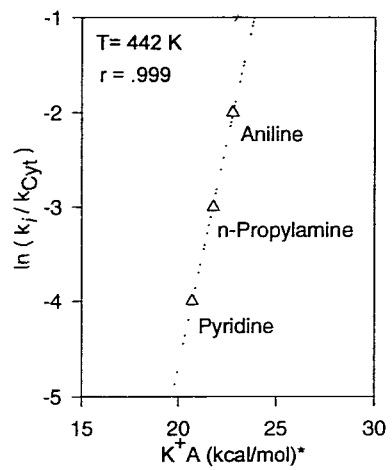

Figure 1. Effective temperature for cytosine.

METAL ION ASSISTED DERIVATIZATION OF BUCKMINSTERFULLERENE

Steven Z. Kan, Yong G. Byun, Samuel A. Lee, Young C. Xu and Ben S. Freiser
Department of Chemistry, Purdue University, West Lafayette, IN 47907 USA

The development of new materials and new chemicals based on C_{60} and other fullerenes is currently an area of intense study. In particular, a large effort has been focused on the production of fullerene derivatives through C-C bond formation.[1-3] Here we demonstrate that the derivatization of C_{60} can be catalyzed by a metal center through two potential routes - reactions of metallated C_{60} ions with neutral molecules and reactions of metal-ligated ions with C_{60}.

The study is carried out on an Extrel FTMS-2000 Fourier transform mass spectrometer. C_{60} is introduced by using a solids probe at 350 °C and the source temperature is kept at around 220 °C to maintain a static background pressure of C_{60}. Neutral reactants are introduced via either a leak valve or a pulsed valve. Argon at ~10^{-6} Torr is used as the collision gas for collisional activation experiments. FT-ICR ion ejection techniques are used to isolate ions and to determine ion/molecule reaction pathways.

Co^+ generated by laser desorption undergoes both charge transfer and attachment with C_{60}. **Figure 1** shows the reactions of CoC_{60}^+ with cyclopropane (c-C_3H_6) in which both metallated and unmetallated C_{60} derivatives are formed via reactions 1 and 2. Collision-induced dissociation (CID) experiments and ion/molecule reaction results indicate that C-C bonds are formed in these product ions.

$$CoC_{60}(CH_2)_n^+ + c\text{-}C_3H_6 \xrightarrow{n = 0-2} CoC_{60}(CH_2)_{n+1}^+ + C_2H_4 \quad (1)$$

$$\xrightarrow{n = 0-3} C_{60}(CH_2)_n^+ + CoC_3H_6 \quad (2)$$

$$Fe(C_6H_4)_n^+ + C_{60} \xrightarrow{n = 1-4} FeC_{60}(C_6H_4)_n^+ \quad (3)$$

$$FeC_{60}(C_6H_4)_n^+ + C_6C_5Cl \xrightarrow{n = 1,2} C_{60}(C_6H_4)_n^+ + [C_6C_5FeCl] \quad (4)$$

Figure 2 shows that the ligated ions $Fe(C_6H_4)_x^+$ (x=1-4), formed by reacting Fe^+ with chlorobenzene,[4,5] react with background C_{60} to form metallated and unmetallated C_{60} phenylene derivatives, reactions 3 and 4. A coupling mechanism that accounts for the formation of $FeC_{60}C_6H_4^+$ and $C_{60}C_6H_4^+$ is shown below. **1** also represents a new class of C_{60} derivatives with C_{60} being an η^1 ligand and suggests that it will be possible to prepare similar metallacyclic C_{60} derivatives in the condensed phase.

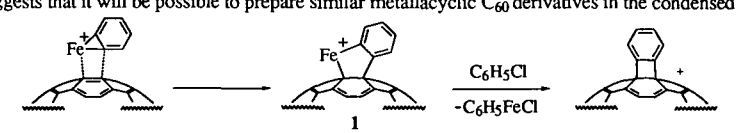

Figure 3 illustrates the reactions of RhC_{60}^+ with both iodomethane and diiodomethane, reactions 5 and 6. Upon CID, $C_{60}CH_3^+$ fragments at a center-of-mass energy of ~ 6 eV, while $C_{60}CH_2^+$ fragments at ~ 16 eV, suggesting that the former contains one C-C bond and the latter contains two C-C bonds.

$$RhC_{60}^+ + CH_3I \longrightarrow C_{60}CH_3^+ + RhI \quad (5)$$

$$RhC_{60}^+ + CH_2I_2 \longrightarrow C_{60}CH_2^+ + RhI_2 \quad (6)$$

Amino Acid and Peptide Reactions with Ground State Metal Ions Studied by FT-ICR

Q. Paula Lei and Jonathan Amster*

Department of Chemistry, University of Georgia

Athens, GA 30602

I. INTRODUCTION

Electrospray ionization and laser desorption are reliable methods for ionizing biomolecules to measure molecular weights, to obtain structural information for sequencing a protein or DNA, controlled fragmentation of the molecular ion would be useful. Collisional dissociation method such as SORI, VLE CAD, MECA and multiphoton dissociation of large molecules etc have been used in several groups. A great deal of work in gas phase chemistry has shown that transition metals exhibit high reactivity toward hydrocarbons, carbonyl compounds and amines. Based on the idea of using metal ions to fragment peptides and studying the chemistry of metal ion reactions, we have implemented a systematic study on the metal ions Cu^+ and Fe^+ reactions with 20 common amino acids, the building blocks of proteins, and two dipeptides, by laser desorption /chemical ionization - combined with FT-ICR.

II. EXPERIMENTAL

A Fourier transform mass spectrometer has been specifically designed and constructed for LD/CI experiments. The magnetic field used in the experiments was 1 tesla The analyzer cell of the mass spectrometer (4 4cm cube) was housed in a UHV chamber evacuated to a base pressure of $2x10^{-10}$ torr by a turbo molecular pump The solid samples, which are prepared by electrospray deposition, are first introduced into the antechamber and later to the main chamber by a magnetically coupled manipulator Metal ions formed by laser ablation were axialized by tens of thousands of thermalizing collisions with N_2 gas by using quadrupole excitation The neutral molecules are produced by the substrate assisted laser desorption method. Metal ions are then allowed to react with the neutral amino acid molecules in the ICR cell

III. RESULTS AND DISCUSSION

Figure 1 shows some representative spectra of amino acids reaction with Cu+ and Fe ions, and **Figure 2** summarizes the reaction pattern of amino acids and dipeptides A similar pattern of the amino acids reaction with the metal ions and dipeptide reaction with metal ions has been observed Metal attachment appears to be directed around the carbonyl function, with loss of CO, CO_2 or CO_2+H_2 For the dipeptides, fragmentation around the peptide bond with metal adduction such as (b1+metal)+ and (x1+metal)+ has have also been seen

MS AND MS/MS OF COORDINATION BETWEEN NATIVE GANGLIOSIDES AND ALKALI METAL IONS

Lambert C. M. Ngoka and Catherine E. Costello, Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139*

Complexation of gangliosides with alkali metal ions is involved in fundamental biological processes, control of ionic equilibria, neuronal signal transmission, regulation of transport enzymes, stabilization of secondary and tertiary structures of macromolecules, and long term adaptive processes such as learning, memory and ecophysiological adaptation[1,2]. Examination of ganglioside-metal complexes by mass spectrometry may provide some insight on the factors that govern selectivity in these interactions. Liquid SIMS and tandem mass spectrometry in conjunction with collisional activation on a four sector JEOL HX110/HX110 instrument have furnished novel structural and physicochemical data on gas phase complexes between gangliosides and alkali metal ions. The complexes were formed in the ion source by bombarding the appropriate ganglioside sample on the probe tip with a 25 keV Cs^+ beam from a cesium ion gun. The ganglioside sample was dissolved in a 1:1 glycerol/*m*-nitrobenzyl alcohol matrix which had been saturated with the appropriate alkali metal iodide(s). Gas phase complexes were accelerated to 10 keV and collided with helium gas in a collision cell (floated at 3 kV) located between MSI and MSII. Product ions were recorded on MSII during linked scans at constant B/E.

Both Liquid SIMS and MS/MS studies show that monosialogangliosides bind to two alkali metal ions with elimination of a proton to form $[M - H + 2m]^+$, where M is ganglioside and m is an alkali metal ion. Disialogangliosides form $[M - 2H + 3m]^+$ and trisialogangliosides form $[M - 3H + 4m]^+$. Free carboxyl groups of the sialic acids are required for the formation of these complexes.

Figures (a) and (b) show MS/MS spectra of $[M - H + 2Li]^+$ and $[M - H + 2Cs]^+$ of monosialoganglioside G_{M1}. Fragment ions arise from both carbohydrate and ceramide portions of the molecule, and represent glycosidic and ring cleavages. Ability to form complexes depends on the formation of metal dimers. In passing from Li to Cs, the ability to form dimers increases, the absolute abundances of all precursor and fragment ions increase, the degree of ring fragmentation decreases and the relative abundances of free metal cations increase. These studies have lent insights into (a) the coordination chemistry of the alkali metals with native gangliosides, (b) new aspects of the chemistry of the alkali metals, for example, trends in the formation of dimers. (c) information on possible origins of selectivity and mechanisms by which gangliosides regulate sodium and potassium ion fluxes across plasma membranes. Fundamental physicochemical data (affinities, for example) and improved structural determination of gangliosides are some of the new perspectives from these studies.

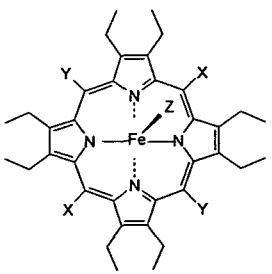
Electron Affinity and Catalytic Activity of Fe(octaethylporphyrin(NO_2)$_n$)

Lei Jin†, T. Wijesekera‡, P. E. Ellis, Jr‡., J. E. Lyons†,‡ and D. P. Ridge†

Department of Chemistry and Biochemistry and
Center for Catalytic Science and Technology
†University of Delaware, Newark, DE 19716, and
‡Sun Company, P. O. Box 1135, Marcus Hook, Pennsylvania 19061

Previous work in our laboratories has shown that the electron affinities of halogenated metal tetraphenyl porphyrins (TPP) are correlated with catalytic activities of those metalloporphyrins.[1] We also found that comparison of the electron affinities with the condensed phase reduction potential of the met TPPs revealed the nature of the LUMO of the neutral metal TPP. We report here the extensiion of our previous study to a different class of metalloporphyrins. Instead of tetraphenyl porphyrins with phenyl substituents in the meso positions, we examined octaethyl porphyrins (OEP) with ethyl substitutents in the β-pyrrole positions. The species examined are indicated below.



Fe(OEP)	X=Y=H, no Z
Fe(OEP)Cl	X=Y=H, Z=Cl
Fe(OEP(NO_2)$_2$)	X=H, Y=NO_2, no Z
Fe(OEP(NO_2)$_2$)Cl	X=H, Y=NO_2, Z=Cl
Fe(OEP(NO_2)$_4$)	X=Y=NO_2, no Z
Fe(OEP(NO_2)$_4$)Cl	X=Y=NO_2, Z=Cl

Electron Affinities were measured by examining charge reactions between the metalloporphyrins and species of known electron affinity. Using FTMS methods (FTMS 2000, Extrell FTMS, Madison Wisconsin) equilibrium constants and ΔG for the charge transfer processes could be determined. From ΔG, ΔH could be estimated giving an electron affinity difference. The resulting electron affinity ladder is shown in Fig. 1. Double headed arrows indicate equilibrium constant measurements and single arrows represent cases where all that could be determined was the sign of ΔG.
Fig. 2 shows the relationship between the catalytic activity and the electron affinity. The turn-over number (TON) is a measure of the rate constant for the catalytic oxidation of cyclohexane to cyclohexanol by O_2. The squares represent Fe(OEP(NO_2)$_2$)Cl, Fe(OEP(NO_2)$_4$)Cl and two halogenated

Fe(TPP)Cl species. These two families of catalysts follow the same correlation suggesting that electron affinity measures the electronic properties critical for catalytic efficiency. The crosses indicate unsubstituted Fe(OEP)Cl and Fe(TPP)Cl. In these cases the LUMO is thought to be a d orbital on the metal rather than a π orbital on the ligand. That these data point are not on the line suggests that the electronegativity of the ligand is the important factor in determining catalytic activity. This can be rationalized in terms of the stability of metal oxo species thought to be important in the catalytic mechanism.

Tandem Mass Spectrometric Study of $C_5H_5FeR^{+\cdot}$ Ions.

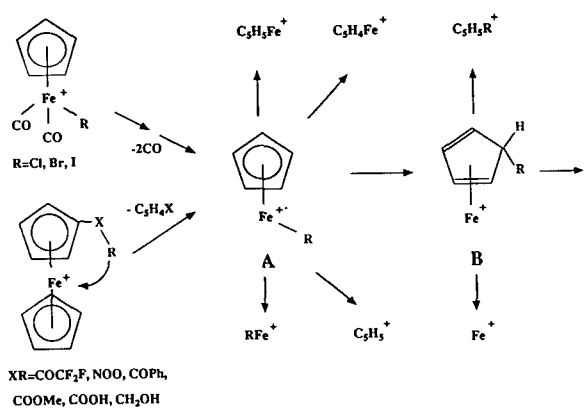
Dmitri V. Zagorevski and John L. Holmes

Chemistry Department, University of Ottawa, Ottawa, Ontario K1N 6N5, Canada.

Structure and unimolecular reactivity of $C_5H_5Fe^{+\cdot}R$ ions were studied by tandem mass spectrometry methods. All ions were generated in the ion source or from metastable precursors by reactions shown in Scheme 1. These reactions resulted in ions having cyclopentadienyl and R groups separately attached to the metal atom (structure **A**). Structure **A** may rearrange by the migration of group R to the hydrocarbon ligand producing structure **B** (Scheme 1), which may also undergo further isomerization.

Structures **A** and **B** exhibited different unimolecular reactivities (Scheme 1). Ion **A** dissociated by C_5H_5-Fe and Fe-R bond cleavages giving rise to $C_5H_5Fe^+$, RFe^+ and $C_5H_5^+$ ions The loss of HR (R=F, Cl, OH) also originated from isomer **A**. The major characteristic of ion **B** and related isomers was the formation of positively charged or neutral C_5H_5R and Fe. In addition, only isomer **A**, possessing the π-cyclopentadienyl and σ-R ligands strongly bound to the metal atom, had a realistic chance to survive neutralization-reionization (NR) conditions and to exhibit a recovery signal.

Scheme 1.



The behaviour of all halogen-containing derivatives was consistent with their existence as structure **A**. NR mass spectra of these ions showed intense recovery signals, demonstrating that stable neutral counterparts were generated in the gas phase. Collision induced dissociation (CID) mass spectra of ions generated in NR mass spectra were closely similar to that of ions before neutralization, indicating no isomerization in the course of NR.

Metastable ion (MI), CID and NR mass spectra of $C_5H_5FePh^+$ ions were dominated by ions corresponding to structure **B**. The dissociation of this isomer produced neutral or positively charged C_5H_5Ph and Fe. Fragmentation corresponding to isomer **A** was not found in the MI and CID mass spectra of ion source generated ions and a recovery signal was not observed in the NR mass spectrum. To identify isomer **A**, $C_5H_5FePh^+$ ions having low internal energies were generated by the decomposition of the metastable precursor. The CID mass spectrum of these species showed intense signals corresponding to $C_5H_5Fe^+$ and $PhFe^+$ ions.

All oxygen-containing $C_5H_5FeR^+$ ions (R=O, OH, OMe) underwent rearrangement of structure **A**. For the methoxy-derivative the initial reaction was a hydrogen atom shift from the methoxy group to the metal atom, followed by the migration of the H-atom to the cyclopentadienyl ring:

$$C_5H_5FeOCH_3^{+\cdot} \Rightarrow C_5H_5Fe(H)(OCH_2)^{+\cdot} \Rightarrow C_5H_6Fe(OCH_2)^{+\cdot}$$

The CID mass spectrum of $C_5H_5FeOH^+$ exhibited peaks due to $C_5H_5Fe^+$ and $HOFe^+$ ions, and the NR mass spectrum showed a recovery signal. All these data were consistent with structure **A**. The observation of intense signals corresponding to CO and Fe losses indicated a significant isomerization of these ions to structure **C**.

The loss of CO was the major dissociation of $C_5H_5FeO^+$ ions, which existed mostly as isomer **D**. No $C_5H_5Fe^+$ and OFe^+ ions, corresponding to structure **A**, were found in the CID mass spectrum, but they were present in the NR mass spectrum. The latter also exhibited a recovery signal demonstrating the formation of neutral counterparts of ion **A**.

C **D**

In conclusion, the behaviour of $C_5H_5FeR^+$ ions, originally formed as isomer **A**, was studied by tandem mass spectrometry and some other isomers were identified. Stable neutral counterparts of ion **A**, having no other ligands or solvent molecules in the coordination sphere of the metal atom, were generated by neutralization-reionization mass spectrometry It was the first observation of these extremely labile molecules. NR mass spectrometry was also successfully employed to characterize organometallic ion structures.

RAPID AND SENSITIVE SEQUENCING OF PROTEINS ISOLATED BY GEL ELECTROPHORESIS

M. Mann, M. Wilm, A. Shevchenko and T. Houthaeve
European Molecular Biology Laboratory (EMBL)
Postfach 10.2209, D-69012 Heidelberg, Germany

In recent years increasingly more sensitive mass spectrometric methods have been developed.for obtaining sequence information of peptides. Biological research demands such amino acid sequencing of extremely small amounts of proteins for their identification using sequence databases or for the cloning of the corresponding genes. However, the "raw material" is almost always proteins on polyacrylamide gels - a notoriously difficult medium to work off for mass spectrometrists. Here we describe sequencing of peptides from proteins isolated by one - dimensional or two - dimensional polyacrylamide gel electrophoresis at levels well below the micro gram level of protein starting material.

An *in gel* digestion procedure was developed which is optimized for the subsequent use of electrospray mass spectrometry and which can handle popular staining methods such as coomassie, reverse and silver staining:

- Excision of the protein band and a blank
- Washing of the gel plugs with water / acetonitrile and amm. bicarbonate / acetonitrile
- *In spot* reduction and alkylation with iodo-acetamide
- Washing with ammonium bicarbonate / acetonitrile
- Drying down in speed vac. Swelling of gel pieces in tryptic digest buffer at 4 oC
- Removing of excessive trypsin and overnight incubation at 37 °C
- Extraction of tryptic peptides with 5% formic acid /acetonitrile
- Drying down of pooled extracts

This procedure is followed by a transfer of the redisolved digest mixture into a specially prepared capillary which has been loaded with 100 nL of POROUS material (fig.1). Peptides are adsorbed onto this support and are then step eluted in one micro liter solution into a "NanoES" spraying needle[1]. The unseparated peptide mixture is then sprayed without pumping for 30 to 90 minutes and as many peptides as possible are sequenced. No electroblotting or high performance liquid chromatography is necessary in the sample preparation, reducing the risk of sample loss by transfer steps or non - specific adsorption to sample containers. Thus, the procedure is vastly simplified and, in our hands, more robust than current Edman or MS sample preparation protocols.

The procedure has been tested on Bovine serum albumine (fig 2) and has been applied to a wide variety protein micro characterization problems at EMBL. These examples showed that amino acid sequence data can now be obtained with extremely small quantities of sample by NanoES tandem mass spectrometry. Not only is the sensitivity up to hundred fold higher than what is practically obtainable by current techniques using Edman degradation, but the procedure is also much faster and involves fewer purification and manipulation steps. We anticipate that sequencing by NanoES tandem mass spectrometry will become a method of choice for many future protein sequencing projects.

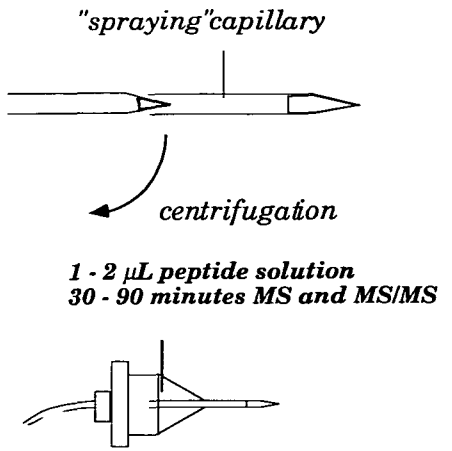
Elution

Unseparated peptide mixture is step eluted (60% MeOH, 5% formic acid)



Operation

1 - 2 µL peptide solution
30 - 90 minutes MS and MS/MS

Figure 1. Elution and spraying of the unseparated peptide mixture.

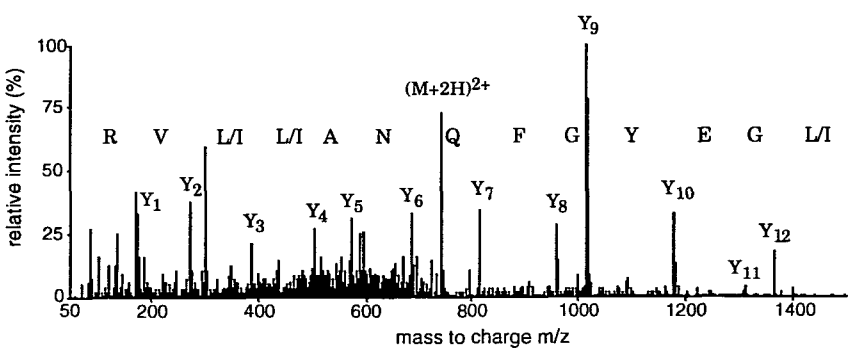


Figure 2. Model study on bovine serum albumine. 800 fmoles of BSA were applied to a 1D gel, excised, prepared as described above and the peptide mixture sequenced by NanoES. The figure demonstrates good sequence readability even at these low amounts.

In Situ Chemical Modification, Digestion, and Characterization of Proteins Utilizing a 2-D HPLC/MS Approach

R. K. Blackburn[1], J. Mark[2], and D. B. Kassel[1]

[1]Glaxo Wellcome, Inc., 5 Moore Drive, RTP, NC 27709
[2]PerSeptive Biosystems, Inc., Framingham, MA 01701

Introduction

Recent advances in MS instrumentation, particularly in the areas of matrix-assisted laser desorption and electrospray ionization, have lowered routine peptide/protein detection limits to the low picomole/femtomole levels. In order to take full advantage of these lowered detection limits, a 2-D HPLC system was investigated as a way to chemically and enzymatically manipulate proteins on-line in order to eliminate sample handling steps prior to MS analysis, thereby reducing sample losses from sample handling steps. Specifically, a technique has been developed in which a protein sample can be preconcentrated, reduced and alkylated, and tryptic digested on-line with no extraneous sample prep steps. Using the Poroszyme™ immobilized enzyme technology, these manipulations can be accomplished in minutes as opposed to hours or days. This approach can be applied to proteins in solution or proteins purified on SDS-PAGE gels. This approach was applied to the the Src Homology 2 Domain protein SH2.

Experimental

For all experiments, the 2-D Integral™ Microanalytical workstation was configured as shown in Figure 1. A solution containing SH2 was de-salted and preconcentrated onto a Poros R1 column in the first dimension. Alternatively, a gel purified sample of SH2 was electroeluted onto a Poros R1 cartridge using the method of Moyer and coworkers (1), and the Poros R1 column placed in the first dimension on the Integral. Next, a 40 µL plug of 4-vinylpyridine and DTT in a Tris/Guanidine Buffer, pH 8.6, was injected onto the immobilized protein and allowed to incubate at 37 °C for 15 min Following extensive washing, the protein was eluted from the Poros R1 column, thru a mixing tee for pH adjusting to 8.5, onto a Poroszyme™ trypsin column. After passing through the trypsin column, a third LC pump delivered a 0.5% TFA pH adjusting solution, and the digest was subsequently trapped on a Poros R2 or ODS trapping cartridge. After trapping, the trapping cartridge was connected to a longer Poros R2 analytical column, and the contents analyzed by LC/MS using a Sciex API-III mass spectrometer.

Results and Discussion

Initial experiments involved evaluating recovery of SH2 tryptic peptides when collected into an eppendorf or trapped on a reversed-phase cartridge after elution from the Poroszyme™ trypsin column. As shown in Table 1, recoveries of SH2 tryptic peptides collected into an eppendorf from a 20 pmol digest are < 50% compared with a 20 pmol trapped digest. These data demonstrate the importance of trapping rather than eppendorf collection to maximize recoveries of tryptic peptides in the 2-D approach.

Figure 2 shows a mass chromatogram comparison of tryptic maps of SH2 for a preconcentration/digestion/trapping experiment using 2-D system with and without an alkylation step. Note in Figure 2A and 2B that tryptic maps obtained with and without an alkylation step are comparable, with Cys-containing peptides shifting in retention time as well as molecular weight (data not shown) upon pyridylethylation. Other data (not shown) obtained after alkylating SH2 for 15 min without a tryptic digestion step showed full alkylation of the protein with no evidence of partial alkylation products.

Experiments with SH2 purified from an SDS-PAGE gel and electroeluted onto a Poros R1 cartridge and subjected to the alkylation/digestion/trapping procedure showed a 50% recovery of tryptic peptides relative to a standard SH2 sample without electroelution (data not shown). The 50% loss is consistent with losses reported for electroelution alone (1), showing that no significant sample losses occurred as a result of the alkylation/digestion procedure.

Summary

A rapid, 2-D HPLC approach has been developed which enables the pre-concentration/cleanup of protein samples, followed by on-line reduction/alkylation and tryptic digestion which eliminates sample handling steps prior to MS analysis. This elimination of sample handling steps greatly improves recoveries of tryptic peptides following digestion, allowing for smaller amounts of proteins to be analyzed. This approach should be particularly useful for generating high sensitivity MW maps of proteins to be used for database searching. Future plans include improving the robustness of the approach for applicability to proteins in general.

Identification of Peptides from Combinatorial Libraries with ACE-ESI-MS

Daniel P. Kirby*, Yen-Ho Chu, Yuriy Dunayevskiy, Barry L. Karger and Paul Vouros, The Barnett Institute and Department of Chemistry, Northeastern University, Boston, MA 02115

The use of on-line CE-ESI-MS has continued to expand since its introduction in 1987, and this growth has been stimulated by the incorporation of additional CE operational modes, such as CITP, into the combination. In this work, we report on the use of another CE mode, affinity capillary electrophoresis (ACE-MS), with the on-line system: ACE-ESI-MS.

ACE in its own right is a powerful technique and has been shown to be useful for the measurement of binding constants, estimation of kinetic rate constants, and determination of binding stoichiometries of receptor-ligand interactions. The technique has also been shown to be useful for selecting from a mixture a compound that binds most tightly to its receptor. By itself, however, ACE is limited in that no structural information is provided for the selected ligands. In this work we show that, upon coupling with MS, ACE is capable of not only selecting but also identifying peptidyl ligands from a combinatorial library of peptides.

We have developed a simple procedure using ACE-ESI-MS for the on-line separation and sequence determination of ligands from combinatorial libraries that bind most tightly to a receptor. In this procedure, the receptor is present in the CE buffer and the library is introduced as the sample. Ligands that bind tightly to the receptor are retained and, thus, separated from non-interacting species in the library. Then, ligands are detected and structurally identified by on-line MS-MS. Vancomycin-peptide binding with a library of 100 all-D, Fmoc-DDX(1)X(2) tetrapeptides was used as a model system. The technique is economical, rapid, experimentally straightforward and versatile, and, most significantly, is performed in homogeneous aqueous solution so that nonspecific interactions are minimized.

Figure 1 shows the reconstructed ion electropherograms (RIE) and selected ion electropherograms for ligands that were found in the retained peaks. The left side of the figure was for a buffer containing no receptor and the right side for buffer containing 70μM vancomycin. CID of each retained peak was performed to determine the sequence of the ligand An example is shown in Figure 2.

Under these experimental conditions, Fmoc-DDAA, the known ligand, was only slightly retained, whereas peptides with aromatic amino acids in the X_2 and alanine in the X_1 position bound more tightly--a previously unknown motif. Binding constants were verified separately for the discovered ligands. Note that the isobaric peptides Fmoc-DDAY, Fmoc-DDAF and Fmoc-DDAH (Figure 1A, B and D) did not bind to vancomycin under these conditions, showing clearly that binding is sequence specific.

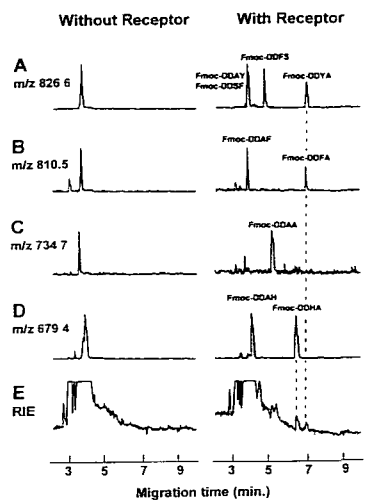

Figure 1. Affinity capillary electrophoresis-mass spectrometry (ACE-MS) of a synthetic all-D, Fmoc-DDXX library of 100 tetrapeptides using vancomycin as the receptor. A-D selected ion electropherograms of the masses indicated; E reconstructed ion electropherogram (RIE) for runs without (left) and with (right) vancomycin in the electrophoresis buffer. **ACE conditions: capillary:** 360μM O.D. x 50μM I.D. x 38cm long, coated with neutral hydrophilic polymer, **buffer:** 20mM Tris acetate (pH 8.1) containing no receptor (left) or 70μM vancomycin (right); **electric field:** -19.2kV (500V/cm), 5μamp; **sample:** hydrodynamically loaded, 10cm/8sec, ~10nL. **MS conditions: instrument:** Finnigan TSQ-700 with Finnigan API interface operated in +ESI mode, ESI: +4 2kV; gas sheath: 40cc/min N_2; liquid sheath 2μL/min 10mM tris acetate (pH 8.1) in H_2O-MeOH (25-75, v/v); **MS: scan range:** 525-925 amu in 2sec.

CZE-ESMS of Peptides and Proteins using a Sheathless Interface*

J.F. Kelly[1,2], P.Thibault[1], L.R. Ramaley[2]

[1]Institute for Marine Biosciences, NRC, 1411 Oxford St., Halifax, Nova Scotia, B3H 3Z1; [2]Dept. of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J3.

Over the past six years, considerable advances have been made in the coupling of capillary zone electrophoresis (CZE) with electrospray mass spectrometry (ESMS). The most widely used interface utilizes a concentric flow of sheath liquid [1] in order to maintain electrical continuity at the interface and to ensure stable electrospray conditions. Low femtomole detection limits are typically obtained for the analysis of peptides and proteins using this interface. Significant improvements in sensitivity have been reported with sheathless interfaces using metallized capillary tips [2,3]. Original designs, however, suffered from a rapid erosion of the metal from the tip leading to the destabilization and eventual loss of electrospray. Recently, Kriger et al. [4] described a method for making a durable, gold-coated capillary tip and demonstrated its use as a sheathless interface.

This presentation describes the procedure we have developed for producing a durable gold-coating. The capillary tip was initially sputter-coated with gold. This coating was then augmented with gold by electrodeposition. Columns coated in this manner were used for 3-4 days without significant loss in performance. In addition, it was found that heat-tapering the capillary tip prior to coating provided the most sensitive and stable electrospray, though very small i.d. tips (i.e., < 10 μm) were prone to blockage. In practice, a tip i.d. of ≈20 μm provided the best compromise between sensitivity and prevention of blockage during production and use. Furthermore, by permanently derivatizing the inner capillary with a cationic polymer (MAPTAC) and using volatile acid electrolytes, efficient CZE separations can be realized without reconditioning the capillary surface which often leads to blockage of the capillary tip.

A comparison of the sheathless and co-axial CZE-ESMS interfaces revealed that the former was 10-50 times more sensitive for peptides smaller than 3500 Da (Figure 1). This improvement resulted from both an increase in analyte signal intensity and a reduction in background noise (usually by a factor of two or more). For a mixture of peptide standards ranging from 555 to 3495 Da the limit of detection was typically in the mid to low attomole range for SIR acquisition, and low femtomole range for full mass scan. Furthermore, the relatively strong acid electrolytes used for this work (up to 0.1M HCOOH) provided good peak resolution and separation efficiencies (150,000-200,000 plates). The present procedure was also applied to the analysis of complex digests of proteins such as α-casein and ovalbumin. Meaningful full scan mass spectra and electropherograms were obtained for 23 fmoles of CNBr digest of ovalbumin (a glycoprotein) using a strong acid electrolyte (0.5M HCOOH). Similar enhancements in sensitivity were observed for intact proteins.

An obvious benefit to the sheathless interface is the ability to obtain CZE-MS/MS data on significantly lower quantities of material. As an example, CZE separation followed by low energy CAD MS/MS was carried out on a mixture of peptides. On-column amounts ranged from 130 to 360 fmoles. The electric field strength across the capillary was reduced by a factor of about 3 just prior to the detection of the first peptide (Figure 2A). This reduced the rate at which the peptides eluted thus ensuring sufficient time to obtain full range mass scans for each peptide and at an acceptable resolution. Meaningful daughter ion spectra, displaying relevant sequence ions, were obtained for most of the peptides examined (Figure 2B).

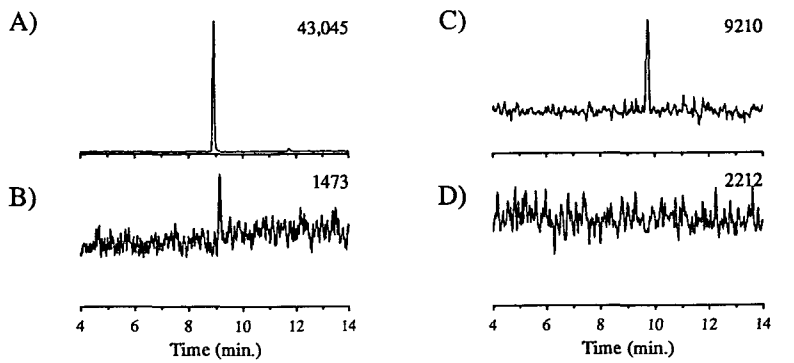

Figure 1: Sensitivity comparison of CZE-ESMS (SIR) for the peptide Leu-enkephalin (m/z 556.2) using a sheathless (A and B) and co-axial (C and D) interface. Conditions: 2pg for (A) and C), and 50 fg for (B) and (D), 1m x 50 µm i.d. capillary derivatized with MAPTAC, 50 mM HCOOH, -28.5 kV. Co-axial sheath liquid: 0.2% HCOOH in 25% MeOH at 2 µL/min. Numbers at top right are signal intensities.

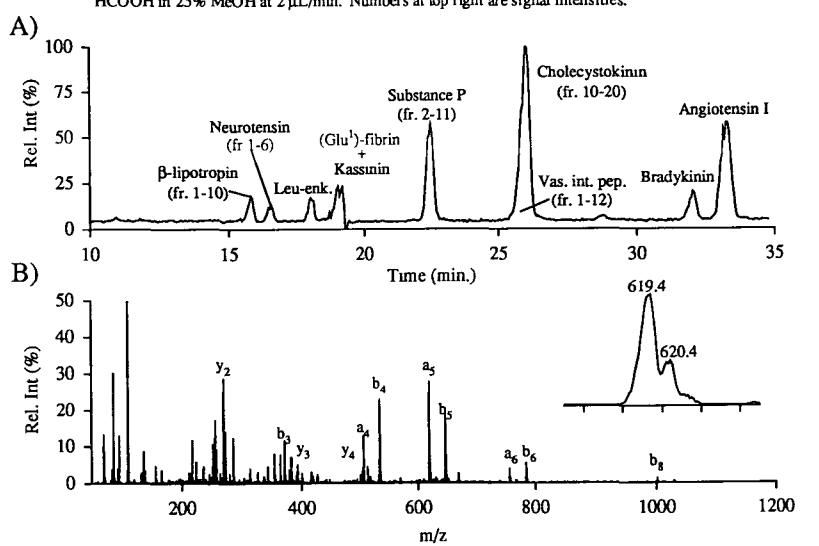

Figure 2: CZE-MS/MS of peptides using a sheathless interface. (A) Full scan TIE (m/z 300-1200). Conditions: 230pg each on column, 1m x 50 µm i.d., 0.1M HCOOH, -28.5 kV for 7 min., -8.5 kV thereafter. (B) CZE-MS/MS spectrum for Angiotensin I (m/z 433). Conditions: 154 fmoles on-column, 75 V (lab. frame), CGT = 4 x 10^{15} atoms.cm^{-2}, 0.1 Da step size, 3 msec dwell. Inset exhibits the m/z 615 to 625 range of this spectrum.

Novel Modifications and Clinical Applications of Membrane Preconcentration CE-MS

Andy J. Tomlinson, Linda M. Benson and Stephen Naylor
Biomedical Mass Spectrometry Facility, Mayo Clinic, Rochester, MN 55905, USA

On-line CE-MS is an emerging technique for the structural characterization of a wide variety of components in complex mixtures. However, the relatively poor concentration limits of detection (CLOD) of CE-MS reduces applicability for analysis of dilute analyte solutions. This is due primarily to the finite volume of the CE capillary (typically 1-2 µL) causing poor analyte focusing upon injection of large sample volumes. Electrophoretic focusing techniques such as analyte stacking, field amplification and transient isotachophoresis have been developed and clearly improve the CLOD of CE-MS. However, the analysis of several microliters of a sample by CE-MS is not possible even when such focusing techniques are used. Therefore, we have been developing preconcentration-CE-MS (PC-CE-MS). This technique uses a bed of adsorptive material at the inlet of the CE capillary. For convenience, we have developed a PC-cartridge (Figure 1) that contains the adsorptive membrane. This arrangement permits easy conditioning of the CE capillary and off-line activation of the adsorptive phase. We have found PC-CE-MS to be an effective means of analyte preconcentration and sample cleanup permitting the removal of salts, buffers, etc. from biologically derived matrices on-line with CE-MS and we term this mPC-CE.

Initially, we used a solid phase HPLC packing material at the CE capillary inlet. However, we have found that component elution from the solid phase PC-CE cartridge was a critical step. Large volumes of organic phase within the CE capillary results in anomalous behavior of EOF, leading to broad analyte zones and compromised component separations (Figure 2a). Reducing the volume of the organic elution buffer results in only a slight improvement in PC-CE-MS performance (Figure 2b). This obvious limitation of solid phase PC-CE-MS, can be only slightly improved using tITP after analyte elution from the solid phase (Figure 2c). Clearly, the bed volume of the solid phase had to be minimized. This was achieved by substituted the solid phase by a suitably impregnated membrane (mPC-CE-MS). This development improved the efficiency of analyte elution from the membrane PC-cartridge in a smaller volume of organic phase. However, while this leads to an enhanced performance, CE-MS was still superior. Therefore, we developed tITP conditions that are implemented after analytes removal from membrane. This enhanced the performance afforded by mPC-CE-MS such that component resolution and separation efficiency was comparable to that of CE-MS even for a sample loading of tens of microliters (Figure 3).

In addition to peptide analysis, mPC-CE-MS methods are applicable for investigation of small molecules (e.g., drug metabolites), polypeptides, and proteins. Figure 4 shows the detection of metabolites of the neuroleptic agent haloperidol by analysis of 10 µL of patient urine using mPC-CE-MS. We have also used mPC-CE-MS for clinical research by analysis of a patient urine for confirmation of the presence of Bence Jones protein (a 25 kDa protein that is indicative of multiple myeloma). Figure 5 shows the mPC-CE-MS analysis of a 24 hour urine collection from a patient diagnosed with multiple myeloma. The family of proteins observed in this sample confirmed that this patient was close to renal failure.

We thank Mayo Foundation for funding these studies. We also acknowledge the support of Finnigan MAT.

LC/MS Using an Ion Trap/reflectron Time-of-flight Mass Spectrometer

Mark G Qian, Jian Bai, Yan-Hui Liu, Kefei Zheng, and David M. Lubman

Department of Chemistry, The University of Michigan
Ann Arbor, MI 48109-1055

Introduction. The use of mass spectrometry as a detector for on-line separations of mixtures in solution has recently become an important method for characterization of proteins and peptides. Its use as a detector for on-line separations has become especially significant with the development of electrospray ionization (ESI) as a means of producing molecular ions of large proteins and peptides from solution The result is that large ions can be detected at a relatively modest mass/charge so that inexpensive quadrupole mass spectrometers have become widely-used detectors for chromatographic separations An inherent problem in interfacing on-line separations with scanning mass spectrometers such as quadrupole and sector devices is the duty cycle of the experiment Most of the ion signal is lost due to the poor duty cycle of these scanning instruments. Moreover, in the case of very narrow chromatographic peaks, a scanning mass spectrometer may provide a skewed response since the concentration changes during the scan time

In the work presented herein, we demonstrate the capabilities of the ion trap/reflectron time-of-flight mass spectrometer (IT/reTOFMS) as a fast and sensitive detector for microbore chromatography Microbore HPLC separations of tryptic digests of various proteins are separated and interfaced to an ion-spray version of the ESI source, operating at between 40-50 μL/min. Ion storage times of 500 ms are used to achieve long term ion integration for enhanced sensitivity of low concentration samples, with a resulting high duty cycle in detection Using the total ion storage capabilities of the trap, total ion chromatograms of tryptic digests of cytochrome C and bovine ß-casein are obtained with detection limits in the low picomole range In addition, using software developed in our laboratory the selected ion chromatogram can be displayed for enhancement of the S/N and for identification of a chromatographic peak with a particular mass Also the mass spectrum of each chromatographic peak can be displayed in order to search for unresolved chromatographic peaks. The entire data file can ultimately be displayed as a 3-D spectrum in analogy to a 2-D gel used for separations in the biological sciences

Methods. The experimental set-up consists of an HPLC separation system interfaced to an electrospray ionization source with detection using the IT/reTOF system. A gradient elution liquid chromatography system using reversed phase columns was initially used to optimize separation of mixtures of peptides and protein digests The liquid eluent of the separation is delivered through a fused silica capillary tube into an electrospray assembly where the sample is ionized The electrospray source utilizes gas on-axis nebulization methods or ionspray to accommodate higher flow rates The droplets produced are then sampled through a heated stainless steel (s.s.) capillary to desolvate the droplets leaving highly charged peptide ions The ions are then injected into a differentially pumped interface, where the on-axis component of the ion beam passes through a skimmer into the mass spectrometer region The ions are transported via a set of Einzel lens into the quadrupole ion trap storage device The ions are stored and accumulated to an optimal sensitivity for detection of electrospray-produced ions Ultimately, an extraction pulse is applied to the exit endcap and the ions are ejected into the reTOFMS for detection and mass analysis. The use of the reflectron device provides the enhanced resolution observed in these experiments. The ions are detected by a triple 40-mm microchannel plate assembly A data system based

on a high speed transient recorder is used to digitize and process the resulting mass-detected chromatogram that results.

Results. One example of the capabilities of the IT/reTOFMS for on-line analysis of a tryptic digest is demonstrated in Figure 1 and 2. In Figure 1a is shown a microbore HPLC separation of 100 pmol tryptic digest of bovine cytochrome C detected via a UV absorption detector. Figures 1b were obtained by monitoring the total ion current over a broad mass range (60-1500 u) as a function of time There are some differences in the relative peak heights of the corresponding peaks in Figures 1a and 1b, which is due mainly to the relative differences in UV absorption efficiency versus the detection of ion peaks by mass analysis. The data can be reprocessed by our computer software to provide the ion chromatogram for selected massed only. This procedure provides a selected ion chromatogram (SIC) for each mass in the spectrum detected. Figure 2a shows an SIC at *m/z* 634, which corresponds to the chromatographic peak at ~25 min. The relevant mass spectrum is shown in Figure 2b

Direct Coupling of Thin Layer Chromatography with Matrix Assisted Laser Desorption Ionization

Arkady I. Gusev[a], Andrew Proctor[a], Yakov I. Rabinovich[b] and David M. Hercules[a,c]
[a] Department of Chemistry, University of Pittsburgh, Pittsburgh PA 15260.
[b] Center for Coal and Mineral Processing, Virginia Polytechnic Institute and State University, Blacksburg VA 24061.
[c] Present address: Department of Chemistry, Vanderbilt University, Nashville, TN 37235.

The use of thin layer chromatography (TLC) with mass-spectrometry (MS) combines the simple separation method of TLC with the specific detection capabilities of MS. Several MS methods have already been used for direct TLC/MS coupling, including secondary ion mass spectrometry, fast atom bombardment and laser desorption [1]. Although various applications, including several examples of two dimensional imaging have been reported, there are still several problems associated with such TLC/MS combinations i.e. fragmentation, poor detection limits and analyte spreading which degrade the image.

To compensate for these problems we employed the relatively new MS method of Matrix Assisted Laser Desorption Ionization (MALDI) [2]. The direct coupling protocol involves analyte extraction from inside the TLC plate and its transport to the surface followed by matrix deposition and crystallization. The extraction procedure was optimized to minimize analyte planar diffusion and to achieve high sensitivity.

Various MALDI matrices were evaluated for use with silica gel and cellulose TLC plates [3]. No signal was obtained from plate points without visible matrix crystals. The best detection limit was obtained with ferulic acid (FA), sinapinic acid (SA) and α-Cyano-4-Hydroxycinnamic acid (α-CHCA) matrices. These matrices also showed high sodium and potassium salt tolerance.

Figure 1 shows mass spectra of angiotensin II and III separated on a silica gel TLC plate. An absolute detection limit of 2-4 ng was demonstrated for angiotensin, bradykinin and enkephalin derivatives [3]. It should be noted that use of a wet TLC plate improved detection limits by a factor of 1.5-2. The method also worked for larger peptides and small proteins like bovine insulin chain B, insulin, horse heart cytochrome c and myoglobin, but TLC separation was poor. Only minor fragmentation was found for all analytes. The influence of ninhydrin on spectral quality was also investigated. Although the spectra were very complex, an increased signal was observed for several analytes when ninhydrin was applied to the TLC plate [3].

The TLC/MALDI method was found to be suitable for direct TLC imaging. However direct matrix deposition and matrix crystallization processes induced additional analyte planar diffusion of 0.5 -3 mm. Analyte spreading can be minimized by suitable matrix selection and controlling the matrix crystallization. Figures 2 A and B show the two dimensional image and contour plot of Rhodamine B obtained on a silica gel plate. Direct TLC imaging was carried out using the α-CHCA matrix with a spatial resolution of 250 μm. The Rhodamine B cation absolute intensities were used to plot the image.

Thus direct coupling of TLC separation and MALDI detection has been demonstrated. The major advantages of TLC/MALDI are low detection limits, minor fragmentation, high contamination tolerance and its suitability for imaging.

Flow Injection Analysis - Mass Spectrometry for In-Process Control of Drug Synthesis

Stephen T. Colgan, Thomas R. Sharp, Phillip D. Hammen,
Robert H. Reed, George J. Horan, Paul W. Gwiazda
Central Research Division, Pfizer Inc., Groton, CT 06340 U.S.A.

We describe the application of flow injection analysis coupled with an atmospheric pressure chemical ionization LC-MS interface (FIA-MS) to in-process control (IPC) procedures to support commercial synthesis of a drug substance -- CP-93,393. Its commercial synthesis entails nine steps. IPC procedures are needed to monitor completeness of reactions. Such procedures need to provide for rapid analysis, to be simple procedures, and to be usable for more than one synthetic step.

The production synthesis for this compound is shown in the accompanying reactions, and illustrates the variety of compound structures which must be accomodated by our procedure. Steps 7 and 8 of the process are not shown, as they are optical resolution and salt conversion steps rather than synthetic steps.

CP-93,393 itself (Figure 1) is an ideal molecule for APCI mass spectrometry. It produces an abundant $[M+H]^+$ and little fragmentation. Examination of the seven other molecules in the synthetic sequence shows that all respond nearly as well. A flow solvent of 50% H_2O and 50% methanol was used initially to test mass spectral performance of the compounds. Only one compound -- compound 1 -- requires the addition of a buffer salt to the flowing solvent to promote ionization. The flow solvent now in use contains 50% of a 0.05M aqueous solution of ammonium acetate. The rest of the compounds work equally well with and without the added buffer salt.

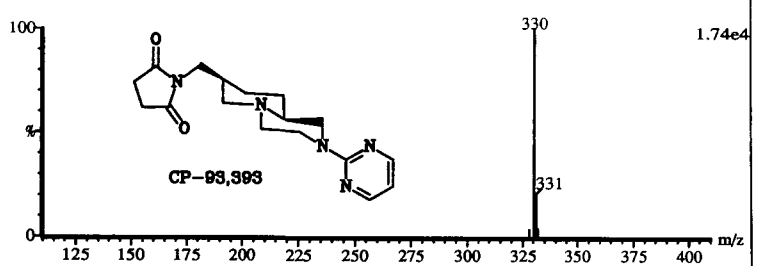

Figure 1: APCI mass spectrum of CP-93,393, $C_{17}H_{23}N_5O_2$, 329 daltons.

Compound 4 (Figure 2) exhibits the most extensive spontaneous fragmentation. A number of instrument operation parameters, solvent flow conditions and injection sizes were investigated in order to minimize this fragmentation. One instance (step 1), where one compound could generate a fragment which would be indistinguishable from the $[M+H]^+$ of the other compound, were found to present minimal interference and could be controllable by judicious choice of instrument operating parameters.

Step 6 in the synthesis presents the most difficulty regarding the development of an IPC method. Compound 6 is difficult to do by gas chromatographic assay. Compound 7 is not compatible with GC. The reaction introduces the pyrimidine chromophore into the product molecule, which allows its detection by UV-Vis in an HPLC assay. However, compound 6 does not have a chromophore. Both

compounds respond in APCI by producing exclusively $[M+H]^+$. They can now both be observed in a single assay, and by the same method as all of the other compounds.

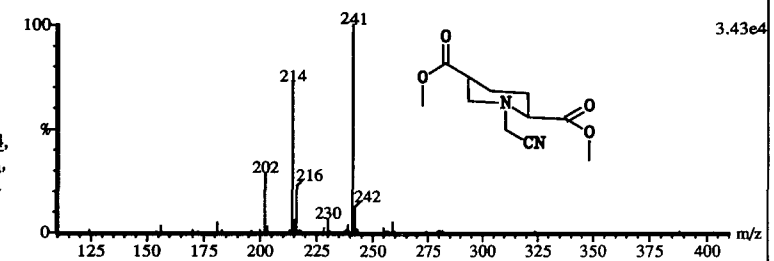

Figure 2: APCI mass spectrum of compound 4, $C_{11}H_{16}N_2O_4$, 240 daltons.

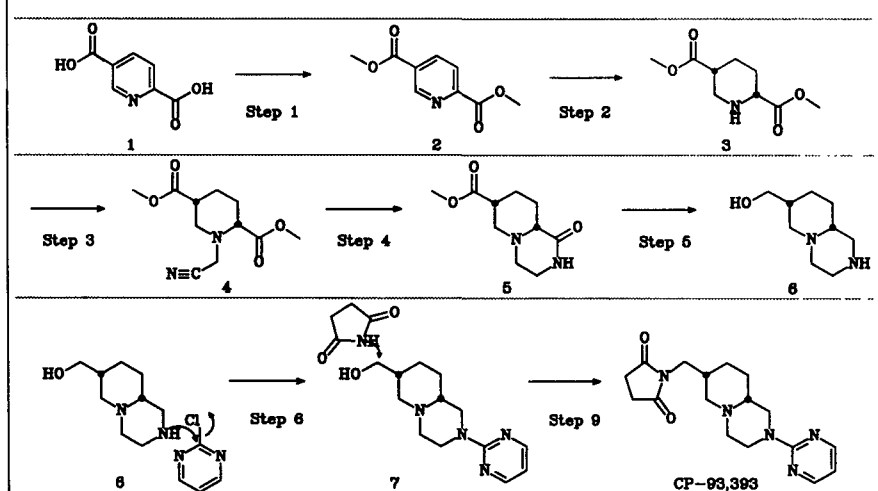
For this process synthesis, FIA-MS allows the use of a single analytical technique and a single instrument for IPC of the entire synthesis. The method replaces a gas chromatographic assay for the first five steps of the synthesis, HPLC assays for the latter steps, and provides an IPC procedure for step 6, in the middle of the reaction sequence, for which no other good IPC method exists. The only feature which our FIA-MS approach does not address is evaluation of the chirality of products of the optical resolution steps of the synthesis. Enantiomeric purity must still be evaluated by a conventional chiral procedure.



GLP FOR QUALITATIVE MASS SPECTROMETRY FROM AN ACADEMIC PERSPECTIVE,
Jack Henion, Analytical Toxicology, Cornell University, 927 Warren Dr., Ithaca, NY 14850.

INTRODUCTION

Mass spectrometers are now used in a wide variety of routine as well as research application areas As sophisticated measurement devices these systems provide information that may be important or even critical for analytical problem solving. Since any precise measurement device must be carefully maintained and monitored to assure reliable performance, we must all be reminded of the relevant factors that influence the performance of our mass spectrometer systems. We must then implement procedures in the routine use and operation of mass spectrometer systems that document and ensure the generation of reliable data.

In addition to the many aspects of good analytical chemistry including record keeping, equipment maintenance, and regular checks of accuracy and precision, we should all remember some of the fundamental factors that influence the data obtained from mass spectrometers. These include mass-axis accuracy and mass resolution as well as effects of matrix components on the ionization efficiency, etc. Since an error of just one dalton can negatively influence an unknown structural elucidation, it is imperative that the mass assignment of a mass spectrometer be accurate to within specified limits. For quadrupole mass spectrometers this is usually within ±0.1 Da. For a high resolution mass analyzer this could very well require mass accuracy measurements within just a few ppm. Routine performance verification and the determination of system suitability of the mass-axis accuracy is essential to ensure dependable measurements. The factors that affect mass accuracy include the electronic stability of the instrument, the mass resolution, and the peak mass assignment algorithm of the data system. Since mass accuracy also affects sensitivity for selected ion monitoring (SIM) and selected reaction monitoring (SRM) experiments, careful attention to these factors should be taken to ensure the required performance criteria.

Other factors that are important to control for reliable measurements include mass discrimination, relative abundances, space-charge effects upon ion peak shape, matrix suppression of ionization, artifacts of the ionization process such as in FAB, electrospray, and MALDI, factors associated with multiply charged ions from electrospray and MALDI, ion source and collision cell experimental conditions for MS/MS, and ancillary factors associated with coupled chromatography systems for GC/MS and LC/MS, etc. It is important to be aware of these issues which may influence the performance of mass spectrometric measurements.

DISCUSSION

An essential aspect of GLP procedures is record keeping regarding the "health" and performance of the mass spectrometer. Records should be maintained regarding regularly scheduled maintenance such as ion source cleaning, pump oil changes, detector replacement, etc. Non-scheduled maintenance should also be documented and explained in the normal course of record keeping. If performance problems begin to appear the operator should record observations to provide a history that can facilitate diagnosing a problem by service personnel. Records of data obtained under "normal" operation for the instrument should also be recorded on a regular basis and archived as a record of

performance characteristics for the instrument These data should include normal tuning results plus actual on-line GC/MS, LC/MS, LC/MS/MS, etc. results from reference compounds common to the laboratory's work. In the case of LC/MS the recorded experiments should not be obtained by simple "infusion" or flow injection. The latter do not adequately represent actual LC/MS conditions.

There is a developing tendency to "under-resolve" masses on mass analyzers of quadrupole mass spectrometers for certain analyses under SRM acquisition conditions. This is often done to achieve greater sensitivity or more stable ion current measurements. In some cases this may be appropriate provided control experiments indicate that there is no interference and that all requirements for an analysis are met. However, when one uses a mass resolution where the ion peak width at half-height is greater than one dalton, ion current differing by one dalton will also be measured resulting in reduced specificity This can occur in LC/MS/MS analyses when a co-eluting component differing by one dalton from the other component occurs. A specific example is when a mixture contains a sulfonic acid and its corresponding sulfonamide. If the two components coelute these two functionalities of the same parent compound cannot be distinguished by SRM using less than unit mass resolution conditions in the first mass analyzer. If they are chromatographically separated as shown in Figure 1 the CID ion current of one (RSO_3NH_2) can contribute ion current to the other (RSO_3H) under low mass resolution conditions (both Q1 and Q3 operated under low mass resolution conditions). In a full-scan mass spectrum obtained under less than unit mass resolution conditions the isotope ratios would also be inaccurate due to the lack of adequate mass resolution. To ensure that accurate and reducible data are routinely obtained mass spectrometry laboratories should address and monitor those factors which can affect the results desired from their equipment.

Providing Evidence Of Structural Validity As Part Of GALP Compliance

M Canales, Ph.D
R Coyle
T Hall
J Shofstahl, Ph D.

Summary

As pointed out in a recent ASMS workshop, validation of a mass spectrometer and the data system for the intended use is the end user's responsibility. Nonetheless, the vendor can be an important partner in assuring the success of that validation.

This talk discusses a software development process that is focused on providing evidence that quality was built-in and not just tested in. The focus is on structural validity, which is difficult for the end user to judge, rather than functional validity, which only the end user can determine.

As part of the ISO 9000-3 guidelines for software development, the vendor must show evidence of the following:

- Documented Product Development
- Management Oversight
- Peer Review
- Testing
- Product Documentation
- Change Control After Initial Release

The same information can provide evidence of the structural validity of the product in the Good Laboratory Practices or Good Automated Laboratory Practices environment.

The talk will suggest a Software Development Life Cycle that meets the user's need for quality while recognizing advances in software development since the invention of the "waterfall" model. It will describe a process for change control as well as a mechanism to revise existing applications to meet emerging quality standards.

The key phases of the life cycle are:

- Feasibility
- Software Requirements
- Rapid Prototypes → Visual Freeze
- Implementation
- Test Phases
  - Alpha
    Verifying the Functional Specification
  - Beta
    Validating the System for its intended use

Next the talk will make suggestions about what can be done with "mature" products. It will cover the issues of "Fix versus Enhance", change control, and "Use Validation"

Finally the talk will discuss the kinds of tools a vendor might provide to help the end user functionally validate the basic features of the system. Validation for the intended use can proceed from there with the assurance that the quality of underlying system is not a concern

Validation Aids A Vendor Might Provide At Factory

- Review of SOPs, Tool Descriptions, Coding Style Guides, System Life Cycle
- Review of Project Documentation
- Examples of Code Walk-throughs, Internal Documentation
- Review of Test Plans
- Examples of Test Reports
- Examples of Source Code (if you must)

Validation Aids A Vendor Might Provide At User Site

- Certificate of Compliance with internal factory procedures
- Release Notes
- List of Known Problems
- Manuals (on-line?)
- Test Suites (Procedures and files)

GOOD LABORATORY PRACTICE AND DATA MANAGEMENT

Steven M. Musser[1], James A. Sphon[1], Martin Browning Jr[2]. and Stan W. Woollen[2]

[1]Office of Scientific Analysis and Support, Division of General Scientific Support, U.S. Food and Drug Administration, Washington, DC 20204 and [2]Office of Regulatory Affairs, Division of Compliance Policy, U.S. Food and Drug Administration, Rockville, MD 20857

Compliance with good laboratory practice (GLP) regulations is required by the Food and Drug Administration (FDA) for conducting nonclinical laboratory studies as part of the safety evaluation submitted to FDA for a products' approval. The GLP regulations, 21 Code of Federal Regulations (CFR) Part 58, cover a wide variety of laboratory practices and are general in nature. Unfortunately, this generates considerable confusion when specifics are needed for technical operations such as mass spectrometry. This problem was clearly evident at the ASMS sponsored "Fall Workshop on mass spectrometry and GLP" where there were a number of questions regarding FDA's interpretation of GLP regulations as applied to mass spectrometry laboratories. Since many of the questions pertained to acquisition and storage of "raw data", some clarifications may be helpful.

What is raw data in the context of mass spectrometry applications? To better understand the interpretation of raw MS data and GLP regulations it is important to distinguish between detector output signal and recordable data (raw data). This is a rather fine point and some elaboration is necessary. Since the analog signal would be essentially meaningless in the modern MS laboratory, without first being digitized and in many cases averaged or smoothed before being written to magnetic disk (storage device) it is not considered to be raw data in the context of GLP. In order for the data to be considered raw data it must be in a recorded form. By this definition the information which is passed from the A/D converter and signal filters/averagers and recorded on disk (storage device) is the raw data. Raw data in this form is sometimes referred to as primary data. Transformations done to the data at this point are considered secondary data and would include: mass assignment based on a calibration file, background subtraction, integration results, or any other transformation done to the primary data.

The GLP requirements for storage of data are fairly straightforward, however there are several details which pertain to MS data that need to be addressed. First, data from a GLP study must be retained for 5 years after being submitted to the FDA. What this means for example is, if the data is not submitted to the FDA until 8 years after being originally reported, it must be retained for a total of 13 years. Second, it is not sufficient to simply file the data away, it must be in a readily accessible, readable format. Finally, all pertinent information needed to reconstruct the study results submitted with the final report, including calibration files, spectra used for background subtraction, the smoothing algorithm, integration results and the original chromatographic data must be saved. Because storage and retrieval of data in an electronic format over an extended period of time may be a problem, due to obsolescence of hardware and physical deterioration of the storage media, the data may be saved as a paper hard copy. Data may be stored electronically or in hard copy format, there is no preference as long as the data can be retrieved quickly and it is possible to generate the same findings as recorded in the final report. Regardless of how the data is stored, the following information must also be stored with the data; (a) general information including operator, date, time and calibration file used, (b) a calibration spectrum, (c) a mass spectrum of the test

43rd ASMS Conference on Mass Spectrometry and Allied Topics

article using the ionization method of the analysis, (d) if background subtraction is performed, then a copy of the background spectrum used for subtraction must be provided, (e) if the data is smoothed, then the amount of smoothing must be indicated, and (f) if the data is integrated, then the area to be integrated should be clearly marked and the integration results indicated. If the data is stored as a paper copy of the electronic data it must also include an authorized signature verifying that it is an exact representation of the raw data.

There are several other considerations which fall into the category of data management and they have to do with software control. While GLP regulations do not require the instruments' software programming code to be kept on site, the code must be accessible if needed. Additionally, a description (not the code) of transformations done to the primary data must be retained with the study results. For example, if the chromatographic data is smoothed, an explanation describing the algorithm used and how it was applied, along with the version of software used, would be required. This statement may be as simple as the following; using version 2.3.7 of brand X software (release date) a standard 3 point smooth was performed on the chromatographic data using the Einstein smoothing algorithm. This information would most likely be contained in the protocol describing post-acquisition processing of the data. Another important software control that needs to be addressed pertains to the integrity of data files. It is very important to be certain that the software cannot simply overwrite a previous data file of the same name without some record of the deletion being made. Ideally, it would not be possible to overwrite or delete any data file obtained in a GLP study, however in reality it is very difficult to provide this type of data security. There are two practical alternatives to assure this type of safety. First, the software developer designs the system such that files cannot be easily overwritten. Failing this, the facility must provide procedures to prevent files from being overwritten, ie. through the use of a standard operating procedure (SOP).

Validation of an On-Line Archiving System for Quantitative Mass Spec Data

Patricia M. Coleman, Thomas D. Oglesby, Robert J. White, Lisa P. Werdal
Taylor Technology, Inc., 107 College Road East, Princeton, NJ 08540

A typical problem encountered in any high volume Mass Spectrometry facility is the necessity of archiving large quantities of electronic data. Archiving procedures must be established to assure that all data is securely stored, and easy to identify, locate, and retrieve for an extensive period of time. Automating the archiving system is desirable from the standpoint of reducing personnel time requirements and, perhaps more importantly, eliminating some of the errors which occur in manual systems.

Installing an automated archiving system in a GLP facility requires compliance with FDA/EPA guidelines for the validation of computer systems. Validation is defined as "establishing documented evidence which provides a high degree of assurance that a computer system will consistently produce a product meeting its predetermined specifications and quality attributes"[1]. Two critical phrases of this definition are *documented evidence* and *meeting predetermined specifications*. It is clear from the definition that simply "testing" a computer system is not sufficient to meet regulatory requirements.

Proper validation of a computerized system requires the use of a System Development Life Cycle (SDLC) approach. A written Validation Protocol should be developed which describes all phases of this life cycle. Although ISO 9000, IEEE, and others have specified somewhat different terminologies in the SDLC, the basic framework remains the same. Each company should define the framework and terminologies which work best for them, making sure not to leave out any critical parts of the validation process.

Taylor Technology's framework for the SDLC is outlined as follows:

Phase I - Initiation
- A. System Overview
  - Describe System and its Context
  - Identify Responsibility for the System
- B. User Specifications
  - WHAT the system needs to do
  - User defined requirements

Phase II - Design
- A. Vendor Requirements
  - Adequate Market Experience
  - Quality Software Development Standards
- B. Design Specifications
  - HOW the System will do what is needed
  - Detailed system design by programmer/developer

Phase III - Testing
- A. Structural Testing (White Box Testing)
  - Verifies structural integrity of system
  - Performed by developer/programmer
- B. Functional Testing (Black Box Testing)
  - Verifies system's ability to meet User Specifications
  - Focus on outputs generated by selected inputs
  - Must follow written Test Plan and document results
    - Test Condition/Expected Result/Actual Result

Phase IV - Implementation
- A. Installation in Working Environment
  - Additional Functional Testing
  - User Approval
- B. On-going System Maintenance
  - Change Management / Periodic Review
  - System Documentation / Training Requirements
  - System Security / Backup Procedures

After the basic need for a new archiving system was agreed upon at Taylor Technology, a committee was formed to manage the project which included representation of Mass Spec Users, Information Systems, Quality Assurance and Management. General Requirements for the System were identified including the following:

Current Network Compatibility
Large Storage Capacity and WORM Media Compatibility
Minimal Hands-On Operation Requirements
Easy Retreival of Project/Client Specific Data

After several months of product research, a system was identified which had the potential of meeting the defined requirements. A period of Vendor qualification began which included a review of vendor's programming procedures and quality assurance program, two days of training for all members of the archiving committee and a test installation of a system prototype in our facility.

Because of the complexity of the project and the critical nature of the data involved, a decision was made to implement the system in two phases. In Phase 1, Data is manually identified for archive and then automatically collected by the system and stored to WORM media. An automatic byte by byte comparison of archived files is then performed and results reported. A Validation Protocol was started which described the Initiation of the project and the User and Design Specifications. A Test Plan for Phase 1 was written which identified the tests to be performed and the expected results. After testing was complete, the preliminary system was installed. The completed Validation Protocol included on-going maintenance information such as training, security and backup requirements, and references to internal SOP's and User's Documentation.

The Validation Protocol contains only a brief summary of Phase 2, in which Quantitative Mass Spec Data will be sent to the Archive System immediately after it is acquired. Specifications for Phase 2 are currently in development. When they are complete, the Protocol will be updated to include the second phase of the project.

Each Validation Project is unique. Meeting Regulatory Requirements mandates starting with a Systems Development Life Cycle approach and documenting the process using a Validation Protocol. Beyond that, common sense and logical decision making should guide the process.

An Electronic Sample Logbook for the VG 11/250J Data System

Kenneth J. Rosnack and Thomas R. Sharp
Analytical R&D, Central Research, Pfizer Inc., Groton, CT 06340 U.S.A.

A significant part of conducting any chemical analysis is documenting the identity and source of the sample being analyzed. If such documentation is not done, the analysis may as well not have been conducted. This activity is even more important in situations where the results may be subject to regulatory and/or legal scrutiny. Quality assurance concerns also dictate that the information about the sample be accurately propagated from initial recording through to a final report. The multiple times such information is copied from analysis of sample to final report afford many opportunities to introduce simple transcription errors, which create complex information tracking problems. If such sample identity information could be recorded once, stored intimately with the analytical data, and propagated through the use of reliable computer systems, many of these quality assurance concerns can be addressed.

Toward this end, we have developed an electronic sample logbook system for our VG Analytical 11/250J mass spectrometer data system which provides for one-time entry of sample identification information, intimate association of this information with the analytical results, and at least sets the stage for further use of this information in archiving/retrieval and indexing of analytical results.

The system consists of several "macro programs" which make use of the RPG, MACRO, RUN and DBE features of the 11/250J data system software. Sample information is entered once into a spreadsheet format. A portion of a logbook page, showing the format we use, is reproduced below. The name to be used for the data file, identification of the sample submittor and of the sample itself, notes on operation and experimental conditions, and necessary accounting information are entered. The time and date are left blank. The contents of these fields are generated from the computer system time and date and recorded in the spreadsheet when data acquisition is initiated. While the time does not reflect the exact time that the data acquisition was started, it is reasonably close.

The identification fields in the data acquisition program are then filled in électronically from this spreadsheet by running a RUN program, thus eliminating a source of transcription errors. The data file name is filled in. An account number is generated. The program assembles a TXT field from the name of the sample submittor and the sample identification, the intials of the operator, and the instrument identification, and inserts it into the TXT field. The RUN program then terminates, leaving the system poised, ready to start the data acquisition run. After completing acquisition of data for a given sample, the process is repeated, filling in information for the next sample on the next available line of the logbook page. After the page is filled, a new page is crated, and the process repeated.

Hardcopy of the logbook pages can be generated. The computer files of logbook pages can be archived. With the appropriate additional software, these logbook page files could be used as the data source for indexing of analyses, generation of sample throughput statistics, and accounting purposes.

The updating of parameters can be extended for more involved experiments, such as GC-MS runs, by adding additional commands to the RUN program to modify parameters in the GCC parameter page.

This system has evolved and has been in use on our mass spectrometer data system for several years. It is reasonably robust, and has provided the means to decrease the amount of effort and improve the accuracy of our sample record keeping tasks.

VALIDATION OF MASS SPECTROMETRY DATA SYSTEMS IN A REGULATORY ENVIRONMENT

Cynthia A. Palmer, Michael S. Alexander and Craig R. Abolin
Drug Metabolism and Pharmacokinetics, Sandoz Research Institute
59 Route 10, East Hanover, NJ 07936-1080
email: abolin.craig@ehccgate.sandoz.com

Regulatory pressures have been dramatically changing the extent, means of documentation, data archiving and report generation in quantitative mass spectrometry (MS) laboratories. An entirely new set of requirements beyond the presently accepted scope of Good Laboratory Practices is being placed on the MS laboratory, which must still attempt to meet ongoing analytical demands. In response to this need, we have initiated the development of a robust validation procedure for our specialized data acquisition and reporting system.

Our approach to validation is outlined as a flow diagram in Figure 1. There are two convergent pathways in the validation process: the creation of the overall validation framework with its supporting documentation, and the actual testing of the system with appropriate sets of data. The framework includes, but is not necessarily limited to, a comprehensive review of the current system, an outline of the rationale for the new system, predefined performance acceptance criteria, and provisions for security (physical and electronic), maintenance, data handling, system changes and upgrades, disaster recovery and training. The testing must demonstrate that the expected results with allowable tolerances (if any) are obtained. The actual data sets used must be able to test the system thoroughly.

The system must also be tested to determine its operating boundaries. If possible, the results should be compared to an acceptable standard method. Finally, the entire validation package must be audited and properly archived and a final validation document written.

The guiding principles of the MS data system validation are that: (1) all components of a data system must be thoroughly tested, both individually and in concert; (2) all steps in the generation and processing of analytical results must be unambiguously traceable to the raw data; (3) all steps in the process must be thoroughly documented. A validation plan example is presented for weighted nonlinear regression for LC/MS calibration curves, illustrating the development life cycle and system testing.

Validation can be achieved within reasonable cost and time constraints by breaking the overall validation process into a series of small steps. These goals are achievable without compromising laboratory productivity or quality by careful advance planning. We have found that validation can be performed in an incremental manner, with some portions in parallel (illustrated in Figure 2), and that basic questions about the actual mechanism of the data system validation process are not yet clearly defined in the MS user or regulatory community.

With the advent of electrospray and ion spray interfaces, the analysis of macromolecules by mass spectrometry has emerged as an important tool in modern biological research. Four years ago, we reported the first studies in which noncovalent receptor-ligand and enzyme-substrate complexes were detected in the gas phase directly out of aqueous solution. That work established for the first time that the cumulative effect of weak intermolecular forces -- e.g. hydrogen bonding, charge transfer complexation, π-stacking, hydrophobic effects, charge-charge, charge-dipole, and dipole-dipole interactions -- could provide enough stabilization for such host-guest complexes to survive the gentle ion evaporation process.

Even though such intermolecular interactions are influenced differently by solvation, and display qualitatively different structural and distance constraints, it is now apparent from the efforts of numerous groups that electrospray and ion spray mass spectrometry can be used to detect molecular recognition phenomena in a wide variety of biologically important association complexes. Examples to date have included several active site directed enzymatic complexes (e.g. with substrates, products, and inhibitors), oligonucleotide duplexes, drug-nucleic acid complexes, heme-globin complexes, antibody-hapten complexes, hydrophobic leucine zipper peptide dimers, and carbohydrate association complexes on cell-surfaces.

These studies have paved the way for more ambitious applications of mass spectrometry designed to probe the higher order structure of macromolecular and supramolecular assemblies within biological systems. For example, the role of the modern mass spectrometer in unravelling the stoichiometry of multimeric chemical and biochemical architectures, in ascertaining the functional role of subunits in complex catalytic processes, and in studying the structures of membrane-bound proteins will be discussed.

Protein-DNA interactions are crucial to the regulation and control of a host of functions within living organisms. Among the techniques for the study of protein-DNA interactions are x-ray diffraction, NMR, and electrophoresis (e.g., mobility shift assays). Electrospray ionization (ESI) has recently been shown to result in ionization of large biomolecules while preserving noncovalent biomolecular associations. The preservation of these associations is significant because mass spectrometry (MS) is a highly sensitive and structurally informative technique that is directly applicable to the analysis of mixture components.

We have made the first ESI-MS characterization of protein-DNA complexes. Gene V protein from bacteriophage f1 is known to bind strongly to single stranded DNA. Under mild interface conditions from solutions in 10 mM NH4OAc, gene V protein was observed as dimer ions from ESI. The binding stoichiometry was investigated using different lengths of ssDNA. Figure 1 shows a 4:1 protein:DNA complex was observed with a 16-mer ssDNA. A 12-mer ssDNA formed primarily a 2:1 protein:DNA complex. This indicates the protein binds as a dimer and with a stoichiometry of one dimer for eight nucleotides. The complex with 16-mer ssDNA was examined independently by gel filtration and a 4:1 complex was also found by this method.

PU.1, a member of the Ets family of transcription factors, is a sequence specific DNA binding protein that has a recognition sequence GGAA/T in double stranded DNA. Figure 2 shows a 1:1 complex is formed with a 17-bp dsDNA containing the recognition sequence. A competition experiment with a 19-bp dsDNA not containing the recognition sequence showed that only the 17-bp dsDNA formed complex with the protein, even when the 19-bp was present in 20 fold excess. A band shift assay confirmed the selectivity of the protein.

The results of these studies demonstrated the potential utility of ESI-MS in the characterization of stoichiometries and relative binding energies of protein-DNA complexes.

The research at PNL was supported through the U.S. Department of Energy. PNL is operated by Battelle Memorial Institute through Contract No. DE-AC06-76RLO 1830.

The electrospray (ES) technique provides a suitably gentle ionization method for obtaining information on the higher-order structure of proteins and their interaction with other biomolecules [1,2], but the limited *m/z* range of most quadrupole mass spectrometers has been a major obstacle. This limitation is particularly significant when proteins and/or complexes of biomolecules are studied in their native conformations from solutions at near physiological conditions. We have interfaced an ES source to a time-of-flight mass spectrometer [3], which has in principle an infinite *m/z* range. Recent incorporation of nano-spray [4] and an RF-quadrupole ion guide [5] into the instrument has led to further improvements both in sensitivity and resolution and minimized mass and *m/z* discrimination. These features make the ES-TOF instrument suitable for studies of non-covalent complexes, as demonstrated by several examples below.

Studies have been carried out on the enzyme 4-oxalocrotonate tautomerase (~6810u), prepared by total chemical synthesis [6]; they showed that the enzyme forms a hexamer in solution at pH 7.5, which falls apart at pH<5. Ions of a site-specific immunoconjugate $F(ab')_2$-CPG2, prepared from an $F(ab')_2$-like fragment of the monoclonal anti-CEA murine IgG1 A5B7 and a mutant of the dimeric enzyme carboxypeptidase G2 [7], were recorded with m/z>6000 and were the dominant ions in these spectra, as shown in Fig.1. The complex was observed at pH ~6, and it fell apart at pH<4.5. Protein-protein non-covalent interactions in soybean agglutinin (SBA), a glycoprotein with monomer mass ~30,000 u, have been examined in this instrument [8]. Only monomer ions were observed in 30% acetonitrile, only tetramer ions (and tetramer clusters up to the 20-mer, M.W.~578,000 u) in pure water. Further information on the quaternary structure of SBA was obtained by collision-induced dissociation (CID) of the tetramer within the ion source. Although most of the experiments were carried out with a conventional ES source, nano-spray turned out to be very efficient in studies of non-covalent complexes. It produces a stable spray from almost any solution and allows use of as little as ~1 microL of solution. An example of a nano-spray spectrum of SBA is shown in Fig.2.

Catalase HP II from E.coli [9], a tetrameric protein with M.W.=339,100 u, was also studied with nano-spray. Earlier it was demonstrated that the performance of ES-TOF MS for heavy ions (>50,000 u) is deteriorated significantly by collision-induced dissociation inside the vacuum chamber at pressures ~10^{-6} Torr [10]. However, mass spectrum of HP II did *not* change when the pressure in the vacuum chamber was increased from $2*10^{-7}$ to $1.3*10^{-6}$Torr (Fig.3). The narrow peaks in this spectrum recorded at high declustering voltage (ΔU=200 V) allowed determination of the mass with an accuracy of 0.03%. At lower ΔU (Fig.4), the peaks became wider and clusters up to the 16-mer (M.W.>10^6 u) were clearly observed.

All the complexes mentioned above required observation of high *m/z* ratio (3,000 to 16,000), as provided by ES-TOF instrument.

Detecting Conformational Changes in Cytochrome C upon Binding of Membranes

Paul W. Stoker, Jocelyn H. Ng-Ilag, and David L. Smith
Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304

Understanding the interaction of proteins with phospholipid membranes and the conformational changes caused by this membrane contact is necessary to ascertain the proteins' function. The binding of cytochrome C, an extrinsic mitochondrial membrane protein, to synthetic lipid membranes has been studied. One valuable technique employed is monitoring of the exchange of hydrogen for deuterium at the amide nitrogens all along the protein backbone. The incorporation of the deuterium for small proteins can be detected by NMR[1] and FTIR[2], but are not as useful for larger proteins and membrane bound proteins. In these more difficult cases, more useful information may be acquired by digestion of the deuterated protein followed by the analysis of the resultant peptide fragments by HPLC FABMS[3]. We have used the hydrogen exchange method HPLC ESIMS to examine the interaction of cytochrome C with a synthetic phospholipid membrane.

The synthetic phospholipid membrane was made to resemble the inner mitochondrial membrane upon which the cytochrome C is naturally bound. The composition of membrane consists of phosphotidylcholine, cardiolipin, phosphotidylethanolamine, and cholesterol. These lipids were purchased commercially and made into large unilamellar vesicles. Cytochrome C was added to the vesicles and allowed to complex for two hours. The cytochrome C-lipid complexes were washed with buffer to remove the unbound protein. Deuterated buffer at pD 6.0 was added to the complexes. To insure that little H_2O remained in the solution, the complexes were centrifuged and the buffer was removed, additional D_2O buffer at pD 6.0 was added, and then the tube was inverted several time to mix the sample. The complexes were incubated in the D_2O buffer for a prescribed time period (1-55 min). At the end of the time period the D_2O buffer at pD 6.0 was removed and the complexes were washed with cold D_2O buffer at pD 5.0 to remove any unbound cytochrome C and to slow the exchange reaction. After the removal of the cold D_2O buffer (pD 5.0), cold 200 mM $MgCl_2$ was added to the complexes, followed quickly by the addition of cold 1M D_2O buffer at pD 2.0. The resulting solution was filtered to remove the lipid membrane and the filtrate was frozen in liquid nitrogen and stored at -80° C until analysis. The samples were thawed quickly, digested by pepsin, and analyzed by HPLC ESIMS. In addition to the analysis of the membrane bound protein, control experiments were run with free cytochrome C for comparison.

Comparison of the results of the analysis of the peptide fragments for the free versus the bound cytochrome C indicate that there are two regions of the protein where a decrease in deuterium incorporation was observed. Figure 1 shows the peptide fragments that were analyzed and the regions of decreased incorporation. The largest region of decrease incorporation is in the 95-104 peptide fragment. The plot of the deuterium uptake versus time of the 95-104 fragment can be seen in Figure 2. In an earlier work this region of cytochrome C was postulate to be embedded in or on the surface of the lipid membrane[4]. The plot of the deuterium uptake versus time for a fragment in which very little difference is seen is also shown in Figure 3.

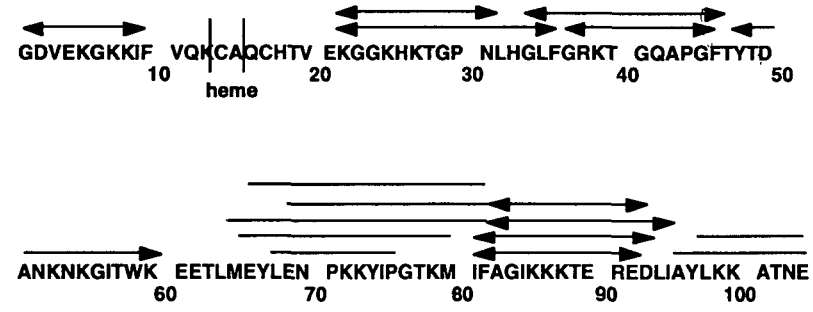

Figure 1. Peptide fragments formed by peptic digestion of cytochrome C. These peptide fragments were analyzed by HPLC ESIMS to determine the level of deuterium incorporation. The lines represent peptide fragments which showed a decreased incorporation of deuterium when bound to a phospholipid membrane as compared to free cytochrome C. The lines with arrowhead represent the peptide fragments which showed very little change in deuterium incorporation.

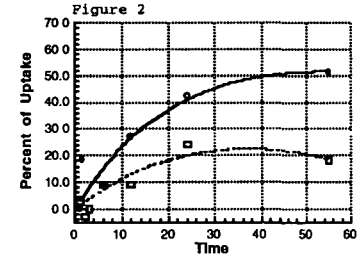

Figure 2: Plot of the deuterium uptake versus time for the peptide fragment 95-104 of the cytochrome C. The fragment is the result of pepsin digestion of the membrane-bound and free protein after the incubation period. The squares are the membrane-bound cytochrome C and the circles represent the free protein.

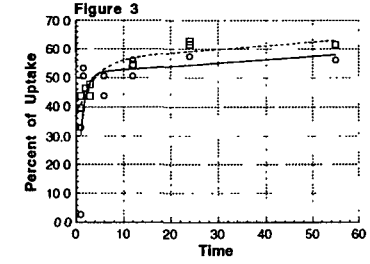

Figure 3: Plot of the deuterium uptake versus time for the peptide fragment 22-36 of the cytochrome C. Conditions and labeling of the data points are the same as described for Figure 2.

PROTEIN DENATURATION STUDIED BY HYDROGEN EXCHANGE AND MASS SPECTROMETRY

Zhongqi Zhang and David L. Smith
Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588

The study of protein denaturation may provide important information for the mechanism of protein folding and unfolding, as well as the basis for the thermodynamic stability of proteins. Most of the studies of protein denaturation were done by differential scanning calorimetry, circular dichroism, fluorescence, infrared spectroscopy, etc., which give very limited space-resolved structural information. Some detailed information about protein denaturation has been obtained from NMR studies of several small proteins, but few studies have been done on structurally resolved denaturation of large proteins A new technique, based on protein fragmentation and mass spectrometry to determine hydrogen exchange behavior in a protein, provides a new tool for the studies of denaturation of large proteins (Zhang and Smith, *Protein Sci.* 2, 522, 1993). In this technique, deuterium labeled protein is digested by an acid protease, and the deuterium content on each peptide fragment is determined by directly coupled HPLC/mass spectrometry This presentation describes the results obtained when this technique was applied to the study of heat, acid and urea induced denaturation of rabbit muscle aldolase

In this study, a capillary perfusion column was connected directly to VG Autospec electrospray mass spectrometer equipped with an array detector. The perfusion column was used to reduce the time of analysis, and thus minimize the deuterium loss during analysis. The whole HPLC/ESIMS analysis can usually be finished within 5 minutes.

In the study of thermal denaturation of aldolase, aldolase was incubated in D_2O at different temperatures Because the amide hydrogens in a segment have much higher exchange rates when the segment is unfolded, the level of deuterium incorporation in each segment reflects the thermal stability of this segment The result shows that with the increase of temperature, loop areas loosen gradually, and α-helices and β-sheets unfold cooperatively at the denaturation temperature of 45-50 °C The last step of irreversible thermal denaturation of aldolase is the loss of its quaternary structure

In a mild denaturing condition, as shown in Fig 1, there is usually an equilibrium between the native state and a partially unfolded state. Hydrogen exchange occurs mostly in the unfolded state The distribution of deuterium labeling in an unfolded segment depends on the rates of the hydrogen exchange (k_2) and the refolding of the segment (k_{-1}). If $k_2 >> k_{-1}$, all amide hydrogens in the unfolded segment will be replaced with deuterium (EX1 mechanism) As a result, a bimodal isotopic pattern will be observed, and the unfolding rate constant of the segment k_1 equals the rate constant at which the envelope with high deuterium content increases with time

The study of acid induced denaturation of aldolase shows that at p^2H 4 0, aldolase is in an equilibrium between a folded state and an unfolded state, and the hydrogen exchange is through EX1 mechanism, as indicated by a bimodal isotopic pattern for most of the segments studied Further analysis of the patterns shows that most of the segments studied have unfolding rates of 0 2-0.4 hr^{-1}, suggesting that the unfolding of aldolase induced by acid is mostly cooperative When aldolase was incubated in D_2O with 4 M urea, it was found that the areas on the surface of the protein have an unfolding half-life of 1-2 minutes and the regions at the subunit interface have unfolding half-life of about 2 hours (see Fig 2 for examples) This tells us that urea induced denaturation of aldolase is a two-step process. The first step is the unfolding of the surface area and the second step is the unfolding of the subunit interface area

Mass spectrometry is very powerful in the study of protein folding and unfolding when combined

with the hydrogen exchange technique The technique described here can be used to study large proteins, and very importantly, to separate segments from different conformational states of the protein Since this technique has fewer restrictions than other methods and gives important information other methods fail to provide, it will become one of the most important methods for studies of protein folding and unfolding

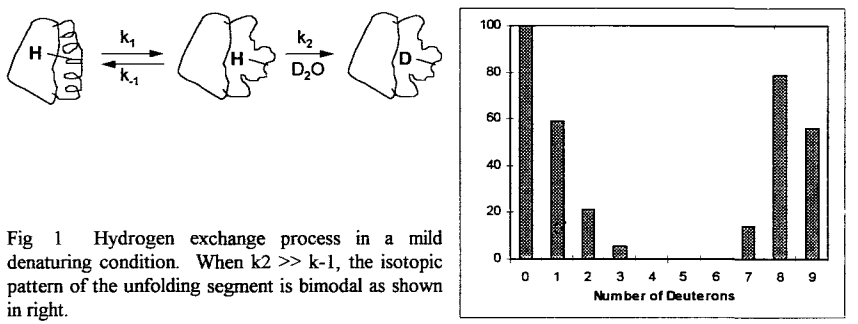

Fig 1 Hydrogen exchange process in a mild denaturing condition. When k2 >> k-1, the isotopic pattern of the unfolding segment is bimodal as shown in right.

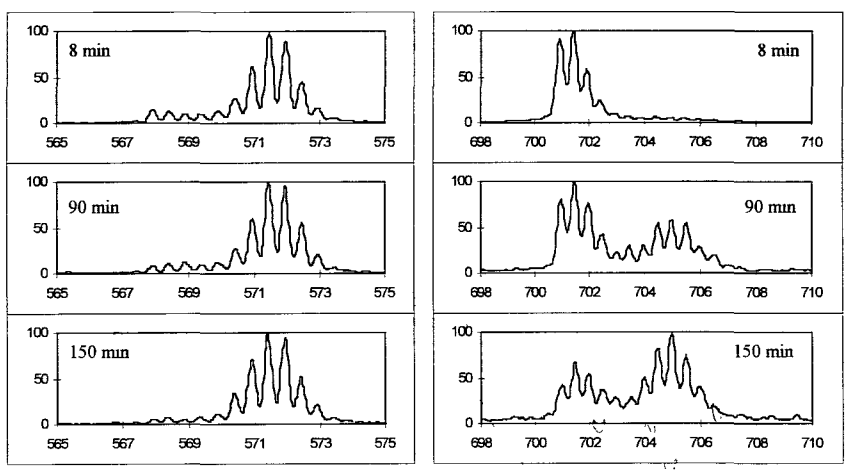

Fig. 2 Electrospray mass spectra of peptide 327-336 $(M+2H)^{2+}$ (left) and peptide 257-269 $(M+2H)^{2+}$ (right) when aldolase was incubated in D_2O with 4 M urea for different periods of time Peptide 327-336, with an unfolding half-life of 1-2 minutes, is from the surface of aldolase, and peptide 257-269, with an unfolding half-life of 2 hours, is from the subunit interface area

Mass Spectrometric Characterization of Non.covalent TT EF.Tu / Ts Complexes.

M.O. Glocker[1], S. Nock[2], M. Sprinzl[2] and M. Przybylski[1]

[1]University Konstanz, Faculty of Chemistry, P.O Box 5560 M732, 78434 Konstanz, Germany.
[2]University Bayreuth, Institute for Biochemistry, Universitätstr. 30, 95440 Bayreuth, Germany.

Bacterial elongation factor Tu (EF-Tu) is a GTPase which promotes the binding of aminoacyl-tRNA to the codon-programmed ribosomes EF-Tu from *Thermus thermophilus* consists of 405 amino acids and has a molecular weight of 44636 Da. The crystal structure of intact EF-Tu from *Thermus thermophilus* has been determined in the presence of a nucleotide GppNHp, a structural homolog of GTP [1]. It contains three domains, domain I (aa residues 1-211, GTP/GDP binding domain) carries the nucleotide binding region and consists of α-helical and β-sheet structure elements, while domain II (aa 212-311) and domain III (aa 312-405) show β-sheet secondary structural features. EF-Tu is an essential component of bacterial protein biosynthesis and forms a ternary complex with GTP and aminoacyl-tRNA. During its functional cycle it consecutively binds several ligands, GDP, elongation factor Ts, GTP, aminoacyl-tRNA and ribosomes [2] The common feature of ribosomal regulatory elongation cycles is the switch from an "inactive" GDP binding to an "active" GTP binding conformation of EF-Tu which is promoted by EF-Ts, a nucleotide exchange factor [3]. Elongation factor Ts (EF-Ts) is a homodimer and when isolated, forms an intermolecular disulfide bond. EF-Ts consists of 195 amino acids and has a molecular weight of 44618 Da for the homodimer. Not much is known about the regions through which both proteins are interacting and the tertiary structure of EF-Ts is unknown. Recently, mass spectometric methods were shown to be able to characterize protein tertiary structure features [4]. Also, mass spectrometric methods in combination with tertiary structure-selective chemical modification reactions were shown to present a useful tool for the characterization of protein surface topologies [5,6].

In this study we describe the use of protein tertiary structure-selective lysine acetylation combined with mass spectrometric analyses for the characterization of elongation factors EF-Tu and EF-Ts and their interacting regions. Acetylation reactions were carried out using EF-Ts, EF-Tu complexed with GDP (EF-Tu*GDP), and with non-covalent complexes formed between EF-Ts and EF-Tu*GDP The molecular weights of the proteins and partially acetylated derivatives were determined using electrospray mass spectrometry (ES-MS) and matrix assisted laser desorption / ionization mass spectrometry (MALDI-MS) and showed increasing molecular weights with increasing excesses of acetic anhydride. ES-MS, additionally, was used to study changes in

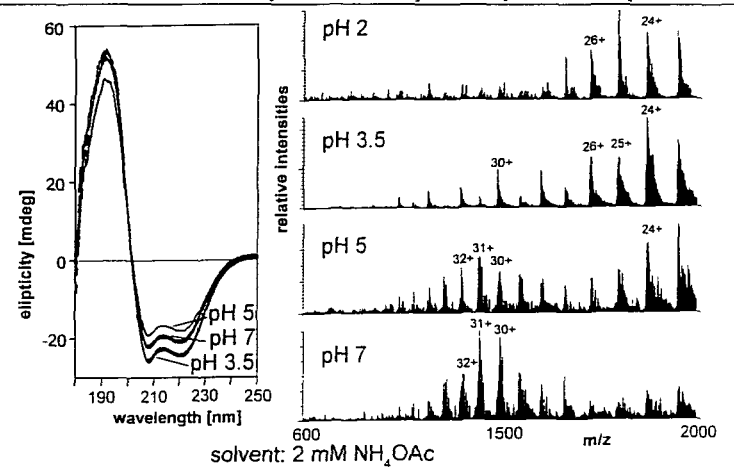

Figure 1. CD- and ES-MS spectra of EF-Ts at different pH.

protein conformations by comparison of charge structures of unmodified and acetylated EF-Tu and EF-Ts derivatives. Both, EF-Tu and EF-Ts derivatives with small degrees of acetylation showed similar charge structures than the unmodified proteins. In contrast, pH variation had extreme effects to the charge structure of EF-Ts (Fig. 1) At high pH EF-Ts showed a maximum around the 31+ molecular ion, while at low pH the maximum had shifted to the 25+ molecular ion. Mass spectrometric peptide mapping analyses of tryptic peptide mixtures of partially modified protein derivatives yielded the exact identification of acetylation sites Acetylation reactions with EF-Tu*GDP showed that lysine residues involved in nucleotide binding remained unacetylated. Differences in acetylation of EF-Tu*GDP alone in comparison to EF-Tu - EF-Ts complexes were observed for Lys45 and Lys52 in domain I, indicating that this region was shielded in the non-covalent complex. Also, acetylation reactions with EF-Ts alone enabled the differentiation between relative reactivities of all lysine residues Comparison of the acetylation pattern of the free EF-Ts with the acetylation pattern of the non-covalent complex of EF-Ts with Ef-Tu*GDP indicated that Lys119 of EF-Ts is shielded by the interaction with EF-Tu.

Mass Spectrometry as a Tool for Protein X-ray Crystallographic Analysis

*S. L. Cohen, X. Xie, U. A. Mirza, S. K. Burley, and B. T. Chait
The Rockefeller University, 1230 York Avenue, NY, NY 10021

Mass spectrometry can complement as well as facilitate the structural characterization of proteins by X-ray crystallography and NMR spectroscopy. In this report we demonstrate the mass spectrometric contributions to a crystallographic structural study of a recently cloned pair of eukaryotic proteins, p42 and p62 [1]. The two proteins have been shown to associate with each other *in vitro* forming tight heterodimeric and weaker tetrameric complexes. The proteins may play an important role in activated transcription.

The proteins show sequence similarity to the oligomeric histone proteins. Initially, a sequence alignment with the histone proteins allowed for the design of truncated versions of p42 and p62 to facilitate the crystallization attempts (p42: 99 residues, 11.3 kDa; p62: 93 residues, 10.2 kDa). The truncated proteins were expressed and purified. ESI- as well as MALDI-MS verified the correct masses as well as the purity of the recombinant proteins.

Electrospray was also used to monitor the oligomerization of the proteins. Under moderately gentle electrospray conditions, a pure water solution of truncated p42/p62 exhibits strong multiple-charged peaks that correspond to the non-covalent p42/p62 complex (**Figure 1**). Monomer peaks are also observed in the spectrum but *no peaks corresponding to homodimers were measured.* Under even gentler conditions, there appear low intensity peaks that correspond to tetramers (i.e., a dimer of the heterodimers). Under harsh ESI conditions, the dimer peaks disappear leaving only the monomers. Taken together, these results suggest that the solution-phase non-covalent interactions between the truncated p42 and p62 can be maintained into the gas phase with high specificity.

Early attempts to crystallize the truncated p42/p62 yielded crystals that diffracted to low resolution. Coincidentally, MALDI-MS showed that the proteins slowly degraded from their N-and C-terminals in solution. This MALDI finding suggested that the terminals were "floppy" —a result which could account for the poor X-ray diffraction.

In an attempt to better define the minimal folding domains of the protein, the p42/p62 protein complex, formed from the truncated versions of the protein, was subjected to a limited proteolysis study. Three experiments were performed using trypsin, chymotrypsin and subtilisin proteases. MALDI-MS was used for rapid and accurate mapping of the proteolytic digestions. Results of the digestions are summarized in **Figures 2** and **3,** which show the observed sites of proteolytic cleavage superimposed on linear representations of the two proteins. The vertical arrows in both figures point to sites in the proteins which were proteolytically cleaved —the long arrows indicate rapid cleavage (minutes to hours), whereas the shorter arrows indicate sites of slower cleavage (hours to days). Based on the proteolysis results, we designed new constructs of the protein. For p42 this included two forms consisting of residues 1-94 and 10-94. For p62 one new construct consisting of residues 1-84 was planned. The new constructs were expressed and purified. ESI-MS verified that they retained a non-covalent heterodimeric association when sprayed from pure water. Using the the new constructs, we have succeded in growing stable crystals of the p42/p62 complex that diffract to high resolution.

In-line SID Modes: Characterization and Comparison with High-Energy CAD

David A. Durkin and Kevin L.Schey, Dept. of Pharmacology, Medical University of South Carolina, 171 Ashley Ave, Charleston, SC 29425

A novel mode of operation for an in-line surface induced dissociation (SID) device has been evaluated with particular emphasis on comparison with high-energy collision activated dissociation (CAD). Ion optical considerations are discussed for several in-line SID modes using SIMION trajectory calculations. A series of ions ranging from small organic radical cations to cesium iodide clusters to peptides were used to evaluate both dissociation methods with respect to internal energy deposition and dissociation efficiency.

Ion/surface collisions were carried out in a JEOL HX110/HX110 tandem mass spectrometer equipped with an in-line SID device[1]. Precursor ions were generated by electron impact ionization, LSIMS ionization, and by electrospray ionization (ESI). Precursor ions selected by MS-1 were allowed to collide with a perfluoropolyether (Krytox) coated brass surface at collision energies ranging from 40-100 eV. Dissociation efficiencies were determined by dividing the sum of product ions signals (measured using detector three) by the precursor ion signal (measured with detector one). Differences in detector gains were taken into account in calculating dissociation efficiencies.

This new mode of operation causes ions to be deflected by two deflection electrodes which, according to SIMION trajectory calculations (Figure 1), delivers a focussed precursor ion beam to the target surface. SIMION calculations also predict that product ions are most efficiently extracted from the portion of the target closest to the extraction electrodes. Product ion signals are three to five times larger with the dual deflection mode compared to single deflection mode where ions collide with deflector 2 (as shown in Figure 1).

Typical ion/surface reaction products were observed with this device including extensive ion/surface reactions, chemical sputtering, and ion dissociation. Dissociation efficiencies measured using both SID and CAD are summarized in Figure 2. For radical cations, CAD efficiencies are slightly higher than SID efficiencies presumably due to the high probability of neutralization in SID. Efficiencies measured for CsI clusters are different for CAD and SID depending on the cluster examined. This result is likely due the high internal energy required to dissociate m/z 393 which is easily provided by SID. That is, internal energy deposition may play a role in observing efficient dissociation when high energy reactions are examined. Lastly, peptide ions are clearly dissociated more efficiently by SID.

SID spectra for leucine enkephalin produced by LSIMS and ESI are shown in Figure 3. Clearly, the SID process is efficient enough to produce abundant sequence information from lower ion currents provided by ESI.

In conclusion, SID compares favorably with high-energy CAD in terms of internal energy deposition and dissociation efficiency. Improvements in design and operation mode will continue to make SID a viable dissociation method in sector instruments.

Influence of Peptide Sequence, Size and Basicity on ESI/SID Spectra

Jennifer L. Jones, Ashok Dongré, Hari Nair, Árpad Somogyi and Vicki H. Wysocki
Virginia Commonwealth University, Department of Chemistry, Richmond, VA 23284-2006

Electrospray ionization/surface-induced dissociation (ESI/SID) is used to investigate the effect of peptide sequence, size and gas-phase basicity on fragmentation efficiency. We recently reported results that show a sequence dependence of protonated peptides on fragmentation efficiency.[1] In summary, high energy onsets are detected when a protonated peptide is stabilized in any particular way (e.g., proton localization, intramolecular hydrogen bonding or structural rigidity) and shifts to lower energy are observed when the peptide is destabilized (e.g., proton randomization).

In the work presented here, synthetic peptides are used to systematically investigate the shift in fragmentation efficiency (e.g., AAAAA, PAAAA, KAAAA, and RAAAA) as a function of basicity. As the amino acid substituted at the first position is varied, differences in the onset energies for fragmentation are detected (see Figure 1). The shifts detected for each curve are in agreement with the order of increasing gas-phase basicity of the amino acid substituted as shown by the linear plot in Figure 2.[2,3] This figure is a plot of the internal energy at the inflection point for each peptide versus the reported gas-phase basicity[2] of the amino acid residue being substituted at the first position.

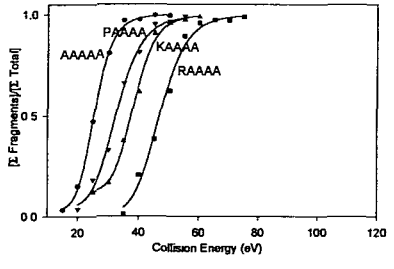

Figure 1.

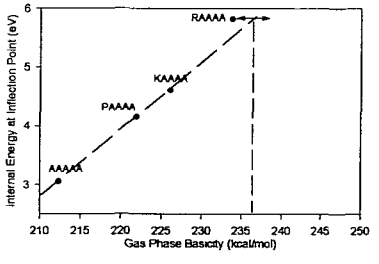

Figure 2

Other parameters that affect the overall position of the fragmentation efficiency curves are the size of the peptide and sequence effects (i.e., structural rigidity or intramolecular hydrogen bonding). Several oligomers of alanine plus other non-basic peptides are used to estimate the contribution of peptide size to the overall position of the fragmentation efficiency curves. As the size of the peptide increases, higher collision energies are needed to cause fragmentation. This effect is represented in Figure 3; the collision energy at the inflection point of the fragmentation

efficiency curves is plotted against the number of vibrational degrees of freedom for all non-basic residue-containing peptides investigated.

We can estimate the additional energy needed to fragment protonated peptides which contain a basic amino acid residue by using the shifts detected in Figure 1. We subtract out both the contribution of peptide size and gas-phase basicity on the overall position of the fragmentation efficiency curves; this allows an approximation of the influence of peptide sequence effects on the overall position of the fragmentation efficiency curves. The results are displayed in Figure 4; as the peptide sequence becomes more complex (i.e., various combinations of different amino acid residues), the more likely that secondary structure or intramolecular interactions within the peptide provide stabilization and require more energy to fragment

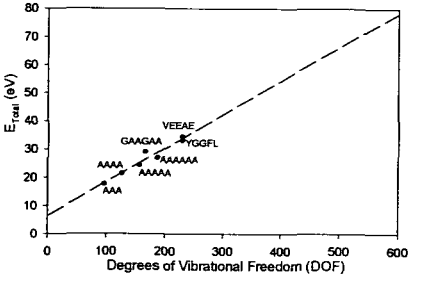

Figure 3.

For example, the bradykinin analogs (i.e., PPGFSP, PPGFSPFR and RPPGFSPF) have similar collision energies necessary to fragment the peptide as a result of structure. A logical explanation for this extra energy is that the prolines present in each bradykinin analog add structural rigidity to the peptide and also induce β-turns which allow the peptides to form more rigid structures than fully extended conformations. In agreement with a mobile proton model for fragmentation,[1] the extra rigidity hinders the proton transfers necessary to initiate charge-directed formation of typical sequence ions.

Ion/Surface Reactions: Towards a Better Understanding of Mechanisms, B. Feng, X. Jiang, S. Miller, J. Patrick, T. Pradeep, H. Rohrs, T. Ast and R.G. Cooks, Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393

The goal of these studies is to provide insights into mechanisms involved in ion/surface reactions using ion/surface collisions by comparison with gas-phase ion/molecule reactive collisions. Reactions involving the collision of low energy beams of bare and ligated metal ions as well as small organic ions with a variety of surfaces have been investigated.[1,2] These studies have demonstrated the ability of various ions to abstract multiple ligands from surfaces which include liquid perfluorinated polymers, fluoroalkyl self-assembled monolayers (F-SAM), alkyl SAMs and others. Reactions include the abstraction of fluorine atoms by W^+, CH_nX^+ (X = Cl, Br or I) and other projectiles upon collision with an F-SAM.[3] Chemical sputtering is used after reactive collisions to explore the modified surface. For example, Xe^+ sputtering of an F-SAM after ion bombardment with CH_2Br^+ shows the presence of CF_2Br^+ (Figure 1), indicative of halogen exchange. Similar results have been obtained for SIMS-TOF analysis of an F-SAM surface after modification by $SiCl_4^+$.[4] Gas-phase studies have also been undertaken to evaluate the formation of WF_n^+ from complexes of $W(CO)_n^+$ with perfluorocarbons.[3,5] The above results lead to the proposal of a working mechanism for surface modification involving formation of a multi-center complex. For example, a four-centered complex is shown in Figure 2. Evidence supporting the proposed mechanism for ion/surface reaction is provided in the current work by experiments in which P, Si, W and I-containing ions, believed to cause surface modification, are collided at low energy with volatile neutrals in the second quadrupole of a triple quadrupole instrument. Experiments performed under single-collision conditions show product ions corresponding to abstraction of multiple fluorine atoms from fluorinated targets as well as complexes of the projectile with substituted alkyl groups. These findings parallel the observations from ion/surface collision experiments and suggest formation of a multi-center complex (analogous to an ion/molecule collision complex)of the projectile with the surface. The effects of chain length and the nature of the target were investigated using tetrafluoromethane, perfluoroethane, 1,1-difluoroethane, perfluorohexane, 1-fluorohexane, trichlorotrifluoroethane as targets. Competitive abstraction of species from gaseous targets show relative extents of adduct formation which correlate inversely with C-X bond strength (X=H,F,Cl,Br,I). The nature of the abstraction product observed is controlled by the number of fluorines the number of carbons (Figure 3; only 1 F abstracted from CF_4 (3A) while 2-3 F atoms are abstracted with perfluoroethane (3B)), and the nature of the substituents on the target. Specifically, multiple abstractions require longer carbon chains (n > 2) containing multiple fluorines. Furthermore, the observation of product ions corresponding to one-to-one complexes, and related fragments of the target molecules and projectiles under gas phase single collision conditions, supports the role of a long-lived collision-complex in the modification of surfaces through reactive ion/surface collisions.

The use of gas-phase collisions to explore the mechanisms for ion/surface reactions has been demonstrated and parallels between the two conditions have been found in the chemical systems examined here.

Construction of a Tandem Quadrupole Mass Spectrometer for the Study of Ion Surface Interactions Occurring Under Ultra High Vacuum (UHV) Conditions

Mark J. Hayward†‡, Frederick D.S. Park†, Lynn M. Manzella†, and Steven L. Bernasek†*
†Department of Chemistry - Princeton University - Princeton, NJ 08544 and
‡Agricultural Research Division - American Cyanamid Company - Princeton, NJ 08543

A new tandem quadrupole mass spectrometer has been constructed which allows the study of the interactions of mass selected ions with surfaces prepared and characterized at UHV. The entire surface induced dissociation (SID) tandem mass spectrometer is contained on a single 8" conflat flange (as shown in the accompanying figure) thereby permitting it to be combined with virtually any standard surface analysis system. The ion source and primary ion mass filter utilize two stages of differential pumping to allow mass selected ions produced by electron impact (EI) ionization to be delivered to the surface without affecting the pressure at the surface. This SID instrument has been combined with a surface analysis system which contains additional mass spectrometers (for desorption analysis of the surface and monitoring neutrals emerging from the surface during SID) and an Auger spectrometer. In the short time that the instrument has been operable, the following interesting results have been obtained:

1) Proton sputtering is a major process which results from the collision of ions with hydrocarbon surfaces.

2) Observation of proton sputtering is strong evidence of a charge exchange mechanism leading to hydrogen addition during SID.

3) There is little (if any) dependence on momentum transfer required for proton sputtering.

4) Protonation of neutralized molecular ions has a strong kinetic energy dependence which may be the result of a requirement for sufficient interaction time.

5) While there are many possible routes to the formation of $C_7H_7^+$ during SID of benzene molecular ions (see accompanying spectrum), the experimental evidence suggests that the primary mechanism involves the reaction of neutralized benzene with $C_3H_5^+$ sputtered from the hydrocarbon overlayer.

6) Ion surface reactions (at hydrocarbon covered surfaces) which lead to associative alkylation products take place in a manner that is like methane and/or isobutane CI. The use of CI as a model (where the CI reagent ions are considered equivalent to sputtered ions in SID) should facilitate greater understanding of alkylation reactions in future SID experiments.

Strongly Enhanced Secondary Ion Yields in TOF-SIMS Studies with Very Highly Charged Primary Ions up to Th^{71+}

T. Schenkel, M. A. Briere, A. E. Schach von Wittenau and D. Schneider

Physics and Space Technology, Lawrence Livermore National Laboratory, Livermore, CA 94550 USA

The advent of new ion source technologies, such as the LLNL EBIT[1] (Electron Beam Ion Trap), has made low emittance (~0.2 π mm mrad) beams of slow (several keV/amu) very highly charged ions (up to U^{92+}) accessible for ion solid interaction studies. The prominent feature in the interaction of highly charged ions with surfaces, compared to conventional singly charged ions, is a dominance of electronic over collisional effects. Up to several hundreds of electrons (for Th^{70+} on Au[2]) are emitted from an area of a few square nanometers per incident ion. In insulators, this local disturbance of the charge equilibrium produces a "Coulomb explosion", resulting in the emission of large numbers of secondary particles, and the production of nanometer size defects[3]
Negative and positive secondary ion yields are determined using a single detector time of flight arrangement shown in Fig. 1. High pulses generated by the many secondary potential electrons and photons that are emitted at the impact of each highly charged ion provide the start signals; stop signals are given by the low pulses generated by single secondary ions Fig. 2 shows a typical pulse height distribution for this arrangement with the sample (SiO_2 on Si) biased at -2 kV and an incident Th^{65+} beam. The pulse height discrimination is accomplished via standard electronics, with a delay between the amplifier output and the start constant fraction discriminator allowing to determine the effect of the single hit TAC setup on the measurement of multiple ion production[4]
Fig. 3 shows a mass spectrum of negative secondary ions emitted from a SiO_2 film (100 nm on Si) for Th^{70+} impact. Clusters from two molecular series are present with masses up to 676 amu. The total positive and negative components of the secondary ion yield (detection efficiency and single hit[4] correction included), as a function of incident ion charge, are shown in Fig. 4. The yields increases linearly with incident ion charge above about 25+, with the total yield dominated in each case by the atomic species; O^+,Si^+,O^- Given a detection efficiency of ~5%, the total (i.e. sum of all positive and negative species) secondary ion production rate, for Th^{70+}, is in the order of 20-50, up from 10^{-4} to 10^{-2} for singly charged primary ions[5]. Theoretical estimates of the ionization probability for this process range from 5 to 20 % [6], suggesting that the total yield for highly charged ion induced sputtering can exceed 500 atoms/incident ion The enhanced ionization probability for both atomic and molecular species can be applied to improve the analysis of surfaces on micron and submicron scales

This work was performed under the Auspices of the US Dept. of Energy by Lawrence Livermore National Laboratory under contract No W-7405-ENG-48.

Ion Neutralization during Surface-Induced Dissociation at Ni(111) and NiO(111)

Samuel B. Wainhaus, John A. Burroughs, and Luke Hanley
University of Illinois at Chicago
Department of Chemistry, m/c 111
Chicago, IL 60607-7061

When a positive molecular ion is neutralized by the transfer of an electron from the surface, the scattered neutral can no longer be readily detected with a mass spectrometer. Such neutralization is a major problem in the surface-induced dissociation of molecular ions since it reduces the sensitivity of this method. Most polyatomic ions neutralize when scattered at low energies off clean metal surfaces. One approach to reducing charge transfer and increasing scattered ion yields is to form an oxide layer on the metal surface [1]. We examine here the neutralization of a typical organic ion, pyridine, when it was scattered at low energies off a clean metal surface, an oxygen adsorbed metal surface, and a well characterized oxide thin film. We also measured the relative neutralization efficiencies of $FeCp_2^+$ (Cp = cyclopentadiene) and $SiMe_3^+$ ions scattered off three different organic multilayers.

We measured the neutralization of a pyridine ion, $C_5H_5N^+$, when it was scattered at 20 and 40 eV off a clean metal surface, Ni(111); an oxygen adsorbed metal surface, p(2x2)O/Ni(111); and a well characterized oxide thin film, NiO(111)/Ni(111). These experiments used a tandem mass spectrometer coupled to an ultrahigh vacuum surface analysis chamber [2]. There was a large enhancement in the scattered ion signal upon going from the clean Ni(111) to the oxygen modified surfaces at both collision energies. At 20 eV, both modified surfaces showed a 30x enhancement of the scattered ion yields with respect to the clean surface. At 40 eV, the oxygen covered surface showed a 75x enhancement while the oxide showed a 150x enhancement (Figure 1).

These enhancements cannot be explained solely by changes in the surface work function or the surface dielectric layer thickness. These enhancements resulted from oxygen induced changes in the surface density of states which affected the resonant charge transfer of an electron from the surface to the scattered ion. Figure 2 is a schematic diagram of how the surface density of states changes with oxidation and how the ion state shifts when approaching the surface.

Other experiments support these arguments. The relative neutralization efficiencies of $FeCp_2^+$ and $SiMe_3^+$ ions scattered off organic multilayers do not follow the trend expected by consideration of the ionization potentials of the adsorbate molecules alone: the ionization potentials for C_3H_6, C_3F_6, and C_2Cl_4 are 9.73, 10.60, and 9.33 eV, respectively. One would expect from these values that the scattered ion yields in these experiments would have decreased as $C_3F_6 > C_3H_6 > C_2Cl_4$. However, we have observed the scattered ion yield trends to be $C_2Cl_4 \geq C_3F_6 > C_3H_6$.

Alcohols	163, 472, 727, 911
Aldehydes	838, 1043, 1159, 1161
Alkaloids	526
Alkynes	156, 321, 1044
Amides	367, 77, 150, 243, 390, 467, 500, 872, 914, 956, 1030
Amino Acids	166, 420
Anabolic Steroids	511, 575, 577
Anion	159, 1147, 1151
Anion(s)	64, 65, 243, 316, 426, 604, 635, 779, 799, 814, 863, 867, 962, 1035, 1038, 1113, 1142, 1177
Antibiotics	172, 308, 315, 317, 332, 427, 502, 520, 544, 863, 866, 1137, 1282
Antibodies	289, 291, 292, 925, 981, 982
Aromatics	474, 530, 746, 759, 900, 960, 1008, 1059
Aromatics, Polycyclic	200, 201, 509, 515, 667, 815,. 957, 962
Artificial Intelligence	727, 731
Atm.Press Chem Ioniz'n (API)	99, 147, 195, 207, 222, 226, 233, 311, 330, 334, 335, 341, 373, 422, 423, 424, 426, 452, 485, 504, 510, 521, 535, 541, 551, 561, 570, 572, 578, 666, 669, 781, 841, 858, 867, 869, 890, 992, 999, 1053, 1054, 1078, 1318
Atmo Press. Ionization	100
Automation	112, 143, 147, 240, 335, 478, 569, 649, 719, 735, 739, 743, 856
Azo-dyes	161, 953, 1139
Benzynes	1031
Binding	637
Biodegradation	210, 506, 842
Biomarkers	200, 474, 495, 530, 747, 830, 919, 923, 1023, 1132, 1156, 1157, 1315
Biomolecules	7, 115, 137, 298, 329, 416, 445, 453, 484, 606, 637, 663, 678, 680, 684, 885, 925, 927, 930, 931, 937, 960, 990, 994, 996, 997, 1060, 1061, 1084, 1148, 1153, 1181, 11831, 202, 1223, 1261, 1266, 1278, 1285, 1303, 1305, 1315, 1326
Biopolymers	39, 125, 301, 448, 940, 998, 1085, 1176, 1210, 1235, 1247, 1255, 1256, 1275
Biotransformation	284
Biradicals	369, 1031
Blood	284
Bond Strengths	11, 16, 52, 53, 696, 1006, 1033, 1051, 1305
Bond, Peptide	1051
Breakdown Curves	388, 399, 766
Calculations	118, 722, 786, 1106, 1130
Calculations, Ab Initio	10, 12, 15, 17, 50, 56, 65, 71, 72, 74, 262, 329, 368, 372, 383, 695, 710, 1031, 1041, 1042, 1043, 1046, 1051
Calculations, Molecular Orbital	157, 723, 1047, 1241
Calculations, RRKM	1047
Calculations, Trajectory	717, 1070, 1095, 1108
Capillary Electrophoresis	103, 104, 105, 124, 236, 248, 249, 328, 449, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 493, 528, 590, 592, 629, 890, 977, 999, 1167, 1189, 1313, 1314, 1314
Carbamates	205, 211, 222, 327, 463, 879
Carbazoles	210
Carbohydrates	170, 245, 359, 360, 620, 812, 830, 925, 975, 1168, 1173, 1174, 1175, 1176, 1177, 1178, 1180, 1184, 1186, 1187, 1188, 1191, 1193, 1194, 1196, 1197, 1198, 1200, 1201

Electrospray Ionization (ESI)	23, 28, 29, 32, 34, 35, 36, 37, 38, 39, 82, 88, 89, 98, 101, 102, 103, 104, 105, 112, 120, 122, 125, 126, 138, 148, 159, 160, 172, 177, 178, 189, 193, 202, 203, 205, 207, 208, 216, 217, 234, 235, 236, 238, 239, 240, 241, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 260, 261, 262, 263, 264, 265, 266, 267, 270, 272, 273, 274, 275, 276, 277, 285, 290, 298, 300, 301, 303, 309, 311, 312, 313, 315, 317, 318, 320, 323, 324, 332, 335, 337, 345, 347, 348, 349, 350, 351, 352, 354, 355, 362 ,376, 378, 379, 381, 388, 390, 403, 408, 410, 425, 426, 427, 428, 429, 435, 436, 437, 439, 440, 443, 444, 446, 450, 451, 453, 454, 455, 456, 457, 460, 461, 483, 485, 488, 492, 493, 497, 498, 499, 500, 501, 502, 507, 512, 516, 518, 519, 520, 522, 524, 525, 528, 529, 534, 536, 538, 539, 544, 546, 547, 548, 554, 555, 557, 566, 592, 593, 594, 595, 596, 597, 598, 601, 602, 604, 605, 606, 607, 610, 612, 616, 618, 621, 623, 628, 630, 631, 632, 634, 635, 646, 648, 650, 651, 655, 657, 658, 659, 660, 661, 667, 668, 669, 671, 672, 673, 674, 678, 680, 703, 744, 749, 755, 779, 780, 787, 789, 794, 800, 801, 822, 824, 839, 849, 851, 853, 856, 857, 862, 863, 866, 871 ,872, 885, 886, 891, 892, 894, 895, 896, 898, 899, 900, 901, 902, 903, 905, 906, 907, 908, 909, 910 ,911, 912, 913, 975, 976, 977, 978, 980, 987, 988, 994, 999, 1005, 1012, 1074, 1083, 1084, 1085, 1086, 1113, 1117, 1143, 1144, 1146, 1147, 1152, 1153, 1160, 1164, 1167, 1169, 1175, 1177, 1178, 1180, 1185, 1188, 1192, 1193, 1194, 1198, 1199, 1200, 1202, 1257, 1258, 1259, 1261, 1262, 1264, 1267, 1268, 1269, 1271, 1272, 1275, 1278, 1279, 1282, 1283, 1285, 1286, 1290, 1293, 1294, 1296, 1297, 1299, 1300, 1301, 1302, 1303, 1304, 1311, 1312, 1313, 1314, 1316, 1325, 1326, 1327, 1328, 1329, 1331, 1333
Elemental Analysis	4, 40, 41, 42, 43, 45, 49, 127, 722, 767, 768, 769, 770, 772, 775, 848, 964, 1088, 1099
Energy	17, 673, 770, 1135
Energy Defect	895
Energy Transfer	922
Energy, Activation	72, 382, 397, 756, 894, 1073, 1125
Energy, Binding	16, 236, 257, 716, 1033, 1264
Energy, Dissociation	13, 677, 803, 1014
Energy, Internal	415, 1027, 1060, 1242, 1250
Energy, Kinetic	348, 398, 894, 895, 1084, 1231
Energy, Kinetic -, Distribution	126, 684, 686, 690, 998, 1125, 1246
Energy, Kinetic -, Release	55, 421, 1199
Enolates	93, 1043
Environmental	1, 4, 44, 48, 116, 151, 162, 180, 181, 182, 183, 185 ,186, 187, 188, 189, 190, 191, 193, 194, 195, 196, 198, 199, 200, 207, 208, 210, 212, 214, 215, 218, 219, 220, 221, 222, 227, 228, 229, 231, 264, 337, 338, 339, 340 ,342, 343, 344, 345, 346, 404, 437, 476, 479, 515, 724, 815, 816, 817, 818, 819, 821, 822, 823, 825, 826, 827, 828, 829, 830, 832, 836, 838, 840, 841, 842, 843, 844, 845, 847, 848, 957, 962, 964, 1009, 1017, 1019, 1020, 1021, 1022, 1078, 1109, 1110, 1141, 1299
Enzymes	182, 286, 301, 306, 315, 506, 531, 584, 611, 615, 925, 997, 1165, 1166, 1285
Epoxides	505
ESI LC/MS	532
ESI/MS	179, 306, 1288
Essential Oils	142
Ester(s)	93, 152, 746, 949, 1052
Ester(s), Fatty Acid	76, 157, 514, 516, 882, 1048, 1145
Ethers	74, 81, 400
Ethylchloroformate	166
Exact Mass Measurement	32, 175, 231, 346, 676, 1213
Excitation	803, 1102, 1103, 1130
Excited State(s)	1040, 1051
Exhaust Analysis	197
Experimental Design	784, 912, 990, 1081, 1093, 1095
Explosives	155, 193, 342, 1140
Extraction	107, 192, 196, 204, 837, 847, 857
FAB (Fast Atom Bombardment)	90, 95, 164, 165, 169, 170, 277, 282, 283, 356, 404, 419, 451, 471, 514, 549, 599, 603, 606, 609, 678, 714, 715, 746, 844, 1035, 1038, 1055, 1066, 1151, 1156, 1174, 1175, 1176, 1181, 1183, 1186, 1193, 1239, 1274
FAB, Continuous Flow	469, 533, 585, 1056, 1150, 1212, 1273, 1292, 1295

Key Word	Page Number
FAB, Dynamic	1154, 1191
FAB/MS	179
Faraday Cup	770, 1076
Filtered noise field	1104
Flames	6, 78
Flavanol Glycosides	258
Flow Injection	150, 194, 823, 1318
Flowing Afterglow	12, 50, 58, 62, 85, 368, 374, 693, 695, 713, 1031, 1032, 1040
Fluorescence Spectroscopy	1090
Forensic Chemistry	571
Fourier Transform IR (FTIR)	1039
Fourier Transform MS	656, 794, 795, 1094
Fourier Transform MS (FTMS)	38, 39, 52, 70, 71, 75, 87, 92, 93, 188, 347, 349, 351, 354, 355, 366, 376, 414, 416, 449, 450, 459, 637, 650, 651, 675, 676, 677, 678, 679, 680, 681, 682, 699, 701, 704 ,706, 707, 708, 709, 710, 711, 733, 783, 786, 787, 789, 790, 791, 792, 793, 796, 797, 798, 800, 801, 802, 803, 804, 805, 806, 807, 808, 812, 813, 814, 815, 886, 902, 959, 965, 966, 967, 973, 1011, 1025, 1026, 1080, 1081, 1083, 1084, 1086, 1088, 1090, 1091, 1092, 1093, 1097, 1215, 1216, 1217, 1240, 1306, 1307, 1309
Fragmentation	140, 156, 169, 170, 213, 225, 227, 246, 318, 359, 377, 405, 494, 694, 722, 748, 926, 1005, 1006, 1044, 1049, 1050, 1059, 1144, 1151, 1161, 1164, 1177, 1192, 1203, 1244
Fragmentation Mechanism/Pathways	63, 74, 92, 161, 171, 333, 382, 403, 483, 486, 498, 539, 627, 681, 683, 761, 872, 974, 1035, 1047, 1052, 1053, 1054, 1142
Fragmentation, Chg.-Remote	353, 415, 1145, 1160
Fragmentation, Peptide	316, 380, 381, 382, 383, 384, 385, 625, 627, 628, 631, 632, 635, 683, 886, 920, 931, 1249, 1263, 1274, 1333
FTMS	720, 1096, 1195
Fuel	758, 761, 1009, 1010, 1013
Fullerenes	422, 899, 967, 1025, 1026, 1027, 1028, 1306
Functional Groups	748
Fundamentals	136, 280, 281, 348, 375, 389, 494, 671, 672, 689, 785, 798, 896, 956, 986, 1030, 1063, 1119, 1120, 1128, 1226, 1237, 1238, 1319, 1337
Furans	230, 399, 993, 1016, 1019
GC/MS	166, 727
Geology	1156
Glow Discharge	41, 42, 45, 66, 96, 168, 466, 767, 768, 775, 1176, 1140
Glutathione conjugates	532
Glycerol	283, 1066
Glycines	265
Glycoconjugates	213, 336, 1178, 1184, 1186
Glycolipids	516, 1178, 1179, 1180, 1308
Glycoproteins	299, 359, 360, 646, 975, 980, 1164, 1165, 1166, 1167, 1169, 1171, 1172, 1173, 1221, 1296
Glycosides	754, 1181, 1183
Glycosylation	245, 299, 1166, 1172
Good Laboratory Practice (GLP)	1319, 1320, 1321, 1323, 1324
Halocarbons	50, 62, 84, 694, 1023, 1036
Hard and soft ionization	154
Herbicides	151, 204, 208, 209, 213, 215, 405, 914
Heterocyclic Compounds	190, 195, 486, 500, 540
High Mass Ions	786, 810, 1069, 1084, 1085, 1087, 1099 1217
High Resolution	720
Histones	33
HPLC/ESIMS	636
Hydrocarbons	58, 704, 714, 758, 760, 762, 1009, 1010, 1011, 1014, 1057
Hydrogen/Deuterium Exchange	58, 85, 86, 87, 175, 1257, 1260, 1266, 1267, 1268, 1328, 1329
Hydrogen/Deuterium Exchange, Labeling	46, 237, 523, 631, 1265
Hydrolysis	216, 582
ICP MS (Inductively Coupled Plasma MS)	40, 43, 44, 769, 770, 983, 1088, 1104
ICR	64, 67, 68, 69, 697, 782, 785, 788, 799, 809, 810, 811, 963, 1082, 1085, 1088, 1089, 1095
ICR MS (Ion Cyclotron Resonance MS)	52, 59, 257, 369, 370, 637, 675, 679, 680, 716, 733, 797, 804, 805, 806, 967, 1011, 1090, 1097, 1149, 1213, 1242
Imaging	9, 20, 1226, 1317
Imide	756
Immunoassay	204, 294, 876, 930, 976, 1295
Infrared Spectroscopy (IR)	357
Insecticide	219, 228
Instrumentation	4, 46, 97, 104, 105, 111, 114, 118, 120, 125, 129, 132, 134, 135, 140, 154, 357, 447, 467, 481, 675, 717, 732, 738, 771, 801, 802, 807, 808, 888, 891, 897, 984, 986, 991, 998, 1069, 1070, 1071, 1072, 1077, 1080, 1081, 1082, 1086, 1091, 1092, 1093, 1096, 1098, 1103, 1109, 1110, 1114, 1115, 1116, 1118, 1121, 1128, 1233
Internal Standard	162, 1231
Ion Acceleration	717, 1096, 1219, 1246
Ion Adduct	178, 776, 777
Ion Clouds	788, 1088, 1127
Ion Cooling	416, 796, 807, 1091, 1106, 1217
Ion Desorption	69, 106, 897, 1057, 1061
Ion Detection	125, 790, 984, 1000, 1075, 1076, 1096, 1097, 1121, 1211, 1220
Ion Ejection	107, 135, 790, 1105, 1112, 1118, 1129
Ion Energetics	385, 399, 690, 702, 1250
Ion Focusing	717, 1001, 1002
Ion Imaging	20, 717, 995, 1076
Ion Injection	102, 168, 892, 1117, 1140
Ion Isolation	134, 801, 802, 1102, 1107
Ion Isomeric	392, 393, 394
Ion Loss	417, 810
Ion Mirror	130, 133, 413, 771, 1205, 1209
Ion Mobility	571, 674, 889, 1029
Ion Optics	130, 786, 1001, 1002
Ion Pairing	242, 247, 431, 903, 1048, 1190
Ion Reactivity	62, 369, 370, 697, 702, 704, 712, 1025, 1026
Ion Solvation	250, 410, 674, 907
Ion Source	96, 97, 100, 102, 107, 109, 110, 119, 364, 463, 466, 567, 670, 891, 892, 1210
Ion Storage	119, 782, 785, 1077, 1092, 1108, 1112, 1118, 1123, 1128, 1138, 1316
Ion Structure	77, 171, 380, 393, 394, 407, 699, 700, 974, 1310
Ion Suppression	255
Ion Trajectories	140, 798, 808, 1118, 1127, 1130
Ion Transport	101, 102, 126, 132, 135, 892, 1083, 1087, 1138
Ion Trap	97, 118, 122, 168, 276, 325, 391, 408, 444, 446, 447, 458, 460, 487, 519, 530, 576, 577, 626, 652, 655, 675, 734, 737, 738, 784, 792, 795, 797, 819, 831, 833 ,836, 849, 861, 885, 992, 1019, 1077, 1078, 1079, 1094, 1098, 1101, 1103, 1107, 1114, 1120, 1121, 1126, 1130, 1134, 1135, 1140, 1141, 1202
Ion Trap -, Electrodynamic	119
Ion Trap -, ICR	675, 788, 791, 795, 804, 805, 807, 808, 1029, 1090, 1097
Ion Trap -, Quadrupole	3, 40, 41, 54, 73, 79, 84, 86, 91, 121, 153, 155, 160, 191, 223, 230, 302, 358, 367, 409, 410, 461, 475, 476, 477, 478, 548, 616, 641, 649, 653, 654, 687, 735, 769, 775, 783, 803, 808, 816, 817, 818, 832 ,839, 888, 890, 931, 936, 946, 964, 971, 983, 984, 985, 986, 987, 988, 989, 990, 991, 993, 1010, 1100, 1102, 1104, 1105, 1106, 1107, 1109, 1110, 1111, 1112, 1113, 1114, 1115, 1116, 1117, 1118, 1119, 1121, 1122, 1123, 1124, 1125, 1127, 1128, 1129, 1131, 1132, 1133, 1137, 1138, 1139
Ion(s)	348, 350, 390, 426, 619, 644, 658, 670, 679, 1151, 1242
Ion(s), Metastable	624, 1048
Ion(s), Product	133
Ion, Metastable	68, 83, 86, 383, 387, 392, 395, 400, 412, 413, 514, 581, 683, 1205
Ion, Molecular	10, 66, 70, 80, 82, 374, 693, 714, 715, 1040, 1176
Ion, Multiply Charged	55, 89, 91, 239, 245, 265, 267, 351, 352, 353, 354, 410, 600, 725, 768, 789, 892, 896, 903, 1200, 1232, 1336
Ion, Precursor	421, 1207
Ion, Product	502
Ionization	49, 64, 106, 141, 251, 400, 451, 494, 667, 679, 776, 881, 884, 895, 900, 1005, 1048, 1155, 1163, 1245
Ionization Efficiency	49, 108, 482, 772
Ionization Energy	13, 52, 60, 1006, 1043
Ionization Mechanism	97, 243, 247, 282, 668, 670, 683, 884, 896, 901, 914, 922, 1240, 1241, 1248, 1249, 1252
Ionization Process	90, 686, 690, 1056, 1246
Ionization, Field	107, 757, 1014, 1089
Ionization, Penning	42
Ionization, Pulsed	889
Ionization, Single Photon	761, 1036
Ionization, Surface	48, 108, 398, 417, 482, 692
Ionspray	143, 146, 150, 165, 174, 278, 431, 435, 517, 526, 527, 545, 563, 564, 594, 600, 604, 615, 662, 840, 848, 864, 888, 889, 893, 903, 1171, 1190, 1276

Key Word	Page Number
Isomerization	319
Isomers	66, 144, 145, 157, 715, 1037, 1145, 1175, 1177, 1197
Isotachophoresis	449, 459
Isotope	47, 242, 828
Isotope Dilution	208
Isotope Distributions	283,725
Isotope Effects	375, 508
Isotope Enrichments	47, 875
Isotope Exchange	852
Isotope Ratio MS	44, 46, 47, 48, 49, 773, 774, 775, 828
Isotope, Isotope	806
Isotope, Stable	156, 508, 566, 666, 722, 852, 875, 1044, 1152, 1159
Ketones	77, 1043
Kinetics	59, 391, 694, 701, 713, 765, 899, 973
Labeling	177, 251, 324, 531, 1052
Labeling, C-13	875
Labeling, Deuterium	27, 46, 95, 287, 336
Laser	21, 411, 809, 811, 963, 1021, 1229
Laser Ionization	6, 8, 127, 686, 956, 959, 965
Laser Spray	1204
Laser Vaporization	688, 941, 965
Laser, Ablation	3, 44, 688, 772, 944, 945, 967, 1087
Laser, Desorption	2, 5, 8, 24, 124, 155, 187, 360, 366, 692, 708, 709, 711, 760, 764, 789, 791, 814, 815, 918, 946, 947, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 966, 968, 1007, 1028, 1063, 1080, 1136, 1168, 1170, 1176, 1194, 1201, 1211, 1221, 1231, 1232, 1239, 1248, 1256, 1271, 1307
Laser, Tunable	807, 1063, 1235
LC/MS	540
Levodopa	551
Library Searching	643, 728, 729, 730, 1055
Linked Scan	145, 169, 170, 225, 228, 258, 328, 412, 421
Lipid	331, 514, 721, 773, 1142, 1143, 1144, 1146, 1150, 1152, 1154, 1155, 1156, 1159, 1160, 1161
Lipopolysaccharides	516, 917, 1174
Local Area Network	742, 1324
Macrocycles	53, 94, 255, 347, 371, 780, 970
Magnetic Sector MS	35, 98, 138, 145, 248, 266, 267, 358, 372, 386, 648, 657, 732, 770, 846, 1074, 1211, 1292, 1299, 1302
MALDI	7, 445, 904, 1266
MALDI/MS	179, 306, 1288
Mass	1236
Mass Accuracy	305, 438, 492, 805, 950, 1092
Mass Calibration	579, 1127, 1205, 1206
Mass Discrimination	131, 134
Mass Displacement	1059, 1120, 1124
Mass Range	1071
Mass Resolution	364, 581, 985, 1003, 1069, 1070, 1071, 1092, 1097, 1121, 1128, 1205, 1209, 1228, 1243
Mass Spectrometer	99, 119, 447, 494, 853, 879, 1000, 1081, 1098, 1116, 1213, 1322
Mass Spectrometer -, Double Focussing	231, 346, 385, 412, 481, 763
Mass Spectrometer -, Gas Chromatograph (GC/MS)	113, 149, 158, 162, 181, 192, 196, 198, 209, 214, 218, 220, 221, 224, 225, 227, 474, 475, 476, 477, 481, 506, 529, 576, 577, 721, 742, 745, 747, 759, 820, 821, 830, 832, 834, 835, 837, 846, 870, 877, 882, 1010, 1017, 1109, 1119
Mass Spectrometer -, High Resolution	232, 602, 732, 1003, 1016, 1085
Mass Spectrometer -, Infrared (IR/MS)	479, 1063, 1247
Mass Spectrometer -, Liquid Chromatograph (LC/MS)	122, 173, 176, 195, 200, 202, 203, 212, 222, 238, 258, 274, 285, 293, 296, 313, 330, 334, 422, 425, 427, 428, 429, 432, 433, 434, 436, 437, 439, 444, 450, 465, 468, 469, 491, 494, 502, 503, 512, 515, 524, 525, 527, 541, 542, 547, 552, 554, 555, 561, 563, 564, 568, 589, 611, 612, 660, 662, 671, 673, 744, 781, 824, 840, 854, 855, 856, 857, 858, 860, 866, 867, 870, 873, 887, 894, 895, 905, 980, 1074, 1114, 1117, 1143, 1152, 1162, 1171, 1190, 1192, 1301
Mass Spectrometer -, Neut.-Reioniz'n	17, 377, 395, 694, 1030, 1037, 1049, 1310
Mass Spectrometer, Double Focussing	1212
Mass Spectrometer, Energy-Resolved	16, 1053, 1054
Mass Spectrometer/LC	29, 31, 33, 36, 37, 143, 172, 174, 177, 199, 204, 205, 208, 270, 293, 295, 336, 342, 430, 431, 432, 438, 446, 464, 466, 467, 487, 499, 503, 505, 508, 510, 517, 518, 538, 545, 548, 553, 557, 558, 559, 560, 562, 569, 570, 578, 632, 646, 652, 661, 739, 753, 754, 774, 841, 842, 846, 851, 859, 861, 862, 864, 868, 875, 992, 999, 1014

Key Word	Page Number
1148, 1267, 1282, 1298, 1316	
Mass Spectrometry, GC	76, 108, 128, 129, 145, 190, 219, 220, 221, 223, 228, 229, 333, 337, 340, 471, 473, 479, 480, 481, 482, 511, 531, 537, 571, 575, 724, 728, 737, 815, 816, 817, 819, 826, 827, 829, 838, 844, 845, 846, 847, 878, 880, 881, 883, 993, 1008, 1009, 1013, 1020, 1079, 1099, 1101, 1115, 1123, 1156, 1161
Mass Spectrometry, High Resolution	210, 214, 231, 267, 346, 396, 496, 725, 760, 786, 844, 951, 1007, 1009, 1011, 1020, 1074, 1120, 1124, 1129
Mass Spectrometry, LC	213, 216, 278, 288, 291, 440, 551, 556, 567, 573, 719, 848, 865, 885, 1260, 1277, 1329
Mass Spectrometry, LC Matrix	32, 148, 163, 332, 335, 424, 426, 442, 504, 572, 613, 687, 822, 850, 863, 884, 1012, 1163, 1182, 1301, 1312
Mass Spectrometry-CE	103
Massive Cluster Impact	465
Matrix Assisted Laser Desorption/Ionization	1195
Matrix Effects	269, 462, 685, 951, 1060, 1062, 1191, 1196, 1222, 1224, 1225, 1227, 1240, 1243, 1244, 1247, 1248, 1250, 1251, 1254
Matrix Isolation	43, 316, 1039, 1061
Matrix-Ass'd Laser Desorp. Ion. (MALDI)	18, 19, 21, 22, 23, 34, 117, 121, 123, 124, 131, 133, 138, 182, 268, 269, 270, 271, 284, 285, 286, 287, 288, 291, 292, 297, 298, 299, 304, 305, 310, 314, 323, 324, 326, 357, 358, 359, 361, 362, 363, 364, 365, 366, 414, 447, 448, 451, 462, 484, 490, 492, 520, 550, 565, 579, 580, 582, 583, 584, 586, 598, 614, 615, 617, 624, 625, 633, 642, 663, 664, 665, 676, 678, 683, 684, 685, 686, 687, 689, 690, 691, 692, 726, 743, 751, 755, 791, 793, 805, 812, 813, 876, 915, 916, 917, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 942, 943, 946, 947, 948, 949, 950, 951, 952, 961, 968, 980, 981, 982, 989, 990, 994, 997, 998, 1003, 1026, 1062, 1063, 1081, 1082, 1100, 1102, 1149, 1165, 1166, 1167, 1170, 1172, 1173, 1179, 1184, 1185, 1187, 1189, 1193, 1196, 1204, 1205, 1206, 1207, 1208, 1209, 1210, 1211, 1212, 1213, 1214, 1215, 1216 ,1217, 1218, 1219, 1220, 1222, 1223, 1224, 1225, 1226, 1227, 1228, 1229, 1230, 1233, 1234, 1235, 1236, 1237, 1238, 1239, 1240, 1241, 1242, 1243, 1244, 1245, 1246, 1247, 1248, 1249, 1250, 1251, 1252, 1253, 1254, 1255, 1263, 1272, 1277, 1283, 1289, 1295, 1297, 1304, 1317, 1331
Membrane Introduction	114, 116, 118, 151, 152, 153, 191, 339, 818, 823, 833, 836, 934, 1133
Metabolic Profiling	148, 240, 432, 433, 524, 541, 542, 545, 553, 558, 560, 562, 564, 568, 569, 872, 887
Metabolism, Metabolites	93, 226, 252, 272, 327, 328, 334, 432, 498, 499, 500, 505, 507, 508, 517, 519, 521, 523, 525, 527, 528, 529, 531, 533, 534, 535, 536, 538, 539, 541, 543, 544, 546, 549, 550, 551, 552, 553, 558, 560, 562, 563, 564, 565, 566, 567, 574, 582, 842, 849, 850, 854, 858, 859, 860, 874, 878, 882, 992, 1133, 1315
Metal Ion Chemistry	238, 260, 261, 262, 263, 280, 281, 378, 379, 403, 609, 698, 700, 702, 703, 704, 705, 708, 709, 710, 711, 714, 715, 779, 780, 1198, 1199, 1200, 1306, 1307, 1308, 1309
Metal Ions	608
Metalloprotein	309, 319, 322
Metals	42, 43, 47, 53, 279, 376, 377, 589, 596, 697, 712, 713, 777, 847, 900, 1137, 1305
Micelles	1065
Microanalysis	489, 1223
Microdialysis	37, 274, 518, 530, 568
Microparticle Analysis	1, 2, 5, 187, 765, 958, 961
Microprobe	9
Microsomes	511, 529, 542, 887
Microwave Plasma	100, 705, 1045
Mixture Analysis	106, 115, 118, 144, 192, 283, 285, 290, 433, 456, 462, 489, 682, 731, 757, 819, 906, 923, 990, 1143, 1158, 1162, 1189, 1207, 1296
Molecular Beams	24, 109, 407, 960
Molecular Dynamics	922
Molecular Recognition	53, 94, 250, 251, 253, 682, 970, 971
Molecular Weight Distribution	19, 22, 23, 366, 755, 806, 950, 952, 1007
Monitoring, Air	183, 766, 831, 835, 991, 1078, 1138
Monolayer	417, 418

MS/MS	3, 16, 30, 31, 32, 37, 56, 66, 79, 81, 84, 92, 109, 117, 123, 130, 134, 137, 138, 139, 146, 159, 160, 161, 165, 168, 171, 176, 177, 191, 194, 202, 203, 209, 212, 214, 217, 223, 226, 230, 233, 238, 240, 244, 249, 252, 274, 276, 277, 296, 302, 318, 321, 322, 326, 328, 329, 341, 342, 343, 345, 355, 358, 378, 380, 382, 384, 386, 387, 390, 394, 395, 396, 401, 402, 405, 406, 409, 411, 412, 415, 421, 425, 430, 433, 436, 442, 449, 457, 459, 470, 475, 476, 477, 478, 483, 486, 487, 489, 491, 492, 493, 502, 505, 510, 513, 514, 518, 525, 526, 527, 532, 535, 537, 538, 542, 544, 545, 549, 552, 553, 554, 555, 557, 558, 559, 560, 562, 563, 568, 569, 573, 574, 576, 577, 587, 592, 594, 597, 607, 617, 621, 624, 625,626, 627, 629, 635, 640, 647, 649, 650, 651, 652, 654, 659, 661, 662, 671, 714, 715, 722, 750, 751, 754, 757, 781, 824, 832, 839, 840, 850, 851, 856, 859, 860, 861, 862, 865, 866, 868, 869, 887, 943, 974, 975, 976, 977, 987, 1004, 1023, 1030, 1052, 1055, 1073, 1101, 1106, 1107, 1113, 1117, 1119, 1131, 1139, 1141, 1142, 1145, 1149, 1153, 1163, 1164, 1174, 1178, 1179, 1181, 1183, 1186, 1197, 1198, 1200, 1201, 1202, 1203, 1209, 1273, 1274, 1278, 1279, 1281, 1282, 1283, 1290, 1291, 1293, 1294, 1296, 1303, 1310, 1311, 1313, 1314, 1325, 1337
Multi-photon Ionization	24, 772, 953, 954, 955, 960, 964, 1047
Multipoles	101
Natural Products	148, 181, 182, 273, 428, 429, 526, 540, 548, 1144, 1148, 1158,1181, 1182
Nebulization, Nebulizer	425, 668, 1204
Network	1324
Neuropeptides	37, 272, 274, 275, 518, 556, 1262
Nitroaromatics	66, 197
NMR	146, 549, 720
Non-polar Solvents	910
Nonvolatiles	338, 817
Nucleobases	158, 247, 587, 591
Nucleosides	247, 552, 608
Nucleotides	28, 34, 38, 361, 420, 457, 590, 594, 602, 609, 935, 1197
Oligomers	22, 75, 776, 928
Oligonucleotides	244, 248, 249, 350, 361, 362, 364, 376, 580, 581, 582, 583, 593, 594, 595, 596, 597, 598, 599, 600, 601 602, 603, 604, 658, 677, 934, 935, 936, 939, 940, 941, 942, 943, 1214, 1261, 1326
Oligosaccharides	182, 359, 923, 1166, 1168, 1185, 1187, 1189, 1190, 1191, 1192, 1195, 1199, 1201, 1202, 1203
On-line Analysis	5, 116, 152, 153, 186, 260, 339, 446, 457, 461, 510, 543, 592, 773, 890, 958, 961, 1198
Organic analysis	154
Organometallics	106, 127, 165, 266, 451, 699, 701, 706, 707, 781, 848, 966, 1012, 1067, 1306, 1310
Organophosphorus Esters	206, 373, 406, 1053, 1054
Organosilanes	17, 391, 908
Oxidation	69, 189, 190, 254, 270, 331, 333, 338, 429, 567, 591, 871, 1139
Parmacokinetics	158, 852, 854, 855, 861, 1023
Particle Beam	199, 205, 211, 464, 465, 466, 467, 566, 841, 870
Particles	184
Penicillins	315, 909
Penning Ionization	154
PEPICO	399
Peptide hormone	924
Peptide Structure	256, 271, 277, 279, 300, 312, 313, 381, 387, 458, 490, 598, 620, 647, 743, 896, 916, 922, 979, 989, 1046, 1051, 1100, 1206, 1272, 1281, 1300, 1307
Peptide(s)	28, 123, 124, 241, 261, 263, 265, 267, 268, 269, 270, 276, 280, 281, 282, 283, 285, 302, 303, 310 ,311, 314, 325, 347, 354, 363, 379, 384, 386, 439, 443, 447, 454, 455, 456, 460, 513, 611, 612, 619, 621,623, 624, 626, 627, 630, 634,639, 640, 641, 654, 655, 664,665, 669, 726, 743, 906, 908,918, 921, 924, 926, 927, 929,942, 976, 978, 988, 989, 1038,1061, 1214, 1216, 1218, 1225, 1228, 1230, 1249, 1252, 1274,1276, 1289, 1290, 1291, 1292, 1293, 1294, 1295, 1298, 1302, 1314, 1316, 1332, 1333
Peptide(s), Cyclic	628, 1046, 1213, 1280, 1282
Peptide(s), MAP	287, 288, 291, 614, 652, 676, 685, 1208, 1253
Peptide(s), Modified	30, 34, 278, 323, 498, 629, 1272, 1281, 1283, 1284, 1302
Peptide(s), Support-bound	483, 484, 490
Peptide(s), Synthetic	30, 34, 277, 278, 312, 487, 490, 873, 1273

LC/MS Workshop

Thomas Covey (PE/Sciex) and Mike Balogh (Waters)

The workshop had the following agenda designed to cover the broad interests of the LC/MS interest group.

A. Non-Scanning Mass Analyzers
  1. Ion Traps by Adrian Land, Finnigan
  2. Ion Traps vs Quads by Jack Henion, Cornell University
  3. Electrospray TOF by Fred Banks, Analytica
B. Vacuum System Maintenance by Kevin Bentley, Inland Vacuum Industries
C. Novel Mechanisms in APCI by Paul Goodley, Hewlett-Packard
C. Environmental LC/MS
  1. Bob Betham, Alta Analytical
  2. Paul Winkler, Quanterra Environmental Services
D. Pharmaceutical Open-Access MS by Lester Taylor, Burroughs-Wellcome
E. Micro-Chromatographic Techniques by Jean-Pierre Salzman, LC Packings

There were ≈ 450 attendees, as indicted from the return of questionnaires that were distributed. Adrian Land spoke about the new LCQ electrospray ion trap system emphasizing its ease of use, multiple experiment capability (triple play), and MS^n capability for structure elucidation. Some examples of quantitation of pharmaceuticals in plasma by MSMS were also highlighted.

Jack Henion showed a comparison between a modified Varian ion trap with electrospray and a benchtop triple quad, the LC 300 from PE/Sciex. Performance in the single MS mode appeared to be roughly similar based on the signal to noise in full scan total ion current traces of some small molecular weight drugs.

Fred Banks of Analytica gave a presentation of the orthogonal ESP TOF with particular reference to the fast scanning capabilities for high resolution chromatographic separations such as CZE. One hundred full scans/second could be achieved.

Kevin Bentley presented some very practical information regarding vacuum system maintenance, a topic not usually discussed but of daily interest to mass spec facilities. His emphasis was on pump oils and the extreme conditions LC/MS ion sources put on this weak link in the system. The relationship between the chemical properties of the oil and expected lifetime were detailed

Paul Goodley described some novel observations they had made regarding the introduction of liquids at high flow rates (>1mL/min). No discharge voltages to initiate chemical ionization or liquid charging voltages to assist the electrospray process were used. Impressive sensitivities were shown. It was explained that the liquid was charging as a result of the triboelectric effect (static charge accumulation) thus promoting the ion evaporation process. This effect can be demonstrated with glancing blows between two ice cubes which will generate sparks.

Bob Betham gave a crisp overview of the growth of LC/MS in the environmental field, with reference to regulatory implications and future application areas. It appears that there is a shift in the focus of environmental analyses in the future toward LC/MS techniques. Paul Winkler showed an excellent example from the pesticide field.

Lester Taylor gave a presentation of the open access mass spectrometer concept. Atmospheric pressure ionization instruments have been appropriately software configured so that synthetic and medicinal chemists can drop a sample in an autosampler, log in an appropriate identifier, and obtain a molecular weight within minutes. An average of 80-100 samples per day have been run over the past 9 months. A significant increase in the use of

mass spectrometry for structural elucidation has occurred with the introduction of this approach.

A questionnaire was distributed in order to gather information pertaining to the format, content and direction of this session next year. There were more than 100 respondents. Below is a summary of the results.

The first question, "If LC is common in your lab which of the following do you use?" was clearly carried by ESI/MS/MS by 3:1 over thermospray and particle beam. The interest areas for applications to be presented were strongly centered on drug discovery and natural products, as one selection, and toxicology, pharmacology and metabolism as the other (68% and 53% respectively). Environmental and industrial chemistry followed at 23% and 10%.

Future presentations were requested from LC generally in both practice (65%) and theory (42%) with the interest between microcapillary and techniques using flow rates above 50 ul/min evenly divided. CZE and quantitation were both highly requested (approximately 50% each). Other areas on the form received less interest. There was little interest in software and interpretation specifically.

The practical application of hardware was highly requested in both categories available on the form (Applications-hardware and Hardware-analyzers/interface design). In addition, we received comments indicating a better knowledge of hardware and design could be useful toward increasing performance.

Overall the comments we received on the format indicated a shorter session with a more limited focus was needed but was evenly divided as to whether it should be held at lunch or during the evening. A panel of experts focusing on audience questions was suggested although many were satisfied with the current format.

The group, like ASMS itself, reflects changes in its constituency and we are attempting to identify and respond to it. Numerous individuals took the time to express their thoughts in detail and the effort is greatly appreciated by the organizers. We hope you will see the benefits of your efforts in next year's program.

ION TRAP INTEREST GROUP WORKSHOP

The topic of the (Quadrupole) Ion Trap Interest Group Workshop was "Theory vs. Reality". This was an informal workshop based around informal contributions from the attendees. Doug Goeringer of Oak Ridge National Laboratory was drafted to start the discussions and presented some recent work concerning modeling of the ion temperatures in the ion trap. He noted that due to the relatively high helium pressure used for normal operation that a boltzman temperature distribution provided a good model for the ion temperature. The theory is based on the ion transport in gases and provides a useful model for the kinetics of CID in the ion trap. These results suggest that heating the ion trap will lower the resonant excitation energy required to effect dissociation in the ion trap. A bit more discussion ensued concerning the internal and kinetic temperatures of ions in the trap.

Richard Morrison, from Australia but currently working with Ray March at Trent University, initiated a discussion of the mass displacement in the ion trap. He showed theoretical results in which the secular frequency of an ion depends upon the radial and axial amplitudes of ion, which can lead to mass shifts in the detected mass spectrum. Work was done with both an ideal quadrupole trap and the stretched trap which is commonly used. The stretched trap introduces a component of higher order fields. Vladimir Doroshenko, Johns Hopkins University, then discussed their approach and basis for varying the amplitude of the resonant ejection voltage with mass to provide a better calibration for the ion trap. Curt Clevin, Purdue University, then discussed some of their pertinent experimental results which indicated that the stretched geometry reduced mass shifts in the ion trap. These results were obtained by performing photodissociation of ions as a function of their position in the ion trap.

Frank Londry of Trent University was the next discussion volunteer and he talked about work involving practical high resolution in the ion trap. The most significant problem for obtaining high resolution is unstable peak position. A significant improvement can be obtained by phase locking the various rf and ac voltages associated with the ion trap. When this is done, the practical limit of resolution seems to be peak widths of 30 millimass units, achieved at a scan rate of 100 u/s. The mass accuracy improves as the helium pressure is reduced but is variable over the mass range.

The next volunteer speaker was Sohrab Habibi from Jack Henion's lab at Cornell. He addressed the issue of comparing the ion trap with triple quadrupoles. He stressed the importance of making sure that comparable experimental conditions were used. Jenny Brodbelt then discussed work in her lab on determining critical energies of ion dissociation. This worked focussed on the study of H-bonding. The final speaker was Steven Boue from Rick Yost's group at the University of Florida. He presented some preliminary data on their electrospray system combined with photodissociation. The systems they are exploring include oligosacharrides and oligonucleotides.

After the technical session, a short business meeting was held. The major topic of discussion was defining the focus of the interest group, since this is a new interest group. This discussion centered on whether the focus should be narrowly described as pertaining only to quadrupole ion traps or should it be more inclusive, including other types of ion trapping techniques. A vote was taken and it was decided that all ion trapping techniques should be included but there was enough opposition so that it was agreed that this topic would be revisited next year.

43rd ASMS Conference on Mass Spectrometry and Allied Topics

FTMS INTEREST GROUP WORKSHOP

MOST RECENT RESULTS IN FTMS

The second annual workshop of the FTMS users group focused on recent results from FTMS research, preferably work performed after the submission of ASMS abstracts in January. A variety of chemists from both industry and academics gave short presentations. The lead-off speaker was Cliff Watson from the University of Florida, who discussed a method for apodizing the beat pattern in the free inductance decay (FID) that is associated with interfering frequencies from equally spaced ^{13}C isotope peaks in electrospray FTMS. This pattern results in dead areas of the FID that contain only noise; apodizing these areas to zero increases the signal-to-noise ratio of the spectrum. Jared Drader from David Laude's group at the University of Texas at Austin then spoke on the LabView data system that is being developed for interfacing with the group's FTMSs. This is a graphical software with an open architecture that facilitates addition of peripherals to the system. The third speaker of the evening, Pete O'Connor from Fred McLafferty's group at Cornell University, discussed dissociation studies on multiply charged ions produced by electrospray. Among the data presented were spectra for ion isolation of a single ^{13}C isotope for large proteins using the stored waveform inverse Fourier transform (SWIFT) technique. CID was then performed on this isolated isotope peak. Ron Heeren of the Institute for Atomic and Molecular Physics in Amsterdam then described his group's recently acquired Bruker FTMS. The group has modified the vacuum system using turbodrag pumps in order to obtain a very fast pump down time and an ultimate base pressure of 10^{-11} mb. Ron also discussed recent MALDI-FTMS results obtained for polymers and microprobe LD-FTMS for studying artworks.

The evening's fifth speaker, Chris Hendrickson from the High Field Magnet Laboratory at Florida State University, discussed the FTMS facilities at this laboratory. Chris invited audience members to be external users of the facility, indicating that in years 2-5 75% of the site's funding is earmarked for external users. He indicated that long term visitors, for example graduate students, may be eligible for airfare, tuition, or lodging funds. The following speaker, Bill Reents of Bell Laboratories, discussed a unique FTMS that utilizes a split-pair 5.3 T superconducting magnet. This design features ports on the side of the magnet to allow easy access to the cell for light sources. Bill's presentation centered on the best cell design to maintain decent performance and avoid space charge effects. Cell design was also the topic of the next talk, which was presented by Kent Gillig from David Russell's group at Texas A&M University. Kent discussed an ICR cell with a wire ion beam guide running through its center; this is a modified electrostatic Kingdon trap. Kent was followed by the first ion chemistry talk of the evening. Young Xu from Ben Freiser's group at Purdue University discussed the first known example of a metal-containing distonic ion, an iron pyrobenzene species.

Brian Winger spoke on Extrel FTMS's work in peptide analysis by electrospray. He presented examples of using SWIFT to eject ions from the cell in order to increase the resolving power and m/z accuracy. Brian's colleague at Extrel FTMS, Sanford Shew, then discussed FTMS on the Internet. There is a usernet MS group and Extrel FTMS has a world-

wide web (WWW) page and a bulletin board. The evening's eleventh speaker, Karl-Peter Wanchez from the University of Breman, spoke on his group's research in the area of in-cell MALDI. The sample target was positioned as a part of the grid on the trapping plate electrode and spectra exhibiting very nice resolution were obtained. This was followed by another instrument company representative, Steve van Orden, from Bruker. Steve discussed several recent Bruker instrumental developments including a pneumatic assist in electrospray and the coupling of a massive cluster ionization (MCI) source to FTMS. The MCI source bombards the sample with extremely large matrix clusters (e.g., glycerol clusters) and produces singly and mutliply charged ions from species as large as ubiquitin (MW 8565).

David Weil from 3M Corporation then lead a discussion of industrial problems related to FTMS. One question that he asked the audience dealt with m/z discrimination in laser desorption. In general, this had not been observed by many audience members which could mean that it is not a problem or that it has not been specifically looked for. Dave also asked for input on the need to standardize experimental FTMS parameters from lab to lab. The general audience view was that this was not feasible due to the many different configurations of FTMS instruments that exist. The final speaker of the evening was Ben Freiser of Purdue University. Ben first spoke on metallocarbohedrenes and their adduct formation, yielding, for example, $V_8C_{12}(CH_3CN)_4^+$. He concluded by describing a pulse-leak valve system developed in his laboratory in order to admit a constant pressure of a gas for a pulse of time into the FTMS vacuum chamber. In this system, the gas inlet was connected to a leak valve that was then connected to a tee. One part of the tee went to a pulsed valve that then went to the main MS vacuum chamber; this allowed a static pressure to be introduced when the pulse valve was open. The second part of the tee went to another pulse valve that was also connected to a pump; opening this valve allowed the reservoir between the leak and pulsed valves to be pumped out thus preventing pressure buildup.

Users group members are encouraged to provide feedback to Carolyn Cassady (CCASSADY@MIAMIU.ACS.MUOHIO.EDU or 513-529-2494) by late next fall concerning topics that they would like to see discussed at the 1996 workshop.

GOOD LABORATORY PRACTICES (GLP) WORKSHOP
Thursday, May 25, 1995

This is a follow-up to the extremely successful 1994 ASMS Fall Workshop on "Mass Spectrometry and Good Laboratory Practices" organized by Robert K. Boyd and Jack D. Henion. From the Fall workshop, it was clear that, unlike the rigid regulations put forth by the US EPA, GLP required by the US FDA is highly subjective to interpretation. In the 1994 Fall Workshop, we had heard "The viewpoint on GLP for Mass Spectrometry" from a FDA scientist, Dr. Steven M. Musser. Therefore, one objective of this workshop is to invite a representative from the FDA Compliance branch to present his view of GLP. The second objective is to facilitate an exchange of views on this evolving subject amongst mass spectrometry practitioners.

The workshop began with an announcement by Dr. Robert Boyd that a report on the Fall Workshop had been drafted and submitted to JASMS for publication. To obtain the draft version of the report, one simply needs to contact Dr. Robert K. Boyd at National Research Council, 1411 Oxford Street, Halifax, NS, B3H 3Z1, Canada. Dr. Boyd's e-mail address is BOYDRK@IMB.LAN.NRC.CA.

Five scientists from the academia, agricultural and pharmaceutical industries were invited to give a 5 to 10 minutes presentation on a specific GLP related topic to stimulate discussion. These topics have been chosen because they were raised or not addressed at the 1994 Fall Workshop.

Dr. Jane Gale of Bristol-Myers-Squibb (BMS) led the discussion on "Automation and GLP: RECORD, RECORD, RECORD!!". Dr. Gale described the automated sample login, storage, and retrieval system at BMS. The system included a LIMS, robotics apparatus, autosamplers for GCMS, LC/MS, or other analytical instruments, and electronic data transfer and archive. Dr. Gale stressed the importance of documentation of the sample's progress from generation to discard, which can easily be done by the computers in an automated system. The steps that are documented for GLP purposes include sample generation, unique identifier assigned via bar coded label, shipment from study site to BMS analysis site, receipt at BMS, log in, decontamination, storage, retrieval, analysis, return to storage, and discard.

Professor Jack Henion of Cornell University / Advance Bioanalytical Services (ABS) led the discussion on "Operator Training". Dr. Henion emphasized that it is essential to properly train personnel to understand the fundamental physico-chemical principles underlying the operation of the various instruments. He also advocated the importance of recurrency training (every six to twelve months) to refresh the understanding and to update with new developments. To train operators in his laboratory, Dr. Henion listed 19 items ranging from ions productions, ion optics and energetics, detections, calibrations, data acquisitions, and different type of mass spectrometric experiments. For GLP purposes, these training are documented by the signature of a well qualified senior personnel on the checklist of the 19 training items for the trainee.

Dr. Tom Oglesby of Taylor Technology led the discussion on "Instrument Validation for Quantitative Analysis". Dr. Oglesby employs, as suggested at the 1994 Fall Workshop, the performance base full system validation method. He validates the entire GC or LC/MS/MS/DS as one unit by meeting a specified set of performance criteria such as injecting a certain amount of a standard would result in a chromatographic peak with certain S/N ratio. Dr. Oglesby also indicated that instrument validation is an on-going process. In a bioanalytical assay, standards and quality control samples (QCs) are analyzed with unknowns in each set of samples. Criteria on the performance of the standards and QCs are established and documented in the analytical method or standard operating procedure for the laboratory. These criteria must be met in order to accept the data from the analysis of unknown samples. Therefore, one is essentially validating the instrument in each analytical run For GLP compliance, documentation of the instrument performance and in process validation is essential.

Dr. Steve Unger of Glaxo addressed the issues related to "GLP vs. Non-GLP Work in the Same Laboratory". Dr. Unger indicated that whenever possible, laboratory functions supporting GLP and non-GLP studies are separated. However, this separation may not be practical because the same resources often support both GLP and non-GLP studies. At Glaxo, all work are done in the "spirit-of-GLP". Developmental toxicological

studies are conducted with GLP compliance. Discovery support and metabolite identification are considered non-GLP work. Laboratory practices, whenever possible, adhere to the higher (GLP) standard. However, acceptance criteria are often relaxed in non-GLP studies since speed and volume is more important. This common sense approach represents the general view of the audience.

Dr. Joe Snodgrass of American Cyanamid described the approach to GLP in the agricultural industry, which is also regulated by the US FDA. In general, there is no different in how the agricultural and the pharmaceutical industries view GLP. "The Nine Pillars of the GLPs" described by Dr. Snodgrass are 1) Personnel, 2) Facilities & Equipment, 3) SOPs and Protocols, 4) Quality Control, 5) Documentation, 6) Management Oversight, 7) Quality Assurance Unit, 8) Test Substances & Reference Substances, and 9) Archives.

The highlight of the workshop was a keynote lecture on "GLP: The Viewpoint from FDA Compliance" by Dr. Charles A. Snipes, an inspector for US FDA. Dr. Snipes described the two types of inspection: routine and directed. Routine inspections may involve general surveillance or study specific audit. Directed inspections usually are study specific or for a specific purpose. The content of Dr. Snipes' presentation are similarly general as in the published Code of Federal Regulations, Title 21, Part 58 : "Good Laboratory Practice for Nonclinical Laboratory Studies." However, Dr. Snipes did stress the importance of the availability of organization chart, master study schedule, personnel training record, and audits by internal quality assurance unit.

In his lecture, Dr. Snipes indicated that computer software validation is necessary and invited further question. This was the major topic of discussion after the lecture. Upon questioning, Dr. Snipes did agree that validation of the performance of the complete system (the "black box" approach) as suggested by S. Musser in the 1994 Fall Workshop and described by T. Oglesby earlier in the session is acceptable. Dr. Snipes indicated that, although he is asking the user to have access to the source codes or to perform validation of computer software, he understands that it may not be possible, especially for older software. The consensus at the workshop among the users, FDA scientists, and mass spectrometer manufacturers in the audience is that mass spectrometer data system software should be validated by the manufacturers and that documentation of the validation should be available to the end users.

On issues related to data archive, Dr. Snipes indicated that it is imperative to be able to reproduce the raw data. For example, the area of a chromatographic peak must be exactly the same in archived data. This raised the concern that new hardware or software of mass spectrometer data system, or manual integration, may not be able to re-integrate electronic data to the exact same number. Thus, the consensus amongst workshop participants is to keep the paper copy of raw data for archive purpose.

Dr. Snipes ended his lecture with a description of the FDA Form 483. This is a written report of the inspection. The Form 483 is formally named "Inspectional Observations". Dr. Snipes indicated that this is purely documentation of the observations made by the inspector. The Form is not a citation nor would it necessary invalidate the study being audited. Furthermore, the recipient of Form 483 can contact the FDA office for clarification or correction of the observations.

The workshop was very well received as evidenced by the approximately 180 attendees and the lively and spirited discussion which lasted until about 11:00 pm. The workshop was very useful for the organizer because I got the opportunity to ask the question which a FDA inspector asked during a study specific audit. The question is whether any laboratory has a SOP for manual chromatographic peak area integration. Among the 180 attendees of the workshop, no one has such a SOP. This is probably due to the almost impossible task of describing all possible chromatographic interference or anomalous situation in the chromatographic/mass spectrometric analysis of biological samples. Finally, I would like to thank all the speakers for leading the discussion, the participants for their active interactions, and ASMS for sponsoring the travel of Dr. Snipes. I would also like to acknowledge Professor Jack Henion for his encouragement to organize this workshop.

Respectfully submitted,
Kelvin Chan, Workshop Organizer

ELEMENTAL INTEREST GROUP WORKSHOP

"Comparison of Mass Analyzers for ICP and GD Ion Sources"

The objective of the workshop was to compare the benefits and limitations of various plasma-analyzer combinations, primarily focusing on attributes of the combinations, rather than the well-known benefits of the analyzers itself. Efforts to address noted limitations were described, as well as future expectations for each. The presenters and plasma mass analyzer combinations addressed are shown below.

Panelist	Affiliation	Plasma/Analyzer Combination
Sam Houk	Iowa State University	ICP / Quadrupole
Ken Marcus	Clemson University	GD / Quadrupole
Fred King	West Virginia University	GD / Time-of-flight
Pat Mahoney	Indiana University	ICP / Time-of-flight
John Eyler	University of Florida	GD / FT-ICR
David Koppenaal	Pacific Northwest Laboratory	ICP / ITMS
Doug Duckworth	Oak Ridge National Laboratory	GD / ITMS

Presentations

ICP / Quadrupole
This combination is the tried and proven mainstay in ICP-MS and enjoys the benefits of quadrupole mass filters — robustness, simplicity, and reliability. Limitations include sequential data acquisition (a problem when using very limited sample sizes), unit mass resolution, and mass discrimination (bias). New means of improving transmission and reducing mass bias are under development. Improvements in transmission are observed with a variable potential lens system, which operates at the optimum voltage for the element of interest. Mass bias is being addressed through the extraction of ions from a shock wave set up by the collision of the ions with a barrier.

GD / Quadrupole
As in ICP-MS, GD applications enjoy the benefits inherent with quadrupole mass filters. This is particularly true for depth profiling applications, which exploit their rapid scanning capabilities. In quadrupole GDMS, isobaric interferences are often the limiting factor in terms of sensitivity and accuracy. Many efforts have been made to eliminate or reduce polyatomic species — heating/cooling the ion source, variation in discharge parameters, optimization of sampling position, and collisional dissociation. Recent efforts at ORNL have concentrated on improving the purity of the discharge gas through appropriate conditioning of the getter purification system. Sub-ppm detection limits for problematic elements (e.g., Si, Fe, Cr) are observed.

GD / Time-of-flight
TOF instruments perform nicely in terms of selectivity, sensitivity speed and simplicity. Inherently, they are the most simple mass analyzer, providing a large mass range and rapid spectral acquisition. Limitations observed in current GD / TOF instruments include limited

dynamic range (~10^4), abundance sensitivity, detection limits (low ppm), mass (temporal) resolution, and duty cycle. It was stressed that the limitations in these areas lie in the detection system and stressed the need for development, particularly for the low mass (fast event) range.

ICP / TOF
The multiplex advantage of ICP-TOF instruments was demonstrated in the isotopic analysis of laser ablated material. Precision better than 2% was observed. Using boxcar averaging, $^{206}Pb/^{208}Pb$ ratio precision reached the statistical limit (0.2%). The need for better data acquisition systems was reiterated. Detection limits could be improved by approximately 100x by limiting the divergence of the ion beam.

GD / FTICR
The primary advantage of this combination is the ability to mass resolve polyatomic and atomic isobaric interferences. Mass resolutions of 2 million ($m/\Delta m_{1/2}$) have been observed on instruments with very high magnetic fields (7 Tesla). Clearly such resolution is not needed for most applications; permanent magnet systems may provide mass resolving powers on the order of 50,000 in the low mass range. Other advantages are the possibility of using gas-phase ion chemistry and the multiplex advantage. Disadvantages are the limited dynamic range (~10^4-10^6), cost, complexity, and sensitivity. Dynamic range can be improved through the ejection of majors and axialization/remeasurement techniques. Resulting sensitivity has been demonstrated to be on the single to sub ppm level.

ICP / ITMS
The ion trap, new to atomic mass spectrometry, appears to have several real and potential advantages. It is potentially the most sensitive of all mass analyzers; detection limits are in the low part-per-trillion. Its ability to dissociate polyatomic species and neutralize highly electronegative species (Ar in particular) are notable benefits. The possibility for high mass resolution exists. It was stressed that the ITMS is not a panacea for ICP-MS, however. For example, oxide and hydroxide formation can be problematic (though reduced with a Zr getter pump in the analyzer). The ion trap is a reaction cell and the reactions occurring therein can be advantageous or disadvantageous.

GD / ITMS
The ion trap hold promise for the analysis of glow discharge generated ions. Fortuitous ion-molecule reactions, analogous to the ICP / ITMS observations, in which argon and argon-related species are removed through charge transfer reactions are observed in the GD / ITMS system. Loosely bound polyatomic species tend to dissociate upon collision with the He bath gas. Dissociation of strongly bound polyatomics (MS/MS) has been demonstrated with efficiencies of ~100%. As a new mass analyzer for atomic ions, the ion trap has many parameters remaining to be evaluated. Dynamic range, abundance sensitivity and abundance precision were identified as the most critical issues for highly sensitive multi-element analysis. To this end, the use of highly selective methods of ion accumulation become important. The use of filtered noise fields was presented as a highly selective means of accomplishing this.

Douglas C. Duckworth

PROCESS MASS SPECTROMETRY WORKSHOP

"On-Line Mass Spectrometry for Process Control and Diagnostics"

Organized by Steven J. Doherty[1] and Mark A. LaPack[2]

[1] The Dow Chemical Company, Analytical Laboratories, Freeport, TX 77541
[2] The Dow Chemical Company, Analytical Sciences Laboratories, Midland, MI 48667

This was the second workshop on process mass spectrometry at ASMS. The goal of these workshops is to discuss the experiences and challenges encountered by those who develop, apply, and commercialize on-line mass spectrometric applications. Approximately fifty people were in attendance representing industry, academia, national laboratories, and instrument manufacturers. As with last year, the workshop was structured around three informal presentations, separated by periods of discussion. Following the final discussion period, several people remained for over thirty minutes to discuss specific topics of interest.

Most attendees of last year's workshop had suggested that future workshops address novel ways to deal with complex samples and future directions for process monitoring. The underlying message from this year's workshop supported the trends revealed in the literature. Smaller, less expensive, and more powerful mass spectrometers are making their way out of the laboratory and into the field and production areas. These non-traditional uses of mass spectrometry to solve non-traditional problems are driving the use of hyphenated techniques such as membrane introduction-mass spectrometry (MI-MS) and gas chromatography-mass spectrometry (GC-MS).

Anthony J. Borgerding (Los Alamos National Laboratory, Los Alamos, NM) began this workshop with a review of the current state of the art for fast gas chromatography and fast GC-MS as well as his own current work in the area. Tony described the problems and some solutions associated with the application of fast GC-MS for on-line applications. The goal was to produce GC-MS data at one-tenth the time of conventional chromatographic separations. By producing ten millisecond injections and using short, small diameter columns, five compounds could be reproducibly separated in five seconds. With peak widths of a few hundred milliseconds, scan rates of 100 scans per second are required. Quadrupole, ion trap, and time of flight (TOF) mass analyzers were discussed, with TOF described as the most promising for this application. Ideally, ions would be stored in the ion source prior to mass analysis to optimize the sensitivity of the technique. Parts per million detection limits were reported for halogenated solvents with parts per billion detection limits easily obtainable with improvements in the technology. This approach appears promising as it provides a very good compromise to the inevitable trade-off between speed and selectivity for on-line techniques.

Mary E. Cisper (Los Alamos National Laboratory, Los Alamos, NM) presented an overview of recent studies performed at Los Alamos for developing methods to monitor volatile organic compounds (VOC's). For monitoring VOC's in air using an ion trap, it was found that MI-MS provided at least

ten times better detection limits when compared with introducing the sample via a molecular leak valve. Both flat sheet and hollow fiber membrane separators were described. A configuration in which the membrane separator was interfaced to the mass spectrometer through a jet separator was shown to further enhance the introduction of VOC's relative to air in the analyzer. With this configuration, sub-parts per billion detection limits were reported. A variety of experimental parameters were varied to determine the optimum operating conditions of the analyzer. During these studies, it was found that higher air pressures in the ion trap resulted in a charge exchange process that enhanced the sensitivity of the VOC's by a factor of 150. Mary also provided a preliminary report on work being performed to compare results from a field analysis using a portable analyzer with conventional lab analyses of VOC's in soil and water samples. Although the results have not yet been finalized, one of the goals of this study is to demonstrate to the regulatory agencies that the two methods are at least equivalent so that the "near-real-time" technique may be accepted for reporting purposes.

Mark Dearth (The Ford Motor Company, Dearborn, MI) presented a description of Ford's interactions with government agencies, national laboratories, universities, and various business consortia to address environmental issues. The auto industry is using a great deal of resources to measure the components of auto emissions. Historically, techniques such as total organic carbon, optical spectroscopies, mass spectrometry, and chromatographic techniques have been used for on-line and off-line studies. A tremendous challenge has arisen from requirement to determine parts per billion levels of specific "reactive" (i.e., unsaturated and aromatic) hydrocarbons and oxygenated species in auto exhaust. On-line analysis is expected to provide the most reliable data and to reduce development and testing time. Mark stated that sampling is a key component to these studies. The analyzer for this application should possess the following characteristics: twenty parts per billion detection limits, one to ten samples per second acquisition rate, robust, small, and inexpensive. An analyzer is currently being developed in cooperation with Oak Ridge National Laboratory that is expected to meet many of these criteria. This analyzer is based on ion trap technology with glow discharge ionization, which will provide the combination of soft ionization, good analyzer signal to noise, and tandem mass spectrometry capabilities. We look forward to future updates from all three speakers.

Those who remained for continued discussion following the presentations agreed that the needs are diverse for on-line and environmental field monitoring. Instrument manufacturers do not currently meet these needs with standard, commercially-available instrumentation. The manufacturers in attendance concurred that there is a large market that is as yet untapped, but as for the technology that will satisfy that market, the picture remains cloudy.

Finally, the growing interest in the field of on-line mass spectrometry was demonstrated again when it was announced that one - and possibly two - up-coming volume of the *Journal of Process Control and Quality* will be devoted to applications and developments of on-line mass spectrometry. A call for papers was formally issued by the organizers of the workshop.

DESORPTION / IONIZATION INTEREST GROUP WORKSHOP

"MICRO-ELECTROSPRAY: CAN LESS GIVE MORE?"

The workshop was held on Tuesday evening, May 23, with about 300 attendees. Panel members were Richard M. Caprioli (University of Texas Medical Center), Kelsey D. Cook (University of Tennessee), Matthias Mann (EMBL, Heidelberg, Germany), Jean-Pierre Salzmann (LC Packings), and Richard D. Smith (Pacific Northwest Laboratories). In addition, presentations were made by Tom Covey (Perkin-Elmer Sciex) and Gary Valaskovic (Cornell University).

Workshop organizer Richard Cole (University of New Orleans) introduced the topic of 'micro-electrospray', which he referred to as the 'miniaturization' of the electrospray technique to accomodate submicroliter/min flow rates and accompanying small sample volumes. Electrospray ionization MS at higher flow rates is often termed a "concentration-sensitive" technique, i.e., for quantitative purposes, signal response is related to analyte concentration. Moreover, increasing the flow rate of solution (thereby increasing the absolute quantity of analyte entering the mass spectrometer per unit time) does not usually augment the signal. For ultra-trace analyses, increasing the analyte concentration via solvent evaporation can improve detection ability. However, the analyst may be left with a sample volume of only one microliter or less, thereby necessitating special handling to introduce it into the mass spectrometer. Equally challenging may be a low volume sample which contains a high level of competing analytes or impurities, thus necessitating a micro-scale separation or clean-up to avoid signal suppression by these competing species.

Interest in micro-electrospray has surged in the past year, spurred primarily by work presented at the 1994 ASMS meeting by Matthias Mann, Kelsey Cook, and Richard Caprioli who independently reported 10-100 fold gains in sample utilization efficiency. Dick Smith, whose work with low flow rate systems dates back even further, reminded the audience that low flow rate electrospray ionization mass spectrometry is a concept that has been with us for a while, attributing the statement that the optimum flow is "as low as possible" to John Fenn's early electrospray work of one decade ago.

Matthias Mann and colleague Matthias Wilm described different approaches to micro-flow systems. They presented their version of a micro-electrospray device which is readily distinguished from other approaches because the sample is introduced in a discrete portion at the beginning of the experiment, as opposed to continuous sample introduction via direct infusion, HPLC, or CE. In their method a small volume of sample (~ 1 µl) is deposited into a 1 mm i.d. borosilicate glass pipette which had been drawn out to a 1 micron i.d. tip, then gold plated by vapor deposition. The electrospray process itself sustains a flow of about 20 nL/min enabling measurements to be made for ~ 50 min. Attomole sensitivity for MS-MS experiments on peptides was achieved by employing signal averaging techniques. The issue of capillary blockage was raised, but it was noted that *in situ* protein digests taken off 2-D gels could be run with these sprayers without problems. A list of equipment and suppliers was distributed to those interested in using the method.

The remaining speakers described continuous introduction devices. Kelsey Cook described a procedure for preparing gold coated fused silica capillaries with the unique feature of being extremely durable. The tip of the capillary is first tapered to a fine point, then treated with (3-mercaptopropyl)trimethoxysilane, afterwhich a thin film of gold is vapor-deposited on the outer surface. These spray devices can be made from commercially available fused silica capillaries having inner diameters of 10 µm or greater. High voltage contact is made directly on the gold coating. Sample utilization efficiency was shown to improve by a factor of 30 with the 10 µm i.d. capillary, relative to a 32 gauge needle. The advantages of this system for on-line CE-MS were discussed. However, a 25 µm i.d. was suggested to be the best compromise between sensitivity improvements and blockage problems.

Dick Smith showed a low flow rate sprayer comprised of a small diameter fused silica capillary whose tip had been tapered via etching using 40% HF. Electrical contact was made at the capillary tip which had been coated with a conductive silver epoxy. The capillary inner diameter may be as small as 10 µm. The improved sensitivity of the reduced flow sprayer was discussed, with the ion sampling efficiency estimated to be > 10 %. Other data was presented showing improved sample utilization efficiency with decreasing capillary inner diameter. The use of microsprayers for sheathless CE-MS was predicted to allow the lowering of detection limits from the (current) attomole level into the zeptomole range.

Jean-Pierre Salzmann described practical aspects of interfacing micro-flow liquid chromatography (200-400 nL/min) to electrospray MS. He described the advantages and disadvantages of various injector, pumping and gradient configurations. He also discussed low volume sample handling, and stressed the importance of avoiding dead volumes to minimize band broadening outside of the column. It was evident that the low flow rates delivered to the 50-320 µm i.d. capillary LC columns were ideally suited to coupling to the micro-sprayers discussed in the workshop. It was pointed out that nanoliter/min flow rates are often achievable using hardware intended for higher flow delivery when flow splitting is employed.

Richard Caprioli's version of micro-electrospray utilizes fused silica of greater than 10 µm i.d. and 150 µm o.d.. The voltage is not applied directly to the sprayer tip, so no metal adhesion is required. Instead, voltage is applied to a metal junction made a few centimeters away from the spray tip. For capillary LC-MS, the stationary phase can be packed directly into the spray capillary itself. This minimizes dead volumes which have proven to be lethal at these low flow rates. The use of 10 µm C-18 particles as packing material created an integrated de-salting / preconcentration / fractionation set-up for use at 50-500 nL/min flow rates allowing attomole/µL detection levels for peptides.

Tom Covey presented work evaluating several of the above micro-sprayer systems employing inner diameters from 2 to 100 µm. The Mann/Wilm discrete sprayers were reported to give the highest sample utilization efficiency, providing flows in the 10-25 nL/min range. This flow hovers just above the lower limit to workable flow rates, while providing close to the upper limit of sample utilization efficiency when working at concentrations below 100 fm/µL (~ 1 in 10 analyte molecules present enter the mass spectrometer). The improvement in efficiency likely originates from increases in both ionization efficiency and transfer efficiency through the atmospheric pressure-to-vacuum orifice. With very small aperture sprayers, resistance to flow is minimized when the restriction length is kept as short as possible.

Lastly, Gary Valaskovic presented some micro-electrospray data obtained using higher analyte concentrations. Each presenter entertained questions and comments by workshop participants.

In summary, there was a general consensus among the panel members that micro-electrospray is only worth doing if the added sensitivity is truly needed. Additional problems (e.g., capillary plugging and high back pressure) complicate analyses, so if sensitivity is adequate at higher flow rates, micro-electrospray is probably unnecessary. A capillary inner diameter of about 20 µm seemed to represent the point where sensitivity improvements became overshadowed by added headaches originating from excessive back pressures and capillary blockage. Plugging often can be directly linked to poor solubility. It was noted that the 'Taylor cone' (from which charged droplet formation originates) is no longer stable at very low flow rates (e.g., < 20 nL/min). Below this level, the Taylor cone retracts into the electrospray capillary. For low flow LC and CE coupling, unions and other dead volumes must be avoided.

Validation of Mass Spectrometry Data Systems

This workshop provided a follow-up to the successful ASMS 1994 Fall Workshop on *Mass Spectrometry and Good Laboratory Practices, but with a tighter focus, that of* validation of the data systems and software provided with modern mass spectrometers. Among the issues which surfaced at the Fall Workshop was, "To what degree are end users and data system vendors required to validate the computer hardware and software provided with their instruments?" Auditors from the US Food and Drug Administration have great flexibility when assessing GLP compliance, leading study directors to often prepare for the worst, possibly a line-by-line validation of the vendor's *data system source code.*

In the ensuing seven months, the FDA's Office of Regulatory Affairs has had time to consider some of these problems. The FDA spokesman at the Fall Workshop, Steve Musser, was invited back to speak at this evening workshop. Representatives from the software development groups at four instrument vendors were also invited to describe their software development efforts.

Steve Musser distributed copies of an FDA technical report furnished to auditors investigating software development activities, and summarized the report with seven key points. A software validation package must contain these critical elements:

- Design specifications, both high and low level
- A test plan, covering module, worst case, and typical use testing
- Test results evaluation, with emphasis on demonstration that the specifications have been met
- Procedures for controlling changes and revalidation
- Documentation of the individuals responsible for approving and executing the validation plan
- Risk analysis for critical software functions
- An archive of the whole of the above, including all versions of specifications and specific details of test results

If a vendor of a mass spectrometry data system can provide the end user a sufficiently detailed summary of this validation package, then this will generally satisfy an auditor's requirements. Steve stressed, however, that individual auditors were still free to require additional documentation.

Gerry Bentley (PE-Sciex), David Stranz (VG Organic), Mark Canales (Finnigan MAT), and Wayne Duncan (Hewlett-Packard) *each described the software development* process at their respective companies. All of these vendors are ISO-9000 and TickIT compliant, and all follow a similar procedure. Modern software development activities

focus on what is called the "software lifecycle", the flow of activities from a software product's inception through its commercial lifetime. The software lifecycle generally begins as a proposal for a new product or application. This proposal is formally investigated for feasibility, commercial potential, and resource requirements. If the investigation results in approval, a functional requirements document is produced, which describes all of the features the product must have. Next, one or more technical specification documents are written, detailing how the functional requirements must be implemented in software and providing procedures for testing that the resulting code meets both technical and functional specifications. Finally, the actual code is written, reviewed, debugged, and tested, first at the module level, then integrated at the system level, and finally as a finished product. Most vendors perform both in-house and external testing to uncover defects in the software and in the design and functional requirements. These testing programs evaluate software under worst-case as well as typical use conditions. All vendors have in place a defect and change request tracking process, with only certain individuals able to assign responsibility for and approve changes. Priorities are assigned to changes, and statistics are computed to help improve the process of finding and correcting defects, and avoiding new defects.

The software lifecycle is generally not a linear process; the various steps may run in parallel at times. There is generally iteration between design, implementation, and testing stages, as problems or alternatives are uncovered. It is nearly impossible to completely specify a complex software product from the outset of the project, because new requirements are constantly being introduced as the field or market changes. The lifecycle and its accompanying documentation must remain flexible enough to cope.

Following the presentations, the workshop opened to a lifely discussion among the thirty or so attendees. While most comments were favorable regarding the FDA's recommendations and the vendors' procedures, there was considerable concern about the FDA auditors' flexibility and whether the vendors could provide appropriate documentation, particularly for older systems.

While Steve acknowledged the open-endedness of an auditor's potential requirements, he stressed that the FDA is looking at the overall quality and documentation of a study, and that a sufficiently detailed vendor-supplied validation package would usually suffice.

The vendors present acknowledged that, while this modern software development lifecycle was being followed in the development of new software products, such *procedures were generally not in place five to ten years ago, when older data systems* were being developed. All agreed that they would work with the end user and the FDA to provide acceptable documentation in the event of an audit of an older system, and all stated that the seven points presented by Steve were being met in their current practices and could be documented in the summary validation package.

Progress and Prospects for TOF Mass Spectrometry

A Workshop Sponsored by the Time-of-Flight Interest Group
Monday, May 22, 1995; 8-10:20 PM

A brief business meeting introduced this new interest group. **Robert J. Cotter** (Johns Hopkins University) encouraged members to suggest topics for 1996 oral sessions, plenary lecturers and possible recipients of the Distinguished Contributions to Mass Spectrometry Award. Attendees were recorded on a mailing list that will enable the group to construct a TOF bulletin board and listserver on the Internet. Finally, Dr. Cotter noted that the ASMS will shortly have a homepage on the Web.

Marvin Vestal (PerSeptive Biosystems) then gave an informal presentation of a *delayed extraction MALDI* technique for improving mass resolution. Using an extended (15 meter) geometry his group has been able to achieve mass resolutions of 5000 for insulin and 1050 for a DNA 50mer. **Jack Holland** (Michigan State) and **Rebecca O'Malley** (University of South Florida) both reminded the attendees that delayed extraction techniques had first been developed by Wiley and McLaren in 1955. **Marshall Siegel** (American Cyanamid) asked whether there were any calibration problems associated with pulsed extraction. Vestal replied that timing is based upon the extraction pulse rather than the laser pulse.

Liang Li (University of Edmonton) described a *time-lag focusing* scheme using a 280ns delay that is not adjusted with mass. Using a 1 Gsample/second digitizer he achieved a mass resolution of 4072 for bradykinin.

Werner Ens (University of Manitoba) described an orthogonal injection electrospray TOF mass spectrometer that achieved 10,000 resolution for insulin using pulsed extraction. In response to a question by **Ron Stein** (Applied Physics Laboratory), Ens noted that timing in this instrument was also based upon the extraction pulse. **Marvin Vestal** (PerSeptive Biosystems) noted that resolution is in many cases limited by the bandwidth (generally 50 MHz) even on 1 Gsample/second digitizers.

Scott Weinberger (Hewlett-Packard) stressed the importance of developing small, simple-to-use instruments and keeping the background pressure low. He also described in detail the problems associated with the poor beam profile of nitrogen lasers. He noted that people tend to define the *desorption threshold* differently, and that combined bandwidth limits of 100 to 500MHz in detectors and digitizer preamplifiers are common.

Timothy Cornish (Johns Hopkins University) described improvements to a coaxial, dual-channelplate detector that enable one to record peak widths of as little as 1.5 ns without ringing. **Ron Stein** (Applied Physics Laboratory) asked about the coaxial cables used; and **Marvin Vestal** (PerSeptive Biosystems) asked whether the interleaving mode was used on the digitizer. Cornish replied that the peak was recorded as a single transient for a single ion.

Steve Thompson (Kratos Analytical) described a new detector manufactured by Ballatini, that consisted of small, fused glass spheres with the active surface on the outside of the spheres. These 1 mm thick detectors can be made in any size and in any shape. **Winston Chen** (Oak Ridge National

Laboratories) noted that these had been described in the most recent issue of *Vacuum Science*.

Robert J. Cotter (Johns Hopkins University) described *post-source decay* mass spectra using a *curved-field reflectron*. This reflectron eliminates the need for acquiring and stitching together spectra obtained at different reflectron voltages, and therefore provides *seamless* amino acid sequencing spectra.

Douglas Beussman (University of New Mexico) described *photon-induced dissociation* (PID) fragmentation of alkanes at 193 nm. **Marvin Vestal** (PerSeptive Biosystems) asked about the possibility for background CID resulting from laser vaporization of background material from surfaces. Contributions from CID were determined by firing the laser early and were minimal.

Jack Holland (Michigan State University) described the technique known as *time-compressed chromatography* using time array detection on an integrating transient recorder.

Kai Tang (Sequenom, Inc) described work with oligonucleotides, including high mass resolution (1000 for 20mers) and spectra of an exonuclease digestion mixture. **Chris Becker** (SRI International) described progress in the Sanger approach using 5 fmol of 14, 21 and 41mers on a 12mer primer scheme in which the 40 and 41mers can be resolved at a resolution of 200.

Mark T. Qian (University of Michigan) described results on the CID spectra of bradykinin and the M_2H^{+2} peak of angiotensin 1, using an electrospray, reflectron TOF mass spectrometer

James Reilley (Indiana University) returned the discussion to the subject of delayed extraction. He described the technique as different from that of Wiley and McLaren in that they were not attempting to simultaneously focus both kinetic energy (velocity) and spatial distributions. Rather, they converted the initial kinetic energy distributions common in MALDI to a spatial distribution Mass spectra were shown for lysozyme using a 4500V drawout pulse. He noted that at longer delay times there was considerable metastable decay in the source. **Rebecca O'Malley** (University of South Florida) commented that pulsed, delayed extraction had previously been used by Cotter for both IR laser desorption and MALDI of peptides, and by her group for the analysis of polymers.

The workshop then adjourned at 10:20 PM.

Respectfully submitted,

Robert J. Cotter

Historical Interest Group Report

The meeting was called to order on Wednesday, 24-MAY-95. A brief report was presented by Mike Grayson, Archivist for the Society, regarding an increase in financial support of the Chemical Heritage Foundation (CHF) in Philadelphia. Based on the fact that CHF has acquired a new facility for their offices, the Beckman Center for the History of Chemistry and the Othmer Library, space for a museum of chemical instrumentation will be made available. The increased level of support by ASMS provides one seat on the CHF Board and two seats on the Chemical Instrumentation Group Board.

The new home of CHF is in the heart of the historic district of Philadelphia. Sometime during 1996, 1400 square feet of space will be made available for a display of instrumentation. The long-range plan is to devote approximately 12,000 square feet to the instrumentation museum.

Plans for 1996 meeting were discussed. It was decided that the historical interest group would submit a request to the vice-president for programs for one oral session and one poster session at the Portland meeting. The theme would be history of various mass separation techniques:

Magnetic Sector
Time-of-Flight
Quadrupole Mass Filters
Preparative Scale Instruments (Calutrons)

An oral presentation would be planned for each of these topics with the presentor giving an overview of the history of the separation technique in general terms. Poster presentations would be solicited that focused on particular instruments or instrument manufacturers such as CEC 110, Bendix TOF, etc. Presentors will be encouraged to make use of all available resources including oral histories of significant individuals. History session authors will be provided four pages in the bound volume for their manuscript instead of the usual two pages and longer articles will be encouraged for submission to JASMS. Several individuals volunteered to make presentations.

Ken Busch made a timely suggestion that the Historical Interest Group begin to plan for the 50th anniversary of the Society which is now seven years away. This suggestion was met with enthusiasm and volunteers for a planning committee were solicited. The following individuals offered their services in planning for the 50th anniversary of the Society:

Ken Busch
Mike Grayson
Burnaby Munson
Larry Phillips
G. Siuzdak
Mike Story
Al Yergey

Mike Grayson will chair the 50th anniversary planning committee during the coming year.

Several suggestions were made for topics for future meetings between now and the 50th anniversary meeting:

- Timelines for instrument companies and/or instruments
- History of various techniques and applications
- History of mass spectrometry societies both in US and abroad
- Pre-history of mass spectrometry (Aston to Nier)
- History of important mass spectroscopists
- History of important developments in mass spectrometry

Besides topics for future meetings, a number of other suggestions were made to commemorate the 50th anniversary of the Society:

- Reissue J. J. Thomson's book
- Create a multi-media CD-ROM of historical highlights in mass spectrometry
- Gather Accounts and Perspectives from JASMS and publish as a book
- Publish a collection of important works in the field

These various ideas will be discussed among the planning committee in the coming year to form a plan for review by the Historical Interest Group, the ASMS Board and the Editor of JASMS.

Larry Phillips is completing his two year term as Chairman of the Historical Interest Group. Charles Judson and Burnaby Munson were nominated to chair the group in the coming two years. Their names were submitted to the President for appointment.

Any ASMS member interested in participating in the Portland Historical session is encouraged to contact any member of the planning committee. Contributions, ideas, and volunteer labor are needed and welcome.

Larry Phillips (301) 846-1234
Mike Grayson (314) 233-2541

BIOMEDICAL APPLICATIONS INTEREST GROUP WORKSHOP

"PROBING BIOMOLECULAR NON-COVALENT INTERACTIONS: TRICKS AND TRAPS"

The workshop was held on Thursday evening June 1, with about 120 attendees present. Prior to beginning the workshop, opening comments were offered by the current interest group chairperson, Pam Crain, who noted that about 1300 registrants at the previous ASMS meeting (Chicago) had declared the Biomedical Applications Interest Group to be their first or second interest group, thus making this the largest of ASMS's interest groups. She informed the attendees how interest groups are formed and how they are intended to function, and solicited volunteers for the position of chairperson, who will be appointed by the board summer 1995 to a two-year term. The chairperson solicited suggestions about what specifically the interest group could do to be of greater use to affiliates who may analyze biomolecules but who may not be experienced with the chemistry and properties of biomolecules. Such assistance could take the form of compilations, tutorials, or the like. There was some discussion of the utility of a tutorial or workshop on handling biomolecules (properties, preparation etc.) The chairperson noted that because of the size of the interest group and of the importance of biomedical applications as reflected in the large number of presentations in the biomedical area, the ASMS Board will listen, and she urged attendees to make their wishes and needs known to them and to the incoming chairperson, to be appointed.

Attendees were polled regarding the effectiveness of JASMS as a vehicle for scientific communication of results in our area of interest. As evidenced by a show of hands, more than half of the audience had published in the journal, and no dissatisfaction was expressed with any aspect of the journal. It was noted that our group generally tends to represent end users, not innovators, of mass spectrometric techniques, and generally publishes where our findings, themselves, are what is relevant. Suggestions for plenary lecturers and symposium topics for next year's meeting were solicited and all were given to Veronica Bierbaum (V-P, Programs).

The workshop was structured as an informal open discussion, with topics selected from written questions submitted from the attendees, and it was intended to emphasize practical aspects of using the mass spectrometer to determine the nature and extent of non-covalent ligand:biomolecule (or other bi-molecular) interactions. It soon became readily apparent that the audience was rather strongly divided into two opposing camps. One consisted of skeptics with generic concerns (or direct experience) that one could (or actually does) obtain different ligand:biomolecule ratios according to how the mass spectrometer is tuned. There was an equally fervent group of proponents testifying that if the samples and selected controls are prepared carefully, and appropriate tuning and solvent considerations are adopted, then valid measurements can be made mass spectrometrically. It was noted that an actual example of an interaction for which the stoichiometry was unknown was

correctly determined mass spectrometrically, and was subsequently confirmed by "classical" methods. Several in the audience suggested that perhaps too many papers reporting these kinds of measurements are being reviewed by mass spectrometrists and that we might decline to do so with the suggestion that these papers be reviewed by experts in binding measurements by more conventional methods. There was unanimous agreement that great care should be exercised before undertaking these kinds of analyses, with regards to tuning and using the proper controls, although in the latter matter, there was no agreement on any "universal" control sample. Audience participation was notable, and although the discussion was at times spirited, a uniformly high level of civility was maintained by all. The workshop adjourned at 10:00 p.m.

Respectfully submitted

Pam Crain

ASMS BUSINESS MEETING, ATLANTA, GA

May 24, 1995

The Business Meeting, which was held in conjunction with the ASMS Annual Conference, was chaired by President Christie G. Enke who opened proceedings at 8:15 a.m. by welcoming all present. A number of presentations by members of the ASMS Board of Directors were made, summaries of which are given below.

President's Report (Chris Enke)

The Society is continuing its healthy growth, both in size and in membership services offered. The 1995 Conference in Atlanta broke new records in attendance (about 2,500, up 304 from Chicago) and in number of presentations (1,461 vs. 1,266 in Chicago). The Board is actively working to find ways to accommodate this growth and to better serve the now over 3,000 members of ASMS. Board members' responsibilities are being redefined and extended and the role of the interest groups, in providing activities of value to their constituents, is being expanded.

In an effort to allow the non-member conference attendees an opportunity to enjoy full and continuous membership status, starting with the 1996 Conference, non-member registrants had the option of becoming full members for the period May 1, 1995 through March 30, 1996 by paying $20 dues (in addition to the non-member registration fee). A total of 70 non-member registrants took advantage of this opportunity. Conference registrants who joined ASMS at the time of the Annual Conference will receive all 12 issues of *JASMS*. Membership will expire March 1 of the following year. They will be able to renew their full membership by the same arrangement at the 1996 Annual Conference or by paying the regular annual membership dues before March 30, 1996

Treasurer's Report (Chris Enke for Charles Evans)

ASMS is perhaps one of the most literally non-profit organizations around. It has been our aim to have each activity self-sustaining. Roughly, the general income from dues and interest pay for the operating expenses (Society office and expenses) and journal costs (currently $27 per member.) The conference registrations and short course fees generally cover current conference costs and a small fraction of the operating expenses. The fall workshop and the Sanibel and Asilomar conferences are planned to have break-even budgets. However, the 1994 Conference in Chicago resulted in a lost of $4,174 which led to a net loss for the year of $12,029. This is a small amount compared to the total 1994 Society expenses of $777,977, but represented a continuing trend of increased operating and conference expenses. This observation led to the Board's action to adopt a modest raise in 1995 dues and conference registration fees.

Vice President for Programs' Report (Veronica Bierbaum)

The Vice President for Programs thanked all participants in the Conference, and the Program Review Committee in particular (who had reviewed some 1,500 abstracts), for making the Meeting such a success. She also acknowledged the efforts of the oral session chairs and co-

chairs, workshop organizers, mass spectrometry tutorial organizers and chair (Brian Musselman), poster session chair (Herman Bierbaum) and the ASMS office staff for all of their hard work

Vice President for Arrangements' Report (Brian Musselman)

The presentation from the Vice President for Arrangements confirmed that Portland, OR will be the site of our next meeting in 1996 (May 12-16, 1996). The Conference dates were presented, along with the identities of the cities for future meetings Those cities included: Palm Springs, CA which replaces Kansas City (June 1-6, 1997); Orlando, FL (May 31-June 5, 1998) and the newest site, Dallas, TX (June 13-18, 1999).

Ms. Carol Gibbs, a representative of the Portland Oregon Visitors Association, made a short presentation on the virtues of Portland at our meeting site. She encouraged the members to attend the 1996 Meeting and include time for a vacation in Oregon

Members-at-Large for Measurements and Standards' Report (Sharon Lias)
Meeting of the Measurements and Standards Committee

The Measurements and Standards Committee met at 12:30 p m. on Monday, May 22, in the Presidential Suite. Attending were Committee members: Sharon Lias (Chair), John Bartmess, Anne Giordani, James Little, Phil Price and guests Jane Gale (who will replace Anne Giordani in July) and Jack Henion (previous Chair).

Discussion included: (1) projected Committee work on again updating the list of keywords used in ASMS Conference abstracts (revisions to be submitted to Sharon Lias by August 1); (2) a discussion (led by Jack Henion) of an activity he initiated while on the Committee - the possible development of a generic "suggested" SOP for mass spectrometry; (3) the planned update of the 1991 ASMS article, "Standard Definitions of Terms Relating to Mass Spectrometry," and (4) a discussion (led by John Bartmess) about the problems brought about by the fact that thermodynamic conventions used by mass spectrometrists are non-standard. (Sharon Lias and John Bartmess will examine possible solution to the problem).

Meeting of the Sanibel Committee

The Sanibel Committee met at 12:30 p.m. on Tuesday, May 23, in the Vice Presidential Suite. Attending were Sanibel Committee members Rebecca O-Malley (Chair,), Lester Taylor (Budget Officer), Susan Graul, Thomas Covey, and Sharon Lias (representative to the ASMS Board and Secretary), as well as 1996 Meeting Organizers Jonathan Amster and Jennifer Brodbelt. Details of the 8th Sanibel Conference on "Metal Containing Ions and Their Applications in Mass Spectrometry" were discussed with the organizers All planning appears to be on schedule, with a complete list of speakers and topics already available, with a preliminary budget in preparation.

The Business Meeting of the Sanibel Conference Committee followed, with the Committee choosing Ion Traps as the subject to be proposed to the ASMS Board for the 1997 Sanibel Conference. A list of possible organizers was drawn up, and Lester Taylor, as the new Chair of

the Committee, will line up organizers for the conference once the topic has been approved by the Board.

At the end of the meeting, Rebecca O'Malley stepped down as Chair of the Committee. Lester Taylor is the new Chair and Susan Graul is the new Budget Officer.

Members-at-Large for Education Report (Robert Boyd)

The major undertakings of the Education Committee are the Fall Workshop and the Short Courses offered prior to the Annual Conference. In 1994, the subject of the Fall Workshop was "Good Laboratory Practices for Mass Spectrometry," organized by Jack Henion. This turned out to be a highly successful workshop, reflecting current concerns of the mass spectrometry community involved in activities regulated by the EPA and, in particular, by the FDA. A report of this Workshop has been submitted for publication in *JASMS*. Four Short Courses were offered prior to the 1995 conference in Atlanta, namely "GC/MS for Environmental Analysis," "Interpretation of Mass Spectra," "Practical MS/MS," and "Liquid Chromatography - Mass Spectrometry." The dates for the Fall Workshop are October 13 and 14, 1995 and will be held at the Ramada Hotel in Alexandria, VA. The Committee thanks all those colleagues who contributed to the success of the 1994 Workshop and of the 1995 Short Courses. The subject of the 1995 Fall Workshop will be "Capillary Electrophoresis- Mass Spectrometry," to be organized by Pierre Thibault. New Short Courses for 1996 will include one on biological applications of mass spectrometry and one on ion optics

Member-at-Large for Publications' Report (Mark Ross)

The Member-at-Large (MAL) position for the *Proceedings* on the ASMS Board of Directors has changed and will now be referred to as MAL for Publications. The responsibilities of this position have been expanded beyond that for the extended abstracts, which are published in the *Proceedings*. The new duties include assisting the Society Office with Society publications such as announcements, brochures and the *Spektaker*. Second, this MAL will be responsible for identifying, developing and disseminating pre- and post - conference publicity. Finally, the MAL will serve as the liaison between the ASMS Board and *JASMS* The liaison efforts will focus on working with ASMS Board and *JASMS* Editor, with Society Member suggestions, to make efficient use of *JASMS* for Society information, encourage contributions and in general enhance the connections between the Society and the *Journal*.

***JASMS* Editor-in-Chief's Report (Mike Gross)**

Mike Gross briefly reviewed the status of *JASMS* and pointed to a number of reasons why Members should publish their work in the Society's *Journal*. These included the widespread circulation (>4,000 copies) and modest institutional subscription rate ($326 for 1995). *JASMS* is a journal of wide scope which has grown from 6 issues per year to 12 at present. Gross noted that the number of submissions continues to increase steadily, and the ISI Impact Factor of *JASMS* in its field is second only to *Analytical Chemistry*.

Secretary's Report (Tom Baillie)

The Secretary announced the result of the elections for the three Board positions which will become vacant on July 1, 1995. The new board members are Hee-Yong Kim (Secretary), Charles McEwen (Vice President for Arrangements) and Anne Giordani (Member-at-Large for Publications). A motion was made by President Enke to accept these candidates for office, and was seconded by past President Fales. The vote was unanimous in favor of the motion The Secretary then thanked the unsuccessful candidates for their willingness to stand for election, and members of the Nominating Committee for their efforts in connection with the election.

Following the above reports, President Enke thanked and made a presentation to each of the outgoing Board Members, (Brian Musselman, VP for Arrangements; Tom Baillie, secretary; and Mark Ross, MAL for Publications), and also acknowledged the efforts of Judith Sjoberg and her staff at the ASMS office for their continued outstanding service to the Society President Enke then introduced the winner of the ASMS Research Award (Kermit Murray), made possible by a generous grant from Finnigan Corporation (award presented by Phil Warren), and the ASMS and Corporate Member Research Award (Lee Sunderlin), which was funded by contributions from a number of ASMS Corporate Members and the Society itself. These presentations were followed by the announcement of Student Travel Awards (of which there were 24 this year) and of the Best Student Paper Awards for articles published in the *International Journal of Mass Spectrometry and Ion Processes* The recipients of the latter awards (sponsored jointly by Elsevier and Finnigan) were Matthias Wilm and Massimiliano Aschi (award presented by Mike Bowers and Egbert van Wezenbeek).

Finally, President Enke called for any new business There being none, the Meeting was formally closed at 9:05 a.m.
